laboratory environment [9]. This fabrication approach allows the flexible development of miniaturized compact sensing devices, microfluidics delivery systems and the possibility of fabricating multiple sensors on one chip, opening the way for high-throughput screening. Additional advantages are the robustness, reliability, potential for mass production with consequent reduction of production costs, low energy consumption and simplicity in the alignment of the individual elements [9].

Such nanobiosensors based on optoelectronics and nanomechanics platforms are excellent examples of devices developed with such technologies, and these platforms offer more possibilities for being used in real applications in the near future.

### 10.2.2

#### **Biological Functionalization of Nanobiosensors**

For biosensing purposes, a layer of receptor molecules (proteins, DNA, etc.) capable of selectively binding the substances to be analyzed has to be previously immobilized on the biosensor surface. We must not forget that the immobilization of the receptor molecule on the nanosensor surface is a key step towards the final performance of any biosensor device as it affects to the reproducibility, selectivity and resolution of the device.

The immobilization procedure employed must be stable and reproducible, and must retain the stability and activity of the receptors. Even though the nanodevice that we develop would be the most sensitive one, if the immobilization fails, then the performance of the device will be poor and the theoretical extreme sensitivity of the nanodevice will never be achieved. For handling such diminutive areas, immobilization can be performed with *ex situ* techniques as ink-jet, dip-pen or micro/nanospotting [3] or by *in-situ* techniques through dedicate microfluidics and nanofluidics.

Generally, direct adsorption is not adequate, giving significant losses in biological activity and random orientation of the receptors. Two immobilization strategies are the most employed at the biosensor field: (a) covalent coupling and (b) affinity noncovalent interactions. Covalent coupling gives a stable immobilization as the receptors do not dissociate from the surface or exchange with other receptors in solution. In affinity bonding, a high-affinity capture ligand is nonreversibly immobilized on the sensor surface. The most employed method is the immobilization on gold-coated surfaces using thiol self-assembled monolayers (SAMs) [10]. For example, a widespread method is functionalization of single-stranded (ss) DNA (or proteins) with an alkane chain terminating in a thiol (-SH) or disulfide group (-SS) as sulfurs form a strong bond with gold. This can also be applied for silicon surfaces, using silane monolayers covalently attach to silicon, SiO<sub>2</sub> or Si<sub>3</sub>N<sub>4</sub> sensor surfaces [11]. Several aspects must be taken into account in the development of the immobilization procedures, such as how to avoid nonspecific interactions, getting an optimized surface density of the receptor in order to prevent steric hindrance phenomenon or regenerating the receptor for continuous measurements.

Further details about this subject can be found in the specific literature [12, 13];

it is beyond the scope of this chapter to discuss in detail the immobilization procedures which can be used for (nano)biosensing.

## 10.3

### Nanophotonic Biosensors

#### 10.3.1

##### Overview

Photonic biosensors are providing an increasingly important analytical technology for the detection of biological and chemical species [2, 14]. Most optical biosensors make use of optical waveguides as the basic element of their structure for light propagation and are based on the same operation principle – evanescent field sensing (EFS). With the emergence of nanotechnology, new photonic structures have been suggested as possible highly sensitive transducers for biosensing, such as photonic crystals [15], ring resonators [16] or hollow waveguides [17], but almost no biosensing demonstrations have appeared in the literature using such structures.

Evanescence wave detection combined with nanophotonics structures is proving to be one of the most highly sensitive biosensors. In evanescent wave detection, a receptor layer is immobilized onto the waveguide and the exposure of such a surface to the partner analyte molecules produces a biochemical interaction, which induces a change in its optical properties. This change is detected by the evanescent wave. The extent of the optical change will depend on the concentration of the analyte and on the affinity constant of the interaction, in this way obtaining a quantitative sensor of the interaction. The evanescent wave decays exponentially as it penetrates the outer medium and, therefore, only detects changes taking place on the surface of the waveguide since the intensity of the evanescent field is much higher in this particular region. For that reason, it is not necessary to carry out *a priori* separation of nonspecific components (as in conventional analysis) because any change in the bulk solution will hardly affect the sensor response. In this way, evanescent wave sensors are selective and sensitive devices for the detection of very low levels of chemicals and biological substances, and for the measurement of molecular interactions *in situ* and in real-time [18].

The advantages of optical sensing are significantly improved when the above approach is used within an integrated optics context [19]. Integrated optics technology allows the integration of passive and active optical components (including fibers, emitters, detectors, waveguides and related devices) onto the same substrate, permitting the flexible development of miniaturized compact sensing devices, with the additional possibility to fabricate multiple sensors on a single chip. The integration offers some additional advantages to the optical sensing systems, such as miniaturization, robustness, reliability, potential for mass production with consequent reduction of production costs, low energy consumption and simplicity in the alignment of the individual optical elements [19].

## 10.3.2

**Integrated Mach–Zehnder Interferometer (MZI) Nanodevice**

One of the most sensitive direct biosensor is the MZI. This device fabricated at the micro/nanoscale has shown sensitivity levels close to  $10^{-3}$  nm in adsorbed molecular layers, which means a sensitivity in the picomolar range for biomolecular interactions in a direct assay (without labels) [20].

In a MZI device [18] the light from a laser beam is divided into two identical beams that travel through the MZI arms (sensor and reference areas) and are recombined again into a monomode channel waveguide, giving a signal which is dependent on the phase difference between the sensing and the reference branches. Any change in the sensor area (in the region of the evanescent field) produces a phase difference (and therein a change of the effective refractive index of the waveguide) between the reference and the sensor beam, and thus in the intensity of the outcoupled light. A schematic diagram of this sensor is shown in Fig. 10.2.

When a chemical or biochemical reaction takes place in the sensor area, only the light that travels through this arm will experience a change in its effective refractive index. At the sensor output, the intensity ( $I$ ) of the light coming from both arms will interfere, showing a sinusoidal variation that depends on the difference of the effective refractive indexes of the sensor ( $N_{\text{eff},s}$ ) and reference arms ( $N_{\text{eff},r}$ ) and on the interaction length ( $L$ ):

$$I = \frac{1}{2} I_0 \left[ 1 + \cos \left( \frac{2\pi}{\lambda} (N_{\text{eff},s} - N_{\text{eff},r}) L \right) \right] \quad (1)$$

where  $\lambda$  is the wavelength. This sinusoidal variation can be directly related to the concentration of the analyte to be measured.

For evaluation of specific biosensing interactions, the receptor is covalently attached to the sensor arm surface, while the complementary molecule binds to the receptor from free solution. The recognition of the complementary molecule by the receptor causes a change in the refractive index and the sensor monitors that change. After the molecular interaction, the surface can be regenerated using a

**Figure 10.2.** Scheme of the MZI nanodevice configuration and its working principle. The biomolecular interaction in the sensing area, where the receptors are attached, induces a

phase change of the light traveling through that area as compared to the light traveling through the reference area.

suitable reagent in order to remove the bound analyte without denaturing the immobilized receptor.

The interferometric sensor platform is highly sensitive, and is the only one that provides an internal reference for compensation of refractive index fluctuations and unspecific adsorption. Interferometric sensors have a broader dynamic range than most other types of sensors and show higher sensitivity as compared with other integrated optical biosensors [18, 21]. Due to the high sensitivity of the interferometer sensor, direct detection of small molecules (e.g. environmental pollutants where concentrations down to  $0.1 \text{ ng mL}^{-1}$  must be detected) would be possible with this device.

The detection limit is generally limited by electronic, chemical and mechanical noise, thermal drift, and light source instabilities. However, the intrinsic reference channel of the interferometric devices offers the possibility of reducing common mode effects like temperature drifts and nonspecific adsorptions. A detection limit of  $10^{-7}$  (or better) in the refractive index can be achieved with this device [20], which opens the possibility of the development of highly sensitive devices for *in situ* chemical and biologically harmful agent detection, for example.

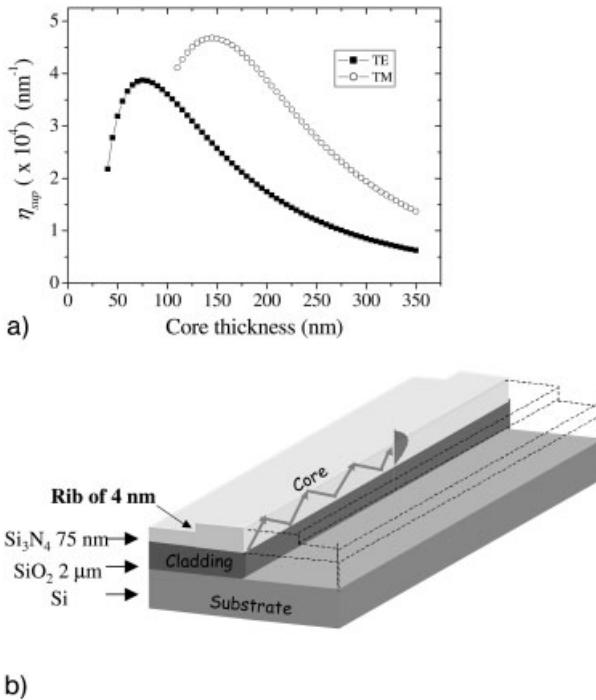

### 10.3.2.1 Design and Fabrication

For biosensing applications, the waveguides of the MZI device must be designed to work in the monomode regime and to have a very high surface sensitivity at the sensor arm towards biochemical interactions. If several modes were propagated through the structure, each of them would detect the variations in the characteristics of the outer medium and the information carried by all the modes would interfere between them. The design of the optical waveguide satisfying the above requirements and the dimensions of the Mach-Zehnder structure is achieved by using modeling programs such as the finite difference methods in a nonuniform mesh, the effective index method and the beam-propagation method. Parameters such as propagation constants, attenuation and radiation losses, evanescent field profile, modal properties, and field evolution must be calculated [22]. In order to quantify and optimize the surface sensitivity, the variation of the effective refractive index of the guided modes must be calculated when the thickness of a homogeneous biological layer ( $d_1$ ) changes:

$$n_{\text{sup}} = \partial N / \partial d_1 \quad (2)$$

In Fig. 10.3(b) the surface sensitivity is represented as a function of the core thickness, assuming that the refractive index of this layer is  $n_b = 1.45$ , the external medium is water ( $n_e = 1.33$ ) and the light wavelength is 632 nm.

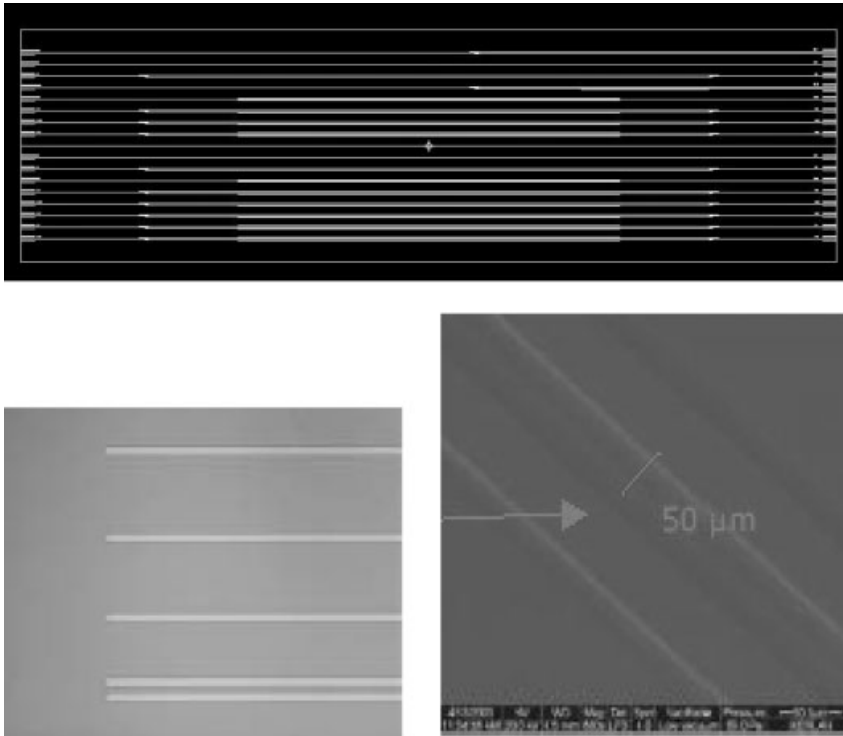

If we want to use total internal reflection (TIR) waveguides for the sensors, we must come to an agreement between single-mode behavior, low attenuation losses for the fundamental mode and high surface sensitivity. For those reasons, the structure that has been finally chosen [20], for an operating wavelength of  $0.633 \mu\text{m}$ , has the configuration shown in Fig. 10.3(b). In this configuration, the monomode behavior is obtained for core thickness below 200 nm and rib depths

**Figure 10.3.** Cross-section of the optical monomode waveguides used in the Mach–Zehnder device. Note that a rib of only 4 nm is needed for monomode and high-biomolecular sensitivity characteristics.

below 4 nm when the rib width is 4  $\mu\text{m}$ . The small dimensions of this device imply some drawbacks: the reduced core dimensions for monomode behavior (thickness of less than hundreds nanometers and rib depths of a few nanometers) introduces a technological disadvantage for mass production and large insertion losses when coupling light with single-mode optical fibers (with a core thickness of several micrometers). However, the high surface sensitivity for biosensing applications justifies the development of these devices.

The fabrication is done through the following geometry: (a) a conducting silicon wafer of 500  $\mu\text{m}$  thickness, (b) a 2- $\mu\text{m}$  thick thermal  $\text{SiO}_2$  layer on top with a refractive index of 1.46, and (iii) a low-pressure chemical vapor deposition (LPCVD)  $\text{Si}_3\text{N}_4$  layer of 75 nm thickness and a refractive index of 2.00, which is used as a guiding layer. To achieve monomode behavior we needed to define a rib structure, with a depth of only 4 nm, on the  $\text{Si}_3\text{N}_4$  layer by a lithographic step. This rib structure is performed by reactive ion etching (RIE) and is the most critical step in the microfabrication of the device. Finally, a  $\text{SiO}_2$  protective layer is deposited by LPCVD over the structure with a 2  $\mu\text{m}$  thickness and a refractive index of 1.46,

**Figure 10.4.** Photographs of the mask used for MZI fabrication and some of the fabricated devices. The details of the marks alignments and the reference/sensor areas of a device can

be observed. Note that the MZI waveguide cannot be observed due to its dimensions, but is underneath the reference and sensor area.

which is patterned and etched by RIE to define the sensing and reference arms of the interferometer. The final devices (within all the fabrication processes) are CMOS compatible. The MZI configuration is designed to be symmetric with a circular Y-junction (radii of 80 nm). Separation between the sensor and reference arms is of 50  $\mu\text{m}$  to avoid coupling between modes traveling through both branches. Finally, the sensors must be cut in individual pieces and polished for light coupling by the end faces.

In Fig. 10.4, the mask designed for the fabrication of such devices is shown as well some details of the alignment marks and the reference/sensor areas of one fabricated device. Due to the nanometric rib dimension, the device can only be observed by AFM as shown in Fig. 10.5.

### 10.3.2.2 Characterization and Applications

The devices must be implemented with a microfluidics unit, electronics, data acquisition and software for optical and biochemical testing. For the experimental

**Figure 10.5.** Image of the sensing area of a nano-MZI device. The AFM photograph of the rib of the waveguide clearly shows the 4-nm step achieved during fabrication. The monomode behavior can be observed at the output light collected from the device.

characterization, the light coming from a connected laser diode at a wavelength of 632 nm is end-fire coupled into the interferometers by a single-mode optical fiber. The light coming out of the interferometer is collected by another single-mode fiber, which is connected to a photodiode. The photodiode signal is amplified, digitalized and processed. The different dissolutions used in the characterizations are controlled by a peristaltic pump and a polymeric flow cell.

The evaluation of the sensitivity is done by flowing dissolutions of varying refractive index and measuring the output signal of the MZI in real-time. With these measurements, a calibration curve is constructed where the phase response of the sensor is plotted versus the variation in the refractive index as depicted in Fig. 10.6.

The lower detection limit measured is  $\Delta n_{o, \min} = 2.5 \times 10^{-6}$ , corresponding to an effective refractive index change of  $\Delta N = 1.4 \times 10^{-7}$ . It can be estimated that the lowest phase shift measurable would be around  $0.03 \times 2\pi$ . The detection limit value corresponds to a very high surface sensitivity around  $2 \times 10^{-4} \text{ nm}^{-1}$ , which means that picomolar detection of a biomolecular interaction in a direct way is feasible using this nanodevice.

As a proof of the utility of MZI technology towards biosensing detection, the application of MZI nanobiosensors for the direct detection of DNA is described. The first step is the immobilization of the biomolecular receptors in the sensor area. This immobilization must be strong and stable to perform the sensitivity measure-

**Figure 10.6.** Experimental and theoretical evaluation of the sensitivity to changes of refractive index for MZI sensors with  $\text{Si}_3\text{N}_4$  core layers of 75 and 200 nm, and for the TE and TM polarizations. In the case of the sensor with a 75-nm core layer, the TM mode is not guided.

ments of the device and for reusability. For that reason, a covalent immobilization protocol through SAMs using silane chemistry is employed.

First, the  $\text{Si}_3\text{N}_4$  surface is cleaned with oxygen plasma and 10% nitric acid in distilled water to oxidize the surface. Second, the  $\text{Si}_3\text{N}_4$  layer is immersed in 10% 3-mercaptopropyltrimethoxysilane (MPTMS) in toluene at room temperature for 12 h. The MPTMS functionalizes the sensor surface with a thiol group, allowing the thioled DNA to be covalently immobilized on the silanized  $\text{Si}_3\text{N}_4$  surface by a disulfide bond. A ssDNA probe (28 nucleotides) with the thiol linker group [SH-( $\text{CH}_2$ )<sub>6</sub>] at the 5' is used. The 15-T tail is employed as a vertical spacer chain to increase the accessibility to the complementary DNA. For the immobilization, a 45-nM solution of the ssDNA probe in phosphate-buffered (PB) solution (pH 7) is used. Figure 10.7(a) shows the real-time detection of the covalent immobilization of the DNA probes by means of a phase change of  $\Delta\phi_S = 7.75 \text{ } 2\pi$  rad.

The hybridization with the complementary ssDNA strand is detected using a 58-nucleotide strand and flowing a 100-nM solution in the same PB buffer. Figure 10.7(b) shows the real-time detection of the hybridization between the complementary sequences inducing a total phase change  $\Delta\phi_S = 2.5 \text{ } 2\pi$  rad. In order to test the specificity of the DNA hybridization, 100 nM dissolutions of a noncomplementary DNA sequence flow after the regeneration of the surface with 10 mM NaOH. This measurement shows a null response of the sensors, ensuring the specificity of the DNA binding. A calibration curve has been obtained by using different DNA concentrations. The lower experimental limit of detection is 10 pM, as can be observed in Fig. 10.7(c). This result clearly demonstrated the high sensitivity which can be obtained for the direct detection of biomolecular interactions by using this nanophotonic concept for a biosensor.

**Figure 10.8.** Scanning electron microscopy image of the cross-section of the polymer microfluidic channels over the sensor area of the photonic MZI device.

### 10.3.3

#### Integration in Microsystems

The integration of optical transducers is a key issue in the further development of “lab-on-a-chip” microsystems [23]. The main advantage of the Mach–Zehnder devices fabricated with standard microelectronics technology comes from the possibility to develop a complete “lab-on-a-chip” by optoelectronic integration of the light source, photodetectors and sensor waveguides on a single semiconductor package together with the flow system and the CMOS electronics [19]. There are many advantages to shrinking down these devices and integrating them for use in high-throughput microsystem applications such as single-molecule detection and DNA sequencing. A complete system fabricated with integrated optics will offer low complexity, robustness, a standardized device and, what is more important, portability. Devices for on-site analysis or point-of-care operations for biological and chemical detection are geared for portability, ease of use and low cost. In this sense, integrated optical devices have a compact structure and could allow fabricating optical sensor arrays on a single substrate for simultaneous detection of multiple analytes. Mass production of sensors will be also possible with the fabrication of miniaturized devices by using standard microelectronics technology.

For the development of a complete MZI microsystem, several units must be incorporated on the same platform: (a) the micro/nanodevices, (b) the flow cells and the flow delivery system, (c) a modulation or compensation system for translating the interferometric signals into direct ones, (d) integration of the light sources and the photodetectors, and (e) CMOS processing electronics. As an example, Fig. 10.8 shows the integration of a nano-MZI device with a microfluidic sys-

**Figure 10.7.** (a) Detection of the covalent immobilization of ssDNA receptor probes from a 45-nM solution by a MZI sensor. (b) Detection of the hybridization with the complementary ssDNA strand (100 nM). (c) Calibration curve for DNA hybridization. A lower detection limit of 10 pM can be achieved.

tem. The microflow cells are specifically designed and fabricated using a novel fabrication method of three-dimensionally embedded microchannels using the polymer SU-8 as structural material [24]. Integration of sources will be achieved by connection with optical fibers or using embedded diffraction gratings.

## 10.4

### Nanomechanical Biosensors

#### 10.4.1

##### Overview

Over recent years, biosensors based on microcantilevers have arisen as interesting devices for measuring biomolecular interactions in a direct way with very high sensitivity [25]. These sensors derive from the microfabricated cantilevers used in AFM and are based on the bending induced in the cantilever when a biomolecular interaction takes place on one of its surfaces. Microcantilevers transduce the molecular recognition of biomolecules into a nanomechanical motion [26] (from a few to hundreds of nanometers), which is commonly detected by an optical or piezoresistive readout system [27–29]. Research in this new type of sensors grew exponentially after the landmark paper of Fritz and coworkers in 2000, where the ability of microcantilever sensors for discerning single-base variations in DNA strands without using fluorescent labels was demonstrated [26]. This paper made a deep impact on the biotechnology area and marked the beginning of a major research effort on this field. Shortly after, microcantilever sensors were used in other works like DNA hybridization [30, 31], detection of proteins involved in cancer [32] and other diseases [33, 34] with increased accuracy, as well as in applications in environmental sciences [35]. Cantilever sensors have also been used for the detection of such chemical molecules as volatile compounds, warfare pathogens, explosives, glucose and even ionic species [25].

Microcantilevers are fabricated by using standard microelectronics technology in arrays of tens to thousands of microcantilevers. For that reason they are a promising alternative to current DNA and protein chips because they could permit the parallel, fast and real-time monitoring of thousands of analytes (proteins, pathogens, DNA strands, etc.) without the need for labeling. When fabricated at the nanoscale (*nanocantilevers*) the sensitivity increases and expected limits of detection are in the femto–atto regime with the astonishing possibility of detection at the single-molecule level in real-time [29].

#### 10.4.2

##### Working Principle

The physical working principle is based on the bending of the cantilever when a biomolecular interaction takes place. The bending arises as consequence of a sur-

**Figure 10.9.** Scheme of cantilever bending due to a biomolecular interaction between an immobilized receptor and its complementary target. Only the specific recognition causes a change on the surface stress driving the bending of the cantilever.

face stress change induced by the molecular recognition when this phenomena happens just on one of its sides (with regard to the other). Hence, immobilization has to be selectively performed only on one side of the cantilever, allowing the target molecule to react onto the functionalized side (see Fig. 10.9 for details). Detection based on cantilever bending is known as *static mode* detection.

At the same time, the cantilever resonance frequency also varies due to mass loading. This type of detection is known as *dynamic mode* detection. Resonance frequency changes can be detected by measuring the thermal cantilever noise. However, to achieve high-sensitivity resolution, especially when working in liquids, it is necessary to produce a previous excitation of the cantilevers by using alternated electric, magnetic or acoustic fields.

Both static and dynamic modes have proven to be very sensitive when working in air. However, when operated in liquids, the resonance peak and the quality value shift toward much lower values than in air due to the damping effect of the liquid. This factor dramatically affects measurements based on the dynamic mode, making this method less suitable to monitor biochemical process in aqueous environments than when using the static mode. For this reason, as biological reactions take place in liquids, microcantilever sensors operating in the static mode are especially suitable as a platform for performing nanomechanical biomolecular assays. In fact, there are only a few demonstrations of biomolecular interaction detection by using the resonant frequency method [36].

Factors and phenomena responsible for the surface stress response during molecular recognition remain unclear. Several factors are considered to be involved, but a great controversy already exists in the scientific community [30, 37, 38]. Electrostatic interaction between neighboring adsorbates, changes in surface hydrophobicity and conformational changes of the adsorbed molecules can all induce stresses which may contrast with each other and make the change in stress not directly related to the receptor–ligand binding energy. This is particularly the case for biological adsorption due to the complexity of the interactions involved.

## 10.4.3

**Detection Systems**

The readout signal is critical to the real-time measurement, accuracy and possibility of integration of microcantilever biosensors. Therefore, a crucial area is the implementation a readout system capable of monitoring changes with subnanometer accuracy. The bending or/and the resonant frequency changes can be monitored by several techniques including optical beam deflection, piezoresistivity, piezoelectricity, interferometry, capacitance and electron tunneling amongst the most important [27]. In addition, under real conditions, sensors have to be stable long-term, selective and sensitive to the target molecule with no crosstalk reactions. Nonspecific binding of molecules and noise sources such as vibrations and temperature changes have to be avoided. These problems can be overcome by using differential measurements using cantilever array platforms in which a passivated cantilever is used as a reference. Optical and piezoresistive readouts are the most popular, and are compatible with array formats.

For the optical readout, the displacement of the free end of the cantilever is measured using the optical deflection of an incident laser beam on a position-sensitive photodetector which allows us to calculate the absolute value of the cantilever displacement [Fig. 10.10(a)]. This method provides sub-angstrom resolution and can be easily implemented for one cantilever; however, implementation for readout of arrays is technologically challenging, as it requires an array of laser sources with the same number of elements as the cantilever array. This technique is employed

**Figure 10.10.** (a) Scheme of the optical readout method for cantilever bending evaluation. (b) Scheme of the piezoresistive readout and the Wheatstone bridge configuration.

in optically based commercialized array platforms, but sequential switching on and off of each laser source is necessary to avoid overlapping of the reflected beams on the photodetector. This problem can be elegantly solved by using a scanning laser source, where the laser beam is scanned along the array in order to sequentially illuminate the free ends of each microcantilever [39].

Recently, Zinoviev and coworkers introduced a new type of optical waveguide cantilever [40, 41], where the cantilever act as a waveguide for the light. Light going out from the cantilever can be collected by other waveguides or by a photodetector. This new device has shown good performance and offers an interesting approach for further integration in “lab-on-a-chip” microsystems. The design and fabrication of this device is covered in Section 10.4.3.2.

Piezoresistive readout is based on the changes observed in the resistivity of the material of the cantilever as a consequence of a surface stress change [42, 43]. To measure the change on the resistance, silicon cantilevers must be included into a DC-biased Wheatstone bridge (Fig. 10.10b). This configuration is very suitable for further integration using arrays of cantilevers [44]. However, the main disadvantage is the intrinsic high noise level that directly affects to the resolution and the sensitivity when compared to optically detected cantilevers [45], although the reduction of the thickness of piezoresistive cantilevers could increase the sensitivity. However, the cross-sectional structure of piezoresistive cantilevers is complex, with the consequent technological limits in fabricating thin and highly sensitive cantilevers. Moreover, the piezoelectric readout requires electrical connections to the cantilever and their isolation from the solution. For all those reasons, the optical method is the one most employed. In addition, the best detection limits found in the literature are achieved with the optical method [30, 32].

#### 10.4.4

##### **Design of a Standard Microcantilever Sensor**

Microcantilevers are typically made on silicon/ $\text{Si}_3\text{N}_4$  or polymer materials, displaying dimensions ranging from tens to hundred of micrometers long, some tens of micrometers wide and hundreds of nanometers thick. Silicon,  $\text{Si}_3\text{N}_4$  and  $\text{SiO}_2$  cantilevers are available commercially with different shapes and sizes in analogy to AFM cantilevers, with typical lengths between 10 and 500  $\mu\text{m}$ , and ultra-thin cantilevers up to 12 nm thick. However, for specific applications (as in highly sensitive biosensors) cantilevers must be designed and fabricated to satisfy such requirements.

Previous modeling is needed in order to know the ranges of thickness, length and width which could give the highest sensitivity. Several factors must be taken into account. Reducing the thickness and increasing the length results in an increase of sensitivity of the device, but also leads to complex fabrication technology. The width of cantilevers is rather important when cantilevers are used in dynamic mode. A reduction in the width of the beam, in a certain range, results in an increase of the damping and subsequently in a decrease in the quality factor [27]. The effect of the frame and the material must be also taken into account. Cantile-

ver sensitivity depends critically on their spring constant. The lower the constant, the higher the sensitivity for measurements in liquids based on the static method. A key factor that dramatically affects the spring constant of a cantilever is the Young modulus, which is directly related to the characteristics of the cantilever material. Cantilevers are normally made of silicon or related materials that have a high Young's modulus. A cantilever made of a softer material would be more sensitive for static deflection measurements. For that reason, polymers with a much lower Young's modulus than that of silicon have been used as a substitute material for fabricating cantilevers [46]. Among polymers, SU-8 has been shown to be very sensitive, exhibiting a Young's modulus about 40 times lower than for silicon. In addition, the cantilever fabrication process is relatively inexpensive, fast and reliable. It also provides a convenient way to realize arrays of multiple sensors and to integrate them into a miniaturized biochemical analysis system. However, there is still no proof of biosensing testing using polymer cantilever sensors, mainly due to the difficulty in achieving a stable immobilization of the receptor layer.

Modifications of cantilever shape and dimensions could also improve the cantilever spring constant – longer and thinner [47, 48] cantilevers can address very small spring constants. Microfabrication technologies allow fabricating micrometer-sized cantilevers with a high length:thickness ratio in a reproducible and inexpensive way. However, thermal motion of the cantilever severely limits the extent to which the spring constant of the cantilever can be reduced [29]. Modeling can be done by using, finite element programs (ANSYS), for example.

#### 10.4.4.1 Fabrication of a Standard Microcantilever Sensor

Cantilevers are batch fabricated using well-established thin-film-processing technologies which provide low cost, high yield and good reproducibility. Such fabrication techniques include thin-layer deposition, photolithographic patterning and etching, and surface and bulk micromachining. Usually, a sacrificial layer is first deposited on a pre-patterned substrate before the deposition of the cantilever structural material. This structural layer must be free of stress gradients, otherwise problems with the initial bending of cantilevers will appear. The thickness of the layer must be uniform enough around the wafer to make sure that all the beams will be identical. It is possible to fabricate arrays of thousands of identical cantilevers on one wafer.

The cantilevers might be fabricated extended over the border of the chip or they might be located in individual cavities inside the chip. This depends on the type of flow cells to be employed – a common one or a discrete one with independent inlets and outlets for each cantilever. For the chip with cantilevers in a common window, the immobilization of the receptor can be conducted on each cantilever individually using, for example, ink-jet and nanojet printing. The individual cavity design is more complicated from a technological point of view, but allows the immobilization of different receptors in each cantilever *in situ* by using the discrete flow cell and also allows parallel screening of different substances.

As an example, the technology for the fabrication of arrays composed of 20 silicon cantilevers is described. Both types of chips with discrete and common win-

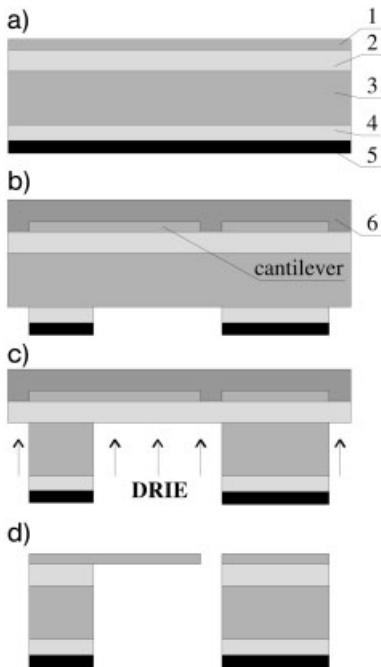

**Figure 10.11.** Photographs of nanomechanical sensors based on microcantilever arrays fabricated at the author's Clean Room facilities. Two different arrays of microcantilevers can be observed, with common and discrete windows (see text for explanation).

dows were fabricated. The cantilevers in the array were separated by a distance of  $250\ \mu\text{m}$ . Photographs of the fabricated devices with common and discrete windows are shown in the Fig. 10.11. The chips were  $3 \times 7\ \text{mm}^2$  in size. The dimensions were chosen small enough to fabricate as many as possible devices on one wafer and large enough to be conveniently handled for measurements.

SOI wafers were chosen as a starting material. The structural silicon layer was free of intrinsic stress gradients and any superficial defects. In this way, it is possible to fabricate arrays of thousands of identical cantilevers on one wafer. To fabricate the cantilevers, the most simple approach is to use bulk micromachining using anisotropic etching of silicon, but this method does not allow us to form a gap between the cavities due to lateral etching. For that reason, deep RIE (DRIE) must be employed to obtain windows with vertical walls.

The sequence of the technological steps is shown in Fig. 10.12. The front side contains a structural silicon layer (1) and a sacrificial  $\text{SiO}_2$  layer (2). The reverse side of the silicon substrate (3) has a  $\text{SiO}_2$  layer (4). As a first step, the reverse side was covered with an aluminum layer (5), the most adequate mask material for the following DRIE. The initial multilayer structure used for the fabrication of the cantilevers is shown in Fig. 10.12(a). Cantilevers on the front side were defined by dry etching of silicon through the pattern obtained by previous photolithography. The aluminum mask was deposited on the reverse side and the  $\text{SiO}_2$  was removed from the areas where the silicon substrate must be etched. Before the next step, the components side was covered with a photoresist layer (6) (Fig. 10.12b).

**Figure 10.12.** Fabrication steps for microcantilever arrays (see text for details).

The etching with DRIE of the silicon substrate resulted in almost vertical walls in the cavities with a small (about  $20\ \mu\text{m}$ ) lateral undercut at the top. At this stage, clean  $\text{SiO}_2$  membranes with cantilevers and a photoresist layer on top were obtained (Fig. 10.12c). The photoresist layer (6) prevented the membranes cracking. To release the cantilevers, the membranes were etched in vapors of HF (49%). Afterwards, the wafers were briefly rinsed with deionized water. The photoresist film was removed by oxygen plasma etching.

The next step was dicing the wafers. Common sawing could not be employed as it would break the cantilevers by the cooling water flow and might leave residuals on the sensor surface. As a solution, a DRIE step was applied to have wafers “preliminary diced”. As the cavities under the cantilevers were etched, a groove around every chip was etched to make the array of cantilevers joined to the wafer by two thin hinges, which could be broken manually. With this technology a 100% yield for the cantilever fabrication (2500 cantilevers per wafer) was obtained [49]. All cantilevers were identical and the initial bending was almost negligible. Typical profiles of the fabricated cantilevers are shown in Fig. 10.13. The dispersion did not exceed  $0.6\ \mu\text{m}$ , which corresponded to  $0.005\ \text{rad}$  dispersion of angular deflection. Even cantilevers with an extreme low spring constant ( $k = 0.000061\ \text{N m}^{-1}$ ) can be obtained following this fabrication procedure (cantilever dimensions  $800 \times 20 \times 0.334\ \mu\text{m}^3$ ).

**Figure 10.13.** Typical cantilever profiles after fabrication. Cantilevers are 200  $\mu\text{m}$  long, 40  $\mu\text{m}$  wide and 0.334  $\mu\text{m}$  thick.

Table 10.1 shows the main parameters experimentally evaluated for the fabricated devices and the comparison with the values for the commercial ones, demonstrating the feasibility of the designed and fabricated devices for higher sensitivity than the commercial devices.

#### 10.4.4.2 Optical Waveguide Microcantilever: Design and Fabrication

The optical method is normally employed for microcantilever sensors readout, but has several disadvantages – the major one being the difficulties experienced while performing parallel monitoring of several cantilevers at the same time. In order to achieve further integration, a new optical cantilever sensor has been recently proposed [40, 41]. The detection method is based on monitoring the light exiting a

**Table 10.1.** Main mechanical parameters of fabricated microcantilevers, and comparison with commercial and polymer microcantilevers.

Length $\times$ width $\times$ thickness	$K$ ( $\text{N m}^{-1}$ )	Frequency (kHz)	$Q$
$500 \times 20 \times 0.3$	$9.1 \times 10^{-3}$	1.5	1.8
$200 \times 20 \times 0.3$	$7.4 \times 10^{-3}$	9.9	6.3
$100 \times 20 \times 0.3$	$6.1 \times 10^{-3}$	34.9	13.6
$50 \times 40 \times 0.3$	$7.9 \times 10^{-3}$	86.5	20.7
$200 \times 20 \times 1.5$ (polymer)	$2.5 \times 10^{-3}$	17	15
$550 \times 40 \times 0.8$ (silicon commercial)	$11 \times 10^{-3}$	23.9	34.7

Figure 10.14. Scheme of the novel optical waveguide microcantilever device.

waveguide microcantilever (see Fig. 10.14 for details). This integrated waveguide cantilever sensor can be fabricated as an array of independent waveguide channels designed for monitoring bio-specific reactions. The sensor can work in static or dynamic modes, either by monitoring the deflection or by monitoring the changes in the resonance frequency of the cantilever. The advantage of the device is that the transducer is integrated with the receptor on one chip and the external photodetector is only used for optical power readout. No preliminary alignment or adjustment is needed, except for light coupling into the chip, which does not seriously affect the performance of the device if the coupler is well designed. The sensitivity of the device is comparable to standard microcantilever sensors discussed above.

**10.4.4.2.1 Principle of Operation and Theoretical Analysis** The principle of operation is based on monitoring the coupling efficiency between two butt-coupled waveguides. The energy transfer between the waveguides is very sensitive to their misalignment with respect to each other. In this device the transducer is an optically transparent cantilever beam of submicron thickness. It is located in a cavity and acts as a symmetrical optical waveguide. Light from the cantilever is injected through a short gap into an output waveguide, called a receptor. After exiting the cantilever, light diverges very quickly in the transversal direction and after a few microns its intensity distribution is much larger compared to the distribution of the receptor waveguide modes. Thus, the near field of the cantilever is probed by the receptor, which is a single-mode asymmetrical waveguide. The changes in the power of light exiting the output waveguide, which are attributed to the cantilever bending caused either by the surface stress and/or by vibration of the cantilever, are monitored by a conventional photodetector [41].

The simulations of the coupling efficiency and the sensitivity of the waveguides to their misalignment with respect to each other can be done using overlap integrals [50]. The simulations are performed separately for the fundamental and for the first propagating modes of the cantilever. Two electric field distributions have been overlapped. The first one was the distribution of light exiting the cantilever after propagation through the gap. It was obtained using finite difference beam propagation method (FDBPM) [51]. The second distribution was the fundamental mode of the output waveguide. It was built using the solution of Maxwell equations with appropriate boundary conditions [50]. Waveguide parameters close to

**Figure 10.15.** Modeling of the coupling efficiency and the noise level permitted in the acquisition system for the detection of a 1-nm optical cantilever displacement versus the gap width.

those of the fabricated device were used for the simulations. The cantilever and the receptor were made of  $\text{SiO}_2$  and  $\text{Si}_3\text{N}_4$  materials, respectively.

The sensitivity of the device is defined as the relative change in the output signal per unit cantilever free end displacement. It was calculated as the change in the output power required for the detection of 1-nm cantilever displacement with respect to the power of light exiting the cantilever. This accuracy is equivalent to the noise level allowed in the system. This parameter, further called the noise level, is expressed in relative units. The results of simulations are shown in Fig. 10.15. The noise level demonstrates similar behavior for both modes. The coupling efficiency for the zero mode is higher than that for the first mode. The curves of Fig. 10.15 were produced assuming the cantilever is biased to the most sensitive point which depends on the gap width as well. In general, the width of the gap is a trade-off since a small gap allows for high sensitivity and efficiency, whereas a wide gap makes fabrication tolerances less strict.

**10.4.4.2.2 Fabrication and Characterization** The most difficult step in fabrication of the device is the fabrication of the cantilevers aligned with the output waveguides, implying that the cantilevers should be very flat. A thermally grown  $\text{SiO}_2$  layer was used for the fabrication. The film demonstrated no stress gradient if the bottom layer of a few hundred nanometers was previously eliminated. This allows us to fabricate straight cantilever beams 200  $\mu\text{m}$  long, 40  $\mu\text{m}$  wide and 600 nm thick. The gap between the cantilever and the receptor waveguide was fixed to 3  $\mu\text{m}$ . As the refractive index of  $\text{SiO}_2$  is low, it is not possible to conform a total internal reflection waveguide over the silicon substrate, unlike a  $\text{SiO}_2$  cantilever in air. Therefore, light was launched over the substrate to the cantilever by using a  $\text{Si}_3\text{N}_4$  waveguide, called an input waveguide (IWG). At the cantilever anchoring area, the IWG deposited over the silica buffer forms a junction with the cantilever beam, which is

**Figure 10.16.** Technology for the fabrication of the optical waveguide cantilevers.

an extension of the buffer (Fig. 10.14). Light coupling into the cantilever was carried out by means of the evanescent field of the fundamental mode of the IWG. The efficiency of coupling is inversely proportional to the square root of the thickness of the IWG. It can reach 75% if the thickness is close to the value defined by the cut-off condition for the fundamental mode. The silica buffer thickness was  $1.0\ \mu\text{m}$  – enough to avoid leakage of energy into the substrate assuming the thickness of the input and output waveguides was  $140\ \text{nm}$ .

The device was fabricated using standard silicon technologies (Fig. 10.16). First, a  $\text{SiO}_2$  layer was thermally grown by wet oxidation on both sides of a silicon wafer. Then, a high-temperature LPCVD  $\text{Si}_3\text{N}_4$  layer was deposited on the front side and a PECVD  $\text{SiO}_2$  on the reverse side. Standard photolithography and RIE were applied to define the waveguides on the  $\text{Si}_3\text{N}_4$  layer and the cantilevers on the  $\text{SiO}_2$  layer. The same processes were used to obtain the mask for DRIE on the reverse side of the wafer. DRIE was applied to both sides in order to define the cavities under and around the cantilevers. Finally, the cantilevers were released by etching the rests of silicon using TMAH solution. A yield close to 100% was achieved, which means more than 2500 cantilevers per wafer. Figure 10.17 shows some photographs of a fabricated array of waveguide cantilevers. The cantilevers on the chip are located in a common cavity, which is a reach-through chip hole located in the center.

For characterization, the chip was located on a piezoelectric actuator connected to a sine waveform synthesizer. Light from a He–Ne laser ( $632.8\ \text{nm}$ ,  $7.5\ \text{mW}$ ) was coupled into the chip using direct focusing through an objective lens at the exiting light collected by another objective and then directed to a silicon photodetector. The coupling efficiency into the IWG was about 5%. Near 40% of light was transmitted from the IWG into the cantilever. The power of light exiting the output waveguide was  $0.015\ \text{mW}$ . Total losses were  $-27\ \text{dB}$  with respect to the laser output power. The mechanical resonance of the cantilevers was close to  $13.1\ \text{kHz}$ . The spectrum of the output signal measured with AC ( $11.1\ \text{kHz}$ ) voltage of  $50\ \text{mV}$  supplied to the piezoactuator is shown in Fig. 10.18. At this frequency, a small modulation of the output signal was observed, attributed to the modulation of coupling efficiency at the input. AC voltage ( $50\ \text{mV}$ ) applied to the piezoactuator

Figure 10.17. Photographs of the fabricated waveguide cantilevers.

Figure 10.18. Spectrum of the output signal of a waveguide cantilever. The peak at 13.1 kHz corresponds to the cantilever vibration at resonance frequency induced by a piezoelectric actuator. The excitation voltage of the piezoactuator was 50 mV. The cantilever oscillation amplitude was about 1.7 nm at this frequency.

produced a periodic change in the output signal. At a frequency of 13.1 kHz, the cantilever was subject to resonance vibration with an amplitude of about 1.7 nm. The sensitivity, calculated as fractional change ( $\Delta U_{\text{out}} = 1.0$  mV after amplification by factor 100 and subtracting the modulation at the input, see the inset in Fig. 10.18) in the output voltage ( $U_{\text{out}} = 60$  mV) per unit cantilever displacement was  $10^{-4} \text{ nm}^{-1}$ . The signal to noise ratio, which was about 40 at these frequencies, would allow us to register a 0.05-nm cantilever free end displacement. This shows the potential for using this novel structure as a nanomechanical sensor for biomolecular interaction detection with high sensitivity and with a much more integrated approach than that for standard microcantilever sensors.

#### 10.4.5

#### Biosensing Applications of Nanomechanical Sensors

One of the first applications of nanomechanical sensors was in the field of genomics. Fritz and coworkers [26] demonstrated the detection of a single-base mismatch with a detection limit of 10 nM using an array of two cantilevers. One of the cantilevers was functionalized with a control (noncomplementary) oligonucleotide and the DNA probe (complementary) was immobilized in the other. They achieved hybridization deflection signals as small as 10 and 16 nm for 12 and 16mer DNA targets, respectively, within a deflection noise of 0.5 nm. More recently, McKendry and coworker reached a detection of 75 nM for target oligonucleotides in an array of eight microcantilevers [30]. Both results include the specific immobilization by microcapillarity with a 40- $\mu\text{M}$  solution of the thiolated DNA probe. Figure 10.19 shows the cantilever response for a DNA immobilization step. The discrimination of single-nucleotide polymorphisms has been also reported by Thundat and coworkers [31], although with a single cantilever. Other DNA detection schemes have been reported, e.g. the one which used a capture oligonucleotide combined with a DNA probe attached to a gold nanoparticle. This method can detect at least 0.05 nM and is able to discriminate single mismatch measured by resonance [52].

**Figure 10.19.** Simultaneous 2  $\mu\text{M}$  thiolated DNA (27mer) immobilization detection using the cantilever array platform showed in Fig. 10.11.

Proteins have also caught the attention of nanomechanics applications, mainly motivated by the possibility of achieving protein microarrays based on arrays of cantilevers with lower-cost fabrication methods, no labeling of the target protein and improved sensitivity. Recently, Wee and coworkers [53] reported the detection of prostate-specific antigen (PSA), a useful marker for earlier detection of prostate cancer, and C-reactive protein (CRP), a specific marker of cardiac disease, by an electromechanical biosensor using self-sensing piezoresistive microcantilevers. Majumdar and coworkers [32] reported the detection of two isoforms of PSA with an excellent range of discrimination and a detection limit of  $6 \text{ ng mL}^{-1}$  (deflection signal of 20 nm) in a background of  $1 \text{ mg mL}^{-1}$  of BSA protein. In addition, a novel development for early osteosarcoma detection has been described, sensing the interactions between vimentin antibodies and antigens with a single-cantilever-based biosensor [54]. Other clinical applications included the detection of different pathogens like *Salmonella enterica* by Weeks and coworkers [55], vaccinia virus by Gunter and coworkers [56] or fungal spores from *Aspergillus niger* by Nugaeva and coworkers [57]. The use of aptamers as the bioreceptor element has also been widely probed on a number of microcantilever biosensing platforms [58–61].

Biosensing with microcantilevers also extends to applications in environmental sciences. Alvarez and coworkers [35] used this nanodevice for the detection of the organochlorine insecticide compound dichlorodiphenyltrichloroethane (DDT). A competitive assay was performed, in which the cantilever was exposed to a mixed solution of the monoclonal antibody and DDT, and direct detection was proven. With this detection strategy DDT concentrations as low as 10 nM were detected involving deflection signals in the range of 50 nm (Fig. 10.20). Many other applica-

**Figure 10.20.** DDT pesticide detection using a single microcantilever sensor in a real-time competitive immunoassay. The cantilever surface was regenerated with 100 mM HCl.

tions have been described for the detection of pesticides and avidin–streptavidin [28].

Nowadays, there are several commercial platforms based on cantilever array sensors available that demonstrate the potential of nanomechanical biosensors as a reliable sensing tool for biochemical applications [62–65].

## 10.5

### Conclusions and Future Goals

This chapter has provided an overview of most of the technical aspects related to two important branches of nanodevices for biosensing (nanomechanical and nanophotonic biosensors), including design, fabrication and applications of some specific devices. Nanomechanical and nanophotonic biosensors constitute a promising technology as a suitable solution for an important number of problems in the biosensor field. The improvement of the reproducibility and sensitivity along with the integration of microfluidics and detections systems is the main aim of the present research.

Nanobiosensors are still undergoing considerable diversification with respect to technologies, but those fabricated by using standard microelectronics and related MEMS/NEMS approaches could allow the development of portable microsystems platforms which could be employed outside the laboratory. However, limitations in the technology, problems in the integration of all the components in one microsystem and the connection of such tiny devices with the “real” world must be appropriately solved. There is no doubt that such limitations will be overcome in the near future, opening up immense possibilities for early, personalized diagnosis and high-throughput screening.

### Acknowledgments

The authors would like to acknowledge financial support from European and national projects, and thank their colleagues working within the Biosensors Group for their contribution. The authors thank F. J. Blanco and K. Mayora (Ikerlan Corp., Spain) for the microfluidics image.

## 11 Fullerene-based Devices for Biological Applications

Ginka H. Sarova, Tatiana Da Ros, and Dirk M. Guldi

### 11.1 Introduction

The great excitement commencing with the advent of fullerenes and their large-scale production was the inception of a wealth of scientific projects focused on two major disciplines – material chemistry and biomedical applications. Research and development of biomedical applications was, however, penalized by the necessity to work with soluble and biocompatible materials. Still, the outstanding physicochemical features of fullerenes, in general, and [60]fullerene, in particular, together with their unique shape, renders this class of carbon nanostructures as a candidate *par excellence* for biological applications. The ability, for example, to uptake electrons causes fullerenes to act as a very appropriate radical sponge, which is unequivocally reflected in their neuroprotective action. Photoexcitation of fullerenes, however, produces selectively reactive oxygen species (ROS) that are known to be cytotoxic. In this chapter we report on the solubility, toxicity and major biological applications of C<sub>60</sub>, considering both milestone achievements and the most recent advances in these intriguing areas.

### 11.2 Solubility

Considering the unique and hydrophobic structure of fullerenes, it is not surprising that C<sub>60</sub> renders absolutely insoluble in polar solvent. This aspect is, however, detrimental for developing biological and medical applications, and it consequently slowed down research activities in this intriguing field. To overcome this limitation, different approaches have been used – suspension in co-solvents, encapsulation into water-soluble hosts and chemical functionalization were mainly pursued as potent alternatives. In a number of instances the last two methods have been combined through the preparation, for example, of covalently linked cyclodextrins (CDs), which play a double role, i.e. providing solubilizing features and also physically entrapping the carbon cage.

Suspensions of fullerenes are achieved by dissolving them first in a nonpolar organic solvent, such as benzene, adding medium polar tetrahydrofuran (THF) and then acetone. In the last steps, the addition of water to the mixture and the subsequent evaporation of the organic solvents are performed to produce yellow stable suspensions [1, 2]. Notably, such suspensions are composed of fullerene aggregates of variable sizes.

The encapsulation and/or the association of fullerenes into CDs or calixarenes eventually led to the solubilization of fullerenes in aqueous media [3–12]. In this context, the complex formation, for example, between sulfonated thiocalix[4]arene and calix[6]arene and fullerene has been reported [13]. In this case, the stoichiometry between  $C_{60}$  and complexing molecules depends mainly on the dimension of the latter, and it is 1:1 in the case of calix[6]arene and 1:2 for calix[4]arene.

Poly(vinyl pyrrolidone) (PVP), dimethyldioctadecylammonium bromide, Triton X-100, dihexadecyl hydrogen phosphate and lecithin also gave interesting results, leading to rather concentrated solutions of pristine fullerenes with concentrations as high as  $10^{-5}$  M [14].

The covalent functionalization of fullerenes with hydrophilic groups is, however, by far the most powerful strategy to obtain water-soluble derivatives. Different functionalities, including ethylene glycol chains [15, 16], hydroxyl groups [17], carboxylic acids [18], ammonium groups [19] and CDs (Fig. 11.1) [7, 20–22], have been introduced onto the carbon cage in recent years with good results.

In the same manner, preparation of monosaccharide and oligosaccharide fullerene derivatives has been recently re-proposed [23–26]. Similarly, fullerene amino acids and fulleropeptides emerged as other important classes of soluble fullerene compounds that are abundantly reported [27]. Functionalization of the carbon cage has been performed by either direct attachment of amino acids [28] or by tra-

Figure 11.1. Example of covalent functionalization of fullerene with CDs.

ditional cycloaddition reactions that are followed by subsequent modification of the appendage [29–31].

A parallel development involves the synthesis of polyadducts to increase fullerene solubility. Nevertheless, the best results are currently achieved through the monofunctionalization of fullerenes – in the form of dendrofullerene **1** – that reaches water solubilities of the order of 34 or 254 mg mL<sup>-1</sup> at pH 7.4 or 10, respectively [32].

1

### 11.3 Toxicity

The wide-ranging appeal of fullerenes has triggered concern about their potential toxicity. If they are employed widely, it is important that the toxicity of fullerenes be measured and counteracted, if possible. Of key consideration is fullerene solubility in water. Although they are inherently hydrophobic, their water solubility is essential for many emerging biomedical technologies.

Early work focused on studying the effects of unfunctionalized C<sub>60</sub>, raw soot and fullerene black on bovine alveolar macrophage cells and macrophage-like cells. Raw soot and fullerene black are often the intermediaries and byproducts created during the bulk production of fullerenes in the laboratory. Enzyme tests for lysosomal damage and generation of ROS were undertaken as indicators for toxicity. Such tests demonstrate that C<sub>60</sub> and the raw soot did induce a slight cytotoxic effect on alveolar and HL-60 cells after 48 h of incubation [33].

Functionalization of normally hydrophobic fullerenes is primarily done to render them hydrophilic. Cells, tissues and living systems all operate in a hydrophilic environment, and functionalization aids in the interaction between the fullerene and the biological system of interest. Their toxicity, both in tissue culture and *in vivo*, is

an important characteristic for defining and constraining these applications. In fact, there have been a few papers on the influence of  $C_{60}$  and its derivatives on cell growth as well [1]. Surprisingly, no toxic effects of unfunctionalized  $C_{60}$  on biological samples were noted in these early assays.

Some water-soluble fullerene derivatives were found to cross the cellular membrane and localize in the mitochondria of HS 68 human fibroblast and COS-7 monkey kidney cells, but no toxicity studies of this derivative have been performed [34]. Carboxylic acid  $C_{60}$  derivatives inhibited excitotoxic cell death of mouse cortical neurons *in vitro*, and delayed the death and functional deterioration of a transgenic mouse containing the human superoxide dismutase (SOD) gene responsible for the neurodegenerative disease called familial amyotrophic lateral sclerosis (ALS; also known as Lou Gehrig's disease) [35].

When  $C_{60}$  was solubilized with PVP in water and the aqueous solution was applied to a mouse midbrain cell differentiation system, both cell differentiation and proliferation were potently inhibited [36, 37]. However, water-soluble fullerene carboxylic acids derived from  $C_{60}$  and  $C_{70}$ , which were examined for photocytotoxicity toward Raji cells (B lymphocytes), did not show any photocytotoxic effect even at 50  $\mu\text{M}$  [38].

In some cases, the phototoxicity of fullerene molecules has been identified as a feature useful for therapeutics [39, 40]. Other work has sought to minimize the toxicity of water-soluble fullerenes so as to permit their use in drug-delivery applications.

Recent attention has been drawn to the environmental effects of nanoscale aggregates of  $C_{60}$ . This form results when pristine  $C_{60}$ , from either the solid state or organic solution, is placed into contact with neutral water [41]. Rather than completely precipitating, some  $C_{60}$  will form suspended and water-stable aggregates up to 100-p.p.m. concentrations. The environmental and biological significance of fullerenes in water was examined by comparing the cytotoxicity of several important types of water-soluble fullerenes using human liver carcinoma cells and dermal fibroblasts. It has been shown that nanoscale aggregates of  $C_{60}$  are cytotoxic to HDF and HepG2 cells at the 20-p.p.b. level [42].

In conclusion, fullerenes are toxic to human cells as well, but surface modifications can significantly reduce the effect. Fullerenes are toxic because they have a high affinity for electrons and in the presence of oxygen they can generate radical species that damage cell walls. Some studies even postulate that blockage of the cell cycle might be a mechanism of this activity [43]. The low-energy, unoccupied molecular orbitals that make it easy for fullerenes to accept electrons also make them electrically conductive. Such results could help pave the way for the general use of fullerenes.

## 11.4 DNA Photocleavage

DNA cleaving and lipid peroxidation activities of fullerenes have attracted considerable attention [44–46]. Importantly,  $C_{60}$ , if exposed to light, can either make singlet

oxygen (type II energy transfer pathway) or be an electron donor to make superoxide radicals. For example, photoirradiation of  $C_{60}$  results in the formation of the singlet excited state  $^1C_{60}^*$ , which undergoes efficient intersystem crossing to give the triplet excited state  $^3C_{60}^*$ .  $^3C_{60}^*$  reacts with nearly diffusion-controlled rate constants with molecular oxygen to yield singlet oxygen [47]. In principle,  $^1O_2$  would then cleave DNA [48].

Possible involvement of  $^1O_2$  was examined in some detail by comparing the reactivity of a fullerene–oligonucleotide linked system with a similarly linked eosin–oligonucleotide [49]. Fullerene–oligonucleotides that either bind single- or double-stranded DNA cleave the strand(s) proximal to the fullerene moiety upon exposure to light and oxygen. DNA damage occurs predominantly at guanine bases, without revealing a significant specificity between the various G sites [44]. Only when  $C_{60}$  was conjugated to an oligonucleotide was a good selectivity observed [50]. A key observation was that addition of a singlet oxygen quencher, sodium azide, largely inhibits the eosin–oligonucleotide cleavage, while no discernable effect was noted for the fullerene–oligonucleotide cleavage. A likely rationale suggests that the fullerene–oligonucleotide cleavage does not involve the singlet oxygen mechanism, but rather an alternative mechanism must be involved.

The alternative mechanism implies an electron transfer scenario – the type I electron transfer pathway. More precisely, the triplet excited state  $^3C_{60}^*$  is subject to reactions with reductants to afford the radical anion of  $C_{60}$ . In this case, the rate constant for electron transfer quenching as a function of donor oxidation potential typically follows the Weller relationship [51]. Evidence for this pathway comes from early work by Foote and coworkers, who reported that  $^3C_{60}^*$  directly oxidizes guanine in a DNA stack, because the oxidation potential of a guanosine derivative is located at 1.26 V, which is close to the reduction potential of  $^3C_{60}^*$  (1.14 V). Conceptually similar is the sequence of reacting the radical anion of  $C_{60}$  with molecular oxygen to generate superoxide radicals and then indirectly cleaving DNA through reductive electron transfer. Such a reductive activation of molecular oxygen by photoexcited fullerenes was shown to be highly feasible under physiological conditions.

However, the poor solubility of fullerenes in water precluded in most instances the detailed mechanistic studies of  $C_{60}$  photosensitized DNA damage. However, of course, the binding to and recognition of DNA by synthetic organic compounds – fullerenes – is important.

Photoinduced DNA cleavage occurs efficiently by  $C_{60}$  in  $O_2$  saturated solutions containing NADH – the most important redox coenzyme acting as the source of electrons in the living system – through superoxide radicals. In fact, spectroscopic and kinetic studies using a laser flash photolysis technique enabled the detection of superoxide ( $O_2^-$ ) through the use of a radical scavenger – 5-diethoxyphosphoryl-5-methyl-1-pyrroline *N*-oxide (DEPMPO) [52, 53].

Highly efficient DNA cleavage by small amounts of water-soluble poly(fullerocyclodextrin)s under visible light conditions and the photocleavage of DNA by pristine fullerene in mixed organic solvent system have also been observed [54]. The cleaving is followed by a strong interaction between cleaved DNA fragments and  $C_{60}$  leading to DNA– $C_{60}$  conjugates in high yields. Similarly, water soluble  $C_{60}$ –

homooxacalix[3]arene complexes and lipid-membrane-incorporated C<sub>60</sub> acted as efficient DNA photocleavage reagents [11, 55].

Several concepts were followed to enhance the fullerene DNA interactions. A promising strategy involves fullerene derivatives that bear DNA minor groove binders, such as triple-helix-forming oligonucleotides. The rational design of this synthesis is based on a reinforced effect due to the simultaneous presence of two different agents able to confer sequence selectivity [56]. This, for example, is expected to assist in targeting the fullerene moiety to a desired DNA sequence. Although the triplex formation was demonstrated, the presence of fullerene moieties gives rise to a high degree of instability. In this context, the approach to introduce nucleic acid-specific agents such as acridine [57] or netropsin [45] to understand the mechanism of action of these classes of conjugates and to increase both cytotoxicity and sequence selectivity was unsuccessful.

An alternative concept implies that DNA can be used as a framework for the assembly of fullerene materials – bearing cationic functionalities – through electrostatic interactions with the phosphate groups along the DNA backbone [58, 59]. This concept was driven by the finding that a simple carboxylic acid derivative does not bind to DNA and hence it is unlikely that DNA undergoes direct chemical reaction with the fullerene derivative. However, some mediating function – most likely due to the involvement of superoxide radical anions – helped in cleaving DNA fragments at guanine residues upon exposure to light [60].

#### 11.4.1

#### Photodynamic Therapy (PDT)

Photosensitizers that are typically employed in PDT are aromatic molecules, able to efficiently form long-lived triplet excited states. The latter display the potential to generate ROS with high quantum yields. In addition, these compounds should possess low energy absorptions, low toxicity *in vivo* and high selectivity towards biological target in order to avoid side-effects.

Due to the small singlet-triplet energy gap and to the forbidden nature of the radiative S<sub>1</sub> → S<sub>0</sub> transition, the dominant deactivation pathway of the fullerene photoexcited singlet state is S<sub>1</sub> → T<sub>1</sub> intersystem crossing. The quantum yield of triplet formation is close to unity for both C<sub>60</sub> and C<sub>70</sub> [61, 62]. The triplet excited state with lifetimes in the range of hundreds of microseconds is photoactive and gives rise to the formation of cytotoxic species such as O<sub>2</sub><sup>•-</sup>, <sup>•</sup>OH and H<sup>•</sup>. For instance, quenching of the fullerene triplet by oxygen through triplet-triplet annihilation is close to diffusion control:

The fact that the reverse process, i.e. quenching of the singlet oxygen by ground state fullerene, proceeds at a rate much lower than diffusion control, together with the low fluorescence quantum yield of fullerenes, makes this class of compounds good photosensitizers with a great potential in PDT [61].

The main drawback for the application of fullerenes as photosensitizers *in vivo* is

the lack of significant absorption at longer wavelengths. However, this disadvantage can be overcome when functional groups are appended that act as a “light harvesting” antenna. Indeed, this pathway was considered and reported first by Cheng and coworkers [63] and later by other authors [64].

To characterize fullerenes  $C_{60}$  and  $C_{70}$  as photosensitizers in biological systems, the generation of active oxygen species through energy and electron transfer was studied *in vitro* [60]. It was found that  $^1O_2^*$  is generated effectively in nonpolar solvents, such as benzene, whereas in water,  $O_2^{\cdot-}$  and  $\cdot OH$  were produced instead, especially in the presence of a physiological concentration of reductants including NADH. These redox active species were shown to contribute to the photoinduced DNA cleavage under physiological conditions.

The effect of the fullerene core substitution on singlet oxygen formation has revealed interesting trends [65]. The efficiency of singlet oxygen production from a series of fullerene derivatives – epoxides and diethylmalonate derivatives – was evaluated by measuring the near-IR emission at 1268 nm, which corresponds to the  $O_2(^1\Delta_g) \rightarrow O_2(^3\Sigma_g^-)$  transition. Overall, it was shown that functionalization of the fullerene core reduced the photodynamic activity. Fascinatingly, the effect was independent of the nature of the addend, but dependent on the number of addends. Higher degrees of functionalization, for example, lead to decreasing efficiencies of singlet oxygen production with greater effects imposed by adjacent addends compared to more remotely placed addends. Complementary studies showed that even multifunctionalized fullerene compounds, such as fullerol  $C_{60}(OH)_n$  ( $n > 18$ ) and fullerene-core star-like polymer,  $C_{60}[>N-CH_2CH_2(OCH_2CH_2OCH_3)]_6$ , are efficient  $^1\Delta_g$  generators *in vitro* [66]. Although the photophysical capabilities of fullerols have been shown to be reduced by hydroxylation, when compared to pristine  $C_{60}$ , sufficient photoactivity remains to trigger sizeable effects on aqueous systems [67]. Indeed, fullerol  $C_{60}(OH)_{24}$  has been shown to produce a mixture of singlet oxygen and superoxide under both visible and UV irradiation.

2

**R = CO(CH<sub>2</sub>)<sub>2</sub>CO<sub>2</sub>H (a)**

**R = H (b)**

**R = CO(CH<sub>2</sub>)<sub>2</sub>CO<sub>2</sub>H.NEt<sub>3</sub> (c)**

Fullerenes **2a** and **2c**, incubated with HeLa S3 cells, were shown to be cytotoxic upon irradiation [44]. Cells in the presence of fullerenes were not affected when not exposed to light. Compound **2b** was found to be noncytotoxic even when irra-

diated, possibly due to its lower water solubility compared to **2a** and **2c**. A reference compound lacking the fullerene moiety was inactive when incubated with cells and exposed to light. These interesting results were explained by the formation of singlet oxygen through fullerenes.

Li and coworkers reported a 2-fold proliferation of human cervix cancer cells incubated with liposome-encapsulated  $C_{60}$  and irradiated for a short period of time relative to unirradiated cells [68]. The authors concluded that the cancer cells were likely to be killed only if the laser power was above a certain threshold during the irradiation time, otherwise it would have promoted cell growth.

$C_{60}$  derivatives bearing poly(ethylene glycol) (PEG) chains were found to be cytotoxic to L929 cells, but only when photoirradiated with visible light – measurements in the dark disclosed no appreciable impact [69]. The authors considered the generation of singlet oxygen as the critical step. Moreover, cytochrome *c* was reduced when irradiated in the presence of the fullerene derivative and addition of SOD suppressed the cytochrome *c* reduction. However, when SOD, cytochrome *c* and the  $C_{60}$  derivative were administered all together to the cells, no change in cytotoxicity was noted that would have been caused by adding SOD.

**3**

PEG-modified  $C_{60}$  fullerene **3** was shown to accumulate in tumor tissues to a greater extent than in normal tissues upon intravenous injection into tumor-bearing mice, exhibiting prolonged  $C_{60}$  retention at the tumor tissue [70, 71]. Light irradiation that was applied after the injection of **3** significantly suppressed the volume increase of the tumor. The compound was basically released from the mice within 1 week.

Derivative **4** was not active at all up to concentrations of 50  $\mu\text{M}$ , whereas at higher concentrations the cell growth was inhibited – even in the absence of light [38]. The light-triggered oxidative properties of singlet oxygen were considered responsible for a series of biological activities exhibited by fullerene solutions.

**4**

In the search of new photosensitizers for PDT, the attachment of sugar moieties to the fullerene chromophores attracted considerable attention, since carbohydrates

play, in general, an important role in cell–cell interactions [72, 73]. Sugar-pendant monofunctionalized and bisfunctionalized fullerene derivatives were recently synthesized starting with carbohydrate-linked azides, and their photocytotoxicity against HeLa cells was studied [74]. The photosensitizing ability of the sugar-pendant derivatives to produce singlet oxygen in dimethylsulfoxide solution was demonstrated by the direct observation of the emission due to the  $O_2 (^1\Delta_g) \rightarrow O_2 (^3\Sigma_g^-)$  transition at 1268 nm. In agreement with the established trend that functionalization of fullerenes reduces the efficiency of singlet oxygen production [65], mono-adducts were shown to produce singlet oxygen with higher efficiencies than the corresponding bis-adducts. The cells were incubated for 12 h prior to the addition of photosensitizer and further incubated for an additional 6 h. After washing and irradiating with  $10 \text{ J cm}^{-2}$  of laser energy, cells were further incubated for 24 h before the numbers of living cells were counted by the MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] assay. Overall, the dark cytotoxicity of all investigated compounds was found to be quite small, while significant phototoxicities were observed for D-glucose, D-mannose and D-galactose derivatives bearing a single carbohydrate unit. However, D-xylose and maltose derivatives were less toxic despite the fact that comparable amounts of singlet oxygen were produced *in vitro*. Also, under the chosen experimental conditions the bis-adducts failed to display any meaningful phototoxicity, since they gave rise to poorer performance in terms of generating singlet oxygen than the analogous mono-adducts.

Recently, two new fullerene-bis-pyrophephorbide *a* derivatives, i.e. a mono-adduct **5** and a hexakis-adduct **6**, were synthesized and tested *in vitro* with regard to their intracellular uptake and photosensitizing activity towards human leukemia T lymphocytes (Jurkat cells) [75, 76].

5

The uptake of **5**, **6** and the reference compounds **7–9** by Jurkat cells was investigated with confocal laser scanning microscopy and by measuring the fluorescence intensity of cell extracts at the emission wavelength of pyrophephorbide *a*. The intracellular concentrations of fullerene complexes and **9** were 27 times lower than that of the free sensitizers after 24 h of incubation. They also showed slower

accumulation in cells. The authors rationalized these results on the basis of different uptake mechanisms – lipophilic molecules with molecular weights lower than 100 Da normally diffuse through the membranes, while bigger molecules, such as fullerene–sensitizer complexes **5** and **6**, and **9** can be taken up only by endocytosis or pinocytosis, which have slower kinetics than passive diffusion through cell membranes.

**Figure 11.2.** Hybrid nanotube rope controlling protein activity *in vivo* by near-IR radiation.

The phototoxicity of fullerene–sensitizer complexes was tested in comparison with the fullerene-free sensitizers. The rates of necrotic and apoptotic cells were determined 24 h after irradiation with a laser diode (688 nm,  $2.12 \text{ mW cm}^{-2}$ ). The fullerene complexes were found to be less phototoxic compared to the fullerene-free sensitizers **7** and **8**. This is mainly due to the high molecular weight of the fullerene complexes, leading to lower intracellular concentration.

The hexakis-adduct **6** showed significant phototoxic activity (58% dead cells after a dose of  $400 \text{ mJ cm}^{-2}$ , 688 nm), while the mono-adduct **5** showed very low toxicity even at higher doses of irradiation. The latter was attributed to a low intracellular uptake for **5** and to an efficient electron transfer process from the pyropheophorbide singlet state to the fullerene moiety, resulting in low yield of the intersystem crossing (ISC) and low quantum yield of singlet oxygen formation.

No dark cytotoxicity was found towards Jurkat cells after 24 and 48 h of incubation with all studied sensitizers.

Recently, it has been demonstrated that chemical reactions of importance for PDT could be directly activated by a hybrid carbon nanotube (CNT) rope consisting of two adjacent metallic CNTs, where one is filled, i.e. the peapod, and the other is empty [77]. Under electric bias, a substantial charge transfer from the entrapped metal ion to the fullerene cage in metallofullerenes occurs. In the CNT rope this process also involves the peapod and the twin (empty) CNT, thus the two CNTs become oppositely charged. This process can be partly inverted at elevated temperatures, since the metallofullerenes have levels close to the Fermi levels. In this way, by heating with near-IR excitation, recharging of the CNTs is expected that would result in a change of the local electric field and further to a deformation of proteins selectively attached to the CNT (Fig. 11.2).

#### 11.4.2

##### **Fullerene-mediated Electron Transfer Across Membranes**

Both  $C_{60}$  and  $C_{70}$  embedded within a lipid bilayer act as efficient electron acceptors at interfaces [78, 79]. Moreover, fullerenes can efficiently transport negative charges across membranes [80]. Mauzerall and coworkers have observed that transmembrane electron transfer takes place via electronic conduction mediated by fullerene aggregates [81]. The possible role of small fullerene aggregates, which act as an an-

tenna for collecting photons, in the presence of monomers was also discussed by Seta and coworkers [82]. In a study of the photoconductivity of ultra-thin bilayer lipid membranes doped with  $C_{60}$ , the authors suggested that since the extinction coefficient of the aggregated form is higher than that of the monomeric form, the absorption spectrum is dominated by the contribution of the aggregates. Thus, the energy absorbed by the aggregates is transferred to the monomers via singlet-singlet energy transfer and the excited monomers are then reduced by the donor species at the membrane interface. The reduction can take place either in the singlet excited state or in the triplet excited state of the fullerene. An alternative mechanism could be exciton-induced charge injection at the interface of the  $C_{60}$  aggregates with the bilayer membrane.

Photoinduced charge transfer across membranes has also been achieved in the composite assembly of  $C_{60}$  and CdS nanoparticles prepared by the Langmuir-Blodgett technique [83]. The CdS nanoparticles exciton emission was quenched due to efficient electron transfer from CdS nanoparticles to  $C_{60}$  across a lipid layer (2–3 nm). The fatty layer between  $C_{60}$  and CdS played an important role in preventing charge recombination in the composite assembly.

Amino acid derivatives of  $C_{60}$  were shown to penetrate through the lipid bilayer of liposomes without destroying the membrane integrity [84]. The L-isomer was able to diffuse through the phospholipid membrane into the liposome interior, whereas the D-isomer localized in the region of the outer membrane surface. These derivatives were also able to carry bivalent metal ions through phospholipid bilayers as a result of the formation of complexes. The study of the effects of the two stereoisomers on lipid peroxidation in mitochondria of rat cortex brain showed that  $C_{60}$ -L-Arg exhibits a prolonged inhibition in the malonaldehyde accumulation, whereas  $C_{60}$ -D-Arg led to no discernable effects on malonaldehyde accumulation. This data showed that amino acid derivatives of  $C_{60}$  affect membrane-bound enzymes. In particular, the L-isomer stimulates the catalytic activity of monoamine oxidase A (MAO) A, while the main action of the D-isomer is an increase in the catalytic activity of MAO B. It is worth pointing out that MAO is a known redox enzyme. This led to the postulate that the observed effect of the amino acid derivatives of  $C_{60}$  on the catalytic activity of MAO A and MAO B is due to an intra-protein electron transfer process.

10

11

Recently, fullerene derivatives **10** and **11** were studied as counteranions in the activation of oligo/polyarginine-anion complexes in living cells, and, thus, to modulate cellular uptake and anion carrier activity of oligo/polyarginines [85, 86]. The fact that cell-penetrating peptides (CPPs) are anion carriers and that bilayer pene-

tration is regulated by amphiphilic anions suggested that the carrier activity of oligo/polyarginines occurs via counterion exchange, which facilitates the reversible adaptation of their solubility to a changing environment. An efficient counteranion activator should, therefore, have one or more negative charges for ion pairing with guanidinium cations of the oligo/polyarginine. In addition, an amphiphilic character with large hydrophobic domains and an aromatic surface is expected to favor interactions with bilayer membranes. R-rich CPPs usually exist as complexes  $R_n(X)_m$  ( $X$  = hydrophilic counteranion) to minimize intramolecular charge repulsion and the exchange of the scavenged  $X^-$  with an activator  $Y^-$  yields the active complex  $R_n(X)_m'(Y)_m''$  at the membrane water interface. This active complex can then shuttle across the bilayer. In this respect, the activator  $Y$  should have also the ability to form stable, but labile, guanidinium anion complexes.

The key finding in the aforementioned study was that the efficiency of counteranion activators significantly depends on activator membrane and activator carrier interactions. Specifically, the activator efficiency was found to increase with increasing aromatic surface of the activator, decreasing size of the transported anion, increasing carrier concentration as well as increasing membrane fluidity. Fullerenes **10** and **11** were the most efficient counteranions in egg yolk phosphatidylcholine, where compound **10** showed an extraordinary  $EC_{50}$  value. Below the binding of one activator per carrier, fullerene activators acted at catalytic concentrations [86]. At high concentrations, fullerenes **10** and **11** became inhibitors of CPP uptake. However, in sol-phase dipalmitoyl phosphatidylcholine (DPPC) and in gel-phase DPPC, as well as in HeLa cells, the efficiency of the planar activators (pyrene and coronene) exceeded that of spherical activators (fullerenes and calixarenes). These results showed that spherical activators, particularly fullerene **10**, may specifically mediate CPP uptake.

The transmembrane extraction of fullerenes  $C_{60}$  and  $C_{70}$  across a membrane having  $\gamma$ -CDs as molecular recognition sites attached to a poly(vinyl alcohol) matrix was achieved [87].  $C_{60}$  molecules were transported from a feed aqueous phase, in which fullerene was rendered water soluble in the form of  $\gamma$ -CD: $C_{60}$  complexes, to a stripping organic phase such as toluene, xylene or tetralin. The high affinity of the fullerene  $C_{60}$  towards  $\gamma$ -CD allows their interfacial exchange and penetration into the membrane core. The loading of the membrane was confirmed by the observed color change of the membrane to magenta. During the first 20 h of the experiment the flux of permanent  $C_{60}$  rapidly reached a constant value. However, the membrane was far from saturation as the majority of the  $\gamma$ -CD cavities were unoccupied. It was suggested that steric hindrance due to crosslinking prevents the formation of the inclusion complex and the occurrence of a complex involving more than two  $\gamma$ -CDs due to the high local concentration of these moieties is possible. Moreover, small aggregates of fullerenes, which are surrounded by several CD cavities, were observed in the membrane. In this way the membrane acted as a reservoir of  $C_{60}$  molecules that were afterwards slowly released into the receiving solution. The rate-limiting step of the membrane transport was demonstrated to be governed by the dissociation of the inclusion complex at the stripping interface. This led to a low overall membrane transport flux.

The good electron acceptor properties of fullerenes stimulated studies on their possible applications as biosensors. A novel biosensor for the amperometric detection of glutathione was obtained by co-immobilizing a redox enzyme with a redox mediator (fullerene derivative **12**) realized at the glassy carbon electrode by the use of an amphiphilic pyrrole derivative **13** ( $n = 2$ ) [88]. The reversible reduction of **12**, which is entrapped within the poly-**13** film, was deduced from the coefficient of variation curves and the electron transfer was likely to occur via a vectorial charge-hopping mechanism involving neighboring fullerene molecules that are coupled to the diffusion of the counterions. The poly-**13**/**12**/GR film was investigated for its electrocatalytic properties. The biosensor showed a fast and reproducible response to glutathione.

A C<sub>60</sub>-containing lipid bilayer membrane was shown to function as a light-sensitive diode and to be useful for electrochemical biosensor electronic device developments [89].

The potential of glycosylated fullerene layers as biosensors for glycoproteins was reported [90]. The amphiphilic C<sub>60</sub> dendrimer conjugates **14** and **15** with one or two glucodendrion headgroups form stable, ordered monomolecular Langmuir layers at the air/water interface, which were further transferred onto quartz slides as X-type Langmuir–Blodgett films. The bulky glucodendrion headgroups were very effective in suppressing fullerene aggregation.

15

## 11.4.3

**Neuroprotective Activity via Radical Scavenging**

Excess production of superoxide and/or nitric oxide radicals, as well as nonradical  $\text{H}_2\text{O}_2$  and hypochloric acid, is considered as one of the primary initiators of neurodegenerative diseases. Endogenous cellular antioxidants, vitamin E analogs and SOD enzymes, have evolved in organisms – from bacteria to mammals – to inactivate low levels of free radicals produced under regular metabolic conditions. However, their antioxidant defense may be overwhelmed by ROS in the cells that are generated in the pathogenesis of a number of neuronal injuries and, as a result, they are no longer able to achieve meaningful therapeutic results.

In this respect, compounds that act as free radical scavengers were shown to reduce neuronal death. Fullerenes and related derivatives reveal promising antioxidant properties, i.e. their ability to react with multiple radical species at diffusion-controlled rates [91]. To this end, several  $\text{C}_{60}$  derivatives, including carboxyfullerenes [18, 35, 92–112], polyhydroxyfullerenes [113–116] and a limited number of other derivatives [19, 107, 117–120] have been investigated as neuroprotective agents.

In particular, two different tris-adducts,  $\text{C}_3$  (16) and  $\text{D}_3$  (17), of  $\text{C}_{60} \cdot [\text{C}(\text{COOH})_2]_3$ , have been confirmed to be the most promising compounds for preventing neuronal damage [35, 92]. The presence of six carboxylic functional groups improves the solubility in biological media and avoids the fullerene aggregation that is commonly encountered in polar solvents. As a result of an improved intercalation into biological membranes, the  $\text{C}_3$  isomer has been studied in more detail. These studies demonstrated that the  $\text{C}_3$  isomer is an excellent radical scavenger, which reacts both with hydroxyl radicals,  $\cdot\text{OH}$ , and  $\text{H}_2\text{O}_2$  at micromolar concentrations [35, 93].

Dugan and coworkers also evaluated the ability of  $\text{C}_3$  to eliminate superoxide generation in intact cells [94]. Using confocal microscopy and a superoxide-sensitive fluorescent compound, dihydroethidium, they determined that this iso-

mer can reduce basal mitochondria production of superoxide in cortical astrocytes and neurons. In addition,  $C_3$  blocks iron-induced lipid peroxidation *in vitro* [92] and *in vivo* [95]. The free radical nitric oxide, produced by three different synthase isoforms and responsible for the generation of citrulline, is also an important effector molecule in immune and cardiovascular system.

Although Dugan and coworkers have found that  $C_3$  is unreactive with  $NO\cdot$  itself, in another study [96] carboxyfullerenes **16** and **17** were shown to exert some inhibition on the three synthases. This work also substantiated a reduction in the level of nitric oxide production and the rate of citrulline formation. However, this effect was attributed to interactions of the fullerene molecules with the enzyme and not to their properties as radical scavengers. The same authors also reported that these compounds inhibit the Arg-independent nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity of one of the synthase isoforms without affecting its catalyzed cytochrome *c* reductive activity.

To explore the neuroprotective and cytoprotective properties of the malonic acid tris-adducts, Dugan and coworkers prepared neocortical cell cultures from fetal (E15) Swiss-Webster mice (Simonson). These were subjected to tests with different antioxidants after carrying out a brief exposure to *N*-methyl-D-aspartate (NMDA) [97]. Both the  $C_3$  and  $D_3$  isomers produced a dose-dependent decrease of the excitotoxic death of cultured cortical neurons.  $C_3$  fully blocked NMDA receptor-mediated toxicity at 100  $\mu$ M concentration, showing greater protection and efficacy against acute toxicity initiated by brief (10 min) exposure to high-dose NMDA. This isomer also provided protection against AMPA ( $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptor-mediated injury in neurons [35] and oligodendroglia [98], the cell type responsible for central myelin formation. The authors stressed that the observed behavior not only reflects the antioxidant properties of the compound, but other features of the molecule, e.g. its amphiphilic nature.

Moreover, the carboxyfullerene **16** limited apoptotic neuronal death produced by several insults, including serum deprivation and exposure to the Alzheimer's peptide  $A\beta_{1-42}$  [18], and has shown robust neuroprotection in a number of other cell culture models of neurological disease including Parkinson's disease [35].

In a study of neurotoxin-mediated death of dopamine neurons, the same authors have pursued the concept that carboxyfullerene derivatives could block the toxic effect of the neurotoxins 6-OHDA (6-hydroxydopamine) and  $MPP^+$  (1-methyl-4-phenylpyridinium). 6-OHDA and  $MPP^+$  are widely used to generate animal models of Parkinson's disease, since after administering *in vivo* they cause Parkinsonian conditions. Parkinsonian conditions are marked by decreased dopamine

levels and tyrosine hydroxylase activity, impaired dopamine uptake, and an ensuing loss of dopaminergic neurons. With regard to oxidative injuries, the  $C_3$  isomer dramatically rescued dopaminergic neurons from 6-OHDA-induced cell death in a dose-dependent manner (92% recovery at the highest dose), whereas it quickly plateaued in the case of MPP<sup>+</sup> (37.5% recovery). Concentrations of  $C_3$  in excess of 100  $\mu$ M were found to be cytotoxic [99]. The  $D_3$  isomer was also found to be protective against 6-OHDA injury and MPP<sup>+</sup>-mediated death, but to a lesser extent than the  $C_3$  isomer. The  $C_3$  isomer proved more effective than the dopaminergic neuroprotectant glial cell line-derived neurotrophic factor (GDNF) in rescuing dopamine neurons from 6-OHDA- or MPP<sup>+</sup>-mediated cell death.

A parallel assay that focused on utilizing the two isomers,  $C_3$  and  $D_3$ , of tris-adducts, among other antioxidant agents, showed that these fullerene derivatives inhibited apoptosis of human hepatoma HEP-3B cells, induced by transforming growth factor (TGF)- $\beta$  [100]. The mechanism of action is supposed to be indirect, because all other actions induced by TGF- $\beta$  remained, surprisingly, unaltered.

The same carboxyfullerenes have been demonstrated to protect human keratinocytes from apoptosis induced both by UV-B irradiation and exposure to deoxy-D-ribose [101]. However, **16** and **17** failed in preventing the downregulation by UV-B light of the Bcl-2 levels. This suggested that these compounds protect human keratinocytes from UV-B damage via generation of ROS from depolarized mitochondria without the possible involvement of Bcl-2.

The same group of authors reported the protective activity of carboxyfullerenes against oxidative stress-induced apoptosis in human peripheral blood mononuclear cells [102]. Two models of apoptosis were used – one, induced by 2-deoxy-D-ribose, a reducing sugar capable to induce oxidative stress and glutathione depletion, and second, induced by tumor necrosis factor (TNF)- $\alpha$  plus cycloheximide. In both models, the studied fullerene derivatives were able to inhibit apoptosis, likely acting as an antioxidant drug and partially preventing the depolarization of mitochondrial membrane potential as in the case of keratinocyte cells [101].

In another study, the  $C_3$  isomer was shown to inhibit lymphotoxin- $\beta$  receptor-mediated apoptosis signal-regulating kinase 1 activation in Hep3BT2 cells treated with LIGHT-R228E [103].

In recent work, Prato and coworkers synthesized and investigated a water-soluble fullerene derivative **18** that bears three ethylene glycol chains and three ammonium groups for increasing the water solubility as a potential neuroprotecting agent [19]. This compound was designed as a monofunctionalized derivative in order to resemble the free radical scavenging ability of pristine  $C_{60}$ , as it is known that higher numbers of addends on the fullerene moiety decreases its radical scavenging features [91]. As observed by UV-vis spectroscopy, this mono-adduct showed aggregation at concentrations higher than  $10^{-5}$  M not only in water, but also in water/ethanol and water/dimethylformamide mixtures. In a series of spectrophotometric assays employing the xanthine/xanthine oxidase system for the generation of superoxide radicals and ferricytochrome *c* reduction for measuring superoxide concentration, this new fulleropyrrolidine derivative did not show a significant re-

18

action with  $O_2^{\cdot-}$ . In a neuroprotection model, in cerebral cortical cell death induced by glutamate, the compound was not only found to be ineffective, but also showed a significant concentration-dependent toxicity. The authors explained this undesirable toxicity by the lipophilic character of the derivative, which coupled with its hydrophilic part confers surfactant properties favoring its interaction with cell membranes, with their possible disruption and subsequent cell death. An important conclusion from this work is that the neuroprotective activity of  $C_{60}$  derivatives correlates more with the number of substitutions than with their nature. Increased number of polar groups on  $C_{60}$  probably prevents its interaction with the cell membrane and, consequently, effects its disruption.

Although *in vivo* studies bear great importance for understanding how well the neuroprotective activity of novel antioxidant agents – observed in cell cultures – translates to an intact organism, only a limited number of *in vivo* studies have been published in this field so far [35, 92, 94–95, 109]. Continuous intraperitoneal infusion of **16** into a transgenic mouse model of ALS, carrying the human mutant (G93A) SOD gene responsible for a form of familial ALS, delayed both death and functional deterioration [35]. The initial *in vivo* studies of two models of Parkinson's disease have shown that **16** when co-injected with iron, intrastrially injected to produce striatal injury, reduced dopamine depletion [95]. A first proposed rationale prompts the ability of **16** – once injected – to reduce injury, reflecting its interaction either directly with iron or direct involvement in lipid peroxidation. A second model, in which **16** was delivered systemically for 1 month to rats intrastrially injected with 6-OHDA to provoke Parkinsonian conditions, indicated that dopaminergic terminals and behavior were significantly improved by  $C_3$  treatment [94]. Due to their antioxidizing action,  $C_3$  tris-adducts also prevent iron-induced stress in rat brain, and lipid peroxidation induced by superoxide and hydroxyl radicals [95, 109].

Towards the goal of reducing the oxidative stress in brain damage, the neuroprotective effect of carboxyfullerenes on transient focal ischemia reperfusion injury was recently studied in rat brains [95, 104]. Carboxyfullerene was administered either intravenously or intracerebroventricularly to chloral hydrate-anesthetized Sprague-Dawley rats 30 min prior to transient ischemia reperfusion. The data

showed that intravenous injection did not inhibit the reperfusion injury. This is likely due to the limited permeability of this compound to the blood–brain barrier. In contrast, pre-treatment with local carboxyfullerene-attenuated cortical infarction prevented both elevated lipid peroxidation and depleted glutathione (GHS) levels in the infarcted cortex induced by transient ischemia reperfusion. Adverse behavior changes were simultaneously observed in rats receiving intracerebroventricular infusion of carboxyfullerene, including writhing accompanied by trunk stretching and even death.

Intravenous administration of hexasulfobutylated  $C_{60}$  (FC4S) has been found to reduce the total volume of infarction produced by transient ischemia reperfusion in rat brain [117].

The redox properties of carboxyfullerenes correlate with another interesting activity exhibited by this class of compounds – they were shown to inhibit bacterial meningitis [105, 106]. The effect of the  $C_3$  isomer on the regulation of brain inflammatory responses after intracerebral injection of *Escherichia coli* in B6 mice that induced TNF- $\alpha$  and interleukin (IL)-1 $\beta$  production and recruited neutrophil infiltration at 6–9 h post-injection was studied [106]. Pre-treatment of each mouse with  $C_3$  protected 40% of mice in a dose-dependent manner. Fullerene-treated showed less TNF- $\alpha$  and IL-1 $\beta$  production compared with the levels of production for non-treated mice. TNF- $\alpha$  and IL-1 $\beta$  production is typically detected in the cerebrospinal fluid of patients infected with bacterial meningitis and in experimental animals. The authors conclude their work by ascribing the inhibition of *E. coli*-induced meningitis not due to direct antimicrobial activity, since  $C_3$  did not exhibit the growth of *E. coli* in LB broth culture. Moreover, the *E. coli* cells were cleared from the brain after 24 h in fullerene-treated mice. At the same time they were found to replicate significantly in untreated mice. This leads to the suggestion that  $C_3$  might have enhanced the natural antibacterial defense in the brain. A series of similar fullerene mono- and bis-adducts was also able to suppress *E. coli* growth [105, 107].

Some cationic fullerene derivatives were found to exhibit bacteriostatic effects [118, 107].  $C_{60}$ -bis(*N,N*-dimethylpyrrolidinium iodide), for example, in low concentrations inhibits *E. coli* growth and dioxygen uptake caused by *E. coli* and glucose [119], whereas at high concentrations dioxygen was consumed and converted to  $H_2O_2$ .

Derivative **16** was tested *in vitro* against apoptotic neuronal death in rat cerebellar granule cells [108]. Cerebellar granule cells represent one of the best *in vitro* models of neuronal apoptosis, both for the mitochondria and the nucleus, which is strictly related to the generation of ROS.

Dugan and coworkers studied the effect of polyhydroxy fullerols  $C_{60}(OH)_n$  ( $n = 6–15, 24$ ) on apoptotic death of culture neurons and found that these compounds reduced excitotoxic and apoptotic death of cultured neurons by 80% following NMDA treatment [113].

Polyhydroxylated fullerols also display excellent efficiency in quenching superoxide radicals ( $O_2^{\cdot-}$ ) generated by xanthine/xanthine oxidase [114]. The same fullerols  $C_{60}(OH)_n$  ( $n = 6–15$ ) were shown to attenuate bronchoconstriction induced

by the xanthine/xanthine oxidase system in guinea pigs [115]. The intratracheal instillation of xanthine/xanthine oxidase caused a marked decrease in dynamic respiratory compliance, which was significantly reduced by these fullerenes [116].

Whereas carboxyfullerenes were indicated as effective neuroprotection against excitotoxic cell death, apoptosis initiated by several different types of triggers and metabolic insults in cultured cells, the molecular mechanism behind the antioxidant reactions of  $C_{60}$  compounds, particularly the mechanism of  $O_2^{\cdot-}$  removal by malonic acid  $C_{60}$  derivative, remains controversial. Krusic and coworkers first suggested that direct reactions between radical species and the highly conjugated double-bond system of  $C_{60}$  were responsible for the antioxidant action of carboxyfullerenes and attributed this property to their delocalized  $\pi$  system [91]. The spherical structure of  $C_{60}$  was also believed to increase the reactivity towards free radicals compare to that of the planar aromatic and polyene compounds. The study by Bensasson and coworkers [110], however, failed to detect a  $C_{60}$  radical intermediate in the reaction of  $C_3$  and several other malonic acid derivatives with  $O_2^{\cdot-}$ . In addition, no correlation was found between the  $IC_{50}$  values and the reduction potentials of various carboxyfullerenes [111]. A recent study of SOD mimetic properties of **16** has made a step forward showing that the reaction between **16** and the superoxide is not via stoichiometric scavenging, where  $O_2^{\cdot-}$  donates an electron to  $C_{60}$ , but through catalytic dismutation of superoxide [112]. The catalytic mechanism was indicated by the time invariability of the concentration and structure of **16** during the exposure to a continuous flux of  $O_2^{\cdot-}$ , produced by xanthine/hypoxanthine metabolism, regeneration of oxygen, production of hydrogen peroxide, as well as absence of paramagnetic intermediate products, detectable by electron paramagnetic resonance (EPR) spectroscopy. In particular, a mechanism has been proposed in which electron-deficient areas on the  $C_{60}$  sphere work in concert with the malonyl addends to electrostatically guide and stabilize superoxide, promoting dismutation. The latter process occurs at a rate of  $2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ , approximately 100-fold slower than what is known for SOD, but within the range of several biologically effective, metal-containing SOD mimetics. To determine whether **16** is capable of acting as a SOD mimetic *in vivo*, the authors tested its efficacy in *Sod2*<sup>+/-</sup> mice, which lack expression of mitochondrial manganese SOD (MnSOD) and found that treatment with this compound increased the lifespan of mice by 300%. These data, coupled with the evidence that **16** localizes to mitochondria [34], suggested that the  $C_3$  isomer functionally replaces MnSOD, acting as a biologically effective SOD mimetic.

#### Enzyme Inhibition and Antiviral Activity

The inhibition of enzymes by fullerene derivatives became one of the most important fields of biological application of fullerene since the publication of milestone works in 1993 [44, 121]. Tokuyama and coworkers reported the inhibition of papain, cathepsin, trypsin, plasmin and thrombin by derivative **3**, while Wudl's group described the inhibition of HIV protease (HIV-P) by compound **19**.

19

The HIV-P is one of the key enzymes in HIV replication. This protease bears a hydrophobic cavity, whose diameter is about 10 Å, in which two catalytic aspartic acid residues are present. Considering the dimensions of C<sub>60</sub>, this fullerene is a perfect match for the cavity size of HIV-P. Furthermore, the presence of C<sub>60</sub> might prevent interactions between the catalytic portions of HIV-P and any virus substrates. The inhibition constant ( $K_i$ ) of compound **19** is 5.3 μM *in vitro*, but fullerene derivatives with positive charges, able to interact with the aspartic negative residues, are expected to raise the binding constant up to 1000 times and consequently dramatically decrease the  $K_i$  [121].

Although current therapy against HIV infection utilizes HIV-P inhibitors active at nanomolar and subnanomolar concentrations, the potential use of fullerene derivatives can be taken into account considering the common problem of resistance versus the used drugs – a phenomenon partially caused by the tendency of the virus to present frequent genetic mutation.

A selection of fullerene derivatives was studied by Schuster and coworkers as potential inhibitors of HIV on human peripheral blood mononuclear cells infected with HIV-1 and three of these compounds presented an EC<sub>50</sub> in the range of 0.9–2.9 μM [122]. In the same way, a peptidic fullerene bearing the C-terminal sequence of peptide T, which is able to activate chemotaxis of human monocytes through CD4/T4 antigen and to inhibit HIV-P activity, was prepared by Toniolo and coworkers [123].

Better results were achieved with compound **1** [124] and the *trans-2* isomer of **20** [125]. In both cases the EC<sub>50</sub> was 0.2 μM. Is it interesting to note that, in the cases of bis-adducts, the regioisomers are not equally active, with the *trans-2* regioisomers presenting the highest activity among the studied compounds [125, 126].

Recently, the same salts (**20**) have been used, together with fulleropyrrolidine **21**, to study the inhibition of HIV reverse transcriptase – yet another enzyme that plays a determinant role in the HIV replication. The results obtained are outstanding. In fact, the IC<sub>50</sub> of derivative **21**, bearing three carboxylic functions, is 100 times lower than nevirapine. Interesting results have also been obtained on hepatitis C virus RNA-dependent RNA polymerase when assaying the same derivative [127].

Other important biological enzymatic targets blocked by fullerene derivatives are glutathione-S-transferase, P450-cytochrome-dependent monooxygenases, plasmatic reticulum enzymes of hepatic cells and mitochondrial ATPase in the process of oxidative phosphorylation [128, 129].

The inhibition of all the three forms of nitric oxide synthase (NOS), i.e. neuronal, epithelial and inducible, has been found by trimalonic tris-adducts of C<sub>60</sub>, mainly C<sub>3</sub> (16) and D<sub>3</sub> (17) [96]. The same compounds have been reported as potential inhibitors of  $\beta$ -lactamase [130].

#### 11.4.5

##### Antibacterial Activity

One of the first experiments developed to study the effect of fullerene derivatives on bacteria was performed in 1996 [16]. Derivative 22 was tested on *Candida albicans* (eukaryote), *Bacillus subtilis* (Gram-positive bacterium), *E. coli* (Gram-negative enteric bacterium) and a clinical isolate strain 261/6 of *Mycobacterium avium* (acid-fast, emerging pathogen resistant to most antimicrobial drugs) with promising results. No particular reaction mechanism was demonstrated for this action, but the disruption of the cell wall was hypothesized.

Further studies on the antibacterial activity of fulleropyrrolidinium salts have been reported [118]. Lately, however, attention has been re-focused on bis-adduct mixtures (Fig. 11.3), which demonstrate bacteriostatic effects on *E. coli* and the inhibition of oxygen uptake. In this context, blocking the energy metabolism seems to be the mechanism of action [107]. Additional studies on antimicrobial PDT have

Figure 11.3. Mono-, bis- and tris-*N,N*-dimethylfulleropyrrolidinium salts.

been performed, testing the same mixture of cationic bis-adducts, cationic fullerene and a combination of tris-adducts/parent mono-adduct (Fig. 11.3). In this particular case a very interesting selectivity for microbes (*Staphylococcus aureus* and *E. coli*) over mammalian cells was demonstrated [131]. At present, the question remains if the reaction mechanism involves the formation of singlet oxygen or the generation of hydroxyl and superoxide radicals.

The *trans*-2 and *trans*-4 *N,N*-dimethyl-bisfulleropyrrolidinium salts exhibit their antibacterial action by inhibition of the respiratory chain, with a biphasic effect on oxygen uptake [132]. A fullerene derivative concentration up to 5  $\mu\text{M}$  decreases the oxygen uptake, while at higher concentrations of  $\text{C}_{60}$  salts, an increase of oxygen uptake is found and oxygen is converted to  $\text{H}_2\text{O}_2$  correspondingly. Fascinatingly, irradiation with light did not affect the results at all. In terms of mechanistic aspects this observation indicates that the electron transfer from the respiratory chain to  $\text{C}_{60}$  is independent of light.

Another water-soluble derivative, i.e. one that bears six sulfo-butyl chains, inhibits environmental bacteria. In contrast to the preceding studies, the noted effects have been ascribed to singlet oxygen – produced by photoexcitation. Apparently, in this case, the multifunctionalization does not seem to alter the yield of singlet oxygen formation with respect to comparable mono-adducts. Its incorporation into coated polymers and their subsequent irradiation with fluorescent visible light leads to germicidal effects on *E. coli* [133].

Very recently, the utilization of  $\text{C}_{60}$  water suspension, also called nano- $\text{C}_{60}$ , was reported in studies on cell association and toxicity versus *E. coli* and *B. subtilis* [2]. For the first bacterium, the minimum inhibitory concentration (MIC) was 0.5–1  $\text{mg L}^{-1}$ , while for the bacillus it is slightly higher (1.5–3.0  $\text{mg L}^{-1}$ ). The presence of this nano- $\text{C}_{60}$  inhibits bacterial growth independent of the presence of light, both in aerobic and anaerobic conditions [134]. Notably, higher concentrations of fullerenes were detrimental to the antimicrobial action because of aggregating nanoparticles, followed by subsequent precipitation that consequently causes the reduction or loss of activity [2].

A different group of fullerene derivatives with good potential antibacterial activity is represented by fulleropeptides. Amino acid  $\text{C}_{60}$  derivative **23** has been utilized in solid-phase synthesis for the preparation of derivative **24**. It was tested on *S. aureus* and *E. coli*, with MICs of 8 and 64  $\text{mM}$ , respectively [135, 136].

#### 11.4.6

#### Fullerenes as Nanodevices in Monoclonal Immunology

Recent studies with antibodies of the IgG isotype focused specifically on  $C_{60}$  derivatives conjugated to bovine thyroglobulin [137–139]. Such work pointed towards the potential of fullerenes in the development of nanodevices applicable in monoclonal immunology. However, only a limited number of reports on the use of fullerenes in this field have appeared so far.

To produce an antibody with specificity to fullerenes, Chen and coworkers [137] successfully linked water-soluble fullerene derivatives to large foreign proteins – including bovine thyroglobulin, and bovine and rabbit serum albumin. Immunization of mice with these  $C_{60}$ –protein conjugates produced a polyclonal immune response comprised of IgG antibodies specific for  $C_{60}$  fullerene and a subpopulation that crossreacted with a  $C_{70}$  derivative. This study showed for the first time that the immune system could recognize and process fullerenes as protein conjugates, and display the processed peptides for recognition by T cells to yield IgG antibodies. Later [138], the sequences of light and heavy chains of this IgG antibody were determined. Using X-ray crystallography of its Fab' fragment, it was found that the binding cavity was formed by the clustering of hydrophobic amino acids, several of which participate in stacking interactions with the fullerene core. Alternatively, weak hydrogen bond interactions between the fullerenes and the antibodies are considered to contribute to the  $C_{60}$ –antibody complex stability. Molecular dynamics simulation studies revealed that the fullerene molecule in the corresponding  $C_{60}$ –antibody complex is readily accommodated in the suggested binding site of the antibody [139]. In particular, an eminent trend towards predominant surroundings by hydrophobic amino acid side-chains, which are involved in  $\pi$ -stacking interactions with the fullerene molecule, evolves. Moreover, fullerenes inside the binding site undergo a small relative translational motion and a much larger rotation motion. However, no favored axis of rotation was found to exist. About 17% of the surface is exposed to the solvent that might potentially be used for functional derivatization.

The discovery that the mouse immune repertoire is diverse enough to recognize and produce antibodies specific for fullerenes has allowed the indirect determination of the distribution of fullerenes within a cellular environment. For the first time, Foley and coworkers reported that the water-soluble fullerene derivative  $C_{61}(CO_2H)_2$  is able to cross the cell membrane and to bind preferentially to the mitochondria [34]. The finding that fullerenes locate close to this organelle indicates the protective effects of fullerenes, in general, with respect to ROS [35].

Furthermore, the selective binding of proteins to carbon nanostructures has been extended from fullerenes to CNTs [140–142]. For example, particular antigens have been attached to the CNT walls, while retaining their conformation and thereby inducing an antibody response with the right specificity [143].

Erlanger, Chen and coworkers have shown that the monoclonal IgG  $C_{60}$ -specific antibody recognizes and specifically binds to aqueous suspensions of single-wall CNT (SWNT) bundles [144]. The authors considered these findings to have practical application. For example, the antibody-coated SWNTs can be used as probes of cell or membrane function. The antifullerene antibody on the surfaces of CNTs can be covalently decorated with probes of cell function, e.g. redox or luminescent probes, and after insertion, the probe molecule can be optically excited or electrically addressed via the conducting SWNT wire.

Using a polymer coating that is receptive to selected proteins, while rejecting others, is an elegant way to render nanotubes capable of interacting selectively with biomolecules. A variety of polymer coatings and self-assembled monolayers (SAMs) have been used to prevent nonspecific binding of proteins on surfaces for biosensor and biomedical device applications [145]. Among the coating materials, PEG is one of the most effective and widely used polymer materials that irreversibly adsorbs onto SWNTs. In this context, it has been shown that the protein streptavidin adsorbs spontaneously onto multiwalled CNTs (MWNTs) via hydrophobic interactions and thereby forms close packs. On the contrary, in the case of SWNTs that are coated with a surfactant and PEG, the protein nonspecific binding is prevented. A feasible way to circumvent this problem and to achieve selective binding involves the co-functionalization of SWNTs with PEG and biotin [146]. Surfactants, such as Triton X-100 or Triton X-405, that are prior adsorbed onto the surface of SWNTs as a wetting layer, significantly enhance the PEG adsorption and, thus, lead to high resistance of CNTs to the nonspecific binding of streptavidin. In the final step biotin was added through the covalently linkage of amine-terminated PEG chains and amine-reactive biotin reagents – biotinamidocaproic acid 3-sulfo-*N*-hydroxysuccinimide ester. For CNTs that are coated with Triton/PEG–biotin, selective binding of streptavidin was revealed by the high density of adsorbed proteins along the CNTs after exposure to a streptavidin solution. No appreciable adsorption was seen when CNTs functionalized in the same manner were exposed to streptavidin plugged with four equivalents of free biotin. These results demonstrate that functionalization of CNTs is one way to achieve specific protein recognition, while eliminating or minimizing nonspecific protein binding, and, thus, this has important implications for the biocompatibility of CNTs and specifically for the development of potential bioelectronic devices that integrate CNTs [147].

The design of selective piezoelectric crystal immunosensors that assist in the detection of IgG and hemoglobin in aqueous media utilizing water-soluble immobilized C<sub>60</sub>-antibodies as coating material has recently been demonstrated successfully [148]. The piezoelectric biosensors were prepared by coating C<sub>60</sub> fullerene from a toluene solution of poly(vinyl chloride) and C<sub>60</sub>, using spin coating at 10 cycles s<sup>-1</sup> (Hz) and subsequent adsorption of the antibodies.

The prepared biosensors exhibited linear frequency responses to the concentration of human IgG and hemoglobin with sensitivities of  $1.25 \times 10^2$  and  $1.56 \times 10^4$  Hz (mg mL)<sup>-1</sup> and reveal detection limits of 10<sup>-4</sup> mg mL<sup>-1</sup>. The optimal conditions for the IgG sensor were found at pH 6.7 and 30 °C. Important implications from the findings are that species such as urea, uric acid, cysteine, tyrosine and ascorbic acid imposed no interference on the biosensor activities. This corroborates the high selectivity.

##### Fullerenes as Radiotracers

Encapsulating metal atoms inside the fullerene interior bears promising prospects for biomedical applications that might lead ultimately to nanodevices for diagnostic and therapeutic nuclear medicine. The rigid structure of the fullerene cage protects the encapsulated metal ion from external chemical attack and toxic metal ion release *in vivo*. Wilson and coworkers have, for example, demonstrated the feasibility of metallofullerenes as *in vivo* radiotracers [149]. Biodistribution studies of <sup>166</sup>Ho<sub>x</sub>@C<sub>82</sub>(OH)<sub>y</sub> in mice over a 48-h period showed selective localization of the tracer in the liver, but with continued slow excretion as well as retainment in the bone.

The same group has explored the concept of utilizing the nontoxic scaffold of C<sub>60</sub> for the development of new X-ray contrast agents [150, 151]. Like other contemporary contrast agents (25), the C<sub>60</sub>-based agents use iodine active X-ray attenuating vehicles. However, these compounds take advantage of the unique structure of fullerene. For instance, in contrast to the disk-like shape of contemporary contrast agents, the inherited globular shape of the fullerene-based contrast agent reduces viscosity in clinical formulations, which allows rapid intravenous injection of the agent. The fullerene core may also block one side of the tri-iodinated phenyl rings in 26 and 27 from having hydrophobic interactions with blood plasma proteins, and, thus, would lead to decreased protein binding and increased *in vivo* tolerability. Additionally, the existence of more than three iodine atoms will allow lower concentrations of contrast agents to be used.

Gadolinium-containing metallofullerenes have recently emerged as a new generation of magnetic resonance imaging (MRI) contrast agents. This development is driven, largely, by the high proton relaxivities of these metallofullerenes and the complete lack of Gd<sup>3+</sup> release under metabolic conditions. The most extensive study on the potential of gadofullerenes has been carried out by Wilson's group. Recently, they reported the synthesis and *in vivo* biodistribution study of the first water-soluble Gd@C<sub>60</sub> derivative [152–154]. The respective malonate derivative

$\text{Gd@C}_{60}[\text{C}(\text{COOH})_2]_{10}$  was found to possess a relaxivity ( $4.6 \text{ mM}^{-1} \text{ s}^{-1}$  at 20 MHz and  $40^\circ \text{C}$ ) comparable to that of commercially available Gd(III) chelate-based MRI agents. Moreover, an *in vivo* MRI biodistribution study revealed that  $\text{Gd@C}_{60}[\text{C}(\text{COOH})_2]_{10}$  is the first-water soluble endohedral metallofullerene with decreased uptake by the reticuloendothelial system (RES) and facile excretion via the urinary tract, consistent with its lack of intermolecular aggregation in solution.

Other polyhydroxyl derivatives of gadolinium-containing metallofullerenes and endohedral fullerenes with a series of lanthanide metal ions for  $\text{M@C}_{82}(\text{OH})_n$  ( $\text{M} = \text{La}, \text{Ce}, \text{Dy}, \text{Er}$ ) [155] have also been proposed as potential MRI agents, with  $\text{Gd@C}_{82}(\text{OH})_2$  being the most efficient relaxing agent [156, 157].

Studies by Dorn and coworkers are currently focusing on the development of trimetallic nitride templated endohedral metallofullerenes as a powerful, new generation of imaging contrast agents and radiotracers. These endohedral fullerenes are designed at the nanoscale level with improved contrast features as well as multi-

modal imaging potential (X-ray, MRI). Recent milestones in the development of tri-metallic nitride templated endohedral metallofullerenes involve the synthesis of a lutetium-based series of mixed metal species of gadolinium/lutetium and holmium/lutetium  $\text{Lu}_{3-x}\text{A}_x\text{N}@C_{80}$  ( $x = 0-2$ ) endohedral metallofullerenes [158], and the subsequent functionalization of both diamagnetic  $\text{Sc}_3\text{N}@C_{80}$  and paramagnetic  $\text{Er}_3\text{N}@C_{80}$  [159].

#### 11.4.8

##### Fullerenes as Vectors

Finally, biological use of fullerenes should be discussed that finds frequent mention over the years, but has only been scarcely pursued, i.e. the application of  $C_{60}$  as a drug vector. In particular, the hydrophobic nature of fullerenes should expedite membrane crossing. The paclitaxel fullerene derivative **28** has been prepared by Wilson and coworkers, who design a  $C_{60}$ -based slow release system of paclitaxel for a liposome aerosol delivery system in lung cancer treatment [160].

This initial work shows the first attempts to use fullerenes in pro-drug design and synthesis, while derivative **29** was the first compound – and up to now the only one – utilized to transfect DNA materials into cells [161]. The presence of four positive charges is particularly promising in light of facilitating DNA binding through electrostatic interactions with the phosphate groups of the oligonucleotide, but without specific recognition of the bases. The cells take up the complex through phagocytosis, triggering the release of duplex DNA in the cells.

## 12 Nanotechnology for Biomedical Devices

*Lars Montelius*

### 12.1 Introduction

The pace of employment of advanced microfabrication technology for realizing biomedical devices has been accelerated with the development of a seemingly never-ending increased packing density of functionalities in semiconductor chips [1] as a consequence of the downscaling of device dimensions in such chips [2]. This area of microelectronic development has been one of the major drivers in the development of our modern, technological society. However, this success has not only been brought to us by simple dimensional downscaling, but also by impressive developments in the fields of material sciences that have led to several new basic material discoveries [3–5]. Such inventions have, in turn, been brought into the engineering sciences, realizing these devices into everyday life. One can especially think about the invention of the concept of hetero-structures, making it possible to fabricate semiconductor lasers and optical detectors – the key to modern fiber optic-based communication [4–7]. In the area of biomedical devices, the development in material sciences has brought diagnostic tools such as computer-based imaging systems relying on the interplay between tissue and X-rays, magnetic radiation and ultrasound, etc. [8–10]. We have also witnessed various electronic devices being developed for enhancing impaired senses such as hearing aids, etc. Several devices have made life easier for those suffering from glucose-related diseases, for example [11, 12]. Handheld devices have been developed allowing individuals to monitor the sugar content of their blood in their own environment and, hence, also permitting the use of insulin delivery when needed.

With the introduction of nanotechnology for fabrication of significantly down-scaled materials, we are now facing another even more rapid development. These materials do not only occupy an immensely small volume, but they also possess certain functions being created just due to the reduction in size [4–7, 13–15]. A conservative and often heard definition of nanodevices is that at least one of the scalar dimensions is below 100 nm and that the functionality of the device itself is changed due to its nanometer size.

The development of microfabrication methods and technologies in the nanometer domain is considered by many people not only to be a simple evolutionary step, but also to have a more revolutionary aspect [13, 15]. Basically, this is achieved through the downscaling that led not only to an added packing density of functions, which means higher modality, but also to objects with certain unique properties. Such evolution has not yet been experienced by mankind on any large scale and right now we are in the middle of it. Although we have developed a lot of new tools for fabrication, characterization, imaging and manipulation of matter at the nanoscale [15–25], we must still consider ourselves to be in a time rather similar to the “hammer and sledge” stage in the stone-age. Nevertheless, we have already experienced an enormous impact in many of today’s consumer products, e.g. recently a new cellular phone was announced having silver particles on its surface, killing bacteria and germs [26]. During the 5 last years we have also seen the introduction of various kinds of garments making the fabric more or less impossible to stain [27]. Recently, nanotechnology-based methods have been implemented to spin fibers, creating possibilities for enhanced fabrics having built-in intelligent functions [28]. Today we can buy self-cleaning windows that use a catalytic process to break down inorganic dirt that will eventually be washed off the window during next rain fall [29]. We can tailor-make surfaces with certain hydrophilic properties so that they can serve either as a surface that a liquid just wets or that a liquid will form droplets on. Such droplets may encapsulate drugs or reagents for future fluidic “factory-on-a-chip” applications, and can be manipulated by their surface tension [28] and/or by electro-wetting, making it possible to move droplets of liquids at will on a two-dimensional (2-D) surface [30]. In the area of biomedical devices, there are many devices that rely on absolute modern microfabrication standards; however, when talking about real nanotechnology-based devices (in the concept of the definition given above), such devices are much less numerous.

In this chapter, I introduce the reader to various forms of nanotechnologies and try to explain why some of these methods are more likely, and more suitable, than others to be employed in the biomedical field. I try to describe how modern nanotechnology may impact the fields of biomedical engineering by giving some examples of nanotechnologies applied in the domain of life sciences. Of course, it is impossible to cover fully the fields of nanobiological and nanomedical research and development, and there are various journals and other publications that cover these areas of nanotechnology. What I present here is solely an attempt to give some representative and, hopefully, interesting examples that may bring the interest and excitement in this field to the reader.

I have divided this chapter into various main parts, each part being divided in subsections. In the first part, I describe various forms of nanotechnologies and nanotools, mainly coming from the field of inorganic nanotechnology. After an overall introductory discussion, some technologies are described in more detail in various subsections. In the second part, I give an overview of various forms of applications having a relation to biomedical devices and technology. In further subsections, I describe a couple of such applications in more depth. The final part presents a discussion and a short speculation of what the future may bring.

## 12.2

### Nanotechnologies

#### 12.2.1

##### Overview of Nanotechnologies and Nanotools

In order to create nanostructures, one is bound to follow two approaches – either top-down or bottom-up. The former is considered to be the driving force for nanotechnology development, while the latter can often be described as a molecular nanotechnology approach [13]. However, these two approaches are more and more blending together, and one is often obliged to make use of both methods in order to fabricate functional devices. Hence, both technologies are just as important for the development of the field. In the top-down approach, one usually relies on a lithographic technology where one can pattern a surface into a relief structure by using some kind of a polymer layer that is put on top of a hard material, e.g. a piece of silicon. The lithographic tools necessary for making nanostructures are based on either electromagnetic [31–37] interactions with the polymer chains or mechanical deformation of it [20, 38–41]. Table 12.1 presents a summarized compilation showing some of the important characteristics. For the electromagnetic lithographies, one often uses optical illumination [31–34]. This is the method used by most semiconductor companies. However, the smallest dimensions using these methods are around 50 nm and if one needs smaller size definition, one is bound to utilize other technologies. Here, electron beam lithography (EBL) dominates [34–36], either using a vectorial or a circular exposure strategy depending on the application [42]. In all cases, the energized electrons either break or make molecular junctions in the polymer layer, making it either harder or softer for the subsequent solvent to develop the latent pattern, i.e. one can obtain both a positive and negative contrast [34–36]. With this method, one can obtain resolutions down to a few nanometers. After the exposure and development of the resist, one usually employs an etching method to induce a surface relief in the underlying substrate material [34]. One can also utilize lift-off methods [43] in order to make a metal pattern on the surface or a combination of both, possibly repeated time after time, thereby creating a complex pattern on a surface. Alternate technologies, also based on radiation, rely on the use of X-rays [35]. Most often the X-rays are produced as a consequence of Bremsstrahlung in synchrotron rings [44] or due to laser-induced emission [45].

Another more recent approach is to employ various forms of mechanical deformations of the polymer layer, e.g. nanoimprint lithography (NIL). This technology was pioneered by Chou, presently at Princeton [19, 37–41]. The method resembles, in some sense, the way compact discs (CDs and DVDs) are fabricated. The difference is that for CDs one uses an embossing tool to make an all-plastic structure, while in NIL (Fig. 12.1) one makes a mechanical indentation into a polymer layer, having been spun onto a solid support, usually a silicon wafer [46]. It is also fair, in this connection, to mention the close resemblance of NIL to microcontact printing [41, 47–49]. Classically that denotes a technology that transfers a molecular layer

**Table 12.1.** Compilation of top-down lithographies. In the table is shown some key data of the major top-down lithographies. The numbers are not absolute but more given as indicative numbers to define in which “ball-park” the various lithographies presently belong. Interesting to note is that the various printing technologies show an overall good performance making them to be the possible preferred choices in a future perspective. For more discussions and references, see text.

Technologies	Generation of pattern	Exposure field per “exposure”	Possible feature resolution	Type of interaction	Throughput 10–12 inch diameter Wafer/hour
UV-lithographies	Mask	Chip (Dize)	$\geq 50$ nm	Electro magnetic	>50
X-ray	Mask	Chip	$\geq 100$ nm	Electro magnetic	$\approx 10$ –30
Focussed Ion beam lithography	Serial	Chip	$\geq 50$ nm	Electro magnetic	1
E-beam lith	Serial	Chip	$\geq 5$ nm	Electro magnetic	0.1
SPM lithography	Serial	Chip	$\geq 10$ nm	Electro magnetic	<0.1
SPM manipulation	Serial	Chip	Individual atoms	Mechanical	<0.01
Micro-contact printing	Stamp	Wafers, $\approx 6$ inch	$\geq 20$ nm	Mechanical	>20
Nanoimprint lithographies	Stamp	Wafer scale $\approx 8$ –10 inch	$\geq 5$ nm	Mechanical	>50
Injection moulding	Stamp	Wafer scale 130 mm	$\geq 50$ nm	Mechanical	$\geq$ several 100

by soft contacting of a stamp, made of a soft polymer inked with a layer of molecules, to the substrate. Thereby transferring the inked layer from the protruding features of the stamp. After this “fabrication” step, one may continue with etching or metal deposition, or by building another molecular layer on top of the first layer, sometimes utilizing covalent binding chemistry. It is also fair to mention the so-called step and flash technology [39, 41, 50–53], being heavily pushed as a NIL, although the process is a bit different. In this concept (Fig. 12.2) one utilizes a floating resist and a stamp that deforms the floating resist so that a relief structure is obtained (still in a liquid phase). By applying a UV exposure through the transparent mask/stamp, one can UV-harden the resist so that it is possible to remove the stamp leaving a UV-cured, structured polymer on the surface. These different “mechanical deformation” technologies can be denoted as a family of technologies, but one could also place the step and flash technology, for example, in the category of

**Figure 12.1.** The process flow of NIL. (From Ref. [41].)

optical lithography. Nowadays, there is often a blending of technologies and one has come up with a hybrid technology, based on ideas borrowed from both areas. Here, one uses a hard stamp and spun on resist, but the actual hardening of the resist is not by temperature as in classical NIL, but by illumination. This technology, often denoted UV-NIL [41, 53–58], is maybe one of the most promising technologies for future high-volume manufacturing (HVM) of nanostructures. I will continue a bit longer on nanoimprint-related methods, since they offer an opportunity for fabrication of biomedical devices [59]. Using this technology, one can fabricate many samples having nanostructures in a very economical way [60]. This has previously been the limiting factor for not introducing nanotechnology in the biomedical field. There is a need in biomedical research to be able to make many structures in order to be able to build significance in the observations. This is in-

**Figure 12.2.** The process flow of step and flash NIL. (From Ref. [41].)

deed different from in physics, where one observable “always” will behave in a similar fashion from measurement to measurement. In biology, there is a natural spread due to the biological variability between species, etc., which necessitates that many samples need to be analyzed in order to obtain statistically significant results. Due to the importance that NIL may have in the future [61–63], I spend more time describing it in more depth in a separate subsection below.

The invention of scanning tunneling microscopy [64] and related atomic force microscopy (AFM) [18] has brought tools to nanoscience with which it is possible to image, characterize and manipulate individual atoms, molecules and structures [16–19, 21–25]. It is even possible to image a few magnetic spins of a few atoms below a sharp magnetic tip [66]. Also, as we see later, it has been instrumental for another class of sensor structures [65] as well as inspiring some of the nanotechnologies described above. Hence, it is fair to conclude that this technology has probably been the single most important one for the development of the nanotechnology field as we know it today. Scanning probe technology is discussed further in a separate subsection.

Lately, there has been considerable interest for making and exploring nanowires, e.g. carbon nanotubes (CNTs) and epitaxial wires [67–74], being made by a bottom-up approach (Figs. 12.3 and 12.4). This is a new class of materials with large pos-

**Figure 12.3.** Epitaxial nanowires of, in this case, InP as defined by a bottom-up approach. The lateral position is governed by catalytic metal particles (Au) deposited by a lift-off procedure before growth has taken place. The shape and length can be controlled in the

process, while the diameter is determined by the size of the catalytic metal particle. The wires can be branched by putting additional metal particles on the sides, making an additional growth run and thereby creating a 3-D network. (From Ref. [68].)

**Figure 12.4.** Epitaxial nanowires patterned by using NIL allowing exact control of the wire positions over a large surface area. (From Ref. [70].)

sibilities for future applications in many different areas of science. They offer extremely small sizes with extremely large aspect ratios. They are not made by top-down lithography; hence, their electronic properties have not been damaged or affected by the processing. Their smallness offers mechanical properties that may be explored for various nanomechanical applications. Some of the foreseeable biomedical applications of nanowires are described below in more detail. The nanomechanics of small objects [74–77] also offer several opportunities for applications as sensors in the biomedical area. Coupled with the increased efforts in nanotechnology is the possibility to utilize nanoparticles for various applications. These particles can be solid, semipermeable, hollow or core–shell particles. They have immediate medical applications, such as magnetic nanoparticles [78–79] that may be used as mobile reporters in magnetic imaging, allowing 3-D capabilities.

There are a lot of other research areas of great importance for handling molecular materials and cells at the nanoscale, e.g. the employment of biomimetic ideas, which is a field on its own. Modifying surfaces using biomaterials can be very important for the development of methods allowing construction of model biological structures for studies of various bio-reactions and for sensor applications, etc. For instance, lipid bilayer membranes supported on surfaces can be very valuable since they may offer possibilities to investigate membranes and membrane proteins in an artificial environment [80–86].

Presently, there is an increased interest for using optical techniques based on surface enhanced Raman scattering (SERS) and surface plasmon resonance (SPR) as mediators for biomolecular interactions [87]. There is also an increased interest in the use of light-emitting point sensors [88] as passive reporters for various chemical and biological reactions/processes. However, due to space limitations, these techniques will not be further explored in this chapter. The interested reader is instead referred to other articles/reports (e.g. Ref. [88]).

### 12.2.1.1 NIL

The process of NIL (Fig. 12.1) is essentially a rather simple process based on pressing a pre-patterned substrate into a layer of polymer spun onto a hard support, the substrate, usually a silicon wafer. The stamp must be pre-processed containing the relief structure that is going to be printed into the polymer layer. For stamp fabrication, one usually employs EBL in combination with etching [89]. In order to be able to press the tool into the polymer layer one usually heats up the sandwiched tool–substrate to a process temperature, where the polymer layer has become fluid, i.e. one heats everything above the glass transition temperature ( $T_g$ ) of the polymer. We have investigated several polymers [90] and found, as a rule of thumb, that the process temperature should be slightly above the  $T_g$  [91]. After applying a pressure high enough for the stamp to be pressed into the polymer layer, one cools down the sandwich, whilst relieving the pressure. Then one can separate the stamp and substrate from each other. This last separation is easier if one has put an anti-sticking layer onto the stamp [92–95]. There are several problem areas associated with such a process. If the stamp and substrate are made of different materials, heating may cause large problems due to the different thermal expansion coefficients, making the materials move laterally with respect to each other. Hence, one has been trying to come up with new polymers enabling patterning at lower temperatures [96]. Also, for HVM, one considers possibilities such as keeping the process temperature constant and pressing/removing at process temperature, thereby also minimizing the problem of any lateral mismatch between expansions of the stamp and substrate, respectively. An outstanding problem with NIL is the necessity of being able to align subsequent stamps to previous structures on a substrate [97]. A lot of activity is presently being pursued in order to solve this problem, [97–100]. Nevertheless, this technology is promising and it can fabricate nanostructures on a wafer scale [40, 46, 101, 102], and the imprint time can be less than seconds [103]. Hence, it is a very powerful technology for future nanoscale materials that may be employed in a variety of application fields.

### 12.2.1.2 Other Lithography Techniques

Just as NIL is a very good alternative as one of the next-generation technologies (NGL) [1, 13, 61, 62] of importance for the information technology sector, other printing techniques, such as microcontact printing [41, 51–53, 104], offer similar advantages. The method (to be more precise, the family of microcontact printing technologies) offers additional benefits as compared to NIL, since the process is simpler, it is a room temperature process, does not require a high pressure (although that problem can be circumvented by using soft NIL [41, 55–57]), has limited stamp–substrate sticking problems, etc. The major drawback is the flexible stamp commonly used that limits the resolution to the order of 100 nm and its use for wafer-scale single printing with high resolution. However, there is presently a tremendous development in nanoimprinting, microcontact and other printing technologies, so we will certainly soon experience an even larger variety of such technologies [105]. For instance, a method based on “printing” was reported recently by Yuand coworkers where they used DNA as a template in a repli-

cation “printing” process, making it possible to replicate DNA assemblies in a hybridization–contact–dehybridization process, which they denoted as “supramolecular nanostamping” [106]. In a similar way, high-density metal lateral nanowires were reported to be transferred from a template to a silicon surface through a contact mechanism. The authors employed “stamps”, fabricated from a superlattice of III–V materials, combined with cleaving and selective etching and metalization. Using such an approach, it is possible to make very high-density and ordered lines that would be very difficult to make using other top-down approaches [107, 108].

A candidate for NGL has for many years been X-ray lithography [1, 35, 44, 45] and with the continuous push from the microelectronic industry for using UV lithographies there has been a merge of the two into the concept of extreme (E)-UV lithography where one utilizes light with wavelengths in the 10-nm regime (for a compilation of papers on E-UV lithography, see Ref. [109]). Usually, such light is generated from plasma sources [2, 45, 109]. The positive aspect of this technology is that the main processing infrastructure technology is rather similar that already employed in the big fabrication facilities. The drawback of E-UV, however, is the enormous costs required in order to put it into a working technology. The costs will not stop it, but it will effectively limit the number of facilities that can afford the investment. Hence, its importance for the biomedical field as a technology for making small series of chips is limited, since the initial cost for such a small series will be high. Another type of lithography technology is based on scanning probe microscopy (SPM) [110]. It will probably have a limited impact on wafer-scale processing. However, it is still one of the most important since it will allow small series of samples to be made in a rather inexpensive way. The needed development, which is making steady progress, is the increase of scanning speed, allowing both imaging and lithography to be made fast enough. However, the limitation of the method, even when it has gained real-time speeds of scanning, is the same as for EBL, i.e. the serial nature of pixel-by-pixel exposure. However, in contrast to several attempts made over the years for making an array of small electron-beam-based exposure sources that could expose a wafer in parallel, the use of an array of scanning probes might just overcome this problem (see also Sections 12.2.3 and 12.3.8). Dip-pen lithography [111, 112] has also been introduced, presenting us with another possibility to fabricate “molecular” lines or patterns without the need for going through the cumbersome pattern transferring method that is needed for other lithographies. Here, one has a tool that makes it possible to write only on those parts of a surface that one needs in a direct way, using the fountain pen principle. It is, to some extent at least, principally a scanning probe lithography method, based on the fact that there is always a water layer on a surface in air. If two surfaces are in contact with each other, the content of the water layer may, depending on the respective hydrophobicity of the two surfaces in contact with each other, be transferred from the tip to the surface and the water layer on the tip may not be consumed if it is connected to a reservoir of liquid or if it is dipped (inked) into a reservoir repeatedly. This is a method that naturally has a large potential for writ-

ing various forms of important molecular patterns for use in protein chip applications, etc. Some examples are given in the next section. In a further extension of the technique, one can fabricate a hollow cantilever tip with a small opening at its end allowing molecules to be transferred from the hollow tips to surfaces [113]. Using concepts from the old days, when one used shadow mask evaporation masks for making electrical (metal) contacts to semiconductors, one has refined the shadow mask technology into stencil mask nanolithography, enabling us to draw metal lines arbitrarily on surfaces in a vacuum [114, 115]. The technique allows a fine pattern to be made by moving the stencil (the shadow mask) while metal (or molecules or something else that can be evaporated) is flowing through the apertures of the stencil. This is a nice method that may have its specific areas application. It can easily be parallelized by having an array of such nanostencil masks moving in unison, allowing large areas to be covered in a short time. The drawback is the clogging of the nanoscale aperture that has to be overcome in order to find a real industrial use for it. The possibilities to develop the tools being described above have been enabled by the development of nanotechnologies in a pull–push fashion. One nanofabrication method that has been instrumental in this aspect, and actually is just in its initial phase of development at the moment, is the use of focused ion beams [116], allowing extremely nice structures to be fabricated in a true 3-D space. The method is often combined with scanning electron microscopy (SEM), allowing observation of the structures being made (although it is also possible to use the ions for scanning and imaging purposes). The principle is to make local and directed deposition or etching of materials due to the energetic ions impinging onto the surface. The method has the same limitations as EBL systems – it is a serial method. Still, it is not at all a mature technology at this stage and I guess that we will experience a tremendous development in other technologies, since it is such a generic technology.

### 12.2.1.3 Scanning Probes

Scanning probes offer many other possibilities in addition to imaging capabilities. For instance they have been utilized to make a new kind of memory device, the Millipede [117], which in principle is an array of cantilevers (Fig. 12.5) that can be controlled individually, allowing the possibility to melt a plastic material and press the tip into it, thereby cause cooling. Hence, it is possible to write information on the nanoscale. Such information, consisting of local deformations, can easily be read out with the cantilevers in imaging mode. Using the technology behind AFM [65], basically a cantilever beam that can be moved in the  $xyz$  directions with a sharp tip mounted at the end, one can make an analysis tool that will be able to detect interactions on the cantilever surface being observed through induced bending as a function of, for example, heat, or stress as a function of molecular adhesion to one of the surfaces, thereby creating a bimetal-like switching behavior [118] (Fig. 12.6). Such cantilever-based sensing, transforming molecular recognition into a mechanical displacement [119], has been used for many aspects, e.g. detection of antigen–antibody reactions [118]. These results are discussed further below. AFM

**Figure 12.5.** The Millipede chip: optical micrograph of a  $64 \times 64$  cantilever array chip (A), and SEM images of the center of the array (B), one cantilever (C) and a tip apex (D). Data can be written at extremely high densities (greater than  $1 \text{ TB in}^{-1}$ ). The cantilevers have separate

heaters for reading and writing, and utilize electrostatic actuation for the z-direction. The cantilevers are around  $70 \mu\text{m}$  long, with a  $500\text{--}700 \text{ nm}$  tip integrated directly above the write heater. (Reprinted with permission from IBM.)

has been utilized for force detection, allowing a detailed understanding of binding forces between molecules. One could denote this as “molecular fishing”. It is based on coating the tip with a certain type of molecule and having another molecule that will bind to it on the substrate. When the tip is lowered into the molecules at the surface, a mechanical bond may be formed and, by subsequent retraction of the AFM tip from the surface, one can follow the sequence when breaking the chemical bonds. This provides valuable information about bond strengths and other molecular properties. This technology has been advanced to the level where it is possible to identify single molecular binding events [120]. Such detailed knowledge will be of great value in the biological area, e.g. in order to increase the understanding of cell signaling mechanisms and protein folding [121]. To fully use SPM for enhancing our understanding in biology, we must continue the development of probes so that they can obtain information from both time and space simultaneously, i.e. allow the possibility to capture images revealing important biological processes in real-time.

**Figure 12.6.** Operating modes of cantilevers employed as sensors: (A) static deflection mode, (B) dynamic resonance mode and (C) bimetallic heat mode. (From Ref. [118].)

## 12.3 Applications

### 12.3.1 Introduction

Here, I explore various directions of nanotechnology in the life sciences sector paving its way into the biomedical sector. However, so far, very few examples of real employment of nanotechnology in the biomedical sector can be found. Nanotechnology offers many chances for applications, but hitherto the development has been mainly focused on being used as sensors. In the following section, I show how passive and active nanostructures surfaces can be explored, how nanotechnology can affect the area of proteomics, and how nanowires and nanomechanics may be employed as sensors for molecular detection.

### 12.3.2 Biomedical Applications based on Nanostructured Passive Surfaces

For many life sciences applications, one might need to detect only a few substances dispersed into a solution and blended with other substances. One needs to have a functionality of the substances, giving them a kind of a handle. This can be solved by utilizing different kinds of chemistry, often in conjunction with attaching cer-

tain dyes in order to be able to detect various reactions. However, what one really would like to have is a system providing identification without the use of a marker, i.e. a label-free diagnostic method. The reason is 2-fold – a marker may change the biological function of the substance and there is a probability that markers may not attach with 100% fidelity. In order to find a species at low concentration, it would be advantageous to increase the concentration. Many of these aspects can be dealt with using nanotechnology and passive surfaces. By passive we mean a surface that may or should have a function, but we cannot influence that function from the outside during a measurement, observation or reaction.

#### 12.3.2.1 Separation, Concentration and Enriching Structures

Separation can be achieved by employing nanotechnology in various ways. One form is to use a system of nanoscaled posts (functioning as bumpers) in an array format, together with time-alternating electric fields, making it possible to separate various molecules according to the entropic force they experience in the confined region, which in turn limits the natural conformation possibilities that they have [122, 123] (Figs. 12.7 and 12.8). Since the entropy of a molecule depends on its length, these confined space structures act as a sorter of molecules with various lengths, e.g. lengths of sequences of DNA. Such a molecular sorter at the nano-scale has been fabricated by EBL. Similar confinement-related devices, but instead of posts, using nanochannels in an array format have been proposed and realized utilizing NIL [41, 124, 125]. Here, NIL was employed (Figs. 12.9 and 12.10) creating ultra-narrow channels, forcing fluorescently labeled DNA to stretch out while passing through the narrow channel [124]. The vision for these kinds of structures is to be able to integrate light emitters along the channel and to determine the DNA code down to individual bases by reading them as they pass the emitters using near-field excitation/detection mechanisms. The first steps have been realized (Fig. 12.11), allowing the detection of a marker attached to the DNA at a certain position, using excitation through narrow slits positioned perpendicular to the channels [125, 126].

**Figure 12.7.** A fluidic device consisting of an array of nanopillars in between a roof and a floor. (From Ref. [122].)

**Figure 12.8.** (A) An optical micrograph of the fabricated device. (B) A close-up showing the 35-nm pillars with a center-to-center distance of 160 nm. (From Ref. [122].)

It is especially interesting to note the use of another polymer, Topaz, with important benefits when it comes to biocompatibility and nanofluidicity in combination with optical spectroscopy [127]. The properties are such that it is an ideal candidate for integration of a waveguide directly in the polymer (Figs. 12.12 and 12.13). Furthermore, it would be possible to insert dye molecules acting as local emitters for locally addressing, for example, a DNA chain being swept in a channel close to the emitter. The full utilization of these concepts has not yet been reported. Similar kinds of nanofluidic structures have been employed to create a cell-based assay

**Figure 12.9.** SEM images showing (a) the cross-section of the NIL-fabricated nanochannels and (b) the top view displaying the channels. (From Ref. [124].)

**Figure 12.10.** CCD image showing DNA stretched out in the nanochannels. Scale bar is 30  $\mu\text{m}$ . (From Ref. [124].)

[128], and in a recent paper a nanofluidic transistor (Fig. 12.14) was reported enabling control of ion and molecular flow in a channel [129].

#### 12.3.2.2 Molecular Motors Transported in Nanometer Channels

Other kinds of nanoscaled channel structures have been reported in the field of molecular motors (Figs. 12.15 and 12.16). This work, using nanoscaled structures, has been pioneered in a collaborative effort by the author and Mansson at Kalmar University [130–135]. Several other groups have reported micrometer-sized channels [136, 137], showing a performance similar to that obtained by us. However, we have, in contrast to the others, a precision in the motor guidance at the nanometer level [132, 135]. We have further refined the concepts and have built a com-

**Figure 12.11.** SEM image of a device with 100-nm wide slits for optical detection of DNA molecules as they pass by in the 5- $\mu\text{m}$  wide channel. At the outer ends are nanopillars for stretching the DNA filaments before entry into the channel region. (From Ref. [125].)

**Figure 12.12.** A photo of the microfluidic device made from Topaz with incorporated laser resonator. (From Ref. [127].)

plete toolbox system (Fig. 12.17) around this activity, where we can direct motion by fabrication of rectifiers, roundabouts, injectors, etc. [135]. Basically, we have combined nanolithography and surface functionalization (Figs. 12.18 and 12.19) using silane procedures, resulting in a very robust structure permitting detailed studies of the actomyosin system [134–136]. Such a system may be explored as a “lab-on-a-chip” system for use in drug development. For instance, one can imagine using a circular pattern into which individual motors are directed and, by counting the rotation speed of the motors in these circles as a function of the added drug, for instance, one may be able to investigate the effect of various formulas or concentrations of added drugs. If so, maybe such a system can work favorable as a pre-screening system for drug development.

### 12.3.2.3 Topographical Structures, Cells and Guidance of Neurons

Another class of passive structures is topographical patterns in conjunction with cell survival, growth and adhesion, with important implications for medical im-

**Figure 12.13.** A SEM image showing the laser resonator structure located in the flow region. (From Ref. [127].)

**Figure 12.14.** A nanofluidic transistor. (A) Schematic representation of the device. (B) Micrograph showing the 35 nanochannels running from left to right and the three electrode lines perpendicular to the nanochannels. (From Ref. [129].)

plants and prosthetic devices. Several investigations have been performed showing the positive effects of micrometer structures with respect to individual cell attachments, but results employing real nanometer-sized structures are sparse [138]. For the single-cell case and microstructures, grooved topography especially has been found to interact [139] and cells have been reported to change their shape in order to follow the grooves (and ridges) [140]. It has also been observed that cell regulation and transcription may be affected [141]. For nanostructures, macrophages, endothelial and fibroblast cells have been reported to interact in one way or another way [142–144]. We have recently performed a pilot study in which we have utilized nerve cells and studied the possibility of aligning nerve cells during growth [145]. Using NIL we made a large number of nanostructured surfaces containing grooves in the commonly employed polymer poly(methyl methacrylate) (PMMA). We made both positive and negative structures in  $200\ \mu\text{m} \times 200\ \mu\text{m}$  squares, containing lines with dimensions varying between 100 and 400 nm, while the distance in between the lines varied from 200 to 1200 nm. Ganglia, both sympathetic and sensory, were dissected from an adult female NMRI mouse and mounted on the chip surfaces, about 1 mm from 17 nanostructured squares, as described above. After 5–7 days in culture media, we found that most axons had regenerated along all of the lines with an apparent preference to grow along the line peripheries (Figs. 12.20–12.22) [145]. The aim of the study was to investigate if we could separate

**Figure 12.15.** Schematic presentation of the nanochannels defined by a lithographic method followed by immobilization of myosin heads to the patterned surface, and addition of fluorescently labeled actin filament and ATP. The actin filaments will, with the proper choice of material for the lines, be effectively transported through the channels. (From Ref. [130].)

a large number of axons on a small area and, indeed, we showed that possibility. Such spatial separation and the possibility to organize axons have important consequences for the possible ability to make electronic connections to the nervous system [146]. State-of-the-art implanted electronic devices found in practical use today

**Figure 12.16.** Similar nanochannels defined by NIL (a) and a snapshot of fluorescently labeled actin filaments (white colored) being transported in the lines (b). (From Ref. [131].)

**Figure 12.17.** Three nanotools, rectifiers, roundabouts and directional couplers, put together to transport actin filaments (fluorescently labeled) first in a rectified way from left to right (green colored), and then in a roundabout structure being forced to make a 360° turn and go back into the same channel

as before, moving in the opposite direction (red colored) and then halfway back it will follow a route downwards (directional coupler) and out to a reservoir. Note that the filament cannot enter into this downward branch on its move from left to right. (From Ref. [135].)

are the cortical implant BrainGate [147] and the very well-known cochlear implant. These devices have only a hundred electrodes on a 1-mm<sup>2</sup> area and such a density is not sufficient for making a functional brain-machine interface (BMI). Our results above show that it may be possible, using NIL, to increase the spatial resolution considerably; we found hundreds of axons on an area of 0.4-mm<sup>2</sup> [148]. Our

**Figure 12.18.** Cross-section of the double layer of resists combined with selective silanization of the channels employed to achieve the nanometer control of the movement of actin filaments. It consists of a LOR layer and on top of a PMMA layer. By proper patterning and processing, an undercut as shown in the cross-section picture, can be obtained. As illustrated, the slit along the wire (opening) serves an

important role – through this opening ATP can be inferred and products such as ADP can be removed. If we employed sealed nanochannels we would eventually get clogging and we would also be limited by diffusion of ATP, leading to unstable conditions. The bottom layer is functionalized through a vapor-phase silanization procedure to enhance motility. (From Ref. [132].)

**Figure 12.19.** A top view of the pattern showing the loading zone to the left and nanochannels going to the right in the picture. An actin filament (fluorescently labeled) is

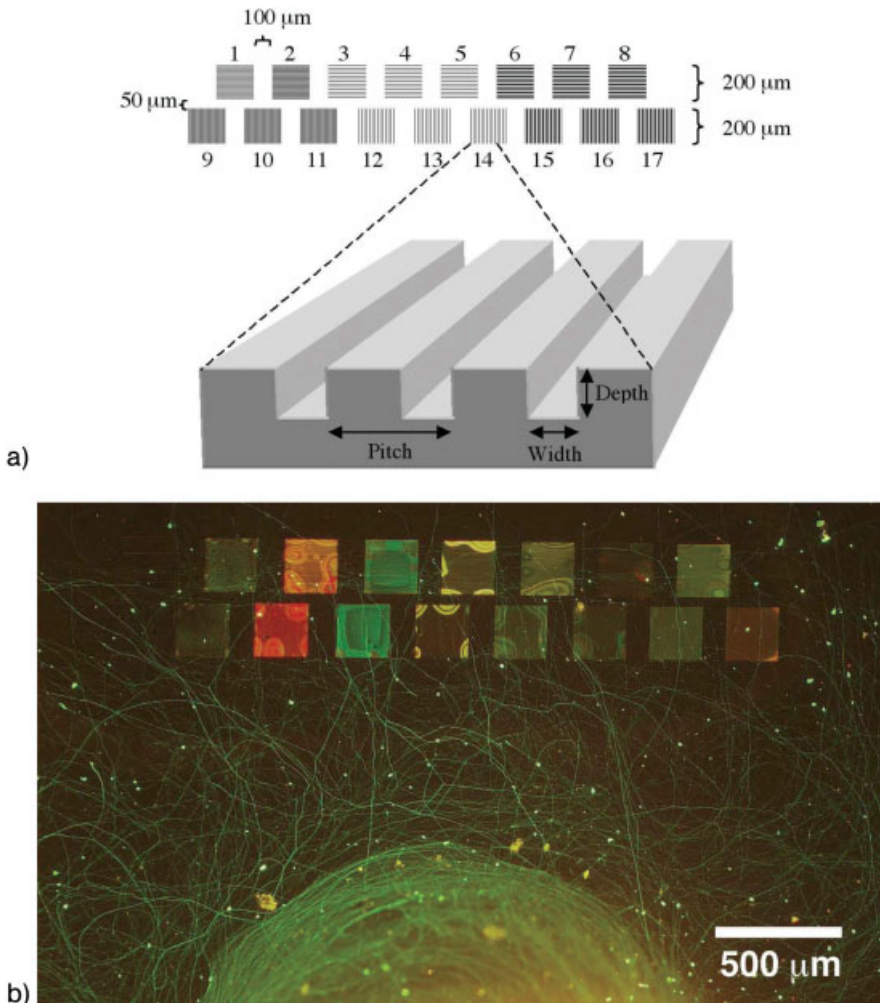

shown to have followed the edge of the loading zone (under the undercut) until a suitable nanochannel made the filament turn right and follow the nanochannel. (From Ref. [132].)

simple, nonoptimized study shows the possibility to concentrate and separate nerve cells on a small area of a surface. Furthermore, the topographical structures are highly stable and NIL, as a method, is scaleable, providing additional support for possible future BMI applications based on nanostructured surfaces. Recently, we have also employed epitaxial nanowires as a support surface showing excellent guidance of neuronal outgrowth (Fig. 12.23). Further details are reported elsewhere [149]. The review by Melechko and coworkers [69] showed various life sciences applications of carbon nanowires. Large sets of interconnected CNTs with cell membranes were recently reported, showing that the biological properties of the membrane were retained and that they could perform electrical measurements [150].

### 12.3.3

#### **Biomedical Applications utilizing Active Nanostructured Surfaces**

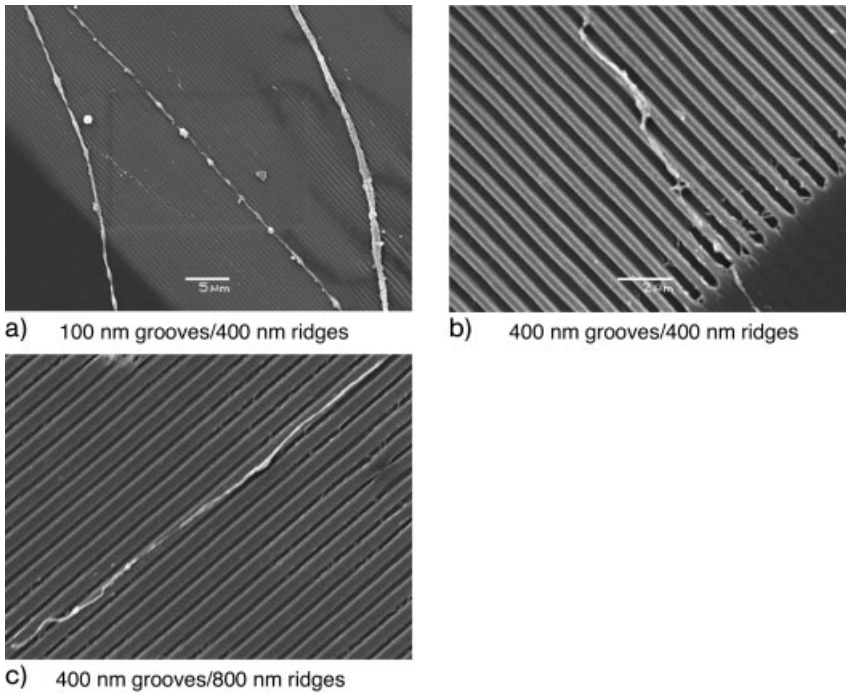

In contrast to the previous topics, active nanostructured surfaces can be activated from the outside world in order to investigate the interaction of various forms of

**Figure 12.20.** A number of NIL-patterned squares ( $200\ \mu\text{m} \times 200\ \mu\text{m}$ ) containing grooves oriented horizontally (the two at the bottom) and vertically (the two top ones) having different widths and pitches. As can be

seen, the axonal outgrowth (mouse cervical ganglion) follows the orientation of the grooves in the squares and changes growth direction when the grooves turn  $90^\circ$ . (From Ref. [145].)

biomolecules that such activation may invoke. A paper by Hamad-Schifferly reported remote inductive control of local DNA hybridization events by the use of a nanocrystal serving as an antenna covalently linked to DNA [151]. Another such class of structures that are made at the nanoscale is the so-called interdigitated array (IDA) of electrodes (Fig. 12.24). Although several groups have been able to fabricate such devices [152–155], few have been able to report any useful information

**Figure 12.21.** SEM images showing axons growing on a positive pattern. The ridges are 400 nm on the (A) and (B), and 800 nm wide on (C). The linewidths are 100, 400 and 400 nm, respectively (A–C). The ridges are all

100 nm high. Note especially that all axons seem to grow on top of the ridges and not in the grooves between the ridges. (From Ref. [145].)

having the IDA in the nanometer regime. One of the common obstacles is the noisy environments for all kind of electrical measurements. However, in a set of publications, we have been able to follow some results as a consequence of using nanosized interdigitated electrodes. Choi and coworkers [155] report the possibility to detect DNA binding events by monitoring the impedance (Figs. 12.25 and 12.26). In the paper they report, using NIL in combination with certain nanoprocessing steps, that an array of electrodes having nanogaps of the order of 50 nm provided a way to make label-free detection of DNA hybridization events. Figure 12.25 shows a SEM image of the fabricated structure and the schematics for detection, and Fig. 12.26 displays the frequency-dependent capacitance. Clearly, the hybridized structure of T–A base pairs is detected by the capacitance increase at lower frequencies, in contrast to the nonconjugated base pair reference measurement. The explanation given is that the single- and double-stranded DNAs have different geometrical structures, and hence a different induced counterion profile. In another report [156] using IDA, the authors have investigated the relative increase in signal due to the nanoscale of various scaled IDAs (Fig. 12.27).

**Figure 12.22.** Neurons supported on a surface consisting of randomly located epitaxial GaP nanowires on GaP substrate, revealing a healthy appearance. Note that some wires are bent and in some cases wires are inserted into the neuronal cells and processes. (From Ref. [149].)

**Figure 12.23.** Nanowires were placed in rows with varying pitch and wire diameters. As can be seen, the neurons align to the wires and follow them in a very nice way, allowing governance of the growth direction to be engineered by the sample morphology. (From Ref. [149].)

part of the transducer chip, (c) area of a 100-nm IDA and (d) part of a 200-nm IDA electrode. Note the contact areas with holes making it possible to print both nanometer lines and micrometer-sized regions in one printing step. (From Ref. [153].)

#### 12.3.4

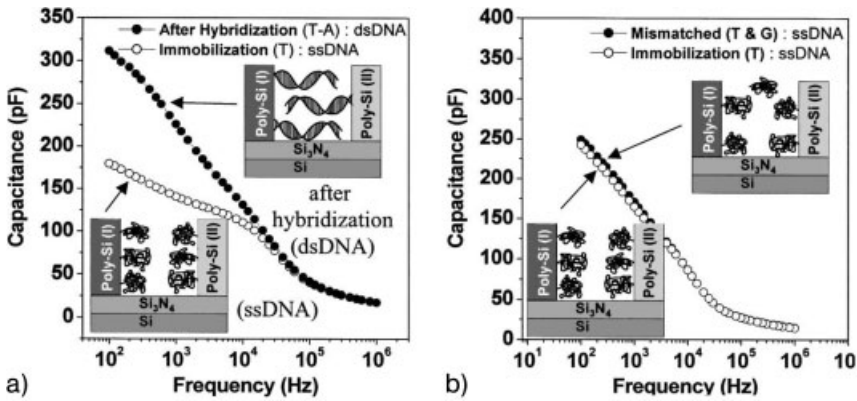

#### Protein Chips

Protein-binding detection devices are an important class of devices that may have a large impact on drug screening in conjunction with drug development. They may

**Figure 12.25.** (a) The process flow for the creation of the nanogaps and a SEM image. (b) A schematic cross-section showing the measurement principle. The nanogap can be controlled by the deposited oxide film thickness. (From Ref. [155].)

also have a potential to be developed into small and portable handheld devices for point-of-care analysis or even as home-doctor kits. For this, the main direction is to utilize antibody–antigen detection [157, 158]. Hence, what it boils down to is an ability to detect whether molecular binding between an antibody and an antigen has taken place. Of course, one usually makes measurements of large arrays of antibodies distributed on a surface using some kind of spotting procedure. Then, by spotting a liquid containing an unknown blend of antigens, one will detect which reactions take place and hence a fingerprint will be obtained. By comparing this individual fingerprint with a set of control fingerprints, it is possible by using various decision mechanisms to tell which antigens were present in the liquid and what disease that set of antigens is a representation of. In order to fully understand the various expressions as a consequence of a certain disease, one would like to make the antibody library extensive [159]. Present-day arrays contain hundreds of

**Figure 12.26.** Measured capacitance versus input frequency after immobilization and hybridization. Capacitance increases as the frequency decreases for the conjugated pairs, whereas there is no significant effect of the capacitance for the nonconjugated base pairs. (From Ref. [155].)

antibodies, but using nanotechnology it is foreseeable that one could make arrays containing millions of antibodies, if one could confine (pattern) the antibodies onto a small surface spot [159–161]. In a prototype study we have fabricated such structures using EBL [162]. They are fabricated by making nanocontainers in the

**Figure 12.27.** Normalized signal strength for redox current as a function of nanogap width showing the increased signal as the gap size is reduced. The increase of current is an effect of more effective redox cycling when the electrodes are closer to each other. (From Ref. [156].)

form of small holes (down to 50 nm in diameter) in a PMMA layer on top of a solid substrate with a waveguide as a surface layer. This means that antibodies can be immobilized inside the nanowells and by excitation through the evanescent field created by establishing a standing wave in the waveguide, one will excite only those molecules situated at the bottom of the well directly on top of the waveguide layer. The other molecules found on top of the polymer around the nanowells will not be excited due to the fast decaying electromagnetic field as a result of the near-field excitation mechanism. This approach has allowed us to study specific antibody–antigen interactions of biological interest [162]. Similar ideas using nanotechnology have been published, but they did not confine the antibodies to the surface effectively, leading to a larger analyzing droplet, or alternatively they employed larger nanowells [160, 161].

### 12.3.5

#### **Protein Interactions**

The field of protein patterning is not only limited to protein chip applications, but also used in other kinds of applications. The reason is that proteins are essential for so many life functions – force production in molecular motors, intra- and extracellular transport, mechanical stability, sensing and signaling, etc. What they all have in common is the procedure to make a surface functionalized in one way or another. Usually, functionalization is based on (covalent) coupling of the primary molecule to a certain surface structure. An example of a popular covalent coupling is thiol coupling to gold surfaces. If the surface is a silicon wafer, then one can utilize the large variety of well-established silanization procedures commonly found in conjunction with separation columns based on silica particles.

An often employed silanization procedure is to covalently bond chlorosilanes to a hydroxylated  $\text{SiO}_2$  surface layer, expelling  $\text{HCl}$  as a result of the binding [163]. The chlorosilanes can then have functional amine, carboxyl or hydroxyl (or fluorine if one likes to have a repelling surface, compare this with NIL stamp fabrication [92–95]) groups at the other end. These functional groups may interact with a second molecular group that one intends to attach to the surface, e.g. enzymes. Hence, many approaches to make patterns in various silane layers on the nanoscale can be found [41, 164–166]. After patterning, one must retain the function of the functional groups and nanoprocessing, in general, is rather harsh to many of these molecular layers. Other approaches found in the literature are results obtained by nanoscale patterning of protein layers (compare also the functional protein layers in the tracks for the motor proteins as described above and in Refs. [130–135]). Several such reports have been made, usually employing some kind of model protein–protein reaction as the probe of success. Most often one employs streptavidin–biotin reactions to show proof of the patterning. In the report by Falconnet and coworkers [166], they combined standard NIL with a lift-off procedure of a biotin functionalized poly(ethylene glycol)–poly(L-lysine) (PEG–PLL) copolymer (Fig. 12.28). After lift-off, a backfilled layer of a non-biotin-

**Figure 12.28.** The NIL and protein patterning process. (I) Spin coating the PMMA layer and pre-bake. (II) Imprinting of the PMMA layer with the quartz stamp. (III) De-molding of stamp from substrate. (IV) Etching of the residual layer of PMMA opening the niobium oxide surface. (V) Dipping into solution of

biotinylated PEG-PLL-mixture. (VI) Lift-off of the remaining PMMA layer leaving a patterned layer of biotinylated PEG-PLL on the surface. (VII) Filling of the background with non-biotinylated PEG-PLL. (VIII) Selective binding of streptavidin to the biotinylated layer. (From Ref. [166].)

**Figure 12.29.** Scanning near-field micrograph of 100-nm wide biotinylated PEG-PLL lines with Alexa-conjugated streptavidin in a background of nonbiotinylated PEG-PLL showing the successful selective lateral patterning of active protein binding lines. (From Ref. [166].)

functionalized PEG–PLL copolymer was established. In this way, they managed to produce patterned biotin-functionalized lines surrounded by PEG. They then successfully managed to selectively bind streptavidin to the 100-nm wide biotin lines (Fig. 12.29), showing that the biotin properties remained after a common nanoprocessing lift-off procedure. They also discuss the versatility of the process since the PEG copolymer can be functionalized in many different ways. In previous reports by Hoff and coworkers [167] and Gou [41], successful NIL-based protein patterning was displayed. Hoff and coworkers performed NIL and fluorine passivation of the naked silicon surface after reactive ion etching (RIE) exposure, but before removal of the unpatterned resist. A covalent immobilization step of an aminosilane monolayer was performed in combination with a series of subsequent covalent binding events of biotin, streptavidin and, finally, a biotinylated fluorescently labeled protein layer, respectively (Fig. 12.30), creating a sandwich structure. Using epifluorescence, the resulting structures were observed, proving the success of a very uniform sub-100 nm patterning and biofunctional NIL-based process (Figs. 12.31 and 12.32).

**Figure 12.30.** Process flow diagram of substrate-selective lateral patterning and subsequent protein immobilization. Spin-coated PMMA polymer is patterned by NIL. Exposed SiO<sub>2</sub> regions are etched and passivated by a RIE-deposited CF-based monolayer. The remaining PMMA is lifted off and an

aminosilane is covalently attached to the exposed SiO<sub>2</sub> through a gas-phase deposition procedure. A layer of biotin is covalently linked to the amino layer followed by streptavidin attachment and then, finally, a biotinylated protein is linked to the streptavidin. (From Ref. [167].)

**Figure 12.31.** Proteins patterned onto sub-100 nm patterns. (A) SEM image showing the nanolines after NIL, oxidation and passivation. The inset shows that the linewidth is less than

100 nm. (B) Fluorescence micrograph of the lines after linking rhodamine-labeled streptavidin to the biotin-modified aminosilane-functionalized lines. (From Ref. [167].)

### 12.3.6

#### Biomedical Applications using Nanowires

Nanowires having diameters of the order of tens of nanometers have been employed as extremely sensitive charge sensors. This is based on the fact that if one employs contacts at the two ends of the wire, there will be a possibility (depending on the wire conductivity) for the formation of a narrow 1-D current path along (inside) the wire. If a charge is exposed to the outer surface, this path will be quenched (or opened) (Fig. 12.33) in a way very similar to how a modern CMOS gate functions. By proper functionalization of the wire surface, one may use it as a sensor able to detect specific binding to the wire surface. Wang and coworkers have re-

**Figure 12.32.** Epifluorescence image showing bioactivity on NIL-patterned surfaces. The contrast arises from rhodamine-labeled catalase bound to the antibody anticatalase patterned in 2-μm dots using the process described in Fig. 12.31. (From Ref. [167].)

ported label-free detection of molecular binding to silicon nanowires [168], and Chen and coworkers [169] discussed non-covalent functionalization of such CNTs and biosensor applications. Other reports have been made dealing with virus detection [170]. Hahm and coworkers [171] showed label-free DNA detection by first attaching streptavidin, then biotin with a linker to peptide nucleic acid, which in turn contained a specific sequence of base pairs that enabled specific binding to DNA. They reported a 2-fold increase of wire conductance attributed to increased negative charge on the nanowires. In the near future, such structures may become very important as direct label-free detectors for clinical use. In a paper by Zhao [172], nanowires consisting of nanotube–metal clusters are discussed, providing proof-of-principle for a novel high-specificity molecular sensor utilizing the possibility to bind various kinds of molecular receptors to metal clusters. Further uses of nanowires are exploited in recent reviews [69, 173].

### 12.3.7

#### **Biomedical Applications using Nanoparticles**

Nanoparticles are excellent transducing components with the ability to report on interactions of biomedical relevance in various ways. The reporting mechanisms are often based on the fact that the magnetic, electronic, mechanical, chemical and optical properties of small objects differ from bulk materials, and small changes in size and shape can often be more easily monitored, since the effects are large. One such class of small objects is the “semiconducting quantum dot” that may change its luminescence (or fluorescence) properties as a function of surface coverage [174–176]. Generally speaking, also for this class of devices, one needs a handshaking procedure in order to utilize them as sensors, for example. This means that different surface functionalization procedures are also highly relevant for these kinds of structures. For instance, a magnetic particle having a certain molecule chemically linked to it can be manipulated using magnetic fields. In a paper by Nam and coworkers [177], such a use was discussed for the detection of proteins; specifically, they showed detection of prostate-specific antigen with a sensitivity 6 orders of magnitude higher than standard clinical assays.

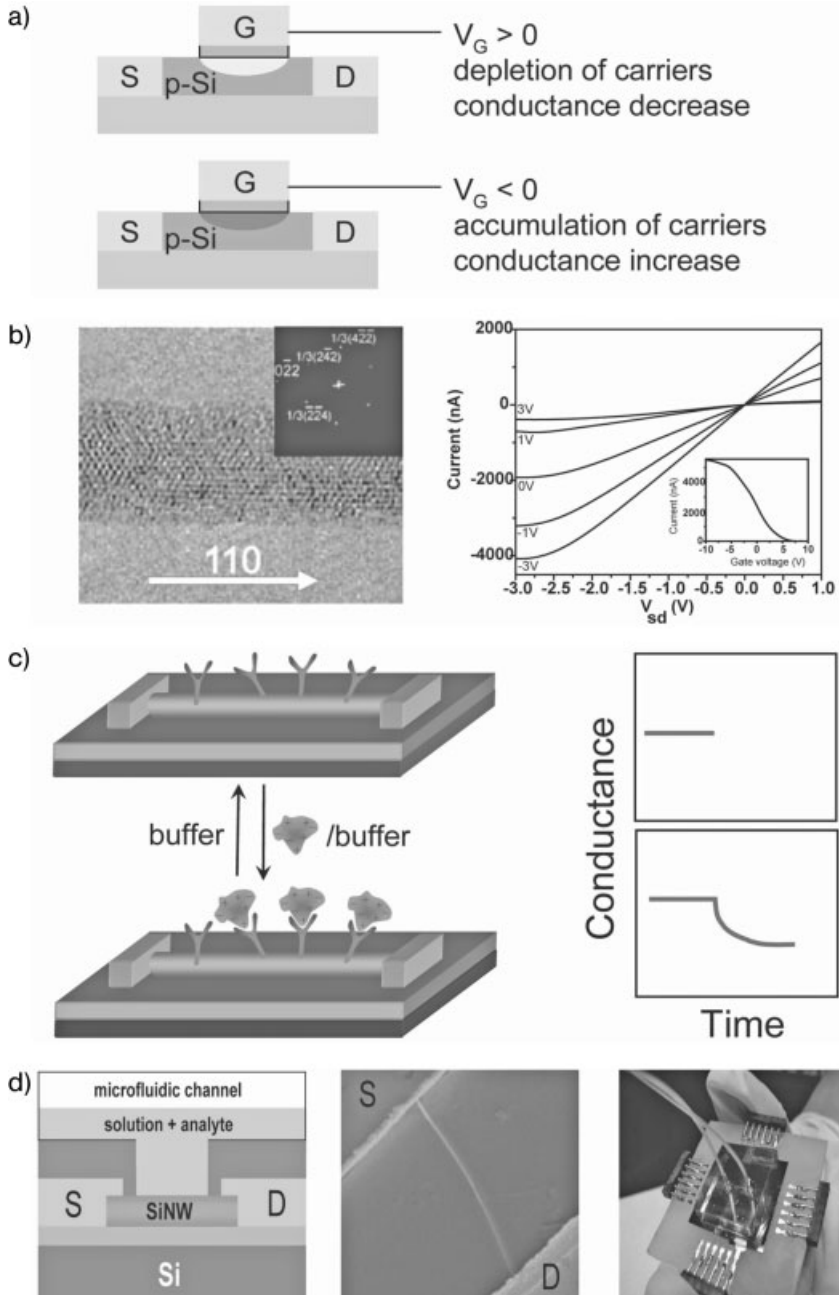

The preparation and use of magnetic particles is a whole scientific field on its own, and interested readers are referred to additional publications [172–181]. Other classes of nanoparticles of great relevance for the biomedical community are soft core–shell nanoparticles and capsules [182–184] with a pharmaceutical content. For example, the core is envisaged to be able to locate a tumor and then by an enzymatic process the core is opened, allowing directed drug delivery to the tumor. Here, readers are also referred to other publications [182–184].

### 12.3.8

#### **Biomedical Applications using SPM Technology**

Here we can distinguish between investigations performed in microscopy mode, chemical force detection and as a sensor structure giving a multitude of possibilities.

### 12.3.8.1 Imaging of Biomolecules using SPM

AFM is often employed for high-resolution microscopy aiming at molecular resolution of soft material, such as tissues, etc. AFM, in contrast to many of the other relatives in the large family of scanning probes, can be used in a liquid environment without losing much of its resolving power [185, 186]. To image soft and delicate materials it is mainly used in one of the noncontact modes or the intermittent-contact mode equipped with super-sharp tips. For this purpose, nanowires have been integrated in various ways with the usually pre-formed tip on the cantilever in order to serve as the sharp tip. A review in this subject area has been published by Hansma [187]. Recently, AFM has been taken to new dimensions, and a publication by Imer and coworkers describes how a minute AFM may be placed inside the body [188] in order to be able to report to an external source about how a knee joint surface develops after a surgical procedure.

### 12.3.8.2 Force Detection of Single Molecular Events

In force detection mode, using a chemically modified tip that will bind to a single molecule on a surface when lowered towards the surface, it is possible to study conformation changes and the mechanics of individual molecules. Such investigations have led to detailed knowledge about DNA recoiling, forces involved in antigen–antibody binding and receptor–ligand interactions, as well as cell–cell adhesion due to discrete adhesion proteins [118–121, 189]. An excellent review of this field is given by Gimzewski and Joachim [190] and many details can be found in the papers by Gaub, who is one of the key drivers in Europe in this field [120, 191]. Gaub's group have, for instance, recently published measurements revealing single base pair mismatches [192].

### 12.3.8.3 Cantilever-based Detection of Molecular Events

The remaining class of scanning probe activities with biomedical relevance utilize the mechanical movement or properties of a cantilever when a chemical interaction has taken place on the cantilever arm [118, 119, 193]. Here, one can distinguish between two classes – a static displacement of the cantilever or a shift of the dynamic motion of the cantilever, e.g. a shift in resonance frequency. For these investigations one can utilize an AFM set-up and a standard AFM cantilever with a tip, but the tip in itself does not play any role since the instrument *per se* is not go-

---

**Figure 12.33.** Nanowire FET sensor. (A) Schematic view of a normal p-type FET device where a positive (negative) voltage applied to the gate (G) led to depletion (or enhancement) of the current path between the source (S) and drain (D) contacts. (B) Transmission electron microscopy image and diffraction pattern of a 4.5-nm diameter silicon single-crystal nanowire and typical electrical characteristics for a p-type nanowire. (C) Schematics of a p-type nanowire employed as a sensor with antibodies and positively charged protein that upon binding quench the conductance of the wire (similar to the positive bias situation in A). (D) Schematics of the nanowire sensor configuration and SEM image showing the nanowire between the two contacts and a photo of the complete biochip with integrated fluidic sample delivery. (From Ref. [172].)

**Figure 12.34.** Schematic of a cantilever array-based hybridization sensor. (A) Each cantilever is functionalized with different self-assembled monolayers (SAMs) of thiolated oligonucleotides. (B) Upon injection of complimentary sequences to the oligonucleotides on the

various cantilevers, recognition and binding occurs to one of the cantilevers, and the cantilever bends down due to the stress. (C) After rinsing, the cantilevers are ready to detect again. (From Ref. [118].)

ing to give any images. There is usually no need to have a scanner able to sweep the cantilever in the lateral directions. In order to achieve a static deflection, one often employs a scheme like a bimetal switch, i.e. when one side of the cantilever is influenced by chemical interactions, such that a strain or compression is experienced, the cantilever will bend. Typical levels of stress are of the order of  $10^{-3}$   $\text{N m}^{-1}$ , causing deflections to be around 10 nm or so; the bending will of course depend on the cantilever employed. Therefore, one usually coats one side of the cantilever with a metal that interacts with the molecules of interest, possibly by having a coating on the metal surface permitting only one kind of molecule to bind onto that surface (Fig. 12.34 and 12.35). Using this principle, it has been possible to follow chemical interaction and DNA hybridization, detect explosives, determine pH, detect of bacteria, detect of various vapors, etc. [118]. For dynamic detection, instead of monitoring surface strain or stress, one actually measures the mass being adsorbed on the cantilever surfaces [194]. The basic equation for a cantilever in resonance ( $df/dm \sim f/m$ ) involves the mass, and hence a measurement of the change of the resonance frequency directly measures the added mass (or removed mass if one performs such an experiment). This method resembles quartz crystal mass (QCM) technology, although the QCM crystal is macroscopically large. Nevertheless, the use of QCM, and especially the dissipative mode of QCM, is frequently used for studying various biological processes and reactions to surfaces [195, 196]. The drawback of QCM is the sensitive surface area, which cannot be

**Figure 12.35.** (A) Deflection traces of two differently oligonucleotide-functionalized cantilevers upon injection of the complement entity to one of the cantilevers. (B) Differential signal between the two deflection curves. Buffer = rinsing. (From Ref. [118].)

miniaturized in order to study processes happening on a small lateral scale. In order to detect very small masses, interest in the cantilever detection community is, at this stage, directed towards the development of small cantilevers. This is due to the increased mass detection ability that follows if the eigenmass is low and the unloaded resonance frequency is high. However, most of the cantilevers reported in this field have micrometer dimensions. The reason being that there are plenty of opportunities for good research and technology development using these more conventional cantilevers [197–199]. In particular, the coating of functionalized layers with the resulting exclusive binding is still not yet at a fully mature level. There is a necessity to make real systems with arrays of cantilevers (Fig. 12.36) hav-

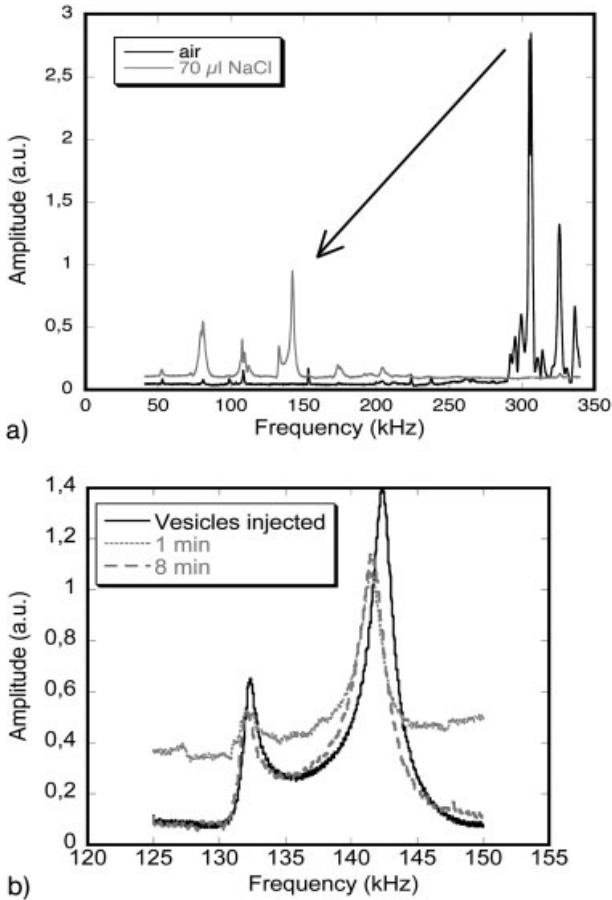

**Figure 12.36.** Schematic view of the array format used together with cantilever sensors. Each cantilever has a different coating. (From Ref. [118].)

**Figure 12.37.** Cantilever cross-section view of a true nanosized metal cantilever having a width of 200 nm and a thickness of 50 nm. When the mechanical properties were investi-

gated on this and similar metal cantilevers, it was found that they appear to be softer than one could predict from classical mechanics. (From Ref. [201].)

ing different kinds of coatings in order to detect and discriminate various contents in, for example, an unknown liquid [118, 200]. (Compare with Sections 12.3.4 and 12.3.5.) However, a few papers have recently reported [201, 202] cantilevers in the true nanometer regime, with thicknesses well below 100 nm (Fig. 12.37). In these papers, the nanomechanical properties of solid metal cantilevers were investigated as a function of length and thickness. It was found that the properties of thin cantilevers shift as compared to bulk material, making the cantilevers increasingly softer than expected as they get thinner. The cantilever-based nanomechanical concept is nice, since it allows investigations to be performed in a liquid, e.g. in body fluid or whole blood (serum). For static measurements, this is rather straightforward [203–205], although care has to be exercised when making a flow system, allowing the actual detection to work. For the dynamic case, the situation is more tricky – the main reason being the drastic decrease of the  $Q$ -value of such dynamic systems when operated in liquid. During the many years of investigations, very few papers have yet been published. Just recently, two such papers have appeared, one from Professors Gerber's group in Basel and one from the author's group [206, 207]. In the paper by Braun and coworkers they have, in a model experiment, investigated binding of streptavidin-coated latex beads onto biotinylated cantilevers, while in the paper by Nilsson and coworkers [207] they have addressed the challenge to combine detection of adsorption of lipid vesicles onto cantilevers (Fig. 12.38). In that report, it was shown that the lipid vesicles formed a close-packed layer keeping their spherical shape and the mass resolution obtained was of the order of  $3 \text{ fg Hz}^{-1}$ . This low value is promising when compared with similar measurements of mass performed in vacuum [208], where a mass sensitivity of  $0.2 \text{ fg Hz}^{-1}$  was reported. Using an oscillating cantilever of poly-silicon,  $1 \text{ }\mu\text{m}$  long,

**Figure 12.38.** (A) The cantilever resonance spectra before and after being immersed in NaCl buffer liquid. (B) The shift of frequency due to immobilization of phospholipid vesicles onto the cantilever. The nonoptimized mass detection sensitivity was found to be  $3 \text{ fg Hz}^{-1}$ . (From Ref. [207].)

500 nm wide and 150 nm thick with an integrated  $1\text{-}\mu\text{m}^2$  paddle, functionalized with antigen, specific virus detection has been reported with a detection sensitivity of single viruses [209]. The detection of ultra-low masses leads us into another important class of nanotechnologies – nanomechanical systems. Using nanomechanics, it has been possible to make wonderful devices that can elucidate mechanical motion close to the quantum limits. A recent review on this subject can be found in *Physics Today* [210] and in Ref. [211]. Here, the authors, in a fascinating way, describe the development of the nanoelectromechanical systems (NEMS) field and how it interacts with quantum physics. This development leads the way to

be able to construct measurement apparatus that may be able to discriminate and analyze individual macromolecules with atomic-level detection in 3-D. Recently, Roukes and coworkers have shown exceptional weighing measurements down to a few molecules, the sensitivity reported to be 7 zg [212]. The sensitivity of MEMS and NEMS devices, as already mentioned in the Introduction, has also enabled measurements of single electron spins [66] and individual nuclear spins may soon be distinguished.

## 12.4

### Discussion and Outlook

In this chapter, we have seen how modern nanotechnology is increasingly accepted and employed in the biomedical field, and especially in the field of sensors, genomics and proteomics [213–214]. Most of the issues dealt with here and in other similar overviews [215] are of great importance for the development of nanobio research, i.e. controlled surface functionalization, high-resolution imaging, fluidic governance, sensor principles, nanomechanics, etc. In order for nanotechnology to increase its impact on the biomedical field, we have to continue to develop basic technologies, as well as trying to utilize them in the biomedical area in a “play and see” fashion; by doing so one may find uses of the technologies in fields and areas of sciences that one could not otherwise envisage. The Nobel Laureate Herbert Kroemer has formulated a lemma [63] stating that any sufficiently new and innovative technology will find its own principal application created by that technology.

As is obvious from this chapter, most nanotechnologies so far have been employed for sensor purposes or as passive surfaces for molecular interactions. The main reason for this is that nanotechnology offers several orders of magnitude higher sensitivity than present technology. The step for nanoscientists, most often coming from the hard inorganic (top-down) nanotechnology scientific field, is smaller to take, as they can apply well-known concepts in order to study some biological processes, together with the fact that most nanotechnology efforts are presently driven from that field into the medical or biological field, in contrast to the reverse mechanisms. The day when scientists from very different fields start to collaborate in a more mutual way may also witness fundamentally new uses of nanotechnology in the biomedical sector. In this context, it is foreseeable that new nanoscience educational programs that presently are starting all over the world will be instrumental for this interdisciplinary development.

The area of using nanomechanics for biomedical applications and for probing cellular, intracellular as well as intercellular, events and interactions will probably entertain us in the coming years. Surely the class of epitaxial nanowires will be of specific instrumental importance, providing functional tools that, for example, may give full 3-D information when employed as large arrays of point detectors. Another area that will have a large influence on our understanding of biology and biological processes is the development of techniques for achieving fast imaging,

using SPM. Such possibilities to gather both nanometer-scale space and millisecond time information will open new avenues for life sciences research. The further development and utilization of printing-like methods, based on nanoimprint and nanoprinting methods, and similar printing nanotechnologies, to create large arrays of nanostructured surfaces of one or another kind will surely be of great future importance, both for high- and low-volume applications. Such printing methods are already able to create small series of nanostructured surfaces economically enough to be used in research applications in the life sciences domain. The development of mega-dense protein chips and DNA sensors may, in combination with hand-held devices, provide us with efficient point-of-care analysis or home-doctor kits that will fundamentally change our way of living. Within the next 10 years the mortality rate in the USA from various cancer forms is predicted to be close to zero due to increased early detection principles with significantly higher sensitivities than at present [215]. We will probably also witness the use of nanotechnology for various forms of prosthetic devices giving freedom back to impaired persons. In this context, however, stem cell research may be of even larger future importance, providing natural means to connect new functional nerve cells to the impaired nervous system, maybe in combination with nanotechnology. Increased abilities in the form of enhanced functions, such as IR vision for use during darkness when driving, may soon be within reach. Research and development activities for increased abilities for learning, enhanced memory and cognitive functions, as well as personalized medical treatments, etc., are presently also being pursued, often under the term “converging technologies” [216].

Most importantly, we should not forget that the tools being developed to handle nanomaterials are still very young, actually being in their caring or nursing stage; typical development time scales are of the order of 10–15 years before a real impact can be judged.

It is my hope that this overview will have inspired the reader to engage in this vigorous research field with so many possibilities open for exploration, where maybe the only limitations are governed by the individuals own ingenuities.

### **Acknowledgments**

This chapter would not have been possible without the collaboration, support, friendship and sharing of knowledge from all my Lund University colleges within the Nanometer Consortium, Division of Solid State Physics, and at the Departments of Physics, ElectroScience, Electrical Measurements Technology, Chemistry, Analytical Chemistry Immunotechnology, Cell & Organism Biology, Neurophysiology, Hand Surgery and Philosophy, as well as all international friends and collaborators in various EU programs (Charge, Nanotech, Chanil, Nanomass, Nano2Life, NaPa, Bionel, Parnass, etc.), and of course also my previous and present graduate students supplying a constant flow of joy and enthusiasm. Last, but not least, the support from my loving daughters Caroline and Cecilia is of great and very special importance for me.

## 13 Nanodevices in Nature

*Alexander G. Volkov and Courtney L. Brown*

### 13.1 Introduction

Living organisms are intricately designed with systems of “checks and balances” which regulate biological processes and minimize malfunctions. Biological nanodevices are largely responsible for the nearly flawless function of various organisms. The use of biological organisms as model systems for the engineering of new technologies is a form of applied case-based reasoning. The wealth of information generated from the study of biological systems creates a database that can be utilized to find solutions to various problems.

In this chapter, we discuss the role of various nanodevices in a wide variety of biological processes. Furthermore, we focus specifically on nanoreactors in multi-electron reactions, the biological function of cytochrome oxidase, nanodevices in photosynthesis and phototropism, membrane transport, molecular motors, and electroreceptors. There are many publications that focus on isolated nanodevices within very specific model systems; however, this approach allows us to analyze the role and significance of nanodevices in a variety of life forms, including plants, animals and bacteria. The study of nanodevices has limitless applications in bioelectronics, biology, chemistry, genetics, biophysics, bioengineering, technology and other fields of scientific study.

Nanodevices are molecules or molecular complexes that have clear and specific functions, and are a few nanometers in size. Millions of nanodevices exist in nature and in this chapter we discuss a few examples. Natural nanodevices include photochemical, electrochemical and synthetic nanoreactors. Photosystem (PS) I and PS II, enzymes, enzymatic systems in the citric acid cycle, and carbon fixation in the reductive carboxylic acid cycle are also common nanodevices in nature. Molecular motors such as ATP synthase, myosin, kinesin, DNA helicases, DNA topoisomerase, DNA helixase, RNA polymerase and bacterial rotary motors are vital nanodevices that serve to regulate biological processes. Molecules in electron transfer chains act as nanorectifiers and nanoswitches. Biological applications for nanodevices include information transfer, molecular computing, mechanosensors, elec-

troreceptors, magnetoreceptors, magnetosomes, neuronal networks, light sensors and ion channels.

## 13.2

### Multielectron Processes in Bioelectrochemical Nanoreactors

Vectorial charge transfer and molecular recognition at the interface between two dielectric media are important stages in many bioelectrochemical processes such as those mediated by energy-transducing membranes [1–5]. Many biochemical redox reactions take place at aqueous medium/membrane interfaces and some of these reactions are multielectron processes. About 90% of the oxygen consumed on Earth is reduced in a four-electron reaction catalyzed by cytochrome *c* oxidase. Multielectron reactions take place during photosynthesis, which is one of the most important processes on Earth.

Synchronous multielectron reactions may proceed without the formation of intermediate radicals. These radicals are highly reactive, and can readily enter a side-reaction of hydroxylation and destruction of the catalytic complex. Since multielectron reactions do not pollute the environment with toxic intermediates and are ecologically safe, they are used by nature for biochemical energy conversion during respiration and photosynthesis. In the multielectron reaction that takes place in a series of consecutive single-electron stages, the Gibbs energy necessary for single-electron transfer cannot be completely and uniformly distributed over the stages. The energy demand for various stages is varied and the excess energy in the simpler stages is converted into heat. In a synchronous multielectron reaction, the energy is used very economically [6–9].

An important parameter in the quantum theory of charge transfer in polar media is the medium reorganization energy,  $E_s$ , that determines activation energy. The energy of medium reorganization in systems with complicated charge distribution was calculated by Kharkats [10]. Reagents and products can be represented by a set of  $N$  spherical centers arbitrarily distributed in a polar medium. The charges of each of the reaction centers in the initial and final state are  $z^i$  and  $z^f$  respectively. Taking  $R_k$  to represent coordinates of the centers and  $\epsilon_i$  for dielectric constants of the reagents, it follows that:

$$E_s = 0.8 \left( \frac{1}{\epsilon_{\text{opt}}} - \frac{1}{\epsilon_{\text{st}}} \right) \times \left\{ \sum_{p=1}^N \left[ \frac{(\delta z_k)^2}{2a_p} + \sum_{\substack{k=1 \\ k \neq p}}^N \frac{(\delta z_p)(\delta z_k)}{2R_{pk}} + \sum_{\substack{k=1 \\ k \neq p}}^N \sum_{\substack{l=1 \\ l \neq p}}^N \frac{(\delta z_p)(\delta z_l) a_p^3 (\vec{R}_{pk} \vec{R}_{pl})}{R_{pk}^3 R_{pl}^3} \left( \frac{3\epsilon_{\text{st}}^2}{(2\epsilon_{\text{st}} + \epsilon_i)^2} - \frac{1}{2} \right) \right] \right\} \quad (1)$$

where  $(\delta z_k) = z_k^f - z_k^i$ ,  $R_{pk} = R_p - R_k$ , and  $z_k^f$  and  $z_k^i$  are charge numbers of particle  $k$  in the initial and final states, respectively. The term  $a_p$  is the radius of

particle  $p$ ,  $R_k$  is the coordinate of  $k$ -particle center and  $\epsilon_i$  is the dielectric constant of reactant. Reactions with synchronous transfer of several charges present a particular case of Eq. (1).

It follows from Eq. (1) that  $E_s$  is proportional to the square of the number of charges transferred. Homogeneous multielectron processes are unlikely, due to the high activation energy resulting from a distinct rise in the energy of solvent reorganization. For multielectron reactions, the exchange currents of  $n$ -electron processes are small compared to those of single-electron multistep processes, which makes the stage-by-stage reaction mechanism more advantageous. Therefore, multielectron processes can proceed only if the formation of an intermediate is energetically disadvantageous. However, conditions can be chosen which reduce  $E_s$  during transfer of several charges to the level of the reorganization energy of ordinary single-electron reactions. These conditions require systems with a low dielectric constant and large reagent radii. Furthermore, the substrate must be included in the coordination sphere of the charge acceptor with several charge donors or acceptors bound into a multicenter complex. Recent papers have presented theoretical studies on the kinetics of heterogeneous multielectron reactions at water/oil interfaces, which proved to be capable of catalyzing multielectron reactions and sharply reducing the activation energy.

The most effective coupling of ion and electron transport can be obtained if the activation energy of the coupled process is lower than that of the charge transfer in the electron transport chain. It is obvious from Eq. (1) that this requires a simultaneous transfer of opposite charges, so that the second and the third terms of Eq. (1) are negative. An optimal geometry between the centers of charges of donors and acceptors must also be chosen.

To illustrate this point, we can consider two instances of multielectron reactions: simultaneous transfer of  $n$  charges from one donor to an acceptor and simultaneous transfer of several charges (one from each of the centers) to  $m$  acceptors ( $m \leq n$ ). In the former case,  $E_s$  is proportional to  $n^2$ , while in the latter it may be significantly lower (depending on the sign of the charge being transferred and the reciprocal positions of reagents). The concerted multicenter mechanism of multielectron reactions markedly reduces  $E_s$  and, hence the activation energy, compared to a two-center multielectron process. With the appropriate arrangement of the reactants, the activation energy associated with electron transfer in a heterogeneous multielectron reaction may be lower than the energy of reorganization of the media.

### 13.3

#### Cytochrome Oxidase: A Nanodevice for Respiration

The function of the enzymes of the mitochondrial respiratory chain is to transform the energy of redox reactions into an electrochemical proton gradient across the hydrophobic barrier of a coupling membrane.

Cytochrome oxidase (EC 1.9.3.1, PDB 2OCC) is the terminal electron acceptor of

**Figure 13.1.** Scheme of the structural organization of cytochrome *c* and cytochrome *c* oxidase monomer in the inner mitochondrial membrane.

the mitochondrial respiratory chain. Its main function is to catalyze the reaction of oxygen reduction to water using electrons from ferrocycytochrome *c*:

Reaction (2) is exothermic and this energy can be used to transport protons across the mitochondrial membrane (Fig. 13.1). Mitochondrial cytochrome *c* oxidase is a dimer; each monomer is composed of 13 subunits. The enzyme contains cytochromes *a* and *a*<sub>3</sub>, one binuclear copper complex Cu<sub>a</sub>, one mononuclear copper site Cu<sub>b</sub>, and one bound Mg<sup>2+</sup> per monomer. It has a molecular weight ranging from 180 000 to 200 000 kDa for the most active form [11–13]. Cytochrome oxidases can transport a maximum of eight protons across the membrane per oxygen molecule reduction [14, 15]. Four of the protons bind to the reaction complex during the reduction of oxygen to water and up to four other protons are transported across the membrane. The resulting chemiosmotic proton gradient is used in ATP synthesis.

There are two types of respiration in photosynthetic organisms – dark respiration and photorespiration. Dark respiration includes O<sub>2</sub> reduction and the oxidation of NADH and FADH<sub>2</sub> in mitochondrial membranes, glycolysis, the Krebs cycle, and the oxidative pentose phosphate pathway. Respiration is commonly subdivided into two functional components – growth respiration and maintenance respiration. Growth respiration supplies energy for the production of new biomass; however, maintenance respiration provides the energy needed to maintain the integrity of existing structures and their turnover.

The respiratory chain of mitochondria is an integral part of the inner mitochondrial membrane. It is composed of four electron-transporting protein complexes (NADH dehydrogenase complex I, succinate dehydrogenase complex II, cytochrome reductase complex III and cytochrome *c* oxidase complex IV), ATP synthase (complex V), and mobile electron carriers ubiquinone and cytochrome *c*.

Plant mitochondria have additional enzymes not found in mitochondria of animals – the cyanide-insensitive alternative oxidase, an internal rotenone-insensitive NADPH dehydrogenase and an externally located NADPH dehydrogenase, which does not conserve energy. The alternative oxidase catalyzes the oxidation of ubiquinol to ubiquinone and the reduction of oxygen to water. It is inhibited by salicylhydroxamic acid.

Kharkats and Volkov were the first to present proof that cytochrome *c* oxidase reduces molecular oxygen by synchronous multielectron mechanism without the formation of an  $O_2^-$  intermediate [7–9, 14, 15]. The calculations predicted that the first step in oxygen reduction by cytochrome *c* oxidase should be a concerted multielectron process. As the field progresses, it became clear that the first step of oxygen reduction is a two-electron concerted process. The possible concerted molecular 2:1:1-electron and 2:2 proton pump mechanism of cytochrome *c* oxidase function is discussed in this chapter.

The 1:1:1:1-electron mechanisms of oxygen reduction by cytochrome oxidase were most frequently discussed in biochemistry. The reaction implies that the Gibbs free energy of the first electron transfer from cytochrome oxidase to  $O_2$  is positive (Fig. 13.2). As a result, this route should be abandoned or the reaction rate should be extremely low. Since the Gibbs free energy of  $O_2$  binding in the catalytic site of cytochrome oxidase is  $-21 \text{ kJ mol}^{-1}$  [16], cytochrome *c* redox potential is 0.25 V. The Gibbs free energy of the first electron donation to oxygen at pH 7 is  $+33 \text{ kJ mol}^{-1}$ . The Gibbs free energy of the reaction

in a cytochrome oxidase catalytic site is equal to  $+79 \text{ kJ mol}^{-1}$ . Activation energy for  $O_2$  reduction by fully reduced cytochrome oxidase is equal to  $16 \text{ kJ mol}^{-1}$  [17].

**Figure 13.2.** Energy diagrams for possible routes of the reaction  $O_2 + 4H^+ \leftrightarrow 2H_2O$ .  $G_m$  is the reaction midpoint Gibbs free energy at pH 7.

**Figure 13.3.** Scheme of the 2:1:1-electron reduction mechanism at the cytochrome *c* oxidase active site and its coupling to proton pumping. Starting from the oxidized form (O), the one-electron reduced form (E) and the doubly reduced form (R) are generated. Upon

binding, compound (A) is observed. Next the peroxy-intermediate (P) is formed. The oxoferryl state (F) and a hydroxyl state (H) are formed after protonation of the iron-bound oxygen atom. After water formation and release, the O state is regenerated.

Since the Gibbs free energy of the endothermic reaction (3) is 5 times the measured activation energy for  $\text{O}_2$  reduction by cytochrome oxidase, the single-electron mechanisms 1:1:1:1, 1:2:1, 1:1:2 and 1:3 at room temperature are unlikely. These reaction mechanisms are favorable when the binding energy of the single-electron intermediate is less than  $-52 \text{ kJ mol}^{-1}$  in magnitude. The significant covalent bonding energy allows this intermediate to be experimentally detected. However, it has not been detected thus far.

The fact that the first electron addition to  $\text{O}_2$  is endothermic accounts for the relative chemical inertness of oxygen in nature and it permits the existence of life on Earth.

A possible mechanism of oxygen reduction by cytochrome *c* oxidase is outlined in Fig. 13.3, and is to be considered in detail after the discussion of the thermodynamic and kinetic aspects of the problem.

### 13.3.1

#### Nanodevice Architectonics

Equation (1) sets the conditions for the structure of cytochrome *c* oxidase catalytic site necessary for oxygen reduction to occur by the concerted  $n$ -electron mecha-

nism. In order to reduce the reorganization energy of the medium, and thus the activation energy, several conditions must be met.

- The dielectric constant of the medium where oxygen reduction takes place should be low. Simply stated, the catalytic site should be immersed in a hydrophobic phase of the membrane (protein).
- There should be  $n$  spatially separated electron donors. For the proposed mechanism, heme and protein–copper complexes satisfy this condition.
- Cation, preferably a proton, transport should accompany electron transport via cytochrome  $c$  oxidase. Based on Eq. (1), when opposing charges are simultaneously transferred in close directions, the reorganization energy of the medium may be reduced due to a dependence on the third and fourth terms in Eq. (1). It implies that the coupling of the electron and proton pumps in cytochrome oxidase can be attained if the simultaneous transfer of opposing charges in close directions neutralizes medium reorganization. If electron transfer via cytochrome oxidase is coupled with proton transport across the mitochondrial membrane, then the energy liberated in the second reaction is consumed as opposed to being converted to heat.
- The radii of electron donors should be sufficiently large. This condition is achieved by utilizing the metal ion components of organic complexes (e.g. hemes and cysteines), the systems of conjugated bonds and ligands capable of undergoing redox reactions.

### 13.3.2

#### Activation Energy and Mechanism of Oxygen Reduction

The dependence of oxygen reduction rate on temperature reveals that cytochrome oxidase exists in two conformations – “hot” (h) and “cold” (c). The respective activation energies  $E_a^h$  and  $E_a^c$  are  $16 \text{ kJ mol}^{-1}$  (at  $23\text{--}35 \text{ }^\circ\text{C}$ ) and  $60 \text{ kJ mol}^{-1}$  (below  $20 \text{ }^\circ\text{C}$ ) [18]. A phase transition accompanied by conformational changes and absorption spectrum takes place between  $18$  and  $23 \text{ }^\circ\text{C}$ . The temperature  $T^c$  depends on the surrounding lipid composition. The low  $E_a^h$  value suggests that the single-electron mechanisms 1:1:1:1, 1:2:1, 1:3 and 1:1:2 are unlikely at temperatures above  $T^c$  since the enthalpy for the transfer of first electron from the reduced cytochrome oxidase to oxygen is 5 times more than the measured activation energy.

For the multielectron reaction 2:1:1, according to Eq. (1),  $E_s$  for two-electron reactions between  $\text{O}_2$ ,  $a_3$  and  $\text{Cu}_b$  strongly depend on geometry and distances in a catalytic site. Only the 2:1:1 mechanism of oxygen reduction by cytochrome oxidase can be realized *in vivo* in both “hot” and “cold” conformations.

Consider the molecular mechanism of oxygen reduction outlined in Fig. 13.3 in more detail [9, 14, 15].

The oxidized catalytic site of cytochrome oxidase is composed of cytochrome  $a_3$  and  $\text{Cu}_b$ . It is reduced via the bridge mechanism by two electrons supplied from the electron reservoir of the respiratory chain. This reduced complex then binds an oxygen molecule. The reaction center is oxidized to the initial state in a double-

electron reaction with the formation of a peroxide bridge between  $a_3$  and  $\text{Cu}_b$ . The partially reduced (to peroxide) oxygen molecule must be bound in the reaction center since cytochrome oxidase is known to reduce oxygen to water without the release of any intermediates from the membrane. Next, the catalytic complex accepts two electrons from the electron reservoir  $\text{Fe}(c) \rightarrow a_3$ . In the next step, the peroxide bridge undergoes 1:1-electron reduction and protonation to water.

### 13.3.3

#### Proton Pump

Water molecules released in the course of oxygen reduction are transferred from the hydrophobic catalytic site to the aqueous phase. The continuous movement of the product away from the reaction center causes the equilibrium of the second reaction to shift to the right. Energy liberated in the exothermic reaction (2) is sufficient for transporting 8  $\text{H}^+$  ions across the membrane. Four of the  $\text{H}^+$  ions couple with  $\text{O}_2$  to form two  $\text{H}_2\text{O}$  molecules. The remaining  $\text{H}^+$  ions can be transported across the hydrophobic zone of the membrane and used for ATP synthesis in ATP synthase complex. As follows from thermodynamics (Fig. 13.2), the energy needed for the function of the  $\text{H}^+$  pump is liberated only at the last steps of water formation on the addition of third and fourth electrons independently of the reaction route [9, 14]. The functioning of protons pump after formation of ferryl intermediate is possible only if the difference between Gibbs energy of ferryl and peroxy intermediates binding is less than  $-35 \text{ kJ mol}^{-1}$ .

The binding energy of the ferryl intermediate is negative. This energy supports the proton pump function not only during the addition of the fourth electron, but also after the formation of the three-electron oxygen intermediate. The stoichiometry of proton pumping by cytochrome oxidase can be 0:2:2 [14].

As it follows from Eq. (1), media reorganization energy corresponding to simultaneous electron and proton transfer is minimized when the transfer directions are close.

Alternative cytochrome oxidase in green plants can reduce  $\text{O}_2$  without concomitant proton transfer. In such a case, the enzymes work like machines converting the energy of electron transfer to heat.

## 13.4

### Photosynthetic Electrochemical Nanoreactors, Nanorectifiers, Nanoswitches and Biologically Closed Electrically Circuits

Life on Earth has been supported by the continuous flow of solar energy over billions of years. The power of this flux is extremely high:  $4.14 \times 10^{15} \text{ kWh day}^{-1}$  or  $1.5 \times 10^{18} \text{ kWh year}^{-1}$ . These values are extremely vast and difficult to imagine. According to Einstein's equation  $E = mc^2$ , the energy equivalent of 1 kg of mass is approximately  $2.5 \times 10^{10} \text{ kWh}$ . The net daily energy flux incident upon Earth can thus be expressed as 165 tons and the thus net annual flux is 60 000 tons. By

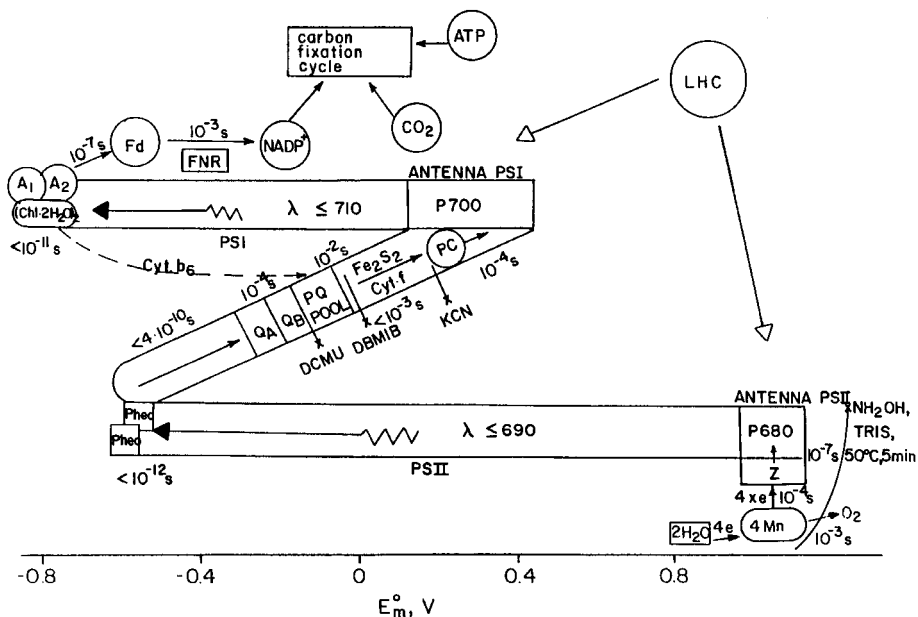

comparison, the annual production of electric energy in United States corresponds to an equivalent mass of about 100 kg and the total use of all kinds of energy corresponds to about 800 kg. At present, the annual consumption of energy by mankind is  $4 \times 10^{17}$  kJ, rising rapidly and doubling every 20 years. The known reserves of fossil fuels are limited to an estimated energy equivalent of  $5 \times 10^{19}$  kJ, so new sources of energy are of fundamental importance. One obvious possibility is solar energy. The amount of solar energy incident on the Earth is about  $5 \times 10^{21}$  kJ year<sup>-1</sup>, of which  $3 \times 10^{18}$  kJ is converted into chemical energy by photosynthesis in plants and microorganisms [5].

The vast majority of the pigments in a photosynthetic organism is not chemically active, but functions primarily as an antenna. The photosynthetic antenna system is a nanodevice that collects and delivers the excited state energy by means of excitation transfer to the reaction center complexes where photochemistry takes place. The antenna system increases the effective cross-section of photon absorption by increasing the number of pigments associated with each photochemical complex. The intensity of sunlight is sufficiently dilute so that any given chlorophyll molecule only absorbs at most a few photons per second.

By incorporating many pigments into a single unit, the reaction centers and electron transport chain can be used to maximum efficiency. A remarkable variety of antenna complexes have been identified from various classes of photosynthetic organisms. Excitation transfer must be fast enough to deliver excitations to the photochemical reaction center and have them trapped in a short amount of time compared to the excited state lifetime in the absence of trapping. Excited state lifetimes of isolated antenna complexes, where the reaction centers have been removed, are typically in the range of 1–5 ns. Observed excited state lifetimes of systems where antennas are connected to reaction centers are generally on the order of a few tens of picoseconds, which is sufficiently fast so that under physiological conditions almost all the energy is trapped by photochemistry.

In water-oxidizing photosynthesis two membrane-integrated protein complexes PS II and PS I are operating in series (Fig. 13.4). The electron transfer starts in both photosystems vectorially across the membrane. Light energy is harvested by photosynthetic pigment systems in which the electronic structure of excited-state chlorophyll donates an electron to a primary acceptor pheophytin, the first component of an electron transport chain. The electron is fortified with it the energy of the original photon of light it absorbed. In the process of electron transport, the energy is captured in two ways. The first involves the coupling a proton pump mechanism to the sequential redox reactions in the electron transport chain, so that a proton gradient is established across the thylakoid membrane. The electrochemical energy of the proton gradient is then used to drive ATP synthesis by the ATP synthase enzymes embedded in the membrane. The second energy capture occurs when an acceptor molecule such as  $\text{NADP}^+$  is reduced to NADPH, which in turn is used to reduce carbon dioxide in the Calvin cycle. Systems modeling photosynthesis should have the capability of carrying out relatively simple versions of these fundamental reactions.

The redox map of photosynthesis in green plants can be described in terms of

**Figure 13.4.** Scheme of electron transfer in photosynthesis in higher plants.  $E_m^o$  on the abscissa stands for midpoint redox potential at pH 7.0. Light quanta ( $h\nu$ ) are absorbed in two sets of antenna chlorophyll molecules, the excitation energy is transferred to the reaction

center chlorophyll a molecules of PS II (P680) and PS I (P700) forming (P680)\* and (P700)\*, and the latter two initiate electron transport. (Reproduced from Ref. [21] with permission from Elsevier Science.)

the well-known Z-scheme proposed by Hill and Bendall [19]. The molecular organization of a thylakoid membrane is shown in Fig. 13.5. The spectral characteristics of PS II indicate that the primary electron donor is the dimer of chlorophyll P680 with absorption maxima near 680 and 430 nm. Water can be oxidized by an oxygen-evolving center (OEC) composed of several chlorophyll molecules, two molecules of pheophytin, plastoquinol, several plastoquinone (PQ) molecules and a manganese-protein complex containing four manganese ions. The OEC is a highly ordered structure in which a number of polypeptides interact to provide the appropriate environment for cofactors such as manganese, chloride and calcium, as well as for electron transfer within the complex. Figure 13.6 shows the electronic equivalent circuit of PS I and PS II.

Manganese-binding centers were first revealed in thylakoid membranes by electron paramagnetic resonance (EPR) methods and it is now understood that four manganese ions are necessary for oxygen evolution during water photooxidation. PQ acts as a transmembrane carrier of electrons and protons between reaction centers of two photosystems in the case of noncyclic electron transfer. It may also serve as a molecular "tumbler" that switches between one- and two-electron reactions. Pheophytin is an intermediate acceptor in PS II. Direct formation of P680

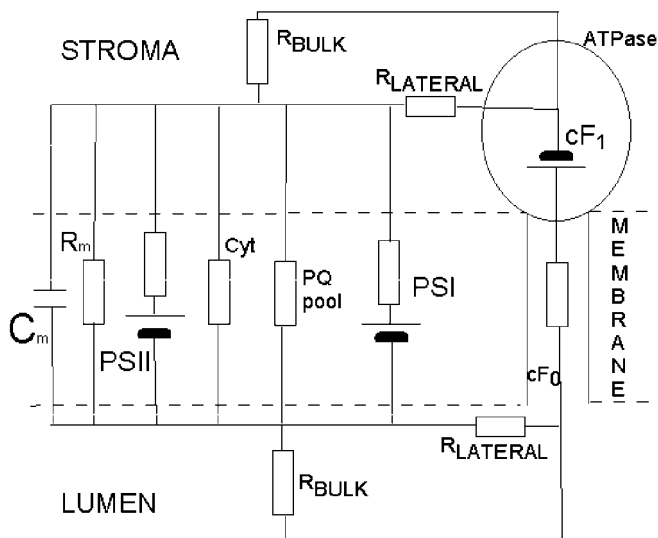

Figure 13.5. A stylized model of the electron transport chain with most of the light-harvesting pigment–protein complexes omitted. (Reproduced from Ref. [21] with permission from Elsevier Science.)

pheophytin ion radical pairs was revealed by experiments on magnetic interactions between pheophytin and PQ as reflected in the EPR spectra.

The photocatalytic oxidation of two molecules of water to oxygen cannot be a single-quantum process since the total energy expenditure of a catalytic cycle cannot be less than  $476 \text{ kJ mol}^{-1}$ . However, there is no fundamental reason why one quantum process should not induce the transfer of several electrons. For instance, a two-quantum process would require light with a wavelength less than 504 nm, while a four-quantum process would involve a sequential mechanism in which each light quantum is used to transfer one electron from photocatalyst to an electron acceptor. The threshold wavelength for the oxidation of water in this case is 1008 nm. The eight-quantum scheme which is actually used in photosynthesis can be explained by the need to compensate for energy losses in a long electron-transfer chain of redox reactions.

Water oxidation to molecular oxygen is a multielectron process that proceeds with surprisingly high quantum efficiency. The water oxidation reaction can proceed upon illumination at 680 nm – a wavelength of light that excludes one-electron mechanisms using hydroxyl and oxygen radicals. For a three-electron reaction an oxidant stronger than the cation-radical  $\text{P680}^+$  is needed. A synchronous two-by-two electron pathway of the reaction is thermodynamically possible if the standard

**Figure 13.6.** The equivalent electrical circuit of thylakoid membrane. C, capacity; R, resistance;  $cF_1$ , coupling factor; cyt, cytochrome.

free energy of binding of the two-electron intermediate is about  $-40 \text{ kJ mol}^{-1}$ . This value corresponds to the energy of formation for two hydrogen bonds between  $\text{H}_2\text{O}_2$  and the catalytic center. For this case a molecular mechanism was proposed [20, 21] and is discussed below (Fig. 13.7).

Membrane-bound P680 enters an excited state upon illumination. In dimers and other aggregated forms of chlorophyll, the quantum efficiency of triplet states is

**Figure 13.7.** Possible 2:2-electron mechanism of water photooxidation by a manganese nanodevice in PS II.

low. It is the singlet excited state that undergoes photochemical transformations. In several picoseconds, an electron is first transferred to pheophytin, then to PQA, and from PQA to polypeptide-bound PQB in thylakoid membranes (Fig. 13.4), resulting in an oxidized pigment and a reduced acceptor. The cation radical  $P680^+$  successively oxidizes four manganese ions, which in turn drives the production of molecular oxygen. Formation of a cation radical of chlorophyll or oxidation of manganese ions is accompanied by dissociation of water bound to the reaction center and ejection of protons. A synchronous multielectron process that describes all four oxidizing states of the OEC was proposed earlier. The transfer of electrons in a 1:1:1:1 series from a manganese cluster to the electron transport chain is accompanied by the ejection of 1:0:1:2 protons and the evolution of molecular oxygen [20, 21].

#### **Phototropic Nanodevices in Green Plants: Sensing the Direction of Light**

Plants continually gather information about their environment. Environmental changes elicit various biological responses. The cells, tissues and organs of plants possess the ability to become excited under the influence of environmental factors, referred to as irritants [22–25].

Nerve cells in animals and phloem cells in plants share one fundamental property – they possess excitable membranes through which electrical excitations, in the form of action potentials, can propagate. Plants generate bioelectrochemical signals that resemble nerve impulses and these are present in plants at all evolutionary levels [26].

The conduction of bioelectrochemical excitation is a rapid method of long-distance signal transmission between plant tissues and organs. Plants quickly respond to changes in luminous intensity, osmotic pressure, temperature, cutting, mechanical stimulation, water availability, wounding, and chemical compounds such as herbicides, plant growth stimulants, salts and water [27–30]. Once initiated, electrical impulses can propagate to adjacent excitable cells. The change in transmembrane potential creates a wave of depolarization or action potential, which affects the adjoining resting membrane.

The phloem is a sophisticated tissue in the vascular system of higher plants. Representing a continuum of plasma membranes, the phloem is a potential pathway for transmission of electrical signals. It consists of two types of conducting cells – the characteristic sieve-tube elements and the companion cells. Sieve-tube elements are elongated cells that have end walls perforated by numerous minute pores through which dissolved materials can pass. Sieve-tube elements are connected in a vertical series known as sieve tubes. Sieve-tube elements are alive at maturity; however, before the element begins its conductive function, their nuclei dissipate. The smaller companion cells have nuclei at maturity and are living. They are adjacent to the sieve-tube elements. It is hypothesized that they control the process of conduction in the sieve tubes. Thus, when the phloem is stimulated at any

point, the action potential is propagated over the entire length of the cell membrane and along the phloem with a constant voltage.

Electrical potentials have been measured at the tissue and whole-plant level. At the cellular level, electrical potentials exist across membranes, and thus between cellular and specific compartments. Electrolytic species such as  $K^+$ ,  $Ca^{2+}$ ,  $H^+$  and  $Cl^-$  are actively involved in the establishment and modulation of electrical potentials [31–35]. The highly selective ion channels serve as natural nanodevices [25]. Voltage-gated ion channels, as nanopotentiostats, regulate the flow of electrolytic species and determine the membrane potential [25].

Light is an essential source of energy on which many of the biological functions of plants depend. The sun's radiant energy optimizes germination, photosynthesis, flowering and other processes needed to maintain homeostasis. Plants contain specific photoreceptors that perceive light ranging from UV to far-red light. Natural radiation concurrently excites multiple photoreceptors in higher plants. Specific receptors initiate distinct signaling pathways leading to wavelength-specific light responses. Photoreceptors, phototropins, cryptochromes and phytochromes have been identified at the molecular level [36–42].

Phototropins, such as PHOT1 and PHOT2, are the flavoprotein photoreceptor that responds to light with a wavelength of 360–500 nm (blue light). It regulates phototropism and intracellular chloroplast movements. PHOT1 contains two 12-kDa flavin mononucleotide (FMN)-binding domains. LOV1 (light, oxygen and voltage) and LOV2 are located within its N-terminal region and a C-terminal serine/threonine protein kinase domain. Phototropin, when activated by light, undergoes a conformational change. PHOT1 and PHOT2 bind FMN, and undergo light-dependent autophosphorylation. PHOT2 is localized in the plasma membrane. Cryptochromes and phototropin have different transduction pathways, but similar traits.

Phototropism is one of the best-known plant tropic responses. A positive phototropic response is characterized by a bending or turning toward the source of light. When plants bend or turn away from the source of light, the phototropic response is considered negative. A phototropic response is a sequence of the four following processes: reception of the directional light signal, signal transduction, transformation of the signal to a physiological response and the production of directional growth response.

After 1–2 min of irradiation, a change in the direction of irradiation generates action potentials in soybean (Fig. 13.8) depending on the wavelength of light irradiation. Irradiation at wavelengths 400–500 nm induces fast action potentials in soybean with duration time of about 0.5 ms; conversely, the irradiation of soybean at wavelengths between 500 and 600 nm fails to generate action potentials. Irradiation between 500 and 600 nm does not induce phototropism. Irradiation of soybean by blue light induces positive phototropism.

The sensitive membranes in phloem cells facilitate the passage of electrical excitations in the form of action potentials. The action potential has a stereotyped form and an essentially fixed amplitude – an “all or none” response to a stimulus. Each impulse is followed by the absolute refractory period [43, 44]. The fiber cannot

**Figure 13.8.** Action potentials in soybean induced by irradiation at 450 nm 2 min after changing the direction of irradiation. Irradiance was  $10 \mu\text{E} (\text{m}^2\text{s})^{-1}$ . Distance between electrodes was 5 cm. The soil was preliminary treated by water every day. Volume of soil was 0.5 L. Frequency of scanning was 50 000 samples  $\text{s}^{-1}$ .

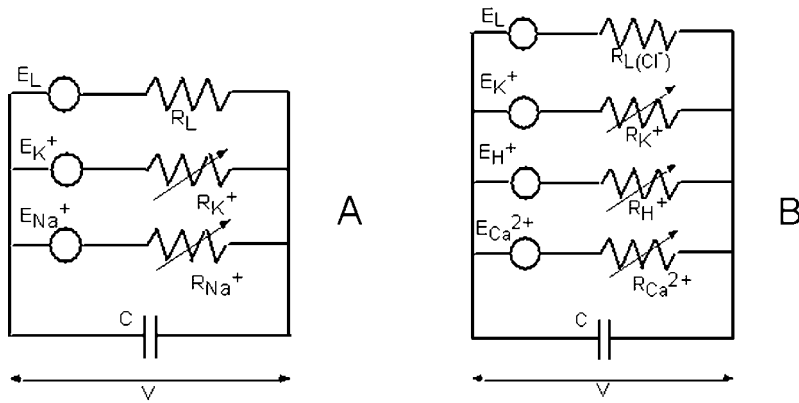

transmit a second impulse during the refractory period. The integral organism of a plant can be maintained and developed in a continuously varying environment only if all cells, tissues and organs function in concordance.

These propagating excitations are theoretically modeled as traveling wave solutions of certain parameter-dependant nonlinear reaction–diffusion equations coupled with some nonlinear ordinary differential equations. These traveling wave solutions can be classified as single- and multiple-loop pulses, fronts and backs waves or periodic waves of different wave speed. This classification is matched by the classification of the electrochemical responses observed in plants. The experimental observations also show that under the influence of various pathogens, the shapes and speeds of the electrochemical responses undergo changes. From the theoretical perspective, the changes in the shapes and wave speeds of the traveling waves can be accounted by appropriate changes in parameters in the corresponding nonlinear differential equations.

Hodgkin and Huxley's membrane model [45] accounts for  $\text{K}^+$ ,  $\text{Na}^+$  and ion leakage channels in squid giant axons (Fig. 13.9A). The membrane resting potential for each ion species is treated like a battery and a variable resistor models the degree to which the channel is open. In an axon there is the  $\text{K}^+$  and  $\text{Na}^+$  transmembrane transport; conversely, in phloem cells the  $\text{K}^+$ ,  $\text{Ca}^+$  and, more than likely,  $\text{H}^+$  channels are involved in this process (Fig. 13.9B).

Some voltage-gated ion channels work as plasma membrane nanopotentiostats. Blockers of ion channels such as tetraethylammonium chloride and  $\text{ZnCl}_2$  stopped the propagation of action potentials in soybean plants induced by blue light and inhibited phototropism. Voltage-gated ionic channels control the plasma membrane potential and the movement of ions across membranes, thereby regulating various biological functions. These biological nanodevices play vital roles in signal transduction in higher plants.

All processes of life have been found to generate electric fields in every organism that has been examined with suitable and sufficiently sensitive measuring tech-

**Figure 13.9.** The Hodgkin–Huxley (HH) equivalent circuit for an axon (A) and the modified HH circuit for sieve tubes in phloem (B).

niques. The conduction of electrochemical excitation is regarded as one of the most universal properties of living organisms. It arose in connection with a need for the transmission of a signal in response to an external influence from one part of a biological system to another. The nature of regulatory relations of the plant organism with the environment is a basic bioelectrochemical problem, one that has a direct bearing on tasks of controlling the growth and development of plants.

### 13.6 Membrane Transport and Ion Channels

Membrane transport is vital to cell survival. Two major mechanisms used to transport ions and solutes across biological membranes are ion pumps and ion channels [1, 5, 46–48]. Ion transport is essential to the generation of membrane potentials, signal transduction and other biological processes. A membrane potential is a difference in electrical potential between intercellular and extracellular aqueous solutions. The membrane potential is influenced by the unequal distribution of electrolytic species inside and outside of the cell. Many intercellular proteins are negatively charged and remain inside the cell. The leakage of  $K^+$  and  $H^+$  ions is largely responsible for the generation of membrane potentials. The open  $K^+$  ion channel facilitates the outward diffusion of  $K^+$  ions without hydrolyzing ATP.

Ion channels are integral proteins that quickly facilitate the movement of specific ions across a biological membrane down their electrochemical gradient. Ion channels can facilitate the movement of approximately  $10^6$ – $10^8$  ions  $s^{-1}$  [49]. These channels are classified as mechanically gated, non-gated, voltage gated or ligand gated. Non-gated channels remain permeable to specific ions. Voltage-gated chan-

**Figure 13.10.** General architecture of the voltage-gated inward rectifying  $K^+$  channel AKT1.

nels become permeable when the membrane voltage is modulated above its threshold. Ligand-gated channels become permeable when the bound ligand is removed. Ion pumps employ a different mechanism. Ion pumps undergo conformational changes and they require energy to move specific ions against the electrochemical gradient. Ion pumps can facilitate the movement of approximately  $10\text{--}100$  ions  $s^{-1}$ . Ion channels are highly specific filters, allowing only desired ions through the cell membrane. Ion channels are devices in the engineering sense – they have signal inputs, power supplies and signal outputs. They use their complex structure to convert input signals to output signals [50, 51].

Voltage-gated channels open or close depending on the transmembrane potential. Examples include the sodium and potassium voltage-gated channels of nerve and muscle cells that are involved in the propagation of action potentials, and voltage-gated calcium channels that control neurotransmitter release in presynaptic endings. Voltage-gated channels are found in neurons, muscle cells and plant cells. Voltage-gated ion channels are membrane proteins that conduct ions at high rates regulated by the membrane potential [52–54]. Voltage-gated channels consist of three major parts – the gate, the voltage sensor and the ion-selective conducting channel (Fig. 13.10). The voltage sensor is a region of protein-bearing charged amino acids that relocate upon changes in the membrane potential. The movement of the sensor initiates a conformational change in the gate of the conductive pathway thus controlling the flow of ions. The voltage-gated  $K^+$ ,  $Na^+$  and  $Ca^{2+}$  channels have a common domain of six helical transmembrane segments S1–S6. The fourth segment, S4, is the voltage sensor of the channel and has a symmetrical arrangement of charged residues, with each third residue being arginine or lysine. A voltage-sensing domain consists of membrane segments S1–S4 and controls the conformation of gates located in the pore domain S5–S6.

Ligand-gated channels open in response to a specific ligand molecule on the external face of the membrane in which the channel resides. Examples include the

“nicotinic” acetylcholine receptor, AMPA receptor and other neurotransmitter-gated channels. Cyclic nucleotide-gated channels, Calcium-activated channels and others open in response to internal solutes, and they mediate cellular responses to second messengers. Stretch-activated channels open or close in response to mechanical forces that arise from local stretching or compression of the membrane around them. Such channels are believed to underlie touch sensation and the transduction of acoustic vibrations into the sensation of sound. G-protein-gated channels open in response to G-protein activation via its receptor. Inward-rectifier K channels allow potassium to flow into the cell in an inwardly rectifying manner, e.g. potassium flows into the cell, but not out of the cell. They are involved in important physiological processes such as the pacemaker activity in the heart, insulin release, and potassium uptake in glial cells. Light-gated channels like channelrhodopsin 1 and channelrhodopsin 2 are directly opened by the action of light [55]. Resting channels remain open at all times.

### 13.7 Molecular Motors

A molecular motor is a protein that uses energy from ATP hydrolysis or the gradient of electrochemical potentials of protons or cations to generate directed movement along filamentous track, or rotation [56–59]. There are three different classes of motor proteins that move along either actin or microtubule tracks – myosin moves along actin filaments; the kinesins and dyneins move along microtubules. Protein motors are used in nature for force generation and motion. Motor proteins convert chemical energy into mechanical force via conformational changes. One important difference between molecular motors and macroscopic motors is that molecular motors operate in an environment where thermal noise is significant relative to the motor’s energy consumption.

Myosins contain common motor domains that are responsible for muscle contraction. Myosin, like other molecular motors, uses energy obtained from ATP to travel along the action filament. Normally, myosin is bound to ADP. In the process of muscle contraction, the ADP molecule is freed when the myosin head binds to actin. An ATP molecule replaces ADP and induces a conformational change. Once changed into a ready state, the ATP is hydrolyzed. This process influences the protein to migrate from the negative end to the positive end. This migration, in addition to other processes, compels the muscle fibers to contract.

Dynein is another type of motor protein that also transforms energy from ATP hydrolysis into a form of energy that may be used to do mechanical work. This motor protein complex is composed of multiple heavy chains, intermediate chains and light chains. The heavy chain weighs approximately 530 kDa, and has four ATP-binding sites and a microtubule-binding site. The intermediate chains range from 53 to 79 kDa. The larger of the intermediate chains binds the protein to the cargo site. This binding equips the dynein with the ability to move the cargo to the negative end of a microtubule. Additional motor proteins known as kinesins move the cargo in the opposite direction to the positive end.

DNA helicases are classified as nanodevices, because they are molecular motors. One of their functions is to detach conjoined strands of DNA during genetic processes. Another function of DNA helicases is to transform the chemical energy produced from ATP into a form that may be used to perform mechanical work. A hexamer is a common type of helicase found in many organisms. Traditionally, this motor protein utilizes its multimeric structure to provide numerous DNA-binding sites.

Rotary motor proteins present in flagella are another class of motor proteins and, thus, nanodevices. The electrochemical energy is provided from the  $H^+$  or  $Na^+$  transmembrane gradient (Fig. 13.11). *Escherichia coli* and other bacteria employ rotary proteins in conjunction with the flagella to propel them in aqueous solutions. This small, yet powerful, protein complex has the capacity to rotate at a speed of approximately 20 000 r.p.m. and it is extremely energy efficient. These

**Figure 13.11.** The bacterium flagellar motor is a rotary motor that sits in the cell envelope of bacteria. It is driven by the flow of ions ( $H^+$  or  $Na^+$ ) across the cytoplasmic membrane, and its purpose is to rotate long helical filaments that protrude from the cell and propel

swimming bacteria. The diagram depicts a Gram-negative envelope. Torque is generated by the flow of ions across the inner membrane via ion channels MotA–MotB and by interactions between MotA (stator) and FliG (rotor).

proteins reverse their rotation patterns by inducing conformational changes in the filament and the uncoupling of the associated flagellar complex, to influence the traveling direction of the bacteria. *E. coli* flagellar motors have the ability to oscillate between counterclockwise and clockwise motions, while bacteria like *Rhodobacter sphaeroides* employ clockwise motions and then pause.

### 13.8

#### Nanodevices for Electroreception and Electric Organ Discharges

Living organisms have the ability to gather, translate and respond to information regarding their environment. Electroreceptors are also classified as nanodevices; they play a crucial role in the sensory systems of various categories of animals. Sensory systems that rely on electroreception mechanisms are sophisticated in certain families of fish [60–63]. However, this sensory system is significantly more primitive in small families of amphibians and mammals. In its passive form, the electroreceptors are used to filter and map electric fields present in their surroundings. This mechanism aids in an organism's awareness of other organisms and objects within close proximity. The more active form of electroreceptor-based sensory involves the production of currents that work in harmony with sensory organs to distinguish the organism's electric field from that of any objects in the surrounding area. Once the perceived electric fields are distinguished, they are analyzed with respect to spatial and temporal structure.

Species such as the *Torpedo*, commonly referred to as the electric ray, and *Electrophorus*, also known as the electric eel, have well-developed electric organs which aid in the visualization of their present venue. The electric sensory organs dedicated to the production of high and low currents arise from altered muscle cells and nerve endings; yet the primary mechanism for the sustained electromotive force is the ion pump – a well-known nanodevice.

An electric discharge is generated when one side of the electromotor cell is stimulated, causing a potential difference to develop across the faces of the cell. The continuum of charged membranes within the electric organ is able to discharge an electric current into the environment.

The arrangements of the nerve endings in the electric organ determine the discharge patterns. In the case of the electric eel, the stimulated face discharges while the other face is at rest. Shortly following the discharge, the resting face is stimulated and then discharges. This alternating sequence allows for a series of currents to be released. Other aquatic organisms send low and irregular currents. Species employing this tactic are referred to as “pulse fish”. However, some fish expel currents at regular time intervals and are known as “wave fish.” This sensory mechanism allows for a continuous exchange of information between the organism and the environment in real-time. Lateral line nerves innervate the electric organ. Ampullary receptors are unable to perceive stimuli above 20 Hz. Conversely, tuberous receptors are unable to perceive stimuli below 30 Hz. Various species increase the rate of impulses or shorten their response times.

Figure 13.12. Morphology of a neuron.

### 13.9

#### Neurons

The human body is made up of approximately  $10^{13}$  cells and roughly  $10^{11}$  of them are neurons [64]. The brain is the major component of the central nervous system; it is a highly sophisticated network of neurons. There are three standard classes of neurons – afferent, efferent and interneurons. Afferent networks channel information from the surroundings to the central nervous system and efferent networks channel information away from the central nervous system to the peripheral nervous system.

Neurons are classified as microdevices, which include many nanodevices such as ion channels, enzymatic systems and different proteins. The average neuronal cell has a body, axon and dendrites (Fig. 13.12). Often referred to as the soma, the body houses the nucleus and is not extremely active in the conduction of impulses. The axons are slender projections of the soma that allow signals to travel away from the soma. In most neurons, the axon is protected by a myelin sheath. Glial cells are the main components of the sheath. Not only does the sheath serve as a protective covering, it also facilitates the rapid propagation of action potentials. The dendrites are small branches at the ends of the neuron. They are intricately connected to other dendrites forming a plexus or dendritic tree. Primarily, dendrites are responsible for receiving information. Gaps between dendrites are known as synaptic gaps and they serve as avenues for neurotransmitters to travel.

Neurons have the capability to become excited in response to various internal and external stimuli. The excitations induced are characterized as action potentials. These characteristic responses can be induced by stimuli such as applied pressure, chemical substances, thermal stimuli, electrical stimuli and mechanical stimuli.

# Nanomaterials – Toxicity, Health and Environmental Issues

## Contents

	<b>Preface</b>	<i>XII</i>
	<b>List of Authors</b>	<i>XVI</i>
<b>I</b>	<b>Toxicity</b>	<i>1</i>
<b>1</b>	<b>Biotoxicity of Metal Oxide Nanoparticles</b>	<i>3</i>
	<i>Amanda M. Fond and Gerald J. Meyer</i>	
1.1	Introduction	<i>3</i>
1.2	Nanoparticles in the Environment	<i>5</i>
1.3	How Nanoparticles are Introduced into Mammalian Systems	<i>7</i>
1.4	Health Threats	<i>8</i>
1.5	Nanomaterials and Biotoxicity	<i>9</i>
1.5.1	Iron Oxide	<i>9</i>
1.5.2	Titanium Dioxide	<i>13</i>
1.5.2.1	Dark Studies	<i>14</i>
1.5.2.2	UV Irradiation Studies	<i>18</i>
1.5.3	Other Metal Oxides	<i>25</i>
1.6	Conclusions	<i>28</i>
	Acknowledgment	<i>29</i>
	References	<i>29</i>
<b>2</b>	<b>Ecotoxicity of Engineered Nanomaterials</b>	<i>35</i>
	<i>Eva Oberdörster, Patricia McClellan-Green, and Mary Haasch</i>	
2.1	Introduction	<i>35</i>
2.2	Water	<i>38</i>
2.3	Air	<i>42</i>
2.4	Soils	<i>42</i>
2.5	Weathering	<i>43</i>
2.6	Biomarkers	<i>44</i>
2.7	Conclusions	<i>46</i>
	References	<i>47</i>

II	<b>Health</b>	51
3	<b>Possible Health Impact of Nanomaterials</b>	53
	<i>Peter H. M. Hoet, Irene Bröske-Hohfeld, and Oleg V. Salata</i>	
3.1	Introduction	53
3.2	Sources of Nanoparticles	53
3.3	Epidemiological Evidence	54
3.4	Entry Routes into the Human Body	56
3.4.1	Lung	57
3.4.1.1	Inhalation, Deposition and Pulmonary Clearing of Insoluble Solids	57
3.4.1.2	Biopersistence of Inhaled Solid Material	59
3.4.1.3	Systemic Translocation of Inhaled Particles	60
3.4.2	Intestinal Tract	61
3.4.2.1	Deposition and Translocation	61
3.4.2.2	Intestinal Translocation and Disease	62
3.4.3	Skin	62
3.4.3.1	Deposition and Penetration through the Skin	62
3.4.3.2	Irritation of Skin	64
3.5	What Makes Nanoparticles Dangerous?	64
3.5.1	Particle Size – Surface and Body Distribution	65
3.5.1.1	Effect of Size	65
3.5.1.2	Effect of Surface Charges	65
3.5.2	Nanoparticles, Thrombosis and Lung Inflammation	67
3.5.2.1	Prothrombotic Effect	67
3.5.2.2	Oxidative Stress, Inflammation and Endotoxins	68
3.5.3	Nanoparticles and Cellular Uptake	69
3.5.4	Nanoparticles and the Blood–Brain Barrier	69
3.6	Summary and Discussion	69
3.7	What Can be Done?	71
	References	72
4	<b>Dosimetry, Epidemiology and Toxicology of Nanoparticles</b>	81
	<i>Wolfgang G. Kreyling, Manuela Semmler-Behnke, and Winfried Möller</i>	
4.1	Introduction	81
4.1.1	Overview	81
4.1.2	General Background	81
4.1.3	Epidemiological Evidence for Health Effect Associations with Ambient Particulate Matter	83
4.1.4	Toxicological Evidence for Ambient Particulate Matter Induced Adverse Health Effects	84
4.2	Inhaled Nanoparticle Dosimetry	85
4.2.1	Particle Measures	85
4.2.2	Deposition of Ultrafine Particles in the Respiratory System	86
4.2.3	Fate of Particles in the Lungs	87
4.2.3.1	Soluble Particle Compounds	87

4.2.3.2	Slowly Dissolving and Insoluble Particles Deposited on the Airway Wall	87
4.2.3.3	Slowly Dissolving and Insoluble Particles Deposited in the Alveolar Region	87
4.2.3.4	Macrophage-mediated Particle Transport	88
4.2.4	Translocation of Ultrafine Particles into Systemic Circulation	88
4.2.4.1	Studies of Systemic Particle Translocation in Humans	88
4.2.4.2	Studies of Systemic Particle Translocation in Animals	89
4.3	Toxicological Plausibility of Health Effects Caused by Nanoparticles	93
4.3.1	Pulmonary Inflammation Induced by Ultrafine Particles	94
4.3.2	Systemic Inflammation and other Responses	95
4.3.3	Relevant Parameters in Nanoparticle Toxicology	96
4.3.3.1	Number Concentration and Surface Area	96
4.3.3.2	Particle Shape (Fibers and Nanotubes)	97
4.3.3.3	Transition Metals	98
4.3.3.4	Organic Compounds	99
4.3.3.5	Extrapolation of Health Effects Observed in Animals towards Human	100
4.4	Integrated Concept of Risk Assessment of Nanoparticles	101
	References	103
<b>5</b>	<b>Impact of Ceramic and Metallic Nano-scaled Particles on Endothelial Cell Functions <i>in Vitro</i></b>	<b>108</b>
	<i>Kirsten Peters, Ronald E. Unger, Antonietta M. Gatti, Enrico Sabbioni, Andrea Gambarelli, and C. James Kirkpatrick</i>	
5.1	Introduction	108
5.1.1	Origin of Particles in the Human Environment	108
5.1.1.1	Evidence for Size-dependent Toxicity of Particles	109
5.1.1.2	Dissemination and Interferences of Nanoparticles within the Body	109
5.1.1.3	Endothelial Cells and Nanoparticle Exposure	110
5.1.1.4	Testing of Nanoparticle-induced Effects on Human Endothelial Cells <i>In Vitro</i>	110
5.2	Materials and Methods	111
5.2.1	Cell Culture	111
5.2.2	Particles	111
5.2.3	Transmission Electron Microscopy (TEM)	111
5.2.4	Cytotoxicity Assay	111
5.2.5	Detection of Ki67 Expression	112
5.2.6	Quantification of IL-8 Release in Cell Culture Supernatant	112
5.2.7	Quantification of E-selectin Cell Surface Protein Expression	112
5.2.8	Fluorescence Staining	113
5.2.9	Statistical Analysis	113
5.3	Results	113
5.4	Discussion	120
5.4.1	Particle Internalization	121

VIII | Contents

5.4.2	Particle Cytotoxicity	122
5.4.3	Pro-inflammatory Activation	123
5.4.4	Conclusions and Consideration of the Risk of Nanoparticles to Human Health	124
	Acknowledgments	125

## Preface

It is my pleasure to welcome the readers back to *Nanotechnologies for the Life Sciences* with the first volume published in 2006. I am presenting to you, on behalf of yet another dedicated team of contributors and supporters, the fifth volume, *Nanomaterials – Toxicity, Health and Environmental Issues*, of the ten volume series. We are bringing the fifth volume while the fourth is still in print for a number of reasons. The most important being the fact that a potential \$1 trillion nanotechnology market hinges on understanding the toxic effects of nanomaterials on our health and environment. With continuous world-wide increase in both government and private funding in nanoscience and nanotechnology touching close to \$35 billion, the stakes are even higher. With increase in stakes, there is a worldwide awakening to understand the toxic effect of nanomaterials and the scholarly chapters presented in this book are testimony to the efforts of several research groups to understand these effects. While the current knowledge base is small compared to what needs to be understood, it certainly provides a scaffold for this knowledge base to take definite shape.

Some of the critical risk assessment issues that are currently being investigated by the health & environmental nano researchers are toxicology, exposure assessment, environmental and biological fate, transport, persistence, transformation, recyclables and overall sustainability of manufactured nanomaterials. I am aware that the scientific data generated so far is very scanty and requires more worldwide concerted effort in this direction. Nevertheless, the amount of information presented by the authors covers almost everything of what is currently available in the literature. The book is divided into three distinct sections in an attempt to emphasize the three major issues related to nanomaterials, which are toxicology, health and environment. The boundaries are only artificial and have been created for the sake of clarity. I am aware that the three issues are interrelated, yet unique in their own way. I am also aware the field is very nascent and hence there could be some amount of overlap in terms of information that is presented in the chapters. However, the USP of the book is that all the chapters provide very unique and intellectually stimulating perspectives on the most important topics in the field of nanoscience and nanotechnology.

The first section of the book deals, in general, with issues around the toxicity of nanomaterials and begins with a scholarly report on the toxic effects of metal oxide

nanoparticles which are by far, commercially, the most significant materials as they find applications in cosmetics, sunscreens, fillers in dental materials, water filtration processes, catalysis, glare-reducing coating for glasses, and so on. Amanda M. Fond and Gerald J. Meyer from the Department of Chemistry, Johns Hopkins University, USA have reviewed the literature, in addition to capturing their own findings, on biotoxicity of metal oxide nanoparticles keeping the emphasis more on *in vitro* rather than *in vivo* studies. In this chapter entitled, *Biotoxicity of Metal Oxide Nanoparticles*, their critical analysis provides to the reader possible mechanisms by which the metal oxide nanoparticles enter the environment and the body, and the potential health impacts that might be expected. Eva Oberdörster from Southern Methodist University, Patricia McClellan-Green from NC State University and Mary Haasch from University of Mississippi have collaborated to present their critical evaluation in the second chapter, *Ecotoxicity of Engineered Nanomaterials*, impact of nanomaterials on the environment, and more specifically on air, water and soil. In addition, readers will find very useful the authors' insight into how the activity of nanomaterials is effected by extraneous factors such as abiotic factors, microbial degradation/activation and identification of biomarkers associated with nanoparticle exposure.

In the second section of the book, illuminating perspectives on the effect of nanomaterials on health are presented. Relative to the increased use of nanomaterials in a variety of industrial applications, the amount of information regarding their health effects is limited. Peter Hoet from Katholieke Universiteit Leuven, Belgium, Irene Brüske-Hohlfeld from GSF-Forschungszentrum für Umwelt und Gesundheit, Germany, and Oleg V. Salata from Sir William Dunn School of Pathology, University of Oxford, UK, teamed up in order to review the epidemiological studies of the technogenic nanoparticles and to highlight the apparent health effects associated with the inhalation of ultrafine particulate matter. The third chapter by them, aptly entitled *Possible Health Impact of Nanomaterials*, provides information on likely pathways for nanoparticulates in general and nanofibers in particular inside the body, the effects associated with their interactions on the cellular level, and analysis of the origins of bioactivity of nanomaterials. Continuing on the same theme, chapter number four, *Dosimetry, Epidemiology and Toxicology of Nanoparticles*, describes the dosimetry, epidemiology and toxicology of nanoparticles with reference to generally well established principles and paradigms. The chapter is contributed by Wolfgang G. Kreyling, Manuela Semmler and Winfried Möller from GSF-National Research Centre for Environment & Health, Institute for Inhalation Biology, Focus-Network Aerosols and Health, and Clinical Research Group 'Inflammatory Lung Diseases' respectively, from Germany. The highlight of the chapter, in my view, is described best by the authors themselves: "extrapolating findings and principles observed in particle inhalation toxicology into recommendations for an integrated concept of risk assessment of nanoparticles for a broad range of use in science, technology and medicine." Focusing more specifically on ceramic and metallic nanoparticles, the team lead by Kirsten Peters from Institute of Pathology, Johannes Gutenberg University, Germany, discusses in chapter five their effects on primary human endothelial cells which are highly relevant for

nanoparticle transmigration from the blood into tissues. The chapter, *Impact of Ceramic and Metallic Nano-Scaled Particles on Endothelial Cell Functions in vitro*, clearly helps readers to understand, with an example of pro-inflammatory stimulation of endothelial cells by nanoparticles, that even though it is clear that the nanoparticles exert effects that are relevant in vivo, these cannot be easily interpreted and may not be of relevance in vivo. The sixth chapter, *Toxicity of Carbon Nanotubes and its Implications for Occupational and Environmental Health*, written by the team lead by Chiu-Wing Lam from the Division of Space Life Sciences, NASA Johnson Space Center, and Wyle Laboratories, Houston, USA, is a comprehensive review on the toxicological risk of carbon nanotubes (CNT) and the impurities present in them due to inhalation exposures using both rodent and in vitro cell culture studies. In addition, the authors discuss the mechanisms of CNT pathogenesis in the lung and other toxicological manifestations. In view of the growing expectations that CNTs will find extraordinary applications in the field of not only life sciences but also in electronics, computer, and aerospace industries, the chapter is timely and will be a single source of information for the readers. The final chapter in this section is the seventh chapter, wherein the authors review the latest results from various studies on the biological effects of nanoparticles that may be the basis for adverse effects, especially in humans. The chapter, *Toxicity of Nanomaterials – New Carbon Conformations and Metal Oxides*, provides a comparative study on two most important classes of nanomaterials, viz carbon and metal oxide based nanomaterials, with respect to their cellular uptake and possible influence on important cellular mechanisms in vitro. The chapter is a testimony to the intensive analysis on the topic carried out by the authors Harald F. Krug, Katrin Kern, Jörg M. Wörle-Knirsch, and Silvia Diabate from the Institute of Toxicology and Genetics at Forschungszentrum Karlsruhe, Germany.

The final section and the most important one, in my view, is dedicated to the investigations related to impact of nanomaterials on environment. While the chapters 1–7 in the previous sections dealt with possible negative effects of nanomaterials, this section portrays the positive aspects of nanomaterials. The first chapter in this section (8th in the book) is contributed by Glen E. Fryxell and Shas V. Matigod of Materials Chemistry and Surface Research Group, Pacific Northwest National Laboratory, USA. In this chapter, *Nanomaterials for Environmental Remediation*, the authors address one of the key global political and economic issues of the 21<sup>st</sup> century – how does one ensure that the majority of the world population has clean environment in general and air & water in particular in future? An analysis of nanoparticle-based remediation technologies for air and water treatment including field tests on actual waste streams is presented. Moving into the ninth chapter, readers will find more specific information regarding the variety of approaches being utilized for treatment of water with nanomaterials. In this chapter, entitled *Nanomaterials for Water Treatment*, Peter Majewski of Ian Wark Research Institute, University of South Australia, Australia, is upbeat about various technologies currently under development and more specifically about the approach using magnetic iron exchange resin (MIEX) which is already commercially applied in water treatment. It is heartening to read the next chapter, chapter ten, wherein

Heather Coleman from the Centre for Particle and Catalyst Technologies of the University of New South Wales, Sydney, Australia, elaborates on how nanotechnologies are proving to be playing a major role in alleviating the concerns about the release into the aquatic environment of natural and synthetic oestrogens and compounds that have the ability to mimic oestrogens. In this chapter, *Nanoparticles for the Photocatalytic Removal of Endocrine Disrupting Chemicals in Water*, the author describes nanoscale titanium dioxide photocatalysis for the degradation of the natural and synthetic oestrogens in water. Chapter eleven by Wan Y. Shih and Wei-Heng Shih, Department of Materials Science and Engineering, Drexel University, Philadelphia, USA, is very unique in the sense that the authors describe their own investigations into the development of piezoelectric microcantilever sensors of different sizes and types that can perform rapid, in-situ, in-water pathogen detection with sensitivities well above that of the current techniques. The chapter describes both theoretical and experimental studies that were carried out to characterize the sensors. While the information provided in the chapter, *Nanosensors for Environmental Applications*, clearly demonstrates that we have a long way to go before realizing the dream of fabricating truly nanosize sensors, it is hoped that the chapter will form a strong basis for readers in designing their own nanosensors for environmental applications. The final chapter, *Toxicology of Nanoparticles in Environmental Air Pollution* by Ken Donaldson and his collaborators, puts forward the evidence that nano-sized air pollutants play adverse role on our health. I confess that this chapter could have been included in the previous section. However, since the chapter describes nanosized particulate matter present in the natural environment, I have decided to include it in this section. As a final chapter, I also wanted the reader to take home the message that while certainly nanomaterials can be utilized to clean up our environment and treat variety of diseases, one needs to be aware of the deleterious effects of nano-sized particulate matter in the environment.

In the end, I would like to state that I am indeed very grateful to all the authors for their contribution of quality manuscripts on time. I am thankful to my employer, family, friends and Wiley-VCH publishers for making this book a reality. I am always indebted to you, the reader, who is an integral part of this journey into brining nanotechnologies to life sciences and life sciences into nanotechnologies. I am eagerly waiting to receive your comments, suggestions and constructive criticism to make this journey even more enjoyable and a learning experience for all.

March 2006, Baton Rouge

Toxicity

## 1

## Biototoxicity of Metal Oxide Nanoparticles

*Amanda M. Fond and Gerald J. Meyer*

## 1.1

### Introduction

Nanotechnology is a relatively new and evolving field. Although the uses and technological advances in nanotechnology are endless, very little is known about its future consequences or impacts. This leaves some a little skeptical about current research and advances. Concerns range from the health and economic impacts that the once popular material asbestos had on society [1] to nanotechnology careening out of control [2]. However, even though nanotechnology is a fairly new field, nanomaterials are not. Some nanomaterials stem back to the 10<sup>th</sup> century, such as nanometer-diameter particles of gold and silver, which were used in stained glass and ceramics to generate different hues [3]. In addition, Egyptians were thought to have consumed colloidal gold, believing that it would raise vitality [4]. Nowadays, nanoparticles are frequently found in such commercial products as cosmetics and sunscreens (TiO<sub>2</sub>, Fe<sub>2</sub>O<sub>3</sub>, and ZnO), fillers in dental fillings (SiO<sub>2</sub>), water filtration processes, catalysis, and glare-reducing coating for glasses. In addition, they are currently being used in the development of stain and wrinkle-free fabrics and to make longer-lasting tennis balls [5].

Metal oxide nanoparticles have a rich history with applications in food, materials, and chemical and biological studies. The thermodynamically stable form of most metals are their oxides. In many cases metal oxides, e.g., SiO<sub>2</sub>, TiO<sub>2</sub>, ZnO, have been approved by the Food and Drug Administration for decades [6]. It is, therefore, tempting to assume that metal oxide nanoparticles will also be non-toxic. However, as this chapter demonstrates, and asbestos toxicity has taught us, the shape, size and morphology can also play a significant role in biotoxicity [5].

For such a rapidly growing field, surprisingly little is known about either nanotoxicology or the toxicity of nanoparticles. Funding for nanotoxicology is necessary because nanomaterials often behave differently than their bulk counterparts. At the nanoscale, the surface area of particles greatly increases and can result in a higher reactivity of the material, since the surface atoms now dominate the particle's physical and chemical properties. The material's electrical, optical and thermal properties change and quantum effects become significant [1]. For example, gold

particles are inert when in bulk material; however, gold nanoparticles are highly reactive and are used in catalysis.

Donaldson et al. concluded that ultrafine particles cause more inflammation than larger respirable particles of the same material when delivered at the same mass dose. Although the exact role of ultrafine particle toxicity remains unknown, experimental evidence showed that ultrafine particles inhibit phagocytosis more than fine particles of the same mass. In addition, even when composed of low toxicity materials, ultrafine particles caused inflammation in the lungs. Many believe it is because of the large surface area of ultrafine nanoparticles [7, 8].

Both *in vivo* and *in vitro* studies are currently underway around the world to evaluate the biotoxicity of metal oxide nanoparticles. However, difficulty arises in marrying these two sets of experiments. Hart states that the main reason *in vivo* and *in vitro* studies are not complementary is due to biopersistence, which relies on particle dissolution rate and the capability of the particles to be translocated out of the lung [9]. In addition, *in vitro* studies are used to measure more short-term toxicity effects and fail to look at how a specific cell type will interact when incorporated with other cell types within an animal. However, *in vivo* studies can prove to be very time consuming and costly.

This chapter will only review *in vitro* biotoxicity literature reports with metal oxide nanoparticles, and broadly overviews mechanisms by which they enter mammalian systems. *In vitro* studies help in the understanding of toxicity mechanisms at a molecular level, information that is difficult if not impossible to gain from *in vivo* studies. In addition, *in vitro* studies make it possible to determine a relationship between toxicity and particle characteristics [9]. Therefore, this chapter will cover literature studies of metal oxide nanoparticles with cells, bacteria and biopolymers, and will not cover the vast breadth of animal studies found in the literature. Additionally, studies on sulfides, selenides, noble metals or organic coatings are not included. However, notably, these particles may prove to have biotoxic effects as well.

First, it is worth defining “nanomaterial” as descriptions in the literature often vary. The National Nanotechnology Initiative defines nanotechnology as: (1) Research and technology development involving structures with at least one dimension on the 1–100 nm range. (2) Creating/using structures, devices, systems that have novel properties and functions because of their nanometer scale dimensions. (3) The ability to control or manipulate on the atomic scale [5]. Here, we have adopted a broader definition and have included all studies of metal oxide materials with length scales less than 1000 nm, as a result of the size relationships of ultrafine particles and cellular structures described by Donaldson (Fig. 1.1) [8].

In the remainder of this chapter we discuss the mechanisms by which nanoparticles enter the environment and the body, and the potential health impacts that might be expected. We then review literature including biotoxicity studies of cells with metal oxide nanoparticles. The literature in this area is conveniently divided into areas based on materials: (a) iron oxide; (b) titanium dioxide; and (c) other oxides. In addition to reviewing the published literature, some background on the materials is also included.

## 1.2 Nanoparticles in the Environment

According to the U.S. Department of Labor, in the U.S. alone, 2 million people work with nanometer-diameter particles regularly in development, production, and use of nanomaterials and products [10]. The National Institute for Occupational Safety and Health (NIOSH) claimed that between 1997 and 2005 the U.S. government investment went from \$432 million to \$1240 million per year [5], and by 2015 global investment is expected to be \$1 trillion [11]. If growth continues as expected, an additional 2 million workers will be required worldwide [5].

Nature has also utilized “nanotechnology.” Nanoparticles are found everywhere in the environment. Natural materials such as proteins and colloids, like milk, are composed of nanoparticles. Indeed, most subcellular structures are “nanomaterials.” The left-hand side of Fig. 1.2 shows additional examples [12]. Man-made particles produced as a by-product of industry are also a source of nanoparticles in the environment (Fig. 1.2) [12]. However, the lack of information on the environmental impact of nanoparticles has society concerned. Some of these concerns have been brought to the attention of the Department of Health and Human Services. As a result, the National Toxicology Program is assessing the health effects associated with nanoscale materials, such as size and composition dependent biological

disposition of fluorescent semiconductor nanomaterials and the phototoxicity of metal oxide nanoparticles [13].

### 1.3

#### How Nanoparticles are Introduced into Mammalian Systems

Currently, there is a vague understanding of a nanoparticles' path of entry into one's system, cell uptake, distribution, and health effects. Three main routes of nanoparticle exposure are penetration through the skin, ingestion, and exposure by inhalation – from which the particles may then be able to translocate from the respiratory system to other organs [14].

There can be two routes of entry into the skin, transepidermal intercellular or penetration via pores and hair follicles (Fig. 1.3). Bennat et al. believe that  $\text{TiO}_2$  nanoparticles penetrate the skin through the lipids of hair follicles. They found that the more hair follicles in the skin, the deeper the  $\text{TiO}_2$  nanoparticle penetration. Furthermore,  $\text{TiO}_2$  particles from an oily dispersion penetrated deeper than those from an aqueous solution, possibly because the palmitic acid component of the skin lipids was acting as a penetration enhancer [15]. In contrast, a separate study using pig skin samples showed that the stratum corneum layer of the skin effectively prevented dermal uptake of an oil-in-water emulsion of  $\text{TiO}_2$  particles (20–50 nm) [16]. Animal studies, quantified by autoradiography, in which emitted radiation is measured from a tissue specimen that has been treated with a radioactively labeled isotope, have indicated that  $\text{ZnO}$  nanoparticles pass through rat and rabbit skin [17–19]. Therefore, some reports raise the idea that it may be possible for  $\text{ZnO}$  and  $\text{TiO}_2$  nanoparticles to pass through human skin. For example, particles of 10–50 nm in diameter would be able to penetrate skin because the intracellular space in the stratum corneum is around 100 nm [20, 21], and the gap in

**Fig. 1.4.** Potential pathways for nanoparticles once they enter the lung; see text for additional details. (Figure taken from Donaldson [25] with permission from Elsevier.)

the lamellar bilayer is 0.5–1 nm. When filled with topically applied materials, the gap has the ability to enlarge [21–23]. Currently, human skin models, such as Skin<sup>2</sup>™, are being used for *in vitro* penetration studies of UV-irradiated particles [24].

Once inhaled, particles enter the deep lung region where they are engulfed by macrophages and removed before damage to the epithelium occurs. However, with nanoparticles, the burden becomes too large for the macrophages to remove all of the particles. The particles can then interact with the epithelium and cause inflammatory effects, enter the interstitium where they promote chronic effects on cells, or transfer to lymph nodes (Fig. 1.4) [25].

#### 1.4 Health Threats

Some believe that human exposure to most nanoparticles is not large enough to cause significant health effects in healthy individuals [1, 8]. TiO<sub>2</sub> is reported to be harmless when swallowed by man [26]. However, occupational health risks may be significant due to exposure of nanoparticles at levels higher than ambient conditions. In addition, man-made nanomaterials may have novel sizes, and physical and chemical properties, which can lead to biocompatibility problems when intro-

**Fig. 1.5.** Asbestos fiber surrounded by macrophages in the lung. (Figure taken from [www.cdc.gov](http://www.cdc.gov) [5].)

duced into one's system [1, 5, 11, 12]. NIOSH concluded, on the basis of thousands of studies, that it was the shape of the asbestos fibers that caused its high toxicity, not its elemental composition. Indeed, asbestos is a general term used to describe a broad class of alumina silicate minerals (Fig. 1.5). For example, the long, thin dimensions of asbestos fibers enable them to reach the gas-exchanging part of lung when inhaled; however, they are not easily removed by macrophages in the lung, thus leading to inflammation and scarring [1]. Long-term exposure may even lead to cancer. Additional health effects of particulate materials include increased attacks of asthma in asthma patients, silicosis, asbestosis, and “black lung” [1, 8, 27].

## 1.5 Nanomaterials and Biotoxicity

### 1.5.1 Iron Oxide

Iron oxide nanoparticles have been used extensively for biological applications and as pigments [28, 29]. The common oxidation states of iron found in the environment are +2 (ferrous) and +3 (ferric). Nanoparticles with a wide degree of morphologies and crystal structures exist. According to Schwertmann, there are fifteen known polymorphs of ferric oxide [28, 29]. Ferric oxide nanoparticles are in fact one of the few classes of nanomaterials approved by the FDA for prenatal (IV) administration to humans [30, 31].

The magnetic properties of mixed valent  $\text{Fe(II)}$ ,  $\text{Fe(III)}$  oxides are finding increased applications for imaging, drug delivery, and separations [32, 33]. The toxicity of these mixed valent materials is far less clear. The ability of many microorgan-

**Fig. 1.6.** Electron micrographs of magnetosomes found in magnetotactic bacteria. Scale bar: 100 nm. (Figure taken with permission from Safarik [34].)

isms (i.e., magnetosomes), fish and mammals to produce and/or utilize magnetite,  $\text{Fe}_3\text{O}_4$ , demonstrates that they are not toxic under all conditions. Figure 1.6 shows a transmission electron micrograph of  $\text{Fe}_3\text{O}_4$  particles synthesized by a microorganism [34]. Magnetic nanoparticles are also thought to be exploited by more advanced organisms such as trout, migrating birds, and whales. Conversely, the well-known Fenton reaction of  $\text{Fe(II)}$  yields hydroxyl radicals that damage DNA and can oxidize a wide variety of organic and biological reagents [35].

Below we review recent cellular studies of magnetic iron oxide nanoparticles. The vast majority of these studies are focused on superparamagnetic  $\text{Fe}_3\text{O}_4$  particles that respond rapidly to magnetic fields but retain no residual magnetism when the field is removed. Such materials have long been commercially available as micron-sized magnetic beads, in which the superparamagnetic particles are encapsulated within an organic sphere [36]. The use of nanometer-sized materials presents new opportunities for separations and imaging technologies, where possible biototoxicity is a critical concern.

Goetze et al. prepared biocompatible superparamagnetic nanoparticles of 2–30 nm diameter. The particles were coated with citric acid or carboxymethyl dextran (CMD) [37]. Lacava et al. had previously studied the biological effects of ionic and

citrate based magnetic fluids composed of  $\text{MnFe}_2\text{O}_4$  on mice. The citrate and ionic nanoparticles caused diarrhea and ultimately animal death. While citrate alone did not cause toxicity, it was not clear whether the manganese or the iron were responsible for death [38].

Mikhaylova et al. have studied the effects of biocompatible coating layers on superparamagnetic iron nanoparticles. Bovine serum albumin (BSA), poly(L,L-lactic acid), or poly( $\epsilon$ -caprolactone) were coated on 8 nm particles. FTIR spectroscopy was used to characterize the nanoparticles and confirm the presence of the coatings. For uncoated or gold-coated nanoparticles, superparamagnetic behavior was observed. However, Mössbauer and magnetic susceptibility studies indicated significant cluster formation in the case of BSA modified particles, and chain-like structures for the lactic acid and caprolactone modified nanoparticles [39].

Gupta and Gupta reported a cytotoxicity decrease and internalization increase for pullulan-coated superparamagnetic nanoparticles with human fibroblasts. Uncoated, 20 nm iron oxide particles were toxic to human dermal fibroblasts. Internalization of these particles resulted in disruption of the cell cytoskeleton. Pullulan coated particles were non-toxic and had a different effect on the cytoskeleton. TEM data indicated that the internalization mechanisms were different for the two particles – behavior that was attributed to the hydrophilic nature of the pullulan coating [40].

Petri-Fink et al. studied the effects of surface-coated superparamagnetic iron oxide nanoparticles with human cancer cells. Nine-nm iron oxide nanoparticles were coated with poly(vinyl alcohol) (PVA) or PVA with carboxylate, amine or thiol functional groups. The PVA and the carboxyl and thiol functionalized PVA nanoparticles were non-toxic to the melanoma cells. Some cytotoxicity was observed for the amine functionalized PVA nanoparticles, particularly when the polymer concentrations were high. The amine groups increased cellular uptake of the nanoparticles [41].

Stroh et al. reported on studies of rat macrophages incubated with citrate coated iron oxide nanoparticles (9 nm). Atomic absorption and NMR studies showed a large uptake of the nanoparticles that could be easily visualized by confocal microscopy (Fig. 1.7). Rhodamine green-labeled iron oxide nanoparticles were incubated with the cells for 90 min at 37 °C. The cells were then centrifuged, washed with PBS buffer, resuspended in medium, and seeded in six-well plates. The next day the adherent cells were incubated with the lipophilic fluorescent dye ANEPPS, which is a common stain for outer and intracellular membrane structures including vesicles. After 45 min incubation, the cells were washed and studied by confocal microscopy. With 488 nm laser excitation, both the rhodamine green emission and the ANEPPS red emission were simultaneously monitored. Control experiments without the iron oxide nanoparticles are also shown [42].

The confocal results clearly indicate that the iron oxide nanoparticles were taken up by the cells. Even though some cell autofluorescence was seen in the control data, it was much weaker in intensity. The high fluorescence intensity from

**Fig. 1.7.** Cell internalization quantified by confocal microscopy; see text for details. (Figure taken from Stroh [42] with permission from Elsevier.)

ANEPPS in the same region as the nanoparticles led the authors to suggest that the iron oxide nanoparticles form intracellular aggregates in membrane coated vesicles [42].

The cells were lysed at various times after nanoparticle exposure and the levels of malonydialdehyde (MDA) and protein carbonyls were measured. At short incubation times, a significant increase in protein oxidation and MDA was observed. Interestingly, the yields diminished with time and by 24 h there was no evidence for oxidative stress. Therefore, the oxidative stress was transient and the cells remained viable and useful for magnetic imaging applications. Iron chelators and spin traps caused a reduction in the concentrations of MDA and oxidized proteins, leading the authors to conclude that free iron present during the incubation procedure caused the transient oxidative stress [42].

Fig. 1.8. Optical image of a high-aspect ratio  $\text{TiO}_2$  nanoparticle or nanowire.

### 1.5.2

#### Titanium Dioxide

Titanium dioxide is commonly found in three crystalline forms: rutile, anatase and brookite [43]. In all three crystalline forms,  $\text{Ti(IV)}$  is in an octahedral coordination environment.

For bulk  $\text{TiO}_2$ , rutile is the thermodynamically stable form, while for nanoparticles ( $<14$  nm) the anatase form is most stable [44–46]. Therefore, most synthetic routes for the preparation of  $\text{TiO}_2$  nanoparticles yield anatase, and rutile is far less common [47–49]. Some preparations yield a mixture of the three phases. The commercially available DeGussa P25 consists of  $\sim 25$  nm particles of about 80% anatase and 20% rutile. Because of the large effective mass of electrons in  $\text{TiO}_2$ , quantum size effects, which are well known for other semiconductors, are not observed until the particle size is less than 1 nm [50]. While spherical particles are by far the most common, it is possible to synthesize high-aspect ratio particles like those shown in Fig. 1.8.

Titanium dioxide is classified as a wide band-gap semiconductor, the anatase form having a band gap of 3.2 eV (Fig. 1.9) [43]. Much of the biotoxicity of  $\text{TiO}_2$  is attributed to photoeffects wherein the material is illuminated with ultraviolet light. Band gap illumination produces an electron–hole pair excited state that is a much stronger oxidant and reductant than is the ground state. Under standard conditions the excited electron has a reduction potential of about 0.0 V vs. NHE while the hole has an oxidizing power of about +3.2 V [51].

Under many conditions, the initially formed electron–hole pairs trap at specific sites to yield radicals. The nature of these radicals has been the subject of many investigations, particularly because of their possible relevance in splitting water into hydrogen and dioxygen [52]. It is now widely accepted that the electrons trap at localized  $\text{Ti(IV)}$  sites. Titanium<sub>(III)</sub> is a reductant that reduces dioxygen to form superoxide ions [53]. Superoxide has long been thought to abstract hydrogen atoms from various biological substrates [53].

**Fig. 1.9.** Simplified band structure for anatase  $\text{TiO}_2$ . Band gap light excitation produces an electron in the conduction band and a hole in the valence band. The electron reduces dioxygen to superoxide, a reactive oxygen species that can abstract hydrogen atoms from organic biomolecules. The valence band hole

can oxidize water to dioxygen, and can also produce hydroxyl radicals – potent reactive oxygen species that oxidize most organic compounds. Not shown is the trapping of the photogenerated carriers. See text for additional details.

The fate of the photogenerated hole in  $\text{TiO}_2$  is less certain. Electron pair repulsion spectroscopic measurements indicate that the hole is initially trapped at an oxygen bridged between two  $\text{Ti(IV)}$  sites [54]. This “hole” is very reactive and is thought to ultimately yield a hydroxyl radical under ambient aqueous conditions. Much of the environmental photocatalysis of  $\text{TiO}_2$  is best understood by invoking the presence of hydroxyl radicals. Hydroxyl radicals are highly reactive and generally react with the first substrate they encounter [53].

Titanium dioxide nanoparticles are of considerable industrial interest. The high refractive index (2.7) makes it an ideal material for light scattering and it has historically been used in paints, polymers, enamels, and coatings. It is also an ingredient in some suntan lotions and used as a colorant in foods. Growing applications in solar energy conversion and environmental remediation have been envisioned.

The body of literature for  $\text{TiO}_2$  nanoparticle biotoxicity was by far the largest. We have organized the literature descriptions based on whether the nanoparticles were illuminated or kept in the dark.

#### 1.5.2.1 Dark Studies

Donaldson et al. have examined the cytotoxic effects of  $\text{TiO}_2$  by measuring the DNA strand breakage on a supercoiled DNA band caused by free radical activity. A DNA plasmid (290 ng  $\phi$  X174 RF) was incubated with either  $\text{TiO}_2$  (0.5  $\mu\text{m}$ ) or ultrafine  $\text{TiO}_2$  (0.02  $\mu\text{m}$ ) particles. The plasmid was separated into the three possible forms, super-coiled, relaxed coil or linear by electrophoresis and quantified by scanning laser densitometry. Findings showed that  $\text{TiO}_2$  particles had little effect on DNA strand breakage, whereas the ultrafine particles caused complete destruc-

**Fig. 1.10.** Relationship between TiO<sub>2</sub> (NTiO<sub>2</sub>) and ultrafine TiO<sub>2</sub> (UFTiO<sub>2</sub>) particles and DNA strand breakage. (Figure taken from Donaldson [55] with permission from Elsevier.)

tion of the super-coiled DNA plasmid at concentrations greater than 50  $\mu\text{g mL}^{-1}$  (Fig. 1.10). In addition, crocidolite and amosite asbestos caused supercoiled DNA depletion. At lower ultrafine TiO<sub>2</sub> concentrations (5  $\mu\text{g mL}^{-1}$ ) and in both asbestos samples the amount of DNA damage was improved by the addition of a radical scavenger, such as mannitol, indicating the role of free radical activity at the surface of the particles. The researchers also suggested that the surface of the particles can react with reductants generated by inflammatory cells and physiological chelators to generate more free radicals to assist in the destruction of DNA [55].

Tan et al. studied human subjects whom applied sunscreen to skin for 2–6 weeks until up to 2 days before excision of the skin lesion. Studies were performed by removing the stratum corneum by using cyanoacrylate ester and elastic plaster and a tissue sample was obtained. The samples were digested by microwave extraction and analyzed using mass spectrometry. The results showed that the levels of TiO<sub>2</sub> in the dermis were higher, yet not statistically different from, the control samples (post mortem cadavers). However, if the outlier in the control samples was excluded, the TiO<sub>2</sub> concentrations were significantly higher than the control. No correlation was found between the concentration of TiO<sub>2</sub> in the samples and the duration of application. A small test group, and concentrations of TiO<sub>2</sub> close to the detection limits, made it difficult to compare the concentrations of TiO<sub>2</sub> in the dermis samples with the control [21].

In a study by Hart et al., CHO-K1 cells were incubated for 2–5 days with dusts: chrysotile (1.4  $\times$  0.1  $\mu\text{m}$ ), crocidolite (1.8  $\times$  0.2  $\mu\text{m}$ ), and TiO<sub>2</sub> (0.6  $\mu\text{m}$ ). Viability was determined by an esterase activity viability assay, where cells are treated with 5(6)-carboxyfluorescein diacetate, which is a non-fluorescing ester conjugate. When internalized by cells, carboxyfluorescein is cleaved by cytoplasmic esterases and becomes polar and fluorescent. If the cell is not viable, the ester conjugate would not be retained by the cell. In all samples the loss of cell viability was not significant.

However, micronuclei and polynuclei tests with acridine orange staining expressed nuclear abnormalities. Chrysotile was the most cytotoxic sample, while  $\text{TiO}_2$  was the least, indicating a particle size dependence on toxicity. Since viability remained high and only nuclear abnormalities resulted from particle interactions, the proposed mechanism of toxicity involved the interference of the internalized particles with mitosis, which causes a distortion in nuclear morphology and cytostasis, cessation of cell division [9].

In another study by Hart et al., Chinese hamster ovary (CHO) cells were exposed to particles for 3 days and then counted using a Coulter counter. For all fibers tested, ranging from glass, ceramics, and slag wool to asbestos, similar toxic effects were observed. Cultures showed little loss in viability ( $\sim 90\%$ ); however, cell proliferation was almost completely inhibited and a concentration-dependent increase in morphological changes was observed. Unexposed samples retained a viability of 99% and showed a 20-fold increase in cell population [56].

Size comparisons indicated that thinner fibers were more toxic than thicker ones of similar lengths when concentration was a function of fiber mass per unit area. However, when concentration was expressed as a function of number of fibers per unit area, the difference in effects was non-existent [56].

The researchers concluded that cytotoxicity and genotoxicity correlate with fiber length and the mechanism of toxicity was by cytostasis, or the disruption of cell division. Possible explanations include longer fibers being more easily entangled in migrating chromosomes or spindle apparatus, which leads to the formation of micronuclei [56, 57]. In addition, long fibers are more biocompatible because they support cell growth *in vitro* by providing a substratum for attachment and proliferation of fibroblast cell lines [56, 58, 59].

Peters et al. have analyzed the effects of  $\text{TiO}_2$  (14 nm) and  $\text{SiO}_2$  (70 nm) particles on human dermal microvascular endothelial cells. Viability tests along with Ki67, a protein expressed in the nucleus of proliferating cells, and the cytokine interleukin-8 (IL-8) measurements were performed to determine the cytotoxic effects of the metal oxide particles on cells [60]. The CellTiter AQ<sub>ueous</sub> non-radioactive assay was used to determine cell viability by measuring the conversion of an enzymatic tetrazolium salt (MTS) via mitochondrial dehydrogenase [61]. Results showed no significant difference in cell viability; however, an increase in IL-8 production for both the  $\text{SiO}_2$  and  $\text{TiO}_2$  particle ( $50 \mu\text{g mL}^{-1}$ ) treated samples was taken as evidence for pro-inflammatory effects (Fig. 1.11) [60]. The only sample that induced a decrease in Ki67 expression was  $\text{SiO}_2$  ( $50 \mu\text{g mL}^{-1}$ ), indicating a decrease in the number of cells participating in the active part of the cell cycle. Since biocompatible  $\text{TiO}_2$  showed some inflammatory effects, the authors concluded that particles can possess different features when in the nano versus bulk scale [60].

Shanbhag et al. have studied the effects of  $\text{TiO}_2$  particles on P388D<sub>1</sub> macrophages. Viability was measured as a function of  $^3\text{H}$ -thymidine ( $^3\text{H}$ -TdR). Cells were incubated with particles for 8 h followed by the addition of  $^3\text{H}$ -TdR for 16 h.  $^3\text{H}$ -TdR suppresses DNA synthesis and is used as a way to measure DNA fragmentation. The results showed that  $\text{TiO}_2$  decreased  $^3\text{H}$ -TdR levels in macrophages in a size- and concentration-dependent manner [62].

**Fig. 1.11.** A human dermal microvascular endothelial cell exposed to (a) no particles and (b)  $\text{TiO}_2$  particles. (Figure adapted from Peters [60] with kind permission of Springer Science and Business Media.)

Stearns et al. have investigated the effects of  $\text{TiO}_2$  particles (50 nm) on a human epithelium cell line (A549). In as little as 1–2 h, minimal internalization of the particles was observed by energy-filter TEM. Short exposure times to  $\text{TiO}_2$  yielded particles found in the vacuoles; however, longer incubation times showed  $\text{TiO}_2$  in the lamellar bodies. Addition of the inhibitor cytochalasin D (cyto D), which is known to affect actin polymerization and particle internalization, to cells before they were introduced to  $\text{TiO}_2$  neither inhibited phagocytosis of the nanoparticles nor decreased cell viability. However, a change in cell morphology was observed in the presence of cyto D and more particles were internalized in membrane-bound vacuoles rather than the lamellar bodies [63].

Westmoreland et al. have used  $\text{TiO}_2$  as a reference compound because it is known as a “nuisance dust.” In the study,  $\text{TiO}_2$  particles were introduced into an epithelial cell line (16HBE14o-) for 24 h [64]. However, after 24 h, there was no toxicity induced as measured by the MTT reduction assay [65], neutral red uptake assay or transepithelial resistance.

Kilgour et al. have modeled inhalation exposure *in vitro* by exposing olfactory and respiratory turbinates of rats to  $\text{TiO}_2$  ( $<1 \mu\text{m}$ ) for short and long durations. They found that  $\text{TiO}_2$  exposure had no effect on adenosine triphosphate (ATP) or potassium concentrations in olfactory epithelium for any of the times studied. Conversely, when exposed to respiratory epithelium, a minimal decrease in ATP and potassium concentration was observed for the 4 h particle incubation and 20 h fresh media incubation. An observed decrease in potassium concentration at the 24 h exposure time was attributed to mechanical damage arising from  $\text{TiO}_2$  particle precipitation. These studies concluded that  $\text{TiO}_2$  is not acutely toxic to the nasal cavity [66].

Miller et al. found  $\text{TiO}_2$  to have no effect on CHO cells with or without metabolic activation, which is potentially a result of  $\text{TiO}_2$  nanoparticle insolubility. The effect

of the particles was analyzed by micronucleus testing of cells that were incubated with TiO<sub>2</sub> particles for 48 h [67].

The Scientific Committee on Cosmetics and Non Food Products intended for consumers (SCCNFP) has evaluated the acute toxicity, mucous membrane irritation, phototoxicity, genotoxicity, carcinogenicity and percutaneous absorption of TiO<sub>2</sub> and deduced that TiO<sub>2</sub> is safe to use at maximum concentration of 25% w/w in cosmetics. Furthermore, this includes crystalline TiO<sub>2</sub> particles irrespective of particle size and requires no further restrictions or conditions for use in cosmetic products [68].

#### 1.5.2.2 UV Irradiation Studies

In addition to the dark studies mentioned above, it is notable that in the following reports of UV-irradiated nanoparticles, the control groups, often consisting of nanoparticles reacted with cells in the absence of UV light, also showed no evidence of cytotoxicity. Dunford et al. set out to determine the potential ill effects that metal oxide nanoparticles (TiO<sub>2</sub> and ZnO) found in over-the-counter sunscreens can have on DNA. Titanium dioxide (2%w/v – 0.02 µg µL<sup>-1</sup>) and zinc oxide (0.4% w/v) nanoparticles (20–50 nm) were extracted from sunscreens and added to plasmid DNA (50:50 – 25 µL). The samples were then irradiated with UVA (365 nm) light from a 1000-W Hg/Xe lamp for 0–60 min increments. Strand breaks in the DNA were assayed on agarose gels by the transformation of a supercoiled plasmid into the relaxed or linear form. The damage of the photoactive nanoparticles was independent of crystal type, with the most active sample containing as much as 1.95% ZnO. DNA damage was suppressed by hydroxyl radical quenchers, dimethyl sulfoxide (DMSO) and mannitol, and proteins, catalase and bovine serum albumin, but not superoxide dismutase, which provided evidence that the hydroxyl radical rather than superoxide was the source of DNA damage [19].

Uchino et al. probed the effect of TiO<sub>2</sub> crystal form and size on cytotoxicity as well as the relationship between the amount of radicals produced from UV-irradiated TiO<sub>2</sub> particles and cytotoxicity. The effect of the irradiated particles on cell viability was determined by the addition of varying concentrations of Degussa P-25 TiO<sub>2</sub> particles in cultures of a Chinese hamster ovary (CHO) cell line. After incubation for 48 h with TiO<sub>2</sub> particles, the samples were irradiated with UV light for 24 h [69]. Cell viability was determined using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. Upon reduction by living cells, MTT is converted into a purple formazan. The amount of MTT formazan produced can be quantified by using a microplate reader to measure absorbancies at a test and a reference wavelength [65]. The viability of CHO cells with internalized TiO<sub>2</sub> particles decreased significantly after UV irradiation. Although the intensity of the UV light did not influence cytotoxicity, the anatase fraction in the TiO<sub>2</sub> particles had a significant effect on cytotoxicity. In addition, cell viability was proportional to the DMPO-OH radical adduct formed. This was accomplished by electron spin resonance (ESR). The compound 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO) was used to spin trap the OH<sup>•</sup> radical. The ESR results confirmed the presence of a DMPO-OH radical adduct, consistent with the formation of an OH<sup>•</sup>

**Fig. 1.12.** Effects of UV irradiation and TiO<sub>2</sub> particles on Ls-174-t cells. (a) TiO<sub>2</sub> particles in the dark, (b) UV irradiation with no TiO<sub>2</sub>, (c) TiO<sub>2</sub> and UV irradiation. (Figure taken from Zhang [70] with permission from Elsevier.)

radical. The optimum crystal size for OH<sup>•</sup> radical formation was 30 nm for anatase and 90 nm for rutile. The results also demonstrated a dependence of cytotoxicity on hydroxyl radical formation and crystal form and size; however, these variables were independent of each other. For example, hydroxyl radical formation differed with crystal form and size. Most anatase samples produced more hydroxyl radicals than rutile or amorphous TiO<sub>2</sub>. The percentage of anatase in these samples had no effect on the amount of radical generated; however, the viability of the cells was dependent on the amount of DMPO-OH radical formed. This indicated that when anatase forms of TiO<sub>2</sub> are irradiated with UV light, hydroxyl radicals form that have cytotoxic effects. This was not the case for rutile and amorphous samples, indicating the need for further investigation of a different mechanism for radical formation. In addition, ESR data showed no relation between the formation of a DMPO-OH radical adduct and UV absorbance; therefore, radical formation is due to another factor besides UV absorbance [69].

Zhang et al. found that Ls-174-t cells, a human colon carcinoma cell line, had over 90% viability when reacted with TiO<sub>2</sub> nanoparticles alone. However, when the TiO<sub>2</sub>-cell samples were irradiated with UV light, viability fell to a meager 20% when TiO<sub>2</sub> concentration was >200 μg mL<sup>-1</sup> (Fig. 1.12). The effects of TiO<sub>2</sub> concentration on cell viability were investigated using the MTT assay. Cell viability decreased as the concentration of UV-irradiated TiO<sub>2</sub> nanoparticles internalized in the cells increased. Furthermore, the cell morphology changed with increasing nanoparticle concentration, giving rise to shrinkage and fragmentation of the cell. These observations led the researchers to believe that the mechanism of cell death by photoexcited TiO<sub>2</sub> nanoparticles was through reactive oxygen species. The means by which the nanoparticles damage the cells was theorized to occur in two stages. The first stage being oxidative damage by the photoexcited TiO<sub>2</sub> nanoparticle surface as it comes in contact with the cell membrane. This resulted in permeabilization of the cell membrane and did not produce a significant decrease in cell

viability. The decrease in cell viability, and eventually cell death, occurred as a result of intracellular components leaking out of the permeable membrane and additional TiO<sub>2</sub> nanoparticles trafficking into the damaged cells and directly attacking the nucleus and other intracellular components [70].

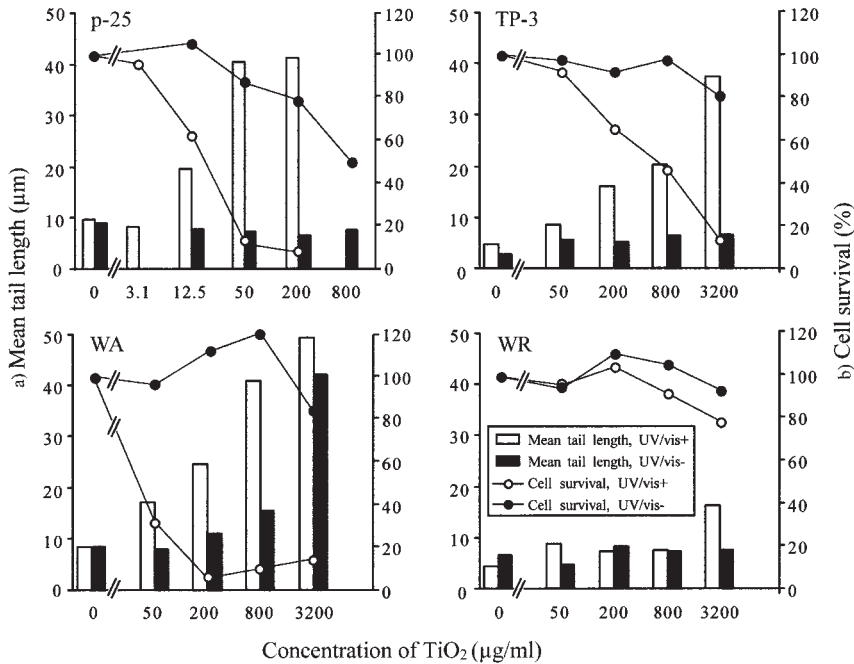

Cai et al. observed that HeLa cells incubated with TiO<sub>2</sub> particles without UV irradiation had 90% survival, as did cells irradiated with UV light for less than 19 min. However, cultures exposed to both TiO<sub>2</sub> particles and UV light showed a dramatic fall in survival rate that decreased with increasing TiO<sub>2</sub> concentration. Irradiation of HeLa–TiO<sub>2</sub> adducts with visible light did not cause any photodynamic effects, and simply raised the temperature of the culture to around 36 °C. Since this is less than the culture temperature of the cells, thermal death is not very likely and the observed behavior with UV light was attributed to photochemistry, not thermal effects. Irradiation with wavelengths greater than 440 nm produced cell survival of 90%, but when the sample was irradiated with a slightly lower wavelength (300–400 nm), for an equal amount of time, all cells in the culture were killed. This same irradiation wavelength range on cells without TiO<sub>2</sub> yielded an 85% survival rate [71].

Cell death was proposed to take place by two possible mechanisms. In the first, cells were oxidized by photogenerated holes in the valence band. In the second, the holes reacted with water to produce OH<sup>•</sup> radicals that can attack the cell membrane and intracellular components [71]. Cai et al. and Sakai et al. deduced that the viability of T-24 cells decreased with both variations in UV irradiation intensity and TiO<sub>2</sub> particle concentration [72, 73].

Saito et al. have investigated the photocatalytic bactericidal effects of TiO<sub>2</sub> particles (21 nm) on three strains of bacteria (*Streptococcus mutans*, *S. rattus*, and *S. cricetus*). TiO<sub>2</sub> particles were introduced to the specimen, irradiated with UV light and incubated for two days. The bactericidal action of TiO<sub>2</sub> increased with TiO<sub>2</sub> particle concentration. In addition, potassium leakage, measured by flame photometry, paralleled the loss of cell viability. In bacteria, a cell wall of peptidoglycan is formed around the cell membrane. When observed by TEM, the TiO<sub>2</sub> particles took over 30 min to reach the cell membrane of the bacteria, yet leakage of intracellular protein and cell death occurred in less than 1 min. Cell death was rapid and the cell wall was not destroyed until after 60–120 min; therefore, the TiO<sub>2</sub> particles could not have been able to attach to the cell membrane directly to cause any damage. Rather, cell death was assumed to result from membrane damage caused by the superoxide and perhydroxy radicals produced from TiO<sub>2</sub> photocatalysis [26].

Nakagawa et al. studied the effects of four sizes of UV irradiated TiO<sub>2</sub> particles on a mouse lymphoma cell line. DNA tail length was measured by means of a SCG assay. The results showed that UV-irradiated Degussa P-25 (anatase, 21 nm), TP-3 (rutile, 420 nm) and WA (anatase, 255 nm) samples all elicited increased DNA damage and a decrease in cell survival (Fig. 1.13) [74, 75, 76].

Warmer et al. determined whether nucleic acids were targets for photooxidative damage caused by UV-irradiated TiO<sub>2</sub> by investigating the effects of UV-irradiated TiO<sub>2</sub> on calf thymus DNA and human skin fibroblasts. A suspension of TiO<sub>2</sub> particles was added to samples of calf thymus DNA and fibroblasts and exposed to

**Fig. 1.13.** Effects of TiO<sub>2</sub> on DNA tail length and cell survival. Abbreviations: p-25, anatase 21 nm; WA, anatase 255 nm; WR, rutile 255 nm; TP-3, rutile 420 nm. (Figure taken from Nakagawa [74] with permission from Elsevier.)

UVA light for 1 h. The calf thymus DNA and cellular DNA samples were then enzymatically hydrolyzed and analyzed using reversed-phase high-performance liquid chromatography (HPLC). HPLC was used to measure the hydroxylation of guanine bases (forms 8-oxodG) and indicated whether any nucleic acids were oxidatively damaged [75].

Results with calf thymus DNA showed that levels of 8-oxodG increased directly with the addition of TiO<sub>2</sub> and fluence of UV irradiation, when they were both present in calf thymus DNA experiment. Furthermore, the fibroblast samples showed that both TiO<sub>2</sub> particulates and UV light must be present to induce oxidative damage, in which case cytotoxicity was 85%. The phototoxicity was UV fluence dependent. Although oxidative damage did not occur in cellular DNA, there was a 3-fold increase in 8-oxoG in the presence of TiO<sub>2</sub> and UV irradiation, indicating the oxidative damage of the guanine bases in cellular RNA. This gave evidence that oxidative stress caused by irradiated TiO<sub>2</sub> particles was occurring in the cytoplasmic and nuclear compartments of the cell. The photocytotoxicity of TiO<sub>2</sub> is a result of intracellular damage induced by reactive oxygen species. However, the relative importance of the reactive oxygen species formed by photoexcited TiO<sub>2</sub> is still unknown.

ESR studies to measure the formation of a DMPO-OH radical adduct were also performed. The formation of adduct increased with time and then leveled off [77]. Since there is evidence of reactive oxygen species, the hydrolysis of guanine in calf thymus DNA can be due to any of the following: hydroxyl radical formation, decomposition of hydrogen peroxide from UV irradiation, or the Fenton reaction [78–80].

Kubota et al. incubated T-24 human bladder cancer cells with TiO<sub>2</sub> particles, cultured them for 24 h and observed the effects. The TiO<sub>2</sub> particles were contained mainly in the cytoplasm and cell membrane of the T-24 cells, as found by transmission electron microscopy (TEM). There was a 90% survival rate amongst cells introduced with up to 300 µg mL<sup>-1</sup> of TiO<sub>2</sub>. However, when exposed to UV light for as little as 5 min there was as much as a 20% decrease in the survival rate even with TiO<sub>2</sub> concentrations as low as 10 µg mL<sup>-1</sup>. They also found that cell killing was more effective in phosphate buffered saline (PBS) than in F-12 media. This is possibly due to either the absorptive abilities of F-12 or the fact that it contains radical scavengers such as mannitol and tryptophan. These researchers also investigated the role that radical scavengers play in irradiated TiO<sub>2</sub> cytotoxicity. Molecular scavengers of both hydrogen peroxide and hydroxyl radicals, catalase and L-cysteine, respectively, effectively diminished cell death when added to the cell samples. This provided evidence of the role of hydroxyl radicals and hydrogen peroxide in cell death [81].

In addition, they investigated the mechanism of photoexcited TiO<sub>2</sub> biototoxicity by depositing TiO<sub>2</sub> nanoparticles onto conductive tin oxide glass. The cells were subsequently cultured on the conductive glass. In the dark, when a potential was applied to the TiO<sub>2</sub> electrode, the cells remained viable. However, in the presence of UV light, cells were killed when the electrode potential was more positive than -0.5 V. The percent of cells surviving was proportional to the photoinduced current. Due to the strong photocurrent, at anodic potentials, the researchers concluded that photogenerated TiO<sub>2</sub> holes were responsible for cell death [81].

An *in vitro* experiment using T-24 cells was also carried out by the same group. TiO<sub>2</sub> particles (0.03–10 nm) were added to cell cultures and irradiated with a 500-W Hg lamp. The cells were cultured for another 10 days before fixing and staining with Giemsa in order to count. With either TiO<sub>2</sub> or UV light alone, survival was >90%, indicating no cytotoxic effects. However, in the presence of both TiO<sub>2</sub> and UV light a cytotoxic effect was observed that increased with increasing TiO<sub>2</sub> concentrations. Scavenger experiments were conducted to determine the mechanism of cell death. In the presence of the hydrogen peroxide scavenger, catalase, and hydroxyl radical quencher, L-cysteine, cell death of the photoexcited TiO<sub>2</sub> samples decreased, pointing to the participation of H<sub>2</sub>O<sub>2</sub> and OH<sup>•</sup> radical in cell death [81].

Cai et al. set out to determine the mechanism behind the photodamaging of cells with TiO<sub>2</sub>. To investigate the mechanism by which TiO<sub>2</sub> can photokill HeLa cells, superoxide dismutase (SOD), which converts the superoxide anion (O<sub>2</sub><sup>-</sup>) into H<sub>2</sub>O<sub>2</sub>, was added to a TiO<sub>2</sub> infused cell culture. The TiO<sub>2</sub> nanoparticles were incubated in cultured HeLa cells for 24 h, while SOD was added to the cell culture for the final hours of incubation. After a short irradiation with UV light, the cells were

counted to determine viability. Cell survival in the absence of SOD was a meager 55%, which indicated that cell death may be due to  $\text{H}_2\text{O}_2$  and  $\text{OH}^\cdot$  radical formed by the irradiation of  $\text{TiO}_2$ . The addition of SOD caused a decrease in survival rate, which increased with SOD concentration when irradiated for the same amount of time. Controls showed that samples containing SOD in the absence of  $\text{TiO}_2$  had no effect on survival rate, therefore indicating that the decrease in cell survival was due to the conversion of  $\text{O}_2^-$  into  $\text{H}_2\text{O}_2$  by SOD [82]. Further evidence of the production of  $\text{H}_2\text{O}_2$  was given by the addition of the fluorophore scopoletin (6-methoxy-7-hydroxy-1,2-benzopyrone), whose fluorescence is quenched by  $\text{H}_2\text{O}_2$  [83]. A much higher concentration of  $\text{H}_2\text{O}_2$  was produced in irradiated HeLa- $\text{TiO}_2$  samples that contained SOD than in samples without SOD. With the addition of catalase (EC 1.11.1.6), which converts hydrogen peroxide into water and molecular oxygen, to the  $\text{TiO}_2$ -SOD sample, the surviving fraction of cells increased, further confirming the production of  $\text{H}_2\text{O}_2$ . In addition, the presence of catalase increased survival even in the absence of SOD, indicating that  $\text{H}_2\text{O}_2$  can be produced by another method:

However,  $\text{O}_2^-$  must also be converted into some other reactive oxygen species because cell death still occurred in the presence of catalase and the absence of SOD [82].

Jang et al. have studied bacterial death by photocatalyzed  $\text{TiO}_2$ . The  $\text{TiO}_2$  was added to cultures of either *Escherichia coli* (*E. coli*) or *Pseudomonas aeruginosa* and were then irradiated with UV light. Smaller particles of  $\text{TiO}_2$  had a larger effect on the degree of decomposition of the bacteria, while increased anatase mass fraction caused an increase in decomposition (Fig. 1.14) [84].

Sakai et al. have investigated the cytotoxicity of  $\text{TiO}_2$  particles (30 nm) on a T-24 human malignant cell line. Cells were incubated with  $\text{TiO}_2$  particles for 24 h and irradiated with UV light. Cell viability was determined by a colony forming assay, and the change in  $\text{Ca}^{2+}$  concentration was monitored by ethidium bromide staining [73]. The  $\text{Ca}^{2+}$  ions play a role in differentiation, intracellular transport, secretion and metabolism [73, 85]. A change in  $\text{Ca}^{2+}$  concentration is linked to cytotoxicity [73, 86–91]. The addition of  $\text{TiO}_2$  particles to T24 cells yielded a 90% survival rate of the cells. Conversely, when the samples were irradiated with UV light, the  $\text{Ca}^{2+}$  concentration increased as determined by ratiometric imaging. With increased  $\text{TiO}_2$  concentration, less irradiation is required to cause an increase in  $\text{Ca}^{2+}$  concentration. However, since the stepwise increase in  $\text{Ca}^{2+}$  concentration remained constant it was concluded that there is a minimum amount of reactive oxygen species needed to trigger their uptake.

The processes for  $\text{Ca}^{2+}$  mobilization include influx through the plasma membrane and release from  $\text{Ca}^{2+}$  storage in the endoplasmic reticulum. The change

**Fig. 1.14.** *Escherichia coli* in (a) absence and (b) presence of  $\text{TiO}_2$  nanoparticles. (Figure taken with permission from Jang [82].)

in  $\text{Ca}^{2+}$  distribution was monitored to determine the mechanism taking place. When the concentration of  $\text{Ca}^{2+}$  was monitored with UV and  $\text{TiO}_2$  present in cell culture, the concentration was greatest near the cell membrane. However, without the addition of  $\text{TiO}_2$  particles, the concentration was low and evenly distributed. The increase was attributed to an increase in cell membrane permeability, but no loss in cell viability, and the  $\text{Ca}^{2+}$  was from the buffer. However, in later stages the cell dies.  $\text{Ca}^{2+}$  cannot directly be responsible for cell death because in buffer without  $\text{Ca}^{2+}$  there is still loss in cell viability. There is a simply an increase in  $\text{Ca}^{2+}$  caused by a change in permeability associated with cell death. Instead, the hydroxyl radical and hydrogen peroxide promote cell death [73].

Cai et al. showed that HeLa cells were effectively killed in the presence of photo-excited  $\text{TiO}_2$  particles. The cytotoxic effects were suppressed in the presence of L-tryptophan and catalase, which quench hydroxyl radicals and scavenge hydrogen peroxide, respectively. This suggests that cell death resulted from the production of reactive oxygen species on the particle surface [72].

Linnainmaa et al. found no effect upon the addition to rat liver epithelial cells of three particle types, uncoated anatase, rutile coated with aluminum hydroxide and stearic acid, and P25 Degussa  $\text{TiO}_2$ . The inhibition of cell growth was measured by the multinuclei assay, in which the addition of cytochalasin B prevents cell division but not division of the nucleus. Cytotoxicity was measured by the increase in the amount of cells that contained only one nucleus after treatment. The micronucleus test assessed the chromosomal damage of cells caused by the addition of  $\text{TiO}_2$ . After 1 h incubation with  $\text{TiO}_2$  particles, the cells were irradiated with UV light for 5 min. The results indicated no inhibition of cell growth or cytotoxic effects with any of the  $\text{TiO}_2$  samples. Small cytotoxic effects were seen in the irradiated samples, but they were not of statistical significance [92].

Donaldson et al. have stated that TiO<sub>2</sub> particles are cleared from the lung by phagocytosis of alveolar macrophages. They studied the impact of ultrafine (20 nm) versus fine (200 nm) particles of TiO<sub>2</sub> and carbon black on a macrophage cell line. Fluorescent latex beads were then added to the cell line to indicate phagocytic uptake. The results indicated that the ultrafine particles inhibited phagocytosis by the macrophages when compared to the fine particles, which may lend one possible explanation for their adverse effects. The mechanism is a result of the increased surface area and increased number of ultrafine particles present, due to inhibited phagocytosis, that interact with the epithelium and lead to oxidative stress and thus inflammation [8].

Wilson et al. have stated that the surface of particles may be a source of reactive oxygen species. Ultrafine and fine particles were incubated with a compound that undergoes activation to a fluorescent state when oxidized. Fluorescence intensity measurements revealed that ultrafine particles yielded a dose-dependent increase in fluorescence, whereas fine particles did not. This result is likely a consequence of the high surface area of the particles yielding more reactive oxygen species [93].

Maness et al. set out to determine the mechanism by which photocatalytic TiO<sub>2</sub> kills bacteria. They studied the effects of Degussa P25 TiO<sub>2</sub> particles (surface area 50 m<sup>2</sup> g<sup>-1</sup>) on a strain of *E. coli* in the presence of UV light. Membrane damage was determined by measuring the production of malondialdehyde (MDA), a product of lipid peroxidation, by the colored adduct it forms with thiobarbituric acid. More MDA is produced when TiO<sub>2</sub> was present than without. Reactive oxygen species are proposed to play a role because they attack the polyunsaturated phospholipids in *E. coli*, causing deterioration of the cell membrane and loss of functions within the cell [94].

### 1.5.3

#### Other Metal Oxides

Our literature searches revealed a handful of biototoxicity studies with other metal oxide nanomaterials. These studies are described below.

Yamamoto et al. have looked at the cytotoxic effects of metal oxide particles on murine fibroblasts and murine monocyte macrophages. The particles were added to cells and the relative plating efficiency was obtained after 6–8 days, depending on the cell type. The results showed that the cytotoxicity of Al<sub>2</sub>O<sub>3</sub> and ZrO<sub>2</sub> particles ( $d = 500\text{--}700$  nm) were enhanced relative to TiO<sub>2</sub> particles ( $d = 130\text{--}180$  nm). TiO<sub>2</sub> particles and Al<sub>2</sub>O<sub>3</sub>-coated TiO<sub>2</sub> particles both demonstrated similar cytotoxic effects, and showed larger particles to be more toxic than the smaller ones. Shape-dependent cytotoxicity was also determined, and dendritic TiO<sub>2</sub> proved to have the highest cytotoxicity when calculated as a function of number, volume and surface area. When cytotoxicity was determined as a function of volume, the particles ranked as dendritic > spindle > spheric. But when particle toxicity was ranked as a function of surface area the cytotoxic effects changed: dendritic > spheric > spindle. The overall conclusion on cytotoxicity ranked the dendritic particles as the most cytotoxic, followed by spindle and spheric particles. The number

of particle edges is important when determining cytotoxicity – the more edges the more of a cytotoxic effect [95]. Cytotoxicity was then compared to that of the parent metal ions. It was concluded that toxicity results because of two processes: chemical toxicity of released metal ions or other soluble components [95–97] or mechanical stimulation caused by sizes and shapes [95].

Cytotoxicity of metal ions and other chemicals differs among cell lines. Larger particles (only if phagocytosed) tended to have higher cytotoxicity than smaller particles. For example, larger  $\text{TiO}_2$  particles caused a higher inhibition of  $^3\text{H}$ -thymidine incorporation of human monocyte macrophages. However, if the particle is too large to be phagocytosed by the cells, then there is no cytotoxic effect. The authors concluded that the cytotoxicity of insoluble particles does not depend on chemical composition. In addition, cytotoxicity was not dependent on chemical species but on particle size and phagocytic properties [95].

Hanawa et al. have studied the toxicity of metal oxide nanoparticles ranging from 500 to 3000 nm in diameter. The particles were incubated in human fibroblasts for 24 h and stained with haematotoxylin and eosin to determine the magnitude of toxicity. With this assay, cells that adhered to the coverglass would stain, while dead cells would detach from the glass during staining. A digitizer was used to assess the area that was stained. The area stained was considered to be proportional to the magnitude of cytotoxicity of the metal oxide particles. Cells incubated with  $\text{Al}_2\text{O}_3$ ,  $\text{TiO}_2$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{Fe}_3\text{O}_4$ ,  $\text{Co}_2\text{O}_3$ ,  $\text{NiO}$ ,  $\text{Ga}_2\text{O}_3$ ,  $\text{SnO}$ ,  $\text{SnO}_2$ ,  $\text{HgO}$  showed no cytotoxic effects. A difference in formal oxidation state of some of these metals yielded different effects, e.g.,  $\text{CoO}$ ,  $\text{Co}_3\text{O}_4$ , and  $\text{Ni}_2\text{O}_3$  appeared to be toxic. In addition,  $\text{Cr}_2\text{O}_3$ ,  $\text{Cu}_2\text{O}$ ,  $\text{CuO}$ ,  $\text{ZnO}$ , and  $\text{Ag}_2\text{O}$  proved to be cytotoxic. A potential problem would be that the study was based on particles dissolving into elements/ions, which have a cytotoxic response. Therefore, larger areas of affected cells indicated a more cytotoxic effect, which does not necessarily correlate with the components of the particles being more effective at killing cells. Larger cytotoxic effects could have been a result of a higher particle concentration in the medium [98].

Lison et al. have studied the surface area effects of  $\text{MnO}_2$  particles (Fig. 1.15). Mouse peritoneal macrophages were incubated with  $\text{MnO}_2$  particles of varying sur-

**Fig. 1.15.** Scanning electron micrograph of  $\text{MnO}_2$  particles. (Figure taken from Lison [99] with kind permission of Springer Science and Business Media.)

face areas (0.5, 17, and 62 m<sup>2</sup> g<sup>-1</sup>) for 6 h. Lactate dehydrogenase (LDH) release was measured to indicate the degree of membrane damage. At the same particle concentrations, the particle with the highest surface induced the greatest amount of cytotoxic activity. However, freshly ground particles (5 m<sup>2</sup> g<sup>-1</sup>) from the 0.5 m<sup>2</sup> g<sup>-1</sup> sample showed the highest toxicity of all. The researchers concluded that the toxicity of MnO<sub>2</sub> particles is surface dependent, indicating the possible effect of surface chemistry on cytotoxicity [99]. Lehnert et al. have claimed that cytotoxic effects are a result of intracellular dissolution of the nanoparticles in the phagolysosomes [100]. Therefore, since dissolution is a function of specific surface area, toxicity should increase with increasing surface area, which is consistent with the results of Lison. The increased toxicity of the freshly ground particle is attributed to additional reactive sites present on the surface [99].

Keceli et al. have studied the cytotoxicity of various metal oxides. Titanium, tantalum, and niobium are biocompatible due to the native oxide layer formed on the surface. Toxicity studies with these particles were performed with African green monkey kidney cells (Vero fibroblasts). Glass plates were spin-coated with a metal oxide layer (>100 nm) from a sol-gel solution. Cells were then cultured on the metal oxide for 7 days before they were counted. At the end of 7 days, no visible morphology change or apoptosis was observed, indicating that the samples were not cytotoxic. However, there was an effect on cell proliferation, which indicated an effect on biocompatibility. Al<sub>2</sub>O<sub>3</sub> and Nb<sub>2</sub>O<sub>5</sub> showed a 30% decrease in cell proliferation, while Ta<sub>2</sub>O<sub>5</sub> and ZrO<sub>2</sub> showed a 45% and 58% decrease, respectively. The TiO<sub>2</sub> sample did not differ from the control. The observed decrease in proliferation was consistent with the dielectric constants of the metal oxides, showing that metal oxides with a higher dielectric constant have more isolating effects and, as a result, are more biocompatible [101].

Chiu et al. have treated CHO cells with GeO<sub>2</sub> particles of varying concentrations for 12 h to determine their impact on cytotoxicity. Cytochalasin B, a proliferation inhibitor, was then added and an additional 24 h incubation applied. The cells were stained with Giemsa solution and counted to determine the number of binuclear cells. The number of binuclear cells decreased with the addition of GeO<sub>2</sub> particles, indicating that the particles induce G2/M block [102]. G2/M block is indicative of the cells not entering the mitosis stage of the cell cycle (Fig. 1.16). The G<sub>2</sub>, or Gap 2, phase is an intermittent stage that occurs after the synthesis of DNA, but before nuclear and cytoplasmic division of the cell. Prolonged periods in the G<sub>2</sub> phase inhibit cell proliferation (M phase) without inhibiting the formation of daughter cells (S phase), thus yielding binuclear cells [103].

Viability was determined by the sulforhodamine B viability assay [31] in which cells are fixed and stained with sulforhodamine B followed by dye extraction and analysis with an ELISA plate reader at 540 nm. Cell survival decreased with an increase in GeO<sub>2</sub> particle concentration. However, with the clonogenic survival assay, in which cells were cultured for an additional 7 days after treatment with the GeO<sub>2</sub> particles before they were assayed, survival rates were above 80%. This discrepancy is possibly due to delayed cell growth after treatment. Studies were also conducted to determine the phase of the cell cycle that the cells were in after treatment with GeO<sub>2</sub> particles. Treated samples showed a dose-dependent increase in the number

Fig. 1.16. Cell cycle; see text for details. (Figure taken from Ref. [101].)

of cells in the G2/M phase of the cell cycle. Therefore,  $\text{GeO}_2$  particles slow cell proliferation, but do not play a major role in cytotoxicity [102].

Gaudenzi et al. have demonstrated the effects of CdO on a lymphocyte cell line (Jurkat cells). Cells were treated with CdO particles and a survival index, the ratio of the average number of viable cells in the treated and control samples, was calculated. The CdO particles induced a decrease in the survival index of Jurkat cells over time until 24 h when a zero factor was obtained. The mechanism of cell death was probed by FT-IR studies, which showed a decrease in intensity of the amide bands, suggesting a decrease in H-bonding energy and protein degradation. In addition, evidence of additional carbonyl groups was present, which is indicative of protein oxidation [104].

Pigott et al. have found that amorphous  $\text{SiO}_2$  (100 nm) has a biphasic response when exposed to Chinese hamster lung cells. At a dosage of less than  $30 \mu\text{g mL}^{-1}$ , there were little or no cytotoxic effects, based on cloning efficiency; however, there was a progressive increase in cytotoxicity at higher concentrations [105]. Amorphous  $\text{SiO}_2$  was also found to be cytotoxic in other studies, and disrupts cell membrane functions when studied in cell culture [106–108]. However, this should not be of great concern for exposure of airborne amounts of  $\text{SiO}_2$  by inhalation.

## 1.6

### Conclusions

Currently, the National Institute of Occupational Safety and Health (NIOSH) is trying to answer the questions: In what ways might employees be exposed to nanomaterials in manufacture and use? How do nanoparticles enter the body? Once in the body, where would they travel? How would they interact physiologically and chemically with the body's systems [5]? The cellular and subcellular studies described herein provide some clues that address these questions.

In general, the reviewed studies showed that ferric oxide and titanium dioxide nanomaterials are not biotoxic in the dark and that  $\text{TiO}_2$  illuminated with ultraviolet light has a high cytotoxicity to both bacteria and mammalian cells. The toxicity

of ferric oxides under illumination has not been previously studied to our knowledge. There is an environmental photochemistry of ferric oxides with environmental pollutants [28], the products of which often include ferrous ions that could undergo Fenton-like chemistry and produce reactive hydroxyl radicals. Additional studies are warranted in this area.

However, there exist some important exceptions to the generalized statement above. For example, Linnainmaa et al. found no cytotoxicity with illuminated TiO<sub>2</sub> toward rat liver epithelial cells. Since the experimental conditions of light source, TiO<sub>2</sub> materials, and cell lines were different, it is difficult to pinpoint why this study differs. Likewise, Donaldson reported conditions where 20 nm TiO<sub>2</sub> particles linearized plasmid DNA, while 50 nm particles did not. These exceptions underscore some of the difficulties associated with answering NIOSH's questions. When "the body" is replaced by "a single mammalian cell," the answers remain unknown, even for a well-studied nanomaterial like TiO<sub>2</sub>. Additional studies are required before biotoxicity relationships can be understood in more complex human systems at the molecular level.

### Acknowledgment

The authors acknowledge equipment support from the NSF MRSEC Grant number DMR00-80031. The authors also acknowledge support from DARPA/AFOSR Grant F49620-02-1-0307 and from the David and Lucille Packard Foundation Grant #2001-17715. We thank the National Science Foundation (CRAEMS) for support of the environmental chemistry aspects of this work.

## 2

# Ecotoxicity of Engineered Nanomaterials

*Eva Oberdörster, Patricia McClellan-Green, and Mary Haasch*

### 2.1

#### Introduction

To date there has only been one thorough review of the nanotoxicology literature from a biological viewpoint [1], and that review through necessity was based on related work done primarily on the toxicology of ultrafine particulate matter in mammalian models. In this chapter we will not repeat the previous report, but will instead focus on new investigations of engineered nanomaterials in environmentally relevant species and models. Initial “eco-nano” considerations were focused on using nanomaterials in the environment for remediation, in the development of more accurate and sensitive biosensors, and for green energy production, for example (Table 2.1). With these initial efforts there was little concern for engineered nanomaterials functioning as toxicants themselves, and the focus was on technology development. Only since 2004 has the issues of nano-ecotoxicology of highly reactive, lipophilic engineered nanomaterials come to the front. The numerous benefits to society from the development of NP should not be minimized. Decreasing our dependence on highly toxic fossil fuels, remediating superfund sites, creating new and better drug delivery systems and green manufacturing are all processes whose benefits portend great promise. We should not approach these technologies wearing blinders, but rather be cognizant of the big picture. In other words: Be aware of the benefits and the costs.

One issue that immediately confronts any scientist in the area of nanoparticle toxicology is terminology. Standardized terminology is not yet in use, although efforts are underway by Rice University’s CBEN to move forward on this front. In this chapter, we will use engineered nanoparticles (NP) to designate any man-made nanomaterial (one dimension < 100 nm) with specific chemical, size, and shape characteristics, including materials such as fullerenes (C<sub>60</sub>, C<sub>70</sub>), single-walled carbon nanotubes (SWNT), quantum dots, nano-wires-films, -textiles, and so forth. The more general term, nanosized particle (NSP), will include both the NP and naturally occurring particles that are less than 100 nm in one dimension, such as the ultrafine particles (UFP) in air pollution, and small bacteria and viruses. This chapter will focus on engineered nanoparticles (NP).

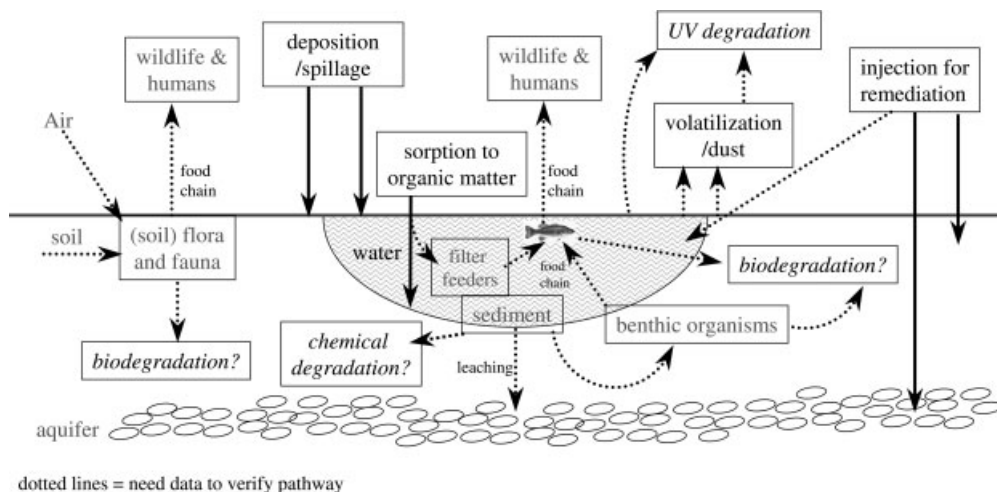

**Tab. 2.1.** Some recent funding by the US EPA to develop applications of NP for use in the environment [38].

Type of NP used	Potential use	Lead PIs and Institutions
	<i>Remediation</i>	
NanoTiO <sub>2</sub>	Photocatalysis of organic contaminants	D.D. Dionysiou Miami University-Oxford, OH; University of Cincinnati, OH
Carbon nanostructures	Sorption of organics	M.B. Tomson Rice University
Nano-metal oxides	Control NO <sub>x</sub> production	S. Senkan UCLA
Nano-iron	Degradation of PAH-based contaminants	G.V. Lowry, S.A. Majetich, K. Matyjaszewski, R.D. Tilton Carnegie Mellon University
Nano-biopolymers	Control of heavy metals	W. Chen, M. Matsumoto, A. Mulchandani UC Riverside
Bi-metallic nano-Fe/Pd	Remediation of inorganics and organics	W.X. Zhang Lehigh University
Nano-crystalline zeolite	NO <sub>x</sub> , photocatalytic oxidation of organics	S.C. Larsen, V.H. Grassian University of Iowa
Nano-magnetite	Groundwater contamination	M. Hull Luna Innovations, Inc.
	<i>Filtration</i>	
Ferromagnetic particles	Using nanocomposites to monitor and filter (smart particles)	W.M. Sigmund, D. Mazyck, C.Y. Wu University of Florida
Nano-crystalline catalysts	Disinfection by-product control in drinking water	S.J. Masten, M.J. Baumann Michigan State University
Nanostructured electrodes	Perchlorate from drinking water	S.M. Jaffe Material Methods LLC
	<i>Sensors</i>	
Carbon nanoparticle based microchip	Analytical chemistry of environmentally relevant endpoints	J. Wang New Mexico State University

Tab. 2.1 (continued)

Type of NP used	Potential use	Lead PIs and Institutions
Nanocrystalline metallic conductors	Gas sensor	V. Subramanian UC Berkeley
Colloidal-metal nanoparticles	Monitoring heavy metals	O. Sadik, J. Wang New Mexico State University
Polystyrene beads coated with peptides	Detection of aquatic toxins	R.E. Gawley University of Miami
Fullerene	Tracers for water pollution	J.B. Callegary University of Arizona
	<i>Green energy/manufacturing</i>	
Nano-clay	Substitute petroleum-based products for nano-composites	L.T. Drzal, M. Misra, A.K. Mohanty Michigan Sate University
Nano-micelles	Replacing VOCs with nano-structured microemulsions	D.A. Sabatini, J.H. Harwell University of Oklahoma
Nano-plastic fibrils and crystals	Alternative to petroleum-based composites	W.T. Winter SUNY College of Environmental Science and Forestry
Nano-TiO <sub>2</sub>	Photocatalyst for solar cells	G. Chumanov Clemson University
Semi-conducting nanoparticles	Catalyst fuel cells	N.Y. Dolney University of Michigan-Ann Arbor

When “nano” first became the hot new technology, immediate environmental applications were sought using these reactive materials. Numerous funding agencies encouraged development of NP use in the environment (applications, Table 2.1) and initially very little consideration was given to the unintended consequences or implications of nanomaterial production or use in the environment. The new technologies developed include a wide array of materials designed for remediation activities (some of which are in commercial use), the development of biosensors for chemicals or biological agents, the development of environmental filtration processes, and green manufacturing. Although one could argue that both applications and implications are important areas of research, the implica-

**Fig. 2.1.** Model of NP movement through the environment. Dotted lines indicate pathways not yet verified, while solid arrows indicate verified pathways. (From Oberdörster et al. [1].)

tions research of NPs has lagged behind. In this chapter, we focus on some of the recent environmental implications of NPs as toxicants, and will discuss issues that need to be addressed through future research.

The complexity of NP in ecotoxicology can be seen in Fig. 2.1. Particle movement through water, air and soils has been poorly studied, and biological uptake and food chain transport have not been considered. Biotransformation and chemical and UV breakdown have been given scant consideration and in-depth chemical analysis or other characterizations, including electron microscopic imaging of NP before and after environmental ageing, have not been conducted. In the following sections, we review these issues along with suggested areas of future research.

## 2.2

### Water

Many NP are poorly soluble in water (e.g., SWNT,  $C_{60}$ ). However, if coated with an appropriate molecule, such as peptides or proteins [2, 3], poly(ethylene glycol) (PEG), or other surfactants, even non-water-soluble NP can be rendered miscible with water, including water-containing humic acids and salts [4]. Another effective method to render lipophilic NP (such as  $C_{60}$ ) water-soluble is to allow the particle powders (clumps of NP) to stir in water for a few days or up to several weeks (longer agitation times equal more dissolution). This slow procedure is a more environmentally relevant method of introducing NP into solution. Recent data shows that using organic solvents as an intermediary to render NP water-soluble leaves

traces of the organic solvent in centers of fullerene clusters. For example, Andrievsky et al. [5], Brant et al. [6], and Fortner et al. [4] have demonstrated that using tetrahydrofuran (THF), a common organic solvent, to solubilize  $C_{60}$  in water resulted in formation of  $nC_{60}$  aggregates that contained residual amounts of THF. This residual THF is of biological concern and toxicologically relevant. In daphnia we have found that the 48-hour  $LC_{50}$  is orders of magnitude different between THF-solubilized  $nC_{60}$  (0.8 ppm) and stirred  $nC_{60}$  (>30 ppm, which was the highest concentration tested). (For a review of solubility levels of NP in various solvents please refer to Nakamura and Isobe [7].) Thus, when performing ecotoxicity tests, it is crucial to determine not only a valid range of concentrations for testing (will we really see ppm levels?), but also to use realistic methods of water-solubilization of NP.

There are several target areas of concern when discussing ecotoxicology of NP. Engineered NP will tend to agglomerate to each other or to larger particles in the environment, and will tend to sorb onto or associate with sediments. These sediments can then be ingested by benthos, creating a food-chain through which these NP can move (Fig. 2.1). In preliminary studies with the suspension-feeding worm *C. elegans*, we have shown that FITC-labeled SWNT (which can be easily tracked through the exposure dishes and inside the worms) move through the digestive tract (DG) and are not absorbed into the animal (unpublished data, laboratory of Eva Oberdörster in collaboration with Jim Waddell, Southern Methodist University and Ya-Ping Sun, Clemson University). This type of tracking has not been done for other NP, but is a crucial step in determining uptake into biota. Even if NP remain solely in the DG tract and do not bioaccumulate, they are still likely to move up the food chain as worms and other organisms are consumed by benthivores (Fig. 2.1). This scenario seems even more likely with a detritivore benthic organism like *Hyalalella azteca* in which the  $nC_{60}$   $LC_{50}$  is greater than 7 ppm. In fact, no toxic effects are observed in *Hyalalella* even when the  $nC_{60}$  is mixed in the food [8].

In contrast to the *C. elegans* study, we have shown that filter-feeding crustaceans (*Daphnia magna*) can accumulate NP when exposed via the water column (Figs. 2.2 and 2.3). Nano-iron used in remediation is ingested by daphnia and can coat their carapace, including filtering apparatus and appendages (Fig. 2.3). Even though the daphnids were coated with nano-iron, they were able to survive in the laboratory test and were able to feed and reproduce. The toxicity of nano-iron was the same as that for bulk iron, approximately 55 ppm (Fig. 2.3). The daphnids containing nano-iron in the gut and on the carapace are much darker in coloration than daphnids without the nano-iron. Since many daphnid predators (fish) are visual feeders, it would be interesting to determine whether the darker daphnids are more likely to be preyed upon than lighter daphnids, similar to what has been shown with melanized (darker) vs. lighter-colored daphnids [9].

Daphnids are generalist filter feeders specializing in larger-sized phytoplankton [9]. However, numerous species are specialized filter feeders, including many rotifers that specialize in nanosized prey, such as Archaea and other small bacteria. The differential impact of NP on filter feeders that are generalists vs. specialists still needs to be determined. A study by Conova [10] has shown that some filter-

**Fig. 2.2.** Uptake of  $nC_{60}$  into *Daphnia magna*. Approximately 15 daphnids were collected at each time point, and were rinsed 5× with reconstituted hard water during 1 h. Water was removed by blotting, and a wet-weight was taken. The  $nC_{60}$  was oxidized, using 1 mL bleach, and extracted overnight into toluene. Absorbance was read at 332 nm and compared to a standard curve.

feeders select their prey by surface chemistry, not necessarily size. Therefore, coating NP to make them more “biocompatible” may make them easier for certain species to selectively filter. In addition, many aquatic and marine organisms, especially crustaceans, carry out their feeding and reproductive behaviors through the use of chemosensory organs. Adherence of NP to the surface of the chemosensory structures such as seen in Fig. 2.3 could disrupt their growth, development or reproduction by interfering both physically or physiologically with these structures. These are not minor considerations given that zooplankton is the basis of aquatic food chains. Specific impacts on zooplankton can significantly alter predator/prey balance and lead to shifts in ecosystem health.

Vertebrates would be exposed not only via the food chain (either by ingesting sediments directly or by ingesting NP-contaminated prey) but also through gill and skin. Observations by Tjälve [11, 12] and Oberdörster [13] have shown that translocation of toxicants, including NP, via the olfactory neuron into the brain is likely in several species of fish. Although most NP will tend to sorb to sediments or onto phytoplankton, NP will likely move up the food chain due to benthos and filter-feeding invertebrates. These types of studies – systematic bioaccumulation/biodistribution – have not been done to date. Considering the current restrictions on fish consumption for humans due to PCBs and methyl mercury [14], it is not only an ecosystem health issue, but also a human-health issue.

Although movement of NP through the food chain is likely, recent studies by Le-coanet [15] have shown that NP are of very low mobility in aquifers. Even though NP are currently injected into aquifers and ground-water for remediation, it has been hypothesized that they will not move far from the injection point. However, the rate of movement of NP in real-life applications has not been tested. The size,

*Daphnia magna* 48 hour mortality after exposure to nano-iron

**Fig. 2.3.** *Daphnia magna* exposed to various concentrations of nano-iron used in remediation. A = control; B = 3; C = 7.5; D = 15; E = 30; F = 125 mg L<sup>-1</sup> (dead daphnid). All daphnids shown are 21-days-old and eggs are visible in their brood pouches (green circles).

Note the darkening of the digestive tract from A (normal greenish color) to D with increased ingestion of nano-iron particles (black arrows). Antennae become clogged with nano-iron in E and F (blue arrows). The 24 and 48 h mortality curves are also shown.

shape and surface chemistry of NPs that make them so attractive in various technologies will also influence their behavior in the environment. Pharmaceutical NPs that have been coated to make them more soluble or to improve the solubility of attached drugs or compounds will surely enter the waste-water stream, similar to what has been observed with other drugs and medicines [16]. Once there, NP will be transported, broken down or accumulated based on their physicochemical properties. For example, polyhydroxylated  $C_{60}$  (fullerenols) or surfactant modified nanotubes are specifically engineered to increase their solubility in water, and could therefore remain in the aqueous phase. But these modifications also increase NP movement through porous media [17]. Movement of specific NPs in environmental media has not been thoroughly investigated, although researchers at Rice University are beginning to address this issue.

### 2.3

#### Air

Most research on airborne NSP has been on ultrafine particles (UFP) of various chemical and size compositions, and of NP in the workplace [1]. NSP can either agglomerate to each other or to other particles in the air, depending on particle number density and time. Particle sizes of less than 5 nm in diameter will behave more like gases, while larger sized NSP behave more like bulk particles; for a review see Ref. [1]. NSP are produced from combustion by-products, and can deposit as dust particles, and can also be re-suspended by wind (Fig. 2.1). Global movement of NSP through atmospheric deposition and re-suspension is likely, similar to what has been found in other gaseous and particle pollutants, such as CFCs. Biswas and Wu have recently reviewed the NP/NSP literature [18]; please refer to that reference and to Chapters 4 and 7 of this text for more details on airborne NSP effects, especially as they relate to workplace exposure.

### 2.4

#### Soils

Soils are a complex mixture of organic and inorganic compounds, and microbial and other living organisms. Soils are so complex that standard “soils” are used in ecotoxicology testing. To date, no studies have been performed using these standard soil protocols, but one recent study shows that at relatively high doses (ppm) microbial growth (*E. coli* and *B. subtilis*) was reduced with nano- $TiO_2$  and  $nC_{60}$  [4]. Since these are relatively high levels of nanomaterials, modeling exercises are needed to determine relevant doses before being able to decide whether there are risks involved in release of NP into soils.

Another source of NP in the environment (especially soils and sediments) are NP-containing matrices that function as slow-release agents for various biocides [19]. These matrices can be applied to various surfaces to inhibit biological growth

(e.g., of fungi), but as the matrices weather or wear off, NP will be released into the environment. What happens to these matrices (how fast do they break down? are NP released from them as they break down?) is unknown.

Toxic NSP can be inadvertently created in soils, as bacteria absorb toxicants, creating “biological” toxic NSP. Pollmann et al. [20] have demonstrated that the outer layer of some bacterial species function as selective matrices for the binding of toxic metals. They demonstrated the S-layer of *Bacillus sphaericus* JG-A12, through its hydrophobic construction and the presence of phosphorylated proteins, possesses an extremely high and reversible binding capacity for toxic metals such as uranium and palladium. This binding creates NSP that can be removed from the environment. But what happens to the inadvertently created NSP? Where do they go? And how does sorption of toxicants, including NP, affect microbial communities?

In addition to effects on microbial communities, it is likely that plants can take-up and bioaccumulate NP. Some interesting solar-cell applications have been developed using synthetic chlorophyll and fullerene [21], but it has not yet been determined whether fullerene can interfere with or enhance natural photosynthesis by bypassing the usual electron transport chain. Given that solar-power research is focused on using nanomaterials, it is critical to determine whether natural solar-power (i.e., photosynthesis) can be disrupted or enhanced by NP. Preliminary studies in our laboratory indicate that  $nC_{60}$  may influence (enhance) the growth rates of blue-green algae (*Anabaena* sp.) (unpublished observation, B. Craig and P. McClellan-Green). The mechanism behind the change in growth is unknown. The  $nC_{60}$  might act as a nutrient source, facilitate uptake of media nutrients, or possibly interact with photosynthesis to accelerate the process. Although it is difficult to predict the types of challenges that could arise due to NP in soils, another area of concern is that these NP could interfere with cell signaling, such as with root nodulation of nitrogen-fixing bacteria. Such interference has been shown with pesticides [22], and could lead to unintended agricultural consequences.

Movement of NP through soil food chains is likely. Owing to the tendency to sorb to particles, NP will likely be ingested or absorbed by soil organisms (bacteria, worms, insects, plants, fungi, etc.) and could move up the food chain (Fig. 2.1). No studies have been performed on soil-food chain transport, but this will likely be an important future area of research given the human manipulation of environmental NP and NSP, and cycling between air deposition and re-suspension in air and water by dust and debris (Fig. 2.1).

## 2.5 Weathering

Currently, studies on NP and ecologically-relevant endpoints have been carried out under laboratory conditions without allowing for action by abiotic factors, such as UV, other chemicals, and dissolved oxygen levels/anoxia. Few studies have been carried out on UV interactions with NP that are either coated or covalently linked to molecules that render the NP less toxic. These studies have shown that even a

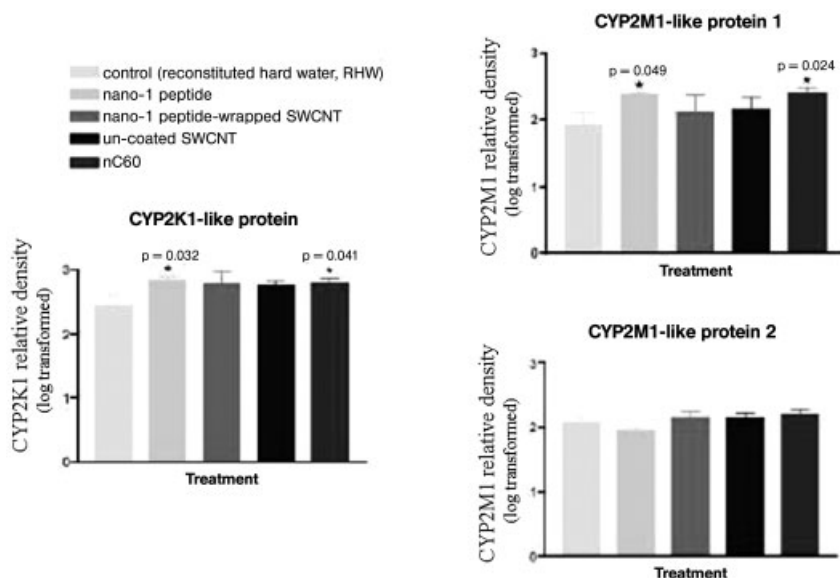

short exposure to UV light can un-coat and/or cleave the covalent linkage to produce the more toxic parent NP [23, 24]. Therefore, studies using standard laboratory procedures are an important first step; however, environmentally realistic exposures need to include UV exposures. This is similar to what has been shown with PAHs, where UV light exposure photoactivates and increases the toxicity of PAHs. In addition to UV, chemical activation of NP must be considered. Molecules such as fullerenes, which are redox active due to their chemistry, may interact with toxicants present or entering the environment. The question of whether other redox active toxicants will enhance or suppress fullerene toxicity has not been addressed. Can fullerenes donate or accept electrons from environmental compounds in such a manner that will create more or less toxic elements? In addition, the level of anoxia, which can increase the oxidative stress response in affected organisms may or may not influence fullerene toxicity. These types of questions, i.e., mixtures studies, studies including UV as co-factors, and varying levels of oxygenation have not been addressed as yet but will be valuable in determining realistic environmental hazards.

Aside from the abiotic factors, microbial degradation/activation may also affect the activity of NPs in the environment. Several studies have shown that bacterial and microsomal P450s can metabolize NP [25–28]. Microbes could, possibly, weather both covalent modifications and coatings from NP, altering their toxicity. Model P450s produce oxidation products of fullerene, including sequential epoxidation products [25]. The introduction of hydroxy groups (as is common with P450 metabolism) makes at least some NP less toxic [4, 29], and therefore microbial weathering may help reduce the environmental impact of NP. Fortner et al. [4] recently found a hormetic effect in *B. subtilis* bacteria exposed to hydroxylated-fullerene – the highly hydroxylated fullerene ( $C_{60}(OH)_{24}$ ) enhanced microbial growth as compared to control and non-hydroxylated  $nC_{60}$ . Could upregulation of key enzymes (e.g., cytochrome P450s) be responsible for this hormetic effect? It is too early to make such determinations, but research is being conducted in this area to develop a database from which to draw better mechanistic conclusions.

## 2.6

### Biomarkers

Given that microbial P450s metabolize NP *in vitro* [25–28, 30], it is possible that this class of enzymes may be useful as biomarkers of NP exposure. Previously, Ueng et al. [27] demonstrated that exposure of mice to fullerenol-1 decreased monooxygenase activities towards the compounds benzo[*a*]pyrene, 7-ethoxycoumarin, aniline and erythromycin. They also demonstrated an inhibition of ADP-induced uncoupling and mitochondrial  $Mg^{2+}$  ATPase activity. In our laboratory, we have found that the CYP2 family of enzymes are upregulated in two species of fish following exposure to SWNT at both the protein and mRNA levels (Fig. 2.4) [31, 32]. Although preliminary, it would be interesting if specific biomarkers of exposure could be developed for NP. To this end, an effort is currently underway in

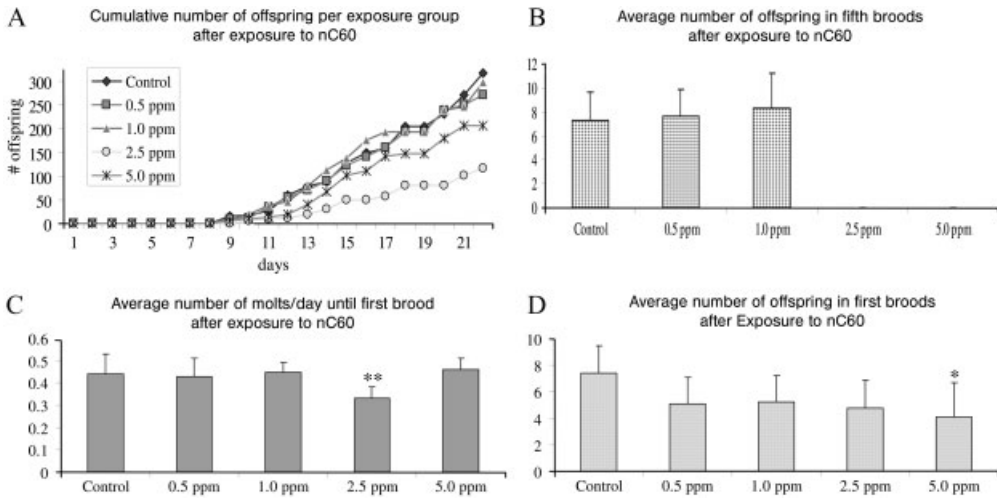

**Fig. 2.4.** Upregulation of cytochrome P450 isozymes in male fathead minnow exposed for 48 h to 0.2 ppm synthetic nano-1 peptide, 0.2 ppm SWNT or 1 ppm water-soluble fullerene ( $nC_{60}$ ) (Oberdörster et al. [31]). It appears that both  $nC_{60}$  and the synthetic peptide used to make SWNT biocompatible induce CYP2-family proteins.

conjunction with the Woodrow Wilson Center for International Scholars, interested NP-producing Industries, and academia to create a “nano-chip” (microarray) that could serve as a basis for both laboratory screening and field-testing to determine exposures to NP [33]. Endpoints of interest would not only include the P450-family of enzymes, but also enzymes related to oxidative stress management, and proteins involved in the inflammatory response. Several studies have shown that NP can cause oxidative stress both *in vivo* and *in vitro* [13, 23, 24, 29, 34–37], and that NP can also cause inflammation; for a review see Ref. [1].

To develop a systematic approach to detecting and validating biomarkers of exposure, it is necessary to adapt current standard toxicity tests for NP. The biggest challenge will be to use uniform NP, both chemically uniform and using a standardized preparation method. Fortner et al. [4] have shown that the preparation method can alter the ultimate end-product of NP, and anecdotal evidence suggests differences between stirring vs. bath sonication vs. probe sonication. As mentioned earlier, we have shown that, in daphnia, the 48-hour  $LC_{50}$  is orders of magnitude different between THF-solubilized  $nC_{60}$  (0.8 ppm) and stirred  $nC_{60}$  (>30 ppm). In addition, the many compounds that are attached to NPs will influence their bioaccumulation, breakdown and toxicity, especially if the attached compounds are removed within different compartments in the environment.

As well as standardized testing, environmentally relevant doses need to be used. Using only high concentrations and looking only for mortality does not give in-

**Fig. 2.5.** Exposure of *Daphnia magna* to sub-lethal levels of  $nC_{60}$  delays reproduction (A), results in one fewer brood (no fifth brood) over 21 days (B), slows molting (C), and reduces the number of offspring in the first brood (D); \*  $p < 0.05$ , \*\*  $p < 0.01$ . Therefore, sub-lethal

endpoints need to be investigated when studying NP effects in environmentally relevant species.  $nC_{60}$  used in this study was prepared by stirring. No organic solvents were used to solubilize the  $nC_{60}$ .

sights into mechanisms of action. For example, in daphnia we have found that sub-LC<sub>50</sub> doses of  $nC_{60}$  can inhibit reproduction by delaying brood production and brood size (Fig. 2.5). Gene chips can also give insights into sub-lethal effects and mechanisms of action. Clearly, a combination of population-level data (such as reproductive output) and protein and gene expression can give a clearer picture of environmental risks posed by NP. To date this information is not available, although several researchers are addressing these issues.

## 2.7

### Conclusions

NP are already in the environment, used either for remediation, or from normal use and wear of products containing NP (tires, clothing, sporting equipment, cosmetics, etc.). As there is almost no data on the toxicity of NP to environmentally relevant species, it is difficult to predict ecosystem risks. Although steps are being taken to remedy this lack of knowledge, several key research areas will need to be addressed. These include, but are not limited to:

1. How far can NP move through air, water and soil? How do size, shape, surface chemistry and agglomeration state affect this movement?

2. What are the most likely routes of exposure for environmentally relevant species (ingestion, dermal, inhalation, root uptake)?
3. Can NP interfere with photosynthesis, with microbial communities, or with inter-species communication (such as root nodulation)?
4. Can NP bioaccumulate?
5. Can NP be metabolized to more or less toxic forms?
6. What biomarkers are relevant for measuring NP exposure levels?
7. What end-points are significant for determining risk of NP?
8. What are the mechanisms of toxicity of NP in environmentally relevant systems?
9. Does the presence of NP in the environment affect the toxicity of other compounds and vice versa?

Many of these questions are currently being addressed by scientists around the world. We may well be able to come to a better consensus on eco-risks of NP once these basic questions are answered. Until then, the numerous benefits of NP should not be underestimated! Decreasing our dependence on highly toxic fossil fuels, remediating superfund sites, creating new and better drug delivery systems and green manufacturing are all processes whose benefits need to be considered alongside any toxic effects of NP.

## Possible Health Impact of Nanomaterials

*Peter H. M. Hoet, Irene Brüske-Hohlfeld, and Oleg V. Salata*

### 3.1

#### Introduction

Nanotechnology is often portrayed as a force that will help to materialize ultimate solutions to today's technological problems. Nanomaterials are the first nanotechnological products hitting the markets. Widespread use of nanomaterials in the consumer and industrial products is also causing some health concerns [1, 2]. Proponents of nanotechnology [3] as well as its opponents find it hard to argue their case due to the limited information available.

How much do we know? To try to answer this question, we start this chapter by looking at the scale and current sources of nanomaterials engineered by men. Next, we use the relative wealth of research data available from the epidemiological studies of the technogenic nanoparticles to highlight the apparent health effects associated with the inhalation of ultrafine particulate matter. The inhalation of ultrafine particles is a well established entry route; hence we discuss the potential entry points of nanoparticles into the human body via airways, and also alternative paths through the skin and gastrointestinal tract. Then, we explore their likely pathways inside the body, the effects associated with nanoparticle interactions on the cellular level, and analyze the origins of the bioactivity of nanomaterials. Nanofibers, a special case of nanomaterials that are known to be hazardous in the micron domain because of their shape, are given some thought. In addition, recent observations on nanoparticle penetration through the blood–brain barrier are evaluated. Finally, the implications of our findings for the field of nanotechnology are discussed. This chapter is one of the very first attempts to overview a rapidly developing field of nanotoxicology, and to sum up and reflect upon recent experimental findings in this field.

### 3.2

#### Sources of Nanoparticles

Nanoparticles can be classified into three groups: natural, anthropogenic and man-made (or artificial). The natural kind is produced, for example, during forest fires

or volcanic eruptions; anthropogenic particles are quite often a by-product of industrial activities like welding or polishing. Diesel exhaust particles are also placed in this group. The last group includes engineered nanomaterials deliberately produced because of their technologically beneficial properties caused by the reduction in particle size. These novel properties of common materials observable only at nano-scale dimensions already have commercial applications [4]. For example, nanomaterials can be found in sunscreens, toothpastes, sanitary ware coatings and even food. The production volumes of man-made nanoparticles range from the multi-ton for carbon black and fumed silica used in plastic fillers and car tires to the microgram quantities of fluorescent quantum dots used as markers in biological imaging.

Following massive investments [5, 6], efforts to exploit the unique properties of everyday materials at the sub-micrometer scale are truly world-wide [7, 8] and consumer products relying on nanotechnology will experience a steady growth [9].

### 3.3 Epidemiological Evidence

Man-made nanoparticles are a relatively recent phenomena. As no data are available yet to evaluate the long-term risks of engineered nanoparticles, the epidemiological evidence on adverse health effects of ultrafine particles will be overviewed as a surrogate source of information.

Environmental air pollution consists of a complex mixture of compounds in gaseous, liquid and solid phases, the latter usually referred to as particulate matter (PM). In general, ambient levels of particulate matter are characterized as total suspended matter (TSP), and particulate matter with an effective aerodynamic diameter of less than 10  $\mu\text{m}$  ( $\text{PM}_{10}$ ) or 2.5  $\mu\text{m}$  ( $\text{PM}_{2.5}$ ). Particles in the sub-micrometer ranges, particularly in the range  $< 100$  nm, are labeled as ultrafine particles in epidemiological studies. Ultrafine particles in ambient air vary in chemical composition and size, as do technically produced nanoparticles. The number concentration of these small particles exceeds by far that of larger ones in urban area, but their contribution to the total mass concentration is relatively low. Therefore, it is standard to measure  $\text{PM}_{10}$  and  $\text{PM}_{2.5}$  in mass concentration ( $\mu\text{g m}^{-3}$ ). For ultrafine particles, the number concentration ( $\text{cm}^{-3}$ ) or surface area concentration ( $\mu^2 \text{m}^{-3}$ ) or particle length concentration ( $\text{mm cm}^{-3}$ ) is more relevant. Particles in ambient air are generated by numerous sources: motor vehicles, power plants, wind blown dust, photochemical processes, cigarette smoking, nearby quarry operation, etc. Some particles are introduced from the source into the air in solid or liquid form, while others are formed in the air by gas into particle conversion.

In the United States, the Environmental Protection Agency set National Ambient Air Quality Standards for particulate matter. According to the 1987 standard of  $\text{PM}_{10}$ , the maximal allowable 24-hour concentration was set at  $150 \mu\text{g m}^{-3}$  and the maximal annual mean was set at  $50 \mu\text{g m}^{-3}$ . From 1988 to 1993, the averages of the annual mean  $\text{PM}_{10}$  concentrations at 799 sites monitored by the US EPA

declined by 20%. Despite these improvements in air quality, Samet and coworkers [10] reported associations between particle concentrations and the number of deaths per day in 20 of the largest cities and metropolitan areas in the United States from 1987 to 1994 with mean 24-hour  $PM_{10}$  concentrations well below the standard. Analysis of the daily number of deaths occurring within an urban region has shown that  $10 \mu\text{g m}^{-3}$   $PM_{10}$  were associated with an increase of 0.2%. The result is based on a recent reevaluation of the National Mortality Morbidity Air Pollution Study (NMMAPS) that included 90 urban areas of United States in these analyses [11]. In 29 European cities, an increase of 0.6% in daily mortality was observed in association with an increase of  $10 \mu\text{g m}^{-3}$  in the study by the Air Pollution and Health Effect Association (APHEA) [12]. Studies on particles mass concentration indicate that there is a linear relationship between  $PM_{10}$  and  $PM_{2.5}$  and various health indicators (like cough, symptom exacerbation, bronchodilator use, hospital admissions and mortality [13]) for concentration levels between 0 and  $200 \mu\text{g m}^{-3}$ , and no threshold in particle concentrations below which health would not be jeopardized.

Within most established monitoring networks, ambient particulate matter is measured as either  $PM_{10}$  or  $PM_{2.5}$ . The epidemiological research has therefore focused on the links between these mass characteristics of ambient particles and adverse health effects. However, with reductions in particulate emissions from industry and power stations, the relevance of the number concentrations of ultrafine particles increased (mainly from traffic emissions). Not much was known about their impact on health. Panel morbidity studies with asthmatic subjects indicated that both fine and ultrafine particles were negatively associated with the respiratory health of the exposed population [14]. A decrease of respiratory functions, e.g., peak expiratory flow [15], and an increase in symptoms and medication use [16], was associated with elevated particle concentrations of ultrafine particles, independently from fine particles. Inflammatory events in the lungs took several days to develop. It was considered as likely that a lag time existed between exposure to ultrafine particles and the acute respiratory health effects of the exposed population. Cumulative effects over 5 days seemed to be stronger than same-day effects. There was an indication that the acute effects of the number of ultrafine particles on respiratory health were stronger than those of the mass of the fine particles [17, 18].

To improve our knowledge on human exposure to particulate matter of different sizes and of different chemical composition in Europe, and to develop standards for air quality in Europe, the ULTRA project was initiated. Specifically, the project aimed to improve exposure assessment to fine particles by assessing the size distributions, including ultrafine particles, and elemental compositions of fine particles in ambient air in three European cities with different sources of particulate air pollution. Three panel studies were carried out, in Amsterdam, the Netherlands, Erfurt, Germany, and Helsinki, Finland, during winter and spring 1998–1999 [19–21]. In all three cities, about 50 elderly persons with coronary heart disease were followed up for six months with bi-weekly intensive examinations, which included measurements of the function of the heart and lungs, blood pressure and of bio-

markers for lung damage from urine. The subjects also kept daily symptom diaries. These studies were limited to the investigation of the acute health effects of short-term exposure by evaluating the impact of day-to-day variation in ambient pollution on health through correlating mortality and morbidity with daily pollution levels. There is an association between exposure to ultrafine particles and cardiovascular morbidity in the population with chronic heart diseases. In Helsinki [22] independent associations between both fine and ultrafine particles and the risk of ST-segment depression in their ECG were observed among subjects with coronary heart disease. ST-segment depression is regarded as an indicator of myocardial ischemia. The study reported increased odds ratios for 45 subjects, ranging from 1.03 to 3.29, with 95% confidence intervals ranging from 0.54 to 6.32. Several plausible mechanistic pathways have been described, including enhanced coagulation/thrombosis, a propensity for arrhythmias, acute arterial vasoconstriction, systemic inflammatory responses, and the chronic promotion of atherosclerosis [23].

A study conducted in Erfurt, Germany, on daily mortality showed comparable and independent increases in mortality in association with fine and ultrafine particles [24]. All particles had a strong seasonal dependency, with maximal concentrations in winter. The concentrations of ultrafine particles showed a pronounced day of the week effect with concentrations during the weekend 40% lower than during the week. This and a clear increase of the ultrafine particles concentrations during the rush hours suggest that the main source for ultrafine particles was automobile traffic. Associations between health effects and particle number and particle mass concentrations have been observed in different size classes, and both immediate effects (lags 0 or 1 days) and delayed effects (lags 4 or 5 days) were found. The effects could be found for total mortality and also for respiratory and cardiovascular causes. There was a tendency for more immediate effects on respiratory causes and more delayed effects for cardiovascular causes. Mortality increased in association with ambient particles after adjustment for season, influenza epidemics, day of week and meteorology, and sensitivity analyses showed the results to be stable.

In summary, both fine and ultrafine particles are associated with respiratory and cardiovascular morbidity and mortality and appear to be so independently of each other. There is also epidemiological evidence of similar responses to fine and ultrafine particles, although the size of the effects is often larger for ultrafine than for fine particles (at least on a per mass basis). One can expect that similar effects can be induced due to the presence of man-made nanoparticles.

### 3.4

#### **Entry Routes into the Human Body**

The above-mentioned health effects result from the inhalation of ultrafine particles. In general, compounds or materials can enter the body via three “natural” portals: skin, intestinal tract and respiratory tract (nose, airways and alveoli), or via intentional delivery through injection, intravenous (i.v.), intraperitoneal (i.p.) or

intramuscular (i.m.). Although our knowledge in this field is partly built on studies concerning drug delivery (pharmaceutical research) and toxicology (xenobiotics) of an intentional dose, in this chapter we will mainly concentrate on the health effects of nanomaterials entering the body via one of the natural portals.

The skin acts as a strict barrier between the body and the environment; no essential elements are taken up through the skin (except solar radiation necessary to build up vitamin D).

The respiratory tract and the intestinal tract allow transport (passive and/or active) of various substances like water, nutrients and gasses. The lungs exchange oxygen and carbon dioxide with the environment, and some water escapes with the warm exhaled air. The intestinal tract is in close contact with all the materials taken up orally; here all nutrients (except gasses) are exchanged between the body and the environment. The anatomy and histology of the three organs in contact with the environment differ significantly.

The skin of an adult human is roughly  $1.5 \text{ m}^2$  in area, and is at most places covered with a relatively thick first barrier ( $10 \text{ }\mu\text{m}$ ) built of strongly keratinized dead cells. This first barrier is difficult to pass for ionic compounds as well as water-soluble molecules.

The respiratory tract consists of three different parts: nose, airways (transporting the air in and out the lungs) and alveoli (gas exchange areas). The nose and the airways are a relatively robust barrier, built of an active epithelium protected with a viscous layer of mucus. In the gas exchange area, the barrier between the alveolar wall and the capillaries is very thin. The air in the lumen of the alveoli is only  $0.5 \text{ }\mu\text{m}$  ( $500 \text{ nm}$ ) away from the blood flow. The large surface area of the alveoli,  $140 \text{ m}^2$  in adults, and the intense air–blood contact in this region make the alveoli less well protected than the airways against environmental damage.

The intestinal tract is a more complex barrier – exchange side, it is the portal for macromolecules to enter the body. From the stomach, only small molecules can diffuse through the epithelium. The epithelium of the small and large intestines, in close contact with ingested material, allows and controls the uptake of nutrients such as disaccharides, peptides, fatty acids, and monoglycerides generated by digestion. The overall surface available to exchange nutrients is about  $200 \text{ m}^2$  in adults.

In the following sub-sections, interactions of the three portals with nanomaterials are briefly discussed. Two critical aspects, from the health effect point of view, will be discussed for each. First, how can nanomaterials have a local effect in each of these organs and, second, can nanomaterials move from the portal into the body.

### 3.4.1

#### Lung

##### 3.4.1.1 Inhalation, Deposition and Pulmonary Clearing of Insoluble Solids

**Inhalation and Deposition** The deposition of solid material in the respiratory tract depends on the physical characteristics of the material, such as particle size and

shape, relative weight, and on the anatomy of the respiratory tract, such as diameter of the airways, air speed, branching angle etc. [25–27].

Spherical solid material can be inhaled when its aerodynamic diameter is less than 10  $\mu\text{m}$ . The smaller the particulates the deeper they can travel into the lung – particles < 2.5  $\mu\text{m}$  will even reach the alveoli. Ultrafine particles (nanoparticles with an aerodynamic diameter of less than 100 nm) are deposited mainly in the alveolar region, largely by diffusion (Brownian movement). Models have shown that the deposition efficiency at the three pulmonary regions is not linear with size: particles of between 5 and 50 nm are deposited mainly in the alveoli, smaller and larger ones are more efficiently deposited in the higher regions [25, 28].

Fibers are defined, in pulmonary sciences, as solid materials with a length-to-diameter ratio of at least 3:1. Their aerodynamic diameter can be used to judge their penetration into the lungs. Fibers with a small diameter will penetrate deeper into the lungs, while very long fibers ( $\gg 20 \mu\text{m}$ ) are easily stuck in the higher airways, although some long fibers can enter the alveolar space [29–34].

**Clearance** The removal of solid material from the lungs is carried out by two distinct mechanisms. The mucociliary escalator dominates the clearance from the airways and the nose; in the alveolar region the clearance takes predominantly place by macrophage phagocytosis.

The mucociliary escalator, driven by the cilia of airway epithelium, is an efficient transport system, pushing the mucus, which covers the airways, together with the trapped solid materials towards the mouth.

The phagocytosis of particles and fibers results in activation of macrophages and induces the release of chemokines, cytokines, reactive oxygen species, and other mediators; this can lead to sustained inflammation and eventually fibrotic changes [35, 36]. The phagocytosis efficiency can be affected by the (physical-chemical) characteristics of the solid material [37] (see below); moreover, fibers too long to be phagocytized (fibers longer than the diameter of the alveolar macrophage, depending on the species studied) will not (or very slowly) be cleared [32, 38–40].

Laboratory exposure studies have shown that if the inhaled concentrations are low, such that the deposition rate of the inhaled particles is less than the clearance rate, then the retention half-time is about 70 days. For fine and nanoparticulates, the alveolar macrophage-mediated clearance is the limiting factor. If the deposition rate of the inhaled particles exceeds this clearance rate, the retention half-time is significantly increased, reflecting an impaired or prolonged alveolar macrophage-mediated clearance function with continued accumulation of lung burden (overload) [41–43].

Clearance from the lung depends not only on the total mass of particles inhaled but also on the particle size and, by implication, on particle surface, as shown in the following studies. A sub-chronic 3 months inhalation exposure of rats to ultrafine ( $\sim 20 \text{ nm}$ ) and fine ( $\sim 200 \text{ nm}$ ) titanium dioxide ( $\text{TiO}_2$ ) particles demonstrated that the ultrafine particles cleared significantly slower and showed more translocation to interstitial sites and to regional lymph nodes than the fine  $\text{TiO}_2$  particles [25].

To summarize, most nanosized spherical solid materials are likely to enter the lungs and reach the alveoli. These particles can be cleared from the lungs, as long as the clearance mechanisms are not affected by the particles themselves or by any other cause. Nanosized particles are more likely to hamper the clearance, resulting in a higher burden [44], possibly amplifying any related chronic effects caused by these particles. Notably, specific particle surface area is probably a better indication for maximum tolerated exposure level than total mass [28, 45], suggesting that the biological effects are linked to surface reactivity.

#### 3.4.1.2 Biopersistence of Inhaled Solid Material

The main determinants of biopersistence are species-specific physiological clearance and material specific bio-durability (physical-chemical processes).

In the alveoli, the rate at which fibers are cleared depends on the ability of alveolar macrophages to phagocytose them. Macrophages containing fibers longer than their own diameter (in humans longer than 20  $\mu\text{m}$ ) may not be mobile and will be unable to clear the fibers from the lung [39].

The bio-durability of a fiber depends on its dissolution and leaching as well as mechanical breaking and splitting [46, 47]. Biopersistent fibers such as amosite asbestos (brown asbestos) [39, 48], where breakage occurs longitudinally, result in more fibers of the same length but smaller diameter. Other types of fibers (e.g., amorphous) break perpendicular to their long axis, resulting in fibers that can be engulfed by the macrophages [49].

Self-evidently, the slower the fibers are cleared (high biopersistence), the higher is the tissue burden and the longer the fibers reside in a tissue the higher is the probability of an adverse response [29]. Despite the crucial role played by the length of the fibers (Stanton hypothesis) [50], it does not strictly indicate that all fibers longer than the lower threshold are equally active or that shorter fibers are not. Although fibers less than 5  $\mu\text{m}$  long did not appear to contribute to lung cancer risk in exposed rats [39], fibers more than 40  $\mu\text{m}$  long impose the highest risk (recent review by Schins [38]).

Inhaled fibers, which are persistent in the alveoli, can further interact with the pulmonary epithelial cells or even penetrate the alveolar wall and enter the lung tissue. These fibers are often described as being in the “interstitial” because they may lie between or within the cells making up the alveolar walls. Biopersistent solid materials, certainly those containing mutagenic potency and which remain for years in the lungs, increase the risk of developing cancer [32, 33].

Not much is known on the long-term health effects of fibrous purpose-made nanomaterials. There are no indications that the bio-durability of fibers with a diameter < 100 nm will differ from larger inhalable fibers. Therefore, great caution must be taken in the case of contact with nanofibers; bio-durability tests must be performed before releasing any products containing them.

Technologically, carbon nanotubes are an important group of nanofibers. Recently, they have been reported to show signs of toxicity in the lung of laboratory animals [51]. This is confirmed in two independent publications, by Warheit et al. [52] and Lam et al. [53], which demonstrated the pulmonary effects of single-

walled carbon nanotubes *in vivo* after intratracheal instillation, in both rats and mice. Both groups reported granuloma formation, and some interstitial inflammation. Warheit et al. [52] concluded that these findings (multifocal granulomas) may not have physiological relevance, and may be related to the instillation of a bolus of agglomerated nanotubes. The other group [53] suggested that if carbon nanotubes reach the lungs they are much more toxic than carbon black and can be more toxic than quartz. These studies have to be read with some caution because a study by the National Institute for Occupational Safety and Health (NIOSH) showed that none or only a small fraction of the nanotubes present in the air can be inhaled [54] (see short review of Donaldson and Tran [55]).

As noted above, at similar lung burdens, spherical TiO<sub>2</sub> ultrafine particles cleared significantly more slowly from the alveoli and showed more translocation to interstitial sites and to regional lymph nodes than did fine particles. Thus, besides the greater biological effects (see below) of ultrafine particles, the difference in toxicokinetics in the lung results in a higher burden [44].

#### 3.4.1.3 Systemic Translocation of Inhaled Particles

The impact of inhaled particles on other organs has been reported in several epidemiological studies. Most research has concentrated on the possible consequences of particle related malfunction of the cardiovascular system, such as arrhythmia, coagulation [56] etc. However, the autonomic nervous system [57, 58] as well as the olfactory nerves may be a target for inhaled particulates [28].

Until recently, the possible passage of xenobiotic particles has not attracted much attention, although the concept is now gaining acceptance in pharmacology for the administration of macromolecular drugs by inhalation [59].

In evaluating the health effects of inhaled nanoparticles, translocation to the systemic circulation is an important issue. Several para- and trans-cellular mechanisms have been described in the pulmonary epithelium, but it is unclear which one allows the translocation of nanoparticulates. Conhaim and coworkers [60] found that the lung epithelial barrier was best fitted by a three-pore-sized model, including a small number (2%) of large-sized pores (pore radius 400 nm), an intermediate number (30%) of medium-sized pores (40-nm pore radius), and a very large number (68%) of small-sized pores (1.3-nm pore radius). The exact anatomical location of this structure, however, remains to be established (see the review by Hermans and Bernard [61]). Possible endocytic pathways have been reviewed by Rejman et al. [62]. Of all endocytic pathways caveolae seem (the most) important portals for large molecules to enter cells or to cross the epithelial border [63–65]. Caveolae allow internalization of particles as large as 500 nm in diameter, though it depends on the surface coating.

In humans, translocation of inhaled ultrafine technetium (<sup>99m</sup>Tc) labeled carbon particles into the blood circulation has been studied independently by Nemmar et al. [66] and Kawakami et al. [67]. However, the translocation mechanism is still unclear. Nemmar et al. demonstrated that technetium (<sup>99m</sup>Tc) labeled carbon particles, which are very similar to the ultrafine fraction of actual pollutant particles, diffused rapidly – within 5 min – into the systemic circulation [66]. The authors

concluded, therefore, that it was unlikely that phagocytosis by macrophages and/or endocytosis by epithelial and endothelial cells are solely responsible for particle translocation to the blood, but that a paracellular mechanism probably also plays a role. More recently, Kato et al. [68] showed, morphologically, that inhaled polystyrene particles are transported into the pulmonary capillary space, presumably by transcytosis.

Aerosolized insulin gives a rapid therapeutic effect [69], although the pathways for this translocation are still unclear [70]. In addition to human studies, extra-pulmonary translocation of ultrafine particles after intratracheal instillation or inhalation has been reported in experimental animal studies [66, 71–73]. However, the amount of ultrafine particles that translocate into blood and extra-pulmonary organs was different. Following intranasal delivery, polystyrene microparticles (1.1  $\mu\text{m}$ ) can translocate to tissues in the systemic compartment [74].

Oberdörster et al. have explored another alley of translocation from the respiratory tract towards other organs [31]. In inhalation experiments with rats, using  $^{13}\text{C}$ -labeled particles, they found that nanosized particles (25 nm) were present in several organs 24 hours after exposure. The most extraordinary finding was the discovery of particles in the central nervous system (CNS). The authors examined this phenomenon further and found that particles, after being taken up by the nerve cells, can be transported via nerves (in this experiment via the olfactory nerves) at  $2.5 \text{ mm h}^{-1}$  [72].

Passage of solid material from the pulmonary epithelium to the circulation seems not to be restricted to nanoparticles, as shown by Kato et al. [68], and depends on the surface characteristics of the material. The issue of particle translocation still needs to be clarified: both the trans-epithelial transport in the alveoli and the transport via nerve cells. Thus, the role of factors governing particle translocation, such as the way of exposure, dose, size, surface chemistry and time course, should be investigated. For instance, it would be very important to know how and to what extent the extra-pulmonary translocation of particles is modulated by the lung inflammation.

### 3.4.2

#### **Intestinal Tract**

##### **3.4.2.1 Deposition and Translocation**

Already in 1926, Kumagai recognized that particles could translocate from the lumen of the intestinal tract via aggregations of intestinal lymphatic tissue (PP) containing M-cells (specialized phagocytic enterocytes). Particulate uptake happens not only via the M-cells in the PP and the isolated follicles of the gut-associated lymphoid tissue but also via the normal intestinal enterocytes. There have been several excellent reviews on the intestinal uptake of particles [75, 76]. Uptake of inert particles occurs trans-cellularly through normal enterocytes and in PP via M-cells, and, to a lesser extent, across paracellular pathways [77]. Initially it was assumed that the PP did not discriminate strongly in the type and size of the absorbed particles. Subsequently, it has been shown that modifying characteristics, such as particle

size [78] the surface charge of particles [79, 80], attachment of ligands [81, 82] or coating with surfactants [83], offers possibilities of site-specific targeting to different regions of the gastrointestinal tract (GIT), including the PP [84].

The kinetics of particle translocation in the intestine depends on diffusion and accessibility through mucus, initial contact with enterocyte or M-cell, cellular trafficking, and post-translocation events. Charged particles, such as carboxylated polystyrene nanoparticles [80] or those composed of positively charged polymers, exhibit poor oral bioavailability [85].

Specific studies on nanomaterials are rather scarce; in general, they show that most of them simply pass through the GIT and are rapidly eliminated. In one study [79], the body distribution after translocation of polystyrene particles was examined in some detail. Polystyrene spheres (ranging from 50 nm to 3  $\mu\text{m}$ ) were fed by gavage to female Sprague–Dawley rats daily for 10 days at a dose of 1.25 mg kg<sup>-1</sup>. As much as 34% and 26% of the 50 and 100 nm particles, respectively, were absorbed. Those larger than 300 nm were absent from blood. No particles were detected in heart or lung tissue. In another study, the oral uptake of radio-labeled functionalized C<sub>60</sub> fullerenes (water solubilized using albumin and PEG) in rats resulted in a 98% clearance (faeces) within 48 h, and the rest was eliminated via the urine, which is an indication for systemic uptake [86]. Kreyling et al. [71], using ultrafine <sup>192</sup>Ir, did not find any significant nanoparticle uptake in the GI tract.

#### 3.4.2.2 Intestinal Translocation and Disease

Crohn's disease is characterized by transmural inflammation of the gastrointestinal tract. It is of unknown aetiology, but it is suggested that a combination of genetic predisposition and environmental factors play a role. Particles (0.1–1.0  $\mu\text{m}$ ) are associated with the disease [87] and indicated as potent adjuvants in model antigen-mediated immune responses. A double-blind randomized study showed that a diet low in calcium and exogenous microparticles alleviates the symptoms of Crohn's disease [88].

Other studies found that material uptake (endocytosis) capacity of M cells is induced under various immunological conditions, e.g., a greater uptake of particles (0.1, 1 and 10  $\mu\text{m}$  diameter) has been demonstrated in the inflamed colonic mucosa of rats compared to non-ulcerated tissue [89, 90] and inflamed esophagus [91].

Clearly, from the literature cited above, engineered nanoparticles can be taken up via the intestinal tract. In general, the intestinal uptake of particles is better understood and studied in more detail than pulmonary and skin uptake. Because of this advantage, it may be possible, with caution, to predict the behavior of some particles in the intestines.

### 3.4.3

#### Skin

##### 3.4.3.1 Deposition and Penetration through the Skin

Skin is an important barrier, protecting against insult from the environment. The skin is structured in three layers: the epidermis, the dermis and the subcutaneous

layer. The outer layer of the epidermis, the stratum corneum (SC), covers the entire outside of the body. In the SC we find only dead cells, which are strongly keratinized. For most chemicals, the SC is the rate-limiting barrier to percutaneous absorption (penetration). The skin of most mammalian species is covered with hair on most parts of the body.

At the sites where hair follicles grow, the barrier capacity of the skin differs slightly from the “normal” stratified squamous epidermis [92]. Most studies concerning penetration of materials into the skin have focused on whether drugs penetrate through the skin using different formulations containing chemicals and/or particulate materials as a vehicle [93]. The main types of particulate materials commonly used are liposomes, solid poorly soluble materials such as TiO<sub>2</sub>, polymer particulates, and submicron emulsion particles, such as solid lipid nanoparticles. The penetration of these particulate carriers has not been studied in detail.

TiO<sub>2</sub> particles are often used in sunscreens to absorb UV light and therefore to protect skin against sunburn or genetic damage. Lademann et al. have reported [94] that micrometer-sized particles of TiO<sub>2</sub> get through the human stratum corneum and even into some hair follicles, including their deeper parts.

Tinkle et al. have demonstrated that 0.5 and 1.0 μm particles, in conjunction with motion, penetrate the stratum corneum of human skin and reach the epidermis and, occasionally, the dermis [95]. It has been hypothesized that the lipid layers within the cells of the stratum corneum form a pathway by which the particles can move [96] into the skin and be phagocytized by the Langerhan’s cells. In this study, the penetration of particles was limited to a particle diameter of 1 μm or less. Nevertheless, other studies reported penetration through the skin to the dermis using particles with diameters of 3–8 μm [92, 94, 97] but only limited penetration was found, often clustered at the hair follicle (see above). This can lead to an interaction with the immune system [93].

Penetration of non-metallic solid materials such as biodegradable poly(D,L-lactic-co-glycolic acid) (PLGA) microparticles, 1 to 10 μm with a mean diameter of  $4.61 \pm 0.8$  μm, has been studied after application on porcine skin. The number of microparticles in the skin decreased with depth (measured from the airside towards the subcutaneous layer). At 120 μm depth (where viable dermis is present) a relatively high number of particles was found, at 400 μm (dermis) some microparticles were still seen. At a depth of 500 μm no microparticles were found [98]. In the skin of individuals who had an impaired lymphatic drainage of the lower legs, soil microparticles, frequently 0.4–0.5 μm, were found, and particles as large as 25 μm in diameter were seen in the dermis of the foot of a patient with endemic elephantiasis. The particles are seen to be in the phagosomes of macrophages or in the cytoplasm of other cells. The failure to conduct lymph to the node produces a permanent deposit of silica in the dermal tissues (a parallel is drawn with similar deposits in the lung in pneumoconiosis). This indicates that soil particles penetrate through (damaged) skin, most probably in every individual, and normally are removed via the lymphatic system [99, 100].

According to Hostynek [101] the uptake of metals through the skin is complex. Both exogenous (e.g., dose, vehicle, protein reactivity, and valence) and endogenous factors (e.g., age of skin, anatomical site, and homeostatic control) are in-

volved. Attempts to define rules governing skin penetration to give predictive quantitative structure–diffusion relationships for metallic elements for risk assessment purposes have been unsuccessful, and penetration of the skin still needs to be determined separately for each metal species, either by *in vitro* or *in vivo* assays.

From the limited literature on nanoparticles penetrating the skin some conclusions can be drawn. Firstly, penetration of the skin barrier is size dependent – nanosized particles are more likely to enter more deeply into the skin than larger ones. Secondly, different types of particles are found in the deeper layers of the skin and, at present, it is impossible to predict the behavior of a particle in the skin. Thirdly, materials that can dissolve or leach from a particle (e.g., metals) can possibly enter the systemic circulation.

#### 3.4.3.2 Irritation of Skin

Glass fibers and Rockwool fibers are widely used man-made mineral fibers, mainly as thermal insulation materials, which have become important as a replacement for asbestos fibers. While in contact with the skin, these fibers can induce dermatitis simply resulting from mechanical irritation. Why these fibers are such a strong irritant has not been examined in detail. In occlusion irritant patch tests in humans, Rockwool fibers with a diameter of  $4.20 \pm 1.96 \mu\text{m}$  were found to be more irritating than those with a mean diameter of  $3.20 \pm 1.50 \mu\text{m}$  [102].

Some recent experimental work that exposed human epidermal keratinocytes (HEK) to carbon nanotubes (CNT) indicates that caution should be taken in handling these materials [103, 104]. Single-wall (SW) CNT induce apoptosis and decrease cellular adhesion ability, in a dose and time dependent manner [104]. Multi-wall (MW) CNT are taken up by the HEK, in vacuoles present within the cytoplasm, but no CNT were found in the nuclei of the cells [103]. In the same study the release, into the culture medium, of IL-8, a marker of irritation in human skin, was found to be dose dependent.

### 3.5

#### What Makes Nanoparticles Dangerous?

Several mechanisms have been proposed to explain the adverse health effects of nanomaterials. In “nanotoxicology”, probably two distinct characteristics would play a role: on the one hand, the material-specific and intrinsic toxicity and, on the other hand, more general but specific nanoparticle-induced responses [1, 45].

Material-specific responses can often be understood and/or explained by material-specific toxic responses, local stimulation of irritant receptors, covalent modification of key enzyme receptors, etc. More general nanoparticle dependent responses, certainly in lung and liver, can often be categorized as inflammatory responses concurrent with cytokine and chemokine release, production of white blood cells, free-radical production, etc. [28, 40]. Certainly, it would be incorrect to separate these two responses too much as, most often, after exposure to a nanomaterial multiple responses can be observed that can influence each other.

Another aspect, which has not been studied in any detail in respect to nanomaterials, is the deposition of nanomaterials at any specific sink in the body [71, 72]. In kidney toxicity, the precipitation of chemicals and formation of crystals, certainly in chronic exposure, can lead to tissue damage [105].

The next section discusses some material characteristics and toxic mechanisms important in the adverse health effects of nanomaterials.

### 3.5.1

#### Particle Size – Surface and Body Distribution

Reports on the surface properties of nanoparticles, both physical and chemical, stress that nanoparticles differ from bulk materials. The biological effects do not just depend on the intrinsic toxicity of the material itself but on the size and surface area the nanoparticles made out of this material. Nanoparticles are not merely small crystals but an intermediate state of matter placed between bulk and molecular material. Independently of the particle size, two other parameters play dominant roles: the charges carried by the particle in contact with the cell membranes and the chemical reactivity of the particle [28, 45, 106–108].

##### 3.5.1.1 Effect of Size

Two samples of carbon black, which can be considered as a relatively inert material, of similar size and composition but with significantly different specific surface areas (300 versus  $37 \text{ m}^2 \text{ g}^{-1}$ ) showed biological effects (inflammation, genotoxicity, and histology) that depend on the specific surface area and not on particle mass. Similar findings were reported in earlier studies on tumorigenic effects of inhaled particles. In the lung, tumor incidence of chronically inhaled  $\text{TiO}_2$  of nanosized particles (20 nm diameter) at low exposure ( $10 \text{ mg m}^{-3}$ ) was significantly higher than for high exposure ( $250 \text{ mg m}^{-3}$ ) of 300 nm particles [109]. Tumor incidence correlates better with specific surface area than with particle mass [25, 110]. *In vivo* and *in vitro*, nanosized particles inhibit phagocytosis when compared to fine particles [111] and can change the chemotactic behavior of macrophages significantly [112].

Size is also a critical parameter in the distribution of particles in the body.

Oral uptake (gavage) of polystyrene spheres of different sizes (50 nm to  $3 \mu\text{m}$ ) in female Sprague–Dawley rats (for 10 days at a dose of  $1.25 \text{ mg kg}^{-1} \text{ day}^{-1}$ ) resulted in systemic distribution of the nanoparticles. About 7% (50 nm) and 4% (100 nm) was found in the liver, spleen, blood and bone marrow. Particles larger than 100 nm did not reach the bone marrow and those larger than 300 nm were absent from blood. No particles were detected in heart or lung tissue [80].

##### 3.5.1.2 Effect of Surface Charges

Beside particle size, surface characteristics play a dominant role in the distribution of material in the body.

Coating poly(methyl methacrylate) nanoparticles with different types and concentrations of surfactants significantly changes their body distribution [113]. Coat-

ing these nanoparticles with  $\geq 0.1\%$  poloxamine 908, a non-ionic surfactant, reduces their liver concentration significantly (from 75% to 13% of total amount of particles administrated) 30 min after i.v. injection. Another surfactant, polysorbate 80, was effective above 0.5%. A different report showed that modification of the nanoparticle surface with a cationic compound, didodecyldimethylammonium bromide (DMAB), facilitates the arterial uptake 7–10-fold [114]. The authors noted that the DMAB surface-modified nanoparticles had a mean zeta potential of +22.1 mV, which is significantly different from the original  $-27.8 \pm 0.5$  mV (mean  $\pm$  sem,  $n = 5$ ). The mechanism for the altered biological behavior is unclear, but surface modifications have possible applications for intra-arterial drug delivery.

Polycationic macromolecules show a strong interaction with cell membranes *in vitro*. The Acramin F textile paint system is a good example. Three polycationic paint components exhibited considerable cytotoxicity ( $LC_{50}$  generally below 100 mg mL<sup>-1</sup> for an incubation of 20–24 h) in diverse cell cultures, such as primary cultures of rat and human type II pneumocytes, and alveolar macrophages and human erythrocytes. The multiple positive charges play, speculatively, an important role in the toxic mechanism [115, 116].

A study of the biocompatibility (cytotoxicity) of polycationic materials [117] as a function of molecular weight found that with increasing molecular weight some macromolecules, such as DEAE-dextran and poly-l-lysine (PLL) [118, 119], dendrimers [120] and polyethylenimine (PEI) [121], become more toxic. The toxic mechanism is not fully understood but membrane integrity plays a role.

Dekie et al. [122] concluded that a primary amine group on poly(L-glutamic acid) derivatives has a significant toxic effect on red blood cells, causing them to agglutinate. Not only the type of amino function but also the charge density resulting from the number and special arrangement of the cationic residues is important for cytotoxicity. Ryser [123] has suggested that a three-point attachment is necessary to elicit a biological response on cell membranes, and speculated that the activity of a polymer will decrease when the space between reactive amine groups is increased. The arrangement of cationic charges depends on the three-dimensional structure and flexibility of the macromolecules and determines the accessibility of their charges to the cell surface.

Branched molecules are more efficient in neutralizing the cell surface charge than polymers with linear or globular structure; the latter are more rigid and so have more difficulty attaching to the membranes [124]. Therefore, high cationic charge densities and highly flexible polymers should cause higher cytotoxic effects than those with low cationic charge densities. Globular polycationic polymer structures [cationised Human Serum Albumin (cHSA), ethylenediamine-core poly(amidoamine) dendrimers (PAMAM)] exhibit good biocompatibility (low cytotoxicity) whereas polymers with a more linear or branched and flexible structure [poly(dialyldimethylammonium chloride) (DADMAC), PLL, PEI] showed higher cell-damaging effects.

The serum half-life and body distribution of CdSe quantum dots with different surface characteristics, coatings with short-chain or long-chain PEG, have been

studied by Ballou et al. [125]. The mPEG-750 coated quantum dots were, 24 h after dosage, found in lymph nodes and the spleen. The long-chain (PEG-5000) coated quantum dots were less apparent in lymph nodes but more in the liver, spleen, and bone marrow. This type of coating allowed a slow clearance from the body and the particles were still observed after 133 days.

Regardless of uptake route, the body distribution of particles is most dependent on the surface characteristics and size of the particles. This is important in drug design in order to help to deliver medication to the right target.

### 3.5.2

#### **Nanoparticles, Thrombosis and Lung Inflammation**

##### **3.5.2.1 Prothrombotic Effect**

Epidemiological studies have reported a close association between particulate air pollution and cardiovascular adverse effects [126] such as myocardial infarction [127]. The latter results from rupture of an atherosclerotic plaque in the coronary artery, followed by rapid thrombus growth caused by exposure of highly reactive sub-endothelial structures to circulating blood, thus leading to additional or complete obstruction of the blood vessel [127].

Nemmar et al. have studied the possible effects of particles on haemostasis, focusing on thrombus formation as a relevant endpoint [128–130]. Polystyrene particles 60 nm in diameter (surface modifications: neutral, negatively or positively charged) had a direct effect on haemostasis after intravenous injection. Positively charged amine-particles led to a marked increase in prothrombotic tendency, resulting from platelet activation. These observations have been confirmed recently by Silva et al. [131] in a comparable model.

A similar effect could be obtained after the intratracheal administration of these positively charged polystyrene particles, which also caused lung inflammation [132]. Importantly, the pulmonary instillation of larger (400 nm) positive particles caused a definite pulmonary inflammation (of similar intensity to 60 nm particles), but they did not lead to a peripheral thrombosis within the first hour of exposure. This lack of effect of the larger particles on thrombosis, despite their marked effect on pulmonary inflammation, suggests that pulmonary inflammation by itself was insufficient to influence peripheral thrombosis. Consequently, the effect found with the smaller, ultrafine particles is most probably due, at least in part, to their systemic translocation from the lung into the blood.

Using pollutant particles, namely diesel exhaust particles (DEP), it was shown that, within an hour after their deposition in the lungs, DEP cause a marked pulmonary inflammation. Moreover, intratracheal instillation of DEP promotes femoral venous and arterial thrombosis in a dose-dependent manner, already starting at a dose of 5  $\mu\text{g}$  per hamster (ca. 50  $\mu\text{g kg}^{-1}$ ). Subsequent experiments showed that prothrombotic effects persisted at 6 and 24 h after instillation (50  $\mu\text{g}$  per animal) and confirmed that peripheral thrombosis and pulmonary inflammation are not always associated [129, 133].

**Fig. 3.1.** Hierarchic oxidative stress model (Bernstein et al. [137] and Li et al. [134]). At low concentrations of PM a small change in oxidative stress can be observed without the induction of changes at cellular or tissue level. At a higher level of exposure, anti-oxidant

defense mechanisms are triggered. With increasing concentrations, an inflammatory response is induced. Finally, at the highest concentration, toxicity and cellular and/or tissue damage can be observed.

### 3.5.2.2 Oxidative Stress, Inflammation and Endotoxins

Particle-induced pulmonary inflammation can induce protective and adverse cellular responses in a dose-dependent manner. Li et al. have proposed a “hierarchical oxidative stress model” in response to DEP exposure (Fig. 3.1) [134]. This model suggests that at a lower oxidative stress level (tier 1) PM induces cytoprotective responses, e.g., through the activation of antioxidant response elements, inducing the expression of several antioxidant and phase II drug metabolizing enzymes (e.g., heme oxygenase 1 and glutathione-S-transferase). If this level of protection fails, the oxidative stress (tier 2) will lead to mitogen-activated protein kinase/nuclear factor  $\kappa$ B activation and pro-inflammatory effects. Further escalation (tier 3), will trigger disturbance of the mitochondrial function, resulting in cellular apoptosis or necrosis. A weakened antioxidant defense can increase the susceptibility toward PM-induced airway inflammation, to infection, and maybe to asthma; it can explain the existence of susceptible human subsets. Xioa et al. showed that the hierarchical oxidative stress model can be applied in a macrophage cell line [135]. The authors demonstrated that in the dose range  $10\text{--}100\text{ g mL}^{-1}$  organic DEP extracts induce a progressive decline in the cellular GSH/GSSG ratio. In parallel, it causes a linear increase in newly expressed proteins, including antioxidant enzymes (e.g., heme oxygenase-1 and catalase), pro-inflammatory components (e.g., 38 MAPK and Rel A), and products of intermediary metabolism that are regulated by oxidative stress.

*In vivo* in rats, Arimoto et al. showed that exposure to DEP and Lipopolysaccharides (LPS) (intratracheal co-instillation) resulted in synergistic enhancement of free radical generation in the lungs, paralleled by a synergistic increase in total protein and by infiltration of neutrophils in the bronchoalveolar lavage fluid of the lungs [136]. The free radicals result from activated macrophages; more specifically, because of enhanced xanthine xanthine-oxidase activity.

### 3.5.3

#### **Nanoparticles and Cellular Uptake**

Reviewing the literature, there are several reports on cellular uptake of micro- and nanosized particles and CNT. Reports on particle uptake by endothelial cells [137, 138], pulmonary epithelium [68, 139, 140], intestinal epithelium [75, 91] alveolar macrophages [41, 73, 111, 141–143], other macrophages [88, 99, 144, 145], nerve cells [146, 147] and other cells [71, 148] are available. This is an expected phenomenon for phagocytic cells (macrophages) and cells that function as a barrier and/or transport for (large) compounds. Except for macrophages, the health effects of cellular uptake of nanoparticles have not been studied in depth.

In designing quantum dots specifically to enter cells, endocytosis is highly size-dependent, and an optimal size of around 50 nm has been suggested [149]. Besides the size, the surface plays a role: quantum dots with amine-modified coating were more efficiently internalized into the various human cells examined [150].

### 3.5.4

#### **Nanoparticles and the Blood–Brain Barrier**

One of the promising avenues of nanotechnology is organ- or cell-specific drug delivery mediated by nanoparticles [151–153]. Transport of nanoparticles across the blood–brain barrier (BBB) is expected to be possible by either passive diffusion or by carrier-mediated endocytosis. Coating of particles with polysorbates (e.g., polysorbate-80) results in anchoring of apolipoprotein E (apo E) or other blood components. Surface-modified particles seem to mimic Low Density Lipoproteins (LDL) particles and can interact with the LDL receptor, leading to uptake by endothelial cells. Hereafter, the drug (which was loaded in the particle) may be released in these cells and diffuse into the brain interior or the particles may be trans-cytosed.

Also, other processes such as tight junction modulation or P-glycoprotein (Pgp) inhibition may occur [154]. The translocation of inhaled nanoparticles via the olfactory nerves to the brain has been reported by Oberdörster et al. [72] and Fechter et al. [155].

## 3.6

### **Summary and Discussion**

In general, in the search for potential adverse effects of a new product, toxicologists initially look into basic mechanisms such as acute toxicity (cytotoxicity), uptake and distribution and excretion of the material in organisms (pharmaco- or toxicokinetics). In a somewhat later phase, the mode of action at the target organs, tissues, and cells is studied.

Reviewing the knowledge collected concerning health effects of nanomaterials we have to conclude that it is still premature to draw final conclusions, simply because too little has been investigated.

A first important remark is that current knowledge is mainly based on epidemiological and experimental work concerning environmental particle pollution, most often referred to as coarse (10–2.5  $\mu\text{m}$ ), fine (2.5–0.1  $\mu\text{m}$ ) and ultrafine particulates (UFP) (<0.1  $\mu\text{m}$ ). We can certainly learn from this research, but it has to be taken into account that exposure to man-made nanomaterials differs from exposure to environmental particles in several ways. UFP, often arising from combustion, have a complex composition, have no uniform size and some compounds are soluble in biological systems, while man-made nanoparticles often have a uniform (crystalline) structure and size, and are often not soluble. Beside these differences it has to be remembered that some effects of particulate matter will be more generic, not discriminating between the nature (chemical composition) of the materials, e.g., activation (or inhibition) of phagocytosis, cellular uptake or other cellular interactions. Also, with decreasing particle diameter their surface area increases significantly, resulting in increased surface activity; health effects can often be better correlated with the total surface area of the material in the exposure rather than with its total mass.

*In conclusion*, some important observations are summarized below:

- Of the three exposure routes, inhalation of nanomaterials is easily the most troublesome for two reasons: (1) the lung itself is a target organ because the inhaled particulates can easily induce inflammation and oxidative stress locally, and the particulates are not always efficiently cleared from the alveoli and (2) the lung is, as far as investigated, a portal to enter the systemic circulation.
- Exposure to skin will not, as far as we know, lead to systemic uptake but penetration into the dermis can induce immunological effects.
- Oral exposure can result in systemic penetration – a feature that can be used in medicine, but unintended penetration from the intestinal tract, given the current state of knowledge, is not a worrying issue.
- Penetration, independent of portal, and the subsequent distribution are related to the size and surface properties of the particles.

From previous studies, using environmental particles, we know that oxidative mechanisms, local inflammation, thrombotic effects, and, only recently reported, uptake into sensory nerves are the important issues. Some of the reported effects will be specific for the complex DEP or Urban Particulate Matter (UPM), but new previously unobserved effects can be expected for man-made nanomaterials, therefore research focused on novel effects due to the specific nanomaterials will certainly be required.

Besides the expected and predictable risks, nanomaterials can induce a biologic response in a way we are not familiar with from previous studies of known compounds. For example, it has recently been observed that green-light-emitting quantum dots are more toxic *in vitro* than red-light-emitting dots, simply because of the difference in DNA damage by the emitted light [156].

Moreover, nanomaterials are often defined as materials with a dimension smaller than 100 nm. The definition proposed by the European Academy at Bad Neuenahr,

Fig. 3.2. “From exposure to decease” flowchart.

Germany is probably more appropriate: “Nanotechnology is dealing with functional systems based on the use of subunits with specific size-dependent properties of the individual sub-units or of a system of those” [157]. This definition takes into account size-dependent activity and/or effect rather than a certain size; following this it is expected that for many materials the border between “bulk” and “nano” will be mainly situated at a size range smaller than 20 nm, thus defining the size window more strictly.

Finally, although nanotoxicology will discover some new or specific toxicological mechanisms, the general concepts describing the process from exposure to disease, shown in Fig. 3.2, will not change. This paradigm can be used for any compound and it stresses the most important steps in exposure related diseases.

Without exposure, no health effects can develop, even not from very harmful compounds. From the portal of exposure, the compound must have the capability to enter the body, and then be distributed to the target tissue(s). In contact with the target tissue the compound can induce malfunction, most often subtle at first, but resulting in irreversible changes after chronic exposure.

This scheme can easily be adopted for nanomaterials; the challenge will be to find those (few) nanomaterials out of the large pool of newly produced materials, with specific sizes, composition and coating, that would induce significant health effects.

### 3.7

#### What Can be Done?

Although few direct reports are available on the health implications of exposure to man-made nanoparticles, the indirect evidence assembled here from epidemiological sources, drug delivery studies, as well as some *in vivo* and *in vitro* results, suggests that potential health risks can not be neglected. With growing volumes of production and their incorporation into more and more products, the chances of exposure of the general public to the engineered nanoparticles are likely to grow. Seemingly safe bulk materials, when reduced to nanoparticles, can drastically change their chemical, biological and catalytic activities, and become toxic. Moreover, their minute dimensions often help to overcome the existing biological barriers and body defense mechanisms. The whole issue is complicated by the difficulties associated with the detection and monitoring of nanoparticles.

On the bright side, most nanomaterials are currently used as additives or property enhancers that are highly diluted in a matrix material. The nanomaterials are

bound to the matrix and unlikely to be released in serious quantities. In addition, most material manufacturers prefer to use liquid dispersions of nanomaterials (as opposed to dry powders) as these are much easier to handle. Unfortunately, some nanomaterials can only be produced in either a dry atmosphere or under vacuum. This raises a series of questions on their safe collection, handling, dispersion, cleaning, disposal, recycling, and environmental protection. At the time of writing, the issue of potential health risks that might be associated with nanomaterials is getting both an adequate press coverage and reasonable attention from the regulatory bodies and governments.

University laboratories are often at the forefront of nanomaterial research. Their laboratory procedures and practices should perhaps be critically re-evaluated in light of the material presented in this chapter. Both small and big manufacturers who state on the MSDS forms that nanomaterials are “safe because the bulk material is considered safe” should, perhaps, reconsider and try to get some proof. Finally, the public should be learning about the benefits and risks of nanotechnology not from scandal-driven tabloids but from the scientific community directly engaged in nanotechnology.

# Dosimetry, Epidemiology and Toxicology of Nanoparticles<sup>1</sup>

Wolfgang G. Kreyling, Manuela Semmler-Behnke, and Winfried Möller

### 4.1

#### Introduction

##### 4.1.1

#### Overview

Nanoparticles are increasingly used in a wide range of applications in science, technology and medicine. Since they are produced for specific purposes that cannot be met by larger particles and bulk material they are likely to be highly reactive, in particular with biological systems. However, a large body of know-how in environmental sciences is available from toxicological effects of ultrafine particles after inhalation. Since nanoparticles feature similar reactivity to ultrafine particles a sustainable development of new emerging nanoparticles is required. This chapter briefly reviews the dosimetry of nanoparticles, including deposition in the various regions of the respiratory tract and systemic translocation and uptake in secondary target organs, epidemiologic associations with health effects and toxicology of inhaled nanoparticles. General principles and current paradigms to explain the specific behavior of nanoparticles in toxicology are discussed. Since the evidence for health risks of ultrafine and nanoparticles after inhalation has been increasing over the last decade, this chapter attempts to extrapolate these findings and principles observed in particle inhalation toxicology into recommendations for an integrated concept of risk assessment of nanoparticles for a broad range of use in science, technology and medicine.

##### 4.1.2

#### General Background

Definition: Since the term “nanoparticle” is used heterogeneously in current discussion we want to define that they are shorter than 100 nm at least in one dimen-

<sup>1</sup> This chapter is based on a recently published article: Kreyling, W.G., Semmler-Behnke, M., Moeller, W., Health implications of nanoparticles. *J. Nanoparticle Res.* DOI 10.1007/s11051-005-9068-z.

Fig. 4.1. Dependence of the percentage of surface molecules, relative to total number of molecules, of spherical nanoparticles on the diameter of the particles. Note: below 100 nm this ratio increases steeply. (From Ref. [7].)

sion, according to a recent suggested definition within the European Union [1]. In addition, nanoparticles are so-called “intended” particles, intentionally produced for specific use in science, technology, medicine, industries and many day-to-day applications. Therefore, they have a well-defined composition and are structured to fit the anticipated properties. As a result they differ from ultrafine particles (UP), a term frequently used in environmental sciences for ambient or occupational particles that are less than 100 nm in size in each dimension and which are unintended particles, originating often from combustion processes, of diverse sources and gas–particle interactions in their environment. Therefore, ultrafine ambient particles are often composed of a multitude of compounds, which may be structured in a highly complex manner. This is an additional basic difference between well-defined intended nanoparticles and unintended ultrafine particles.

Particles in the nanometer size range have two particular properties: (a) anything smaller than about 50 nm is no longer subject to the laws of classical physics but of quantum physics. This means that nanoparticles can exhibit optical, magnetic or electrical capabilities that distinguish them clearly from larger particles or bulk material; (b) with decreasing size the ratio between mass and surface area increases rapidly, i.e., the ratio of atoms or molecules at the surface to the total number of atoms or molecules rises steeply with decreasing particle size (Fig. 4.1). According to their very large specific surface area (surface area per mass), nanoparticles exert a stronger effect on their environment, i.e., with any adjacent materials. In other words, nanoparticles can catalyze chemical reactions at the surface; a given mass of material in nanoparticulate form will be much more reactive than the same mass of material made up of larger particles. For instance, crystalline nanoparticles have abundant atoms on their surface that are less strongly bonded than those in the interior of the particle. Given their unstable situation in the curvature of the surface, the atoms will try to change their binding: they are reactive towards their

environment. This may well be desirable and is usually the purpose of their generation; however, exposure to such particles, for instance by inhalation or ingestion, may have harmful consequences [2–9].

Although the economic and societal health benefits of the introduction of nanomaterials have been welcomed, concerns have been expressed that properties that are being exploited by researchers and industry might have negative health effects and environmental impacts and, particularly, those might result in greater toxicity. Hence, the rapid development of a multitude of nanoparticle applications needs to be complemented by assessing possible implications, assuring a safe and sustainable handling of those nanoparticles. The challenge of an integrated application development and implication assessment is pro-active collaboration at the earliest stage to optimize functionality of the nanoparticle and to minimize its side effects without losses in terms of costs and time because of one-sided mismanagement or unfocused or delayed initiation of risk assessment.

To understand the potential risks to humans from nanoparticles, it is necessary to understand the dosimetry and to consider the body's defenses against particles in general and the properties that particles require to overcome these defenses, as discussed in Chapter 4.2. Throughout much of their evolutionary history, humans have been exposed to small particles, often in very high concentrations, and the mechanisms evolved for defense against microorganisms are also used to defend the body against such particles. Generally, access to the human body can occur through the lungs, the skin or the gastrointestinal tract. Each organ presents a barrier to penetration by microorganisms or particles.

Chapter 4.3 discusses toxicological data that show a specific toxicological response of ultrafine particles, *in vitro* and *in vivo*, that is not found using fine particles of the same composition.

The general approach to assessing and controlling risk, as discussed in Chapter 4.4, involves identification of hazards (the potential of a nanoparticle or parts of it to cause harm) and then a structured approach to determining the probability of exposure to the hazard and the associated consequences. As in any new technology, foresight of possible risks depends on a consideration of the entire life cycle of a new nanoparticle being produced. This involves understanding the processes and materials used in manufacture, the likely interactions between the product and individuals or the environment during its manufacture and useful life, and the methods used in its eventual disposal.

#### 4.1.3

##### **Epidemiological Evidence for Health Effect Associations with Ambient Particulate Matter**

Since safety issues are not yet very well developed in the field of science and technology of nanoparticles, this young rapidly developing interdisciplinary field may make use of existing knowledge. In fact, for over a decade, environmental risk assessment has continuously investigated potential health effects that may be associated with exposure to ultrafine particles in the environment [10, 11]. The need for those toxicological studies came from epidemiological investigations that had

shown consistent associations between exposure to particulate air pollution in urban areas and acute increases in morbidity and mortality rates, especially for persons with obstructive lung and cardiovascular diseases [12]. The relative risk is surprisingly similar in many of these studies although the studies have been performed at very different global locations – predominantly in North America and Western Europe. These data have recently been collected and summarized by the US-EPA in a review of the Air Quality Criteria Document on Particulate Matter in 2004 [13].

Interestingly, epidemiological studies on health effects of ultrafine particles provided the first evidence that this particle fraction may induce adverse health effects independent of those of larger fine particles ( $<2.5\ \mu\text{m}$  aerodynamic diameter) and other air toxics, as reviewed by Wichmann and Peters [10]. Furthermore, none of these single compounds are present at sufficiently high concentrations in the environmental aerosol that they may be considered toxicologically relevant based on occupational hygiene. Therefore, it appeared reasonable to investigate the interactions of complex mixtures of compounds with biological systems. Although the risks from these mixtures of compounds may be low to an individual, the large number of persons at risk can make these compounds an important public health threat. Frequently, health effects are only manifested in specific risk groups, i.e., persons predisposed by genetic susceptibility, age, and/or disease. Translating these insights to the use of nanoparticles, the more widespread the use by the general population the fewer implications are allowed. In particular, particulate nanomedicines specifically generated for treatment of patients – i.e., subjects predisposed by their disease – require extremely high safety standards, taking the specific physicochemical properties of all components on the scale of nanoparticles into account.

#### 4.1.4

#### **Toxicological Evidence for Ambient Particulate Matter Induced Adverse Health Effects**

The adverse health effects shown in epidemiological studies have inspired scientists to use various techniques to study the toxicological mechanisms that form the biological background for adverse health effects associated with gaseous and particulate pollutants. At the beginning of the last decade, classical attempts like lung function tests, etc. were chosen in toxicological studies. This has changed substantially in recent years. An early key study demonstrated that ultrafine  $\text{TiO}_2$  nanoparticles caused more inflammation in rat lungs than exposure to the same airborne mass concentration of larger, so-called “fine”  $\text{TiO}_2$  [14]. Before this study,  $\text{TiO}_2$  had been considered as a non-toxic dust and indeed had served as an innocuous control dust in many studies on the toxicology of particles. Therefore, this report was highly influential in highlighting that a material with low toxicity in the form of fine particles could be toxic in the form of ultrafine particles.

Although many questions are not yet fully answered, it is reasonable to apply this acquired knowledge to nanoparticles. With ambitious expectations of the widespread introduction, use and application of nanoparticles into nearly *everything*, it

cannot be emphasized enough that accompanying safety measures must be devised early enough in their development. A major accident or a development similar to that of, for example, asbestos fibers related to health effects may turn public perception negative with the disastrous result that the promising potential of nanosciences and nanotechnology may be jeopardized in part, or even largely, by emotional arguments of the public that are not based on rational cost–benefit calculations.

This chapter summarizes key issues of risk assessment based on studies on the interaction of inhaled ultrafine particles found in urban atmospheres as well as on some nanoparticles that had been considered innocuous since their larger counterparts had not shown any toxic effect. We outline current understanding of modes of actions and underlying mechanisms involved in the pathogenesis of adverse health effects that eventually lead to disease. Therefore, we only consider the use of nanoparticles as long as they have access to the environment. There is no reason to consider firmly fixed nanoparticles in macroscopic entities that are unlikely to cause any harm. Inhalative exposure needs to distinguish between that of healthy adult workers during their work shift at the workplace in science, technology and industry and rather uncontrolled, eventually continuous, exposure of the entire public, including susceptible individuals such as infants, children, and the elderly, as well as diseased and genetically predisposed subjects.

## 4.2

### Inhaled Nanoparticle Dosimetry

#### 4.2.1

##### Particle Measures

In the past, particle mass concentration was by far the most common metric used. Daily averages range nowadays from 20 to 50  $\mu\text{g m}^{-3}$  in most cities of industrialized countries. Taking the size range of particulate matter (PM) over more than four decades (1 nm–30  $\mu\text{m}$ ) into account, mass concentration overestimates large PM in the coarse fraction and basically neglects ultrafine particles < 100 nm in size. The limitation of this metric is illustrated by the fact that the water solubility of ambient PM may vary from 20 to 80% of PM mass and yet the toxicity of soluble compounds is unlikely to be similar to that of the insoluble fraction. With clearer insights into particle–lung interactions, other measures such as the particle number concentration and/or surface area need to be taken into account, depending on whether ultrafine or larger particles are to be considered. However, exposure measures may be inadequate, since it may be the number of deposited particles per unit surface area of airways and bifurcations and of alveoli, or dose to a specific cell such as macrophages or epithelial cells, that determines the response of specific regions. Therefore, the use of a metric depends on specific questions posed, requiring specifically defined measures.

## 4.2.2

**Deposition of Ultrafine Particles in the Respiratory System**

Particle deposition of ultrafine particles in the respiratory tract is determined predominantly by diffusional motion (thermal motion of air molecules) distorting particles from their stream lines of the inhaled and exhaled air towards the airway walls, where they deposit once they have touched the walls. The diffusion mechanism affects particle deposition through three important components of aerosol properties and respiratory tract physiology during breathing: (a) particle dynamics, including size and shape, and possible dynamic change during breathing; (b) geometry of the branching airways and the alveolar structures; and (c) breathing pattern, which determines the airflow velocity and the residence time in the respiratory tract, and includes nose versus mouth breathing [15].

Regarding regional particle deposition in the respiratory tract, the tract can be considered as a series of filters (Fig. 4.2), starting with the nose or mouth via the various diameters of airways to the alveoli [16, 17]. Figure 4.2 displays the deposition probability of particles of different sizes in the larger and smaller airways, as well as the alveolar region. This means that the toxicity of particles of different sizes can have different effects in different parts of the lungs. This may be particularly important in children with developing lungs or with asthma, which mainly affects the larger airways, or with COPD, which affects both large and small airways and alveoli. These diseases may also cause an up to several-fold increase in deposition of PM in diseased parts of the lungs, which may deteriorate their functions [18].

The ultrafine particle density per airway surface area may, notably, often exceed that of the gas exchange region because the alveolar surface area (adult lungs ~

**Fig. 4.2.** Regional deposition of particles in the human respiratory tract during mouth-breathing at rest. (According to Ref. [16].)

140 m<sup>2</sup>) is 100-fold larger than that of airways. In general, ultrafine particles are very capable of reaching the fragile structures of alveoli; their deposition in the alveoli increases with decreasing diameter until 20 nm. Particles < 20 nm deposit less in alveoli since their high diffusivity leads to their deposition in the airways.

#### 4.2.3

##### **Fate of Particles in the Lungs**

On the walls of the respiratory tract (epithelium) particles contact first the mucous or serous lining fluid and its surfactant layer on top. Therefore, the fate of particle compounds soluble in this lining fluid need to be distinguished from slowly dissolving or even insoluble compounds.

##### **4.2.3.1 Soluble Particle Compounds**

Soluble particle compounds may either be lipid soluble or water soluble. They will be dissolved and rapidly diluted while spreading in the mucous layer or in the serous lining fluid or in the cellular sol. According to their chemical properties solutes and soluble components can undergo absorption and diffusion or binding to proteins and membranous or subcellular structures. Solute and their metabolic products will eventually be transferred to the blood and lymphatic circulation, undergoing further metabolism, with a potential to reach any organ and to produce toxic effects, far from their site of entry in the lungs [19, 20].

##### **4.2.3.2 Slowly Dissolving and Insoluble Particles Deposited on the Airway Wall**

Slowly dissolving and insoluble particles deposited on the airway wall will be mostly moved by mucociliary transport or by cough within 1–2 days to the throat (larynx), where they are swallowed and taken up by the gastrointestinal tract for further metabolism or excretion. While this clearance mechanism removes basically all particles larger than 5 μm, the fraction of long-term retained particles in the airways increases with decreasing particle size such that the uncleared fraction of ultrafine particles is ~80% of those deposited in the airways [21].

##### **4.2.3.3 Slowly Dissolving and Insoluble Particles Deposited in the Alveolar Region**

Slowly dissolving and insoluble particles deposited in the alveolar region will be taken up and digested by specialized defense cells in the alveoli called macrophages within a few hours after deposition – at least under physiological conditions in healthy lungs. Therefore, alveolar macrophages will determine the fate of these particles. While alveolar macrophages are well suited to recognize and phagocytize particles > 200 nm within several hours after deposition, mechanisms of recognition are increasingly less effective for ultrafine particles with decreasing size [21].

Note, cells and solutes of body fluids, like proteins interacting with an insoluble particle, will not recognize what is inside the particle but only react with the molecules according to their structure at the particle surface. In other words, the vast amount of a reactive molecular species attached to the surface of insoluble particles

and of an insoluble particle core (remaining after dissolution of the soluble components) may be the ultimate metric that determines adverse responses, although this species may add only a small fraction to PM mass.

#### 4.2.3.4 Macrophage-mediated Particle Transport

Macrophage-mediated particle transport: we list below the major pathways and actions of macrophages from the human alveolar epithelium and indicate fractions of deposited insoluble particles undergoing these pathways, as reviewed earlier [21]. Particularly, the fractions differ consistently from those observed in rodents as the most common experimental animal models. Macrophage-mediated particle transport is directed:

1. Towards ciliated airways on the epithelium for further removal by ciliary action, passage through the gut and excretion (about a third of deposited insoluble particles).
2. To storage on the epithelium or uptake into the lining cells [together with (3) more than half of deposited insoluble particles].
3. Across the epithelial lining cells towards the spaces between underlying cells.
4. Across the epithelial lining cells towards the lymphatic drainage system (1–10% of deposited insoluble particles).
5. Into and across the epithelial lining cells and eventually into the blood vessels towards secondary target organs. There is evidence for the uptake of ultrafine particles into the blood circulation, depending on the physical structure and chemical composition of their surface. Fractions and rates of uptake are currently under debate. Identified secondary target organs are liver, spleen, kidneys, vasculature and heart, the immune system and the central nervous system.

Ultrafine particles are less effectively taken up by macrophages but interact to a greater extent with epithelial lining cells than large particles. Due to their vast numbers, they provide a very large surface area, which is the interface by which they interact with biological systems. Generally, depending on their molecular surface composition, nanoparticles may have a greater capacity to induce or mediate more adverse effects than larger particles.

#### 4.2.4

#### Translocation of Ultrafine Particles into Systemic Circulation

While a growing number of reports confirms that there is translocation of ultrafine particles into blood circulation and subsequent uptake in secondary target organs, the size of the translocated fraction, the transport mechanisms and the rate-determining parameters are under debate.

##### 4.2.4.1 Studies of Systemic Particle Translocation in Humans

Conflicting translocation data are reported in human studies. Nemmar et al. [22] have demonstrated a rapid 3–5% uptake of radiolabeled carbonaceous ultrafine

particles into the bloodstream within minutes after exposure and subsequent uptake in the liver. In this study, leaching of the radiolabel from the particles was not considered. In contrast, also using radiolabeled carbonaceous ultrafine particles, Brown et al. [18] could not find any detectable particulates (<2% of inhaled ultrafine particles, limit of detection) beyond the lungs when the data were corrected for leaching of the radiolabel off the particles. In another study on healthy subjects as well as mild asthmatics and smokers we found no significant clearance from the lungs of 100 nm carbonaceous particles, for which we carefully controlled radiolabel leaching off the particles to be <2% within 24 h [23]. Due to the limit of detection used in this study systemic translocation and subsequent uptake in organs like the liver was below 1% of the deposited particles.

#### 4.2.4.2 Studies of Systemic Particle Translocation in Animals

Oberdörster and coworkers have observed rapid translocation towards the liver of more than 50% of  $^{13}\text{C}$  labeled ultrafine carbonaceous particles (26 nm size) within 24 h in a rat model [24]. Takenaka et al. [25] showed about 5–10% ultrafine silver particle translocation to the liver. Kreyling et al. [26], however, observed only minute (<1%) translocation of iridium ultrafine particles (15–20 nm and 80 nm in size) into the blood of rats. However, these test particles did not only accumulate in the liver, but also in spleen, kidneys, brain and heart to similar fractions. Uptake of the 15–20 nm particles in secondary target organs was about a factor of 2–3 higher than for 80 nm particles. In this study we challenged the question of particle dissolution and were able to show that these ultrafine particles dissolved to a very small extent, for which the particle data were corrected. Interestingly, in a long-term retention study Semmler et al. [27] have shown that ultrafine iridium particle contents in each of these secondary target organs did not increase with increasing retention time after a single 1-h exposure but peaked after one week at about 0.5% in each secondary organ. Thereafter, fractions declined again and remained detectable but below 0.1% of the initial deposit throughout the six-months-period of observation, indicating clearance mechanisms in these organs.

However, even though the mass fractions of iridium particles were rather low in secondary target organs the number of particles is impressively high. Data at one week and six months after the single inhalation are shown for lungs and all secondary target organs – liver, spleen, heart, brain and kidneys – in Table 4.1 (data taken from Refs. [26, 27]). More than one billion particles were found in each of the secondary target organs one week after a single 1-h exposure; and more than 100 million particles were still determined six months after the inhalation.

Importantly, particle uptake in the brain was not via the neural pathway from the olfactory epithelium in the nose, since extrathoracic airways of the rats were bypassed when ventilated through an endotracheal tube during exposure. Therefore, two principal pathways from the lung epithelium towards the brain are possible: (1) along neural axons and synapses [28–30], as reviewed by Oberdörster et al. [7] or (2) via systemic circulation. While the second route, via blood circulation, intuitively seems likely by analogy to uptake in other secondary organs the neural route should be kept in mind when designing the next generation of investigations. For

**Tab. 4.1.** Retained mass fractions as well as the corresponding numbers of insoluble iridium particles in the lungs and in secondary target organs one week and six months after single 1 h inhalation of 15 nm-sized iridium particles by WKY rats [26, 27]. The corresponding surface area of the retained particles is also calculated, based on the BET surface area of  $123 \text{ m}^2 \text{ g}^{-1}$  or  $1500 \text{ m}^2 \text{ cm}^{-3}$  (per mass or per volume of particles, respectively).

Organs	Retained mass fraction		Retained particles number		Particle surface area ( $\text{cm}^2$ )	
	One week	Six months	One week	Six months	One week	Six months
Lungs	0.6	0.06	$7.00 \times 10^{11}$	$7.00 \times 10^{10}$	$1.26 \times 10^2$	12.6
Liver	0.006	0.0005	$7.00 \times 10^9$	$5.83 \times 10^8$	1.26	0.105
Spleen	0.004	0.0003	$4.66 \times 10^9$	$3.50 \times 10^8$	0.842	$6.32 \times 10^{-2}$
Heart	0.004	0.0005	$4.66 \times 10^9$	$5.83 \times 10^8$	0.842	0.105
Brain	0.003	0.0005	$3.50 \times 10^9$	$5.83 \times 10^8$	0.632	0.105
Kidney	0.006	0.0001	$7.00 \times 10^9$	$1.17 \times 10^8$	1.26	$2.11 \times 10^{-2}$

instance, Hunter and Undem [31] have demonstrated the transport of fluorescent 40 nm polystyrene nanoparticles from the nerve endings in the tracheal epithelium along their neurons to their cell body in the ganglion nodosum and jugular ganglia in the neck of guinea pigs along neurons innervating the trachea. Furthermore, translocation along olfactory nerves from the olfactory epithelium to the olfactory bulb was first reported by Howe and Bodian [32] for 0.03- $\mu\text{m}$  polio virus in monkeys, and was later described for nasally deposited colloidal 0.05- $\mu\text{m}$  gold particles, moving into the olfactory bulb of squirrel monkeys [29]. Carbonaceous ultrafine particles were reported to translocate also along the same pathway to the central nervous system (CNS), based on their presence in the olfactory bulb of rats after inhalation [30, 33].

In addition, the surface area of the retained iridium particles was calculated based on the BET specific surface area of  $123 \text{ m}^2 \text{ g}^{-1}$  or  $1500 \text{ m}^{-2} \text{ cm}^{-3}$  per mass or volume of particles [34]; (BET surface area was determined by nitrogen absorption measurements). Since there is now evidence that the iridium particles are covered with iridium oxide [35], the density of iridium oxide ( $11.7 \text{ g cm}^{-3}$ ) and not that of iridium ( $22.4 \text{ g cm}^{-3}$ ) was used for calculations. One week after inhalation the total surface area of the retained iridium particles is close to  $1 \text{ cm}^2$  and after six months data are still a tenth of the one-week data. Compared to 1- $\mu\text{m}$ -sized particles this retained surface area of the 15 nm particles in secondary target organs is five orders of magnitude larger because of their very large specific surface area. It remains to be investigated what impact that may have, and whether the large number of retained particles and the accordingly large particle surface area may

have any adverse effects on the surrounding biological microstructures, like proteins, extracellular fluids, cells and their multiple functional and structural compartments as well as whole tissue of organs that usually are not considered to be exposed to such foreign bodies.

Recent studies of Nemmar and coworkers have shed light on possible prothrombotic effects in the systemic circulation as a result of activation of platelets [36, 37]. In their hamster model of experimentally induced thrombus formation they observed thrombotic clots in peripheral veins and arteries after intravenous and intratracheal administration of positively charged 60 nm polystyrene nanoparticles. They emphasized the importance of size and surface charge of test particles. In fact, the induced thrombus formation was not detectable after administration of negatively charged or neutral 60 nm as well as 400 nm sized positively charged polystyrene test particles; astonishingly, they observed similar thrombus formation after application of diesel exhaust particles via both routes [36]. These observations were confirmed by another group using a slightly modified approach [38]. From the fact that they observed peripheral thrombus formation even after intratracheal nanoparticle instillation into the lungs they concluded particle translocation from the lung epithelium to circulation. Whether particle translocation really occurred or whether thrombus formation was indirectly triggered by mediators released in the presence of the particles in the lungs needs to be proven in the next generation of studies. Nevertheless, the presence of these ultrafine particles with specific properties obviously was able to trigger biological responses that may initiate adverse health effects.

The fact that surface properties and possibly the particle matrix may play an important role in systemic translocation was demonstrated in a previous study [39, 40] in which ultrafine titanium dioxide ( $\text{TiO}_2$ ) particles were produced basically by the same method as the iridium particles, yielding primary particles of about 5 nm, very similar to those of iridium. Figure 4.3 shows the aggregation of both particle agglomerates of about 20 nm size.  $\text{TiO}_2$  agglomerates were inhaled by endotracheally intubated and ventilated WKY rats and the lungs were morphometrically studied in great detail immediately after the 1-h inhalation and 24 h later to determine the location of the retained  $\text{TiO}_2$  particles within the various lung compartments. Interestingly, a substantial fraction was already found at each time point in the vascular compartment, including the endothelium and the vascular lumen, indicating a rapid systemic translocation, which was obviously not the case after the inhalation of iridium particles. There are hints that these  $\text{TiO}_2$  show a positive zeta potential similar to commercially available  $\text{TiO}_2$  nanoparticles and as opposed to the negative zeta potential of iridium particles.

In studies using radioactively labeled ultrafine particles, the observed translocated fractions always appeared to be higher when less care was taken to minimize particle dissolution and/or the leaching of the radiolabel from the particles. Likewise, analysis of the stable  $^{13}\text{C}$  isotope-label is hampered by the fact that natural  $^{13}\text{C}$  occurs in all biological tissues at the level of 1% of the other stable isotope  $^{12}\text{C}$ , and ultrafine particle deposition in the lungs of the exposed rats made up only about a tenth of the natural  $^{13}\text{C}$  in the lungs; therefore, slight variability of the

**Fig. 4.3.** Agglomerates of primary titanium dioxide particles (left) and iridium particles (right); primary particles are in the size range of 5 nm.

abundant natural  $^{13}\text{C}$  or uncertainties of the estimate of total carbon content in a given organ or tissue may lead to erroneous estimates.

Although the first data on susceptible humans – asthmatics and adults – did not alter the translocation pathway, a recent mechanistic study on excised blocks of heart and lungs of rats indicated increased translocation rates when either or both was compromised experimentally by induced epithelial inflammation or histamine activated endothelium [41].

Recently, more attention has been paid to surface characteristics and charges that could influence this process, as is well known in drug delivery [42]. Studies of drug delivery across the blood–brain barrier further confirmed the importance of surface properties, showing that particle surface components may bind to the ApoE-receptor of endothelial cells, which mediates crossing of this otherwise very tight barrier [43]. In addition, current discussion focuses on other transport pathways: clathrin-mediated endocytosis and non-clathrin-mediated endocytosis, the latter including internalization via caveolae [44–46]. Vesicular caveolae migrate from the luminal to the mucosal side of epithelial and endothelial cells [47]. After internalization caveolae are involved in endocytosis, transcytosis, and pinocytosis. In a recent study Rejman and coworkers showed that both pathways are clearly size-dependent for ligand-devoid polystyrene particles [48]. Using non-phagocytic cells, internalization of microspheres with a diameter  $< 200$  nm involved clathrin-coated pits. With increasing size, a shift to a mechanism that relied on caveolae-

mediated internalization became apparent, which became the predominant pathway of entry for particles of 500 nm in size. Under these conditions, delivery to the lysosomes was no longer apparent. The data indicate that the size itself of (ligand devoid) particles can determine the pathway of entry. The clathrin-mediated pathway of endocytosis shows an upper size limit for internalization of approx. 200 nm, and kinetic parameters may determine the almost exclusive internalization of such particles along this pathway rather than via caveolae. These studies on non-phagocytic melanoma cells B16 are supported by others using primary oral or esophageal epithelial cells [49, 50]. Likewise, endothelial cells are known to have bottle-shape-like caveolar invaginations of the plasma membrane [46]. Interestingly, studies aiming for cell transfection and gene delivery are focusing on these transport pathways [44–46].

Besides transcellular pathways para- or intercellular pathways are other routes by which nanoparticles can penetrate membranous cell barriers. Recently, Heckel and coworkers have shown in an inflammatory rabbit model induced by infused lipopolysaccharide (LPS) that intravenously administered 8 nm gold particles coated with autologous albumin were found on their way between endothelial as well as epithelial cells of the alveolar air–blood barrier [51]. The control rabbits showed the same pathway at a lower extent reflecting the transfer of albumin from the vascular to the luminal side of the air–blood barrier also under physiological conditions. Besides this paracellular pathway they also found albumin-coated gold particles in intracellular caveolae vesicles, indicative of transcellular pathways in both the control and the inflammatory model. At the same time it shows that nanoparticles coated with the appropriate serum protein can rapidly be translocated across a membrane, particularly when there is a protein gradient between the two sides of the barrier. It remains open whether these albumin-modulated para- and transcellular pathways are important in human lungs in the reverse direction, when an inhaled particle deposited on the alveolar epithelium is translocated into blood circulation.

### 4.3

#### Toxicological Plausibility of Health Effects Caused by Nanoparticles

Toxicological experiments can be categorized into *in vivo* and *in vitro* experiments. *In vivo* experiments investigate effects in living organisms such as experimental animals or healthy subjects and patients in clinical studies, whereas *in vitro* experiments are conducted in organs, tissues, cells or biomolecules isolated from the living organism. In general, toxicology studies on air pollutants are shorter-term experimental approaches that tend, for ethical reasons, not to study people but experimental animals. They often analyze the early events rather than waiting for final disease. In addition, in those studies high doses are required to detect significant effects; and they may use cells and biochemical systems rather than whole animals. To compensate for such shortcomings, models of susceptibility are an important experimental approach in which the biological system is predisposed prior

to treatment with air pollutants. Predisposition of the system acts already like a change of the homeostatic balance; such systems may respond more vigorously than the normal system. If, in addition, the predisposition reflects or resembles human diseases or human predisposition, such a model may be a powerful analytical tool, providing insights on how air pollutants may change responses of the susceptible system.

While human clinical studies provide closer insight in nanoparticle related modes of action, they usually are limited in yielding firm dose-response-relationships because of ethical reasons. Such relationships, however, can be provided by toxicological studies on susceptible animal models as well as cell systems. Hence, animal studies are supposed to provide biological explanations and plausibility and create hypotheses that may then be proven in human clinical studies.

#### 4.3.1

##### **Pulmonary Inflammation Induced by Ultrafine Particles**

Many of the effects that occur rapidly after ultrafine particles deposit on the respiratory epithelium are not fully understood. Cells in contact with ultrafine particles like macrophages, epithelial cells and neutrophilic granulocytes are activated and may synthesize compounds referred to as *reactive oxygen or nitrogen species* (including free radicals, hydrogen peroxide, and superoxide) that try to inactivate and eliminate the invading foreign material [52]. Within hours, cytokines and chemokines are synthesized and secreted into the affected area. These molecules are mediators that interact with specific receptors on the surfaces of many cell types and thereby activate cells in the surrounding environment as well as in the blood and other tissues. As a result, cells leave the bloodstream and enter the fluid filled interstitial spaces, where they can attack the foreign material. Consequently, particle-induced cell activation events in the airways frequently result in an *inflammatory response*. This response includes both the activation of cells of the epithelium (including the production of “pro-inflammatory” and reactive oxygen molecules described above) and the activation and migration of cells (particularly, neutrophilic granulocytes and eosinophilic granulocytes in the case of a specific immunological response) from the blood into the airways. While the inflammatory response may occur after interaction of both fine and ultrafine particles with respiratory tissues, the enhanced surface area of ultrafine and nanoparticles compared to fine particles (as the acting interface) suggests a more prominent reaction.

Airway nerve cells may also contribute to inflammation in the airways by synthesizing neurotransmitters [53]. In this *neurogenic inflammation*, the neurotransmitters can affect many types of white blood cells in the lung, as well as epithelial and smooth muscle cells. Inflammatory cytokines synthesized by white blood cells may also affect the nerve cells. The inflammatory response may damage the epithelial cell layer at the surface of the tissue and other cells in the airway (such as macrophages), which results in the loss of integrity of the tissue’s defenses. One potential consequence may be increased exposure to and reduced capacity to defend against microorganisms.

Thus, particle deposition on the respiratory epithelium can trigger a cascade of events in many different cells, potentially resulting in changes in tissues and organs at sites progressively further from the initial stimulus. These defense mechanisms are normal responses in healthy individuals, but they may lead to deleterious changes in the host. Such changes may be rapid and temporary and may resolve quickly but, depending on the level and pattern of exposure and the agent to which the host is exposed to, they may last longer. It is not clear whether or how such modulations are relevant to the development of particle-induced adverse health effects at low levels of exposure. Yet, these changes are thought to have a greater impact on individuals whose respiratory, cardiac, or vascular tissues have been previously altered or damaged.

One possible consequence of damage to the airways is that the individual may become more susceptible to respiratory infections if exposed to viruses or bacteria, as discussed in Ref. [54]. A second possible consequence is that it may further decrease respiratory function in a person whose airways are already damaged by diseases such as bronchitis or asthma. As a result, symptoms of asthma, for example, may be exacerbated [55].

#### 4.3.2

#### **Systemic Inflammation and other Responses**

Recent studies have suggested that exposure to particles results in systemic inflammatory effects within hours [56]. Pathways are discussed as either via direct particle translocation into circulation or via mediators released in the respiratory tract. In particular, the former pathway supports the concept of enhanced cardiovascular responses after ultrafine or nanoparticles exposure due to the higher likelihood of ultrafine particle translocation into circulation when compared with larger particles. Recently, a panel of cardiologists has reviewed the existing literature and compiled a statement in which possible pathways of interference of particulate matter are summarized [57]. They have developed a schematic (Fig. 4.4), which has been adopted in this chapter.

The panel link particle exposure with cardiovascular disease via four major routes: pulmonary inflammation, pulmonary reflexes and systemic translocation to circulation and to the heart. It is currently unclear whether the systemic response is a consequence of an inflammatory response in the respiratory tract, because some studies on systemic inflammation have detected little or no inflammatory lung response after exposure to PM. As described above, there are studies that indicate that either particles per se (ultrafine and nanoparticles in particular) or components that may detach or dissolve from particles may move rapidly into the circulation, triggering either oxidative stress or pro-thrombotic or acute-phase or other responses of the cardiovascular system [22, 56, 58]. Therefore, a direct systemic inflammatory response is possible via particle translocation into the circulation. This pathway of systemic inflammation is thought to be capable of triggering a cascade of responses, leading eventually to atherosclerotic plaque rupture and/or thrombosis as precursors of myocardial infarction. The other two pathways

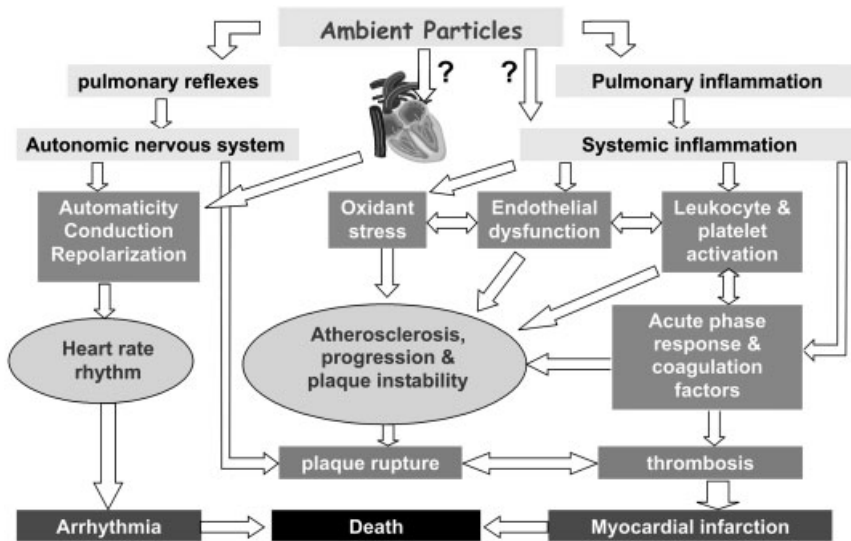

Fig. 4.4. Mechanisms involved in the link between cardiovascular disease and PM exposure. (After Ref. [57].)

of pulmonary reflexes and direct particle action on the heart are thought to interfere with heart rate functions, leading to arrhythmia. Both myocardial infarctions and arrhythmia are severe diseases with a substantial mortality rate.

#### 4.3.3

##### Relevant Parameters in Nanoparticle Toxicology

Biologically, it appears unmeaningful to presume that low solubility ultrafine or nanoparticles are hazards per se, since adverse reactions result from the interaction between the ultrafine particle and biological tissues. Currently, certain parameters of ultrafine particles are considered to trigger or mediate a cascade of reactions, starting with the formation of free radicals, which lead to oxidative stress in extracellular matrix and cells with the subsequent onset of pro-inflammatory processes (outlined in Fig. 4.5) [2, 11, 59]. These particle parameters are now discussed below.

##### 4.3.3.1 Number Concentration and Surface Area

Considering health effects initiated by the exposure to ultrafine and nanoparticles requires a change of the paradigm that effects are correlated with the mass of noxae accumulated during exposure. In ambient air the mass concentration of ultrafine particles is usually less than 10% of the mass concentration of  $PM_{2.5}$ . However, the number concentration of ultrafine particles dominates the number concentra-

Fig. 4.5. Parameters of ultrafine particles considered to be involved in the initiation of oxidative stress and inflammatory processes. (Adapted from [3].)

tion of fine particles by >90% [60]. Therefore, surface area and number concentration appear to be the more reasonable metrics of ultrafine and nanoparticle exposure than mass concentration. Furthermore, exposure metrics may be inadequate since it may be the number of deposited particles per unit surface area or dose to a specific cell (e.g., alveolar macrophage) that determines response for specific regions. Therefore, the use of a metric depends on specific questions posed, requiring specifically defined metrics.

Oberdörster and co-workers have tested the relation between surface area of particles and inflammatory response [61]. Ultrafine TiO<sub>2</sub> with an average particle size of 20 nm and pigment grade (fine) TiO<sub>2</sub> with an average particle size of about 250 nm were used. Doses ranging from 30 to 2000 µg of TiO<sub>2</sub> were intratracheally instilled into rats and mice. When the deposited TiO<sub>2</sub> dose was expressed as particle surface area, there was a unique relationship to the inflammatory responses of these two different sizes of TiO<sub>2</sub> particles. The importance of particle surface area for eliciting inflammatory responses in the lung has been confirmed [62, 63]. This concept of particle surface area as the appropriate dose metric has been recognized as an important principle in particulate matter toxicology [11, 64, 65].

#### 4.3.3.2 Particle Shape (Fibers and Nanotubes)

Newer materials or those under development, such as synthetic organic fibers and carbon nanotubes, may have different toxicology paradigms [3]. The existing paradigm for silicate fibers suggests that respirable fiber types vary in their ability to cause lung disease and that this can be understood on the basis of the length of the fibers and their biopersistence in the lungs. Because fibers are regulated on a fiber number basis and the hazard is understood on the basis of the number of

long fibers, in fiber testing the dose should always be expressed as fiber number (not mass), and the length and diameter distribution also need to be known. Carbon nanotubes are long thin structures that can have diameters of a few nanometers but be many thousands of nanometers long. These could have very unusual toxicological properties, in that they share shape characteristics of both fibers and nanoparticles; such limited toxicology as presently exists supports the contention that these may be harmful to the lungs [3, 66]. Thus, the physiological relevance of these findings needs ultimately be determined by conducting inhalation toxicity studies.

#### 4.3.3.3 Transition Metals

For more than 10 years transition metals have been suspected and proved to cause health effects. Convincing evidence has been provided by a combination of epidemiologic and subsequent toxicological studies. An epidemiological study showed reduced effects of several morbidity endpoints as well as mortality in the population of Utah Valley, Utah, during a one-year period when a steel mill had been shut down, resulting in considerable reduction of transition metals in ambient fine particles, while symptoms and metal-containing air pollution were high in the year prior and after the closure of the steel mill [67–69]. Dust sampled from each period was applied in a human clinical study [70] as well as in a mechanistic study demonstrating pulmonary injury, neutrophilic inflammation and increased airway responsiveness of the metal-rich samples using a sensitive animal model [71]. Hence, the clinical and toxicological animal study provided a better understanding of the modes of actions of the ambient particles that had been found to be associated with adverse health effects within the population of Utah Valley.

Similar combined studies are being applied to air pollution in the city of Hettstedt, in former Eastern Germany, which has a history of several centuries of non-ferrous metal mining and smelting in comparison with the city of Zerbst, serving as a control in a nearby agricultural area. High  $PM_{2.5}$  levels were shown to be associated with significant decline of lung function and with significant increase of prevalence for bronchitis, otitis media, frequent colds, and febrile infections in three surveys on children over a decade in the 1990s. At the same time, high levels of the transition metals zinc, lead, copper, and cadmium were associated with allergic responses [55, 72, 73]. Dusts from Hettstedt and Zerbst were studied in an allergic mouse model, showing increased allergic responses and increased allergic sensitization [74]. This dust also had the capacity to form radical species [75] and further clinical human studies demonstrated that dust obtained from Hettstedt induced distinct airway inflammation in healthy subjects with a selective influx of monocytes and increased generation of oxidant radicals [76].

Both series of combinatory “epi-tox” studies provide comprehensive evidence for the association of adverse health effects in susceptible population groups and modes of actions of these ambient particles in either clinical and animal models studies or in *in vitro* studies. Importantly,  $PM_{2.5}$  is the basic dose metric in these studies and not ultrafine particle parameters. Note that in the second series of epidemiological studies ultrafine particle number concentration was measured in addition and do-

minated the number concentration of the fine particle fraction by 90% [77]. Therefore, additional research is required to demonstrate whether the ultrafine particle fraction plays a role in the observed effects and modes of actions and whether they may even drive the effects because of the very peculiar properties of the ultrafine particle fraction.

#### 4.3.3.4 Organic Compounds

Organic chemicals associated with ultrafine particles play a role in the pro-inflammatory effects of diesel exhaust particles (DEP), as demonstrated in several *in vitro* studies. For example, DEP caused modest stimulation of interleukin-8 (IL-8), granulocyte macrophage colony-stimulating factor (GM-CSF) and RANTES production by epithelial cells, and this activity was lost on extraction of the organic matter [78]; the benzene extracts contained most of the stimulatory activity seen in the whole DEP. Benzene extracts contained almost 90% of the benzo[*a*]pyrene, B(a)P, content and the authors concluded that poly aromatic hydrocarbons (PAHs) such as B(a)P were likely responsible for the stimulation of cytokine production by the epithelial cells. Boland et al. have demonstrated that DEP stimulated IL-8, GM-CSF, and IL-1 $\beta$  release from the bronchial epithelial cell-line 16HBE [79]. Furthermore, they contended, this was related to the amount of adsorbed organic compounds, because carbon black with virtually no adsorbed organic matter did not cause cytokine release. In support of this, exhaust gas post-treatments that diminished the adsorbed organic compounds also reduced the DEP-induced increase in GM-CSF release. Further studies with the organic extracts confirmed that most of the stimulating activity was in the organic fraction [80]. In another study, PAH extracted from DEP induced expression of IL-8 and RANTES in peripheral blood mononuclear cells [81], demonstrating that both macrophages and epithelial cells could be important in the pro-inflammatory effect induced by DEP in the lungs. Chin and coworkers [82] demonstrated that carbon-black treatment of the RAW264.7 mouse macrophage cell line had no effect on TNF $\alpha$  release but that the addition of B(a)P to the particles caused them to become stimulatory for TNF $\alpha$ .

More recently, investigators started to find evidence that amongst the large variety of organic compounds, particularly in the particulate fraction of ambient air originating from combustion processes, there are biologically highly reactive compounds like redox cycling quinones – oxidized and nitrated polyaromatic hydrocarbons, which can catalyze release of reactive oxygen species (ROS), leading to the induction of oxidative stress and inflammation. PM from the Los Angeles basin as well as organic extracts obtained from DEP induce a stratified oxidative stress response leading to Heme-oxygenase-1 expression, followed by activation of Jun kinase and pro-inflammatory interleukin-8 production, and culminated in cellular apoptosis in parallel with a sharp decline of antioxidant levels. These effects were more prominent in the fine particle fraction than the coarse, and they were positively correlated with higher contents of organic carbon and polyaromatic hydrocarbons [83]. Admittedly, the ultrafine particle fraction was not analyzed explicitly; however, the organic carbon load is highly associated with the ultrafine particle

fraction since this fraction predominantly originates from combustion processes. Pro-inflammatory effects in the respiratory tract are related to the particle content of redox cycling chemicals and are involved in the adjuvant effect of DEP in atopic sensitization [84]. Cytotoxicity in epithelial cells and macrophages is the result of mitochondrial damage, which manifests as ultramicroscopic changes in organelle morphology, a decrease in the mitochondrial membrane potential, superoxide production, and ATP depletion.

#### 4.3.3.5 Extrapolation of Health Effects Observed in Animals towards Human

Comparison between rodents and humans is rather difficult due to anatomical and physiological differences, which can result in considerably lower concentrations to sensitive regions of the respiratory tract of animals compared to similar regions in humans.

Laboratory animals used in toxicological studies are genetically very similar within specific strains, whereas human populations are heterogeneous. Thus, extrapolating results from animals to humans must not only take strain and species differences into account, but must also consider inter-individual variation among humans.

With animal studies, the presumed susceptible part of the human population is mimicked by inducing specific cardiopulmonary diseases or focusing on senescent animals. For instance, animal research has been done in the laboratory using a model of asthma, increased blood pressure in lung arteries, lung inflammation and general high blood pressure. An advantage of these models is that hypotheses on the mechanisms of action and biological plausibility can be examined. Using DEP, residual oil fly ash or ambient particles, it has been demonstrated in models for respiratory infection and allergy that symptoms can exacerbate. A drawback with these disease models in animals is that they are not completely equivalent to the human disease counterpart. Yet the development of susceptible animal models is a prerequisite to the search for biological plausibility of the higher vulnerability of susceptible and diseased individuals. A second issue is a certain degree of uncertainty as to whether the laboratory animal used is representative of the reactions of a human being, or whether the endpoints examined are sensitive enough and representative for human endpoints. An additional consideration is whether the timing of exposure and observation has been correctly chosen in the animal studies. However, studies in animals continue to be the main methodology on which to predict adverse health outcomes in humans and to clarify the relationship between exposure dose and toxic effects.

Since the development of ambient particle related health effects is a multifactorial process that may start with genetic predisposition and is propagated by life-long exposure to air pollution and a history of diseases, acute effect studies in animal models seem not to be likely to mimic this progression, which would require long-term exposure studies to carefully controlled fractions of air pollutants. Whether long-term exposures to nanoparticles will occur and whether such precautions are required will depend on the use of future nanoparticles.

#### 4.4

#### **Integrated Concept of Risk Assessment of Nanoparticles**

Nanoparticles are expected to be used in a wide range of new technologies. To highlight the importance of sustainable risk assessment, let us consider the use of nanoparticles in medicine: in this field nanoparticles are designed for therapeutic drug delivery and/or imaging techniques in diagnostics to be administered directly to the patient as multifunctional drug nanocarriers. This may require targeting across several membranes while the drug is sufficiently bound to the nanocarrier, and specific and controlled release of the drug at the target site, allowing for increased efficiency of the drug in target organs or cells, while side effects are minimized in sensitive but not-targeted organs and tissues [9]. This also includes non-toxic effects of the carrier nanoparticles. Although these may be future visions, nanomedicines are likely to represent the most challenging nanoparticles in terms of their safe and sustained application since patients predisposed by their disease are likely to be more susceptible to any such treatments, responding eventually more sensitively than healthy subjects. Hence, the rapid development of a multitude of nanoparticle applications needs to be complemented by assessing possible implications, assuring safe and sustainable handling of those nanoparticles. The challenge of an integrated application development and implication assessment is pro-active collaboration at the earliest stage to optimize functionality of the nanoparticle and to minimize its side effects without losses in terms of costs and time because of one-sided mismanagement or unfocussed or delayed initiation of risk assessment. While most other nanoparticles are not aimed for specific administration in human subjects, possible exposure scenarios still need to be considered.

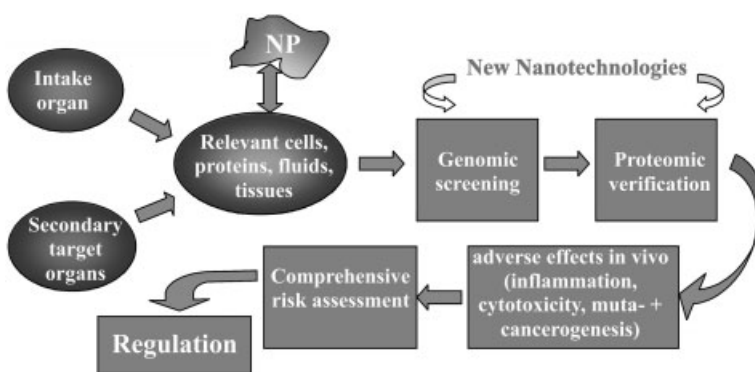

Hence we propose an integrated conception to estimate the health hazards of newly generated nanoparticles during their development. For this risk analysis the whole life-cycle of the newly developed nanoparticle has to be considered, including its scientific or industrial generation, its storage and distribution, its anticipated application and possible abuse, and finally its disposal. That means potential human incorporation may vary at different stages of the life cycle of nanoparticles and different groups of the population may be exposed. During generation an occupational group of healthy adult workers may be exposed to nanoparticles, while its anticipated application may possibly lead to exposure of the whole population, including susceptible people, like infants, children, elderly and diseased individuals. The challenge is to produce a reasonable estimate that takes into account the widespread use of mass-wise produced nanoparticles versus those produced in small quantities.

As a result, possible incorporation pathways can be foreseen for the respective usage of a given nanoparticle, which will include organs of uptake, organs involved in the distribution and secondary target organs. In all these organs the nanoparticles or their metabolic products eventually accumulate in different ways. Within these organs, interaction of the nanoparticles will take place at the level of proteins of body fluids and on the cell surface and within cells; this will eventually be the

beginning of a cascade of reactions, mediating or initiating adverse health effects, leading to disease, as outlined above. Therefore, only those proteins and cells need to be examined that interact with the nanoparticle. Nevertheless, these may be more than those within the organ of predominant uptake and anticipated target organs or tissues.

To assess the interaction between nanoparticles and biological materials, a strategic concept is necessary that (a) classifies nanoparticles according to their chemical compounds, physical structure and, particularly, such properties at their surface; (b) takes into account possible exposures in different phases of the nanoparticle's life cycle; (c) estimates delivered doses to the various biological systems; and (d) stratifies toxicological assessment from simple high-throughput screening methods towards more complex *in vivo* studies only when required and based on previous findings at a lower level of analysis. Initially, simple acellular tests may evaluate free radical formation, oxidative stress, antigen–antibody reactions, etc. followed by genetic (regulation of cytokines and mediators, nucleus-signaling) and proteomic (structural and functional modification of proteins) high-throughput methods. Actually, these methods, which aim to understand the underlying mechanisms, will predominantly make use of modern nanotechnology, such as gene and protein-array chip technology specifically designed to screen nanoparticle–gene and –protein interactions. This genetic and proteomic information will provide guidance to the next step of assessment. As a result a second series of biologically and toxicologically more relevant tests aimed toward specific reactions may become necessary – first on cells, followed by multicell models and *in vivo* animal models, which finally may require clinical phase trials in the case of medicinal nanoparticles. Figure 4.6 shows a schematic of this integrated concept.

From this structured approach, life-cycle-specific recommendations for regulation will be derived for each nanoparticle. Such an approach would even allow the use of a nanoparticle that may have an elevated risk at some stage of its life as an

**Fig. 4.6.** Integrated concept for sustained toxicological risk assessment in relation to newly developed ultrafine particles and nanoparticles.

overall risk–benefit analysis may still be in support of its use while including specific prevention measures when they become necessary – e.g., in the application of nanoparticles in medicine. In fact, controlled application of new emerging nanoparticles will require knowledge-based development, production and application, including sustainable risk assessment prior to their widespread use.

Public perception is an important factor for the future development of nanosciences and nanotechnologies. Efforts need to be undertaken to convince the public of the beneficial potential of nanosciences and nanotechnologies. It would be a tragedy if a major accident jeopardized in part, or even largely, the development of this future technology with its splendid prognoses.

### 5.1

#### Introduction

##### 5.1.1

#### Origin of Particles in the Human Environment

The term “particles” is defined as “very small pieces of solid or liquid matter, light enough to be suspended in the air”. The human body is exposed to many types of particles during its lifetime. These particles can be of natural origin or they can develop as (by-)products of industrial processes, and technical or pharmaceutical engineering. Thus, these particles vary largely in composition, size, shape, surface property and habitat. Dependent on these characteristics, the internalization of particles and their dissemination within the body is variable and may take place by ingestion (by polluted food or food additives) [1], inhalation (smoking, diesel soot, medical aerosols), via the skin (e.g., cosmetics, pharmaceuticals), implantation (e.g., wear from implants), and also injection (e.g., drug delivery and cancer therapy) [2]. Particulate air pollution is associated with enhanced mortality from respiratory and cardiovascular diseases [3]. The World Health Organisation (WHO) estimates that inhalation of particulate matter is responsible for at least 500 000 deaths each year worldwide [4].

Particles can be divided into those that are internalized accidentally (e.g., by air or food pollution) and those that are administered intentionally (e.g., for drug delivery, diagnostic agents). Among the naturally occurring particles in the air are pollen grains and their fragments and other vegetable particles, such as starch granules, which might, for example, carry mold spores with high allergenic potential. Furthermore, particles from volcanic eruptions occur naturally in the atmosphere. Particles evolved by pollution are from industry, motor vehicles, and other sources of thermodegradation. Furthermore, man-made/engineered particles have become relevant in recent years, e.g., due to the enormous progress in industrial use (e.g., in automotive, electronic, textile, household, and chemical industries)

and in pharmaceutical development of nanometer-scaled particles for drug delivery in asthma or cancer diagnosis and therapy [2, 5]. However, this rapid technical development has led to concerns about unknown risks of engineered nanometer-scaled materials [6].

#### 5.1.1.1 Evidence for Size-dependent Toxicity of Particles

Among the most abundant air pollutants in urban areas is particulate matter with a mean diameter of  $\leq 10 \mu\text{m}$  (also called  $\text{PM}_{10}$ , defined as particulate matter  $10 \mu\text{m}$  in diameter and smaller, by environmental toxicologists). Over the years it has become clear that particles with very low sizes (especially those below  $100 \text{ nm}$ ) are more noteworthy than larger particles since they induce more severe effects [7, 8]. There are different reasons for this phenomenon:

1. Particle size as a limiting factor of accessibility to the body's organs and tissues.  
For example, intact pollen grains,  $>10 \mu\text{m}$  in diameter, are too large to enter the lower airways. They are eliminated by mucociliary clearance. However, the naturally occurring break-up of pollen grains (e.g., by osmotic shock) produces smaller pollen fragments that can reach the lower parts of the airways and exert asthma-inducing effects in sensitized patients [9, 10].
2. Particle size as a limiting factor of accessibility to cells and cell compartments.  
Recent studies indicate that particle size alone can strongly affect the efficiency of cellular uptake [11].
3. The surface/size-ratio increases exponentially with decreasing particle sizes, leading to increased surface reactivity. This increased surface reactivity might lead to greater biological activity per given mass compared to larger particles, which in turn might have effects on, for example, particle internalization into tissues, cells and organelles, toxicity, or the induction of oxidative stress [2, 12].

This leads to the question: Are materials that are generally recognized as safe as bulk materials by the accredited standard tests also safe as (nano-scaled) particles? To date no standards exist for testing the safety of nanoparticles.

As mentioned above, particles with sizes below  $100 \text{ nm}$  are especially problematic. By definition, particles smaller than  $100 \text{ nm}$  are called nanoparticles or ultra-fine particles. Nanoparticles are at least 100-fold smaller than mammalian cells and are mostly smaller than viruses. Since the diameter of DNA molecules is  $2 \text{ nm}$  and atoms have diameters between  $0.1$  and  $0.4 \text{ nm}$ , concern about the interference of small nanoparticles with cellular structures at the molecular level is legitimate.

#### 5.1.1.2 Dissemination and Interferences of Nanoparticles within the Body

Owing to the minute size of nanoparticles, internalization into the body's tissues appears to be extremely easy. This has been shown by experiments in human volunteers with radioactive-labeled carbon nanoparticles (i.e., "Technegas") that passed rapidly into the systemic circulation after inhalation. Radioactivity could already be detected in blood after  $1 \text{ min}$  of inhalation [13]. Furthermore, animal studies re-

vealed that inhaled nanoparticles were translocated into the liver [14] and into the brain [15]. Thus, nanoparticles seem to be able to circumvent the tight blood–brain barrier; the movement of nanoparticles across the blood–placenta barrier has also been discussed [16, 17].

The incidence of higher asthma frequency during severe air pollution episodes has long been known [18]. Recent studies indicate that the ultrafine particles in air pollution are especially important in the course of asthma and chronic obstructive pulmonary disease (COPD) [19, 20]. Furthermore, other tissues in addition to the lung seem to be affected by nanoparticle exposure: In mice exposed to nanoparticles in ambient air the levels of pro-inflammatory cytokines were increased in brain tissue so that a coherency between inhaled particulate matter and the development of neurodegenerative diseases was suggested [21]. Moreover, nanoparticles are suggested to be involved in thrombus formation in the blood [22, 23]. There is evidence that fine and ultrafine particles are involved in the pathogenesis of Crohn's disease, a transmural inflammation of the gastrointestinal tract [24].

#### 5.1.1.3 Endothelial Cells and Nanoparticle Exposure

As the sources of internalized nanoparticles (food, air, etc.) and the location of particle detection are generally far apart, a distribution via the blood stream must have occurred. Thus, endothelial cells, which line the inner surface of blood vessels, will have direct contact with the particles. Endothelial cells are important in inflammation and wound healing. Upon pro-inflammatory stimulation of the endothelium, adhesion molecules are expressed on the cell surface, thus mediating leukocyte attachment (e.g., E-selectin and intercellular adhesion molecule-1/ICAM-1). Furthermore, endothelial cells are able to release cytokines, such as interleukin-8 (IL-8, a key factor in neutrophil chemotaxis). Thus, these features contribute to the pro-inflammatory endothelial phenotype that permits the transmigration of leukocytes from the blood into the perivascular space [25]. Activation of IL-8, E-selectin and ICAM-1 is regulated by the same transcription factors, NF- $\kappa$ B (nuclear factor- $\kappa$ B) and AP-1 (activator protein-1) [26–28].

#### 5.1.1.4 Testing of Nanoparticle-induced Effects on Human Endothelial Cells *In Vitro*

Little is known about the effects of nanoparticles on endothelial cell functions. Therefore, their effects on human endothelial cells have been studied *in vitro* and are reported here. Ceramic nanoparticles of TiO<sub>2</sub> and SiO<sub>2</sub> and metallic nanoparticles of Co and Ni were examined with respect to cellular internalization and their influence on cell viability, proliferative activity, and the pro-inflammatory endothelial phenotype. Moreover, due to the effects of the metallic nanoparticles they were compared with metal ion treatment. Endothelial cells *in vitro* were able to internalize many particles and reacted differentially in response to the internalization, dependent on the composition of the different nanoparticles. Furthermore, divergent effects of metallic nanoparticles vs. metal ions were observed. The link between these results and the possible risk of nanoparticles to human health is also discussed.

## 5.2

### Materials and Methods

All chemicals were obtained from Sigma if not otherwise indicated.

#### 5.2.1

##### Cell Culture

Human dermal microvascular endothelial cells (HDMEC) were isolated from juvenile foreskin as described before [29] and cultured in Endothelial Cell Basal Medium MV (PromoCell) supplemented with 15% fetal calf serum (Invitrogen), basic fibroblast growth factor (bFGF,  $2.5 \text{ ng mL}^{-1}$ ), sodium heparin ( $10 \text{ } \mu\text{g mL}^{-1}$ ), penicillin/streptomycin (10 000 units penicillin per mL, 10 000  $\mu\text{g}$  streptomycin sulfate per mL, Invitrogen), cultivated in a humidified atmosphere at  $37 \text{ }^\circ\text{C}$  (5%  $\text{CO}_2$ ) and used in passage 4.

#### 5.2.2

##### Particles

$\text{SiO}_2$  and  $\text{TiO}_2$  particles were produced by flame spray pyrolysis (TAL Materials Inc.). The size spectrum of  $\text{SiO}_2$  particles was between 4 and 40 nm with 14 nm mean particle size. The  $\text{TiO}_2$  particles were between 20 and 160 nm with 70 nm mean particle size. The mean size of Co particles was 28 nm (Nanoamor) and the Ni particles had a mean size of 62 nm (Nanoamor). Particles were added to the cell culture medium and tested at three different concentrations (0.5, 5, and 50  $\mu\text{g}$  per mL of culture medium).

Particles were analyzed by means of an Environmental Scanning Electron Microscope (ESEM-Quanta, FEI-Company). This instrument is called "Environmental" by the Manufacturer, as it can analyze samples in many different modes: at high and medium vacuum, and also at environmental conditions. It can also accept wet or oily samples, which is ideal for biological specimens.

#### 5.2.3

##### Transmission Electron Microscopy (TEM)

Cells were seeded onto fibronectin-coated Thermanox coverslips (Nunc). Exposure to particles was performed two days after seeding (50  $\mu\text{g}$  particles per mL medium). After 48 h incubation cells were fixed in cacodylate-buffered glutaraldehyde (2.5%) and embedded in Agar100 (Plano). Ultrathin sections were made with an Ultracut E microtome (Leica). TEM was performed with a Phillips 410 EM (Phillips).

#### 5.2.4

##### Cytotoxicity Assay

To evaluate cytotoxicity the CellTiter 96® AQueous non-radioactive assay (Promega) was performed according to the manufacturer's instructions. This assay gives

a measure of the enzymatic conversion of a tetrazolium salt (MTS reagent) by mitochondrial dehydrogenase and thus presents indirect evidence for cell viability.

#### 5.2.5

##### **Detection of Ki67 Expression**

Cells were seeded onto fibronectin-coated 96-well microtiter plates (6500 cells per well) and grown to subconfluence. Afterwards, cells were exposed to particles (0.5, 5, and 50  $\mu\text{g mL}^{-1}$  culture medium) and cultivated for an additional 24 h. The cells were fixed with methanol:ethanol (2:1, 15 min, room temperature) and permeabilized with buffered 0.1% Triton X-100 (5 min, room temperature).

Ki67, a protein expressed in the nucleus of proliferating cells, was detected with mouse-anti human Ki67-antibody (Dako). The secondary antibody was a peroxidase-conjugated rabbit-anti mouse-antibody (Dako). The staining reaction was performed by addition of the peroxidase substrate (*o*-phenylenediamine dihydrochloride) for 15 min at 37 °C. The staining reaction was stopped with 3 M HCl. Light extinction was determined with a microtiter plate photometer (ThermoLab Systems) at 492 nm.

#### 5.2.6

##### **Quantification of IL-8 Release in Cell Culture Supernatant**

Cells were seeded onto fibronectin-coated microtiter plates (13 500 cells per well), grown for 24 h and exposed to particles (0.5, 5, and 50  $\mu\text{g}$  per mL of culture medium for different samples) and  $\text{TNF}\alpha$  (300 U  $\text{mL}^{-1}$ ; inflammatory control). Cell culture supernatants were collected 24 h after substance or particle exposure. The IL-8 content in supernatants was assayed using human IL-8 immunoassay/ELISA (Hiss Diagnostics) according to the manufacturer's instructions.

#### 5.2.7

##### **Quantification of E-selectin Cell Surface Protein Expression**

This cell surface antigen is generally only expressed in inflammatory-stimulated endothelial cells and can be detected by using an enzyme-linked immunoassay based on a peroxidase staining reaction and subsequent dye quantification by a microplate reader. Therefore, cells were seeded onto fibronectin-coated 96-well microtiter plates (13 500 cells per well) and grown to confluence. Cells were then subjected to specific cell culture conditions (different particles and  $\text{TNF}\alpha$  as a positive control, 300 U  $\text{mL}^{-1}$ ) and cultivated for an additional 4 h. The cells were fixed with methanol:ethanol (2:1, 15 min, room temperature).

E-selectin was detected with mouse-anti human E-selectin-antibody (Bender MedSystems). The secondary antibody was a biotinylated goat-anti mouse-antibody (Amersham). Afterwards, the streptavidin–horseradish peroxidase conjugate was added (Amersham). The staining reaction was performed by addition of the perox-

idase substrate (*o*-phenylenediamine dihydrochloride) for 15 min at 37 °C. The staining reaction was stopped with 3 M HCl. Light extinction was determined with a microtiter plate spectrophotometer (ThermoLab Systems) at 492 nm.

### 5.2.8

#### Fluorescence Staining

HDMEC were seeded onto fibronectin-coated glass chamber-slides (Nunc). After 48 h, cells were exposed to particles (50  $\mu\text{g mL}^{-1}$ ) or  $\text{CoCl}_2$  (0.7 mM), incubated for an additional 24 h and fixed with buffered 3.7% paraformaldehyde (15 min, room temperature). Staining for Hypoxia-inducible factor-1 $\alpha$  (HIF-1 $\alpha$ ) was performed with the HIF-1 $\alpha$ -antibody (IgG1, BD Transduction Laboratories). Nuclear staining was performed with Hoechst 33342. Fluorescence-labeled cells were covered with GelMount (Biomed/Natutec).

### 5.2.9

#### Statistical Analysis

All results are shown as means  $\pm$  standard deviations (SD). Statistical analysis was carried out with Microsoft Excel software. According to the results of variance ratio analysis (F-test  $p < 0.05$ ) an unpaired t-test for either homoscedastic or heteroscedastic variances was performed ( $p < 0.05$  or  $p < 0.001$  as indicated in the figures).

## 5.3

### Results

Analysis of the different nanoparticles acquired by Environmental Scanning Electron Microscopy (ESEM) revealed a relative homogenous particle size for the ceramic nanoparticles ( $\text{TiO}_2$ , Fig. 5.1a;  $\text{SiO}_2$ , Fig. 5.1b). According to the manufacturer's specification the size spectrum of  $\text{TiO}_2$  particles was between 20 and 160 nm with 70 nm mean particle size and that of  $\text{SiO}_2$  particles between 4 and 40 nm with 14 nm mean particle size. In contrast, the metallic nanoparticles of Co and Ni were more inhomogeneous (Co, Fig. 5.1c; Ni, Fig. 5.1d). Both particle types possess nanoparticle character since the specified mean sizes of Co and Ni particles were 28 and 62 nm, respectively.

Ultrastructural studies (TEM) from perpendicular sections of endothelial cell monolayers demonstrated a flattened cell phenotype. Cytoplasm of the untreated control cells contained numerous organelles and vacuoles (Fig. 5.2a, arrowhead: vacuole with autophagic function containing cellular debris). When HDMEC were exposed to the different particles, internalization of the nanoparticles occurred that was independent of particle composition. The particles were localized within cytoplasmic vacuoles, partially containing cellular debris. Both the  $\text{TiO}_2$  and  $\text{SiO}_2$  particles were partially detectable as large aggregations and partially as smaller particulate matter. However, striking ultrastructural changes were not observed (Fig.

**Fig. 5.1.** ESEM images of the different nanoparticles used in this study. (a)  $\text{TiO}_2$ , (b)  $\text{SiO}_2$ , (c) Co, (d) Ni (scale bar:  $2\ \mu\text{m}$ ).

5.2b/c). The exposure to Co (Fig. 5.2d) and Ni (Fig. 5.2e) particles led to the enlargement of vacuoles; simultaneously, the number of vacuoles appeared to decrease. The Co- and Ni-particle-induced vacuoles partially filled the complete height of the cells (Fig. 5.2d/e). Interestingly, Co-particle exposure induced some annular-shaped, electron-dense material within the vacuoles (Fig. 5.2d, asterisk). Beside this electron-dense material the vacuoles of the Co-particle exposed cells contained a large amount of cellular debris.

Exposure of  $\text{TiO}_2$  particles to HDMEC did not induce an effect on cell number within 24 h (Fig. 5.3a; detected by a DNA staining with crystal violet; 0.5, 5 and  $50\ \mu\text{g mL}^{-1}$  were each tested). Also, the staining for the proliferation marker Ki67 after 24 h (Fig. 5.3b) and metabolic activity after 72 h (shown by the MTS conversion assay, Fig. 5.3c) did not show significant changes after exposure to  $\text{TiO}_2$  particles. High amounts of  $\text{SiO}_2$  particles ( $50\ \mu\text{g mL}^{-1}$ ) induced a slight decrease in cell number after 24 h (Fig. 5.3a). This  $\text{SiO}_2$ -particle-induced decrease is also reflected by a slight decrease of Ki67 protein expression after 24 h (Fig. 5.3b). However, the MTS conversion assay showed no significant reduction after 72 h (Fig.

**Fig. 5.2.** Perpendicular sections of HDMEC monolayers: (a) Nontreated HDMEC (control) and HDMEC exposed to particles of (b)  $\text{TiO}_2$ , (c)  $\text{SiO}_2$ , (d) Co and (e) Ni (TEM, magnification 26 000 $\times$ ).

**Fig. 5.3.** Cytotoxicity of different nanoparticles. Tests were for (a) cell number after exposure of 24 h (crystal violet staining), (b) proliferation after 24 h particle exposure (Ki67 detection), and (c) metabolic activity

after 72 h (MTS conversion). Particle amounts are in  $\mu\text{g mL}^{-1}$ , untreated control set as 100%;  $n = 4$ , means  $\pm$  SDs, significantly different from normoxia: \* $p < 0.05$ , \*\* $p < 0.001$ .

5.3c). Co and Ni particles induced a significant, concentration-dependent decrease in cell number after 24 h (Fig. 5.3a). Also, the reduction of Ki67 expression and MTS conversion in Co-particle treated cells was significantly reduced after Co-particle exposure (Fig. 5.3b/c). Interestingly, the Ni particles, which also induce a concentration-dependent decrease in cell number, showed no significant deviations in protein expression of Ki67 (Fig. 5.3b). Nickel particles led to a significant, concentration-dependent reduction of MTS conversion after 72 h (Fig. 5.3c). Thus, protein expression of the proliferation marker Ki67 was not reduced after Ni particle exposure, although cell number and metabolic activity were decreased.

Four hours after exposure of the different particles the cells did not show

**Fig. 5.4.** Detection of pro-inflammatory effects induced by particle exposure. Detection of (a) E-selectin after 4 h and (b) IL-8 after 24 h particle exposure; TNF $\alpha$ -stimulated cells serve as positive control and set as 100%,  $n = 4$ , means  $\pm$  SDs, significantly different from the untreated control: \* $p < 0.05$ .

E-selectin protein expression except for high Co particle amounts, which induced a significant increase in E-selectin protein expression (Fig. 5.4a, TNF $\alpha$ -stimulated cells served as the positive control and were set as 100%). In addition, ICAM-1 cell surface protein expression after 24 h was induced by high Co-particle amounts only; whereas all other particles did not induce an increase (data not shown). IL-8 release in the cell culture supernatant was stimulated by high amounts of SiO<sub>2</sub>, Co and Ni particles. High amounts of TiO<sub>2</sub> particles induced only a minor, non-significant increase (Fig. 5.4b).

An important protein in cell signaling is the hypoxia-inducible factor HIF-1 $\alpha$ . This protein is not detectable in normoxic cells (controls, Fig. 5.5a/b). Under oxygen deficiency (hypoxia) the protein is stabilized within the cells by complex mechanisms and transported into the nuclei. In this context it was important that divalent cobalt and nickel ions (Co<sup>2+</sup> and Ni<sup>2+</sup>) were able to stabilize and induce a translocation of the protein into the nuclei comparable to hypoxia conditions (results for Co<sup>2+</sup>-treatment shown in Fig. 5.5c/d). Comparable with the effects of Co<sup>2+</sup>, the exposure of Co particles induced the stabilization and translocation of HIF-1 $\alpha$  protein into the nuclei of endothelial cells *in vitro* (Fig. 5.5e/f). These HIF-1 $\alpha$  effects also occurred upon exposure to Ni-ions and -particles (data not shown).

**Fig. 5.5.** Nuclear- and HIF-1 $\alpha$ -staining in HDMEC. (a/b) Control: (a) nuclear and (b) HIF-1 $\alpha$  staining images the same section; (c/d) Co<sup>2+</sup>-treated HDMEC; 24 h, 0.7 mM, (c) nuclear and (d) HIF-1 $\alpha$  staining; (e/f) Co-particle-treated HDMEC; 24 h, 50  $\mu\text{g mL}^{-1}$ , (e) nuclear and (f) HIF-1 $\alpha$  staining.

The major changes after particle exposure, induced by the metallic nanoparticles and the Co<sup>2+</sup>-induced comparable stabilization of HIF-1 $\alpha$  induced after Co particle exposure, suggested that these effects were triggered by the release of metal ions from the particles. Therefore we compared the effects of the respective ions in con-

**Fig. 5.6.** Analysis of HDMEC number after exposure to Co and Ni ions and Co and Ni particles: (a) Co-ions and -particles, (b) Ni-ions and -particles; untreated control set as 100%,  $n = 4$ , means  $\pm$  SDs, significantly different from normoxia: \* $p < 0.01$ , crystal violet staining after 24 h exposure.

centrations that were equivalent to the molarity of the utilized particles (e.g., 50  $\mu\text{g}$  Co-particles per mL corresponds to 0.85 mM cobalt, 25  $\mu\text{g mL}^{-1}$  corresponds to 0.42 mM, and 10  $\mu\text{g mL}^{-1}$  to 0.17 mM; the calculations depend on the assumption that pure Co- and Ni-particles were present and are, therefore, only an approximation).

The cell number was concentration-dependently decreased by Co-/Ni-ions and -particles after 24 h of exposure (Fig. 5.6a/b). Nickel showed more pronounced effects than cobalt (for both ions and particles). Interestingly, both types of particles induced a stronger reduction of cell number than the ions, indicating a higher cytotoxicity of particles than the respective ions: 1 mM of  $\text{CoCl}_2$  induced a 20% decrease in cell number, whereas 50  $\mu\text{g mL}^{-1}$  ( $\sim 0.85$  mM) of cobalt particles induced a nearly 40% decrease (Fig. 5.6a), 1 mM of  $\text{NiCl}_2$  induced a nearly 50% reduction of cell number whereas 50  $\mu\text{g mL}^{-1}$  of Ni particles (also  $\sim 0.85$  mM) induced a 60% reduction (Fig. 5.6b).

We also compared the pro-inflammatory capacity of the Co and Ni ions with the respective particles. Cobalt ions and particles were effective in inducing the cell surface protein expression of E-selectin (Fig. 5.7a, effect after 4 h). Interestingly, only Ni ions showed a concentration-dependent increase in E-selectin expression, whereas the Ni particles failed to induce E-selectin cell surface expression (Fig. 5.7b). The same effect was detectable in the expression of ICAM-1 after 24 h; again Co-particles and -ions induced ICAM-1 protein expression on the cell surface, whereas only Ni ions were able to induce ICAM-1 expression, with the Ni particles eliciting no change (data not shown). Moreover, an increase in IL-8 release after 24 h was effectively induced by Co-ions and -particles (Fig. 5.7c). Nickel ions were also able to induce IL-8 release. Contrary to the absence of pro-inflammatory stimulation of Ni particles in the expression of the cell surface adhesion molecules E-selectin and ICAM-1, release of the pro-inflammatory chemokine IL-8 was induced by Ni particles (Fig. 5.7d).

**Fig. 5.7.** Detection of pro-inflammatory stimulation of HDMEC after exposure to Co and Ni ions and Co and Ni particles: (a) E-selectin protein expression after Co-ion and -particle exposure (4 h), (b) E-selectin expression after Ni-ion and -particle exposure

(4 h), (c) IL-8 release after Co-ion and -particle exposure (24 h), and (d) IL-8 release after Ni-ion and -particle exposure (24 h, TNF $\alpha$ -treated cells serve as positive control and set as 100%,  $n = 4$ , means  $\pm$  SDs, significantly different from normoxia: \* $p < 0.01$ ).

## 5.4

### Discussion

The role of particulate matter of nano-scaled size has received increasing attention in recent years. As mentioned before, this attention evolved due to the accidental internalization of particles with (partially) described effects on human health and also due to the intended administration of pharmaceutical, therapeutic, and diagnostic agents in nano-scaled sizes, which today is an important research field [30, 31]. Independent of the pathway of nanoparticle internalization, the distribution of nanoparticles within the body must occur in large part via the blood stream. Therefore, the endothelium will have contact with the nanoparticles during their passage throughout the body. The endothelium is an important cell population in the development of a multitude of diseases (e.g., tumor growth, atherosclerosis, and inflammatory diseases). Therefore, we focused on the effects of nanoparticles on viability and inflammatory status in human endothelial cells *in vitro*.

Endothelial cells *in vitro* maintain several features that their originals *in vivo* express under physiological situations. Furthermore, endothelial cells *in vitro* can be induced by pro-inflammatory compounds to synthesize and release factors that play an important role in the development of diseases. Thus, endothelial cells *in vitro* are a model system suitable for the examination of physiological and pathophysiological situations. Due to the availability of different recombinant growth factors and highly defined cell culture media several types of human endothelial

cell types can be more or less easily propagated *in vitro* (e.g., macrovascular endothelial cells from arteries or veins and microvascular cells derived from the capillaries of different tissues) [32, 33].

#### 5.4.1

##### Particle Internalization

Our study has shown that human endothelial cells possess a large capacity for the internalization of nanoparticles. All nanoparticles tested were taken up by the endothelial cells and to a major extent into vacuoles. Endothelial cells are able to internalize particles by different mechanisms. A large portion of the endothelial cell population possesses a prominent vesicular system that is called the vesiculo-vacuolar organelle (VVO) that other cells do not have with this specificity. The VVO is, together with specific plasma membrane compartments, the caveolae (invaginations of the plasma membrane), involved in the regulated transendothelial cell passage of macromolecules and particles [34]. Since, primarily, endothelial cells possess such a distinct vacuole system this way of particle internalization might be specific for a part of the endothelial cell population. There is also evidence for other means of particle internalization: In endothelial cells, particle internalization is also suggested to occur via specific receptors (e.g., low-density lipoprotein/LDL-receptor, platelet-derived growth factor/PDGF-receptor, albumin-receptor) since nanoparticles covered with LDL [35], PDGF [36], and bovine serum albumin [37] were shown to be internalized via coated pits/vesicles. It is not yet known if both pathways work independently in endothelial cells or if there is a mechanistic link.

There is evidence that a particle's size also affects the pathway of internalization, e.g., beads of 200 nm diameter were internalized into murine melanoma cells (cell line B16-F10) via clathrin-coated pits, whereas 500 nm beads enter the cells by a clathrin-independent pathway [11]. Whether endothelial cells show these size-dependent differences in internalization mechanisms is not yet known and a particle internalization pathway for the endothelial cells used in this study cannot be defined.

Nanoparticles of the biodegradable compound *D,L*-lactide-*co*-glycolide with a mean size of about 300 nm (larger than the particles used in this study, with mean sizes between 14 and 120 nm) are rapidly internalized by endothelial cells *in vitro* (as early as at 30 min) [38]. Moreover, *in vivo* experiments showed rapid particle internalization by endothelial cells; carbon nanoparticles (~50 nm) injected intravenously into tumor-bearing guinea pigs were detected in vacuoles and in the sub-endothelial space of tumor blood vessels 60 min after administration. However, the endothelial cells of non-tumorous blood vessels did not show carbon particle internalization in this animal model [34].

In our *in vitro* model, particles were detectable within vacuoles. The occurrence of vacuoles containing cellular debris together with the internalized particles was partially detectable. This co-localization of cellular debris and particles indicates an overlap between endocytosis and autophagocytosis [39, 40]. Interestingly, these

“mixed content” vacuoles (called amphisomes [41]) appeared very distinct in the case of the Co and Ni particle treatment, whereas TiO<sub>2</sub> and SiO<sub>2</sub> particle filled vacuoles were mostly free of cellular debris. The vacuole enlargement after Co and Ni particle treatment might be connected directly with the possible endocytotic/autophagocytic overlap and may be regulated by different mechanisms depending on the type of vacuole that evolves. The sizes of autophagic vacuoles can be regulated by vacuole fusion or enlargement of the vacuole [42]. The regulation of amphisomal sizes is unknown. We have suggested a connection between the release of divalent metal ions from metallic nanoparticles and the development of amphisomes in endothelial cells. This is supported by the fact that HIF-1 $\alpha$  was stabilized after Co- and Ni-particle exposure, as described for Co- and Ni-ion exposure [43, 44].

#### 5.4.2

##### **Particle Cytotoxicity**

Whereas the ceramic particles of TiO<sub>2</sub> and SiO<sub>2</sub> showed no significant cytotoxic effects, the nanoparticles of Co and Ni induced a significant, concentration dependent impairment of cellular viability. This impairment is obvious at different levels of cellular function (i.e., decrease of cell number, protein expression of the proliferation marker Ki67, and the metabolic activity).

Due to the stabilization of HIF-1 $\alpha$  (see above) it appeared that the observed metal particle cytotoxicity was induced by the release of divalent metal ions from the particles. Therefore we compared the effects of the nanoparticles with those of the metal ions Co<sup>2+</sup> and Ni<sup>2+</sup> (as chloride salts) in concentrations similar to the solid matter utilized. The particles exerted a higher cytotoxicity than the corresponding ions (e.g., 1 mM Co<sup>2+</sup> and ca. 0.85 mM Co particles induced a reduction in cell number after 24 h of ca. 20% and ca. 35%, respectively). These findings are in agreement with the results of a study on the cytotoxicity of Co nanoparticles and Co<sup>2+</sup> ions in mouse fibroblast Balb/3T3 cells [45].

At this point we can only speculate about the higher cytotoxicity of transition metal nanoparticles compared to the corresponding metal ions. The presence of metal-ion-specific transporters is one possible explanation: Transition metal ions like Co<sup>2+</sup> and Ni<sup>2+</sup> (which are essential trace elements and also toxic when present in excess) are transported into cells against concentration gradients with ion selectivity. Furthermore, mammalian cells have intracellular mechanisms to deliver the metal ions to specialized proteins [46]. This specified delivery system is necessary due to the toxicity of metal ions such as Co<sup>2+</sup> and Ni<sup>2+</sup> [47, 48]. The vacuolar system of eukaryotic cells is important in metal ion homeostasis because it provides several organelles for storage of metal ions and also provides the proper amounts of transporters in the various cellular membranes through the secretory pathway. Thus, the concentration of metal ions is regulated [46]. Therefore, it might be suggested that an excess of metal ions can be regulated via specific transporters or that an excess of metal ions is transferred into cellular organelles possessing mechanisms to avoid damage of sensitive cellular compartments. This would, however,

imply that metal nanoparticles are translocated to regions of the cell that are more sensitive to the release of metal ions than the regions that are attained via the specific metal ion transporters.

Severe problems may not only be a result of ion release but also due to the development of free radicals or reactive oxygen species (ROS) that occur from both transition metal ions [49, 50] and (nano-)particles [51–53]. Furthermore, it has been shown that nanosized particulate matter together with transition metals induces ROS production that exhibits a higher response than the single compounds (tested were carbon black particles with a mean size of 14 nm plus exposure of different iron and cupric salts). This increased ROS production suggested a synergistic effect of nanoparticles together with transition metals [54]. The metal particles used in this study, which are made of transition metals, contained a combination of both of these characteristics, i.e., nano-scaled particles and transition metals. Interestingly, Co particles might produce ROS by mechanisms different from ROS production by  $\text{Co}^{2+}$  ions [55, 56]. In addition, the binding of metal ions to extracellular and intracellular proteins such as transferrin and albumin, which are also known to bind  $\text{Co}^{2+}$  and  $\text{Ni}^{2+}$  efficiently [57–59], might influence the cytotoxicity of metal ions. A recent *in vitro* biokinetic study on simultaneous exposure of mouse fibroblast Balb/3T3 cells to Co particles and  $\text{Co}^{2+}$  ions showed different abilities of the two Co compounds to penetrate cells and cellular organelles. In addition, the study confirmed that serum components, particularly albumin and histidine, play a crucial role in determining the eventual toxic effects [60].

Interestingly, Ni particles did not show a reduction of Ki67 protein although the cell number and the metabolic activity were significantly decreased. In contrast, Co particles showed a very distinct down-regulation of Ki67 protein expression, in accordance with the reduced cell number and metabolic activity. Since we have previously shown that Co ions induced apoptosis whereas Ni ions induced cell death that was most likely due to necrosis (no signs of apoptosis were detectable) [48], we suggest that the absence of down-regulation of Ki67 expression after Ni particle exposure indicates a missing regulation of proliferative activity in the course of cell death. This is absent in necrotic cell death [61].

### 5.4.3

#### **Pro-inflammatory Activation**

A pro-inflammatory effect in HDMEC occurred after exposure to  $\text{SiO}_2$ , Co, and Ni particles and was apparent by an enhanced release of IL-8. Only higher particle concentrations (25 and  $50 \mu\text{g mL}^{-1}$ ) induced this increase in IL-8 release. E-selectin protein expression was enhanced by high amounts of Co particles, whereas Ni particles induced no protein expression of E-selectin. In contrast to the particles, divalent Co and Ni ions induced the expression of all pro-inflammatory markers tested (i.e., IL-8, E-selectin, ICAM-1).

The enhancement of IL-8 release in response to high amounts of  $\text{SiO}_2$  particles indicated a pro-inflammatory state. Since  $\text{SiO}_2$  particles can cause chronic inflammatory lung disease by inhalation [62] a comparable effect might be present in

nanoparticle-induced pro-inflammatory activation of endothelial cells *in vitro*. The SiO<sub>2</sub>-induced inflammation is mediated by the activation of the transcription factors NF- $\kappa$ B and AP-1, which are both involved in the regulation of inflammation. This transcription factor activation appears to be triggered by adverse biologic reactions such as the generation of ROS [63]. Moreover, SiO<sub>2</sub>-induced AP-1 activation plays an important role in neoplastic transformation and tumor promotion [64].

The observed pro-inflammatory activation after Co-particle exposure may be attributed to a release of divalent Co-ions by the particles, since the exposure of endothelial cells with these ions leads to impaired endothelial viability and pro-inflammatory stimulation [65]. In addition, with Co-ions the concerted activation of the above-mentioned transcription factors NF- $\kappa$ B and AP-1 has been demonstrated [66, 67] and the Co particles used in this study induced pro-inflammatory activation with Co-ion comparable dimensions.

This contrasts with the effects of the Ni particles. Here, the suggestion of a Ni ion release by the particles, resulting in an induced pro-inflammatory stimulation, is not congruent with the pro-inflammatory effects induced by the respective ions, since Ni-ions induced both an increase in the release of IL-8 and the protein expression of endothelial cell adhesion molecules (i.e., E-selectin and ICAM-1), whereas Ni-particles induced only an increased IL-8 release and the expression of adhesion molecules was not initiated. This indicates an activation mechanism for the Ni particles that deviates from the Ni-ion-induced activation shown to occur via a cooperation of the above-mentioned transcription factors NF- $\kappa$ B and AP-1 [66, 67]. Such differential activation of IL-8 and ICAM-1 was also shown by the treatment of endothelial and epithelial cells with H<sub>2</sub>O<sub>2</sub> [68, 69]: Whereas H<sub>2</sub>O<sub>2</sub> induced an IL-8 expression in epithelial cells lines without the expression of ICAM-1, endothelial cells expressed ICAM-1 after H<sub>2</sub>O<sub>2</sub> treatment without the expression of IL-8. There is evidence that this cell-type-specific differential induction of IL-8 gene expression by H<sub>2</sub>O<sub>2</sub> (and thus oxidative stress) is by a differential binding of NF- $\kappa$ B and AP-1 to the IL-8 promoter [68]. Since oxidative stress is also a relevant aspect in the mechanisms of (Ni-) particulate-matter-induced effects [52] this mechanism of differential activation of pro-inflammatory gene promoters might play a role. Thus, it can be suggested that Ni-ion release by the nanoparticles remains under the critical limit for pro-inflammatory activation but further Ni-nanoparticle-induced effects (possibly oxidative stress) are responsible for the enhanced IL-8 release. However, this hypothesis requires further examination and is the subject of a separate study.

#### 5.4.4

### Conclusions and Consideration of the Risk of Nanoparticles to Human Health

This study has shown that nanoparticles exert effects that deviate from the effects of bulk materials and also from possible corrosion products. The experiments were performed with a cell type highly relevant for nanoparticle transmigration from the blood into tissues, i.e., primary human endothelial cells. Whether the described effects shown *in vitro* are of relevance *in vivo* remains unanswered. However, nano-

particles clearly exert effects that are not easily interpreted. If a pro-inflammatory stimulation of endothelial cells by nanoparticles occurs *in vivo*, chronic inflammation (such as granulomatosis) could be a possible consequence.

Although much progress has been made in recent years to understand the effects of nano-scaled particulate matter, knowledge about its risk in humans is clearly limited. This lack of knowledge is due to the complexity of the chemical and physical characteristics of nanoparticles combined with the difficulty of predicting reactivity in biological systems. Furthermore, nanoparticles possess an impressively high accessibility to different types of tissues and cells, which large-scaled particulate matter usually does not have (reviewed in Ref. [2]). Thus, two different risk aspects are combined in nanoparticles: The ability of foreign materials to enter biological compartments that are usually not easily accessible and the potential for the exertion of effects on these locations, which are difficult to control.

The above-mentioned characteristic behavior of nanoparticles could be useful for medical applications such as in diagnostic and therapeutic devices. The endothelium is an important target for therapy due to its role in several physiological and pathological conditions. Also, the penetration of physiological barriers with endothelial participation such as, for example, the blood–brain barrier is of interest. Therefore, several diagnostic and therapeutic approaches that involve nanoparticulate compounds are under consideration (reviewed in Refs. [5, 70]). However, the utilization of nanoparticle-formulated drugs appears to be afflicted by a similar complexity described above, e.g., the chemotherapeutic agent paclitaxel showed different rates of clearance and different tissue distributions when formulated as nanoparticles compared to the conventional formulation as emulsion [71]. Thus, both accidental and intended exposure of humans to nanoparticles is connected to a certain risk that could be influenced by the type of particle and the state of health of the affected person. Therefore, detailed toxicological research should be carried out to improve the scientific basis of the risk assessment at all stages of the life cycle of nanotechnology [72].

## Acknowledgments

## 6 Toxicity of Carbon Nanotubes and its Implications for Occupational and Environmental Health

*Chiu-wing Lam, John T. James, Richard McCluskey, Andrij Holian,  
and Robert L. Hunter*

### 6.1 Introduction

#### 6.1.1 Overview

Manufactured carbon nanotubes (CNTs) exist in two forms, single-wall (SWCNTs) and multiwall (MWCNTs). Structurally, a SWCNT is a rolled-up, single-layer graphene sheet with a diameter of  $\sim 1$  nm and a length of several micrometers or longer, whereas a MWCNT contains two or more concentric layers with various diameters and lengths. CNTs are thermally generated from carbon atoms in carbon-bearing sources by electrical arc, laser, or chemical vapor deposition processes; the yield of SWCNTs is increased by the presence of catalytic metals. Because of their unique electrical, mechanical, and thermal properties, manufactured CNTs could have many applications in the electronics, computer, and aerospace industries. These widespread applications would require CNTs to be produced on a large scale. Unprocessed CNTs are very light, and if they entered the environment as suspended particulates of respirable sizes, they would reach the lungs. Concerned about the potential toxicity of these novel materials, several groups have conducted rodent studies to assess pulmonary toxicity of SWCNTs or MWCNTs. The test materials were made by different methods and contained different types and amounts of residual metals. Aqueous suspensions of test dusts were administered to the lungs of animals by intratracheal instillation or by pharyngeal aspiration. The results of these studies collectively showed that CNTs themselves, no matter how they were synthesized or what metals they contained, could produce inflammation, granulomas, fibrosis, and biochemical toxicological changes in the lungs. Results of comparative toxicity studies in animals given equal weights of CNTs, carbon black, and quartz showed that if CNTs reach the lungs they are much more toxic than carbon black. They can also be more toxic than quartz, which is considered a serious occupational health hazard if it is chronically inhaled. MWCNTs have been identified in fine particulate matter (PM) collected from combustion streams of

methane and natural-gas flames of typical kitchen ranges and from indoor and outdoor air. Exposure to fine PM has been shown to be associated with pollution-induced cardiopulmonary diseases. Because manufactured CNTs produce deleterious effects in animals, it is speculated that combustion-generated MWCNTs may play a significant role in pathogenesis of pollutant-induced diseases. Therefore, CNTs from manufactured and combustion sources in the environment could have adverse effects on human health.

### 6.1.2

#### General Background

The growing field of nanotechnology promises to bring a host of innovations that will profoundly affect modern societies. CNTs have helped to lay the foundation of this new technology. MWCNTs have recently been found to be generated in fuel combustion processes and to be present in indoor and outdoor environments. As nanotechnology finds new applications, manufactured CNTs will also become widespread. Although combustion-generated CNTs have probably existed in the Earth's environment for thousands of years, little is known about their effects on health. Several laboratories have studied the toxicity of manufactured CNTs, and their results indicate that precautions should be taken to minimize inhalation exposures to CNTs.

This chapter has five further sections. Section 6.2 describes the promotion of nanotechnology and its expected economic impact. Section 6.3 describes manufactured CNTs in three subsections: their discovery and synthesis, their properties, and the scope of their possible applications. Section 6.4 reviews findings demonstrating the current and past occurrence of CNTs in the environment. Section 6.5 describes methods used to assess the toxicity of respirable dust in the lung and reviews several studies assessing pulmonary toxicity of manufactured CNTs in guinea pigs, mice, and rats. Section 6.6, a discussion of health risk implications of CNTs, summarizes the toxicity of CNTs and addresses the potential occupational exposure risk for manufactured CNTs and the likely impact of manufactured and combustion-generated CNTs on environmental health. This chapter contains more emphasis on environmental implications of CNTs and less detail about the risk of occupational exposures than does a recent toxicological review and risk assessment of CNTs published in *Critical Review in Toxicology* [1].

## 6.2

### Carbon Nanotubes and Nanotechnology

The discovery of C<sub>60</sub> (Buckminsterfullerene) and CNTs has propelled nanotechnology to the forefront of science and engineering research in the last decade. Several government agencies, under the leadership of the National Science and Technology Council, jointly established the Interagency Working Group on Nanotechnology, shortly after the discovery of CNTs and the awarding of the Nobel Prize in

1996 for the discovery of fullerene. In 2000, this federal effort was raised by President Clinton to the level of a federal initiative, which was known as the National Nanotechnology Initiative (NNI) [2]. The NNI is promoting nanotechnology research and development to lead the United States to the next industrial revolution [3]. The National Science Foundation [4] predicted that nanotechnology will drive prodigious nanoscience research and engineering development efforts in materials science, physics, chemistry, biology, medicine, and biotechnology, and will generate, in 10 to 15 years' time, an annual business and economic impact of close to \$1 trillion. One of the major objectives of the NNI is "developing materials that are 10 times stronger than steel, but a fraction of the weight for making all kinds of land, sea, air and space vehicles lighter and more fuel efficient." The materials implicated in the initiative are CNTs.

### 6.3

#### **Manufactured Carbon Nanotubes: Their Synthesis, Properties, and Potential Applications**

##### 6.3.1

##### **Discovery and Synthesis**

CNTs are the most important and most-studied nanomaterials. They are a new allotropic form of carbon similar to fullerene (Fig. 6.1). Buckminsterfullerene was first synthesized in 1985 by a laser ablation process developed by Richard Smalley, a Nobel Prize laureate at Rice University (Houston, TX), and his colleagues [5]. CNTs were discovered in 1991 by Sumio Iijima during his investigation of fullerene formation from atomized carbon dissociated from heated graphite in an arc-discharge process [6, 7]. This Japanese electron microscopist observed CNTs, predominately multiwalled (Fig. 6.1), and other nanoparticles deposited at the graphite cathode. Ebbesen and Ajayan of Iijima's laboratory showed that CNTs could be produced in bulk quantities by varying the arc-evaporation conditions [8]. Iijima found that the synthetic yield of single-wall carbon nanotubes (SWCNTs; Fig. 6.1) could be increased by incorporating cobalt or other catalytic transition metals with the graphite source in the arc vaporization process [9]. Smalley's group at Rice University also succeeded in synthesizing SWCNTs, by adapting the laser ablation process used to make C<sub>60</sub> [10, 11]. In the arc vaporization and laser ablation processes, solid or powdered graphite is used as the carbon source, but in the chemical vapor deposition method, carbon-bearing gaseous compounds such as methane, acetylene, or other hydrocarbons are the source [12, 13]. Using carbon monoxide as a feedstock, Nikolaev in Smalley's laboratory developed a gas-phase catalytic growth of SWCNTs from carbon atoms generated from a stream of continuous-flow high-pressure carbon monoxide [14]. This patented synthesis method is referred to by Smalley's group as the HiPco™ process.

All these synthetic processes involve formation of nanotubes from carbon atoms thermally generated from the carbon-bearing sources. CNT synthesis is generally carried out in an argon or other inert atmosphere at 600–1200 °C [15]. Typically,

**Fig. 6.1.** Drawings of a  $C_{60}$  fullerene, a single-wall carbon nanotube (SWCNT), and a multiwall carbon nanotube (MWCNT); also shown are scanning electron micrographs of SWCNT ropes (A) and MWCNT ropes (B). ((B) is courtesy of Jordi Rodriguez of University of Barcelona, Spain.)

the carbon atoms are formed on the surface of the catalytic metal; they then dissolve in molten metal nanoparticles. From the molten metal, CNTs grow [15]; when they reach a certain length, they drop off from the metal particles. At the temperature of synthesis, the metal(s) needs to be catalytically active and remain in the molten state, allowing dissolution of carbon atoms in the metal(s); these requirements limit the metals that can be used, of which cobalt, nickel, iron, and molybdenum are the most common. All unprocessed SWCNT or MWCNT products contain residual metal(s). Generally metal(s) accounts for up to 30% of a raw SWCNT product; the metal content in a MWCNT product is much less (Table 6.1 below). The metal impurities are undesirable; some products on the market are sold in purified form after removal of metal. CNT products may contain other impurities that consist of non-nanotube carbon. Product purity depends on both manufacturing processes and post-manufacturing treatments.

### 6.3.2

#### Physical and Chemical Properties

Structurally, a SWCNT is a rolled-up sheet of graphene or graphite with its carbon atoms arranged in hexagonal and pentagonal patterns. It is about 1 nm in diameter and several micrometers long. MWCNTs contain multiple concentric layers

with various diameters and lengths. Immense efforts have been devoted to making CNTs longer for practical uses. Because MWCNTs are more heterogeneous, characterization of CNT physicochemical properties has been carried out predominately on SWCNTs.

Theoretical calculations and experimental results have shown that SWCNTs have highly desirable mechanical, thermal, photochemical, and electrical properties. SWCNTs are both strong and stiff, yet flexible; in fact, they are the strongest of all synthetic fibers [16]. According to Smalley, "... calculations show [they] should be somewhere between 30 and 100 times stronger than steel." [17, 18]. The van der Waals force attraction of SWCNTs causes the tubes to bundle into microscopic ropes, which in turn aggregate to form loose clumps. SWCNTs are among the best electrical conductors and can conduct electricity twice as well as copper [19]. SWCNTs have unique electron-transport properties; they may be either metallic or semiconducting, determined by the chiral vector of the tubes [20]. In a typical batch of synthesized material, one-third of the SWCNTs are metal conductors and two-thirds are semiconductors [21, 22]. MWCNTs are made up of concentrically rolled-up graphene sheets. Each rolled-up sheet is like a SWCNT, and MWCNTs probably have many physicochemical properties similar to those of SWCNTs.

### 6.3.3

#### **Applications**

Both SWCNTs and MWCNTs are very light; they are very strong and stiff and yet flexible [16]. These very desirable mechanical properties make them ideal materials, by themselves or in composites, for potential wide applications in engineering structures. Even composite materials containing CNTs may be strong enough for building such things as spacecraft structures, space elevators, artificial muscles, combat jackets, and land and sea vehicles [23]. Commenting on the SWCNTs that have metal-like properties, Smalley stated [24], "... they will conduct electricity better than copper. Membranes made from arrays of these nanotubes are expected to have a revolutionary impact on the technology of rechargeable batteries and fuel cells, perhaps giving us all-electric vehicles within the next 10–20 years." Smalley [24] further predicted that, several decades from now, CNT-based nanoelectronics having vastly greater performance and scope will supplant our current silicon-based microelectronics. CNTs also have many other potential applications.

## 6.4

### **Occurrence of Carbon Nanotubes in the Environment**

#### 6.4.1

#### **Potential Occupational Exposures and Environmental Impact of Manufactured Carbon Nanotubes**

Unprocessed CNTs are very light and can become airborne (Fig. 6.2), and if they entered the environment as fine suspended particulates they could reach the lungs

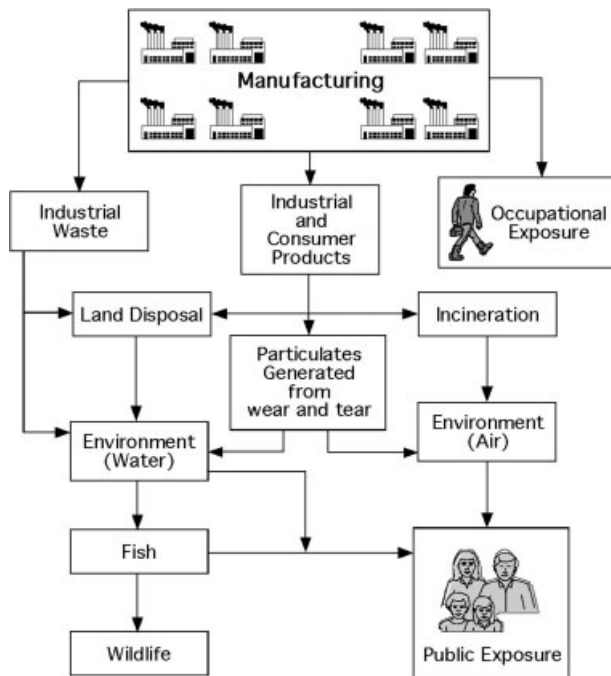

**Fig. 6.2.** (A) SWCNT particles became airborne when the raw material (HiPco CNTs) was poured between containers. (B) Contaminated gloves showing SCWNT particles appearing like black soot. (Courtesy of Dr. Andrew Maynard of NIOSH [27].)

of exposed workers. If CNTs exist in nanosize fibers, they might penetrate unprotected skin (Fig. 6.2). The CNT manufacturing industry is still in its infancy and the products remain expensive. In an interview conducted in 2003 [25], Smalley stated that the price of SWCNTs was hundreds of thousands of dollars per pound. Currently (2005), raw SWCNTs and MWCNTs are sold by BuckyUSA (Houston) at  $> \$100$  per gram (or  $> \$50\,000\text{ lb}^{-1}$ ) [26]. In 2003, Baron et al. [27], of the aerosol group of the National Institute of Occupational Safety and Health (NIOSH) visited CNT synthesis laboratories at Rice University and NASA's Johnson Space Center and the CNT manufacturing facility at Carbon Nanotechnologies Incorporated (Houston) where SWCNT are produced by the HiPco and laser processes. They observed the recovery of CNTs from synthetic ovens and reported that handling of the collected samples was gentle, and losses of this expensive material were minimized. Occupational exposure in the facilities that make these expensive materials is expected to be minimal, with very little CNT industrial waste contaminating the environment.

Smalley [28] predicted, however, that "... in time, millions of tonnes of nanotubes will be produced worldwide every year." The Department of Energy's 2010 target goal for the price of CNTs is  $\$8\text{ kg}^{-1}$  (or  $< \$20\text{ lb}^{-1}$ ). The extent of industrial and commercial applications would depend on the price of CNT products. If millions of tons of CNTs could be produced annually and if the CNT industry achieves the goal of "a couple dollars a pound," [25] occupational exposures to airborne dusts of these lightweight materials during synthesis, processing, and product manufacturing would be very substantial. Because of the potential for rapid merging or incorporation of CNTs into fabrics, plastic, lubricants, composite materials, and household commodities that are used worldwide, concerns have arisen about the adverse impact of CNTs on human health and the environment (Fig. 6.3). If

**Fig. 6.3.** Potential environmental impact and health concern when the production volume of carbon nanotubes becomes very large.

they are incorporated into materials such as plastic and composite structures, the CNT materials will need to be pulverized; working with pulverized CNTs would pose an inhalation exposure risk. In the U.S. we have also witnessed the use of asbestos in automotive brake shoes until it was found that asbestos particles generated from abrasion contribute to environmental pollution, leading the U.S. Environmental Protection Agency to ban the use of this carcinogenic material in automobiles [29]. CNTs are light and strong, and if the price of CNTs drops to a few dollars a pound, a potential exists for finding this type of application for CNTs and for them to contribute to environmental pollution. It is important that the chronic toxicity of CNT dusts be known before CNTs become more widespread.

#### 6.4.2

#### **Combustion-generated Carbon Nanotubes in the Environment**

The fact that thermal processes are used to synthesize fullerenes and MWCNTs from atomized carbon generated from heated graphite [5, 9] and the finding that carbon nanotubes can be produced by chemical vapor deposition methods involv-

ing thermally dissociated methane, acetylene, and other hydrocarbons [30] have triggered interest in looking for these carbon allotropes in the environment.

#### 6.4.2.1 MWCNT Formation from Natural Gas Combustion Indoors

Samples of airborne particulate material (PM) collected from combustion streams of methane, propane, or natural gas (containing 96% methane) of typical kitchen gas-ranges were found to contain aggregates of MWCNTs and other carbonaceous nanoforms [31–33]. The aggregates, which had aerodynamic diameters of about 0.4 to 2  $\mu\text{m}$ , were essentially pure carbon or graphene. They contained several hundred to several thousand individual MWCNTs and other carbon nanocrystals of about 20 nm diameter; individual MWCNTs were ca. 3 to 30 nm in diameter [34]. The authors [34] concluded that CNTs and fullerene nanoparticles are ubiquitous in homes with gas cooking ranges. Their findings suggest that MWCNTs and other carbonaceous nanoparticles may also be produced by water heaters, furnaces, and other appliances that use natural gas.

#### 6.4.2.2 MWCNTs in Metropolitan Outdoor Air

Outdoor airborne PM collected in El Paso (TX) by Murr et al. and analyzed using a transmission electron microscope showed the presence of MWCNTs aggregated with other forms of carbon nanocrystals (shells, spheres, and other structures) (Fig. 6.4a and b) [34]. The structure of these aggregates collected outdoors was similar to that of MWCNTs collected indoors, except that the outdoor PM included agglomerates of other mineral nanocrystals, such as silica, that are common in the atmosphere [34]. The carbon nanocrystals, largely MWCNTs, accounted for 15% of the weight of the dust. Diesel-related aggregates accounted for 5% of the dust collected. According to Murr et al., their laboratory had collected hundreds of samples in El Paso over several years and had previously characterized dusts as silica or other nanocrystals with carbonaceous materials [35]; reexamination of these samples indicated that 90% of them contained MWCNTs and other carbon nanocrystals [33]. Environmental samples collected recently from areas close to a heavy-traffic road in Houston were also shown to contain complex aggregates of MWCNTs and other carbon nanocrystals intermixed with silica nanocrystals (Fig. 6.4c and d) [34]. Murr et al. concluded that MWCNTs and carbonaceous nanoparticles are ubiquitous in the environment, and they speculated that MWCNTs make up a significant portion of airborne PM both indoors and outdoors [32].

#### 6.4.2.3 MWCNTs in Ancient Ice

Nanoparticulates were found in an ice sample from a core drilled into a Greenland ice cap to a depth of 1646 feet and dated at roughly 10 000 years old [36]. MWCNTs, fullerene-like nanocrystal forms, and silica nanoparticles were observed in complex mixtures of nanoaggregates in this sample. The aggregates were less than 1  $\mu\text{m}$  in diameter. The authors reported that the particulate pattern was similar to that they observed in samples collected from metropolitan air. These findings showed that MWCNTs and other carbonaceous nanoparticles were present in respirable particles in the air in prehistoric times.

**Fig. 6.4.** Transmission electron microscope images of environmental particulate matter collected from El Paso, TX (a, b) and from Houston, TX (c, d), showing the presence of

multi-wall carbon nanotubes [33] (Courtesy of Dr. L. Murr of University of Texas at El Paso, TX, and with permission to print from Springer Publishing Company, New York, NY).

#### 6.4.2.4 Concern about Combustion-generated MWCNTs in the Environment

MWCNTs are components of airborne particulate aggregates smaller than  $2.5\ \mu\text{m}$  in diameter ( $\text{PM}_{2.5}$ ) [32, 33]. Natural gas is considered an environmentally clean fuel. Combustion of natural gas produces only 7 pounds of PM per billion BTU compared with 84 pounds for oil and 2774 pounds for coal combustion [37]. The numbers may be underestimated if nanosize particulates were not captured. Even though natural gas produces a relatively small amount of PM, global fuel-gas consumption is very large, making the contribution of MWCNTs to air pollution very substantial. In 1999, 22 096 billion BTU of natural gas was consumed in the U.S. [38]; this was 27% of the global consumption. The consumption of natural gas, especially in indoor activities, is expected to increase, and this can be expected to increase the contribution of MWCNTs to air pollution.

Other well-established sources of  $PM_{2.5}$  include products of fuel combustion by automobiles, power plants, wood burning, industrial processes, and diesel-powered vehicles such as buses and trucks [39]. Combustion processes typically generate very fine particles of from 0.01 to 2.5  $\mu m$  [40]; combustion of fossil fuels is the major contributor of fine particulates [41]. The PM contains elemental carbon, organic carbon, trace elements, and common ions [42]. Commenting on CNTs and fullerenes, Richard Smalley stated [23, 43], “They’re also made in every candle flame and in forest fires.” If CNTs are formed in such mundane places as candle flames and forest fires, MWCNTs are likely to be produced by combustion of other fuels in addition to natural gas. Because airborne MWCNTs are ubiquitous and are present in substantial amounts in the environment, all people are exposed to this newly identified environmental pollutant.

#### 6.4.3

#### **Comparison of Physical Structures of Manufactured and Non-manufactured Carbon Nanotubes**

Manufactured CNTs are produced in ovens that allow them to form bundles, ropes, and clumps. Under optimal conditions, long fibers of high purity are preferably produced for practical applications such as spinning into threads or ropes. Most of the particles produced by CNT manufacture (such as by the HiPco and laser processes) are probably larger than respirable sizes [27]. In the environment outside the laboratory, where fuels are heterogeneous, combustion conditions are various, the reactions are not confined, and metal catalysts are generally not present, combustion-generated CNTs, which are exclusively multi-walled, are expected to be highly irregular in size and quality [34]. This probably decreases the effectiveness of van der Waals forces; MWCNTs thus produced are less orderly, shorter in length, and fewer in number than manufactured CNTs, and are intermingled with other nanoparticles (Fig. 6.4). This may explain why manufactured CNTs generally exist in larger dust aggregates whereas aggregates containing MWCNTs in the environment are often found in particles of respirable size [34].

### 6.5

#### **Toxicological Studies and Toxicity of Manufactured CNTs**

Toxicological studies on CNTs were conducted primarily to investigate the potential toxicity of manufactured CNTs in the lungs for occupational risk assessment. The first study of SWCNT toxicity, in which lung histopathology in exposed mice was examined, was triggered by NASA’s concern that workers in occupational settings could be exposed to the airborne dust of this light material of unknown toxicity [44]. The study was also supported by the Center of Nanoscale Science and Technology of Rice University; both organizations have facilities that make SWCNTs. Particle characterization of the HiPco and laser CNTs by NIOSH aerosol scientists showed that respirable particles can be generated, albeit with difficulty, from bulk

SWCNT materials [27]. Inhalation would be the primary route of occupational exposure. Parallel to the NASA study [44], Warheit et al. [45] of Du Pont Company (Wilmington, DE) conducted a toxicity study in rats of a SWCNT product made by their company. Although the two studies yielded some similar histopathological findings, the two groups reached different conclusions about the toxicity of SWCNTs, which have been a subject of wide debate. Shvedova et al. [46] of NIOSH conducted a very comprehensive study in mice “to resolve this conflict...” The toxicity of MWCNTs had drawn little attention until very recently a Belgian group led by Muller et al. [47] published their study. All these toxicological studies are outlined in Table 6.1 and are the subjects of this chapter.

The portion of dust that could reach the pulmonary region (where air exchange takes place) of the respiratory system is termed the respirable fraction (or dust). For humans, a dust particle of respirable size is generally 10  $\mu\text{m}$  or less, depending on its density and geometry; for rodents, the diameter of a respirable dust particle is a few micrometers less. The extent (fraction) of deposition of respirable dust in different locations in the respiratory system depends on the particle size, density, and geometry. To assess the toxicity of a dust in the lung, the respirable fraction is generally isolated or prepared from the bulk material.

The action of the van der Waals force causes CNTs to have a great tendency to bundle to form ropes, each containing a few hundred parallel tubes [48]. These secondary structures, in turn, aggregate into loose clumps. As shown by the NIOSH aerosol scientists for the HiPco and laser products [27], it would be difficult to isolate and collect enough fine CNT particles or clumps of respirable sizes from the bulk materials to use in an inhalation study, which would require a large amount of fine dust of this expensive material. A controlled CNT concentration would have to be generated in a chamber, and particle sizes and the actual exposure level would have to be monitored. This is difficult even with more workable dusts or powders of other compounds. Because it is technically difficult and costly to conduct inhalation toxicity experiments, investigators often assess the effects of dusts and aerosols in the lungs by intratracheal instillation (ITI) [49–51].

A dust is administered by the ITI route by injecting a suspension of a fine dust into the trachea of a small animal and allowing the dust to be pulled deeper into the lung during breathing. Dust administered by inhalation is inhaled continuously; when dust is administered by ITI it is generally instilled into the trachea as a bolus dose. Administration by the ITI route does not allow investigators to assess the effects of a test dust in the upper respiratory tract, and the distribution of dust in the lung is unnatural and less even than with administration by inhalation. In an ITI study, dust aggregates suspended in an aqueous solution usually need to be dissociated or broken down to respirable sizes by ultrasonication with or without a non-toxic dispersion agent. A dose of dust particles administered by ITI can swamp the respiratory system's dust clearance mechanisms, and ITI results are often exaggerated. However, an ITI study does allow investigators to determine the relative toxicity of the test material by giving reference compounds of known inhalation toxicities to control groups of animals [52, 53]. The ITI administration

route is acceptable for screening dusts for pulmonary toxicity, if the investigators or risk assessors recognize the limitations of this technique [51].

#### 6.5.1

##### **Study of SWCNTs in Guinea Pigs by Huczko et al. of Warsaw University**

Huczko et al. conducted the first animal study on the toxicity of CNTs [54]. They intratracheally instilled two groups of five guinea pigs each with a bolus dose of 0 or 25 mg of CNT-containing soot in saline solution. They found no difference between the two groups in tidal volume, breathing frequency, or pulmonary resistance. Analysis of bronchoalveolar lavage fluid (BALF) obtained from the CNT-treated and control animals indicated that treatment with CNTs had no effect on cell differentials or total protein concentration. The authors concluded that “the soot with a high content of CNTs does not induce any abnormalities of pulmonary function or measurable inflammation in guinea pigs treated with carbon nanotubes.” However, examination of lung pathology, which is the most critical toxicological endpoint of any pulmonary toxicity study with dust, was not included in the study. Lung pathology was examined in the other studies reviewed in this section.

#### 6.5.2

##### **Study of SWCNTs in Mice by Lam et al. of NASA-JSC Toxicology Laboratory**

Lam et al. conducted a pilot 7-day ITI study to determine pulmonary toxicity of an early experimental SWCNT sample made at Rice University by the laser evaporation process and containing nickel. The ITI method used was a modified version of a method previously used in our laboratory [54]. Granulomas were observed in mice (C57/BL/6J) treated with 1 mg SWCNT per mouse. Because the test sample contained 10% (by weight) residual nickel, the lung lesions could not be attributed to the effect of CNTs.

A “core” study was conducted to assess the intrinsic toxicity of CNTs and the influence of the residual metals in the toxicological manifestation of the test compounds. The three types of CNTs we studied had been manufactured by different processes and contained different types and/or amounts of residual metals (Table 6.1) [44]. These materials were (1) unprocessed iron-containing SWCNTs made by the HiPco process, (2) a purified HiPco product that had been vigorously treated with concentrated acid to remove metal residues [56], and (3) a CarboLex SWCNT sample, made by an arc-discharge process, that contained nickel and yttrium. The core study included two standard reference materials: carbon black (Printex 90<sup>®</sup>, a dust with relatively low toxicity) and quartz (Min-U-Sil 5<sup>®</sup>, a fibrogenic dust). Groups of B6C3F<sub>1</sub> mice (4 mice per group for 7 d, 5 mice per group for 90 d) were intratracheally instilled with a suspension of the test dust (0, 0.1, or 0.5 mg 50  $\mu\text{L}^{-1}$  per mouse, equal to about 0, 3.3, or 16.5 mg  $\text{kg}^{-1}$ , respectively). Mice were euthanized 7 or 90 d after the single treatment, and their lungs were excised, fixed, and stained for histopathological study [44].

Lung histopathology results showed that CNTs induced lesions, chiefly intersti-

tial granulomas (Fig. 6.5), in the lungs of the 7-d and 90-d groups of mice [44]. These microscopic nodules, located beneath the bronchial epithelium, were present throughout most of the microscopic fields of lung tissue. The lesions were similar to the ones we saw in the pilot study. The granulomas contained macrophages that had engulfed CNTs, but they contained very few inflammatory cells. The severity of lesions was dose-dependent. Prominent granulomas were found in the lungs of all the mice that received 0.5 mg CNTs per mouse. Granulomas were less prominent but were still observed in the mice each treated with 0.1 mg of HiPco-synthesized CNTs. The lung lesions in the 90-d high-dose groups were generally more pronounced than those in the 7-d high-dose groups. The lungs of some animals in the 90-d groups showed peribronchial and interstitial inflammation, fibrosis, and necrosis that had extended into the alveolar septa. Mice in the group treated with carbon black had black particles in alveolar regions, but tissue reactions were minimal (Fig. 6.5a). The lungs of mice treated with the high dose of quartz had mild to moderate inflammation. The lesions induced by quartz were considered much less severe than those produced by CNTs. Similar results were obtained for all three types of SWCNTs. The lungs of mice in the serum control groups were normal. Lam et al. concluded that SWCNTs are intrinsically toxic to the lungs; these authors advise caution in allowing exposure to the dust and advocate implementation of strategies to minimize human exposures [44].

### 6.5.3

#### **Study of SWCNTs in Rats by Warheit et al. of DuPont Company**

Warheit et al. also presented evidence that CNTs produce granulomas in the lungs of treated animals [45]. These authors instilled a suspension containing a laser-synthesized SWCNT product (containing nickel and cobalt) into the trachea of Sprague–Dawley (CrI:CD(SD)IGS BR) rats. In addition to examining lung histopathology, Warheit's group assessed biomarkers of toxicity in bronchoalveolar lavage fluid (BALF) obtained from the treated rats. The animals were given the CNTs (suspended in saline containing 1% Tween 80) at 0, 1, or 5 mg kg<sup>-1</sup> (0, 0.25, or 1.25 mg per rat) and were euthanized at 1, 7, 30, or 90 d after the single treatment. The high dose in this rat study was comparable to the low dose in the NASA mouse study. Histopathological results revealed multifocal granulomas, which became evident 1 month after the treatment (Fig. 6.6). The authors found that instillation of CNT dust produced granulomatous lesions in the lungs of treated rats, and the lesions were non-dose-dependent, non-uniform, and non-progressive. Quartz was given as a positive control, and was observed to produce cytotoxicity, inflammation, and fibrosis in a dose-dependent manner. Study of the BALF showed that SWCNTs induced only a transient increase in the concentration of lactate dehydrogenase (LDH; marker of cytotoxicity) in the 1-d group. Quartz at a high dose produced increases in LDH and protein concentrations at all time points. Unable to find a dose-dependent and time-dependent granulomatous response, or prolonged inflammation in the lungs, coupled with the observations

**Fig. 6.5.** Lung tissues from mice intratracheally instilled with 0.1 or 0.5 mg per mouse of a test material and euthanized 7 or 90 days (d) after the single treatment. (A) Carbon black, 0.5 mg, 90 d. Particles were scattered in alveoli, and no tissue reaction was observed. (B) Purified HiPco CNTs, 0.1 mg, 7

d. The figure shows a low-grade granuloma. (C) CarboLex arc-produced CNTs, 0.5 mg, 7 d. A well-defined granuloma is shown. (D) Unprocessed HiPco CNTs, 0.5 mg, 90 d. Granulomas, alveolar wall thickening, and some fibrotic tissue are shown. Magnifications 40–200 $\times$ .

**Fig. 6.6.** Granulomas in lung tissues from rats 1 month after they were intratracheally instilled with 1 mg kg<sup>-1</sup> of laser-synthesized CNTs. (Courtesy of Dr. David Warheit.)

that CNTs have a great tendency to aggregate, Warheit et al. concluded that the granulomatous reaction was a nonspecific response to instilled aggregates of SWCNTs and the results may not be relevant to human exposures [45]. Warheit showed that some instilled CNTs stuck in the major airway and the mechanical blockage suffocated 15% of the high-dose group. The proportion of the dose that clogged the airway must have been substantial. The inability of the dose to reach the alveolar region, where CNT-induced granulomas could occur, may partially explain why the results were both non-dose- and non-time-dependent.

#### 6.5.4

##### **Study of SWCNTs in Mice by Shvedova et al. of NIOSH**

As pointed out above, to address the differences in conclusions about the potential hazard of exposures to SWCNTs drawn by Lam et al. and Warheit et al., Shvedova et al. [46] carried out a comprehensive pulmonary toxicity study in mice (C57CL/6), testing a purified HiPco CNT product (>99% SWCNTs) that was exhaustively subjected to purification to remove metals (final iron content 0.23% by weight). The animals were given a single treatment of CNTs, carbon black, or quartz at a dose of 0, 10, 20, or 40  $\mu\text{g}$  per mouse (about 0, 0.5, 1, or 2  $\text{mg kg}^{-1}$ , respectively). Aqueous suspensions of test dusts were aspirated at the pharyngeal area of mice, allowing droplets to be pulled into the lung during inspiration. The mice were then killed 1, 3, 7, 28, or 60 d after treatment. Histopathological examination of the lungs showed an acute inflammation, early onset of formation of granulomas, and progressive fibrosis. The histopathology was characterized by SWCNT-induced granulomas mainly associated with hypertrophied epithelial cells surrounding the dust aggregates, and diffusive interstitial fibrosis and alveolar wall thickening likely associated with dispersed SWCNTs. The total mass of granulomas in the lungs of mice in the 60-d group increased with an increase in the CNT dose. In general, lung lesions were dose-dependent and progressive, like those reported by Lam et al. [44]. Pulmonary function tests showed increases in functional respiratory deficiencies with increased concentrations of CNTs, a finding consistent with fibrosis. Compared with saline-treated controls, CNT-treated mice showed slower bacterial clearance assessed 7 days after bacterial inoculation. The test doses of quartz and carbon black did not induce granulomas or fibrosis.

Like Warheit et al., Shvedova et al. [46] examined the biomarkers of toxicity in BALF from CNT-treated animals. The results showed increases in total protein concentration, cell counts, concentration of transforming growth factor beta (TGF- $\beta$ ), and LDH and  $\gamma$ -glutamyltranspeptidase activities; these biomarkers of inflammation or cytotoxicity in the lungs were dose-dependent. Shvedova et al. concluded that crystalline silica caused less cytotoxicity than CNTs (compared on an equal-weight basis) and recruited fewer polymorphonuclear leucocytes into the lungs. These biomarker results from mice treated with quartz and SWCNTs differ from those of a similar study in rats reported by Warheit et al. and discussed above [45]. Like Lam et al. [44], Shvedova et al. demonstrated that CNTs were intrinsically

toxic and cautioned that exposures of workers to high concentrations of respirable SWCNT particles may pose a risk of developing some lung lesions.

#### 6.5.5

##### **Study of MWCNTs by Muller et al. of Belgium**

MWCNTs have been shown to produce lung lesions similar to those observed in studies with SWCNTs. Muller et al. tested two forms of MWCNTs, unprocessed (unground) MWCNTs and MWCNTs that had been ground [47]. They reported that 60 days after rats (Sprague–Dawley) were each given a single ITI dose of 0.5, 2, or 5 mg MWCNTs (sonicated and suspended in a normal saline solution containing a dispersing agent, Tween 80) their lungs showed inflammation, granulomas, and fibrosis. The unground CNTs remained in the bronchial lumen and produced collagen-rich granulomas. The bronchial lumen was partially or completely blocked, as in the study by Warheit et al. [45]; very few CNT particles were seen in the parenchymal (alveolar) region. The ground CNTs were “better dispersed” in the parenchyma and in the interstitium induced granulomas consisting of macrophages laden with particles, multinuclear giant cells, and some inflammatory cells, like those reported by Lam et al. [44]. Muller et al. [47] also showed that hydroxyproline and soluble collagen, two biomarkers of fibrosis, increased in the lung tissues in a dose-dependent fashion. BALF obtained from rats 3 days after the CNT treatment showed dose-dependent increases in LDH activity, total protein concentration, and neutrophil number. Muller et al. also concluded that CNTs are potentially toxic and advocated strict industrial hygiene [47].

## 6.6

### **Health Risk Implications**

#### 6.6.1

##### **Toxicity Summary of CNTs and Occupational Exposure Risk**

The results of four histopathology studies reported previously in the literature and reviewed here collectively showed that SWCNTs and MWCNTs themselves were capable of inducing granulomas and other lesions in the lungs, regardless of the process by which they were synthesized and the types and amounts of metals they contained. The metal residues and other impurities played only a small role in the formation of these pulmonary lesions (see Lam et al. [1] for detailed discussion). Dust of respiratory size is difficult to separate from bulk materials because CNT bundles or ropes tend to stick to each other. Moreover, all four studies were conducted similarly by ITI to expose a rat or mouse to a fine-particle suspension of a CNT dust ultrasonicated in an aqueous system containing a dispersing agent, or by pharyngeal aspiration of a CNT suspension obtained by boiling and sonicating CNTs. These instillation or aspiration studies, involving CNT particles mechanically dispersed in an aqueous system containing a dispersion agent, are considered

screening assays of CNTs for potential pulmonary toxicity [44, 45]. However, even though these studies do not answer the important health risk question of whether airborne CNT particles can reach the lungs, they do reveal the intrinsic toxicity of CNTs. The findings convey the important message that if a CNT product contains a substantial amount of respirable dust that reaches the lung at a high enough concentration it is likely to produce the types of serious lung lesions seen in rodents. Certainly, it would be very important to conduct inhalation studies to confirm these pathology findings; data from inhalation studies are also needed for setting occupational exposure limits. Because it is difficult to conduct an inhalation study on CNTs, inhalation toxicity data will not be available for some time.

Lam et al. [44] and Shvedova et al. [46], who used carbon black and quartz as references in their comparative toxicity studies, concluded that if CNTs reach the lungs, under the test conditions described here and on an equal-weight basis they are much more toxic than carbon black and can be more toxic than quartz, chronic inhalation of which is considered a serious occupational health hazard. Study with MWCNTs led Muller et al. [47] to reach the same conclusion, i.e., that CNTs are intrinsically toxic. Therefore, it is prudent to assume that if significant amounts of airborne fine CNT particles were present in a workplace, occupational exposures to CNTs could produce substantial injury in the lungs and potentially the upper respiratory tract (see Lam et al. [1] for a detailed risk assessment of occupational exposures). If CNT dust is present in a work environment, strategies to minimize human exposure to it should be implemented.

### 6.6.2

#### **Impact of SWCNTs on Environmental Health**

The manufacture of CNTs is still on a small scale and the products remain expensive; the current impact of manufactured CNTs on environmental health is nonexistent or very minimal. However, if millions of tons of CNTs are produced annually some day, as predicted by Richard Smalley [28], and if the CNT industry achieves the goal of charging “a couple dollars a pound” for CNTs [25], then CNTs will likely be incorporated or formulated into fabric, plastic, composite materials, and household commodities that will touch all aspects of human life. Then CNT-containing industrial wastes and degraded CNT-containing materials will probably appear in the environment (Fig. 6.2). Will CNTs bioaccumulate in the environment? Will ingested SWCNTs in the alimentary canal reach internal organs to produce toxicity? Studies will need to address these environmental health issues.

### 6.6.3

#### **Toxicity of MWCNTs and Impact on Environmental Health**

Murr and colleagues found MWCNTs in fine particulate matter generated from combustion of natural gas in typical kitchen ranges [31–33]. Finding MWCNTs in PM collected indoors and outdoors, they concluded [32] that MWCNTs and carbonaceous nanoparticles are ubiquitous in the environment. They further speculated

that MWCNTs are a major component of indoor and outdoor airborne PM. Because MWCNTs are ubiquitously present in fine airborne particulate aggregates in our environments [34], it is reasonable to postulate that all humans are exposed to low levels of MWCNTs.

Dockery et al. found a positive correlation between fine particulate air pollution and excess mortality in six U.S. cities [56]. In a large-scale epidemiological study with 1.2 million adults, Pope et al. [57, 58] found that fine PM in ambient air is a risk factor associated with cardiopulmonary mortality and cardiovascular and pulmonary diseases. The underlying mechanisms by which exposure to fine PM might play a role in the pathogenesis of cardiopulmonary diseases are not known [59]. Pollutants may produce oxidative lung damage and inflammation [60]. Seaton et al. have proposed that fine particles deposited in the lung provoke alveolar inflammation, which causes potentially harmful cytokines to be released [61].

The pulmonary toxicity of SWCNTs and MWCNTs are similar; collectively, CNTs can produce lung lesions and biomarkers of toxicity, such as inflammation, fibrosis, granulomas, harmful cytokine release, and oxidative biochemical toxicological changes. Shvedova et al. also showed that SWCNTs impaired pulmonary functions and bacterial clearance. In a cell culture study, Monteiro-Riviere et al. have found that MWCNTs caused release of the proinflammatory cytokine interleukin 8 [62].

Gauderman et al. have found that adverse effects on the growth of lung functions in teenagers were associated with exposures to NO<sub>2</sub>, acid vapor, fine PM, and elemental carbon, which had the highest correlation ( $p = 0.007$ ) [63]. Fine PM, derived primarily from combustion, contains elemental carbon; MWCNTs, which are also produced by combustion, were found in fine PM collected in outdoor air in El Paso and Houston. The results of the four studies reviewed here showed that manufactured MWCNTs and SWCNTs were much more toxic than ultrafine carbon black (used as a negative control by Muller et al. [47] and Shvedova et al. [46]) and graphite (used in the study by Warheit et al. [45]). It is probably true that environmental MWCNTs are a minor component in fine PM, but the unique toxicity of CNTs, which has not been seen with other elemental forms of carbon, raises a concern about these combustion-generated fibrous MWCNTs. Very possibly, they play a significant role in the pathogenesis of pollution-related cardiopulmonary diseases. Confirmation of this postulation requires results from toxicity studies on this newly-identified environmental pollutant.

### Acknowledgment

The authors thank Dr. J. Krauhs for technical editing and Dr. D. Warheit of DuPont Company, Dr. A. Maynard of NIOSH, Dr. L. Murr of University of Texas at El Paso, TX, Dr. J. Rodriguez of University of Barcelona, Spain, and Springer Publishing Company, New York, NY, for granting permission to use their figures.

## Toxicity of Nanomaterials – New Carbon Conformations and Metal Oxides

Harald F. Krug, Katrin Kern, Jörg M. Wörle-Knirsch,  
and Silvia Diabaté

## 7.1

### Introduction

Nanomaterials are on the same scale as most elements of living cells, including proteins, nucleic acids, lipids and even cellular organelles. When considering nanoparticles it must be asked how man-made nanostructures can interact with or influence biological systems. On the one hand, nanosystems are specifically engineered to interact with biological systems for particular medical or biological applications. On the other hand, the large-scale production of nanoparticles for either non-medical applications or as side-product of combustion processes may affect a wide range of organisms throughout the environment. Since the 1970s, an increasing number of investigations concerning the use of nanoscale structures, e.g., liposomes, for drug transport and comparable applications have been undertaken [1–9]. In addition to liposomes, nanoparticles produced from other materials came into the focus of physicians for various treatments of diseases [10–16]. This work aims to design inert auxiliary accompanying materials and to use body-friendly and biodegradable excipients. However, dependent on their target organ and functionality, not all of these materials are degradable and some stay in the body for long periods. In light of this, side effects and foreign body reactions may be detectable and a good local and systemic tolerance during and after medication should be a condition *sine qua non*.

Nanostructured materials come into contact with biological systems not only through their use in drug delivery systems or for gene transfer. They are also produced for food and cosmetic chemistry and many other technical applications (Tab. 7.1). The increasing production, particularly of metal oxide nanoparticles and new carbon materials, will enhance the possible exposure at work places, packing stations and during application of the products [17]. In addition, waste treatment and containment at the end of a products life cycle must be considered. For all these reasons, it is of great interest to determine how these materials, when coming in contact with living organisms, are taken up, transported in or through cell layers, and affect biological functions. To cover these questions we review the latest

results from various studies on the biological effects of nanoparticles that may be the basis for adverse effects, especially in humans. Because metal oxides are the most prominent produced variants of nanoparticles and new carbon modifications are the most promising ones we focus on these two types with respect to their cellular uptake and possible influence on important cellular mechanisms *in vitro*. The effects of ambient particulate matter or particulate emissions from combustion devices such as diesel engines or oil burners are not reviewed. These particles, produced unintentionally with a complex chemical composition, are released into the environment and affect the general population. Although these particles stimulated much concern over their health effects, this chapter concentrates on the effects of intentionally produced nanoparticles of low solubility with well-known chemical composition, form and size to provide condensed information for a possible occupational exposure. Our short overview on biological hazards ends with a more general aspect of the risks connected with the production and use of nano-

materials and, on the other hand, the opportunities that are an important component in all long-term considerations.

### 7.1.1

#### **Nanoscale Materials and Adverse Health Effects: Precautionary Measures**

Although nanoparticles have been used in various products for several decades, the expected increase of production and use of newly developed materials makes the question of their safety to life and the environment increasingly important. However, classical risk regulation is not adequate because the risk can not be quantified. At this early stage, where most of the materials are under development and produced only in small amounts for research laboratories, precautionary measures can be taken to keep exposure below particular thresholds and avoid possible adverse effects by employing the “as low as reasonably achievable – ALARA” principle. As soon as the conditions required for the risk management approach are no longer fulfilled, controversies and ambivalent situations result. This is especially the case if fundamental knowledge concerning the toxicity of these materials is missing, controversial, or based on not sufficiently validated experimental models. In past cases, severe adverse effects resulting from the implementation of new materials or technologies were not been detected at an early stage (e.g., asbestos) and the resulting health, environmental, and economic damage has spurred calls for stronger regulatory measures. These debates resulted in the implementation of the precautionary principle in the European Union that reached wide international agreement during the Earth Summit (United Nations Conference on Environment and Development, UNCED) in Rio de Janeiro 1992 and became part of Agenda 21. Based on this, several demands have to be made for nanotechnology and its products:

1. Without knowledge of possible adverse effects, nanoparticle exposure should be avoided at work places as well as in the population and the environment.
2. Multiple studies are necessary to clarify the biological effects of nanoparticles, with the caveat that different materials, sizes and surface characteristics often behave differently.
3. As with normal chemicals, extrapolation from *in vitro* system and/or animal experiments with regards to a specific nanoparticle is reasonable for judging human exposure to the nanoparticle in question, but can not be the base for a fundamental evaluation or assessment of nanoparticles in general.

As past experience has illustrated, precautionary measures are needed for nanotechnological developments, new materials, and nanoparticles [18, 19]. However, the call for a moratorium on nanotechnology is unrealistic because a moratorium for the chemical, physical and pharmaceutical industries (new substances and new techniques are possible new hazards and risks) would logically follow. From the point of view of toxicologists, the database of biological effects of nanoparticles must be increased by intensifying research on adverse health effects of these new

## Risk Assessment

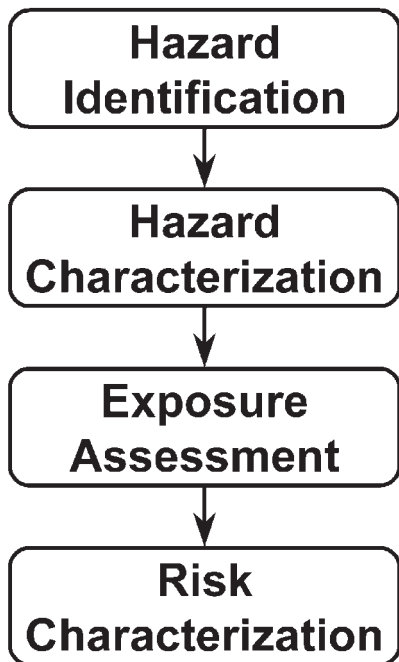

Fig. 7.1. Sequence of events leading to risk assessment.

materials. Most of the presented data in this chapter on nanosized metal oxides and carbonaceous materials are either preliminary or poorly confirmed by other research groups. So far, few nanomaterials have been investigated intensely. These two nanomaterial categories are in production for commercial applications and, therefore, several studies on their health effects have already been performed, whereas information on the impact of nanomaterials on the environment is rare and hence considered marginally.

### 7.1.2

#### **Hazard Identification and Exposure Estimation**

The health and safety issues related to metal oxides and carbon nanomaterials are in a very early phase. Hence, it seems premature to draw far-ranging conclusions regarding the potential hazards related to exposures to these materials. Since the toxicology database for inhalation or dermal exposure to these nanomaterials is rather sparse, efforts to obtain this information must be intensified. Most important is the development of methodologies and protocols concomitant with the implementation of hazard/toxicity studies, as well as workplace exposure assess-

ments, to better ascertain the impact of nanomaterials on human health. For a valid risk assessment both parts of the following equation must be taken into account:

$$\text{Risk} = \text{Exposure} \times \text{Hazard}$$

Within the risk assessment procedure, hazard identification is the first step (Fig. 7.1). Because of the lack of knowledge, it is an open question as to whether established mechanisms of risk analysis and risk regulation may be applied to nanotechnology. Regardless, both hazard characterization and exposure assessment are fundamental pre-requisites, leading to risk characterization.

## 7.2

### Production and Use of “New Carbon Modifications” and Metal Oxides

Nanoscaled insoluble metal oxides are used in applications in almost all fields of technology and industry (Tab. 7.1). They are used as additives in sun screens and textiles to block UV light ( $\text{TiO}_2$ ), to clear apple juice and beer ( $\text{SiO}_2$ ) as well as to degrade toxic chemical waste very efficiently ( $\text{MgO}$ ). While only poor data is available on the toxicity of most synthesized nanoparticles, most investigations on these new materials have been done with titania and silica. At present the assessment of nanoscaled metal oxide toxicity is focused on free and primary particles. As nanoparticles are sintered and agglomerated to larger structures, they lose most of the vast toxic potential to human health that appears in primary particles.

Carbonaceous particles are generated by pyrolysis of gaseous or liquid hydrocarbons, or by spark generation between two graphite electrodes. The most common product is *carbon black*, consisting of amorphous, variably sized colloidal particles of elemental carbon (Fig. 7.2). In contrast to soot, which results from incom-

**Fig. 7.2.** Transmission electron micrograph of carbon black (Printex 90), showing aggregates of primary particles with an average diameter of 14 nm. (T. Detzel, ITG.)

**Fig. 7.3.** Transmission electron micrograph of (a) single SWCNT and (b) MWCNTs forming a bundle. (T. Detzel, ITG.)

plete combustion of carbon-containing material, carbon black contains only low amounts of solvent-extractable organic matter. The material is used as an additive in the rubber of automobile tires, in inks, batteries and protective coatings.

Buckyballs (also known as fullerenes) are cage-like molecules, e.g. the spherical buckminsterfullerene, which consists of 60 carbon atoms ( $C_{60}$ ) and was discovered in the 1980s [20]. They can be generated in the arc between two graphite electrodes in a helium atmosphere. The heat vaporizes the graphite, and fullerenes form as the gaseous carbon cools.

Carbon fibers consisting of amorphous carbon with a diameter of 7–10  $\mu\text{m}$  have been produced by similar methods since the 1980s. The fibers are embedded in resin or plastic to produce composite materials used in aerospace, automotive, sports goods, and prosthetic industries. By modification of the production method, long tube-like *carbon nanotubes* are formed [21]. Single-walled carbon nanotubes (SWCNTs) have a diameter of 1–2 nm and are up to 100  $\mu\text{m}$  long. Multi-walled carbon nanotubes (MWCNTs) consist of several layers of carbon cylinders, which increases the diameter to 10–30 nm (Fig. 7.3). This new material has high potential for new commercial products because it exhibits very interesting properties such as great tensile strength, high conductivity, or unique electronic features. Therefore, it is predicted that tons of carbon nanotubes will be produced worldwide every year in the near future [22].

Recently, carbon fibers with nanometer dimensions have been synthesized [23]. The diameters range from 60 to 200 nm and, unlike carbon nanotubes, they do not possess a helical carbon arrangement (Fig. 7.4). There is evidence that when carbon nanofibers are used as an orthopedic or dental material some of the common problems associated with implant material such as insufficient cytocompatibility may be avoided.

**Fig. 7.4.** Carbon nanofibers of different size and properties. (a) Screws (CNF-SC) are 50 to 200 nm in diameter and 1 to 10 µm long (upper left). (b) Platelets (CNF-PL) are between 150 and 250 nm in diameter and 5–50 µm long. (c) Herringbones (CNF-HB) are

the thickest and shortest fibers, with a diameter of 200–600 nm and a length of 0.5 to 5 µm. These fibers are used as catalysts, part of composite materials, different polymers etc. (Reprinted with permission of FutureCarbon GmbH, Bayreuth.)

### 7.2.1

#### Health Aspects

It is of increasing concern to the public as well as toxicologists and occupational physicians that nanotechnology may create contaminants whose tiny size makes them ultra-hazardous. A further complication is that these very small materials may bind or react with other contaminants in the air or water that are harmful and facilitate their transport into living organisms, thus leading to additional adverse effects.

Most knowledge of the adverse health effects of very small particles comes from recent studies on ambient ultrafine particles (UFP) unintentionally released into the atmosphere. Epidemiological studies have shown that increased levels of UFP (<0.1 µm in aerodynamic diameter) are associated with increased respiratory and cardiovascular mortality and morbidity as well as worsening of asthma. These effects were observed in particular in susceptible persons such as the very young and old, and those with compromised respiratory and cardiovascular systems [24–

**Fig. 7.5.** Scanning electron micrograph demonstrating deposition of inhaled iron carbonyl particles at the alveolar duct bifurcations in the distal lung of a rat. (Reprinted from Ref. [31], with permission from Elsevier.)

26]. The composition of ambient UFP includes organic and elemental carbon, metals, chloride, nitrate and sulfate. Since the core typically consists of elemental carbon [27], it was obvious to study the biological effects using ultrafine carbonaceous particles as model particles.

#### 7.2.2

#### **Uptake and Possible Transport, Depots, and Accumulation in Living Organisms**

Most studies on the uptake and transport of nanoparticles as well as the formation of depots and their accumulation have been performed *in vivo* (Fig. 7.5). The laboratory of Günter Oberdörster carried out fundamental studies during the last decade that delivered basic data on distribution, uptake and retention of titanium nanoparticles in lungs of rats or mice. It was demonstrated that after instillation or inhalation in rats, equivalent masses of 20 nm  $\text{TiO}_2$  were deposited in the alveoli and accessed the pulmonary interstitium to a significantly larger extent than 250 nm  $\text{TiO}_2$  particles [28, 29]. This resulted in a prolonged retention of the smaller particles in the lung. But these studies in rat also indicate that there is a difference between inhalation and instillation of nanoscaled  $\text{TiO}_2$ . As measured by bronchovascular lavage parameters, animals receiving particles via inhalation showed a decreased pulmonary response, in both severity and persistence, compared with animals receiving particles via instillation [30].

Dose–response curves are incompatible when the instilled mass of ultrafine and fine  $\text{TiO}_2$  particles are used as parameters for the measured neutrophil infiltration. Alternatively, when using the particle surface area of the instilled dose, it became obvious that the inflammatory response in the lung for both ultrafine and fine  $\text{TiO}_2$  fitted the same dose–response curve [32]. These results strongly suggest that for particles of the same surface material/chemistry, such as  $\text{TiO}_2$ , particle surface area is a more important dosimetric parameter than particle mass (or particle number). The same authors demonstrated a perfect correlation of the inflamma-

tory response in both experimental animals by fitting the particle surface dose with the lung weights of mice and rats. This assumption to use surface area as a relevant dosimetric parameter to express toxicity data is confirmed by several studies but has to be validated in more detail (for further literature see Ref. [33]).

During the last decade several studies have shown that the response to instillation or inhalation of nanoscaled  $\text{TiO}_2$  in various species such as hamster, rat, or mouse differs. Under conditions of equivalent lung burden with nanoscaled  $\text{TiO}_2$ , rats developed more severe inflammatory responses than mice, while the clearance of particles from the lungs was markedly impaired in both species [34]. In contrast, the clearance rate of hamsters is totally unaffected at all applied particle concentrations. The difference in clearance rates seems to be caused by a translocation of the particles into the lymph nodes of rats and mice. This was not seen in hamsters and thus the retention time in hamsters is shorter. Another variation within the three species was described by histopathological methods. After instillation or inhalation of nanoparticles an accumulation of particle-loaded macrophages surrounded by normal alveolar structures has been observed in hamster, whereas in rats the particle-loaded macrophages accumulate intra-alveolar. Moreover, interstitial fibrosis and alveolar metaplasia of lining epithelium has been demonstrated in rats and were not noted in either mice or hamsters. In contrast, no macrophage accumulation could be detected in hamsters [35]. A further study showed that, compared with mice or hamsters, rats were hypersensitive to a high lung burden of insoluble dust [34].

For ultrafine cadmium oxide particles, *in vivo* studies in rats were performed and showed that the inhaled particles cause an increasing cadmium content in lung, liver, kidney and blood. However, systemic translocation of the particles only appeared if the animals were exposed to high particle concentrations, which generated lung injury. J774 macrophages treated with CdO were swollen with poorly preserved cell membranes, cytoplasmic structures and nuclear morphology [36].

Few studies have been performed within *in vitro* systems dealing with the transport and uptake of nanoparticulate metal oxides and a direct comparison of these studies is not feasible because different cell types and particles differing in size and material were used. Fundamentally, metal oxide and carbonaceous nanoparticles can be taken up by cells by very different mechanisms (Fig. 7.6). In several human cell lines nanoscaled material, such as  $\text{TiO}_2$ ,  $\text{SiO}_2$  and  $\text{ZrO}_2$ , was taken up into the cells [37]. The incorporated particles were detected in autophagic vacuoles, which also contained amorphous cellular material and membranes [38], as well as within the cytoplasm (Fig. 7.7).

Nanoscaled  $\text{TiO}_2$  significantly impaired macrophage phagocytosis at a lower dose than its fine counterpart [39]. Thus, the slower clearance of ultrafine particles from the lung can be in part attributed to a particle-mediated impairment of macrophage phagocytosis. Nanoscaled  $\text{TiO}_2$  caused cytoskeletal dysfunction as decreased phagosome transport and increased cytoskeletal stiffness could be observed in concentrations of  $100 \mu\text{g mL}^{-1}$  per  $10^6$  cells and above in macrophages [40].

A more recent study demonstrated that particle size and particle composition, respectively, were responsible for the observed biological effects by using hematite

Fig. 7.6. Possible cellular uptake pathways for particles of different sizes.

(70 nm) and amorphous  $\text{SiO}_2$  between 40 and 300 nm in diameter. Furthermore, co-culture systems of lung epithelial cells and macrophages showed an increased sensitivity to particle exposure concerning the cytokine release in comparison to the monocultures of each cell type [41].

Fig. 7.7. Fluorescence micrographs of human lung epithelial cells (A549). (a) Caveolin detected with Cy3 coupled antibody, demonstrating the overall appearance of caveoli within these cells. (b) A549 cells after exposure to  $\text{ZrO}_2$  (5 nm in diameter) coated

with Coumarin 307 (blue fluorescence). The particles are equally distributed in the cytoplasm of the cells whereas none could be detected within the nuclei (counterstained with ethidium bromide – red fluorescence). Magnification: 630-fold. (K. Kern, ITG.)

The deposition and fate of inhaled ultrafine carbon particles generated by spark discharge (26 nm) was studied with the stable isotope  $^{13}\text{C}$  [42]. In the rat model, more than 50% of the  $^{13}\text{C}$  particles was rapidly translocated to the liver within 24 h while no significant increase in  $^{13}\text{C}$  was detected in the other organs. In contrast, another study with insoluble ultrafine  $^{192}\text{Ir}$  particles (15–20 nm) detected less than 1% translocation into the extracellular organs. The particles not only accumulated in the liver, but also in spleen, kidneys, brain and heart [43]. Interestingly, in this study a much lesser fraction of ultrafine particles could be removed by bronchoalveolar lavage compared with inhalation studies with larger particles. It was suggested that the ultrafine particles penetrate the epithelium or the interstitium where they are retained. A human study observed an uptake of 3–5% of radiolabeled carbonaceous ultrafine particles into the blood and translocation into the liver [44]. These results differ from those of Brown and colleagues [45] who could not find any particles outside the lungs and the cleared fractions after inhalation of an ultrafine technetium-99m-labeled carbon aerosol in their human study.

Newer studies indicate that inhaled ultrafine  $^{13}\text{C}$  particles translocate into the brain of rats. The particles are suggested to deposit on the olfactory mucosa of the nasopharyngeal region and translocate via the olfactory nerve to the brain [46]. Despite conflicting results, it can be summarized that inhaled ultrafine particles are able to translocate to extrapulmonary organs via the blood; however, this fraction is very low.

**Fig. 7.8.** Near-infrared fluorescence image of one macrophage-like cell incubated with SWCNTs, showing emission detected from 1125 to 1600 nm with excitation at 660 nm. Intensities are coded with false color, and the image was obtained from a z-axis series by

deconvolution processing. Intensity along the yellow vertical line is plotted in the graph on the right, showing high image contrast and localized emission sources. (Adapted with permission from Ref. [50].)

Despite recent investigations in systemic transport, none of the published data strongly illustrate that a substantial amount of the inhaled dose is indeed translocated systemically [43, 47–49]. Carbonaceous particles are particularly difficult to detect in cells and tissues by electron microscopy because of low contrast and small diameters. Recently, near-IR fluorescence was applied to detect SWCNTs after phagocytosis in mouse macrophages (Fig. 7.8).

The image clearly shows the nanotubes inside the cell [50]. Because of their photostability, which is comparable to quantum dots, carbon nanotubes might be applied as fluorescent markers and contrast agents with low toxic potential for cell biology research and medical diagnosis. Diabaté et al. also demonstrated by transmission electron imaging that carbon nanotubes are taken up by macrophages and epithelial cells as bundles [51]. These large agglomerates of carbon nanotubes as well as single nanotubes separated from these bundles can be clearly detected within the cells by this method (Fig. 7.9).

There exist several studies on the uptake and distribution of nanoparticles within cells. In nearly all these experiments the investigated cells have ingested the applied nanoparticles. Only two examples demonstrate the fact that nanoscaled metal oxide particles are found in cellular systems *in vitro* (Fig. 7.10) as well as after inhalation *in vivo* (Fig. 7.11). Transmission electron microscopy is fundamentally a useful and necessary tool. It appears that nanoscaled materials can be found either enclosed within organelles like phagosomes, lysosomes, or endosomes, or are freely distributed within the cytosol [38, 41, 52].

The same is true for carbonaceous nanomaterial that has been found in various cell types after treatment *in vitro* (Figs. 7.8 and 7.9) as well as in exposed mice or rats after instillation [53, 54].

### 7.2.3

#### **Biological Effects on Cellular Mechanisms**

Nanoparticles produced from different materials, such as metal oxides or carbon, have enhanced properties not found in bulk materials. Unsurprisingly, therefore, the enhancement of material properties could also occur when the particles encounter biological components. With the ability to manipulate atoms and molecules, we now can create predefined nanostructures with unprecedented precision and selective affectivity. An improved understanding of the biological effects of nanoscaled materials, as described in this book, also deserves attention. Several investigations of biological interactions with nanometer-scale materials demonstrate the possible impacts on living systems (Fig. 7.12):

1. Cell membrane proteins/adhesion molecules; integrins and extracellular matrix (ECM), receptor molecules, transporters [12, 55–61];
2. phospholipid turnover and lipid mediator release [62–64];
3. ion channels [65];
4. endolysosomes [66–68];

**Fig. 7.9.** Transmission electron micrographs of rat alveolar macrophages (NR8383) and human lung epithelial cells (BEAS2B) ingesting bundles of primary SWCNTs. (a) NR8383 cell ingested a bundle of carbon nanotubes (white arrow) and contacted another one (black arrows); (b) BEAS2B cells ingested a SWCNT-

bundle of similar size, the white square is shown in higher magnification in (c), where single carbon nanotubes can be found next to the bundle in the cytosol (white arrowhead) and at the nuclear envelope (black arrowhead). (T. Detzel, ITG.)

5. mitochondria [69–71];
6. nucleus and DNA [72, 73].

### 7.2.3.1 Metal Oxides

Nanosized materials are easily taken up into cells and are either stored in several compartments or freely located within the cytosol (Section 7.2.2). Metal oxides interfere with membranes, proteins or other structures of the cells (see above). Incorporation takes place via caveoli, clathrin-coated pits or endocytosis (Fig. 7.6),

**Fig. 7.10.** Hematite particles are taken up into the cytosol of alveolar epithelial cells (A549). Light microscopic image of A549 cells (DIC, 630 $\times$ ; A) after 24 h of hematite exposure (100  $\mu\text{g mL}^{-1}$  or 32  $\mu\text{g cm}^{-2}$ ). Transmission electron micrographs of A549 cells after 3 h (20000 $\times$ ; B), 6 h (30000 $\times$ ; C), and 16 h of exposure to hematite particles (50  $\mu\text{g mL}^{-1}$  or 16  $\mu\text{g cm}^{-2}$ ) (12000 $\times$ ; D). (Reprinted from Ref. [41], with permission from Elsevier.)

leaving these nanosized metal oxides in lysosomes [38, 41]. A distinct mechanism for nanoparticle uptake has not been described yet, but it appears to be a dependency on primary particle and agglomerate size. The possible cellular mechanism for the recognition and initiation of the uptake process has recently been suggested to be a member of the Toll-like receptor family [74].

**Size Dependency** Recently, ultrafine (20 nm) preparations of  $\text{TiO}_2$  have been shown to cause a significant loss in viability compared to fine (220 nm) particles [40], similar to results for ultrafine and fine nickel [75]. Additionally, an increase in fibrogenic mediators like procollagen can be observed that appear to be stronger for ultrafine preparations [76]. Proliferation of macrophages is impaired in these samples as well, and to a greater extent than in fine particle treated controls [40]. Inhalation studies revealed a higher pulmonary deposition in rats with ultrafine CdO (40 nm) aerosol than was measured with fine CdO particles [36]. Bermudez and his colleagues have suggested particle clearance in mice and rats is retarded

because of pulmonary particle overload in animals treated with high dosages of nanoscale titania [35].

Koper and his coworkers have described another size-dependent finding [77]. Nanoscale powders of MgO or CaO that tend to be nontoxic as large scale particles were doped with halogens and found to have a very strong degrading effect on certain bacteria and fungi. It was suggested that the activated nanoparticles directly interfere with proteins and nucleotides. If these formulations kill more than 90% of contacted bacteria within minutes, why should these particles (4 nm) not be

Fig. 7.12. Possible intracellular targets of nanoparticles.

harmful to human health? The key to these observations lays obviously in the large surface area of nanoparticles, which can be as high as  $430 \text{ m}^2 \text{ g}^{-1}$  and therefore be very reactive. Klabunde and coworkers suggest a surface reaction of these nanomaterials with P–O and P–F bonds that breaks important chemical compounds, leading to a disruption of the cellular homeostasis [78].

**Inflammation** Several studies have shown that incorporated metal oxide nanoparticles can lead to inflammatory responses. These include the release of pro-inflammatory cytokines like IL-1, IL-6, IL-8 and TNF- $\alpha$ . In addition, fibrogenic factors (PDGF-A and PDGF-B) can be released upon treatment with fine and ultrafine particles in rat tracheal explants [76]. Toll-like receptors (TLR) may be also involved in a nanomaterial specific manner and appeared to be induced after application of different nanoparticles, such as TiO<sub>2</sub>, ZrO<sub>2</sub> and SiO<sub>2</sub>, to human myelomonocytic U-937 cells [74]. These studies observed an increase in IL-1 $\beta$ , TNF- $\alpha$  and IL-1RA release in this macrophage cell line. A change in the cytological profile has been noted recently in inhalation experiments in mice, rats, and hamsters [35]. The mice had significantly elevated numbers of macrophages, lymphocytes and neutrophils in bronchoalveolar lavage fluids even 52 weeks after the end of exposure.

**Acute Toxicity** Several assays have been used and developed to determine the acute toxicity of nanomaterials. By measuring the metabolic activity of mitochondria, many laboratories have determined the viability of various cell cultures after treatment with metal oxides or carbon nanoparticles [38, 41, 74, 79, 80]. Other

studies use bacterial systems by giving the number of colony forming units as a marker for acute toxicity [77]. Consistent across different methods or biological systems, nanoscaled metal oxide particles exhibit a strong decrease in viability.

**Genotoxicity** To overcome severe effects on DNA such as was demonstrated for asbestos, it is very important to increase our knowledge of direct DNA damaging effects or indirect genotoxic mechanisms via oxidative stress by nanoscaled metal oxides.

TiO<sub>2</sub> nanoparticles caused lung tumors in rats at the end of lifetime exposure [81]. Thus, it can be speculated that metal oxide nanoparticles in general exhibit a strong reactivity to induce oxidation or electron transfer reactions because the number of metal atoms on their surface compared to those hidden within the particles is very high. Moreover, it might be assumed that these materials can induce DNA damage, enhancing the risk for tumor development (Section 7.2.3.2). Here, a broad basis of data is missing and knowledge of the retention, biological half-life and accumulation within specific target organs has to be increased.

**Cytoskeletal Organization** Hydroxyapatite, a major building block in bones, is used as a nanomaterial to improve adhesion of human osteoblast-like cells (HOB) to inorganic materials. Upon treatment with a high dosage of 200 particles per cell ( $1 \times 10^8$  per 500 000 cells) of nHA (nanosized, rod-like hydroxyapatite) HOB cells released lactate dehydrogenase into the surrounding media, indicating a loss in cell viability [79]. Surfaces coated with nHA increase the quality of focal contacts in HOB cells and support growth *in vitro* if used in lower concentrations (Fig. 7.13). However, ultrafine particles made of titania (20 nm TiO<sub>2</sub>) cause retarded relaxation and stiffness of the cytoskeleton in macrophages that can not be observed for micronized titania (220 nm) [40]. Moreover, the alveolar ability for clearance is slowed due to reduced macrophage phagocytosis and mobility [39], as has been demonstrated by measuring the uptake of control beads. Recognition of nanoscale metal oxides may take place via a Toll-like receptor (TLR) mediated uptake process that has been described for bacteria and viruses, as suggested by Lucarelli et al. [74]. They observed changes in mRNA expression levels (TLR1-10, MD2 and CD14) upon metal oxide treatment of human differentiated myelomonocytic U-937 cells.

#### 7.2.3.2 New Carbon Modifications

Induction of intracellular oxidative stress seems to be a key biological response to combustion generated [82] and manufactured particles, as well as organic components associated with particles. Furthermore, there is evidence for additive or synergistic interactions between ultrafine carbon black particles and soluble transition metals in causing oxidative stress and inflammation [83]. The oxidative potential of particles can be observed in cell-free systems, e.g., by electron spin resonance (ESR) spectroscopy [84].

If particles with oxidative potential find their way inside cells, that same ability may convert oxygen and other molecules into highly reactive radicals that can in-

**Fig. 7.13.** CLSM images of actin cytoskeleton (green) and vinculin (red), as in (b) after two days culture. Scale bar = 20  $\mu\text{m}$ . (Reprinted from Ref. [79], with permission from Kluwer Academic Publishers.) Scale bar = 40  $\mu\text{m}$ . (c) CLSM image of actin

duce intracellular signaling pathways as a defense mechanism or even damage cellular components, leading to cell death.

Figure 7.14 shows the possible sequence of events occurring after contact of particles with living cells. If particles make contact with proteins located at the outer plasma membrane, they may induce changes in the molecular conformation of these proteins. Many of these proteins are receptors that transmit external signals into the cell, and a conformational change of the receptor may activate it, leading to the onset of a cellular response. Once inside the cell, particles may induce intracellular oxidative stress by disturbing the balance between oxidant and antioxidant processes, e.g., the glutathione system. The oxidative stress may also stimulate an

**Fig. 7.14.** Possible events after interaction of particles with cells. Particles may interact with receptors or may cause oxidative stress that induces an increase in intracellular calcium concentration, decrease intracellular GSH and/

or activate transcription factors via different signaling cascades. Activated transcription factors translocate into the nucleus, leading to gene activation, synthesis of antioxidant enzymes and/or inflammatory mediators.

increase of the cytosolic calcium concentration, possibly via interaction with calcium channels on the plasma membrane or on the endoplasmic reticulum, leading to influx of  $Ca^{2+}$  from the extracellular environment or to release of  $Ca^{2+}$  from intracellular stores [85]. The intracellular calcium concentration strongly regulates signaling pathways via interaction with several proteins such as calmodulin and protein kinases. These changes cause the activation of redox-sensitive transcription factors, such as NF- $\kappa$ B, AP-1 or Nrf2, which translocate to the nucleus and bind to the promoter regions of the genes regulated by these transcription factors. For NF- $\kappa$ B these genes include TNF- $\alpha$ , IL-6, IL-8, ICAM-1, iNOS and others, which are highly pro-inflammatory [86]. Exceeding oxidative stress may also modify proteins, lipids (lipid peroxidation) and nucleic acids, which further stimulates the antioxidant defense system or even leads to cell death.

Experiments with rats have demonstrated that inhalation of particles consisting of elemental carbon may cause considerable injury to the lung and that the toxic potential increases with decreasing particle size and increasing particle surface

area [81, 87]. Freshly prepared ultrafine carbon particles generated from pure graphite electrodes in an electric spark discharge generator [88] induce an increase in heart rate and a decrease in heart-rate variability after 24 h inhalation by healthy rats [89]. These studies indicate a systemic effect of the inhaled carbon particles (38 nm,  $180 \mu\text{g m}^{-3}$ ) without evidence of an inflammation-mediated mechanism. The authors suggest the responses may have induced an alteration of the cardiac autonomic balance mediated by a pulmonary receptor activation.

Frampton and colleagues have conducted a large clinical inhalation study of the effects of laboratory-generated ultrafine carbon particles [90]. Healthy people and people with asthma inhaled 10 or  $25 \mu\text{g m}^{-3}$  of ultrafine carbon particles (average diameter 25 nm) for 2 h. This dose was 10 to  $100\times$  higher than average concentrations of ultrafine particles of this size class reported in urban air. They did not detect changes in any airway inflammatory endpoint in both groups although it was calculated that about 50% more particles deposited in lungs of asthmatic people than in healthy people and over  $4\times$  as many particles were deposited in the lungs of exercising as in the lungs of resting participants. Electrocardiogram analysis after exposure showed a transient reduction of the heart rate variability and a reduced repolarization interval in healthy people and in people with asthma.

**Inflammation** *In vitro* studies with different cell systems also demonstrated that small carbon black particles (14 nm) induced more oxidative stress and pro-inflammatory cytokines than primary particle sizes of 250 nm [84]. These effects could not be explained by adhering transition metals since leaching of the particles with different buffers and complexing iron with desferrioxamin did not reduce the carbon-black-induced effects [91].

Freshly prepared spark discharge-generated ultrafine carbon particles have a higher oxidative potential than both aged particles and larger particles with less surface area [84]. However, the particle-induced release of arachidonic acid and derived lipid mediators in canine alveolar macrophages was independent of their oxidative potential but dependent on their ability to activate cytosolic and secretory phospholipases  $A_2$  (PLA<sub>2</sub>). PLA<sub>2</sub> hydrolyzes membrane phospholipids to release arachidonic acid, which is further metabolized to prostaglandins and leukotrienes. The particle-induced effects were also observed in human alveolar macrophages.

In normal human bronchial epithelial cells, these types of particles induced the expression of the pro-inflammatory cytokine (IL-8), possibly controlled by the p38 mitogen-activated protein kinase (MAPK) signaling pathway. Activation of the transcription factor NF- $\kappa$ B, however, seems not to play a role [92]. IL-8 is a potential chemoattractant for neutrophils. An elevated level of IL-8 in the lung is a characteristic of respiratory diseases such as cystic fibrosis, asthma, chronic bronchitis and acute respiratory distress symptom.

**Genotoxicity** Inhalation of carbon black by rats induced the formation of 8-oxo-7,8-dihydro-2'-deoxyguanosin (8-oxo-dG) in the lungs [73]. 8-Oxo-dG, a modified nucleotide, is a well-known and commonly used biomarker of free radical-induced oxidative DNA damage. This DNA modification may induce point mutations,

which are widely observed in mutated oncogenes and tumor suppressor genes, and is therefore associated with many diseases such as cancer and neurodegenerative diseases. Interestingly, studies with rats showed that particles without organics ( $\text{TiO}_2$ ) or with very low amounts of organics (carbon black) resulted in a similar induction of tumors compared with diesel particles, which contain considerably higher amounts of organics [81]. Therefore, tumor development is suggested to be caused by secondary genotoxic events due to particle-induced persistent inflammation and increased cell proliferation due to lung particle overload rather than by direct genotoxic effects.

While the toxic effects of carbon black or spark discharge-generated particles of elemental carbon have been studied very intensely, few studies with toxicological background exist on fullerenes and carbon nanotubes. Adelman et al. [93] studied the effects of fullerenes in primary bovine alveolar macrophages and HL-60 macrophages using particles generated in the arc between two graphite electrodes in a helium atmosphere. The fullerenes reduced the viability of the cells and induced increased levels of the pro-inflammatory cytokines  $\text{TNF-}\alpha$ , IL-6 und IL-8. The effects were comparable with those of graphite. Another *in vitro* study with  $\text{C}_{60}$  demonstrated low cytotoxicity compared to quartz, a moderate increase of  $\text{TNF-}\alpha$  and IL-8 release, and no oxidative potential compared to zymosan in macrophages [94, 95].

E. Oberdörster has studied the effects of  $\text{C}_{60}$  fullerenes after exposure of fish (juvenile largemouth bass) as a model for the impact of nanoparticles produced in bulk with the potential to be released into the environment [64]. She demonstrated that a 48 h treatment with fullerenes significantly increased the lipid peroxidation in the brain and depleted the glutathione content in the gill. Both parameters are indicators of increased oxidative stress.

For carbon nanotubes, it is uncertain if there are analogous mechanisms to those of other fibrous particles such as asbestos and synthetic vitreous fibers (SVFs), which penetrate into the lung and may persist in the tissue. Large epidemiological studies of SVF manufacturing workers provided very little evidence of harmful effects in humans [96]. However, it is widely assumed that all biopersistent fibers may be harmful if inhaled in large enough doses. Long insoluble fibers are difficult to clear by phagocytic cells. The macrophages die after a long process of trying to engulf the fibers and release inflammatory cytokines into the lung. This may trigger the complex cellular response mechanisms that cause cancer after exposure to asbestos [97]. Nevertheless, a study at the University of Warsaw sought to determine if carbon nanotubes may behave like asbestos [98]. The experiments with guinea pigs revealed that carbon nanotubes do not exhibit effects similar to asbestos and it is suggested that working with soot containing carbon nanotubes is unlikely to be associated with health risks.

Two more studies from the same group in Warsaw have dealt with the dermatological and inhalation effects of fullerenes and carbon nanotubes. In the study on dermatological effects, rabbits were treated and the researchers "did not *find* any signs of health hazards related to skin irritation and allergic risks." This group recommended no special precautions with respect to both fullerenes and carbon

nanotubes in the working environment; in fact, the articles were titled “Fullerenes: Null Risk of Skin Irritation and Allergy” and “Carbon Nanotubes: Null Risk of Skin Irritation and Allergy” [99, 100]. However, these studies may not have been sensitive enough because recently published experimental data suggest a variety of effects in rat, mouse or human cellular systems (see below). Moreover, one has to take into account that carbon nanotubes are always contaminated with catalytic metals used during their production.

For most production processes, predominantly Fe and Ni are used as metal catalysts. They are normally removed from the raw product, but part of the metal is encased in the tubes and cannot be removed completely. Manufacturing of carbon nanotubes leads to bundles of nanotubes forming clumps and aggregates. If they are inhaled or come into contact with the skin during handling, the potential hazard will strongly depend on the metal content and on the size of the aggregates. The hazard of exposure to carbon nanotubes at occupational settings has been investigated by only a few studies. Maynard and his coworkers measured the aerosol mass and number concentration in three laboratories where SWCNTs were generated by different processes and handled manually [17]. They observed concentrations of 0.70 to 53  $\mu\text{g m}^{-3}$  of nanotubes in the atmosphere and considerable masses on gloves during handling.

Because of reports that carbon fibers induced dermal irritation such as contact dermatitis in humans after occupational exposure of the skin to carbon fibers [101], some *in vitro* studies have investigated the effects of carbon particles in immortalized keratinocyte cultures. In a companion article to Maynard et al. [17], the biological effects of SWCNTs before catalyst removal (containing 30% Fe by mass) was studied in human keratinocytes [102]. An observed dose-dependent decrease in cell viability and glutathione (GSH) levels was dramatically reversed by the metal chelator desferrioxamin. This indicates a significant role of iron in the biological effects of the SWCNTs. This study further confirmed oxidative stress in SWCNT-treated cells by the formation of free radical species, increased lipid peroxidation and decrease of the antioxidant reserve. The effects of MWCNTs in human dermal keratinocytes were also studied by Monteiro-Riviere et al. [103]. They demonstrated by transmission electron microscopy that MWCNTs were present in cytoplasmic vacuoles.

Two independent studies with rats [53] and mice [54] reported the appearance of granulomas, interstitial inflammation, and obstruction of the airways after instillation of high doses of aggregated carbon nanotubes. Granulomas are a combination of dead and live tissue surrounding the foreign material. Warheit and his coworkers [53] concluded that the acute effects are normal responses to persistent particulate material and are not specific for carbon nanotubes. Lam et al. [54] observed that the SWCNTs were more toxic than carbon black and quartz particles after instillation in mice and that nanotubes treated to remove the metals were nearly as toxic as raw nanotubes (see Chapter 6). Histological tests showed that all particles reached the alveoli and remained there even after 90 days. The biopersistence of SWCNTs and the induction of granulomatous lesions are important evi-

dences for adverse health effects. Because of strong aggregation on the nanotubes it is necessary to study the effects either by inhalation or by *in vitro* experiments.

*In vitro* experiments with alveolar epithelial cells and macrophages showed that SWCNTs and MWCNTs induced oxidative stress, inflammatory responses, and cell death in a dose-dependent manner [51]. The authors found that the toxic potential of SWCNTs was similar to ultrafine carbon black (Printex 90) and higher than MWCNTs and quartz.

Recently, SWCNTs, MWCNTs and C<sub>60</sub> fullerenes were tested in comparison to quartz in primary alveolar macrophages isolated from guinea pigs [104]. A sequence order of the cytotoxic potential of SWCNTs > MWCNTs > quartz > C<sub>60</sub> fullerenes was found. The C<sub>60</sub> fullerenes were shown to be non-toxic in the MTT test even at the highest concentration of 226 μg cm<sup>-2</sup> while the SWCNTs reduced the viability by 20% at 1.4 μg cm<sup>-2</sup>. These observations are compatible with results obtained with mice where carbon nanotubes are more toxic to the lung than quartz [54]. The carbon nanotubes were ~90% pure; impurities included mainly amorphous carbon and only trace amounts of the catalysts Fe, Y and Ni. The particles also reduced the phagocytic ability of the alveolar macrophages, as seen by microscopic and flow cytometry analysis. Phagocytosis of carbon nanotubes was accompanied by ultrastructural alterations, as demonstrated by transmission electron imaging, indicating the onset of apoptotic processes.

Besides the mechanical and electrical characteristics, carbon nanotubes can be functionalized with different molecules to achieve improved properties and functions such as biocompatibility and biomolecular recognition capabilities. This would enable applications in biomedical engineering and drug delivery. Amino acids and peptides coupled to SWCNTs yield SWCNT derivatives with higher water solubility that can translocate across cell membranes [105]. Furthermore, plasmid DNA associates with ammonium-functionalized CNTs, and these complexes were taken up by mammalian cells. The CNT-mediated DNA delivery to cells was very effective, resulting in a 10× higher gene expression than achieved with DNA alone [105]. These studies indicate that CNTs have a high potential in delivery systems in the molecular therapy of diseases.

#### 7.2.4

#### Possible Hazards – Toxicological Impacts

We tried in the above-described toxicological issues to point to important mechanisms and studies that gave hints where the hazards of nanoparticles could be detected. Obviously, dependent on the material nanoparticles are produced from, their biological effects can be very different. Above all, metal oxides are strongly expected to be harmful because the toxicity of metals and their compounds is well described. The question is do they behave differently as nanosized particles than as dissolved ionic forms or organic compounds? Therefore, it is of interest to know if these materials are soluble in biological fluids, and how long they persist in their target tissues. Such criteria may directly influence the use of metal oxide nano-

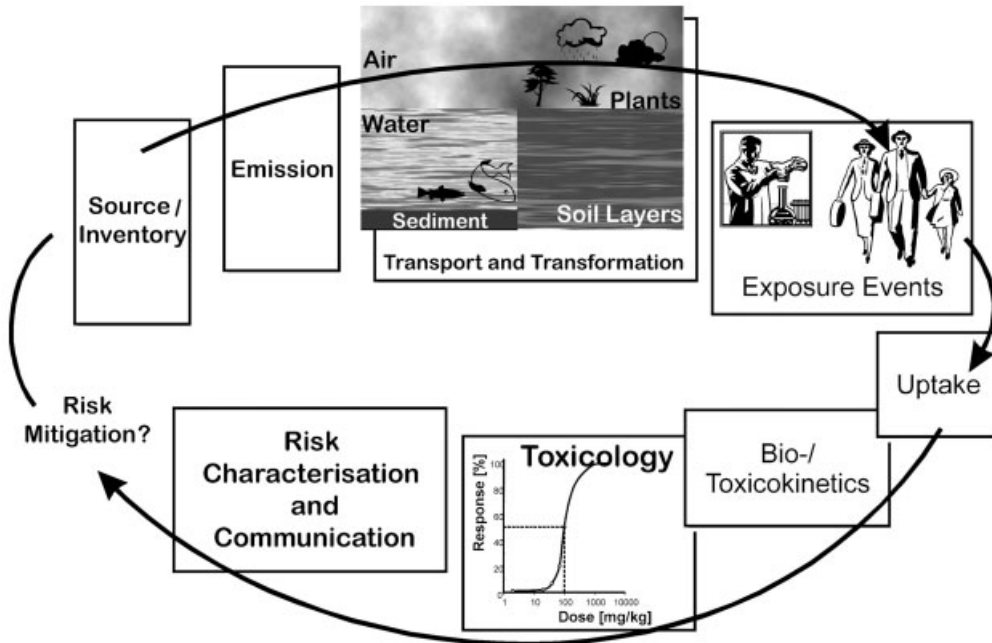

Fig. 7.15. Schematic presentation of life-cycle assessment of nanomaterials. From source to dose, an evaluation loop to the reduction of emission of nanomaterials.

particles in technical, cosmetic, and medical products with which an exposure is obvious. Carbonaceous material, though, has been less intensively investigated and long-term effects are mostly speculative. First results, from studies with animals and cellular systems, point to oxidative mechanisms that might have the potency to kill cells or could be discussed in connection to DNA damage. Regarding these effects, further investigations are needed to clarify such fundamental biological mechanisms before these materials, like fullerenes or carbon nanotubes, are produced in very high amounts and possibly released into the environment. Thus, it is important to include the entire life-cycle of nanomaterials (Fig. 7.15).

### 7.3

#### Risk Characterization – A Conclusion

As stated in Section 7.1.2 risk characterization stands at the end of the sequence of hazard and exposure identification and assessment (Fig. 7.1). To fulfill the criteria of risk assessment, besides the toxicological and pharmacological studies, exposure situations have to be recognized. Therefore, one has to keep in mind that bioaccumulation processes can lead to an enrichment in organisms or organs over several

orders of magnitude. Thus, a minimum catalogue of action has to be set up to reduce the risk at working places and within the environment.

Generally, in a recent report from the Institute of Occupational Medicine in Great Britain [106], it has been postulated to consider:

- the existence of potential routes for human exposure;
- possible industrial sources of occupational exposure;
- the levels of exposure;
- means of, and effectiveness of control measures;
- potential numbers of humans exposed;
- trends in the (potential) use of nanotechnology;
- views as to the likely impact of the implementation of the change from research use to full-scale industrial use.

### 7.3.1

#### **Opportunities and Risks of Nanomaterials**

All the above-described mechanisms of uptake, transport and distribution of nanoparticles in cells of different species and organs are important for their implications and applications. During discussion of the adverse effects of nanoparticles it is always important to consider the positive applications within the environment as well as in biological systems. Only a few are listed here:

- tools in imaging and microscopy;
- diagnostics and analysis (research and therapy);
- production of bioactive compounds and materials (Lab-on-a-Chip);
- targeting and dosing of drugs;
- intervention in biological processes (cell growth);
- nutrition (bioavailability, stability, optics);
- cosmetics (UV-filter, liposomal formulations);
- sensors and detectors;
- biomolecules for information and communication technology (ICT; DNA computing).

### 7.3.2

#### **New Materials without Risks?**

Nanotechnological products are developed with regard to the future: for a presumed need, to solve foreseeable problems, and for a future market. Besides intended effects (the use and functions of nanomaterials), unintended effects (the “side effects”, which also include misappropriation and misuse) might occur and might influence the overall balance of opportunities and risks. Technological risks belong to unintended and undesirable side effects.

Not only environmental or health risks are subject to a risk assessment but also economic risks and potential social problems like technology conflicts as well as

risks for sustainable development in a general sense. Classical types of technical or technologically-initiated risks are [107]:

- *Accidents in technical facilities:* These are disruptions of normal operation. Release of high amounts of material in such cases can enhance public distrust of new technology (e.g., poisonous gas catastrophes in Seveso and Bophal).
- *Consequences for human health:* New materials or completely new emissions can affect human health, e.g., in the production or use of technology. To these belong the known risks and side effects of medicines (e.g., diethylstilbestrol – DES), but also the dramatic history of asbestos. Entire chapters of modern regulations for handling hazardous substances are reactions to actual health problems. Special problems of risk assessment arise in the case of low dose exposures.
- *Consequences for the natural environment:* Air pollution, the ozone hole, chemical residues in ground water and in the soil are well-known, unintended consequences of the use of technology. Other than in the case of accidents in technical facilities alluded to above, these are often *gradual* processes. They are not always readily recognizable, and there is dissent on the question of tolerance limits or “cut-off-” or “threshold values”, from which point on protective or remedial measures would have to be taken.
- *Social and cultural effects of technology:* Social risks connected with technology are, for instance, the loss of many jobs through rationalization and automation, especially as far as less highly qualified work is concerned. Ethical “slippery slopes” in biomedical questions are also felt by segments of the population to be “cultural” risks (e.g., positive eugenics).

Such technological risks show certain characteristics that influence the approaches to their anticipative investigation and evaluation through risk research and technology assessment. Among these, in particular, are:

- local and global effects (atmospheric emissions and the global water cycle);
- enlargement of number of people affected by hazards (even in future);
- the problem of delayed effects: Perceptible damage appears decades after its cause (e.g., ozone hole, asbestos case);
- complexity of cause-relationship connections (e.g., the mad cow disease BSE);
- inability to perceive risks (e.g., radioactivity) with human sensory organs;
- irreversibility of hazards (e.g., persistent pollutants can not be completely retrieved from the environment).

In summary, it has turned out in past decades that side effects can interfere with or even counteract the goals pursued by means of technology. This ambivalence of technology, the greater discrepancy between the intended and the (then) actually realized effects constitutes a *conditio humana* of technological civilization. Two positions are futile: the demand for absolute safe and risk-free technology (“zero risk”) and the disregard or denial of the “dark side” of technology. The challenge consists much rather in addressing, analyzing, and evaluating the risks, comparing

them with the expected benefits, and then taking the results of these deliberations into consideration in decision-making processes [107].

# Nanomaterials for Environmental Remediation

Glen E. Fryxell and Shas V. Mattigod

### 8.1

#### Introduction

Over the last 10–15 years there has been an explosion of activity in the design and synthesis of nanomaterials built around a wide variety of basic architectures. More recently, a portion of this effort has focused on the environmental impacts and environmental applications of these nanomaterials. Why all this interest in nanomaterials? What advantages might these tiny structures provide to environmental remediation efforts? This chapter overviews research in this area, and outlines some of the advantages that these materials provide to environmental clean-up efforts.

The most obvious advantage that nanostructured materials provide for environmental remediation is that they offer very high specific surface areas (measured in square meters per gram). Thus, for a base material of a given density, nanostructured materials can concentrate large amounts of surface area into a very small volume. When the goal is to selectively remove a toxic contaminant from a large volume feed stream (industrial effluent, contaminated groundwater, polluted river, etc.), the ability to selectively treat (sorb or react) a specific contaminant with a small amount of material has clear advantages, both in terms of efficacy and cost. Nanomaterials can do exactly this.

For certain remediation applications, especially those dealing with dilute or trace level contamination, mass-transfer issues can dominate the kinetics of the treatment process. An *in situ* treatment process can address some of this by sending the treatment out after the contaminant in a hunter–seeker sense. The facile dispersion of nanomaterials, especially nanoparticulate materials, facilitates the efficiency of this treatment strategy, particularly in highly channeled flow systems with high tortuosity (e.g., soil matrices).

Another advantage provided by nanomaterials is that the bulk of the reagent is not buried deep beneath the surface, inaccessible to solution-borne contaminants. Whether the intent is sorption or chemical modification of the contaminant, for the treatment method to be effective the contaminant species must be able to access an active reaction/binding site. Anything buried deep beneath the surface is wasted. Because of the high surface area to mass ratios of nanomaterials, most of the material is at, or adjacent to, an accessible surface.

For macroparticulate porous materials, portions of the material in the core of the particle may be kinetically inaccessible if the diffusion path-length from free solution is too long. By tailoring the particle size (or macroporosity), to provide adequate access to the nanoporosity, this limitation can be overcome. Synthetic methods have been actively investigated to develop hierarchical pore structures to address these issues.

The revolution in nanomaterials synthesis started with researchers exploring what shapes and structural motifs could be made (spherical nanoparticles, hexagonal pores, cylindrical nanorods, etc.). This was followed by an exploration of chemical compositions ( $\text{SiO}_2$ ,  $\text{ZrO}_2$ ,  $\text{CdS}$ , etc.). More recently there has been a great deal of interest in making *functional* nanomaterials, either using self-assembly, surface modification chemistry, or by tuning the chemical composition of the material itself for the job at hand. The results of these efforts are a wide variety of functional nanomaterials that have been tailored to address the environmental remediation of several chemical contaminants, including dense non-aqueous phase liquids (DNAPLs), organophosphonate pesticides, polycyclic aromatic hydrocarbons (PAHs), heavy metals, radionuclides, oxometallate anions,  $\text{CO}_2$  management, and more. These functional nanomaterials are aimed at ensuring that we have clean air to breathe and clean water to drink. Clean water, and access to clean water, is emerging as one of the key global political/economic issues of the 21<sup>st</sup> century. Nanomaterials are being designed and synthesized to address these needs. This chapter summarizes nanoparticle-based remediation technologies that use acid–base chemistry, redox chemistry and absorption to remove specifically targeted contaminants. Also included are hybrid nanoporous materials that contain chemically selective ligand fields, based on metal phosphonate chemistry and organosilane self-assembly. Examples of field tests on actual waste streams for reactive nanoparticle and hybrid nanoporous sorbents are also summarized.

## 8.2

### Nanoparticle-based Remediation Materials

The simplest, geometrically, entry into the class of nanomaterials is the spherical nanoparticle. These have been made by imposing either kinetic or thermodynamic controls on the production processes, and by confining chemical reactions and/or nucleation and growth in confined spaces [1]. Nanoparticle synthetic methods result in nanoparticles that range in size from a just a few nanometers in diameter (e.g., the reverse micelle templated synthesis of gold nanoparticles), to methods that produce nanoparticles a couple of hundred nanometers in diameter (e.g., Stöber sphere synthesis).

Nanoparticles tend to be more reactive than the corresponding bulk material because of the increased chemical potential resulting from the high degree of curvature of the interface [2]. This property can make nanoparticle-based remediation methods particularly effective since they are easily dispersed and undergo the targeted chemical reaction more readily.

## 8.2.1

**Acid–Base Chemistry**

An example of the unusual reactivity of nanomaterials and how it has been exploited for the benefit of the environment is found in the work of Klabunde's group [3–6]. For the last 10 years, this group has systematically studied the destruction of halogenated hydrocarbons by nanoparticulate metal oxide aerogels (e.g., CaO). In this work nanoparticulate CaO aerogels were prepared using the “autoclave method” (hydrolysis of calcium methoxide, followed by heating under vacuum to 500 °C for 6 hours). These aerogels typically have surface areas of the order of 120 m<sup>2</sup> g<sup>-1</sup>, and are composed of aggregates of spherical 25 nm nanoparticles. They were found to effectively destroy various chlorocarbon solvents, including CCl<sub>4</sub>, CHCl<sub>3</sub>, trichloroethylene and tetrachloroethylene. Generally, the reaction products are CaCl<sub>2</sub> and CO<sub>2</sub> (or CO) [Eq. (1)]. With the less reactive tetrachloroethylene, higher temperatures were required, and this led to the partial formation of CaCO<sub>3</sub> by reaction of the CO<sub>2</sub> product with CaO starting material.

Similar studies were carried out with aerogel MgO [7]. In this case the autoclave method resulted in material with a surface area of 364 m<sup>2</sup> g<sup>-1</sup>, a crystallite size of 4.7 nm and average pore diameter of 98.7 Å. Compressing these materials with loads of up to 20 000 lbs did not significantly change the surface area of the MgO aerogel; however, the pore volume and average pore diameter could be systematically reduced with increasing compression, introducing an interesting method of nanostructural control. A slight reduction in crystallite size was also noted. These MgO aerogels, of varying pore diameters, were evaluated for their abilities to sorb alcohols of different chain lengths; some size discrimination was noted.

Nanoparticulate aerogel MgO also reacts with 1-chlorobutane at elevated temperatures [8]. Here, the products are a mixture of butanes and MgCl<sub>2</sub>. At 200 °C the reaction stops when a monolayer of MgCl<sub>2</sub> is formed, but at higher temperatures the rate and degree of conversion are enhanced considerably. Coordination of organic molecules onto the surface of these materials has been modeled to gain a better understanding of their reactivity [9].

The “autoclave method” was improved to include a supercritical drying procedure [3]. This resulted in dry Mg(OH)<sub>2</sub> powders with surface areas as high as 1100 m<sup>2</sup> g<sup>-1</sup>, more than twice those observed previously. Solvent effects in this hydrolysis and crystallization were carried out, and increasing the amount of toluene in the alkoxide hydrolysis reaction mixture resulted in faster gelation and higher surface areas in the final product [10]. Subsequent mechanistic studies revealed that solvation of the alkoxide/alcohol mixtures is important to the gelation process and the structure of the subsequently formed dry gel [11]. This was rationalized with a partial charge model, and was found to be purely a solvent effect, and not the result of the high-temperature supercritical procedure.

An interesting manifestation of the unusual reactivity of nanoparticle interfaces is the unusual biocidal activity of aerogel MgO [12]. While aerogel MgO nanoparticles exhibited several properties that made them desirable as a potential disinfectant, when doped with a small amount of Cl<sub>2</sub> (or Br<sub>2</sub>) they displayed effective biocidal action against Gram positive bacteria, Gram negative bacteria and spore cells. This was explained by the fact that many of these small particles could very effectively coat the bacterium, and deliver a localized high concentration of active halogen to the cell membrane. ζ-Potential measurements have shown that the aerogel MgO nanoparticles have a positively charged surface, and thus will experience a Coulombic attraction with the negatively charged cell membrane, helping to drive this targeted delivery process. These chlorinated nanoparticulate metal oxides are also selective catalysts for the chlorination of alkanes [13].

Aerogel MgO nanoparticles have also been coated with various surfactants to improve their dispersability in non-polar media [14]. This is important for the destruction of pesticides (which tend to be applied in non-polar solvents) or chemical warfare agents in the event of a leak or spill. In all cases, the surfactant-coated aerogel MgO nanoparticles dispersed more readily in organic solvents after they were treated with surfactants. The surfactant-coated MgO nanoparticles effectively destroyed Paraoxon (a pesticide); however, there was some variation in efficacy from one surfactant to another. A similar trend was observed for reaction with 2-chloroethyl ethyl sulfide (a “mustard” derivative). The surfactant coating decreased the reactivity of the MgO nanomaterials in all cases, presumably by sterically blocking surface reaction sites.

Similarly, these aerogel MgO nanomaterials have been subjected to CVD carbon treatment to increase their hydrophobicity [15]. These materials have surface areas in the range of 409 to 467 m<sup>2</sup> g<sup>-1</sup>, and pore volumes of 0.39 to 0.48 cm<sup>3</sup> g<sup>-1</sup>. The carbon formed “nanoislands” on the particles, which were estimated to be 1 or 2 graphite layers thick. Partial carbon coating of these nanoparticles has a beneficial effect on their ability to destroy hazardous materials [16]. Detailed characterization of these materials has shown that carbon is first deposited inside the pores of the aerogel aggregates, and the outer surfaces are covered with carbon only after the pores are filled.

One of the many benefits provided by alkaline earth metal oxide nanomaterials is the ability to treat a wide variety of hazardous materials. In addition to those already touched upon (chlorinated solvents, microbes, pesticides and “mustards”), these materials are effective at removing hydrogen sulfide, which is very toxic, corrosive and odiferous, from gas streams. At lower temperatures (e.g., ≤100 °C), ZnO nanoparticles destroyed H<sub>2</sub>S more effectively than CaO or MgO nanoparticles [Eq. (2)], which is consistent with the superior thermodynamic driving force for the Zn sulfidation [17]. However, at higher temperatures (e.g., >250 °C), the CaO nanoparticles were the better choice, due to sintering of the ZnO nanocrystals. ZnO nanocrystals also effectively destroy chlorinated solvents, SO<sub>2</sub>, and Paraoxon [18].

Fig. 8.1. Structures of the chemical warfare agents VX and GD.

These materials have also shown clear efficacy in the destruction of chemical warfare agents. For example, reaction of aerogel MgO nanoparticles with 2-chloroethyl ethyl sulfide [a mimic for bis(2-chloroethyl)sulfide, a.k.a. “HD”, “distilled mustard” or “mustard gas”] in pentane solution destroyed between 25% and 65% of the mustard derivative in 4 h [19]. Addition of trace amounts of water to the mixture slightly enhanced the reaction rate, while larger amounts of water reduced both reaction rate and degree of conversion. When the reaction was performed in tetrahydrofuran (THF), the rate was slower than in pentane. Reaction in methanol resulted in solvolysis. These materials have also been applied against organophosphonate chemical warfare agents, like VX and GD (a.k.a. “Soman”) (Fig. 8.1) [20]. The aerogel MgO nanomaterials were highly reactive towards GD, VX and HD. The rate was a function of surface tension and vapor pressure (these studies were carried out neat, in the absence of carrier or solvent). Similar results were obtained with CaO nanomaterials [21]. In this case, trace levels of water appear to induce an autocatalytic reaction. These chemical warfare agents were also destroyed at room temperature using nanosized  $\text{Al}_2\text{O}_3$  [22]. Here, the reactions proceed to the particle core, resulting in extremely large reaction capacities for these nerve agents.

Similar enhanced reactivities towards halogenated solvents,  $\text{SO}_2$  and Paraoxon were seen for nanocrystalline CuO and NiO [23].

Bimetallic nanocrystalline analogs to these materials have also been made and studied. For example, a mixed  $\text{Al}_2\text{O}_3/\text{MgO}$  phase was prepared and found to have a high surface area ( $559\text{--}834\text{ m}^2\text{ g}^{-1}$ ), to display remarkably high thermal stability (minimal sintering at  $700\text{ }^\circ\text{C}$ ), and to be effective in the destruction of  $\text{CCl}_4$ , Paraoxon and  $\text{SO}_2$  [24]. In a variation on this theme, the alumina may be replaced with ferric oxide; the alkaline earth oxide serves as the support for the second metal oxide. A small amount of  $\text{Fe}_2\text{O}_3$  was layered on top of the CaO support, resulting in sub-monolayer coverage, and no visible island formation [25]. This layered mixed metal oxide system effectively destroyed chlorinated solvents, organophosphonates, carbon disulfide and carbonyl sulfide. The small overlayer of  $\text{Fe}_2\text{O}_3$  induced a remarkable enhancement in reactivity.

A similar layered bimetallic nanomaterial was prepared using an  $\text{Fe}_2\text{O}_3$  overlayer atop of SrO nanoparticles [26]. This system was chosen since its K-edge energy absorption was a better fit for EXAFS analysis. These studies revealed that the  $\text{Fe}_2\text{O}_3$  overlayer enhanced the reactivity of the SrO inner layers, indicating that this is not a surface-limited reaction in these bimetallic nanomaterials.

## 8.2.2

**Redox Chemistry**

Environmental remediation reactions are not limited to the acid–base reactions described above, in which electrophilic hazardous materials are converted into benign species by reaction with a nucleophilic oxide. Another area that has received much attention in recent years is the use of zero-valent metal nanoparticles to reduce certain highly oxidized species that are of environmental concern. Common targets in this area are the DNAPLs that contaminate certain groundwater supplies. As an early example, high surface area (“cryo prepared”) Zn and Sn particles were found to be more effective at reducing chlorinated solvents (e.g., CCl<sub>4</sub>, CHCl<sub>3</sub>, etc.) than their bulk counterparts [27]. Magnesium is a more electropositive metal than either Zn or Sn, and hence might be expected to more efficiently reduce the chlorinated hydrocarbons. However, Mg reacted preferentially with water, emphasizing the need to balance the reactivity of these species for successful *in situ* remediation.

Zhang and coworkers extended this work to use zero-valent iron (ZVI) nanoparticles, and demonstrated their use for *in situ* remediation of chlorocarbon contaminated groundwaters [28]. In this work, the ZVI nanoparticles (made by NaBH<sub>4</sub> reduction of FeCl<sub>3</sub> in water) were more effective than either commercial iron powders or palladized iron powders (Pd enhances reactivity in these reductions) for the dechlorination of trichloroethylene (TCE) [Eq. (3)]. The dechlorination process was complete in approximately 15 min (initial concentration was 20 ppm). Palladized nanoparticle ZVI was even more rapid and more effective than bare nanoparticle ZVI. PCBs were completely dechlorinated in 17 h at ambient temperature with the Fe/Pd nanoparticles, while bare Fe nanoparticles induced less than 25% conversion under the same conditions. These Fe nanoparticles were 1–200 nm in diameter (with most between 100 and 200 nm) and had a bulk surface area of 33.5 m<sup>2</sup> g<sup>-1</sup>.

The mechanistic role of the Pd islands has been studied in detail [29]. Chemisorption of tetrachloroethylene onto the Pd surface was studied by high-resolution XPS, revealing that dissociation of C<sub>2</sub>Cl<sub>4</sub> was complete at temperatures above 291 K. Systematic laboratory testing on all the chlorinated ethenes has shown that these ZVI nanoparticles are tens to hundreds of times faster than commercially available iron powders [30].

Similar reductions were performed using Fe/Ag nanoparticles in the dechlorination of chlorinated benzenes [31]. These materials were noticeably slower than the Fe/Pd nanoparticles reported earlier. Other bimetals (e.g., Cu/Al) have also shown promise for dehalogenating chloromethanes [32].

ZVI has also shown promise for the immobilization/fixation of As(III) in groundwater, both *in situ* and *ex situ* [33].

Mallouk and coworkers have actively studied the synthesis and application of

bimetallic nanoparticles for environmental remediation of DNAPLs and toxic heavy metals. For example, they have shown that ZVI nanoparticles (10–30 nm in diameter) supported on a PolyFlo resin (the authors refer to this adduct as a “Ferragel”) is a very effective reductive sorbent for Cr(VI) or Pb(II) contamination, and suggest that it could be useful as an *in situ* remediation strategy [34]. The surface chemistry and electrochemistry of these Ferragels have been studied in detail [35]. In addition, the Mallouk group has also looked at the synthesis and chemistry of zero-valent Ni-Fe nanoparticles [36]. Previous work had shown the value of incorporating catalytic islands onto the ZVI nanoparticle surface, and in this work they replaced the Pd with the more affordable Ni. These materials were found to have crystallite sizes of 3–5 nm, particle diameters of 10–30 nm and surface areas of 59 m<sup>2</sup> g<sup>-1</sup>. The NaBH<sub>4</sub> reduction resulted in residual boron content within these nanoparticles (~5%). These Ni/Fe nanoparticles dehalogenated all of the TCE in approximately 2 h (initial concentration 23.4 ppm). This is considerably faster than commercial Fe powders, or Fe/Ni powders, but not quite as fast as the Fe/Pd nanoparticles; this difference was attributed to the better ability of Pd to catalyze the hydrogenation reaction. These Fe and Ni/Fe nanoparticles have also been coated with “hydrophilic carbon” (i.e., carbon rendered hydrophilic by reaction with the diazonium salt of sulfanilic acid). Similar materials were coated with poly(acrylic acid). These coatings tend to lower the aggregation tendencies and sticking coefficients of these ZVI nanoparticles, thereby enhancing their transport and delivery to the contamination site. This strategy was effective in some soil types, but not all. These coated materials were also effective at dehalogenating TCE.

### 8.2.3

#### Field Deployments of ZVI

An actual field assessment of the Fe/Pd nanoparticle remediation technology was undertaken to evaluate how effectively these materials could treat a known industrial contamination site [37]. Gravity injection of nanoparticle suspensions into well holes was used to deliver the nanoparticles to the contaminated plume. TCE concentrations declined rapidly after nanoparticle injection (as much as 96.5%), with significant variability from monitoring site to monitoring site (this pattern was consistent with known colloid transport and chemistry in porous media). Details of how these materials react with contaminants in soil and water over extended periods, and *in situ* reactions of the nanoparticles in sub-surface environments, have also been summarized [38].

Quinn and coworkers have reported detailed study of an actual field deployment of *emulsified* ZVI [39]. The thinking behind this strategy is that emulsification of the nanoparticles enhances dechlorination by increasing the contact between the DNAPL and the ZVI, as well as providing vegetable oil, which is hypothesized to increase biological activity (thought to be important to certain stages of the overall reduction process). Significant reductions in TCE levels were observed at nearly all monitoring sites (commonly > 80%).

## 8.2.4

**Absorption Chemistry**

Nanoparticles do not have to chemically alter the target species to effectively remove it from the environment. Lion and coworkers have devised an interesting strategy for removing polynuclear aromatic hydrocarbons (PAHs) from contaminated soils using amphiphilic polyurethane (APU) nanoparticles [40]. These are made by emulsifying and crosslinking certain precursor polymer chains in water, and result in APU particles 17–97 nm in diameter [41]. Several variations on the basic formulation were evaluated for sorption and transport, and it was found that by increasing the size of the hydrophobic backbone it was possible to enhance the APU particle's affinity for the PAH. Increasing the number of ionic groups reduced the APU particle aggregation, and replacing carboxylates with PEG [poly(ethylene glycol)] chains prevented particle aggregation while greatly enhancing particle stability and mobility in the soils.

Similar PEG-modified urethane acrylate (PMUA) nanoparticles enhance bioremediation of PAH contaminants by increasing their bioavailability [42]. PAHs commonly sorb to soil particles and non-aqueous phase liquids (NAPLs), which limits their bioavailability. The PMUA nanoparticles released the sorbed PAHs, thereby increasing their availability to bacteria, suggesting that this might be an effective strategy for *in situ* bioremediation.

## 8.3

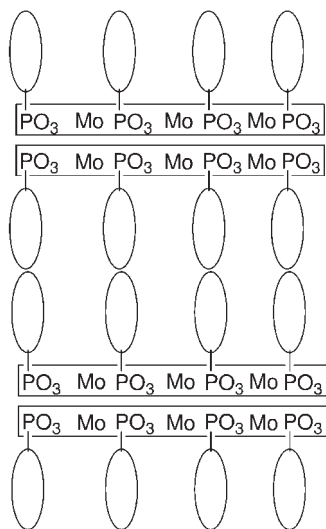

**Hybrid Nanostructured Remediation Materials**

Hybrid organic/inorganic materials allow for the incorporation of complex ligands into the nanomaterial structure, thereby empowering a high degree of chemical selectivity or molecular recognition. Work in this area is typified by two slightly different strategies: The first incorporates the organic ligand into the fundamental building block of the nanomaterial before construction of the scaffold, and the second entails construction of the scaffold first, followed by decoration with the organic ligand. Each approach has its advantages, and both allow for the incorporation of complex ligands and various structural backbones.

## 8.3.1

**Nanostructured Metal Phosphonates**

Abe Clearfield and coworkers have studied in great depth the synthesis and chemistry of nanostructured transition metal phosphonates. Portions of this elegant body of work have been reviewed [43, 44]. Part of the motivation behind this work is to use these nanostructured hybrid materials as ion exchangers [45]. The basic strategy is to build a scaffold based on the strong metal–phosphonate interactions to form the backbone of the material, and to tether an organic ligand to the phosphonic acid. This ligand may participate in dictating the final structure of the ma-

**Fig. 8.2.** Simplified schematic showing the structure of  $\text{MoO}_2(\text{O}_3\text{PC}_6\text{H}_5) \cdot \text{H}_2\text{O}$ .

terial, or it may simply be a spectator. The advantages of this synthetic strategy are that, in general, it is procedurally simple and the products are generally robust and not subject to hydrolysis or other modes of degradation.

It is useful to introduce this class of hybrid materials with the phenylphosphonic acid derivatives to showcase some basic structural features. For example, molybdenyl phenylphosphonate forms double-stranded chains, with the molybdenyl chains held together with hydrogen bonds [46]. This leaves the phenyl rings oriented roughly perpendicular to the double stranded chain, creating a hydrophobic pocket between the polar molybdenyl backbones (Fig. 8.2). Molybdenyl phenylphosphonate was found to intercalate short-chain alkyl amines, but not short-chain alcohols. Zinc phenylphosphonate, however, forms a pleated sheet, in which the zinc–phosphonate interactions form the backbone of the sheet, and the pendant phenyl rings form hydrophobic pockets between the sheets [47]. The zinc materials were also intercalated alkylamines, in this case in a 1:1 stoichiometry. Detailed characterization of the intercalation process revealed that the N atom is coordinated to the Zn center, disrupting a portion of the structure of the zinc phosphonate sheet (opening holes), but the layered sheet structure remained intact. This intercalation can be reversed by washing the adduct with dilute HCl.

A unique structural motif may be created by tying the metal-phosphonate layers together with a diphosphonic acid to create a pillared layer nanostructure. For example, Cu and Zn complexes of short-chain ( $\text{C}_2$  and  $\text{C}_3$ ) diphosphonic acids form such pillared layered structures [48]. In general, these complexes appear to be densely packed, with no open spaces for molecular intercalation. An exception

is the Cu(II) complex of propylenebis(phosphonate), in which the organic groups are about 6.8 Å apart. This is due to the presence of water molecules in the Cu-phosphonate lattice. Longer tethers might allow for increased interlayer spacing, providing more room for molecular intercalation.

Zinc biphenylenebis(phosphonate) is an interesting material [49]. When produced at pH 1.6, it forms a linear chain compound since only two of the three phosphonate oxygen atoms are ionized. When made at pH 4.5, all of the oxygen atoms are ionized and the pillared layer structure is once again obtained. To increase the microporosity (and ion-exchange capacity) of these materials, analogs were made in which a portion of the bis(phosphonate) pillars was replaced with phosphate groups. These mixed systems have notably higher surface areas than the pure pillared structures (35–136, vs. 20–28 m<sup>2</sup> g<sup>-1</sup>), and these phosphate groups were chemically accessible, as shown by acid–base titration.

The structurally similar Zr(IV) biphenylenebis(phosphonate), and the terphenylene analog, were also prepared under acidic conditions [50]. If the HF/Zr ratio was 20 or less, these materials have remarkable surface areas of ~400 m<sup>2</sup> g<sup>-1</sup> and pore diameters on the order of 10–20 Å. These pillared aromatics were also able to be sulfonated by either fuming sulfuric acid or gaseous SO<sub>3</sub>. Acid–base titration revealed an impressive acid functional density of 3.2 mmol g<sup>-1</sup>. These sulfonic acids proved to be effective acid catalysts for several reactions, and would clearly also make fine ion-exchange materials.

#### 8.3.1.1 Iminodiacetic Acids and Related Chelating Ligands

Layered metal phosphonate structures have also been prepared using tethered iminodiacetic acid (IDAA) moieties (the functional subunit of EDTA) [51, 52]. These materials have alternating Zr-phosphonate layers, and iminodiacetic acid layers. The Zr-phosphonate layers provide the structural backbone, while the pendant iminodiacetic acids can serve for molecular recognition and ion-exchange materials (Fig. 8.3). These compounds were found to be effective intercalation hosts for various alkylamines, which packed into the structures in well-ordered bilayers [52]. The complex in which the Zr center was fully substituted (i.e., there were four IDAA phosphonate ligands per metal center, resulting in only IDAA ligands in the interstitial layers) exhibited a surprisingly low affinity for transition metals and lanthanide cations at pH 2 ( $K_{ds} < 100$  mL g<sup>-1</sup> in all cases), presumably due to steric congestion. However, in compounds where a fraction of the IDAA-phosphonates were substituted with phosphate (resulting in vacancies in the interstitial layer), much higher affinities for transition metals resulted, particularly for the lanthanides. In some cases,  $K_{ds}$  as high as 25 000 were measured. Presumably, this is due to a combination of steric relief in the interstitial layer, as well as the ion-exchange capacity of the exposed phosphate hydroxyls in these vacancies.

Analogously, nitrilotris(methylenephosphonic acid) (NTP) has also been used to create functional nanostructured host materials [53]. These ligands undergo a unique self-assembly process when allowed to react with various aromatic amines (e.g., 1,10-phenanthroline, quinoline, acridine, etc.). The products are three-dimensional networks that are extensively stabilized by short, symmetrical hydro-

Fig. 8.3. Simplified schematic showing the structure of Zr N-(phosphonomethyl)iminodiacetic acid.

gen bonds, forming complex open porous structures. Some of these supramolecular structures (e.g., that formed between NTP and 1,7-phenanthroline) have unique chromophoric properties, forming charge-transfer complexes when protonated, suggesting that perhaps these materials might be useful in sensing/detection applications. Metal complexes of NTP have also been prepared [54]. Once again, open, highly hydrogen-bonded structures were obtained. These materials have the potential to be excellent ion-exchange materials, as well as molecular hosts.

#### 8.3.1.2 Macrocyclic Metal Phosphonates

The Clearfield group has achieved an elegant level of molecular sophistication with their design and synthesis of layered metal phosphonates containing pendant macrocyclic ligands, such as crown ethers and azamacrocycles [55]. Once again, in these compounds the metal phosphonate/phosphate forms the structural backbone of the material, while the phosphate hydroxyls and macrocyclic ligands fill the interstitial layers (Fig. 8.4). The presence of an acidic, exchangeable phosphate proton in the immediate proximity of a chemoselective macrocyclic ligand is of obvious value for ion-exchange applications. Bridging diposphonic acid crown ether complexes have also been prepared, and shown to have anion exchange capability (these azacrowns were protonated and could serve as anion hosts) [56]. Changing the metal from Zr to Cu(II) has a profound impact on the structure of these complexes [57], with the Cu(II) ion chelated within the macrocycle, and wrapped up by the phosphonate “arms”. The units were then arrayed in a linear fashion, held together by hydrogen bonds between the phosphonate units. Cadmium(II) was also chelated, in this case to form a dinuclear complex (one in the ring and one between the phosphonates); the bent geometry of this dinuclear complex ultimately gave rise to a convoluted cyclic arrangement of hydrogen-bonded complexes. For optimal exploitation of chemical selectivity of the macrocyclic ligand, it appears that Zr is the preferred metal for making these nanostructured crown ether complexes.

Fig. 8.4. Schematic showing the structure of Zr 1-aza-15-crown-5 phosphonate/phosphate.

### 8.3.2

#### Self-assembled Monolayers on Mesoporous Supports (SAMMS)

The surfactant-templated synthesis of mesoporous ceramic oxides has provided an excellent foundation for environmental sorbent and sensor materials [58, 59]. This foundation provides for the ability to install a wide variety of chemically selective ligand fields with which to bind the target analyte. The first work in this area addressed the need to remove mercury from groundwater [60–62]. This was accomplished by anchoring an organosilane monolayer terminated with a thiol group inside the pore surfaces of these mesoporous materials. The resulting product is called self-assembled monolayers on mesoporous supports (SAMMS) (Fig. 8.5). These hierarchical materials have unprecedented capacity and kinetics for sequestering mercury [63–65]. In addition, the mercury laden sorbent passed the EPA TCLP leachate test, revealing that the Hg is indeed very tightly bound within the mesoporous matrix. By trapping the Hg inside the nanoporous matrix, it is inaccessible to microbial attack and subsequent methylation and release (a limitation of polymer-based ion-exchange resins). Other “soft” heavy metals, like Cd, Au and Ag can also be bound by thiol-terminated SAMMS [63]. Other groups have also attached thiol-terminated monolayers inside similar mesoporous materials [66–68]. Jaroniec has tackled Hg by attaching some related sulfur-based ligand systems inside mesoporous silica phases [69]. Jaroniec’s materials have excellent Hg binding capacity, but can only be partially regenerated.

##### 8.3.2.1 Thiol SAMMS Performance with Actual Waste

Bench-scale treatability tests were carried out at Pacific Northwest National Laboratory (PNNL) on actual waste to evaluate the mercury adsorption performance of

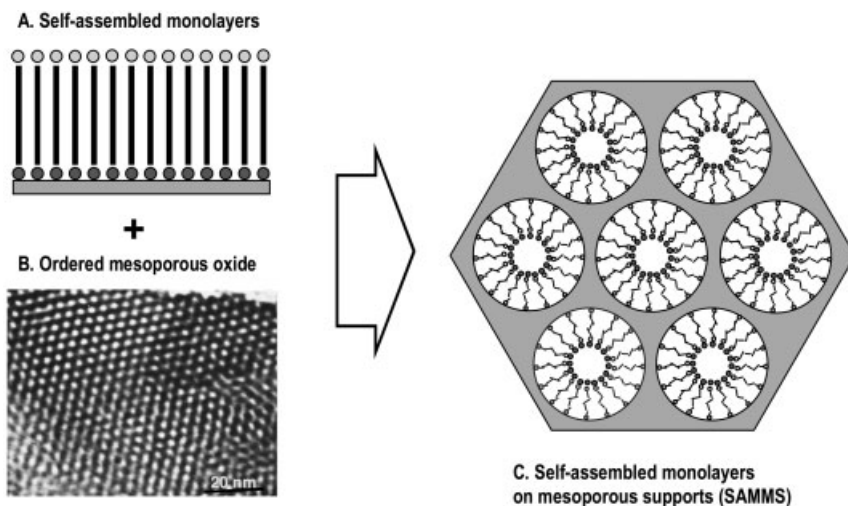

Fig. 8.5. Schematic showing the structure of self-assembled monolayers on mesoporous supports (SAMMS).

thiol-SAMMS from a real-world waste stream, originating from a pilot-scale waste glass melter operation. The principal dissolved components in this alkaline waste stream (pH 8.5) consisted mainly of sodium borate ( $\sim 30$  mM) and sodium fluoride ( $\sim 9$  mM), with minor concentrations of sodium chloride ( $\sim 3$  mM), sodium nitrite ( $\sim 0.9$  mM), sodium sulfate ( $\sim 0.8$  mM), sodium nitrate ( $\sim 0.6$  mM) and sodium iodide ( $\sim 0.2$  mM). The mercury concentration in solution was measured to be  $4.64$  mg L<sup>-1</sup>. Iodide ion is a strong mercury complexing ligand and the speciation calculations for this mixture indicated that all the soluble mercury existed as iodide complexes ( $\text{HgI}_2^0$ ,  $\sim 52\%$ ;  $\text{HgI}_3^-$ ,  $\sim 47\%$ ; and  $\text{HgI}_4^{2-}$ ,  $\sim 1\%$ ). Other dissolved components such as Al, Ba, Ca, Cd, Co, Cr, Cu, Fe, Mo, Ni,  $\text{PO}_4$ , Pb and Zn were present in trace concentrations ( $< 2$  mg L<sup>-1</sup>). To test the effectiveness of thiol-SAMMS in adsorbing mercury from this complexing matrix, a 50 mL aliquot of the filtered solution was treated with 40 mg of thiol-SAMMS (solution to solid ratio 1250 mL g<sup>-1</sup>) and after 8 h of equilibration the residual mercury concentration was determined.

The results (Table 8.1) indicate that thiol-SAMMS effectively removes mercury to meet the U.S. Environmental Protection Agency's (EPA) regulatory level of  $0.15$  mg L<sup>-1</sup> from both filtered and unfiltered samples of waste solution. However, filtering prior to thiol-SAMMS treatment was more effective than treating unfiltered waste solution. By filtering the solution prior to thiol-SAMMS treatment, we can remove  $\sim 99\%$  of mercury in the waste stream, leaving a residual concentration of only  $0.05$  mg L<sup>-1</sup>. Notably, the residual mercury concentration resulting from the first experiment is about an order of magnitude less than the EPA regulatory limit [70]. These results confirmed previous observations that thiol-SAMMS can effectively remove iodide-complexed mercury from solutions [65].

**Tab. 8.1.** Thiol-SAMMS mercury removal data for melter condensate waste solution.

Tr #	Waste solution	Conc (mg L <sup>-1</sup> )	Removal (%)	pH
0	Untreated	4.640	–	8.5
1	Filtered – treated <sup>[a]</sup>	0.052	98.9	8.0
1A	Unfiltered – treated <sup>[b]</sup>	0.179	96.1	8.0
2A	Unfiltered – treated <sup>[c]</sup>	0.148	96.8	8.0

EPA discharge limit for Hg in treated effluent is 0.15 mg L<sup>-1</sup>.

<sup>a</sup> 50 mL of waste solution filtered (0.45 μm) and treated with 40 mg of 35/thiol-SAMMS.

<sup>b</sup> 50 mL unfiltered waste solution treated with 60 mg of 35/thiol-SAMMS.

<sup>c</sup> 50 mL unfiltered waste solution treated with 40 mg of 65/thiol-SAMMS.

### 8.3.2.2 Thiol SAMMS Performance on Contaminated Oil

Not all chemical separation needs to involve aqueous media, and sorbent materials that are effective in aqueous systems are not always effective in hydrophobic media. Previous testing at the Oak Ridge National Laboratory demonstrated that thiol-SAMMS is effective at removing Hg from contaminated vacuum pump oil [71]. These batch tests consisted of equilibrating 50 mL aliquots of oil containing about 650 ppb mercury with thiol-SAMMS (w/v 0.1–1%) for 24 h. Following equilibration, the residual mercury concentration in the treated oil was measured. The data (Fig. 8.6) showed that the residual concentration of mercury decreased logarithmically as a function of thiol-SAMMS added to the solution (w/v). Thus, these

**Fig. 8.6.** Mercury adsorption by thiol-SAMMS from vacuum pump oil.

tests demonstrated that thiol-SAMMS could also effectively remove mercury from viscous, hydrophobic media, such as contaminated vacuum pump oil.

### 8.3.2.3 Anion SAMMS

Anion exchange technologies are not as mature as cation exchange methods, and anion exchange materials tend to be built around quaternary ammonium salt functionalities. While this approach works, it doesn't generally provide a direct anion–cation interaction, and therefore selectivity is dictated by indirect properties, such as anion hydration energies, adduct solubilities, etc. SAMMS have been made in which the pore surfaces have been lined with cationic transition metal complexes, thereby allowing a cationic “docking station” for the target anion [72–75]. With a metal-tris(ethylenediamine) complex (Cu-EDA), the complex contains a trifurcate cleft on the upper surface, with three exofacial protons, creating a stereospecific binding site that is ideally structured for binding tetrahedral oxometallate anions, like arsenate and chromate [72]. By selecting the metal and oxidation state appropriately, it is possible to install a metal cation such that, while forced into an octahedral coordination geometry by the chelating diamines, the cation is electronically predisposed to undergo Jahn–Teller distortion to alleviate orbital degeneracy. This provides a driving force for departing from an octahedral coordination environment and facilitates a direct bond between the anion and the metal center. Indeed, detailed EXAFS studies have revealed that Cu-EDA SAMMS loses two of the primary amine nitrogen ligands and adopts a trigonal bipyramidal coordination environment when binding oxometallate anions (Fig. 8.7) [73]. Sulfate is a ubiquitous tetrahedral anion, commonly encountered in many groundwaters, and while it is indeed bound by Cu-EDA SAMMS, the binding is reversible and it can be displaced by more problematic anions like arsenate and chromate [72]. Binding kinetics are fast, with equilibrium achieved in minutes.

This sort of anion binding can also be used as a synthetic strategy to install more complex interfacial functionality. For example, Cu-EDA SAMMS treated with ferrocyanide anion affords the corresponding Cu-EDA ferrocyanide adduct (Fig. 8.8), which has excellent affinity for binding cesium [76]. Cesium binding capacity is

Fig. 8.7. Schematic showing Cu-EDA SAMMS binding an arsenate anion.

Fig. 8.8. Schematic showing the synthesis of ferrocyanide Cu-EDA SAMMS.

good and binding kinetics are moderately fast, with equilibrium achieved in less than half an hour.

Metallation can also be used as a synthetic strategy to create new classes of SAMMS. For example, thiol-SAMMS used to bind Hg or Ag have an excellent affinity for radioiodide [77].

#### 8.3.2.4 Actinide SAMMS

More sophisticated ligand fields have also been incorporated into mesoporous materials to create highly selective sorbent materials for radioactive actinides [78–81]. In this case, CMPO-inspired [78, 79], or HOPO classes [80, 81] of ligand were installed inside a mesoporous silica matrix and found to have exceptional selectivity and affinity for binding lanthanide and actinide species from complex mixtures. For example, the acetamide-phosphonate (a.k.a. “Ac-Phos”) ligand can be employed in either the ester or acid form, making it well-suited for either hydrophobic (e.g., contaminated cutting oils) or hydrophilic waste streams, respectively. The phosphonate-based ligands exhibited very good affinities for all actinides studied (except  $\text{NpO}_2^+$ ), down to pHs as low as 0.5. The actinide-binding affinities of similar carboxylate-based ligand systems drop off at lower pHs [78, 79]. The HOPO class of ligands is the result of 20+ years of ligand design and development by Ken Raymond’s group at Berkeley, and these ligands are superb actinide binders [82–84]. Incorporation of the HOPO ligands into the SAMMS superstructure has resulted in a superior class of actinide sorbent material [80, 81]. In this case the 3,2-HOPO ligand was the most effective actinide ligand, capable of even binding the hard-to-grab  $\text{NpO}_2^+$  cation very effectively, with  $K_{\text{d}}$ s in excess of 150 000 (Fig. 8.9).

#### 8.3.3

##### Functional CNTs

Self-assembly is not limited to organosilanes on metal oxide surfaces. Chen et al. have reported an interesting variation on this theme [85]. Using this approach, Fif

**Fig. 8.9.** Hexagonal bipyramidal geometry of the complex formed between 3,2-HOPO and the  $\text{NpO}_2$  cation (looking down the  $\text{O}=\text{Np}=\text{O}$  bond). The brown atom in the center is Np, and the red atoms surrounding it are O atoms.

The pair of bidentate 3,2-HOPO ligands (top and bottom) are strongly hydrogen bound to the monodentate 3,2-HOPO ligand (left). The remaining equatorial coordination site is filled by a water molecule (on the right).

field and coworkers have successfully modified carbon nanotubes for selective binding of catalysts, radionuclides and  $\text{CO}_2$  [86]. Here, supercritical  $\text{CO}_2$  was an advantageous reaction medium for the self-assembly process, as it can dissolve the modified pyrenes used as anchors, but provides poor solvent shielding, so that the pyrene/CNT  $\pi$ -stacking interaction is allowed to predominate, thereby facilitating self-assembly. These selectively functionalized CNT's are envisioned to be very useful in environmental sensing and detection applications.

## 8.4

### Conclusions

Nanomaterials offer many useful properties for environmental remediation: high surface area, enhanced interfacial reactivity, easy dispersability, and facile sorption kinetics. Nanoparticle-based strategies have been built around alkaline earth oxide materials, zero-valent metals and crosslinked polymers. These different classes of materials offer widely differing chemistries that can be tailored to address differing remediation needs, from DNAPLs to chemical warfare agents to PAHs. Hybrid nanostructured materials are also finding application in environmental chemistry. The elegant work of Clearfield and coworkers has shown that layered metal phosphonates can be made in which the interstitial layers are composed of a wide variety of ligand structures, including crown ethers, amino acids and arylsulfonates. Surfactant templated synthesis of mesoporous ceramic oxides has provided a versatile foundation upon which a wide range of environmental sorbents can be made,

tailored to sequester “soft” heavy metals, oxometallate anions, cesium and the actinides. Similar self-assembly routes are currently being explored as ways to chemically modify carbon nanotubes. Functional nanomaterials constitute a versatile, and powerful, toolbox for environmental remediation. The future is indeed bright for environmental nanomaterials.

# Nanomaterials for Water Treatment

*Peter Majewski*

### 9.1

#### Introduction

Water is one of the most valuable substances in the world and its availability in the form of potable and drinking water is of great importance for any society. However, the conversion of water from various sources into potable and good quality drinking water can be very demanding.

The recent report entitled “Water for People – Water for Life” of the World Water Assessment Program of UNESCO [1] emphasizes that the availability of potable and drinking water is of major socio-economic importance worldwide. It also clearly states the importance of foreseeing water economy in terms of use, availability, quality, and technologies. The report also emphasizes that organic pollutants in water are the main reason for water-related diseases, such as diarrhea, worm infections, and infectious diseases, and more than 6000 people die every day due to water-related diseases.

Water use is increasing everywhere. The world's six billion inhabitants are already appropriating 54% of all the accessible freshwater contained in rivers, lakes and underground aquifers. By 2025 humankind's share will be 70%. This estimate reflects the impact of population growth alone. If per capita consumption of water resources continues to rise at its current rate, humankind could be using over 90% of all available freshwater within 25 years, leaving just 10% for all other living beings. Currently, on a global basis, 69% of all water withdrawn for human use on an annual basis is soaked up by agriculture (mostly as irrigation); industry accounts for 23% and domestic use (household, drinking water, sanitation) accounts for about 8%. These global averages vary a great deal between regions. In Africa, for instance, agriculture consumes 88% of all water withdrawn for human use, while domestic use accounts for 7% and industry for 5%. In Europe, most water is used in industry (54%), while agriculture and domestic use take 33% and 13% respectively [1].

Shrinking fresh water resources, increasing salinity of bore water, especially in arid areas of the world, and increasing demand for potable, drinking, and irriga-

tion water requires the utilization of sea, brackish, and saline bore water for fresh water supply. The conventional industrial way to desalinate water is reverse osmosis (RO), which is widely used, especially in arid costal areas, such as Arabia, the USA, especially Florida, Australia, and on ships. Although RO has proven to be a robust desalination method, its major drawback is its high demand in electric energy and the related high costs as well as biofouling of the membranes [2]. This fact requires either a relevant infrastructure of electric energy or additional equipment for local supply of electric energy, both of which are not always provided, especially in remote and/or underdeveloped areas as well as disaster and combat areas. Therefore, a simple “coffee filter”-like desalination method without the need of electric energy is highly desired and would significantly facilitate the utilization of sea, brackish, and saline bore water for the supply of potable, drinking, and irrigation water. Another important aspect, especially for underdeveloped and disaster areas, of such a “low-tech” method would be that the actual desalination treatment could be performed by a non-trained person.

Natural organic matter (NOM) is one of the key water quality parameters that affects treatment processes. NOM reduces the effectiveness of water treatment by interfering with the flocculation process, makes treatment with activated carbon and membrane filtration less efficient and is a precursor to the formation of disinfectant by-products (DBP). Furthermore, NOM acts as a food source for microorganisms, resulting in bacterial regrowth in distribution systems. These concerns have resulted in removal of NOM from raw water being of prime concern for water authorities. This has been acknowledged by the United States in the Disinfectant and Disinfection By-product Rule. This rule requires removal of NOM, as measured by total organic carbon (TOC), to minimize the formation of DBP. Enhanced coagulation has been designated as the best available technology for TOC reduction, with the required removal determined by influent TOC concentration and alkalinity. TOC of less than  $2 \text{ mg L}^{-1}$  prior to disinfection requires no treatment while TOC levels above this require removal of between 20 to 50%, with the higher removal required at higher TOC and lower alkalinity.

NOM is also well-known in drinking water. It is a complex matrix of heterogeneous organic material, consisting of particulate and dissolved fractions, harmless and harmful pollutants like pyrogens, such as endotoxins, proteins, and bacteria, as well as colored and non-colored components [3, 4]. Therefore, the ability to remove NOM is a key factor in determining the efficiency of novel methods for water treatment.

DBPs consist of various organic compounds, the best known of which are trihalomethanes (THMs). The presence of chloroform and other THMs in finished drinking water was first associated with the chlorination of drinking water in 1974. It was discovered that, in addition to killing microorganisms, disinfectants react with organic and inorganic substances naturally present in the water to produce various DBPs, which include THMs. DBPs associated with chlorination are THMs, haloacetic acids, haloacetonitriles and halopicrins. Chlorite and chlorate are by-products of chlorine dioxide disinfection, while ozonation may result in bro-

mate formation. Nitrosodimethylamine (NDMA) is a by-product of chlorination and chloramination.

Certain DBPs have been shown to be detrimental to health in laboratory animal studies. As a result the Environmental Protection Agency (EPA) regulated the most prevalent DBPs, the THMs, in 1979, setting the limit at  $100 \text{ mg L}^{-1}$ . With the promulgation of the Stage 1 Disinfectants and Disinfection By-product Rule in December 1998, the trihalomethane limit has since been reduced to  $80 \text{ } \mu\text{g L}^{-1}$  and limits of  $60 \text{ } \mu\text{g L}^{-1}$  for haloacetic acid,  $1.0 \text{ mg L}^{-1}$  for chlorite and  $10 \text{ } \mu\text{g L}^{-1}$  for bromate have been introduced. While haloacetoneitriles, halopicrins, chlorate and NDMA have been identified as health hazards, further research needs to be conducted before identifying appropriate regulatory levels. It is important to achieve a balance between reducing exposure to DBPs and maintaining control of waterborne diseases through regulatory efforts (see also: U.S. Environmental Protection Agency, <http://yosemite.epa.gov/water/>).

Conventional treatment process, i.e., coagulation/flocculation – sedimentation – filtration, is one of the most widely used treatment methods in drinking water treatment. However, especially organic matter with high molecular weight ( $\gg 10 \text{ kDa}$ ), such as pyrogens, are often not or not completely removed by coagulation and flocculation, with major consequences for peoples' health. Consequently, water has to be disinfected, mainly by chlorination and chloramination. However, as mentioned above, DBPs are a health risk and some are known carcinogens. Therefore, a reduction of disinfection of water is highly desired.

Even artificial organic matter such as pesticides, herbicides, and fungicides, drugs like antibiotics, detergents like alkyl aryl sulfonates and laureth sulfonates, organic solvents, such as trichloroethylene (TCE), and also organics from the food processing industry are often not, or not completely, removable from potable water because of their chemical stability against disinfectants. In addition, organic residues are the most frequent pollutants in wastewater of major industry, such as pulp and paper, textiles and leather, iron and steel, and petrochemicals and refineries.

Novel nanomaterials for water treatment and remediation, which in some cases are close to industrial applications, could provide some new innovative concepts to match the above outlined demands. In some cases they also represent more efficient alternatives to conventional treatment technologies, such as coagulation and flocculation, and provide novel concepts for desalination. However, in most cases there is still a long way to go before large-scale applications, i.e., the treatment of giga liters per year by nanomaterials, are commercially and technically feasible. However, the first important steps have already been carried out.

The present chapter provides a comprehensive overview of the most promising approaches to applying nanomaterials for water treatment and remediation. The nanomaterials will be introduced and their synthesis, physical properties, and operating issues reviewed. In addition, as far as the existing literature provides sufficient data about operational issues of the material, their possible application will be assessed.

## 9.2

## Iron Nanoparticles

Iron nanoparticles represent a new generation of materials for water treatment and environmental remediation, which could provide a cost-effective alternative for the solution of some pollution problems [5–13]. Owing to several factors, iron nanoparticles are an extremely versatile tool for water treatment. One important reason for this is their minute particle sizes, ranging from 1 to 100 nm, which is significantly smaller than a typical bacterial cell, which is of the order of 1000 nm. Due to the small size, the surface to volume ratio is huge. This is important because the degradation of pollutants is controlled by their interaction with the surface of the particles. In addition, nanoparticles of iron in water create a highly reducing environment through the rapid consumption of oxygen at the surface of the particles. In field trials, the addition of nanoparticles of iron reduced the oxidation–reduction potential, which favors the growth of anaerobic bacteria, which further enhances biodegradation [5–13].

Unfortunately, free-floating nanoparticles are often not stable and form tight agglomerates, which often exhibit more minor properties than the single nanoparticle. In addition, it is very difficult to separate nanoparticles from the fluid medium, which, however, is crucial with respect to health related issues when nanoparticles are applied, especially in the treatment of drinking and potable water. But nanoparticles can be anchored onto a solid matrix, such as solid substrates of metals, metal oxides, and minerals like zeolite, for the treatment of drinking and potable water, wastewater, and process water.

Metallic or zero-valent iron, as well as FeO, is a moderate reducing reagent, which can react with dissolved oxygen (DO) and to some extent with water, following Eqs. (1)–(4).

Equations (1)–(4) are the classic reactions of electrochemical corrosion, where iron is oxidized due to the exposure to oxygen and water [14, 15]. Like in corrosion chemistry, the function of water and molecular oxygen is typically that of the electron acceptors in aqueous environments. Iron acts as the electron donor, whereas relatively oxidized compounds serve as the electron acceptors and will be reduced. Over the past decade, several detailed studies have demonstrated that diverse well-known environmental contaminants, both organic and inorganic, can be reduced by iron oxidation so that these contaminants are transformed into less toxic or even benign end products [14–19]. For example, contaminants such as tetrachloro-

ethene (TCS,  $C_2Cl_4$ ), a common solvent, can readily accept the electrons from iron oxidation and, in the case of TCS, be reduced to ethene in accordance with Eq. (5).

Corrosion reactions can be accelerated or inhibited by manipulating the solution chemistry and/or solid (metal) composition. Since the early 1990s, the iron corrosion chemistry has been put into productive use in the treatment of hazardous and toxic chemicals [14, 16, 20]. The environmental chemistry of metallic iron has been extensively documented [21].

Nanoparticles of FeO and metallic iron can be prepared by using sodium borohydride as the key reductant to form FeO and Fe nanoparticles from solutions, which contain  $Fe^{3+}$  cations. For example,  $NaBH_4$  (0.2 M) is added into  $FeCl_3 \cdot xH_2O$  (0.05 M) solution with a volume ratio of 1:1.  $Fe^{3+}$  cations are reduced by the borohydride according to Eqs. (6) and (7) [22].

Reduction resulting in the formation of metallic iron nanoparticles has to be performed in an oxygen-free atmosphere. An excess of borohydride is needed to accelerate the synthesis reaction and provide a uniform growth of nanoparticles.

Iron is oxidized more rapidly when it is attached to a noble metal such as palladium and gold. The degradation of pollutants can significantly be enhanced by coupling iron to a noble metal [22–28]. A composite material consisting of iron nanoparticles and patches of a noble metal onto the surface of the particle creates numerous galvanic cells on the surface. Iron represents the anode and becomes preferably oxidized, whereas the noble metal represents the cathode and remains unchanged. Studies also suggest that noble metals such as palladium can promote dechlorination through catalytic functions such as hydrogenation [29, 30].

Palladized Fe particles can be prepared by soaking the freshly prepared iron nanoparticles with an ethanol solution containing 1 wt% of palladium acetate ( $[Pd(C_2H_3O_2)_2]_3$ ). This provides the reduction and subsequent deposition of Pd onto the surface of the particle, following Eq. (8) [22].

Similar methods have been employed successfully to prepare Fe/Pt, Fe/Ag, Fe/Ni, Fe/Co, and Fe/Cu bimetallic particles [25].

Metallic iron has been successfully applied in environmental field tests and is a promising novel technology for wastewater treatment, largely due to the low costs and absence of any known toxicity induced by its use [21, 30–36].

**Tab. 9.1.** Common environmental contaminants that can be transformed by nanoscale iron particles [5].

Chlorinated methanes	Trihalomethanes
Carbon tetrachloride (CCl <sub>4</sub> )	Bromoform (CHBr <sub>3</sub> )
Chloroform (CHCl <sub>3</sub> )	Dibromochloromethane (CHBr <sub>2</sub> Cl)
Dichloromethane (CH <sub>2</sub> Cl <sub>2</sub> )	Dichlorobromomethane (CHBrCl <sub>2</sub> )
Chloromethane (CH <sub>3</sub> Cl)	<i>Chlorinated ethenes</i>
<i>Chlorinated benzenes</i>	Tetrachloroethene (C <sub>2</sub> Cl <sub>4</sub> )
Hexachlorobenzene (C <sub>6</sub> Cl <sub>6</sub> )	Trichloroethene (C <sub>2</sub> HCl <sub>3</sub> )
Pentachlorobenzene (C <sub>6</sub> HCl <sub>5</sub> )	<i>cis</i> -Dichloroethene (C <sub>2</sub> H <sub>2</sub> Cl <sub>2</sub> )
Tetrachlorobenzenes (C <sub>6</sub> H <sub>2</sub> Cl <sub>4</sub> )	<i>trans</i> -Dichloroethene (C <sub>2</sub> H <sub>2</sub> Cl <sub>2</sub> )
Trichlorobenzenes (C <sub>6</sub> H <sub>3</sub> Cl <sub>3</sub> )	1,1-Dichloroethene (C <sub>2</sub> H <sub>2</sub> Cl <sub>2</sub> )
Dichlorobenzenes (C <sub>6</sub> HCl <sub>2</sub> )	Vinyl chloride (C <sub>2</sub> H <sub>3</sub> Cl)
Chlorobenzene (C <sub>6</sub> H <sub>5</sub> Cl)	<i>Other polychlorinated hydrocarbons</i>
<i>Pesticides</i>	PCBs
DDT (C <sub>14</sub> H <sub>9</sub> Cl <sub>5</sub> )	Dioxins
Lindane (C <sub>6</sub> H <sub>6</sub> Cl <sub>6</sub> )	Pentachlorophenol (C <sub>6</sub> HCl <sub>5</sub> O)
<i>Organic dyes</i>	<i>Other organic contaminants</i>
Orange II (C <sub>16</sub> H <sub>11</sub> N <sub>2</sub> NaO <sub>4</sub> S)	N-Nitrosodimethylamine (C <sub>4</sub> H <sub>10</sub> N <sub>2</sub> O)
Chrysoidine (C <sub>12</sub> H <sub>13</sub> N <sub>4</sub> Cl)	TNT (C <sub>7</sub> H <sub>5</sub> N <sub>3</sub> O <sub>6</sub> )
Tropaeolin O (C <sub>12</sub> H <sub>9</sub> N <sub>2</sub> NaO <sub>5</sub> S)	<i>Inorganic anions</i>
Acid Orange	Dichromate (Cr <sub>2</sub> O <sub>7</sub> <sup>2-</sup> )
Acid Red	Arsenic (AsO <sub>4</sub> <sup>3-</sup> )
<i>Heavy metal ions</i>	Perchlorate (ClO <sub>4</sub> <sup>-</sup> )
Mercury (Hg <sup>2+</sup> )	Nitrate (NO <sub>3</sub> <sup>-</sup> )
Nickel (Ni <sup>2+</sup> )	
Silver (Ag <sup>+</sup> )	
Cadmium (Cd <sup>2+</sup> )	

Table 9.1 lists several pollutants in water that have been successfully degraded by iron nanoparticles [5]. Figure 9.1 shows the effect of the addition of iron nanoparticles on water contaminated with TCE. After only a few days the concentration of TCE has been reduced significantly at the well, but also at some distance from the well.

Equations (1) and (2) clearly show that adding iron nanoparticles to water should produce a characteristic increase in pH and decline in the redox potential ( $E_H$ ) of the solution. A highly reducing environment ( $E_H \ll 0$ ) is created due to the rapid consumption of oxygen and other potential oxidants as well as production of hydrogen. Figure 9.2 shows that the oxidation–reduction potential (ORP) decreases after the addition of the nanoscale iron particles into a solution. Typically, in a closed batch reactor, a pH increase of 2–3 units was reported while ORP reduction was in the range 500–900 mV [5, 31].

In poorly buffered water, the increase in pH can be significant. However, most

**Fig. 9.1.** Effect of the addition of iron nanoparticles on water contaminated with TCE. After only a few days the TCE concentration has been reduced significantly at the well, and also at some distance from the well [5].

often, natural water reservoirs contain some buffering capacity and, therefore, the anticipated increase in pH would be less pronounced.

Nanoparticles of iron and FeO surely provide an innovative, simple and cheap alternative to conventional methods. However, crucially, wide range applications, especially for drinking and potable water, require removal of the particles or the resulting iron cations from the water, which will be one of the major challenges facing a future application of the method.

### 9.3

#### Inorganic Photocatalysts

Increased public concern over environmental pollutants as well as waterborne pyrogens has prompted the need to develop novel treatment methods, with photocatalysis attracting a lot of attention concerning the degradation of pollutants [37, 38]. Much of the natural purification of aqueous system lagoons, ponds, streams, rivers and lakes is caused by sunlight initiating the breakdown of organic molecules into simpler molecules and ultimately into carbon dioxide and other mineral products [39].

Photocatalytic detoxification of wastewater combines heterogeneous catalysis with solar technologies [40]. Semiconductor photocatalysis, with a primary focus on  $\text{TiO}_2$ , has been applied to various problems of environmental interest in addition

**Fig. 9.2.** Water chemistry of nanoscale iron particles. Rapid pH and oxidation–reduction potential (ORP) changes were observed after the addition of  $0.11 \text{ g L}^{-1}$  of Pd/Fe nanoparticles in water. A very low ORP can be established in 200 s [5].

to water and air purification. The application of illuminated semiconductors for degrading undesirable organics dissolved in air or water is well documented and has been successful for a wide variety of compounds [41].

Organic compounds such as alcohols, carboxylic acids, amines, herbicides and aldehydes have been degraded via photocatalysis in both laboratory and field studies. The photocatalytic process can mineralize the hazardous organic molecules into carbon dioxide, water and simple mineral acids [42]. Thus, a major advantage of the photocatalytic process over existing technologies is that it provides an almost complete degradation of the organic toxins, whereas other methods, such as conventional coagulation and flocculation, most often only concentrates the toxins, which then have to be separated from the water by filtering or sedimentation of the flocculant. Compared to other advanced oxidation technologies, especially those using oxidants such as hydrogen peroxide and ozone, additional oxidizing chemicals are not required when applying photocatalysis, because ambient oxygen is the oxidant [38].

The photocatalytic process can also be applied to destroy nuisance odors, taste and odor compounds, and naturally occurring organic matter, which contains the precursors to trihalomethanes formed during the chlorine disinfection step in drinking water treatment [43].

Tab. 9.2. Band gap energy of various photocatalysts [44].

Photocatalyst	Band gap energy (eV)	Photocatalyst	Band gap energy (eV)
Si	1.1	ZnO	3.2
TiO <sub>2</sub> (rutile)	3.0	TiO <sub>2</sub> (anatase)	3.2
WO <sub>3</sub>	2.7	CdS	2.4
ZnS	3.7	SrTiO <sub>3</sub>	3.4
SnO <sub>2</sub>	3.5	WSe <sub>2</sub>	1.2
Fe <sub>2</sub> O <sub>3</sub>	2.2	X-Fe <sub>2</sub> O <sub>3</sub>	3.1

During photocatalysis, illumination of a semiconductor photocatalyst with ultraviolet (UV) radiation activates the catalyst, establishing a redox environment in the aqueous solution [40]. The physical and chemical fundamentals underlying this phenomenon are comprehensively described by Bhatkhande et al. [38] and Beydoun et al. [44].

An ideal photocatalyst should be stable, inexpensive, non-toxic and, of course, highly photoactive. Another primary criteria for the degradation of organic compounds is that the redox potential of the H<sub>2</sub>O/·OH couple (OH<sup>-</sup> + ·OH + e<sup>-</sup>;  $E^0 = -2.8$  V) lies within the bandgap of the semiconductor [41]. Several semiconductors have bandgap energies sufficient for catalyzing a wide range of chemical reactions. These include TiO<sub>2</sub>, WO<sub>3</sub>, SrTiO<sub>2</sub>,  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, ZnO and ZnS (Table 9.2). Of these materials, TiO<sub>2</sub> seems to be the most promising for photocatalytic destruction of organic pollutants [45–63]. This semiconductor provides the best compromise between catalytic performance and stability in aqueous media [64]. The anatase phase of titanium dioxide is the material with the highest photocatalytic detoxification properties [65]. Binary metal sulfide semiconductors such as CdS, CdSe or PbS are insufficiently stable for catalysis, at least in aqueous media, because they undergo photoanodic corrosion [45, 66], and, more important with respect to drinking water treatment, these materials are also toxic. The iron oxides are not suitable semiconductors as they are quickly subjected to photocathodic corrosion to FeOOH and other iron hydroxide species. The band gap of ZnO (3.2 eV) is equal to that of anatase. However, ZnO is also not stable in water and forms Zn(OH)<sub>2</sub> on the surface of the ZnO particles, resulting in deactivation of the catalyst [45].

Nanocrystalline photocatalysts are of increasing interest due to their unique photophysical and photocatalytic properties [44, 65, 67]. Several review articles deal with the photophysical properties of nanocrystalline semiconductors and various studies have demonstrated that some properties of nanocrystalline semiconductor particles differ from those of bulk materials [37, 65, 68–71]; for a comprehensive review see Ref. [44].

Nanosized particles, with diameters ranging between 1 and 10 nm, possess properties that represent a transition between the molecular and bulk phases [65]. In bulk material, the electron excited by light absorption finds a high density of states in the conduction band, where it can exist with different kinetic energies [67]. However, the size of a nanoparticle can be the same as or even smaller than the size of the first excited state. Thus, the electron and hole generated by illumination cannot fit into such a particle unless a state of higher kinetic energy is created [72].

Hence, as the size of the semiconductor particle is reduced below a critical diameter, the spatial confinement of the charge carriers within a potential well causes them to behave quantum mechanically [41, 73, 74]. In solid-state terminology this means that the bands split into discrete electronic states representing quantized levels in the valence and conduction bands [72] and the nanoparticle behaves like a giant atom [67]. Nanosized semiconductor particles that exhibit size-dependent optical and electronic properties are called quantized particles or quantum dots [75]. Quantum-size effects occur when the semiconductor particles become smaller than the Bohr radius of the first excitation state [74]. This has also been stated by other authors when the particle size of a colloidal particle becomes comparable to the DeBroglie wavelength of the charge carriers [72, 76].

The excitation radius of TiO<sub>2</sub> nanoparticles has been reported to be between 0.3 and 2 nm [73, 77, 78]. Quantization effects of TiO<sub>2</sub> nanoparticles have been observed at particles sizes at and below about 10 nm [45, 72, 77–81].

One important advantage of the application of quantum-sized particles is the increase in bandgap energy with decreasing particle size. At the critical radius and below, the charge carriers begin to behave quantum mechanically and the confinement of the charge results in a series of discrete electronic states, prompting an increase in the effective band gap and a shift of the band edges. Thus, by varying the size of the semiconductor particles, it is possible to enhance the redox potential of the valence-band holes and the conduction band electrons [82], which results in an increase in the rate constants for charge transfer at the surface [41, 81]. Consequently, the use of quantum-sized semiconductor particles may result in increased photoactivity for systems in which the rate-limiting step is interfacial charge transfer [81]. Hence, semiconductor nanoparticles of sufficient size can possess enhanced photoredox chemistry that might not otherwise exist in bulk materials [73, 79, 81, 83–87].

Another factor that could be advantageous is the fact that a very large fraction of atoms are located at the surface of a nanoparticle [67]. Quantum-sized particles also have high surface area to volume ratios, which further enhances their catalytic activity [82]. One disadvantage of nanosized particles is the need for light with a shorter wavelength for photocatalyst activation – a smaller percentage of a polychromatic light source will be useful for photocatalysis.

The maximum efficiency of photocatalysis of TiO<sub>2</sub> has been observed at a particles size of about 10 nm. However, even a slight decrease or increase of particle size results in a decrease in efficiency [77, 79, 86, 88, 89].

Nanoparticles of titania can be synthesized by flame synthesis [90], chemical vapor deposition [91], wet chemical methods, such as chloride method using TiCl<sub>4</sub>

solutions [92], hydrothermal processing [93], and the alkoxide method [94, 95]. The alkoxide method, better known as the sol–gel method, which is widely used in the synthesis of ceramic materials, has the advantage that it is capable of producing photocatalysts of better homogeneity as well as high purity, involves lower processing temperatures, and can be tailored to control the materials properties [96].

Although photocatalysis exhibits various significant advantages over conventional methods such as flocculation and coagulation, its major disadvantage is that it needs illumination, preferably by UV light. However, with respect to operational aspects of the treatment of drinking, potable, waste, and process water, solar illumination is not always possible or, if provided by UV lamps, causes considerable costs. Thus, even if photocatalysts represent a very efficient, reliable, and innovative alternative to conventional treatment or other oxidizing treatments, such as ozone or H<sub>2</sub>O<sub>2</sub> treatment, operational issues and often the costs will be the main criteria when considering their application.

## 9.4

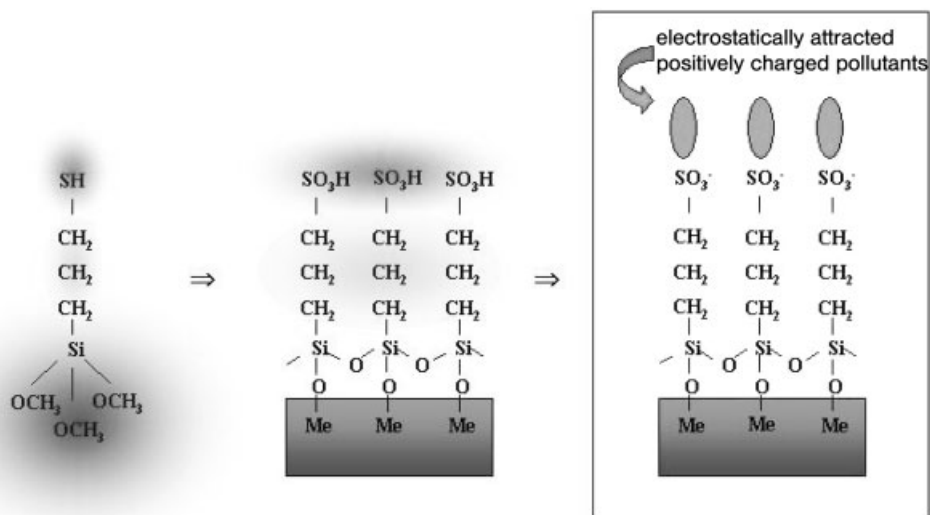

### Functionalized Self-assembled Monolayers

Another nanomaterial for water treatment consists of a particular silica (quartz sand) or silicate material with a nanometer-sized coating, a so-called functionalized self-assembled monolayer (SAM). SAMs for water treatment have been deposited onto solid  $\mu\text{m}$ -sized silicate particles as well as on so-called mesoporous silicates. Mesoporous silicates are silicate particles that contain a nanometer-sized open porosity. This porosity provides an enormous increase of the effective surface area available for interactions between the SAM and pollutants. A few grams of mesoporous silicate provide a surface area the size of three football fields [97].

Although applications of silane-based self-assembled monolayers have been elaborated for surface modification in terms of controlling its hydrophobicity, introducing and controlling the surface chemistry, and the synthesis of crystalline oxide thin films via self-assembled monolayers, the removal of pollutants from water via SAMs has not been considered widely.

A SAM is a close packed, highly ordered array of chained hydrocarbon molecules containing 3–17 CH<sub>2</sub> units (Fig. 9.3). Especially, long-chain molecules (17 CH<sub>2</sub>-units, e.g., octadecyltrichlorosilane) form a highly ordered array of surfactant molecules due to stabilizing van der Waals forces between the molecules, whereas short-chain molecules (three CH<sub>2</sub>-units, e.g., aminopropyltrimethoxysilane) are less perfectly arrayed. Hence, the length of the hydrocarbon molecules and the related thickness of the SAM varies between about 0.6 nm (three CH<sub>2</sub>-units) and about 2.5 nm (17 CH<sub>2</sub>-units) [98].

The SAM is simply described as a hydrocarbon with the general formula X-(CH<sub>2</sub>)<sub>n</sub>-Y. Y represents the “bonding group”, such as trichlorosilyl (–SiCl<sub>3</sub>), trimethoxysilane [Si(OCH<sub>3</sub>)<sub>3</sub>] etc., forming tightly covalent Si–O–Si bonds to the surface atoms of silicon and silica [99, 100]. X denotes the “head group”, chosen from

**Fig. 9.3.** The surfactant 3-mercaptopropyltrimethoxysilane (left) and the resulting sulfonate SAM on a substrate (middle) and immersed into contaminated water (right).

among several possible species, such as  $\text{NH}_2$ ,  $\text{NHNH}_2$ ,  $\text{NH}_3\text{Cl}$ ,  $\text{SH}$ ,  $\text{SO}_3\text{H}$ ,  $\text{COOH}$ ,  $\text{PO}_4\text{H}_2$  etc. When immersed into aqueous solutions, the head groups deprotonate and form negatively surfaces or capture protons at low pH and form positively charged surfaces. Therefore, by carefully choosing the self-assembled monolayer and pH of the aqueous solution in which the SAM is immersed, negatively as well as positively charged surfaces can be obtained [101, 102]. Removal of charged pollutants is due either to electrostatic attraction between the SAM and the counter-charged pollutant or to chemisorption of the pollutants by the functional group of the SAM.

Surfaces are coated with SAMs by simply immersing the substrate material into an organic solution, such as toluene, that contains surfactant molecules, such as 3-mercaptopropyltrimethoxysilane [101–105]. After thoroughly washing with ethanol and water, the SAMs-coated powder is ready for application.

SAMs for water treatment are mainly employed on silica and silicate particles, which are dispersed in the water during treatment, and subsequently filtered. Mesoporous silicates coated with SAMs containing a thiol-functionality ( $\text{SH}$  functionality), so-called thiol-SAMMS (self-assembled monolayers on mesoporous supports), have been developed specifically for the removal of mercury from liquid media [106–118]. They have the unique ability to bind cationic, organic, metallic, and complexed forms of mercury. Because of the high surface area, extensive binding sites, and tailored functional group, results of tests with mercury demonstrate the high loadings (up to 635 mg Hg per gram of SAMMS), high affinity (distribution coefficient, or  $K_d$ ,  $\sim 1 \times 10^8$ ) and rapid kinetics (minutes) possible through the

Tab. 9.3. Binding affinity of thiol-SAMMS for selected metal species [97].

Metal	Initial concentration ( $\mu\text{g L}^{-1}$ )	Final concentration ( $\mu\text{g L}^{-1}$ )	Metal loading ( $\text{mg g}^{-1}$ )	Distribution coefficient ( $K_d$ ) ( $\text{mL g}^{-1}$ )

use of these molecularly-engineered materials. The efficiency of SAMMS in a non-aqueous system (oil) has also been demonstrated with mercury with excellent results.

Selectivity, isotherm, kinetic, stability, and regeneration data on thiol-SAMMS are available for multiple metals. Table 9.3 summarizes the binding affinity of thiol-SAMMS for selected metal species. Results show that thiol-SAMMS can selectively adsorb, in addition to mercury, other soft acid cations: silver, cadmium, copper, and lead. In all cases, thiol-SAMMS show minimal interference from alkali and alkali earth metals, such as  $\text{Na}^+$ ,  $\text{Mg}^{2+}$ , and  $\text{Ca}^{2+}$ . Kinetic experiments exploring the adsorption of mercury in 10 and 500 ppm mercury solutions have demonstrated the rapid binding kinetics of thiol-SAMMS. The SAMMS rapidly reduced the mercury concentration from 500 to 0.5 ppb within 5 min. At a mercury concentration of 10 ppm, a reduction down to 3.1 ppb was observed within 5 min, which is significantly faster than the kinetics of commercial mercury absorbers.

In addition, the use of metal-chelated ligands immobilized on mesoporous silica as novel anion-binding materials for toxic anions such as chromate, arsenate, perchlorate, and selenite has also been demonstrated. Novel chemical interfaces with chelate-SAMMS have shown selective removal of toxic metal oxoanions by a ligand exchange mechanism. This approach allows the construction of binding sites that satisfy the stereoelectronic requirements of tetrahedral anions. This SAMMS form can remove chromate and arsenate to low levels, even with competing sulfate ion present.

Nearly complete removal of arsenate and chromate has been reported in the presence of interfering anions for solutions containing up to 100 ppm toxic metal anions under various conditions. The material remains effective for even higher concentration solutions (in excess of 1000 ppm anions). Anion loading of more

than  $130 \text{ mg g}^{-1}$  ( $1.12 \text{ mmol g}^{-1}$ ) of SAMMS and distribution coefficients of  $>100\,000$  have been observed.

Anion removal tests have been performed in water containing 1, 10, and 100 ppm arsenate and chromate with a solution-to-silica (SAMMS) ratio of 100. In all tests, essentially 100% of the chromate was removed in a single treatment. The addition of 150-ppm-sulfate-competing anions had little effect on the adsorption behavior. At the same solution-to-silica ratio ( $100 \text{ mL g}^{-1}$ ), chromate concentrations  $> 1000$  ppm began to produce saturation of the binding sites. The maximum adsorbing capacity is about  $130 \text{ mg g}^{-1}$  or  $1.12 \text{ mmol g}^{-1}$ . For a much higher solution-to-silica ratio ( $500 \text{ mL g}^{-1}$ ), almost 100% removal of the chromate is observed for chromate concentrations up to 100 ppm. Higher concentrations of chromate under these conditions result in saturation of the binding sites.

Similar results were also obtained for arsenate removal. The maximum loading capacity is  $140 \text{ mg g}^{-1}$  or  $1.0 \text{ mmol g}^{-1}$ . Under the same conditions, the residual concentrations of arsenate are all slightly higher than chromate at low anion concentrations. This suggests the binding chemistry has higher affinity for chromate than arsenate.

Bulk chemical analysis of treated water samples of various sources clearly indicates the capability of SAMs to remove metal cations from water. The amount of powder per liter of water and the treatment time have been identified as important factors in increasing the efficiency of the method. However, the concentration of the contaminant appears to be less crucial, as metal cations of very high as well as very low concentrations could be removed with almost the same efficiency. Recent experiments with seawater show that this method has considerable potential for desalination [119, 120]. The concentration of all analyzed metals could be significantly reduced by the treatment, whereas that of chloride was only reduced by about 20%. However, it may only be a matter of further optimization before the desalination of water by SAMs is technically possible.

These recent studies have also shown that organic matter can be removed by functionalized SAMs [119, 120]. Figure 9.4 shows the absorbance of organic matter of the Myponga Valley reservoir near Adelaide, Australia, at a wavelength of 260 nm versus the molecular weight of the molecules. Clearly, after only a few hours of treatment with a few grams of SAMs-coated silica particles per liter, organic matter with a molecular weight of more than 1 kDa has been almost completely removed. Organic matter with a molecular weight between 300 and 1000 Da has been removed very efficiently ( $>90\%$ ), whereas compounds with a molecular weight below 300 Da are almost untouched. The fact that especially organic matter with high molecular weight, such as pyrogens, could significantly be reduced indicates that the amount of disinfection of the water, such as by chlorination and chloramination, could be decreased significantly when SAMs are applied to water treatment.

Besides natural organic matter, contaminants like sodium alkyl aryl sulfonate and sodium laureth sulfonate based detergents and drugs could also be removed from water. In all cases, the contaminants were removed almost completely after a treatment of about 30 min, as indicated by measuring the UV absorbance of the water

**Fig. 9.4.** UV absorbance at 260 nm of Myponga raw water (black) and treated water (lighter, almost horizontal line) [120].

samples [119, 120]. Although these results are very promising, further detailed studies are necessary to optimize the efficiency of the removal of organic detergents.

Although SAMs for water treatment have great potential, the technology is still at the beginning. For a technical application, SAMs will have to show that they can be recycled, are stable under physical conditions during treatment, and do not contaminate the water due to release of the SAM layers from the substrate during treatment. However, the main innovative aspect of the method is the fact that the actual treatment can be performed without the need of electric or thermal power as well as illumination, which may be a significant advantage over conventional methods such as reverse osmosis for desalination and microfiltration for the removal of pathogens [121].

## 9.5 Other Materials

Some other nanomaterials as well as nanocomposites have been studied for water treatment and remediation [122, 123]. Because these studies are very recent, it is yet not possible to assess whether these approaches offer significant advantages

over conventional methods or more established nanomaterials as described in Chapters 2–4. However, some of the approaches are very promising and further research will clarify their potential.

Paknikar et al. [124] have studied iron sulfide nanoparticles for the degradation of lindane. Lindane is an organochlorine pesticide and a persistent organic pollutant. Lindane residues have been detected in drinking water sources as well as beverages and the development of viable methods for their removal is highly desirable. Iron nanoparticles have already been shown to transform effectively chlorinated organic compounds. However, their use in the treatment of drinking water and beverages has toxicity concerns. This study employed FeS nanoparticles, which were synthesized by a standard wet chemical method and were stabilized by novel polymers of microbial origin. The authors could show that the stabilized FeS nanoparticles dechlorinate lindane rapidly with very high efficiency. Dechlorinated compounds and the stabilized polymers could be completely degraded in a subsequent microbiological treatment, which facilitated precipitation of bulk iron. This novel integrated nano-biotechnological method may offer a safe, viable, and cost-effective solution to the removal of pollutants from various drinking water sources.

Peng et al. [125] have developed a novel adsorbent, consisting of nanoparticles of ceria supported on carbon nanotubes (CeO<sub>2</sub>-CNTs), for the removal of arsenate from water. Their experiments showed that CeO<sub>2</sub>-CNTs are an effective adsorbent for arsenate, and that the adsorption depends on the pH of the water. Cations of Ca and Mg significantly enhance the adsorption capacity, suggesting that this material may be a promising adsorbent for drinking water purification. The loaded adsorbent could be efficiently regenerated by dilute NaOH; a regeneration efficiency of some 90% was achieved. However, the mechanism of adsorption is not yet clear.

## 9.6 Magnetic Iron Exchange Resin (MIEX)

MIEX is, so far, the only approach employing a nanomaterial that is already commercially applied in water treatment [126–130]. MIEX, which is licensed by Orica Australia Pty. Ltd, is used as an alternative material for flocculation and coagulation. It has a very rapid reactivity and high capacity for the removal of NOM and forms the basis of a novel process for NOM removal. MIEX consists of nanoparticles (10–100 nm) of Fe<sub>2</sub>O<sub>3</sub>, which has weak permanent magnetic properties, bounded in a granular resin. Individual particles of the resin have average grain sizes of about 150 μm and, under moderate agitation, will completely separate from one another, giving a high surface area and rapid reaction rates. As soon as agitation is reduced, the particles behave like individual magnets and clump together in an open structure, which has high settling rate. The resin can easily be regenerated and recycled. To provide optimum magnetic properties of the individual granules it is crucial to have the nanoparticulate Fe<sub>2</sub>O<sub>3</sub> homogeneously distributed within the MIEX granules, requiring some expertise in the organic synthesis of the material [130].

# Nanoparticles for the Photocatalytic Removal of Endocrine-disrupting Chemicals in Water

*Heather M. Coleman*

### 10.1 Introduction

There is currently much concern about the release into the aquatic environment of natural and synthetic oestrogens and compounds that can mimic oestrogens. Since the turn of the last century, new testing methods have allowed scientists to detect traces of at least 500 new synthetic chemicals in our bodies. Some of these chemicals are persistent; others that we are regularly exposed to are short-lived. The long-term effects of most of these chemicals are unknown but evidence is mounting that some of these substances, known as endocrine disrupters, could be wreaking havoc with human and animal hormones, reducing the chances of successful reproduction by lowering sperm counts and contributing to an increased incidence of several rare cancers and birth defects [1]. The range of substances reported to cause endocrine-disrupting effects is diverse, and continues to expand as the number of studies increases. Some are likely to be distributed widely in the environment, are long-lived, and can accumulate in the tissues of plants and animals. The term “Environmental oestrogens” includes all oestrogens that may affect the endocrine system (the communication system of glands, hormones and cellular receptors that control the body’s internal functions) [2] and includes the natural oestrogens, synthetic oestrogens, xenoestrogens (oestrogen mimics) and phytoestrogens (plant oestrogens). However, the main compounds of concern are the natural and synthetic oestrogens that have been detected at significant biological levels in sewage effluent [3]. New methods for water treatment, as well as improvements to existing processes, are required because of more severe regulations resulting from increasing awareness of the urgent need to protect our environment. Concerning the new oxidation methods under development (usually termed “advanced oxidation technologies or processes”, AOTs or AOPs), heterogeneous titanium dioxide photocatalysis appears very promising in terms of destroying organic micro-pollutants, leaving them in very low concentrations. The degradation of organic pollutants present in wastewaters using irradiated dispersions of TiO<sub>2</sub> nanoparticles is a fast growing field in basic and applied research.

This chapter describes the use of titanium dioxide photocatalysis for the degrada-

tion of natural and synthetic oestrogens in water. The background to oestrogens in the environment is described in Section 10.2 and titanium dioxide ( $\text{TiO}_2$ ) photocatalysis is discussed along with the main aim and objectives of the work in Section 10.3. Each objective is then addressed in the sections that follow (Sections 10.4–10.7) and conclusions are made and research needs identified (Section 10.8).

## 10.2

### Background to Oestrogens in the Environment

The main substances of concern are the natural oestrogens  $17\beta$ -oestradiol, oestrone and oestriol and the synthetic oestrogen  $17\alpha$ -ethinyloestradiol. This chapter involves the photocatalytic degradation of all of the oestrogens and particularly deals with  $17\beta$ -oestradiol, the principal, natural and most potent oestrogen. Natural oestrogens are steroid hormones made primarily in the female ovaries and the male testes in humans and other animals. Known as the female hormones, oestrogens are found in greater amounts in females than males. These essential molecules influence growth, development and behavior (puberty), regulate reproductive cycles (menstruation, pregnancy) and affect many other body parts (bones, skin, arteries, the brain, etc.) [2]. Oestradiol is the principal, natural and most potent oestrogen, followed by oestrone and finally oestriol (Fig. 10.1).

$17\beta$ -Oestradiol is a potent endogenous oestrogen responsible for the development of female secondary sex characteristics and reproduction [4]. As illustrated in Fig. 10.1,  $17\beta$ -oestradiol and its derivatives oestrone and oestriol are 18-carbon steroids with a phenolic ring. The phenolic A ring is the structural component responsible for high affinity binding to the oestrogen receptor [4].

**Fig. 10.1.** Structures of the natural oestrogens ( $17\beta$ -oestradiol, oestrone and oestriol) and the synthetic oestrogen  $17\alpha$ -ethinyloestradiol.

17 $\alpha$ -Ethinylloestradiol is a synthetic oestrogen used extensively in oral contraceptive formulations. It is structurally similar to 17 $\beta$ -oestradiol, with the exception of an ethynyl substitution at carbon-17 and has a higher affinity for the oestrogen receptor than 17 $\beta$ -oestradiol [4] (Fig. 10.1). Introducing an ethynyl group at the 17 $\alpha$ -position of the oestradiol molecule produces a more stable compound. 17 $\alpha$ -Ethinylloestradiol is the most frequently used oestrogen component in the contraceptive pill. The ethynyl group makes the D ring much more resistant to oxidation. Consequently, ethinylloestradiol is excreted up to 80% unchanged [5]. Oestrogen pharmaceutical products are used in both human and veterinary medicine [6], e.g., oral contraceptives, hormone replacement therapy and livestock yield improvement [4].

Exposure to endocrine-disrupting chemicals (EDCs) in the environment has been associated with abnormal thyroid function in birds and fish; decreased fertility in birds, fish, shellfish and mammals; decreased hatching success in fish, birds and turtles; demasculinization and feminization of male fish, birds and mammals; defeminization and masculinization of female fish, gastropods and birds; and alteration of immune function in birds and mammals [7]. Human illnesses linked to endocrine disruption include breast, prostate and testicular cancer, reproductive abnormalities such as declining sperm counts and malformed male genitals, learning and behavioral problems and immune system deficiencies.

The presence of low concentrations of natural and synthetic steroid oestrogens in the aquatic environment has been reported over the last 30 years [8–10], but only relatively recently was it realized that steroid oestrogens constitute the main oestrogenic component in domestic sewage treatment work (STW) effluents [9]. The major oestrogenic components of STW effluent include the natural oestrogens, 17 $\beta$ -oestradiol and oestrone, and the synthetic steroid oestrogen 17 $\alpha$ -ethinylloestradiol [9]. These steroid oestrogens have been widely reported in sewage effluents [9, 11], rivers [12, 13] and spring water [14]. Steroid oestrogens are eliminated from the body mainly as biologically inactive forms, following their conjugation to water-soluble glucuronide and/or sulfate ester groups [15]. However, a large proportion of these steroid conjugates in wastewater are probably deconjugated before reaching the STW by faecal bacteria (such as *Escherichia coli*), which synthesize large quantities of the enzyme  $\beta$ -glucuronidase [16]. STWs typically remove in excess of 80% of the steroid content (or oestrogenic activity) present within the influent [17–20]. However, due to their extremely high biological potency, even trace amounts of steroid remaining in the effluent are capable of exerting biological effects on fish [21] and other aquatic organisms. The time needed for conventional biological methods to remove total organic carbon, combined with the relatively short hydraulic residency times of many STWs, means that many wastewater discharges still contain environmentally relevant levels of steroid oestrogens and their biotransformation products (Table 10.1). The need to reduce the output of steroid oestrogens in STW effluents is critical in countries with limited water resources, where effluent can become a major component of river flow in the summer months [22]. Therefore, there is a need to consider alternative strategies for the removal of trace amounts of steroid and steroid-like compounds pres-

Tab. 10.1. Oestrogen levels in STWs around the world [9, 23–25].

Location	Concentration (ng L <sup>-1</sup> )	
	17 $\beta$ -Oestradiol	17 $\alpha$ -Ethinylestradiol
United Kingdom (1998)	1–50	0–7
France, Paris (2003)	4.5–8.6	3.1–4.5
Netherlands (1999)	<0.6–12	<0.2–7.5
Germany (1999)	3	15
Canada (1999)	64	42
Sweden (1999)	1.1	4.5
Japan, Tokyo (2003)	15	9

ent in STW effluents before their discharge into rivers. There are also increasing regulatory pressures to reduce environmental levels of many EDCs.

### 10.2.1

#### Advanced Oxidation Techniques (AOTs)

In view of the growing medical use of synthetic steroids and the increasing use of birth-control pills, the synthetic ovulation-inhibiting hormones are expected to increase in concentration in wastewaters. While the concentrations in wastewater are bound to be extremely low at present, their high physiological activity at extremely low concentrations and their relatively greater stability in aqueous media than that of natural urinary hormones deserve consideration as possible contaminants of water to be processed for drinking. Consideration, therefore, needs to be given to the management strategies available in the light of such oestrogenic contamination, as the removal of these substances by current conventional water treatment methods is ineffective. A possible alternative treatment for the purification of water is titanium dioxide semiconductor photocatalysis, which is an advanced oxidation technology and a rapidly growing area of interest to both research workers and water purification companies [26]. Almost all these studies have been directed towards the oxidative degradation of organic pollutants in water [27]. While water purification techniques such as UV, ozonation or activated charcoal could significantly remove these microorganic contaminants, the high costs involved suggest that research into treatment optimization should receive more attention [3].

The common characteristic of all AOTs is the generation of very reactive free-radicals that oxidize pollutants. AOTs include thermal processes, H<sub>2</sub>O<sub>2</sub> or ozone, and light-induced reactions such as homogeneous photolysis, UV/H<sub>2</sub>O<sub>2</sub> photolysis, UV/ozone photolysis, heterogeneous photolysis and radiolysis [28]. Chemical oxidation technologies are useful in the oxidative degradation or transformation of a

wide range of pollutants for the treatment of drinking water, groundwater, wastewater and contaminated soils. Chemical oxidation methods are especially applicable for: the treatment of hazardous organics present at low concentrations, such as in contaminated groundwaters; use as a pre-treatment step before biological treatment of low-volume, high strength wastewaters; treatment of wastewaters with constituents that are resistant to biodegradation methods or upset biological treatment reactors, such as cyanides and complex metals; and use as a post-treatment step following biological treatment to reduce aquatic toxicity. Chemical oxidation methods can also be combined with other treatment technologies to achieve optimum and cost-effective treatment technologies [29]. However, approaches for controlling the release of steroid oestrogens, or other compounds that are natural by-products of our very existence, is a unique challenge.

### 10.2.2

#### **Ultraviolet Photolysis**

Treatment by UV radiation alone was also investigated in this study as a comparison to photocatalysis. Direct ultraviolet photolysis was the first photochemical method used for pollutant degradation. Although several authors have proposed direct photooxidation with ultraviolet light for water treatment [30], there are several limitations to its general applicability. Direct photochemical degradation can be achieved only when the incident light [vacuum ultraviolet (VUV) light:  $\lambda < 200$  nm or UV-light:  $\lambda > 200$  nm] is absorbed by the pollutant. There are numerous reports of UV degradation of organics present in water, including fluorinated or chlorinated aliphatics, chlorinated hydrocarbons, trihalomethanes, dinitrotoluene, chlorophenols, pesticides, PCBs, chlorinated and nitrated aromatics, phenols, halogenated aliphatics, and other hazardous wastes [31]. Direct photolysis procedures are generally of low efficiency than procedures involving hydroxyl radical generation. However, photolysis of pollutants may be important in cases where hydroxyl radical reactions are very slow [30]. UVC disinfection is currently being used in some treatment facilities around the world (e.g., Orange County Water District, California, USA; Sydney Water, Australia; Essex and Suffolk Water, UK).

### 10.3

#### **Nanoparticles for Water Treatment Applications**

Chemists have known for decades that several semiconductor metal oxides are light-sensitive and can initiate redox reactions of adsorbates [32]. In 1972, Fujishima and Honda discovered the photocatalytic splitting of water on titanium dioxide electrodes [33]. This event marked the beginning of a new era in heterogeneous photocatalysis, stimulating a worldwide effort to characterize the physical features that control efficiency in these interfacial reactions [31]. Since then, research efforts in understanding the fundamental processes and in enhancing the photocatalytic efficiency of TiO<sub>2</sub> nanoparticles have come from extensive research performed

by chemists, physicists and chemical engineers. In recent years, applications to environmental clean-up have been one of the most active areas in heterogeneous photocatalysis. This has been inspired by the potential application of TiO<sub>2</sub>-based photocatalysts for the total destruction of organic compounds in polluted air and wastewaters [31]. The degradation of organic pollutants present in wastewaters using irradiated dispersions of TiO<sub>2</sub> is a fast growing field in basic and applied research. The development of this process to achieve complete mineralization of organic pollutants has been widely tested for a large variety of chemicals [31]. Carey et al. first reported, in 1976, the photocatalytic degradation of biphenyl and chlorophenyls in the presence of TiO<sub>2</sub> [34]. Since then, many applications using the TiO<sub>2</sub>/UV process have been investigated. Other semiconductor dispersions have also been used for the photocatalytic degradation of pollutants [31]. There is an exhaustive amount of literature on titanium dioxide photocatalysis. Mills and Le Hunte published an excellent review in 1997 and estimated that over 2000 papers had been published since 1981 [35]. Over the years, reviews have been published [31, 36–39] and books written on the subject [40–43]. Commercial applications of titanium dioxide photocatalysis have been reviewed by Mills et al. [44].

### 10.3.1

#### Titanium Dioxide Photocatalysis

##### 10.3.1.1 The Principle

Photocatalysis, as the name suggests, involves light and a catalyst to bring about a chemical reaction. Mills and Le Hunte define photocatalysis as the “acceleration of a photoreaction by the presence of a catalyst” [35]. In photocatalysis the catalyst is activated by the absorption of photons of light whose energy is used to overcome the activation energy. In this case the catalyst is a semiconductor and it provides a low energy activation pathway for the passage of electronic charge. The charge is effectively transferred from the reactant through the semiconductor (activated by a photon of light) to the product (a redox reaction) [41]. In TiO<sub>2</sub> photocatalysis for water purification the pollutants are usually organic compounds and, therefore, the overall process can be summarized by reaction Eq. (1) [27].

$$h\nu, \lambda \leq 400 \text{ nm}$$

The advantages of TiO<sub>2</sub> over other semiconductors, for photocatalytic treatment of water, are that it is an inexpensive readily available material, and it is non-toxic, insoluble and photostable. In addition, solar illumination is a possibility, organic compounds are completely oxidized, no expensive chemicals need be added and a wide spectrum of pollutants can be degraded [27]. The process can also be turned on and off at the flick of a switch. TiO<sub>2</sub> photocatalysis has potential application in the treatment of both waste and drinking water [45].

### 10.3.1.2 Titanium Dioxide Nanoparticles as a Photocatalyst

The initial process for heterogeneous photocatalysis of organic and inorganic compounds by semiconductors is the generation of electron–hole pairs in the semiconductor particles [31]. Several semiconductors have been evaluated as photocatalysts, including metal oxides ( $\text{TiO}_2$ ,  $\text{ZnO}$ ,  $\text{SnO}_2$  and  $\text{WO}_3$ ) and chalcogenides ( $\text{ZnS}$ ,  $\text{CdS}$ ). For oxidation reactions, the most useful and widely employed is titanium dioxide.  $\text{TiO}_2$  is an intrinsic n-type semiconductor (due to an intrinsic oxygen deficiency, like  $\text{ZnO}$ ). It is ionic and has a wider band gap ( $>3$  eV) than non-ionic semiconductors. To promote an electron from the valence band to the conduction band, light of wavelength less than 400 nm is necessary to supply the required energy to cross the band gap [27].  $\text{TiO}_2$  nanoparticles have long been used in such applications as paint pigments and scratch-resistant optical coatings but can also display high activity for photocatalysis, which chemists and chemical engineers are beginning to exploit [46].  $\text{TiO}_2$  exhibits three different crystal forms: brookite, rutile and anatase. Rutile and anatase are the most stable and most common forms and their unit cells are shown in Fig. 10.2 [37]. They consist of chains of slightly distorted octahedrons of oxygen atoms around a titanium atom. Differences in the distortion of each octahedron by the assembly pattern of the octahedral chains cause differences in the mass densities and electronic band structure. For instance, the band gap for anatase is larger than that for rutile (3.23 and 3.02 eV respectively). The metastable anatase form transforms into the rutile form at high temperatures [37].

Many researchers have evaluated the photocatalytic activity of rutile and anatase

#### Rutile

$$d_{\text{Ti-O}}^{\text{eH}} = 1.949 \text{ \AA}$$

$$d_{\text{Ti-O}}^{\text{AP}} = 1.980 \text{ \AA}$$

$$a = 4.593 \text{ \AA}$$

$$c = 2.959 \text{ \AA}$$

$$E_g = 3.1 \text{ eV}$$

$$\rho = 4.250 \text{ g/cm}^3$$

$$\Delta G_f^\circ = -212.6 \text{ kcal/mole}$$

#### Anatase

$$d_{\text{Ti-O}}^{\text{eH}} = 1.934 \text{ \AA}$$

$$d_{\text{Ti-O}}^{\text{AP}} = 1.980 \text{ \AA}$$

$$a = 3.784 \text{ \AA}$$

$$c = 9.515 \text{ \AA}$$

$$E_g = 3.3 \text{ eV}$$

$$\rho = 3.894 \text{ g/cm}^3$$

$$\Delta G_f^\circ = -211.4 \text{ kcal/mole}$$

Fig. 10.2. Structure of rutile and anatase [37].

and, in general, rutile is claimed to be less active than anatase or even inactive [27, 47]. This is because anatase has a much larger surface area than rutile. Anatase requires photons having energies greater than 3.2 eV ( $\lambda \sim 380$  nm) to excite an electron from the valence band to the conduction band. The separated electron–hole pairs can then be made available for oxidation–reduction reactions. The reduction potential for  $\cdot\text{OH}$  has been assigned a value of +2.85 V. It is, therefore, thermodynamically favorable for the hole site formed in the valence band of  $\text{TiO}_2$  to oxidize water to  $\cdot\text{OH}$  and for the separated electron promoted to the conduction band to reduce oxygen at  $-0.13$  V. The production of an OH radical from water, and the reduction of oxygen, requires a semiconductor with a band gap above 3 eV. Hence, anatase is an ideal photocatalyst for use in aqueous solutions [27, 35]. The most widely used form of  $\text{TiO}_2$ , which was used in this research, with high activity, is actually a mixture of the anatase and rutile forms (ca. 70–80% anatase). It is produced in particulate form (30 nm diameter crystalline size, aggregated together into 0.1  $\mu\text{m}$  macroscopic particle sizes) by the Degussa Corporation and is called Degussa P25. Its high activity is suggested to be because the conduction band of anatase is more positive than that of rutile, and the light-promoted electrons may pass from rutile to anatase, enhancing the separation of holes and electrons [48, 49].

### 10.3.1.3 Mechanism of $\text{TiO}_2$ Photocatalysis

Figure 10.3 shows a schematic of a  $\text{TiO}_2$  particle, illustrating the mechanism of  $\text{TiO}_2$  photocatalysis. When a photon of light of sufficient energy ( $E \geq E_{\text{bg}}$ ) strikes a  $\text{TiO}_2$  particle the energy of the photon is absorbed and used to promote an electron ( $e^-$ ) from the valence band to the conduction band. This movement of an electron leaves a hole ( $h^+$ ) in the valence band. These species ( $h^+$  and  $e^-$ ) produced by the absorption of light can either recombine or migrate to the surface of the  $\text{TiO}_2$

**Fig. 10.3.** Schematic of a titanium dioxide particle, illustrating the mechanism of titanium dioxide photocatalysis (VB = valence band, CB = conduction band,  $E_g$  = band gap energy,  $e^-$  = electron,  $h^+$  = hole, R = organic).

particle where they can react with other species at the interface. The holes can directly oxidize organic species adsorbed onto the  $\text{TiO}_2$  particle or can give rise to hydroxyl radicals ( $\cdot\text{OH}$ ) by reacting with water or  $\text{OH}^-$ . These highly reactive hydroxyl radicals then attack organic compounds present at or near the surface [27]. Electrons promoted to the conduction band must be removed rapidly from the  $\text{TiO}_2$  to prevent recombination with the holes and allow the mechanism to continue. Usually the electrons are passed on to molecular oxygen at the interface [31].

The source of  $\text{OH}^-$  may be related to the nature of the surface-bound water associated with anatase. The hydroxyl radical can oxidize organic contaminants. This process finally affords carbon dioxide and water if the reaction proceeds to completion [45]. The strong oxidizing power of the photogenerated holes, together with the chemical inertness and non-toxicity of  $\text{TiO}_2$ , has made it an attractive photocatalyst [46]. Photocatalysis has seen explosive growth, particularly during the past ten years. The general mechanism of photocatalysis on the  $\text{TiO}_2$  surface involves the oxidation of surface hydroxyl groups, which participate in the photocatalytic oxidation process. Although direct oxidation of substrates by photo-generated holes is possible, the involvement of  $\cdot\text{OH}$  in the oxidation process has gained much experimental support. To drive the photocatalytic reaction and maintain charge neutrality, oxygen undergoes reduction in aerated aqueous media, yielding  $\text{O}_2^-$  and  $\text{H}_2\text{O}_2$ , which in turn participate in further oxidation processes [46]. The band-gap model has proven very useful in explaining the mechanism of semiconductor-catalyzed oxidative degradation of organic material in aqueous systems [36, 37, 50]. The first event in the photocatalytic process is absorption of a photon of ultraband gap energy to produce the electron-hole pair on a particle [Eq. (2)].

The electron in the conduction band can be transferred to adsorbed  $\text{H}^+$ ,  $\text{O}_2$  or a chlorinated pollutant (RX) [Eqs. (3)–(6)], initiating various reactions [30].

The hole ( $h^+$ ) in the valence band can react with surface-bound water, hydroxide groups, and anions ( $\text{A}^-$ ) to give the  $\text{HO}\cdot$  (or  $\text{A}\cdot$ ) radical, and with organic substrate (RH) to give radical cations ( $\text{RH}^+$ ) [Eqs. (7)–(10)] [30, 31].

Scheme 10.1.

Once formed, oxidative intermediates, mainly hydroxyl radicals, can react with the organic contaminant to initiate a sequence of reactions that lead to complete oxidative mineralization. Scheme 10.1 summarizes the material balance of H<sub>2</sub>O<sub>2</sub> and HO<sup>•</sup> formation [31].

The main aim of this work was to investigate the degradation of the natural oestrogens 17 $\beta$ -oestradiol, oestrone and oestriol and the synthetic oestrogen 17 $\alpha$ -ethnyloestradiol in water, using titanium dioxide photocatalysis.

The main objectives were:

- To determine if oestrogens in water can be degraded by titanium dioxide photocatalysis and UV radiation.
- To determine if all oestrogenic activity is removed after treatment with photocatalysis and UV radiation.
- To investigate the effect of varying reaction conditions on the photocatalytic reaction, i.e., initial concentration of pollutant and light intensity.
- To compare photocatalysis with UVA and UVC radiation.

These objectives were investigated and are discussed in Sections 10.4–10.7.

## 10.4

### Photocatalytic Degradation of 17 $\beta$ -Oestradiol in Water over an Immobilized TiO<sub>2</sub> Catalyst

Initial work involved investigating the degradation of the principal most potent natural oestrogen 17 $\beta$ -oestradiol in water by photocatalysis monitored using high-performance liquid chromatography (HPLC) with fluorescence detection in a quartz water-jacketed reactor [51].

Given its low solubility in water, 17 $\beta$ -oestradiol (Sigma > 98%) was initially dissolved in acetonitrile (Labscan) and then diluted with water to the desired concentration. TiO<sub>2</sub> (Degussa P25) was immobilized on Ti-6Al-4V alloy by an electrophoretic method described previously [52]. A 1 cm<sup>2</sup> area of support was coated with a catalyst loading of 1.5 mg cm<sup>-2</sup>. The photocatalytic reactor was a water-jacketed quartz cell that held 8 mL of solution [52]. The supported TiO<sub>2</sub> film was submerged in the reactant solution and irradiated through the wall of the quartz

Fig. 10.4. Quartz water-jacketed reactor [52].

reactor using a 150-W xenon lamp (Sage Analytical) with stabilized power supply (Applied Photophysics) (Fig. 10.4). The incident light was passed through a borosilicate glass filter prior to the reactor to remove  $\lambda < 300$  nm. The solution was purged with oxygen (BOC) before and during illumination and the reactor was thermostatted at  $20 \pm 2$  °C. The photonic flux entering the reactor ( $\lambda = 300\text{--}400$  nm) was determined to be  $8 \times 10^{-8}$  Einsteins  $\text{s}^{-1} \text{cm}^{-2}$  by ferrioxalate actinometry [53] with a 300–400 nm band pass filter (Speirs Robertson).  $17\beta$ -Oestradiol degradation was monitored using HPLC with fluorescence detection. The HPLC conditions were: 25 cm ODS column (Hypersil), P2000 solvent delivery pump (Thermo-separation Products), mobile phase 40:60% acetonitrile:water, flow rate of  $1 \text{ mL min}^{-1}$ . The fluorescence detector (Perkin Elmer LS30) was linked to an  $x - y$  plotter. Excitation and emission wavelengths used were  $\lambda_{\text{ex}} = 280$  nm and  $\lambda_{\text{em}} = 315$  nm.

In the presence of the illuminated TiO<sub>2</sub> film,  $3 \mu\text{mol dm}^{-3}$  ( $0.8 \text{ mg L}^{-1}$ )  $17\beta$ -oestradiol was 50% degraded in 40 min and 98% degraded in 3.5 hours. When the samples were illuminated in the absence of titanium dioxide, there was about 11% degradation in 40 min, and 44% in 3.5 h, showing that some direct photolysis takes place. A semi-log plot of initial concentration versus irradiation time was linear, indicating overall pseudo-first order kinetics. The experiment was repeated with a range of initial concentrations from 0.05 to  $3 \mu\text{mol dm}^{-3}$ . The initial rates for each concentration were determined from the pseudo-first-order rate constants and initial concentrations. The data were then fitted to the Langmuir–Hinshelwood kinetic rate model, which has been applied to the initial rates of photocatalytic destruction of many organic compounds [36]. The rate law is shown in Eq. (11), where  $R_i$  is the initial rate of disappearance of substrate and  $C_i$  is the initial concentration,  $k$  is the reaction rate constant and  $K$  is the Langmuir adsorption constant.

$$R_i = -dC_i/dt = kKC_i/(1 + KC_i) \quad (11)$$

From a plot of  $1/R_i$  versus  $1/C_i$ , with the slope equal to  $1/kK$  and intercept equal to  $1/k$ ,  $k$  and  $K$  were determined as  $4.4 \times 10^{-2} \mu\text{mol dm}^{-3} \text{min}^{-1}$  and  $3.47 \times 10^{-1} \text{dm}^3 \mu\text{mol}^{-1}$ , respectively.

This initial study showed that the principal natural oestrogen  $17\beta$ -oestradiol is readily degraded by semiconductor photocatalysis under oxygen on immobilized  $\text{TiO}_2$  powder and that photocatalysis was much more effective than UV light alone. The initial rate kinetics fit the Langmuir–Hinshelwood model. Micromolar concentrations of aqueous  $17\beta$ -oestradiol were 98% degraded in 3.5 h by photocatalysis over the titanium dioxide powder immobilized on Ti-6Al-4V alloy. The degradation kinetics were fitted to a Langmuir–Hinshelwood model with  $k = 0.044 \mu\text{mol dm}^{-3} \text{min}^{-1}$  and  $K = 0.347 \text{dm}^3 \mu\text{mol}^{-1}$ . The pseudo-first order rate constant was  $0.016 \text{min}^{-1}$ . It is very important to determine if all oestrogenic activity is removed from water samples after treatment with photocatalysis since this is the main concern. This was, therefore, investigated in the same quartz water-jacketed reactor and monitored using a yeast screen bioassay as a test for oestrogenicity (Section 10.5).

## 10.5

### Rapid Loss of Oestrogenicity of Natural and Synthetic Oestrogens in Water by Photocatalysis and UVA Photolysis Monitored using a Yeast Screen Bioassay

The presence of low levels of natural and synthetic steroid oestrogens in the aquatic environment, and their biological and oestrogenic effects on aquatic organisms, are presently issues of concern. In this study, we investigated the temporal removal of oestrogenic activity of the potent and environmentally relevant steroid oestrogens by photocatalysis over an immobilized titanium dioxide catalyst. We used a recombinant yeast assay to measure oestrogenic activity. Application of photocatalysis to remove steroid compounds and their oestrogenic activity within STW effluent released into the aquatic environment is discussed.

Stock solutions of  $17\beta$ -oestradiol, oestriol, oestrone and  $17\alpha$ -ethynylestradiol ( $100 \text{mg L}^{-1}$ ) (>98%; Sigma-Aldrich) were prepared in ethanol and then diluted 10 000-fold to a working stock concentration of  $10 \mu\text{g L}^{-1}$  using sterile double-distilled water (0.01% ethanol final concentration). These working stocks were prepared shortly before the experiments, and were added directly to the reactor. The working stock concentration was chosen on the basis that a  $10\text{-}\mu\text{L}$  aliquot would produce a maximal response in the yeast screen (concentration of  $500 \text{ng-steroid L}^{-1}$  in the assay) without the need for further sample manipulation. Moreover, any removal of steroid during the reactions would result in a readily detectable loss in the assay response, as the steroid concentrations would fall within the linear part of the dose–response curve of the assay.

The quartz water-jacketed reactor with titanium dioxide immobilized on titanium alloy (Fig. 10.4) was used with a 125-W Philips high-pressure mercury lamp placed 3 cm from the reactor. Some 8 mL of freshly prepared steroid ( $10 \mu\text{g L}^{-1}$ ) in

sterile water was transferred to the reactor and allowed to equilibrate for 1 h before irradiation with or without the TiO<sub>2</sub> catalyst (photocatalysis and photolysis, respectively). Duplicate samples (10 µL) were removed at intervals starting at time 0 (before UV light exposure), and then regularly throughout the experiments. The 10 µL aliquots were assayed directly in the recombinant yeast oestrogen assay. Details of the oestrogen-inducible expression system in yeast (validation) and preparation of the medium components have been described previously [54]. In brief, this yeast expresses the human oestrogen receptor (hER $\alpha$ ) and contains expression plasmids containing oestrogen-responsive sequences that control expression of the reporter gene Lac-Z (coding for the enzyme  $\beta$ -galactosidase). In the presence of oestrogens,  $\beta$ -galactosidase is produced and is secreted into the medium, where it breaks down the yellow chromogenic substrate chlorophenol red- $\beta$ -D-galactopyranoside (CPRG) into a red product that can be measured by absorbance at 540 nm. Duplicate water samples (10 µL) from each run were transferred to a 96-well optically flat microtiter plate (Linbro/Titertek, ICN FLOW, Bucks UK) at frequent time intervals throughout the experiments. Seeded yeast medium (190 µL) containing CPRG was then added to the microtiter plate and the plates were then sealed with autoclave tape, shaken vigorously for 2 min on a titer plate shaker, and incubated for 72 h at 32 °C. Each plate contained duplicate rows of samples at each time point, a row of blanks (200 µL assay medium only), a row containing sterile water (solvent control) and a row containing a serial dilution of the appropriate steroid substrate (positive control). After incubation, the plates were shaken and allowed to settle for 1 h, after which the absorbance was read at 540 nm (for color) and at 620 nm (for turbidity) using a Titertek Multiscan MCC/340 plate reader. To correct the oestrogenic response of each test chemical for turbidity ( $A_{\text{corr}}$ ), the correction shown in Eq. (12) was applied to the data in each well.

$$A_{\text{corr}} \text{ Chem} = A_{540} \text{ Chem} - (A_{620} \text{ Chem} - A_{620} \text{ Blank}) \quad (12)$$

Nominal steroid concentrations in the reactor were derived from the appropriate steroid standard curve, using the mean corrected absorbance values from each duplicate sample.

17 $\beta$ -Oestradiol, oestrone and 17 $\alpha$ -ethinyloestradiol were found to be oestrogenic *in vitro*, and their relative potencies agreed with previous findings [54]. Limits of detection for the measurement of oestrogenic activity within the reactor were 53 ng L<sup>-1</sup> for 17 $\beta$ -oestradiol and 17 $\alpha$ -ethinyloestradiol, and 100 ng L<sup>-1</sup> for oestrone. Oestriol did not produce an oestrogenic response in the yeast screen bioassay, indicating that it has insufficient oestrogenic activity to be detected at this level.

Results from the water control experiments were negative, indicating that both the reactor and the sterile water were free of oestrogenic contamination before commencing the experiments (data not shown). Similarly, in control experiments (8.5 h duration) with steroids in the absence of UV light the level of oestrogenic activity was unchanged over that time (data not shown). Therefore, no discernable adsorption of oestrogenic substrate on to the surface of the reactor, immobilized titanium dioxide or magnetic flea had occurred. There was also no difference in activity between standards prepared in ethanol and those prepared in sterile water.

**Tab. 10.2.** Time (minutes) taken for 50%, 90% and 100% removal of oestrogenic activity by photocatalysis and UVA photolysis.

Steroid oestrogen	Photocatalysis			UV radiation		
	50%	90%	100%	50%	90%	100%
17 $\beta$ -oestradiol	10	24	55	195	248	485
Oestrone	7	18	60	68	195	360
17 $\alpha$ -Ethinyl-oestradiol	8	27.5	50	23	72	120

Photocatalysis was the most effective method of inactivating all three steroid oestrogens, with virtually all oestrogenic activity being removed within 55 min. In contrast, UVA photolysis took 9 $\times$  longer for oestradiol, 6 $\times$  longer for oestrone and 2.4 $\times$  longer for ethinyl-oestradiol. For all three oestrogens, 50% of their oestrogenic activity was removed by photocatalysis within 10 min, and 100% within 1 h (Table 10.2 and Figs. 10.5–10.7). The decay rates (measured as loss of oestrogenic activity)

**Fig. 10.5.** Photocatalysis and UVA photolysis of 17 $\beta$ -oestradiol monitored using the yeast screen bioassay. Temporal removal of oestrogenic activity is shown over 90 min (a) and 8.5 h (b) reaction time.

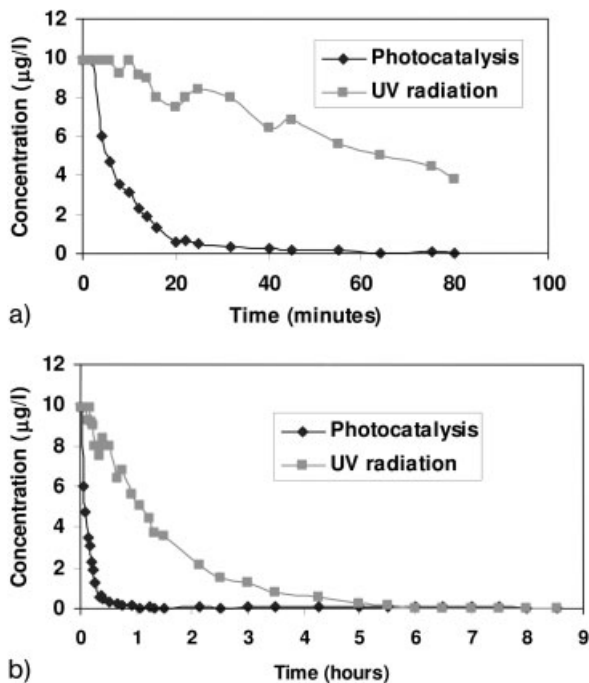

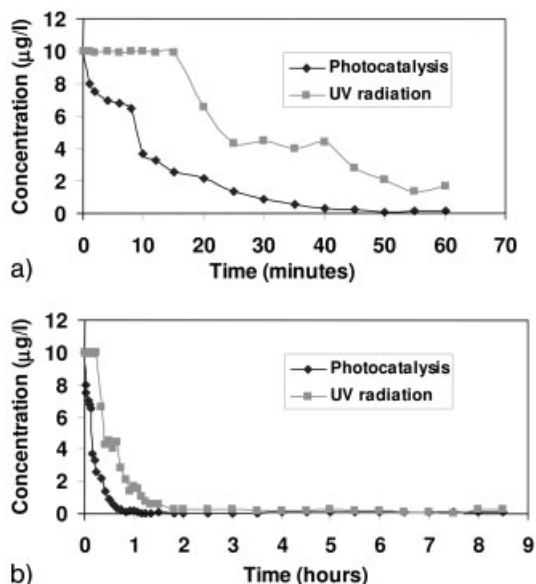

Fig. 10.6. Photocatalysis and UVA photolysis of oestrone monitored using the yeast screen bioassay. Temporal removal of oestrogenic activity is shown over 80 min (a) and 8.5 h (b) reaction time.

were similar for all three oestrogens (Table 10.3). In contrast, there were substantial differences in decay rates of the three steroids by UVA photolysis (no  $\text{TiO}_2$  catalyst), with  $17\alpha$ -ethynylestradiol decaying considerably faster than either of the two other steroids (Table 10.3).

We have directly compared temporal changes in the oestrogenic activity of aqueous solutions (initially  $10 \mu\text{g L}^{-1}$ ) of  $17\beta$ -oestradiol, oestrone and  $17\alpha$ -ethynylestradiol following both UVA photolysis and  $\text{TiO}_2$  photocatalytic degradation. A recombinant oestrogen assay based on yeast was used to measure the biological activity of the reaction mixtures. This yeast screen assay was previously shown to be highly specific for a range of steroid oestrogens and their metabolites, and the relative potencies of the steroids used in this study were found to be consistent with previous findings [54]. The yeast oestrogen screen detects both the parent compounds and any intermediate degradation products that bind to, and activate, the oestrogen receptor, regardless of their identity. Thus, this approach provides a real indication of the ability of the various treatments to affect the biological activity of the reaction mixture over time; information that cannot be obtained by analytical chemistry alone. This is particularly important given the rela-

**Fig. 10.7.** Photocatalysis and UVA photolysis of 17 $\alpha$ -ethinyloestradiol monitored using the yeast screen bioassay. Temporal removal of oestrogenic activity is shown over 60 min (a) and 8.5 h (b) reaction time.

tively persistent and poorly characterized nature of the intermediate products of endocrine disrupters generated during photocatalytic degradation [55, 56].

We have demonstrated that the oestrogenic activity of 17 $\beta$ -oestradiol, oestrone and 17 $\alpha$ -ethinyloestradiol was eliminated at the same rate during photocatalysis, whereas variable (and much slower) removal rates of oestrogenic activity occurred by UVA photolysis, with the order 17 $\alpha$ -ethinyloestradiol > oestrone > 17 $\beta$ -oestradiol. This compares favorably with our work in a quartz coil reactor monitored using fluorescence detection (Section 10.6) [57]. The ability of UVA to

**Tab. 10.3.** Kinetic data for photocatalysis and UVA photolysis of oestrogens.

Steroid	Photocatalysis pseudo-first order rate constant ( $\text{min}^{-1}$ )	UVA photolysis pseudo-first order rate constant ( $\text{min}^{-1}$ )
17 $\beta$ -Oestradiol	0.106	0.011
Oestrone	0.086	0.012
17 $\alpha$ -Ethinyloestradiol	0.086	0.035

remove all three steroids is important given that surface water systems are exposed to natural sunlight, and this may provide a mechanism for the removal of oestrogenic effects. Also, some water treatment plants employ UVC radiation to disinfect potable water, which may help eliminate oestrogenic compounds. The effect of UVC disinfection on degrading oestrogens in water is discussed further in Section 10.7. Although  $17\alpha$ -ethynyoestradiol appears to be more susceptible to UVA degradation than the natural oestrogens  $17\beta$ -oestradiol and oestrone, the ethynyl group of  $17\alpha$ -ethynyoestradiol also increases its resistance to bacterial oxidation, and therefore its persistence during STW aerobic digestion [5]. The similarity in removal rates of oestrogenic activity during  $\text{TiO}_2$  photocatalysis supports a similar mechanism of degradation for the steroid compounds. This may occur via extraction of the benzylic hydrogen to form the  $\cdot\text{CH}$  radical, which combines with oxygen, or via attack of the hydroxyl group to form the quinone. Indeed, Ohko and colleagues previously reported that photocatalysis of  $17\beta$ -oestradiol starts via oxidation of the phenol moiety [58], which is critical for receptor binding and for conferral of oestrogenicity to all steroid oestrogens [59].

Given that most known xenoestrogens are phenolic chemicals, and benzene rings are rapidly photodegraded by preferential hydroxyl radical attack [55, 58], it is likely that photocatalysis may quickly remove the capacity of these chemicals to bind to, and activate, the oestrogen receptor. The measurement of total organic carbon (TOC) may therefore underestimate the true capacity of photocatalysis to inactivate endocrine-disrupting chemicals (EDCs), where early reaction stages are key. However, the production of intermediate products with different types of biological activity must be considered. For example, testosterone-like species were identified by GC/MS during the photocatalysis of  $17\beta$ -oestradiol [58], although any putative androgenic activity of these degradation products was not investigated.

Oestrone is a major and relatively persistent biotransformation product of oestradiol during aerobic digestion [11]. The fact that photocatalysis was able to eliminate oestrone as quickly as  $17\beta$ -oestradiol is therefore encouraging, given that oestrone is only around 2-fold less oestrogenic than  $17\beta$ -oestradiol. However,  $17\alpha$ -ethynyoestradiol is probably the most important steroid pollutant, given that it is biologically active in fish at concentrations as low as  $0.1 \text{ ng L}^{-1}$  [60, 61]. The greater potency of  $17\alpha$ -ethynyoestradiol *in vivo* depends on the 17-ethynyl group, which increases its longevity in the body by reducing the rate of metabolism at C-16 and C-17 compared with endogenous steroids [62]. As photocatalysis was able to eliminate all three steroid oestrogens at a similar rate, it may be a valuable process for reducing the impact of this persistent and highly active group of compounds in the aquatic environment. The initial concentrations of steroids used in our reactor were three to four orders of magnitude greater than reported environmental levels, while the limits of detection for the steroids within the reactor approached levels reported for oestradiol and oestrone measured in influents to STWs [3].

In summary, we have demonstrated rapid temporal removal of the biological activity in aqueous solutions of oestrone,  $17\beta$ -oestradiol and  $17\alpha$ -ethynyoestradiol by photocatalysis over an immobilized  $\text{TiO}_2$  catalyst. Photocatalysis was much

more efficient than UV light alone. Similar rates of removal for all these oestrogens support an identical mechanism of action that is likely to involve oxidation of the phenol moiety of the steroids. Photocatalytic treatment of wastewaters could therefore serve to further decrease the oestrogenic steroid load entering the aquatic environment. In a more detailed study on photocatalysis of the natural and synthetic oestrogens in water we employed fluorescence detection, and also investigated the effects of initial pollutant concentration and light intensity (Section 10.6).

## 10.6

### Photocatalytic Degradation of 17 $\beta$ -Oestradiol, Oestriol and 17 $\alpha$ -Ethinylestradiol in a Quartz Coil Reactor Monitored using Fluorescence Spectroscopy

Photocatalytic degradation of the natural oestrogens 17 $\beta$ -oestradiol and oestriol and the synthetic oestrogen 17 $\alpha$ -ethinylestradiol in water were investigated. Reactions were carried out in a quartz coil reactor coated internally with titanium dioxide (Degussa P25). Degradation by UV light alone was also investigated. Fluorescence spectroscopy was used to monitor the reactions. The effect of both initial concentration and light intensity on photocatalysis and photolysis of 17 $\beta$ -oestradiol in water were also investigated.

A quartz coil reactor and a Hanovia 125-W medium pressure mercury lamp blanketed in nitrogen were used [57]. Coils were prepared from a 1 m length of 2 mm ID quartz tubing with TiO<sub>2</sub> immobilized onto the quartz coil as follows. The coil was first cleaned with chromic acid, rinsed thoroughly and dried. It was then filled with a 20% solution of hydrofluoric acid and allowed to stand for about 30 min, after which it was washed thoroughly with distilled water. The coil was filled with TiO<sub>2</sub> suspension (1% suspension of Degussa P25 TiO<sub>2</sub> powder, sonicated for 20 min) and allowed to stand for a few minutes, drained and then dried by passing warm air through it. A thin white film of TiO<sub>2</sub> was formed on the inside surface of the coil. This procedure was repeated 2–3 times to ensure that the inside surface of the coil is completely covered. After the final drying, distilled water was continuously pumped through the coil to wash away any loose powder [63]. The wavelength of light emitted from the Hanovia lamp also includes the UVB and UVC regions of the spectrum. Experiments with TiO<sub>2</sub> are therefore photolysis as well as photocatalysis. A solution (3  $\mu\text{mol dm}^{-3}$ ;  $\sim 0.8 \text{ mg L}^{-1}$ ) of the oestrogen under study was made up in MilliQ water from a stock solution in acetonitrile. The oestrogen solution was passed through the quartz coil reactor at different flow rates, giving different retention times, and a sample was collected and analyzed by fluorescence detection,  $\lambda_{\text{ex}}$  230 nm,  $\lambda_{\text{em}}$  310 nm. This experiment was repeated using an identical quartz coil without TiO<sub>2</sub>, i.e., photolysis of the oestrogen solution. This procedure was carried out at least twice for each oestrogen. The effect of initial concentration on the reaction with 17 $\beta$ -oestradiol was investigated by repeating the procedure at varying concentrations (3, 2, 1, 0.5, 0.25, and 0.1  $\mu\text{mol dm}^{-3}$ ) (0.8–0.03  $\text{mg L}^{-1}$ ). The effect of light intensity on photocatalysis and photolysis of 17 $\beta$ -oestradiol was investigated by placing the reactor at different distances from the

lamp (3.25, 5, 7.5 and 10 cm, corresponding to light intensities of 2509, 1060, 470 and 265 mW, respectively).

Table 10.4 gives average values obtained for the rate constant,  $k$ , the initial rate and the half-life for photocatalysis and photolysis of  $17\beta$ -oestradiol, oestriol and  $17\alpha$ -ethynyloestradiol.

The fact that the lamp used in this work (125-W Hanovia medium-pressure mercury) emits radiation in the UVA, UVB and UVC region of the spectrum some photolysis as well as photocatalysis takes place. The results show that both photocatalysis and photolysis are effective in degrading all three oestrogens in water. Plots of time against  $\ln(C/C_0)$  for the photocatalysis and photolysis of  $17\beta$ -oestradiol confirm our earlier work [51, 64] (Sections 10.4 and 10.5) that photocatalytic and photolysis of  $17\beta$ -oestradiol and  $17\alpha$ -ethynyloestradiol follow pseudo-first order reactions. More recently, other workers [58, 65–67] have reported similar findings. This work shows that oestriol follows similar behavior to the other natural oestrogens and the synthetic oestrogen. The sets of results are consistent with each other, with a good correlation in each case. This is confirmed by the low standard errors of the average values for the rate constant,  $k$ , initial rate and correlation coefficient ( $R^2$ ) (Table 10.4). The average rate constants for photocatalysis and photolysis show that the photocatalytic degradation of  $17\beta$ -oestradiol and oestriol is almost

1.5 $\times$  faster than degradation by UV light alone. However, photocatalysis and photolysis of 17 $\alpha$ -ethinyloestradiol occur at almost the same rate (Table 10.4).

Table 10.4 also shows that 17 $\alpha$ -ethinyloestradiol has the fastest rate for photocatalysis, followed by 17 $\beta$ -oestradiol and finally oestriol (1.5 $\times$  slower than 17 $\alpha$ -ethinyloestradiol). 17 $\alpha$ -Ethinylloestradiol also degrades the fastest by photolysis, at almost the same rate as photocatalysis, degrading 1.5 $\times$  faster than 17 $\beta$ -oestradiol and over twice as fast as oestriol. '17 $\alpha$ -ethinyloestradiol seems to be a less stable molecule than 17 $\beta$ -oestradiol and oestriol under photocatalytic and photolytic conditions. The addition of the ethynyl group possibly causes the molecule to be less stable and degrade more rapidly under these conditions due to the triple bond of the ethynyl group which would absorb UV light more easily. Oestriol seems to be the most stable molecule of the three oestrogens, degrading at the slowest rate. The addition of the OH group may stabilise the phenolic ring and help resist breakdown by photocatalysis and UV light. The mechanism of degradation of the oestrogens may occur via extraction of the benzylic hydrogen to form the CH $\cdot$  radical which combines with oxygen, or via attack of the hydroxyl group to form the quinone (as outlined in section 5). Ohko *et al.* previously reported that the photocatalysis reaction with 17 $\beta$ -oestradiol starts via the phenol moiety and also confirmed that 17 $\beta$ -oestradiol in water is completely mineralised as a result of the photocatalytic reactions and suggested a mechanism for the reaction, identifying 10 $\epsilon$ -17 $\beta$ -dihydroxy-1,4-estradien-3-one and testosterone-like species as intermediate products [58].

Initial work on photocatalysis of 17 $\beta$ -oestradiol [51] in a batch reactor with TiO $_2$  immobilized on Ti alloy gave a first-order rate constant of 0.016 min $^{-1}$  (Section 10.4). This is much lower than the rate constant obtained in this work (0.174 min $^{-1}$ ), indicating that the quartz coil reactor is a much more efficient system, owing to the increased surface area. The trend obtained here for photocatalysis compares favorably with work [64] detailed in Section 10.5 where photocatalytic degradation of 17 $\beta$ -oestradiol, 17 $\alpha$ -ethinyloestradiol and oestrone were monitored using a yeast screen bioassay as a test for oestrogenicity. The oestrogenic activity of 17 $\beta$ -oestradiol, oestrone and 17 $\alpha$ -ethinyloestradiol was eliminated at the same rate during photocatalysis whereas variable (and much slower) removal rates occurred by UVA photolysis, with the order 17 $\alpha$ -ethinyloestradiol > oestrone > 17 $\beta$ -oestradiol (0.086–0.106 min $^{-1}$ ). The rates of photolysis in this work (0.134 min $^{-1}$  for 17 $\beta$ -oestradiol and 0.195 min $^{-1}$  for 17 $\alpha$ -ethinyloestradiol) are much higher than for this previous work (0.011 and 0.035 min $^{-1}$ , respectively) due to the different lamps used. The lamp used in this work (125-W Hanovia medium-pressure mercury) emits radiation in UVA, UVB and UVC region of the spectrum, indicating that some photolysis is taking place as well as photocatalysis. The increase may also be due to the increased area for reaction in the coil reactor.

Table 10.5 gives the average values for the rate constant,  $k$ , initial rate and half-life calculated for each concentration.

Initial concentration against rate was plotted for the results obtained above for both photocatalysis and photolysis of 17 $\beta$ -oestradiol (Figs. 10.8 and 10.9, respectively).

**Tab. 10.5.** Average values of rate constant,  $k$ , initial rate and half-life for photocatalysis and photolysis of  $17\beta$ -oestradiol at different initial concentrations.

**Fig. 10.8.** Initial concentration against rate for photocatalysis of  $17\beta$ -oestradiol monitored using fluorescence.

Fig. 10.9. Initial concentration against rate for photolysis of 17 $\beta$ -oestradiol monitored using fluorescence.

The results are consistent with each concentration with good correlation (Table 10.5). The slope of the best-fit line is 0.180 for photocatalysis and 0.131 for photolysis (Figs. 10.8 and 10.9, respectively). The results demonstrate that, as the initial concentration of 17 $\beta$ -oestradiol increases, the reaction rate increases proportionally for both photocatalysis and photolysis, confirming that the reactions are first order [51, 57]. The slope of the graph for photocatalysis is 1.5 $\times$  that of photolysis, indicating that photocatalysis coupled with photolysis occurs at 1.5 $\times$  the rate of photolysis alone.

Interestingly, the effect of initial concentration on photocatalysis follows a different pattern than shown previously [51] where the Langmuir–Hinshelwood model applied for the same concentration range. In this model, adsorption of the reactant on the surface of the catalyst is considered. The rate increases with initial concentration of 17 $\beta$ -oestradiol and then levels off at higher concentrations. This is because, at higher concentrations, the surface of the TiO<sub>2</sub> becomes saturated with oestradiol molecules and the reaction rate reaches a maximum. In this work, photolysis occurs at a rate comparable to that of photocatalysis. This competing reaction also consumes 17 $\beta$ -oestradiol, reducing the number of molecules available for saturation of the titanium dioxide surface. This observation may be important in industrial applications of the photocatalytic breakdown of organic pollutants in water. Photocatalysis and photolysis could be applied together to increase rates of reaction at high concentrations of pollutants.

Table 10.6 summarizes results obtained for the effect of light intensity on both photocatalysis and photolysis of 17 $\beta$ -oestradiol. Good correlation was obtained for all the results.

Light intensity ( $I$ ) is an important parameter to consider in photocatalysis ( $R \propto I$ ), especially for industrial applications in terms of cost. Increasing the light intensity affects the rate of the reaction by increasing the number of charge carriers generated in the semiconductor. Most researchers have found different effects at different levels of light intensity [68].

- At low light intensities, the rate increases in proportion to the light intensity, i.e.,  $R \propto I$ ,  $n = 1$ .
- At intermediate light intensities the rate only varies with the square root of intensity [69, 70], i.e.,  $R \propto I^{1/2}$ ,  $n = 1/2$ .
- At high light intensities the rate of photodegradation is independent of light intensity, i.e.,  $R \propto I^0$ ,  $n = 0$ .

For photocatalysis, as light intensity increases the rate increases due to the increased number of oxidizing species produced. The rate increases with light intensity to a power  $n$  (the gradient of a linear log–log plot, [Eq. (14)]). At low light intensities the rate of initial degradation increases directly in proportion to light intensity (gradient  $\sim 1$ ), suggesting that few oxidizing species are lost through recombination processes. At high light intensities the rate of initial degradation increases in proportion to  $I$  to the power of 0, i.e., the rate becomes independent of light intensity and the expected rate-limiting factor is mass transfer. At intermediate light intensities the rate only varies with the square root of intensity [69, 70] and hence efficiency suffers. This was attributed by Egerton and King [71] to energy wasting recombination reactions between electrons and holes and by Kormann [72] to bimolecular combination of hydroxyl radicals.

Increased intensity always results in an increase in the volumetric reaction rate until the mass transfer limit is encountered. However, once intermediate light intensities are reached any increase in  $I$  will not lead to a proportional increase in rate and industrially may not be worth the extra cost. The  $I^1$  to  $I^{0.5}$  rate transition is

**Tab. 10.7.** Dependency of rate of photocatalysis on light intensity for various organic substrates.

said to depend on the catalyst material [73]. The relationship between rate and light intensity can therefore be represented by Eq. (13).

$$\text{Rate} = k_1 I^n \quad (13)$$

The rate constant  $k$  will include terms for the extent of recombination, substrate concentration, etc. This constant will be different for different transition regions. The linear form of this equation is:

$$\ln(\text{rate}) = \ln k + n \ln(I) \quad (14)$$

A plot of  $\ln(\text{rate})$  against  $\ln(\text{light intensity})$  will yield a straight line for each transition region, with a slope equal to  $n$ . For the photocatalysis of 17 $\beta$ -oestradiol, such a plot gave a best fit line with a slope,  $n$ , of 0.461, which is approximately 0.5, indicating intermediate light intensities. Other workers found similar results when investigating light intensities for other substrates. Table 10.7 shows the literature values of  $n$  for different organic compounds.

Dionysiou et al. have reported the photocatalytic degradation of 4-chlorobenzoic acid as a function of light intensity, using a rotating disk photocatalytic reactor [82]. They found that the rate of degradation followed a linear dependency with incident light intensity and attributed it to the existence of low local values of incident light intensity on the illuminated disk. Ohko et al. have investigated the effect of light intensity on the degradation of propan-2-ol and the effect of concentration [83]. They suggested that for small concentrations of contaminant it is more beneficial to operate the process at low light intensities and at the range where the rates are not mass-transport controlled. At high contaminant concentration, the reaction

**Fig. 10.10.** Rate against light intensity for photolysis of  $17\beta$ -oestradiol monitored using fluorescence.

may be light-limited but light utilization efficiency will be higher. This was also reported by Minero [84], who recommended that, in solar photocatalytic applications, concentration of the solar light is unnecessary. Industrially, these are important points to consider if photocatalysis were applied for the treatment of real environmental water samples where oestrogens and other EDCs are present in very low concentrations and also in situations where solar illumination is used as the UV source. Figure 10.10 shows the plot of rate against light intensity for the photolysis of  $17\beta$ -oestradiol.

The relationship is linear at low light intensities up to a certain point (intermediate light intensity) where the rate starts to level off (high light intensities). This suggests that the rate is proportional to light intensity up to a certain point, where it then becomes independent of light intensity. This could be interesting from an industrial viewpoint, where a combination of photocatalysis and UV radiation could be used to increase the rate of reaction instead of increasing the UV light alone, where the rate levels off at high light intensities.

Photocatalysis and photolysis are effective for the degradation of the three oestrogens  $17\beta$ -oestradiol, oestriol and  $17\alpha$ -ethnyloestradiol in water. Photocatalysis coupled with photolysis is much more effective in degrading the oestrogens than photolysis alone. The reactions follow pseudo-first order kinetics.  $17\alpha$ -Ethnyloestradiol degrades the fastest for both photocatalysis and photolysis followed by  $17\beta$ -oestradiol and then oestriol. This was attributed to the triple bond of the ethynyl group, which absorbs UV light more easily. The rate varies linearly with initial concentration both for photocatalysis combined with photolysis and for photolysis of  $17\beta$ -oestradiol in water. Photocatalysis degrades  $17\beta$ -oestradiol at twice the rate of photolysis. The rate was proportional to the square root of light intensity for photocatalysis of  $17\beta$ -oestradiol. The relationship between light intensity and degradation rate by photolysis is linear up to a point, when it then starts to

level off. The ability of UV light to remove all steroids is important given that surface water systems are exposed to natural sunlight, and this may provide a mechanism for the removal of oestrogenic effects. Also, some water treatment plants employ UVC radiation to disinfect potable water, which would help to eliminate oestrogenic compounds in the water. An investigation into the efficiency of UVC disinfection for the removal of the natural and synthetic oestrogen in water was made and compared with photocatalysis and UVA light alone. This work is outlined in section 7 below.

## 10.7

### Comparison of Photocatalysis with UVA and UVC Radiation for the Degradation of Natural and Synthetic Oestrogens in Water

Our previous studies have shown that  $\text{TiO}_2$  photocatalysis is effective for the degradation of natural and synthetic oestrogens in water and that it is more effective than UV light alone. Some water treatment companies currently use UVC disinfection to remove trace organics as a final stage in the water treatment process. UVC radiation uses high intensity light at 253 nm, which is energy intensive and therefore very expensive. In this work we study the effect of UVC disinfection for the removal of the natural and synthetic oestrogens in water and compare it with photocatalysis and UVA light alone.

Photocatalysis experiments were carried out in a spiral Pyrex reactor (85 mL volume), with  $\text{TiO}_2$  immobilized onto the inside wall, with a black light blue fluorescent lamp (NEC, 15 W, maximum emission at  $\sim 350$  nm, emission range 300–400 nm) fitted through the centre of the coil.  $\text{TiO}_2$  was immobilized onto the reactor walls as described previously [57] (Section 10.6). Experiments with UVA light alone were carried out in the same reactor free from  $\text{TiO}_2$ . A similar set-up was used for the UVC radiation experiments except the spiral reactor (85 mL volume) was made from quartz and free from  $\text{TiO}_2$  and was used with a slim line germicidal lamp (UV Air Pty Ltd, emission  $\lambda = 253$  nm). The reactors were connected to a peristaltic pump (Masterflex<sup>®</sup> Quick-Load, Cole-Palmer Instrument Co.) by Masterflex flexible tubing to enable solution circulation through the reactor at  $150 \text{ mL min}^{-1}$  and to an on-line fluorescence spectrometer (Perkin Elmer LS-45 with FLWinLab software), which monitored degradation of the oestrogens at  $\lambda_{\text{ex}} = 230$  nm and  $\lambda_{\text{em}} = 310$  nm.

A standard solution of  $3 \mu\text{mol dm}^{-3}$  of oestrogen (i.e.,  $0.82 \text{ mg L}^{-1}$   $17\beta$ -oestradiol,  $0.86 \text{ mg L}^{-1}$  oestriol and  $0.89 \text{ mg L}^{-1}$   $17\alpha$ -ethinyloestradiol) was made up in MilliQ water from stock solutions in acetonitrile (final pH 5.5). Oestrogen (120 mL) was then pumped through the reactor set-up at  $150 \text{ mL min}^{-1}$  for approximately 5 min to allow the solution to equilibrate before the experiment was started. The UV lamp was then turned on and the “timedrive” method (FLWinLab software), which measured fluorescence intensity over time, was started where measurements were taken every second. This procedure was carried out for each oestrogen in duplicate for  $\text{TiO}_2$  photocatalysis, UVA radiation and UVC radiation.

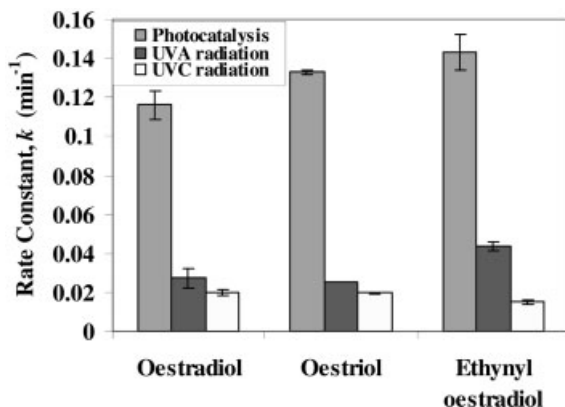

Fig. 10.11. Degradation by photocatalysis, UVA and UVC radiation of natural and synthetic oestrogens in water in a spiral reactor monitored using fluorescence spectroscopy.

Figure 10.11 shows a histogram of the rate constants for photocatalysis of the natural and synthetic oestrogens over  $\text{TiO}_2/\text{UVA}$  compared to UVA and UVC radiation alone. Table 10.8 presents the first-order rate constants for each reaction with standard errors.

Clearly, from Fig. 10.11 and Table 10.8, photocatalysis is much more effective than UVA or UVC radiation for all of the oestrogens. The rates are up to 5× greater for photocatalysis than for UVA light alone and up to 9× faster (17 $\alpha$ -ethynyl-oestradiol) than with UVC disinfection. Photocatalytic rates are quite comparable for all three oestrogens when standard errors are taken into account, although rates for 17 $\alpha$ -ethynyl-oestradiol and oestriol are slightly higher than for 17 $\beta$ -oestradiol. UVA radiation rates for the natural oestrogens 17 $\beta$ -oestradiol and oestriol are comparable. However, UVA radiation for the synthetic oestrogen 17 $\alpha$ -ethynyl-oestradiol is significantly higher. This agrees with previous work in a

Tab. 10.8. Kinetic data for photocatalysis, UVA photolysis and UVC photolysis of oestrogens in water.

Steroid	First order rate constants, $k$ (min <sup>-1</sup> )		
	Photocatalysis	UVA photolysis	UVC photolysis
17 $\beta$ -Oestradiol	0.116 ± 0.007	0.028 ± 0.005	0.0201 ± 0.002
Oestriol	0.133 ± 0.001	0.025	0.196
17 $\alpha$ -Ethynyl-oestradiol	0.143 ± 0.009	0.044 ± 0.002	0.0151 ± 0.001

stirred-tank batch reactor with a 125-W high-pressure mercury lamp (Section 10.5) [64] and a photocatalytic quartz coil reactor and 125-W medium-pressure mercury lamp (Section 10.6) [57] and, as mentioned earlier, may be because the triple bond of the ethynyl group present would absorb UV light more easily. Rates for UVA and UVC radiation are comparable for  $17\beta$ -oestradiol and oestriol. However, UVA and UVC radiation rates for  $17\alpha$ -ethynyloestradiol differ significantly, with UVA radiation being almost  $3\times$  faster than UVC radiation.  $17\alpha$ -Ethynyloestradiol may absorb better in the UVA region of the spectrum than in the UVC region. The blue-black lamp (UVA radiation) covers a broader spectrum ( $\lambda = 300\text{--}400$  nm with maximum emission at  $\lambda = 350$  nm), and so also covers part of the visible and the UVB spectrum, whereas the UVC lamp emits radiation only at  $\lambda = 253$  nm. The UV spectra of  $17\beta$ -oestradiol, oestriol and  $17\alpha$ -ethynyloestradiol show that they absorb at  $\lambda = 230$  nm and  $\lambda = 280$  nm and that absorption is much more intense at  $\lambda = 230$  nm. Both peaks are broad and there may be some absorption at  $\lambda = 300$  nm for the  $\lambda = 280$  nm peak. The rate of photons absorbed per reactor volume for each lamp was calculated using ferrioxalate actinometry [85]. Table 10.9 shows the results.

Table 10.9 shows that the UVC lamp is much more intense than the UVA lamp. However, UVA is sufficient to breakdown the oestrogens in water. This is encouraging from an industrial viewpoint since UVC disinfection requires much more energy and is therefore more costly. Photocatalysis, however, is still much more efficient than UV light alone, with rates up to  $9\times$  faster.

Our initial work on the photocatalysis of  $17\beta$ -oestradiol [51] (Section 10.4) in a batch reactor with  $\text{TiO}_2$  immobilized on Ti alloy gave a first-order rate constant of  $0.016 \text{ min}^{-1}$ . This is much lower than the rate constant obtained in this work ( $0.116 \text{ min}^{-1}$ ), which is comparable with more recent work in a quartz coil reactor ( $0.174 \text{ min}^{-1}$ ) (Section 10.6) [57], indicating that a coil reactor is a much more efficient system due to the increased surface area. The trend obtained here for photocatalysis compares favorably with previous work (Sections 10.5 and 10.6) [57, 64] where  $17\beta$ -oestradiol and  $17\alpha$ -ethynyloestradiol were degraded at the same rate during photocatalysis whereas variable and slower degradation rates occurred by UV radiation, with the order  $17\alpha$ -ethynyloestradiol  $>$   $17\beta$ -oestradiol ( $0.086\text{--}0.106 \text{ min}^{-1}$ ). Nakashima et al. [86] reported rate constants of  $0.033$  and  $0.050 \text{ min}^{-1}$

**Tab. 10.9.** Photons absorbed per reactor volume for each of the lamps measured using ferrioxalate actinometry ( $\mu\text{Einsteins s}^{-1} \text{ L}^{-1} \pm$  standard error).

Lamp	Photons absorbed ( $\mu\text{Einsteins s}^{-1} \text{ L}^{-1}$ )
UVC lamp ( $\lambda = 253$ nm)	$74 \pm 3$
UVA lamp ( $\lambda = 350$ nm)	$57 \pm 1$

for  $17\beta$ -oestradiol in two different types of reactors with  $\text{TiO}_2$  immobilized on PTFE mesh sheets, and, in more recent work [87],  $0.15$  and  $0.12 \text{ min}^{-1}$  for  $17\beta$ -oestradiol and oestrone, respectively.

Titanium dioxide photocatalysis is an effective method for the degradation of the natural oestrogens  $17\beta$ -oestradiol and oestriol and the synthetic oestrogen  $17\alpha$ -ethinyloestradiol in water in an immobilized  $\text{TiO}_2$  spiral coil reactor. It is much more efficient than UVA or UVC radiation alone (up to  $9\times$  faster). Industrially, this is very important as costs and energy requirements can be drastically reduced. Particle-mediated photocatalytic techniques can improve the performance of water treatment systems employing UV by reducing the energy requirements for the UV stage. The successful and efficient degradation of these compounds will potentially provide cheaper and cleaner means of removing them from groundwater, wastewaters and drinking water. Because the only energy source is near-UV light, the technology should, ultimately, be able to function on sunlight alone.

## 10.8

### Overall Conclusions and Identification of Research Needs

The main aim of this work was to investigate the degradation of natural oestrogens ( $17\beta$ -oestradiol, oestrone and oestriol) and a synthetic oestrogen ( $17\alpha$ -ethinyloestradiol) in water using titanium dioxide photocatalysis. This was carried out using different chemical and biological analytical techniques.

The first objective was to determine if oestrogens could be degraded by photocatalysis and UV radiation. Initial studies in a batch reactor monitored using HPLC and fluorescence detection showed that  $17\beta$ -oestradiol in water could be degraded by photocatalysis and was much more effective than UV light alone. The reaction followed first-order reaction kinetics and Langmuir–Hinshelwood behavior was observed.

The second objective was to determine if oestrogenic activity is removed from the oestrogenic water samples after treatment with photocatalysis and UV radiation since the oestrogenic activity of these substances is the main concern. This was carried out using a yeast screen bioassay. It was found that photocatalysis and UV radiation can remove all oestrogenic activity from water samples containing the natural oestrogens  $17\beta$ -oestradiol and oestrone and the synthetic oestrogen  $17\alpha$ -ethinyloestradiol. Again, photocatalysis is much more efficient than UV light alone. The rates of reaction for the three oestrogens studied were very similar for photocatalysis. For UV radiation,  $17\alpha$ -ethinyloestradiol degraded the fastest followed by oestrone and  $17\beta$ -oestradiol.

The work with fluorescence spectroscopy also fulfilled the first objective, showing that all the natural and synthetic oestrogens in water could be degraded by photocatalysis. The results demonstrated that  $17\alpha$ -ethinyloestradiol degraded the fastest followed by  $17\beta$ -oestradiol and oestriol for both photocatalysis and UV radiation combined and for UV light alone. Direct photolysis reactions are generally of low efficiency compared with procedures involving hydroxyl radical generation.

However, here there was no major difference in the rates for photocatalysis and UV light alone. This was due to the lamp used, which emitted in the UVA, UVB and UVC range of the spectrum. The reactions also follow pseudo-first order kinetics.  $17\alpha$ -Ethinylloestradiol degrades the fastest for both photocatalysis and photolysis followed by  $17\beta$ -oestradiol and oestriol. This was attributed to the triple bond of the ethynyl group in  $17\alpha$ -Ethinylloestradiol, which absorbs UV light more easily.

The third objective was to investigate the effect of varying reaction conditions on the photocatalytic reaction, i.e., initial concentration and light intensity. The relationship between initial concentration and rate is linear for both photocatalysis combined with photolysis and for photolysis of  $17\beta$ -oestradiol in water. Photocatalysis degrades  $17\beta$ -oestradiol at twice the rate of photolysis. The rate was proportional to the square root of light intensity for photocatalysis of  $17\beta$ -oestradiol. The relationship between light intensity and the rate of degradation by photolysis is linear up to a point; it then starts to level off.

The final objective was to compare photocatalysis with UVA and UVC disinfection. Here, photocatalysis was found to be much more efficient than UV light alone. Titanium dioxide photocatalysis is an effective method for the degradation of the natural oestrogens  $17\beta$ -oestradiol and oestriol and the synthetic oestrogen  $17\alpha$ -ethinylloestradiol in water in an immobilized  $\text{TiO}_2$  spiral coil reactor. The spiral reactor was much more efficient than a batch reactor with  $\text{TiO}_2$  immobilized on Ti alloy due to the increased surface area of the former. Photocatalysis was much more efficient than UVA or UVC radiation alone (up to  $9\times$  faster). This is very important industrially, where costs and energy requirements can be drastically reduced. Particle-mediated photocatalytic techniques can improve the performance of water treatment systems employing UV by reducing the energy requirements for the UV stage. The fact that solar illumination can be used in these systems is an added advantage for applications in countries with a hot and sunny climate. As the importance of water reuse and water recycling increases, an effective technique is needed to remove trace organics in our water supply.  $\text{TiO}_2$  photocatalysis can be used to develop a safe, cost-efficient water treatment process.

Based on the work presented in this chapter, several research areas and needs can be proposed:

1. Improvements in chemical and biological analysis for the detection of steroid oestrogens at  $\text{ng L}^{-1}$  levels and for real water sample analysis.
2. Investigations into the application of photocatalysis for the removal of steroid oestrogens in real water samples, e.g., treated sewage effluent samples where other substances are present.
3. Improvement in the engineering design of photocatalytic reactor systems with a view to incorporating the photocatalytic treatment stage into existing water treatment systems.

In summary, the challenge is for water treatment scientists to design and apply titanium dioxide nanoparticles for the photocatalytic breakdown of micropollutants such as steroid oestrogens in real water samples.

The principles of organic photoelectrochemistry elaborated over the past decade clearly show that interfacial electron transfer to surface adsorbates can result in oxidative degradation, often leading to complete mineralization of organic pollutants. The wide band gap and high chemical stability of TiO<sub>2</sub> nanoparticles gives them an extremely broad reactivity range. Irradiated TiO<sub>2</sub> nanoparticles efficiently degrade nearly every significant functional group, including the most environmentally hazardous and persistent substances. Since our first report of the use of photocatalysis for the degradation of oestrogens in water [51], its potential use as a method for reducing discharges of EDCs into the aquatic environment has been of increasing interest [57, 64–66, 86–92]. Indeed, the degradation of nonylphenol polyethoxylate surfactants [90] and their biotransformation products [65, 66, 88], Bisphenol-A [83, 86, 89, 92–94], phthalates [93], atrazine [95], resorcinol [96] and amitrole [97] using TiO<sub>2</sub> photocatalysts have been reported. However, the significant proportion of the overall oestrogenic activity of many effluent discharges [9] is due to the steroid oestrogens. Photocatalytic degradation of 17β-oestradiol [51, 57, 64, 83, 86–88, 91, 98, 99], oestrone [51, 57, 64, 98, 99] and 17α-ethynylestradiol [51, 57, 64, 87, 88, 91, 98, 99] has been shown. Solar photocatalytic degradation has also been investigated for the degradation of bisphenol A [100]. TiO<sub>2</sub> nanoparticles are the most widely used for the removal of EDCs in water. However, there is one report of the use of a visible-light-driven BiVO<sub>4</sub> photocatalyst for the degradation of nonylphenols in water by solar radiation [101]. However, titanium dioxide nanoparticles have been shown to be the most effective photocatalyst for water treatment applications. TiO<sub>2</sub> as a suspension, coating, or immobilized catalyst exhibits promising potential for environmental amelioration, particularly as continuing research into the engineering optimization of photocatalyst dispersal builds on the framework of earlier investigations [32]. Few studies have evaluated the efficacy of TiO<sub>2</sub>-assisted photodegradation in the treatment of mixtures of contaminants and actual wastewaters. The process is unlikely to be used in the treatment of high-strength industrial wastewaters or for the large-scale direct clean-up of contaminated soils. Loss of efficiency due to competing substrates in the case of mixtures, interference by dissolved anions and cations, which cause significant reductions in rates of photodegradation, and light interference by high concentrations of soils are likely problems in industrial wastewaters and soils [29]. The literature indicates that oestrogens play an important role in the development of reproductive abnormalities and other health problems. Hopefully, growing awareness that reproductive function may be at risk will stimulate both the basic and clinical research within this field that have received relatively little attention [102]. Biologists, chemists and engineers should continue to work in this area to fully understand the environmental implications of these compounds and in the disposal, monitoring and removal of them. There is a need for the development of an effective technique for the removal of these compounds and other trace organic contaminants in our water supply. Titanium dioxide nanoparticles and UV light to produce the photocatalytic process could be a solution to the problem of EDCs and other micropollutants in the aquatic environment.

### 11.1

#### Introduction

##### 11.1.1

###### Overview

Current water-borne pathogen sensor development relies on colony growth or fluorescent-based techniques, which are not *in situ*, rapid, or sensitive. In our laboratory, we have developed piezoelectric microcantilever sensors that can perform rapid, *in situ*, in-water pathogen detection with sensitivities well above that of current techniques. We have shown that using PZT/glass cantilevers of sub-millimeter length with a 2 mm glass tip, which exhibited  $5 \times 10^{-11}$  g Hz<sup>-1</sup> mass detection sensitivity, *in situ* quantification of *Salmonella typhimurium* was achieved with a concentration limit of  $10^3$  cells mL<sup>-1</sup>; this is lower than the infectious dosage,  $10^5$  cells mL<sup>-1</sup>, which is also the concentration limit of commercial ELISA, QCM, and nanowire-based sensors. Furthermore, we have developed two types of miniaturized piezoelectric cantilevers for even better sensitivity. With 500 μm long PMN-PT/Cu microcantilevers, fabricated from freestanding PMN-PT films, that exhibited  $3 \times 10^{-13}$  g Hz<sup>-1</sup> detection sensitivity we achieved a better than 50 spores mL<sup>-1</sup> detection limit in 1 mL of *Bacillus anthracis* suspension. With PZT/SiO<sub>2</sub> microcantilevers less than 50 μm long, fabricated by silicon-based microfabrication techniques, the detection sensitivity is expected to reach better than  $10^{-16}$  g Hz<sup>-1</sup> and further lower the concentration limit. In addition to ultrasensitive, rapid, *in situ* detection, piezoelectric microcantilevers use simple electrical measurements, which is ideal for portable simultaneous array sensing in environmental applications.

##### 11.1.2

###### Sensor

Current sensing technologies rely on fluorescence [1, 2], laser [3] or fiber-optics-based methods [4], quartz crystal microbalance [5], electrochemical enzyme immu-

noassays [6], amplification schemes such as polymerase chain reaction (PCR) [7–9], and binding to nanometer-size metal particles [10]. Most of the techniques are neither direct nor quantitative and are slow. They do not lend themselves to multiplexing and high throughput. Development of direct sensing technologies relies heavily on silicon-based microcantilevers [11–15] due to their availability and ease of integration with existing silicon-based methodologies. Binding of target antigens to the antibody on the cantilever surface is directly detected by monitoring the cantilever's resonance frequency shift due to the mass of the adsorbed target antigens. Silicon-based microcantilevers offer high detection sensitivity,  $\Delta m/\Delta f \sim 10^{-12}$  g Hz<sup>-1</sup> [16, 17], where  $\Delta m$  and  $\Delta f$  denote, respectively, the mass change and corresponding resonance frequency change due to the binding of target molecules. However, all silicon-based microcantilevers rely on complex external optical components for deflection detection and an external driver for actuation generation. Moreover, immersing silicon-based microcantilevers in water reduces the  $Q$  factor (ratio of the resonance peak frequency relative to the resonance peak width at half peak height) to about one, prohibiting silicon-based microcantilevers from in-water detection [18]. Silicon-based microcantilevers cannot have high resonance peaks in water because they are not piezoelectric. They rely on a vibration driver located at the cantilever base to generate deflections at the cantilever tip, which is ineffective. In comparison, piezoelectric sensors use electrical means for detection and do not have the bulkiness and complexity of silicon-based sensors. However, current piezoelectric biosensors are based on quartz crystal microbalances (QCM) [19], which are disk devices with a mass detection sensitivity of  $10^{-8}$  g Hz<sup>-1</sup>, about  $10\,000\times$  less sensitive than the silicon-based microcantilevers. A QCM is about 1–3 cm in size, and silicon microcantilevers require laser alignment. Both are unfit for high-throughput array environmental applications.

In this chapter, we describe a new type of biosensor: array piezoelectric microcantilever sensors (PEMS) that can simultaneously detect multiple antigens *in situ* both in water and in-air with high sensitivity for water-borne pathogen applications. Section 11.1.3 provides an introduction to piezoelectric cantilever sensors (PECS). Section 11.2 gives a brief theoretical description of PECS without (Section 11.2.1) and with (Section 11.2.2) a nonpiezoelectric tip. Section 11.3 gives various examples of *in situ*, in-water biodetection as well as in-air nerve-gas simulant detection. Section 11.4 describes the miniaturization approaches of piezoelectric cantilever and the detection sensitivity enhancement with a reducing sensor size.

Current commercial enzyme-linked immunosorbent assays (ELISA), which use optical means for detection, offer a concentration limit of  $10^5$  cells mL<sup>-1</sup> for *Salmonella typhimurium*, about the same as the infection dosage. Other nanobiosensors such as nanowire-based sensors that also use electrical measurements for detection offer a concentration sensitivity of about  $10^5$  cells mL<sup>-1</sup> in *Escherichia coli* detection [20]. In comparison, current 400  $\mu\text{m}$  long piezoelectric lead magnesium niobate–lead titanate/copper (PMN-PT/Cu) microcantilevers have already achieved 50 spores mL<sup>-1</sup> concentration sensitivity in a 1 mL *Bacillus anthracis* (which is about the same size as *E. coli* and *S. typhimurium*) suspension, far exceeding the concentration limit of ELISA and that of nanowire sensors. Although silicon-based nano-

cantilevers offer similar detection sensitivity as piezoelectric microcantilevers they require optical measurements in air [17] or in vacuum [21], which prohibits their use for portable, *in situ*, multiplexed detection. As we have demonstrated, in addition to their high sensitivities, piezoelectric microcantilevers offer the advantages of *in situ*, real-time, multiplexed detection, and are thus more suitable for environmental applications.

### 11.1.3

#### Piezoelectric Cantilever Sensors (PECS)

Piezoelectric cantilever sensors (PECS) are a new type of mass sensors we have developed that uses electrical means for detection and can be miniaturized for better mass detection sensitivity [22]. By monitoring the resonance frequency shifts we have demonstrated PECS for rapid, label-free, *in situ* quantitative detection of pathogens with simple all-electrical measurements. We have shown that millimeter size PECS could detect *S. typhimurium* at concentrations below 5000 cells mL<sup>-1</sup> without flow or concentration, which is lower than the infection dosage level (10<sup>5</sup> cells mL<sup>-1</sup>) and more sensitive than enzyme-linked immunosorbent assays (ELISA) and array biosensors [23]. Piezoelectric sensors have the advantage of both driving and sensing the mechanical resonance electrically. Receptors are coated on the piezoelectric device surface to bind the molecules of interest [24, 25]. The change in mass due to the binding of the target molecules shifts the mechanical resonance frequency of the device.

## 11.2

### Theory of PECS

A piezoelectric cantilever is a flexural transducer that consists of a piezoelectric layer, e.g., lead zirconate titanate (PZT) bonded to a nonpiezoelectric layer, e.g., stainless steel. Figure 11.1(a) and (b) show, respectively, a schematic of a piezoelectric cantilever of a uniform thickness (unimorph) and a piezoelectric cantilever with a nonpiezoelectric extension. The nonpiezoelectric extension may also be narrower than the piezoelectric section [26]. Bending vibrations can be generated by applying a small alternating-current (ac) voltage (<1 V) across the thickness of the piezoelectric layer. The stress generated by the bending vibration in the piezoelectric layer in turn induces a measurable piezoelectric voltage in phase with the applied voltage. A piezoelectric cantilever's mechanical resonance frequency and resonance strength can be measured by monitoring the maximum of the real part or the phase angle of the complex electrical impedance. Monitoring a cantilever's resonance frequency has many useful applications. In mass detection, a piezoelectric cantilever's resonance frequency shift is measured to quantify the small mass attached to the cantilever surface [27]. In liquid property characterization, both the resonance peak frequency and the resonance peak width of PECS inserted in the liquid are measured to simultaneously determine the liquid's viscosity and density

**Fig. 11.1.** Schematic of a piezoelectric cantilever of (a) uniform thickness (unimorph) and (b) with a nonpiezoelectric extension.

[28]. In liquid–solid transition detection, an abrupt resonance frequency shift with respect to temperature is measured to identify the transition [29]. A piezoelectric cantilever has the advantage of having a built-in piezoelectric layer to generate strong vibrations that can better withstand damping in water. The ability to withstand damping in water makes piezoelectric cantilevers excellent biosensors for direct and label-free detection. To this end, recent experiments have demonstrated real-time, in-water, direct detection of cells where the mass of the attached cells and the cell concentration in the solution were deduced from the cantilever resonance frequency shift and the resonance frequency shift with time, respectively.

### 11.2.1

#### Unimorph

When an ac voltage is applied to a unimorph cantilever, vibration occurs. The  $n$ th-mode flexural resonance frequency is related to the bending modulus per unit width, the length, and the mass per unit area,  $m$ , of the cantilever as

$$f'_n = \frac{v_n^2}{2\pi} \sqrt{\frac{K}{M_e + \Delta m}} \quad (1)$$

where  $v_n^2$  is the dimensionless  $n$ th-mode eigen value,  $K$  and  $M_e$  the effective spring constant and the effective mass of the cantilever, respectively. For an added mass  $\Delta m \ll M_e$ , the resonance frequency shift,  $\Delta f'_n$ , due to the added mass,  $\Delta m$ , is given by Eq. (2).

a)

b)

**Fig. 11.2.** (a) Phase-angle versus frequency spectrum of a 12 mm long piezoelectric cantilever with a 8 mm long stainless steel extension. As the mass of aluminum foil on the cantilever increases, the resonance frequency shifts to lower values. (b) Resonance

frequency shift per unit mass,  $\Delta f/\Delta m$ , with a normalized width versus cantilever length. Open circles and filled squares denote cantilevers with and without a stainless steel tip, respectively.

$$\Delta f_n = f'_n - f_n \cong -\frac{1}{2} f_n \frac{\Delta m}{M_e} \quad (2)$$

The resonance frequency shift per unit loaded mass is therefore

$$\frac{\Delta f_n}{\Delta m} \cong -\frac{1}{2} \frac{f_n}{M_e} = -\frac{1}{2} \left( \frac{v_n^2}{2\pi\sqrt{12}} \frac{h}{L^2} \sqrt{\frac{\bar{E}}{\bar{\rho}}} \right) \frac{1}{0.236Lwh\bar{\rho}} = -\frac{v_n^2}{4\pi} \frac{1}{L^3w} \left( \frac{1}{0.236\sqrt{12}\bar{\rho}} \sqrt{\frac{\bar{E}}{\bar{\rho}}} \right) \quad (3)$$

where  $h$ ,  $L$ ,  $w$ ,  $\bar{E}$ ,  $\bar{\rho}$ , are the total thickness, length, width, effective Young's modulus, and effective density of the cantilever, respectively. To verify Eq. (3), measurements were carried out with cantilevers of 0.4 and 0.2 cm in width with a PZT layer 0.25 mm thick bonded to a stainless steel 0.1 mm thick. The length of the cantilevers was varied from 1.37 cm to 0.44 cm by changing the clamp position. These

resonant frequencies were identified and monitored by measuring the electrical impedance spectrum with an impedance analyzer (Agilent 4294A, Agilent, Palo Alto, CA). Figure 11.2 shows the experimental results. Note that off resonance the cantilever was a capacitor, exhibiting a phase angle around  $-90^\circ$ . At resonance, the flexural motion gave rise to a peak in the real part of the impedance, and hence a peak in the phase angle due to the direct piezoelectric effect. As an example, Fig. 11.2(a) shows the first-mode resonance frequency spectrum, i.e., phase angle versus frequency, of a cantilever of  $L = 1.37$  cm and  $w = 0.4$  cm without loading (■), loaded with an aluminum foil of  $3.5 \times 10^{-4}$  g (○),  $5.9 \times 10^{-4}$  g (+), and  $7.8 \times 10^{-4}$  g (×) at the cantilever tip. Clearly, the resonance peak shifted to a lower frequency as the mass of the aluminum foil increased. Presently, a 1 cm long cantilever has a  $\Delta f/\Delta m = 3.2 \times 10^5$  Hz  $g^{-1}$ . To compare with Eq. (3), the normalized  $\Delta f/\Delta m(w/w_0)$  versus cantilever length,  $L$ , is plotted in Fig. 11.2(b), where  $w_0$  was 2 mm. Clearly, the log–log plot of the normalized  $\Delta f/\Delta m(w/w_0)$  yielded a slope of  $-3$ , validating Eq. (3). Also plotted in Fig. 11.2(a) are data points obtained with PZT cantilevers with a nonpiezoelectric tip described below. Extrapolating from Fig. 11.2(b), for a cantilever 10  $\mu\text{m}$  long, its  $\Delta f/\Delta m$  will approach  $10^{17}$  Hz  $g^{-1}$ . A more detailed description of the application of a piezoelectric cantilever as a mass sensor and how the sensitivity changes with the length, width, and height of the cantilever can be found in Yi et al. [27].

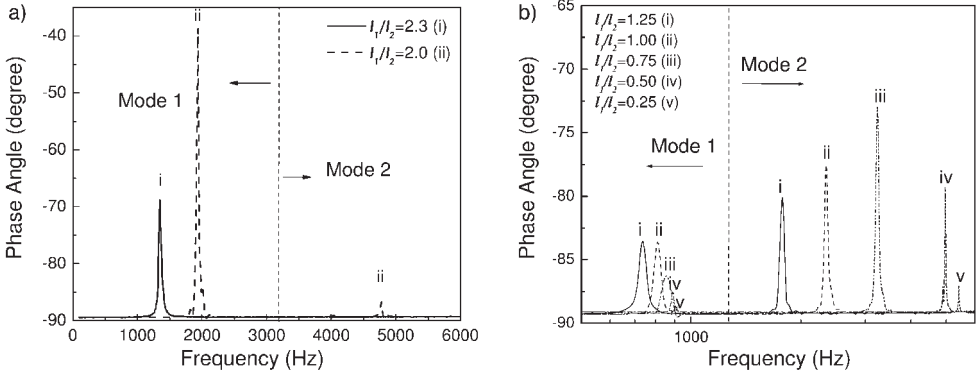

### 11.2.2

#### PECS with a Nonpiezoelectric Extension

A piezoelectric cantilever of uniform thickness (Fig. 11.1a) exhibits the strongest peak intensity in the first mode and the intensity of higher-order resonance peaks decreases with an increasing order [30, 31]. The ratio of the  $n$ th resonance frequency to the first resonance frequency is also predicted by the solution of the vibration wave equation of a uniform beam. Surprisingly, a piezoelectric cantilever with a nonpiezoelectric extension (Fig. 11.1b) could exhibit a higher second-mode peak intensity than the first-mode one and the ratio of the  $n$ th-mode resonance frequency to the first-mode one could be quite different from that of a uniform beam.

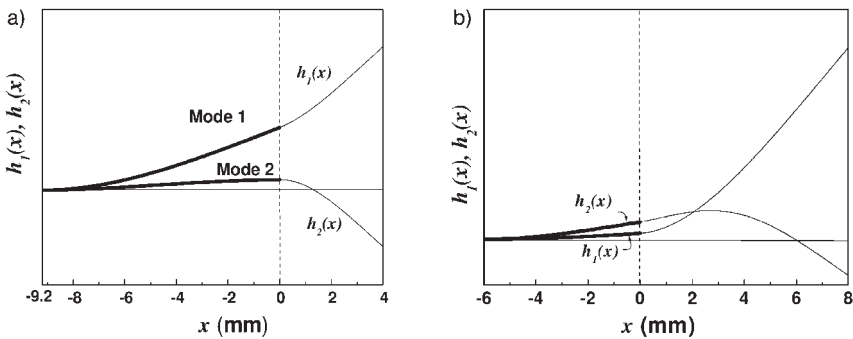

Theoretically, we considered a piezoelectric cantilever with a nonpiezoelectric extension as two distinctive sections, (1) the piezoelectric section and (2) the nonpiezoelectric extension section, with each section possessing a different thickness, elastic modulus and mass density distribution in the thickness direction. We solved the cantilever's flexural vibration equation analytically to derive a transcendental equation that could be solved numerically to obtain the cantilever's flexural vibration wave forms and its resonance spectrum.

Examples of spectra in region I where the first peak was always higher than the second peak are shown in Fig. 11.3(a) with cantilevers of a 8 mm and 9.2 mm PZT section and a 4 mm nonpiezoelectric extension length ( $l_1/l_2 = 2.0$  and 2.3, respectively). Figure 11.3(b) shows examples of spectra in region II with cantilevers of a 2, 4, 6, 8 and 10 mm PZT section and an 8 mm nonpiezoelectric extension length

**Fig. 11.3.** Phase-angle versus frequency of cantilevers with (a)  $l_1/l_2 \geq 1.5$  [ $l_2 = 4$  mm and  $l_1 = 8$  (dashed line) and 9.2 mm (solid line)] and (b)  $l_1/l_2 \leq 1.5$  [ $l_2 = 8$  mm and  $l_1 = 10$  (i), 8 (ii), 6 (iii), 4 (iv), and 2 mm (v)].

( $l_1/l_2$  ranging from 0.25 to 1.25). Clearly, the ratio  $l_1/l_2$  played an important role in determining the resonance peak intensity ratio. This came about because the resonance electrical impedance signals were solely determined by the vibration amplitude within the piezoelectric layer. How the peak height of a higher-mode resonance compared to the peak height of the first-mode depended mainly on how the higher-mode vibration amplitude within piezoelectric layer compared to that of the first mode, which could be strongly affected by the ratio of the length of the piezoelectric section to that of the nonpiezoelectric extension,  $l_1/l_2$ . To illustrate this point, calculated  $h_1(x)$  and  $h_2(x)$  versus  $x$  are plotted in Fig. 11.4(a) for the cantilever with  $l_1 = 9.2$  mm and  $l_2 = 4$  mm ( $l_1/l_2 = 2.3$ ) whose spectrum

**Fig. 11.4.** Calculated amplitudes,  $h_1(x)$  and  $h_2(x)$ , versus  $x$  for a cantilever with (a)  $l_1 = 9.2$  mm and  $l_2 = 4$  mm ( $l_1/l_2 = 2.3$ ) and (b)  $l_1 = 6$  mm and  $l_2 = 8$  mm ( $l_1/l_2 = 0.75$ ).

was shown as the solid line in Fig. 11.3(a), and in Fig. 11.4(b) for the cantilever with  $l_1 = 6$  mm and  $l_2 = 8$  mm ( $l_1/l_2 = 0.75$ ) whose spectrum is labeled (iii) in Fig. 11.3(b). Figure 11.3(a) shows that the second-mode vibration amplitude,  $h_2(x)$ , exhibited a nodal point near  $x = l_1$ . Note that the second peak of this cantilever was absent in Fig. 11.3(a), as is consistent with the presence of the nodal point at  $x = l_1$  shown in Fig. 11.4(a), which indicated that there was little bending stress and therefore little induced piezoelectric voltage near  $x = l_1$ . In contrast, for  $l_1/l_2 = 0.75$ , the second-mode vibration amplitude within the piezoelectric section ( $x \leq l_1$ ) was higher than that of the first mode, indicating a higher stress and hence a higher piezoelectric response, although the first-mode vibration amplitude was higher than the second mode towards the free end ( $x = l_1 + l_2$ ) of the nonpiezoelectric extension section.

### 11.3

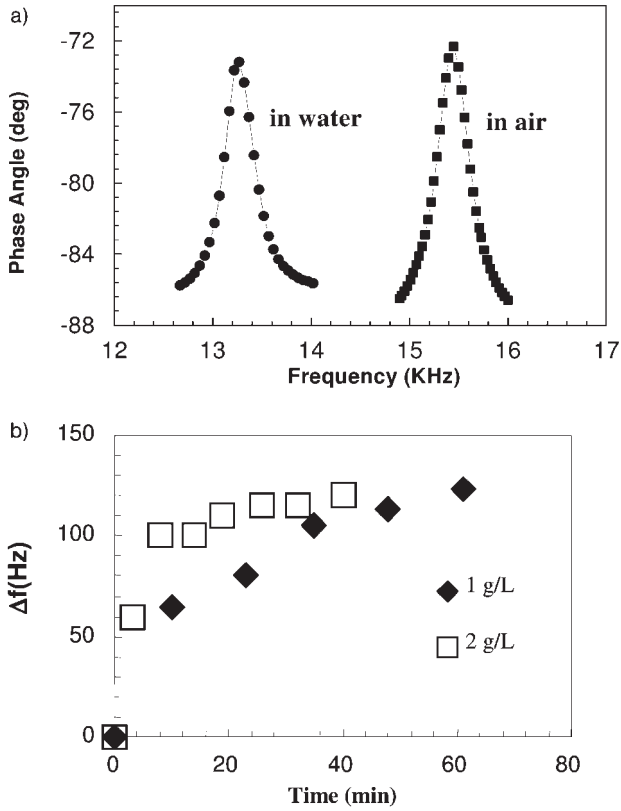

#### Examples of Detections

##### 11.3.1

#### Immobilization and In-solution Quantification of Yeast Cells

A PZT/stainless steel cantilever with a 3 mm long, 4 mm wide, and 0.3 mm thick PZT layer bonded to a 0.1 mm thick stainless steel with a 4 mm long stainless steel tip thinly coated with a poly-L-lysine (Sigma P8920, 0.1% w/v) layer was used for yeast detection. Poly-L-lysine is positively charged, to which negatively charged yeast is attracted and immobilized. The stainless steel tip was immersed in yeast suspensions of 1 and 2 g L<sup>-1</sup> with a 3 mm dipping depth. The in-water resonance peak intensity of this cantilever is similar to its resonance peak intensity in air (Fig. 11.5a) with a  $Q$  factor about 30, making the in-water measurements as accurate and reliable as the in-air ones. Figure 11.6(a) shows the optical micrographs of yeast cells on the stainless steel tip after 60 min of immersion in the yeast suspension. A scanning electron microscopic (SEM) micrograph provided a close-up of the immobilized yeast cells (Fig. 11.6b). Adsorption of the yeast cells indeed caused a shift in the cantilever resonance frequency. Figure 11.5(b) shows a plot of the resonance frequency shift versus time. Note that the resonance frequency changed more slowly in 1 than in 2 g L<sup>-1</sup>, eventually reaching the same saturated  $\Delta f$  in both concentrations. The resonance frequency change with time was used to characterize the cell concentration. The adsorption of cells was limited by the diffusion of cells to the cantilever surface. At short times, e.g.,  $t < 10$  min for 2 g L<sup>-1</sup> and  $t < 40$  min for 1 g L<sup>-1</sup> (Fig. 11.5b), the adsorbed amount and hence the resonance frequency shift should be proportional to  $t^{1/2}$  and the slope of  $\Delta f$  versus  $t^{1/2}$  should be proportional to concentration [3]. For 1 g L<sup>-1</sup> (2 g L<sup>-1</sup>), at  $t < 40$  min ( $t < 10$  min),  $\Delta f$  is linear with  $t^{1/2}$  and the slope for 2 g L<sup>-1</sup> is indeed twice that for 1 g L<sup>-1</sup>, indicating that one can use  $\Delta f$  versus  $t$  to quantify the concentration. More detailed results on yeast detection are presented in a recent paper by Yi et al. [32].

**Fig. 11.5.** (a) First-mode resonance frequency spectra of the yeast-detecting cantilever; (b) resonance frequency shift versus time after the cantilever was immersed in the  $1 \text{ g L}^{-1}$  (filled diamonds) and  $2 \text{ g L}^{-1}$  (open squares) suspension.

**Fig. 11.6.** (a) Optical micrograph of yeast cells immobilized on the poly-L-lysine layer coated on the cantilever stainless steel tip surface after 60 min and (b) SEM micrograph of immobilized yeast cells.

## 11.3.2

**Detection of Binding of Biotinylated Polystyrene Spheres to Immobilized Avidin**

We have demonstrated that a piezoelectric cantilever could detect the binding of a target protein (biotin) to an immobilized protein (avidin) at the cantilever tip. We used a PZT/stainless steel cantilever, 1.3 mm long, 2 mm wide and with a 0.127 mm thick PZT layer bonded to a 0.05 mm thick stainless steel foil, and a 2.87 mm long stainless steel tip coated with a gold layer by sputtering. The cantilever was rigidly set in an epoxy-filled glass tube that served as the clamp [insert (a) Fig. 11.7]. Avidin was immobilized on the gold surface via 3-mercaptopropionic acid (MPA). The carboxyl groups of MPA bind to avidin covalently while the sulfur binds to the gold surface chemically [33–35]. The avidin-coated tip was then vertically immersed in a 0.125 wt% suspension of biotin-coated polystyrene microspheres of 2  $\mu\text{m}$  diameter (Polysciences, Warrington, PA) with a 2.2 mm dipping depth. The resonance frequency of the cantilever decreased with time and the resonance frequency shift with time is shown in Fig. 11.7. The resonance frequency shift increased with time and reached about 240 Hz shift at  $t = 40$  min. An optical micrograph of the immobilized biotinylated microspheres on the avidin-coated stainless steel cantilever tip taken at 20 min is given in insert (b) of Fig. 11.7, which shows about 10% surface coverage and corresponds to about  $1 \times 10^{-6}$  g microspheres adsorbed on the cantilever tip, indicating that the cantilever has a mass detection sensitivity,  $\Delta m/\Delta f$ , of about  $4 \times 10^{-9}$  g  $\text{Hz}^{-1}$ .

**Fig. 11.7.** Resonance frequency shift with time of a PZT/stainless steel cantilever in a biotinylated polystyrene suspension. Inserts: (a) photograph of the cantilever. The PZT layer was 1.3 mm long, 3.35 mm wide. The 2.87 mm long gold-coated stainless steel tip was coated with avidin. (b) Optical micrograph of immobilized biotinylated spheres after 20 min.

**Fig. 11.8.** (a) Resonance spectra at different times due to the immobilization of avidin on the stainless steel tip and (b) the resultant resonance frequency shift versus time.

### 11.3.3

#### Detection of Avidin Immobilization at the Cantilever Tip

To detect the immobilization of avidin we used an even *shorter* cantilever that had a PZT layer *0.7 mm long*, 2.27 mm wide, and 0.127 mm thick bonded to a 0.05 mm thick stainless steel foil. The cantilever has a 2 mm long gold-coated stainless steel tip. The freshly sputtered gold surface was first coated with MPA as described above and then immersed in a  $0.1 \text{ mg mL}^{-1}$  avidin solution. The dipping depth was 1.3 mm. Immobilization of avidin on the cantilever tip was detected by monitoring the resonance frequency shift of the cantilever at around 68 kHz. Figure 11.8(a) shows the resonance spectrum at different times and Fig. 11.8(b) shows the frequency shift with time after the cantilever tip was immersed in the avidin solution. The saturated adsorption amount of avidin was known to be about  $3 \text{ ng mm}^{-2}$  [36, 37]. This indicated that the mass detection sensitivity of this 0.7 mm long cantilever was  $\Delta m/\Delta f \sim 1 \times 10^{-10} \text{ g Hz}^{-1}$ . The saturated adsorption amount of avidin yields a resonance frequency change of 40 Hz with a conventional 5 MHz QCM. The present piezoelectric cantilever's 800 Hz resonance frequency change is already  $20\times$  better than that of a 5 MHz QCM.

### 11.3.4

#### *Salmonella typhimurium* Detection

*Salmonella* is a water-borne/food-borne pathogen that causes more than 500 deaths each year [38]. It is also a category B bioterrorism agent that can seriously contaminate water resources. There is no device at present that can actually monitor a space and perform an analysis of the air or water within that space in real-time. However, such a device would dramatically decrease the “lag time between release of an agent and its detection,” and thus enable more prompt treatment of those

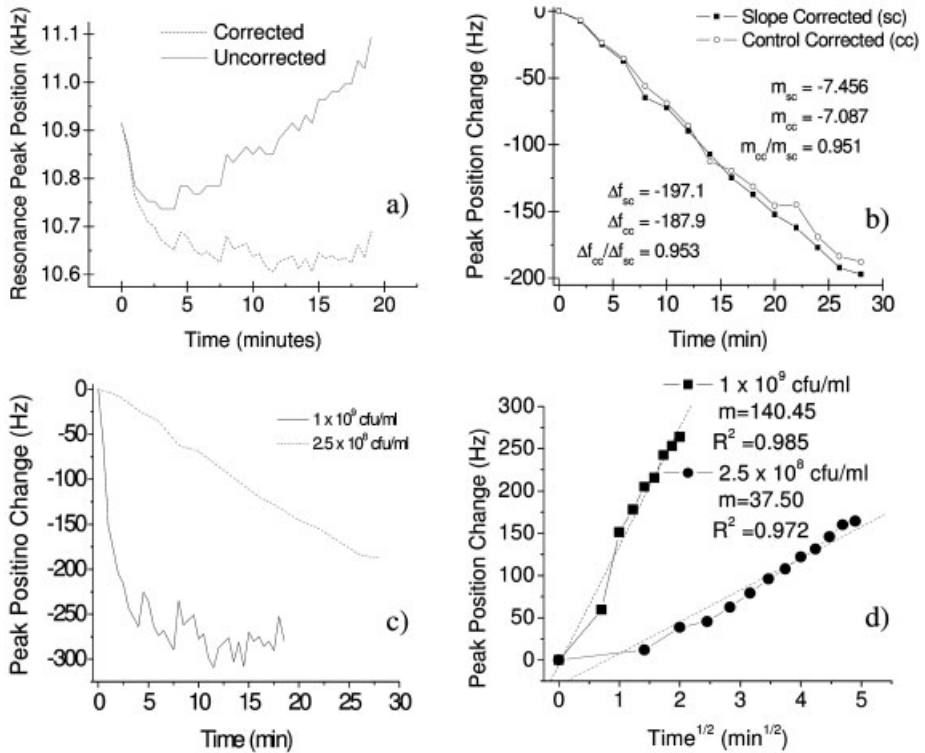

individuals possibly exposed to a particular bioterrorism agent in addition to reducing the total number of individuals affected [39].

A piezoelectric microcantilever was fabricated by bonding a layer of lead zirconate titanate (PZT) 0.127 mm thick, 2 mm long, and 1.5 mm wide to a titanium foil 0.127 mm thick with a titanium tip 3 mm long (Fig. 11.1b). The PZT layer had a piezoelectric coefficient  $d_{31}$  of  $-320 \text{ pm V}^{-1}$  and a Young's modulus  $Y_{11}$  of 62.5 GPa. The titanium foil has a Young's modulus of 103 GPa. The salmonella strain was *Salmonella typhimurium* and the antibody used was an antibody to Salmonella Common Structural Antigens (CSA-1) (both from Krikegaard & Perry Laboratories, Inc., Gaithersburg, Maryland). This antibody is specifically designed to recognize several species of bacteria in the *Salmonella* genera, including our *typhimurium* species. The CSA-1 antibody was immobilized on the tip of a PZT-Ti microcantilever by means of a linking molecule. Titanium was chosen as the non-piezoelectric layer as a result of its good mechanical properties as well as its outstanding biocompatibility [40]. This biocompatibility is demonstrated by its widespread use as a material for implants in the human body.

Though common methods of immobilization on surfaces rely on MPA or 3-aminopropyltriethoxysilane (APS) followed by activation with 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) and *N*-hydroxysulfosuccinimide (NHS) [41], we used a much simpler method adapted from silica-silane chemistry. Since a passivated titanium surface exhibits similar surface chemistry to that of silica [42], a bifunctional linker, glycidoxypropyltrimethoxysilane (GOPTS), was used as the linking molecule [43, 44]. GOPTS presents, on one end, a trialkyloxysilane group, like APS, which allows its incorporation on activated silica or silica-like surfaces. Once GOPTS is deposited on a surface, it exposes epoxy moieties that are unstable and therefore very reactive toward nucleophilic groups such as amines, thiols, and alcohols. These groups will promptly react, causing opening of the bond angle strained epoxide ring. The main advantage of GOPTS over other bifunctional linkers is that it does not require an activation step, whereas activation with EDC/NHS is required for standard carboxylic functionalities. In our work, the trimethoxysilane end of GOPTS was bound to the titanium surface of the microcantilever and CSA-1 antibody was subsequently immobilized on the sensor under basic conditions, through addition of its amine groups to epoxide rings exposed on the surface.

Following functionalization of the microcantilever with antibody, several detections of the *S. typhimurium* cells were performed by lowering the cantilever tip into a vial containing the cell suspension by means of a micropositioner, such that approximately two-thirds of the tip was submerged. This allowed the resonance frequency shift to be monitored with time as described above.

In the present detection set-up, the titanium tip was only partially immersed in the solution to avoid wetting of the PZT layer by the solution. As a result, there was an upward background resonance shift due to a receding water level along with the resonance frequency shift due to cell binding. Consequently, a typical cell-detection resonance frequency shift versus time plot exhibited an initial decrease, reaching a minimum that was followed by an almost linear rise (solid curve

**Fig. 11.9.** (a) Uncorrected salmonella detection data with the corresponding corrected data. (b) Comparison of slope corrected vs. control corrected detection. (c) Detection of  $1 \times 10^9$  and  $2.5 \times 10^8$  cells  $\text{mL}^{-1}$  *Salmonella typhimurium* suspensions. (d) Kinetic analysis of *S. typhimurium* binding.

in Fig. 11.9a). To address the issue of background resonance frequency shift, we carried out three different checks. The first was to obtain the rate of upward background shift in water prior to the detection experiment. The second was to obtain the rate of upward background shift using the later stage of the resonance frequency shift that showed an almost linear increase. The third check was to use a two-cantilever array to perform the detection. One cantilever was treated with the GOPTS as detailed above, while the other cantilever was left passivated but untreated with GOPTS. Then, both cantilevers were simultaneously subjected to the same series of steps associated with a detection process: (a) exposure to the antibody, (b) rinse in phosphate-buffered saline (PBS) and (c) dipping in the cell suspension. We found that the first two corrections were practically the same, indicating that the upward shift in the later stages of detection was indeed a manifest of receding water level. In Fig. 11.9(a), the corrected resonance frequency shift due to

cell binding is shown as the dashed line after subtracting the background upshift from the initial data (solid line). Figure 11.9(b) shows two curves from the same detection of a  $2.5 \times 10^8$  cells  $\text{mL}^{-1}$  *S. typhimurium* suspension. The *control corrected* data represent subtraction of the upward drift based on the control cantilever that was not coated with the GOPTS (and thus was not functionalized with the CSA-1 antibody). The *slope corrected* data represent the removal of the linear drift simply by taking a linear regression of the detection data after cell adhesion on the sensor tip had ceased. As can be seen in the figure, the ratio of the two slopes is nearly unity, as is the ratio of the total resonant frequency shifts. Furthermore, as mentioned above, the cantilever used in Fig. 11.9(a) was also monitored in water alone and the same linear up-drift was obtained, thus providing further substantiation of the post-cell adhesion up-drift subtraction method. Based on these findings, all subsequent cell detection experiments used only the post-cell adhesion linear drift data to correct for the upward drift. This greatly simplified the experiments and thus allowed for more efficient data collection.

Meanwhile, PZT/gold-coated glass cantilever sensors with a 0.127 mm thick, 0.5 mm long and 2 mm wide PZT layer bonded to a gold coated glass layer of 0.150 mm in thickness that had a 2 mm long gold-coated glass tip were also tested in *S. typhimurium* detection. The gold-coated glass surface was coated with MPA, which was treated in a solution of 5 mg  $\text{mL}^{-1}$  EDC and 5 mg  $\text{mL}^{-1}$  NHS in distilled water for 30 min followed by dipping in 1  $\mu\text{L}$  of a 0.1 mg  $\text{mL}^{-1}$  solution of CSA-1 in a phosphate-buffered saline (PBS) solution at pH 7.4 for 30 min. The antibody-coated cantilevers were then used to detect *S. typhimurium* at various concentrations for up to 30 min. Figure 11.10 gives the resultant  $\Delta f$  versus time plots from the PZT/gold-coated cantilevers at various *S. typhimurium* concentrations. As can be seen,  $\Delta f$  decreases sharply initially and reached a plateau after 10 min. The detections were quite repeatable as each curve was the average of 3–4 independent measurements. The standard deviations of  $\Delta f$  were about 10–20%. Table 11.1 lists

**Fig. 11.10.** Resonance frequency shift versus time of the PZT/gold-coated glass cantilever in various *Salmonella typhimurium* concentrations.

**Table 11.1.** Resonance frequency shift of a PZT/Au-coated glass cantilever with  $5 \times 10^{-11}$  g/Hz sensitivity in various concentrations of *Salmonella t.*

Salmonella concentration (cells/ml)	$\Delta f$ (PZT/Au-coated glass)
$10^9$	1500
$5 \times 10^5$	330
$1 \times 10^5$	180
$5 \times 10^3$	90

**Fig. 11.11.** Optical micrographs of a PZT/gold-coated cantilever surface after 30 min detection in a)  $1 \times 10^9$  (b)  $1 \times 10^5$  and (c)  $5 \times 10^3$  cells  $\text{mL}^{-1}$  *Salmonella typhimurium* suspensions.

the average  $\Delta f$  at  $t = 30$  min for various *Salmonella* concentrations, as obtained from the PZT/gold coated glass cantilever. As can be seen, at  $5 \times 10^3$  cells  $\text{mL}^{-1}$ , the  $\Delta f$  obtained by the PZT/gold coated glass cantilevers at  $t = 30$  min was 90 Hz, well above the standard deviation of 20 Hz, and at  $1 \times 10^3$  cells  $\text{mL}^{-1}$  the obtained  $\Delta f$  was no longer meaningful compared to the standard deviation. This puts the detection limit of the current PZT/gold-coated glass cantilever at about the  $1 \times 10^3$  cells  $\text{mL}^{-1}$  range.

To validate the results shown in Fig. 11.10, the PZT/gold-coated glass cantilever surface was examined by optical microscopy after 30 min of detection. Figure 11(a)–(c) shows SEM micrographs of captured *Salmonella* cells on the PZT/gold-coated glass cantilever surface at  $t = 30$  min from  $1 \times 10^9$ ,  $1 \times 10^5$ , and  $5 \times 10^3$  cells  $\text{mL}^{-1}$  suspensions, respectively. With the mass of each cell being  $2 \times 10^{-12}$  g and by counting the number of cells in the micrographs, the mass of the captured cells on the cantilever surface was estimated to be  $5 \times 10^{-8}$ ,  $3 \times 10^{-9}$ , and  $1 \times 10^{-9}$  g for  $1 \times 10^9$ ,  $1 \times 10^5$ , and  $5 \times 10^3$  cells  $\text{mL}^{-1}$  suspensions, respectively. With  $\Delta f$  at 30 min being 970, 300 and 100 Hz for the  $1 \times 10^9$ ,  $1 \times 10^5$ , and  $5 \times 10^3$  cells  $\text{mL}^{-1}$  suspensions, respectively,  $\Delta m/\Delta f$  was  $5 \times 10^{-11}$  g  $\text{Hz}^{-1}$ , which is consistent with the  $5 \times 10^{-11}$  g  $\text{Hz}^{-1}$  as calibrated with a quartz crystal microbalance (QCM) in the antibody immobilization.

### 11.3.5

#### Nerve Gas Simulant Detection

The piezoelectric cantilever sensors we have developed are quantitative and suitable for use in air. As an example of detecting chemical agents, we studied the de-

**Fig. 11.12.** Resonance frequency shift versus time of the uncoated (open squares) and  $18 \mu\text{g}$  (filled squares) microporous silica (MPS)-coated cantilever after spraying 10 mL liquid DMMP in a 66 L chamber. Also shown are

relative humidity (open triangles) and temperature (inverted open triangles) in the chamber during the test. The arrow indicates the injection of DMMP.

**Fig. 11.13.** Resonance frequency shift versus time during the initial DMMP test (filled squares) and after regeneration (inverted open triangles).

tection of the nerve gas simulant dimethyl dimethyl phosphonate (DMMP) using a PZT cantilever that had a PZT layer 1 mm long, 2.1 mm wide, and 0.127 mm thick bonded to a 0.05 mm thick stainless steel foil. The cantilever had a stainless steel tip 2.4 mm long and 0.05 mm thick coated with ultrahigh surface area ( $800 \text{ m}^2 \text{ g}^{-1}$  and pore size  $10 \text{ \AA}$ ) microporous  $\text{SiO}_2$ . The coated cantilever had a lower resonance frequency ( $\sim 80 \text{ Hz}$  shift) due to the mass of the microporous  $\text{SiO}_2$  coating. The  $\text{SiO}_2$ -coated cantilever was placed in a closed chamber with a constant humidity of 11.2% and a constant temperature of  $22.2 \text{ }^\circ\text{C}$ , as shown in Fig. 11.12 for DMMP tests. When 5 mL of DMMP was injected and sprayed into the chamber, the cantilever resonance frequency decreased with time and saturated at about 70 Hz change (■ in Fig. 11.12). Note that without the silica coating, the resonance frequency was stable (□), indicating that silica-coated cantilevers can indeed be sensitive DMMP sensors.

After the initial test, the cantilever was regenerated in air for 5 days. In the second DMMP test, the resonance frequency of the regenerated cantilever decreased at a similar rate as in the initial test, except that the resonance frequency shift saturated at 50 Hz instead of 70 Hz (Fig. 11.13). The smaller saturated resonance frequency shift for the regenerated cantilever was probably due to incomplete removal of DMMP. A clear advantage of oxide adsorbent is that it is readily reusable due to the physical nature of the adsorption.

#### 11.4 Piezoelectric Cantilever Miniaturization

As shown in Fig. 11.2(b), miniaturized cantilevers can achieve higher mass detection sensitivity. We have developed two types of piezoelectric microcantilevers: one

is fabricated from freestanding lead magnesium niobate-lead titanate (PMN-PT) films developed in our laboratory, exhibiting up to  $2 \times 10^{-14}$  g Hz<sup>-1</sup> sensitivity; the other is fabricated using silicon microfabrication techniques with lead zirconate titanate thin films on silicon wafers that can be as small as 50  $\mu$ m long, offering better than  $10^{-16}$  g Hz<sup>-1</sup> sensitivity.

#### 11.4.1

##### PMN-PT/Cu Microcantilevers

The PMN-PT/Cu microcantilevers consisted of a highly piezoelectric layer fabricated from freestanding lead magnesium niobate-lead titanate (PMN-PT) films bonded to a copper layer by electroplating. The microcantilever shape was achieved by wire-saw cutting. As an example, the top-view optical micrograph, cross-section scanning electron microscopy (SEM) micrograph, and a typical resonance spectrum of 500  $\mu$ m long, 700  $\mu$ m wide PMN-PT/Cu microcantilevers made of 22  $\mu$ m thick PMN-PT and 5  $\mu$ m thick copper are shown in Fig. 11.14(a)–(c) respectively. The spectrum shown in Fig. 11.14(c) exhibits multiple resonance peaks with

**Fig. 11.14.** (a) Optical micrograph and (b) SEM cross-section micrograph of 500  $\mu$ m long, 700  $\mu$ m wide PMN-PT/Cu microcantilevers with 22  $\mu$ m thick PMN-PT and 5  $\mu$ m thick Cu on a glass substrate, and (c) a typical resonance spectrum. Note that because of the

highly piezoelectric PMN-PT layer we were able to retain the higher-mode resonance peaks with  $Q > 300$  for better detection sensitivities. This PMN-PT PEMS exhibited femtogram mass detection sensitivity,  $\Delta m/\Delta f = 3 \times 10^{-13}$  g Hz<sup>-1</sup>.

**Tab. 11.2.** Resonance frequency shift of a PMN-PT/Cu microcantilever with  $3 \times 10^{-13}$  g Hz<sup>-1</sup> sensitivity compared with a PZT/Au-coated glass cantilever with  $5 \times 10^{-11}$  g Hz<sup>-1</sup> sensitivity. Note: the PMN-PT/Cu microcantilever lowered the BA concentration limit by two orders of magnitude.

BA concentration (cells mL <sup>-1</sup> )	$\Delta f$ (PMN-PT/Au-Cu) <sup>[a]</sup>	$\Delta f$ (PZT/Au-coated glass)
10 <sup>5</sup>		1200
2 × 10 <sup>4</sup>		600
5 × 10 <sup>3</sup>	6800	110
2 × 10 <sup>3</sup>		50
500	5700	
50	100	

<sup>a</sup> PMN-PT/Cu microcantilever had copper on one side and was cold coated on the other side for antibody immobilization.

$Q > 300$  ( $Q$  is the ratio of the resonance frequency to the resonance peak width at half the peak height). The mass detection sensitivity of this PMN-PT/Cu microcantilever was determined to be  $3 \times 10^{-13}$  g Hz<sup>-1</sup>, with the second resonance peak at 170 kHz, as calibrated by QCM. The PMN-PT/Cu microcantilever was gold coated on both sides for antibody immobilization using the MPA self-assembly monolayer approach (Section 11.3.4). Because the PMN-PT/Cu microcantilevers were about two orders of magnitude more sensitive than the PZT PECS described in Sections 11.3.3–11.3.5, they realized an even lower concentration limit. For example, Table 11.2 lists the resonance frequency shifts of PMN-PT microcantilevers at various *Bacillus anthracis* (BA) concentrations in BA spores detection. Also listed are the resonance frequency shifts of a PZT/Au-coated glass cantilever with a sensitivity of  $5 \times 10^{-11}$  g Hz<sup>-1</sup> (similar to that used in *S. typhimurium* detection in Section 11.3.4). Clearly, the more sensitive PMN-PT/Cu microcantilevers lowered the detection concentration limit to 50 cells mL<sup>-1</sup> – two orders of magnitude lower than that of the PZT/Au-coated glass cantilevers.

#### 11.4.2

##### PZT/SiO<sub>2</sub> Microcantilevers and PZT/SiO<sub>2</sub>-Si<sub>3</sub>N<sub>4</sub> Nanocantilevers

Alternatively, we have successfully fabricated PZT/SiO<sub>2</sub> microcantilevers by depositing 1.6 μm thick PZT films on a Pt/TiO<sub>2</sub>/SiO<sub>2</sub>/Si substrate with a novel sol-gel process and repeated spin coating. The Pt/TiO<sub>2</sub>/SiO<sub>2</sub> substrate was necessary to prevent unwanted interfacial reactions and diffusions. The precursor solution contained 50% excess lead to compensate for lead loss during repeated heat treatment. Figure 11.15(a) shows a SEM micrograph of a 1.6 μm thick PZT film. The film was further made into piezoelectric microcantilevers by integrating the piezoelectric films with the microfabrication process. Examples of a 50 μm long PZT/SiO<sub>2</sub> mi-

**Fig. 11.15.** SEM cross-section of (a) a 1.6  $\mu\text{m}$  thick PZT film and (b) a 50  $\mu\text{m}$  long, 20  $\mu\text{m}$  wide PZT/SiO<sub>2</sub> microcantilever with a 10  $\mu\text{m}$  long SiO<sub>2</sub> tip. (c) Resonance frequency spectrum of the PZT/SiO<sub>2</sub> microcantilever in (b).

crocantilever and its resonance frequency spectrum are shown in Fig. 11.15(b) and 11.15(c), respectively. From our earlier experimental and theoretical work, we expect such piezoelectric microcantilevers to have better than  $10^{-16}$  g Hz<sup>-1</sup> sensitivity. Furthermore, in the making are PZT/SiO<sub>2</sub>-Si<sub>3</sub>N<sub>4</sub> piezoelectric nanocantilever sensors (PENS) with a 20  $\mu\text{m}$  long PZT/SiO<sub>2</sub>-Si<sub>3</sub>N<sub>4</sub> section and a nano-size SiO<sub>2</sub>-Si<sub>3</sub>N<sub>4</sub> tip that is less than 300 nm in width and less than 1  $\mu\text{m}$  in length. Theoretical calculation indicates that such PZT/SiO<sub>2</sub>-Si<sub>3</sub>N<sub>4</sub> PENS will exhibit better than  $10^{-18}$  g Hz<sup>-1</sup> sensitivity (the mass of a single protein or DNA).

## 11.5

### Conclusions

We have developed piezoelectric microcantilever sensors of different sizes and types that can perform rapid, *in situ*, in-water pathogen detection with sensitivities well above that of current techniques. Both theoretical and experimental studies were carried out to characterize the sensors. We showed that using PZT/glass cantilevers of sub-millimeter length with a 2 mm glass tip that exhibited  $5 \times 10^{-11}$  g Hz<sup>-1</sup> mass detection sensitivity, *in situ* quantification of *S. typhimurium* was achieved

with a concentration limit of  $10^3$  cells  $\text{mL}^{-1}$ , lower than the infectious dosage,  $10^5$  cells  $\text{mL}^{-1}$ , which is also the concentration limit of ELISA and QCM. Furthermore, using 500  $\mu\text{m}$  long miniaturized PMN-PT/Cu microcantilevers that exhibited  $3 \times 10^{-13}$  g  $\text{Hz}^{-1}$  detection sensitivity, we showed that in a liquid volume of less than 1 mL the detection concentration limit was lowered to below 50 cells  $\text{mL}^{-1}$ . With PZT/SiO<sub>2</sub> microcantilevers less than 50  $\mu\text{m}$  long and PZT/SiO<sub>2</sub>-Si<sub>3</sub>N<sub>4</sub> PENS less than 20  $\mu\text{m}$  long with a SiO<sub>2</sub>-Si<sub>3</sub>N<sub>4</sub> less than 300 nm wide and less than 1  $\mu\text{m}$  long, we expect the detection sensitivity to reach better than  $10^{-16}$  g  $\text{Hz}^{-1}$  and  $10^{-18}$  g  $\text{Hz}^{-1}$ , respectively and the detection concentration to be further lowered.

## 12 Toxicology of Nanoparticles in Environmental Air Pollution

*Ken Donaldson, Nicholas Mills, David E. Newby, William MacNee,  
and Vicki Stone*

### 12.1 Introduction

The toxicology of engineered nanoparticles is a topic of increasing interest. However the existing toxicology database on nanoparticles rests almost entirely on combustion-derived nanoparticle in environmental air. This research reached a peak in the mid to late 1990s, focused around the ‘ultrafine hypothesis’<sup>1,2</sup>. This suggested that the combustion-derived nanoparticle component of PM was a key component of PM in causing adverse health effects, by virtue of its ability to cause oxidative stress and inflammation and translocate from the site of deposition<sup>3</sup>. This review puts forward the evidence that nanoparticles do play a role on the adverse health effects of environmental particles and what the mechanism may be, in the belief that this may illuminate the toxicology of engineered nanoparticles.

### 12.2 History of Air Pollution

The adverse health effects of air pollution have been recognized for centuries. In the UK, the burning of fossil fuels in towns and cities combined with periods of cold weather, where there is little mixing of air, have been associated with the generation of smogs. Due to the sulfurous nature of the coal, these smogs consisted mainly of sulfur dioxide and particles, the latter measured historically as “black smoke” (Table 12.1). The famous smog that occurred in London in December 1952 saw midday London appear more like midnight, with theatres closed due to the inability of the audience to see the stage! Interestingly, for the underlying theme of this article, analysis of the particles in the lungs of people dying during such episodes showed there to be a large proportion of carbon-centered combustion-derived nanoparticles [1], presumably from domestic coal combustion. The 1952 London smog episode, which was associated with thousands of deaths, had particle levels estimated at up to 4000  $\mu\text{g m}^{-3}$  as compared to average current

**Tab. 12.1.** Size fractions and description of the main size fractions of PM that are usually measured.

Size fraction	Unit	Description
Total suspended particulate (TSP)	$\mu\text{g m}^{-3}$	A TSP monitor measures by mass the atmospheric particulate smaller than about $40\ \mu\text{m}$ in diameter
Black smoke	$\mu\text{g m}^{-3}$	This system was used in the UK and in other countries until the end of the 1980s. Air was drawn through a size-selective filter onto a white paper and the blackness of the “smudge” was measured; this method obviously is biased towards black, i.e., carbon-based, particles; there is a variable relationship between particles as measured by black smoke and $\text{PM}_{10}$
$\text{PM}_{10}$	$\mu\text{g m}^{-3}$	This size-selective sampling convention measures the mass per unit volume air of particles of aerodynamic diameter $10\ \mu\text{m}$ with 50% efficiency; it roughly corresponds to the thoracic fraction of particles as defined by the International Standards Association (ISO) [3]
$\text{PM}_{2.5}$	$\mu\text{g m}^{-3}$	A size-selective sampling convention that measures the mass per unit volume air of particles of aerodynamic diameter $2.5\ \mu\text{m}$ with 50% efficiency; it roughly corresponds to the respirable fraction of particles as defined by ISO [3]
$\text{PM}_{0.1}$ /nanoparticles	$\mu\text{g m}^{-3}$	Also called ultrafine particles, these particles correspond to $\text{PM}_{0.1}$ and have a diameter of $<0.1\ \mu\text{m}$ (i.e., $<100\ \text{nm}$ ).

London pollution levels of about  $40\ \mu\text{g m}^{-3}$ . As a result of such smogs, succeeding Governments introduced the Clean Air Acts that resulted in a steady decline in air pollution, leading to the present relatively clean air in UK cities.

However, in UK cities today there remains an air pollution problem, if lesser in magnitude than was seen in the past. The modern UK pollution environment is dominated by effluent from transport sources due to the increased number of cars on our roads and increased numbers of car journeys. In some cities, such as Los Angeles and Athens, air pollution is much worse than in the UK because of higher traffic density and the action of sunlight combining to produce “photo-

chemical smog”, which is qualitatively different, with ozone and particles as the dominant pollutants.

### 12.3

#### Introduction to Air Pollution Particles

Particles or particulate matter (PM) represent a part of the air pollution cocktail present in ambient air, which also consists of gases such as ozone, nitrogen dioxide etc. Particles have a special problem of nomenclature because they are measured by sampling conventions that collect only some fraction of the particulate material suspended in the air. These size fractions, including nanoparticles, are described in Table 12.1. Particles have received special attention because they are the most potent component of the air pollution mix in causing ill-health in the great majority of epidemiological studies. The adverse health effects of PM are seen at the levels that pertain in UK and other cities today and there is often no threshold. In other words, there is a background of ill-health caused by PM that increases when the ambient particle cloud increases in concentration and goes down when the amount of particles in the air decreases [2].

### 12.4

#### Adverse Effects of PM in Epidemiological Studies

The adverse effects of air pollution have been measured in thousands of studies. The levels of PM in any city vary both temporally – as a fluctuating hourly/daily level – and spatially, dependent on levels or traffic in an area or local industrial sources. The temporal and spatial variations in air pollution underlie the two main approaches to detecting and quantifying the adverse effects of PM (and indeed any air pollutant) in human populations. Time series studies utilize the temporal dimension and seek to relate the moving average of PM level to the moving average of a defined end-point, e.g., mortality [4]. Various lag-times are used to detect the relation between level of PM and the endpoint, e.g., 1 day. Environmental epidemiological studies seek to compare an endpoint such as the death rate in cities or suburbs characterized by high air pollution with the death rate in a city or suburb with lower air pollution [5]. Panel studies form a third category where small, well-characterized populations are followed for a defined endpoint that can be related to PM levels measured by personal or fixed point samplers [6].

When these different approaches are taken together and examined over hundreds of such studies there is good coherence between the acute effects, seen in time series and panel studies, and the chronic effects seen in environmental studies. More importantly, many of these studies show no evidence of a threshold, i.e., these adverse effects are occurring at the levels of PM that pertain in our cities today. Table 12.2 summarizes these adverse effects; the quantitative extent of mortality effects of PM in European studies is shown in Fig. 12.1.

**Tab. 12.2.** Adverse health effects due to PM.

---

Mortality from cardiovascular and respiratory causes  
 Admission to hospital for cardiovascular causes

Exacerbations of asthma in pre-existing asthmatics  
 Symptoms and use of asthma medication in asthmatics

Exacerbations of Chronic Obstructive Pulmonary Disease  
 Lung function decrease

Lung cancer

---

Within a short-lag time of one or two days following an increase in PM there are increases in the following (summarized in Ref. [8]) – (1) all-cause mortality; (2) attacks of asthma and increased usage of asthma medication; (3) deaths in COPD patients; (4) exacerbations of COPD; (5) deaths and hospitalizations for cardiovascular disease. The adverse cardiovascular effects associated with increases in PM are well-documented. Panel studies have documented associations between elevated levels of particles and

1. onset of myocardial infarction [6];
2. increased heart rate [9];
3. decreased heart rate variability [10].

**Fig. 12.1.** Relative risk for mortality endpoints related to a 10  $\mu\text{g m}^{-3}$  increase in  $\text{PM}_{10}$ , summarized from European studies [7].

Chamber studies with concentrated airborne particles (CAPs) have also shown increased lung inflammation [11] and altered brachial artery diameter in relation to increased exposure [12]. A recent epidemiological study of carotid intima-media thickness (CIMT), a measure of atherosclerosis, demonstrated evidence of an association between atherosclerosis and ambient air pollution level. Living in an area with a  $10 \mu\text{g m}^{-3}$  higher level of  $\text{PM}_{2.5}$  was associated with a CIMT increase of 5.9% (95% confidence interval, 1–11%); an even larger effect, 15.7%, was seen in older women.

## 12.5

### Nanoparticles are an Important Component of PM

Urban PM is a complex mixture of particle types that depend on season, time of day, siting of sampler etc. Clearly, however, combustion-derived nanoparticles represent a major toxicologically important component (see below). Table 12.3 shows the common components of PM.

Whilst levels of PM, along with other pollutants, have gone down markedly over the last 35 years, the traffic-derived portion has gone up as the numbers of vehicles on the road has increased [13]. Release of nanoparticles from vehicle tailpipes during diesel and petrol combustion is the predominant source of nanoparticles (Fig. 12.2) although there are other sources, such as energy production (power stations) and industry [14]. The medians of ultrafine (NP) particle number concentrations across three European cities were recently (2005) found to range from 15 000 to 18 000 particles per  $\text{cm}^3$  [15]. However, locally much higher exposures can be experienced. Using a nanoScanning Mobility Particle Sizer, multiple samples were

**Tab. 12.3.** Common components of PM and comments on their origin, nature and likely toxic potency.

<b>PM<sub>10</sub> component</b>	<b>Comment</b>	<b>Toxic potency</b>
Combustion-derived nanoparticles	Nanoparticles containing metals and organic volatiles; derived from combustion, e.g., vehicle exhaust particles	High
Sodium/magnesium compounds	Derived from sea spray	Low
Sulfate	Predominantly ammonium sulfate	Low
Nitrate	Predominantly ammonium nitrate	Low
Calcium/potassium compounds and insoluble minerals	Derived from the Earth's crust, e.g., clay	Low
Biologically-derived materials	For example, endotoxin	High

Fig. 12.2. Pie chart illustrating the source of PM<sub>0.1</sub> emissions in the UK in 1996 [21].

taken in Marylebone Road, a busy London street [16]. These showed that approximately 10 000 to 50 000 particles per cm<sup>3</sup> in the size range 30–100 nm were present. The daily pattern showed a typical one for traffic-derived nanoparticles [16]. A study on US highways suggested that the likely exposure in a vehicle traveling in busy traffic could be 200 to 560 × 10<sup>3</sup> particles (predominantly nanoparticles) per cm<sup>3</sup> [17, 18]. Indoors, there are also sources of nanoparticles such as cooking, vacuuming and burning wax candles [19]. Nanoparticles arise from combustion of domestic gas and in one study three gas rings produced a peak approaching 50 000 particles per cm<sup>3</sup> that underwent rapid aggregation, with increases in particle size and decrease in apparent number within a few minutes [20] (Fig. 12.3). Other sources of combustion, primarily industry, make a contribution to the nanoparticle cloud (Fig. 12.2). Secondary nanoparticles may also arise from environmental

The family of curves shows the particle size distribution 5, 10, 15, 20 min etc. after lighting the rings. Note the decrease in number and increase in size with time, indicative of particle aggregation [20].

chemistry, e.g., nitrates, but these are unlikely to be as toxicologically potent as combustion-derived nanoparticles (see below).

## 12.6

### Role of Nanoparticles in Mediating the Adverse Pulmonary Effects of PM

Epidemiological studies do not readily allow associations of adverse effects with sub-components of PM such as the nanoparticles, dependent as they usually are on a simple mass measure such as PM<sub>10</sub> or PM<sub>2.5</sub>. However, a few epidemiological studies have been able to identify combustion-derived particles as an important component in driving adverse effects of PM [22–24].

Toxicology can more readily address the relative toxic potency of the components of PM. Examining the components of PM toxicologically allows them to be divided into those with a high toxic potency and those with low toxic potency (Table 12.3). Combustion-derived nanoparticles (CDNP) stand out as common components of PM with high potency and several such nanoparticles have been utilized in toxicological studies, including carbon black and welding fume. As the predominant CDNP in PM, diesel soot has been specially studied.

Diesel fuel is a distillate of petroleum that contains paraffins, alkenes and aromatics [25]. On combustion in automobile engines it is transformed into low solubility carbon-centered nanoparticles of complex chemical and physical structure. Sulfates and organics, consisting of unburnt fuel, lube oil and polycyclic aromatic hydrocarbons (PAHs), also condense on the particles [25, 26]. Single diesel nanoparticles are 60 to 100 nm but these readily form complex chains and aggregates [27]. Diesel exhaust particles (DEP) are usually the most common CDNP in urban environmental air and in environmental particulate air pollution (PM<sub>10</sub>) in conurbations generally. In the general environment the concentration of DEP in PM<sub>10</sub> is likely to range from 5 to 30  $\mu\text{g m}^{-3}$ .

Exposure to DEP is also highly inflammatory in rats and mice in non-overload conditions [28–30] and induces pro-inflammatory effects on cells *in vitro* [31–33]. The well-documented link between inflammation and lung cancer [34–36] supports the idea that diesel exhaust may indeed be carcinogenic via an inflammatory pathway. The inflammatory effects of DEP appear to be driven by the particulate component, i.e., the surface area effect [37]. However, the organic [38] and metal components [39] also appear to play a role in pro-inflammatory effects and thereby affect pathogenicity.

CDNP, such as carbon black and diesel soot, show several pro-inflammatory effects that are relevant to pulmonary inflammation (summarized in Table 12.4). Inflammation caused by CDNP in PM could be important in mediating the observed adverse effects (Fig. 12.4).

Studies with several CDNP suggest that various different ones are a hazard to the lungs through the pathways of oxidative stress and inflammation [45] (Fig. 12.5). Heterogeneity in composition and solubility means that the key initiating

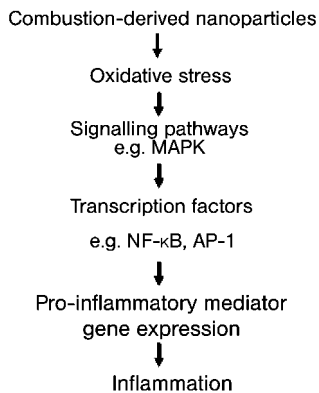

Fig. 12.5. Mechanism of the pro-inflammatory effects of combustion-derived nanoparticles (CDNP).

event of oxidative stress may originate from different components such as surfaces, metals or organics. These may even interact to produce oxidative stress as in the case of metals and organics interacting in the redox-cycling of quinoids [46] or nanoparticle surfaces and transition metals interacting additively in their ability to cause inflammation [47]. Inside the lung cells, oxidative stress can trigger inflammation through well-documented oxidative stress–response signaling pathways, including the MAPK and NF- $\kappa$ B. This culminates in the expression of genes that are involved in the recruitment and activation of leukocytes that are characteristic of inflammation. In addition, CDNP may exert genotoxic effects via well-documented pathways, including both oxidative stress adducts, such as 8-hydroxydeoxyguanosine, and bulky PAH-type adducts.

Lifetime animal exposure studies generally demonstrate that exposures to DEP and other nanoparticulate forms of carbon are carcinogenic [37] but these findings are complicated by the issue of rat lung overload [48]. Rat lung overload is a condition when very high lung surface area burden [49] of low toxicity, low soluble particles leads to failure of clearance. This leads to rapid accumulation of dose with concomitant inflammation and proliferation, which culminates in fibrosis and cancer [50]. Humans are unlikely to experience overload levels of diesel soot, even in occupational settings, and there is a question over whether overload can occur at all in humans. It is, therefore, unlikely that cancer associated with DEP exposure in humans results from a mechanism similar to rat lung overload.

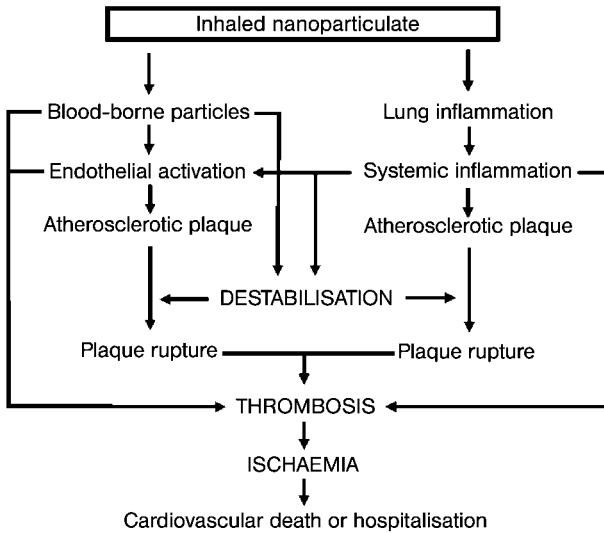

## 12.7

### Effects of Nanoparticles on the Cardiovascular System

Adverse cardiovascular effects associated with increases in PM are well-documented and have been reviewed extensively [51]. Exposure to particulate matter is associated with increases in mortality from ischemic heart disease and hospital admissions with acute myocardial infarction, heart failure and arrhythmia in time-series studies and population studies. Cohort studies have provided insight into the likely mechanisms responsible for these clinical events, and have documented associations between elevated levels of particles and heart rate, heart rate variability, blood pressure, myocardial ischemia and sub-clinical atherosclerosis.

Epidemiological studies cannot prove a causative biological effect of particulate exposure. Systems designed to deliver controlled amounts of ambient and combustion derived particulate now exist to allow a mechanistic approach to determining the effect of inhaled PM. Several plausible interlinking mechanisms have been proposed to explain these observations, and multiple pathways are likely to be involved (Fig. 12.6). These putative biological mechanisms involve direct effects of particles on the cardiovascular system following translocation across the alveolar-epithelial barrier, and indirect effects mediated by pulmonary oxidative stress and inflammation.

**Fig. 12.6.** Hypothetical pathways for the impact of inhaled nanoparticles on cardiovascular endpoints.

## 12.8 Inflammation, Atherosclerosis and Plaque Rupture

Markers of systemic inflammation are elevated in patients with cardiovascular disease [52]. In previously healthy individuals, elevated plasma concentrations of the acute phase reactant C-reactive protein have been shown to predict the development of ischemic heart disease [53], and in particular the risk of a first myocardial or cerebral infarction, independent of other risk factors [54].

Atherosclerosis is widely recognized to be an inflammatory process that is initiated through an injury to the vascular endothelium [55]. The resulting endothelial dysfunction leads to increased expression of leukocyte adhesion proteins, reduced anticoagulant activity and the release of growth factors, inflammatory mediators and cytokines. Continued inflammation results in leukocyte and monocyte recruitment, induction of atheroma formation and further arterial damage. Cycles of further damage cause plaque expansion and disruption that can lead to angina, crescendo angina and acute coronary syndromes, including myocardial infarction.

Inhalation of PM induces changes that are indicative of systemic inflammation such as increases in white blood cells and platelets [56], rises in C-reactive protein [57] and fibrinogen [58]. Experimental exposures mirror these clinical findings [59] and demonstrate evidence of combined systemic inflammation and endothelial dysfunction [60]. Repeated exposure to PM<sub>10</sub> may, therefore, induce or exacerbate the vascular inflammation of atherosclerosis and promote plaque expansion or

rupture. Indeed, using a Watanabe hereditary hyper-lipidemic rabbit model, Suwa and coworkers [61] have described plaque progression and destabilization following instillation of high doses of PM<sub>10</sub>.

## 12.9

### Nanoparticle Translocation and Direct Vascular Effects

It has been proposed that environmental nanoparticulate may translocate from the lung into the circulation and exert a direct effect on the vasculature. Once circulating, particles could interact with the vascular endothelium, or have direct effects on atherosclerotic plaque. Local inflammation could destabilize a coronary plaque, resulting in rupture, thrombosis, and an acute coronary syndrome.

Several factors influence the likelihood of particle translocation, including the properties of the particles themselves, size, affinity for water, rate of aggregation, surface charge, and the integrity or permeability of the alveolar-blood barrier. Inhaled nanoparticles deposit in the nasopharyngeal, tracheobronchial or alveolar regions by diffusion as discussed previously. Particles can evade phagocytosis by the alveolar macrophage and gain access to the interstitium whereupon they may be cleared directly into the circulation or by the lymphatic system. Environmental nanoparticulate may, possibly, gain access to the interstitium through pores in the blood-alveolar barrier. A three-pore model has been proposed to explain the ability of macromolecules to cross the alveolar-airway barrier, where the alveolar epithelial barrier contains many pores of 1 nm (68%) and 40 nm (30%) diameter and a few larger, 400 nm (2%), ones [62]. Alternatively, the mechanism may be analogous to the receptor-mediated transcytosis used by virus particles to enter and transfer between epithelial cells.

The first description of nanoparticulate translocation across the alveolar epithelium identified 30 nm gold particles in pulmonary capillary platelets following intra-tracheal instillation [63]. As well as identifying a novel pathway for the clearance of inhaled particulate, platelet uptake of particulate could result in aggregation and predispose to thrombus formation and atherothrombosis. Since then several studies have used radiolabeling to track the distribution of inhaled particles. Following intra-tracheal instillation of <sup>99m</sup>-technetium-labeled albumin nanocolloid (particles < 80 nm diameter) radioactivity was detected in the blood stream within 5 min, suggesting that particles underwent rapid translocation rather than being phagocytosed [64]. The mass of activity instilled did not alter the proportion of blood-borne radioactivity, suggesting the translocation is passive. Quantification of this process is hampered by methodological difficulties such as leaching of radiolabel and partial solubility of some particles. However, rats inhaling elemental carbon (<sup>13</sup>C; particles 20–29 nm diameter) showed a substantial accumulation of <sup>13</sup>C in the liver 24 h after exposure [65]. The lung is not the only portal where airborne nanoparticles may enter the body and low levels of pulmonary deposition of <sup>13</sup>C suggested that ingestion or up-take through the skin could also be important.

Evidence that inhaled nanoparticulate can translocate in humans is less well es-

established and the only two published studies to date are contradictory. In Nemmar et al. inhaled  $^{99\text{m}}\text{Tc}$ -labeled ultrafine carbon particles (5 nm diameter) were detected almost immediately in whole blood by thin-layer chromatography and accumulated in the liver and other extra-pulmonary organs [66]. In the study by Brown et al. using the same radiolabeled particles no such accumulation of activity out-with the lungs was reported [67]. Leaching of soluble radiolabel from the particles prevents any form of quantification of the extent of particle translocation using these methods. Further studies are required to determine whether alveolar translocation of nanoparticulate is an important pathway for the clearance of inhaled nanoparticles in man, and whether it can potentially explain the extra-pulmonary effects of particulate air pollution.

Oxidative stress increases the permeability of lung epithelium [68], potentially allowing particles, and macrophage laden with particles, to pass into the pulmonary interstitium and enter the circulation. Transfer of particles into the blood stream may be a more important pathway in patients with reduced antioxidant defenses, such as cigarette smokers or patients with underlying lung disease. In support of this, in an *ex vivo* lung perfusion model histamine and hydrogen peroxide perfusion increased alveolar permeability and the proportion of instilled iridium particles detected in the pulmonary venous effluent [69]. Likewise, increased epithelial permeability may encourage molecules produced in the lungs response to particles, e.g., IL-6 or oxidized LDL, to enter the interstitium and diffuse into the circulation.

Once circulating, nanoparticles could incorporate into sites of arterial injury and contribute to the development and progression of arterial atherosclerotic plaque formation. Oxidized LDL particles are typically around 200 nm in diameter and incorporation of these particles into the arterial wall is the central pathological process in the formation of atheroma. There is evidence that non-biological nanoparticles can be incorporated into the arterial wall. Following the infusion of ultrasmall paramagnetic iron oxide particles (USPIOs, 18 nm mean diameter) into hyperlipidaemic rabbits, the particles are phagocytosed by macrophages in atherosclerotic plaques of the aortic wall in quantities sufficient to be detectable by MRI [70]. Fluorescent-labeled nanoparticles, infused intra-luminally after balloon injury to the carotid artery in an animal model, successfully penetrated into the vessel wall and persisted for up to 14 days [71]. In humans, infusion of USPIOs before elective carotid endarterectomy revealed uptake of particles in 75% of ruptured, 54% of rupture-prone and only 7% of stable atheromatous plaques, suggesting that nanoparticles may incorporate into unstable plaques preferentially and potentially precipitate clinical events [72].

## 12.10

### Endothelial Dysfunction and Endogenous Fibrinolysis

The endothelium plays a vital role in the control of blood flow, coagulation, fibrinolysis and inflammation. Following the seminal work of Furchgott and Zawadzki

[73], it is widely recognized that an array of mediators, including cigarette smoking, can influence vascular tone through endothelium-dependent actions, and there is now extensive evidence of abnormal endothelium-dependent vasomotion in patients with atherosclerosis [74–76]. Endothelial dysfunction is one of the earliest pathological processes in atherosclerosis and can predict the likelihood of future cardiovascular events and death in both healthy individuals [77] and those with coronary artery disease [78].

Endothelial dysfunction has been described in both the peripheral and coronary circulation of cigarette smokers [76, 79]. As combustion products and particulate matter are common to both air pollution and cigarette smoke, it is likely that air pollution is likely to have similar detrimental vascular effects. The tar phase of cigarette smoke and combustion-derived particulate may contribute to the oxidative burden and generate equivalent numbers of oxidative radicals. *In vitro* studies provide support for a mechanism of oxidative stress induced vascular dysfunction, with Ikeda et al. demonstrating that the incubation of aortic ring preparations with diesel exhaust particles results in a dose-dependent inhibition of acetylcholine-mediated relaxation, an effect abolished by co-incubation with superoxide dismutase [80].

Whilst endothelium-dependent vasomotion is important, it may not be representative of other aspects of endothelial function, such as the regulation of fibrinolysis. The fibrinolytic factor tissue plasminogen activator (t-PA) regulates the degradation of intravascular fibrin and is released from the endothelium through the translocation of a dynamic intracellular storage pool. Acute endogenous t-PA release from the endothelium regulates the dissolution of intravascular thrombosis and is a critical determinant of cardiovascular outcome. This is exemplified by the clinical observation that in approximately 30% of patients with acute myocardial infarction, spontaneous reperfusion occurs within 12 h of vessel occlusion. Culture of human umbilical vein endothelial cells with particulate matter for 6 h inhibits both the synthesis and release of t-PA in a dose-dependent manner [81].

Direct adverse effects of particulates on the vascular endothelium are important only if sufficient quantities of inhaled particulate reach the circulation. Alternatively, it is possible that the local pulmonary inflammatory response to particulate is sufficient to release inflammatory cells and cytokines into the circulation and induce a mild systemic inflammation. Healthy adults exposed to dilute diesel exhaust for one hour had a mild systemic inflammatory response with increased blood neutrophil levels [82], and mild systemic inflammation also causes a profound, but temporary, suppression of endothelium-dependent vasodilatation [83].

Our group has recently shown that these pathways are adversely affected *in vivo* following controlled human exposures to dilute diesel exhaust [84]. Exposures to particulate at levels encountered in the urban environment for one hour markedly impaired the regulation of vascular tone and endogenous fibrinolysis. This study confirms *in vitro* findings and provides a plausible mechanism linking air pollution to the pathogenesis of atherothrombosis.

The acute effects of exposure to particulate are consistent with recent epidemiological studies that report a significant increase in risk of acute myocardial infarc-

tion as little as two hours after exposure to road traffic [85] or an increase in  $PM_{2.5}$  [6]. Our studies add to those of Brook et al. who demonstrated a reduction in brachial artery diameter immediately after exposure to a mixture of concentrated ambient particles and ozone [12]. In contrast, they found no effect on endothelium-dependent or -independent vasodilatation using flow-mediated and nitro-glycerine induced dilatation. This may reflect differences in the potency of the pollution models used or the technique used to assess vascular function. Exposures to concentrated ambient particulate are inherently variable in magnitude and composition, whereas in our study each volunteer received a standard exposure to combustion-derived particulate of known toxicity. Alternatively, the vascular effects of particulate matter are, possibly, mediated primarily in the resistance vessels assessed by plethysmography rather than in the conduit arteries assessed by ultrasound of the brachial artery.

## 12.11

### Coagulation and Thrombosis

Atherothrombosis is characterized by disruption of an atherosclerotic plaque with thrombus formation and is the major cause of acute coronary syndromes and cardiovascular death worldwide. To explain the association between environmental air pollution and acute cardiovascular events we proposed a hypothetical mechanism whereby particles reaching the alveolar epithelium could influence blood coagulability, resulting in a prothrombotic state and potentially triggering acute thrombus formation in susceptible individuals [86]. Over the last 10 years, experimental evidence has provided support for this mechanism.

Exposure to particulate matter increases the levels of blood fibrinogen, a key component in coagulation cascade and determinant of blood viscosity [11]. Fibrinogen levels are associated with increased blood thrombogenicity, and can independently predict outcome in patients with existing cardiovascular disease [87]. Blood viscosity also increased in association with levels of ambient particulate during a prolonged air pollution episode [88]. In human challenge studies, exposure to diesel exhaust increases the number of circulating platelets [56], and in animal studies exposure to diesel exhaust and ultrafine particles rapidly activates blood platelets and enhances venous thrombosis in a model of endothelial injury [89, 90]. In a subsequent study, the pro-thrombotic effect of diesel exhaust particles was abrogated by intra-peritoneal dexamethasone, suggesting this effect is mediated by either local or systemic inflammation [91].

PM can induce various prothrombotic effects, including enhanced tissue factor expression on endothelial cells [92]. Tissue factor is the main stimulus for thrombin generation, initiates the extrinsic coagulation pathway, and circulating levels are present in patients with coronary artery disease. In an *in vivo* perfusion study, intra-arterial carbon ultrafine particles enhanced endothelial von-Willebrand factor expression and accumulation of fibrin and platelets on the endothelial surface [93]. In addition to altering the properties of endothelial cells and platelets to promote

thrombus formation, nanoparticles may themselves act as a focus for thrombus formation. Scanning electron micrographic evaluation of thrombus on the surface of explanted temporary vena cava filters revealed the presence of foreign nanoparticles within thrombus [94]. These findings taken together support the notion that particulate matter causes inflammation, endothelial activation and can acutely increase the risk of thrombosis, thus predisposing to acute cardiovascular events.

## 12.12

### Cardiac Autonomic Dysfunction

There is an important relationship between autonomic regulation of the cardiac cycle and cardiovascular mortality [95]. Variation in the interval between consecutive heart beats or heart rate variability (HRV) is controlled by the contrasting effects of the sympathetic and parasympathetic nervous systems. Reduction in HRV reflects either an increase in sympathetic drive or a decrease in vagal parasympathetic tone. Reduced HRV increases the risk of cardiovascular morbidity and mortality in both healthy individuals [96] and patients following myocardial infarction [97].

Several panel studies have reported a consistent association between reduced HRV and high ambient PM [98, 99]. The finding of altered HRV in an elderly cohort exposed to concentrated ambient particles (CAPs) provides direct evidence of the effects of PM on autonomic activity [10]. The importance of this effect in the presence of cardiovascular pathology was demonstrated in a canine model of myocardial infarction, where exposure to residual oil fly ash (ROFA) reduced HRV and increased cardiac arrhythmia following infarction [100]. Furthermore, in patients with implanted cardiac defibrillators there appears to be a relationship between ambient PM and the incidence of ventricular fibrillation [101].

The influence of PM on the autonomic nervous system may result in hospitalization or cardiac death by triggering tachyarrhythmia or altering coronary vascular tone. How inhaled PM interacts with the nervous system is unclear. The effects could be mediated by interstitialized particles directly irritating the nerve endings or through the local release of inflammatory cytokines in response to the particles.

## 12.13

### Effects of Nanoparticles on the Liver and Gastrointestinal Tract

As described previously, particles depositing in the lung may gain access to the blood, allowing them to be transported around the body. For many years it has been recognized that the reticulo-endothelial system, a concentration of phagocytic cells in organs such as the liver and spleen, quickly accumulate particles injected into the blood [102]. For example, in 1970 Stuart reported that colloidal carbon injected into the tail vein accumulates in the liver and spleen [103]. NP designed as drug carriers are also sequestered by these phagocytic cells, with negatively

charged carboxylated polystyrene nanoparticles being taken up into the liver via scavenger receptors [104]. The effects of interaction between such cells and nanoparticles is as yet unclear, but some studies suggest that polystyrene nanoparticles can induce mild oxidative stress in the liver via activation of the macrophage phagocytic burst [105]. *In vitro*, both nanoparticles [106, 107] and PM<sub>10</sub> [108] stimulate calcium signaling via oxidative stress, leading to the production of pro-inflammatory cytokines such as tumor necrosis factor alpha. On the whole this work has been discussed in relation to the effects of PM and NP on the lung, but it is also feasible that NP translocated into the blood could initiate an inflammatory reaction in other organs such as the liver via their effects on macrophages.

There have been very few studies on the potentially adverse effects of NP directly on hepatocytes. Ref. [109] investigated the effects of various nanoparticles, differing in size and chemical composition, on hepatocyte viability as assessed by standard assays, including a measure of mitochondrial function (MTT assay) and enzyme leak through dysfunctional membranes (LDH assay). The silver particles studied (10–50 µg mL<sup>-1</sup>) were found to be highly toxic via oxidative stress (glutathione depletion), whereas molybdenum, aluminum, iron oxide and titanium dioxide only exhibited mild toxicity at doses greater than 100 µg mL<sup>-1</sup>. Further studies are required to establish how nanoparticles interact with liver cells and to elucidate the consequences.

The main route of particle clearance from the lung is via the mucociliary escalator, some of which is cleared via the nose, but most of which is swallowed [110]. This means that a significant proportion of the particle dose enters the gastrointestinal system. In relation to drug delivery, translocation of particulate matter across the gastrointestinal tract is now well documented [111]. There is histological, radiological and chemical evidence that 50–100 nm polystyrene nanoparticles cross the gastrointestinal tract and pass via the mesentery lymph supply and lymph nodes to the liver and spleen [112]. In addition, gastrointestinal uptake of particles of 100 nm diameter is 15–250-fold higher than for larger microparticles [113].

Furthermore, the uptake efficiency of the particles was dependent upon the tissue type, with Peyer's patches exhibiting a 2–200-fold higher uptake than non-patch tissue. The 100 nm particles were diffuse throughout the submucosal layers of the gastrointestinal tract while the larger particles were predominantly localized in the epithelium. In fact, histological studies have revealed a build-up of pigment particles accumulated from the diet in Peyer's patches of humans [114]. The ability of NP to cross the gut wall suggests that they would enter the body by the hepatic portal vein that drains the intestine, delivering blood directly to the liver. Hence, this would suggest that the liver would be exposed to particles translocated into the blood from both the lungs and the gastrointestinal tract.

The impact of nanoparticles on the gastrointestinal tract is relatively unknown. Some studies have suggested that exposure to nano- and microparticles in our diet could be associated with worsening of conditions such as Crohn's disease [115] through their ability to act as adjuvants in antigen-mediated immune responses, in tissues such as the Peyer's patches [116]. More work is required to verify these results and to elucidate the mechanisms involved.

#### Effects of NP on the Nervous System

In the past, in relation to the pulmonary toxicology of inhaled particles, most emphasis has been placed on the particles (<2.5 µm diameter) that gain access to the respiratory regions of the lung. This is because those particles depositing in the upper airways are easily cleared via the mucociliary escalator, whereas those depositing in the deeper lung depend upon the phagocytic activity of macrophages to minimize exposure and hence toxicity. However, more recently, Oberdörster et al. have demonstrated the ability of <sup>13</sup>C nanoparticles depositing on the nasal epithelium to gain access to the brain via the olfactory nerve [117]. They pointed out that neurophysiologists have long recognized that polio virus particles can be transported along nerve axons.

### 12.15

#### Summary

We have reviewed the literature pertaining to the role of nanoparticles in the adverse health effects of air pollution particles. Nanoparticles from combustion processes, predominantly automobile engines, are ubiquitous in ambient air and are strongly suspected of driving inflammatory and oxidative stress responses in the lungs. This is a factor in the exacerbations of airways disease seen in association with increases in PM. In addition to effects in the lungs, marked effects are seen in patients with cardiovascular disease. These may be explained by the ability of nanoparticles to gain access to the blood or indirectly through pro-inflammatory effects in the lungs, causing activation and destabilization of atheromatous plaques and leading to atherothrombosis and its associated morbidity and mortality. Nanoparticles may also gain access to the blood and directly affect the endothelium and the coagulation system. Nanoparticles in blood could affect the liver and potentially cross the brain barrier although nanoparticles could also enter the brain via olfactory neurones after deposition in the nose. Nanoparticles in the air are cleared to the gut via the mucociliary escalator and so their potential effects on the gut were considered. Once combustion-derived nanoparticles are resident in tissue they can deliver oxidative stress and affect inflammatory pathways and have genotoxic effects. Combustion-derived nanoparticles are a main driver of pulmonary and cardiovascular mortality and morbidity and, because of their potential to translocate around the body, have the potential to affect a number of extra-pulmonary target organs and systems.

## Contents

Preface XIII

List of Contributors XVII

<b>1</b>	<b>Conventional Chemotherapeutic Drug Nanoparticles for Cancer Treatment</b>	<b>1</b>
	<i>Loredana Serpe</i>	
1.1	Introduction	1
1.2	Cancer as Drug Delivery Target	2
1.3	Nanoparticles as Anticancer Drug Delivery System	4
1.3.1	Conventional Nanoparticles	5
1.3.2	Sterically Stabilized Nanoparticles	6
1.3.3	Actively Targetable Nanoparticles	8
1.3.4	Routes of Drug Nanoparticles Administration	10
1.4	Anticancer Drug Nanoparticles	12
1.4.1	Anthracyclines	12
1.4.1.1	Reverse of P-glycoprotein Mediated Multidrug Resistance of Cancer Cells to Doxorubicin	17
1.4.2	Antiestrogens	19
1.4.3	Anti-metabolites	20
1.4.4	Camptothecins	20
1.4.5	Cisplatin	21
1.4.6	Paclitaxel	21
1.4.7	Miscellaneous Agents	26
1.4.7.1	Arsenic Trioxide	26
1.4.7.2	Butyric Acid	26
1.4.7.3	Cystatins	26
1.4.7.4	Diethylenetriaminepentaacetic Acid	26
1.4.7.5	Mitoxantrone	27
1.4.8	Gene Therapy	27
	References	30

<b>2</b>	<b>Nanoparticles for Photodynamic Therapy of Cancer</b>	<b>40</b>
	<i>Magali Zeisser-Labouèbe, Angelica Vargas, and Florence Delie</i>	
2.1	Introduction	40
2.2	Concept and Basis of Photodynamic Therapy and Photodetection	41
2.2.1	Mechanisms of Photodynamic Therapy and Photodiagnosis	41
2.2.2	Selective Tumor Uptake of Photosensitizers	43
2.2.3	Photosensitizers	45
2.2.3.1	Conventional Photosensitizers	45
2.2.3.2	New Entities	47
2.2.4	Photodynamic Therapy: Advantages and Limitations	51
2.2.5	Photosensitizer Formulations	53
2.3	Non-biodegradable Nanoparticles for Photodynamic Therapy	54
2.3.1	Metallic Nanoparticles	54
2.3.2	Ceramic Nanoparticles	55
2.3.3	Nanoparticles Made of Non-biodegradable Polymers	56
2.4	Biodegradable Polymeric Nanoparticles for Photodynamic Therapy	57
2.4.1	Preparation of Biodegradable Polymeric Nanoparticles	58
2.4.1.1	<i>In situ</i> Polymerization	58
2.4.1.2	Dispersion of a Preformed Polymer	59
2.4.1.3	“Stealth” Particles	60
2.4.1.4	Targeted Nanoparticles	60
2.4.2	<i>In Vitro</i> Relevance of Polymeric Nanoparticles in PDT on Cell Models	61
2.4.2.1	Photodynamic Activity of PS-loaded Nanoparticles	61
2.4.2.2	Uptake and Trafficking of Photosensitizers	66
2.4.3	<i>In Vivo</i> Relevance of Polymeric Nanoparticles in PDT	70
2.4.3.1	Biodistribution and Pharmacokinetics of Photosensitizers Coupled to Nanoparticles	70
2.4.3.2	Vascular Effects	71
2.4.3.3	<i>In Vivo</i> Efficacy on Tumor: Tumor Suppression Effects	73
2.4.3.4	Adverse Effects	74
2.5	Conclusions	75
	Acknowledgments	75
	Abbreviations	76
	References	77
<b>3</b>	<b>Nanoparticles for Neutron Capture Therapy of Cancer</b>	<b>87</b>
	<i>Hideki Ichikawa, Hiroyuki Tokumitsu, Masahito Miyamoto, and Yoshinobu Fukumori</i>	
3.1	Introduction	87
3.2	Principle of Neutron Capture Therapy of Cancer	88
3.3	Boron Neutron Capture Therapy	89
3.3.1	Boron Compounds	89
3.3.2	Delivery of Boron Using Nanoparticles	90
3.4	Approaches to GdNCT	93

3.4.1	Typical Research on GdNCT	94
3.4.2	Delivery of Gadolinium using Lipid Emulsion (Gd-nanoLE)	95
3.4.2.1	Preparation of Gd-nanoLE	95
3.4.2.2	Biodistribution of Gadolinium after Intraperitoneal Administration of Gd-nanoLE	98
3.4.2.3	Biodistribution of Gadolinium after Intravenous Administration of Gd-nanoLE	101
3.4.3	Delivery of Gadolinium using Chitosan Nanoparticles (Gd-nanoCPs)	104
3.4.3.1	Preparation of Gd-nanoCPs	105
3.4.3.2	Gd-DTPA Release Property of Gd-nanoCPs	107
3.4.3.3	Gd-DTPA Retention in Tumor Tissue after Intratumoral Injection	107
3.4.3.4	<i>In vivo</i> Growth Suppression of Experimental Melanoma Solid Tumor	108
3.4.3.5	Bioadhesion and Uptake of Gd-nanoCP in Three Different Cell Lines	109
3.5	Conclusions	113
	References	114
<b>4</b>	<b>Nanovehicles and High Molecular Weight Delivery Agents for Boron Neutron Capture Therapy</b>	<b>122</b>
	<i>Gong Wu, Rolf F. Barth, Weilian Yang, Robert Lee, Werner Tjarks, Marina V. Backer, and Joseph M. Backer</i>	
4.1	Introduction	122
4.1.1	Overview	122
4.1.2	General Background	123
4.2	General Requirements for Boron Delivery Agents	124
4.3	Low Molecular Weight Delivery Agents	124
4.4	High Molecular Weight Boron Delivery Agents	125
4.5	Dendrimer-related Delivery Agents	125
4.5.1	Properties of Dendrimers	125
4.5.2	Boronated Dendrimers Linked to Monoclonal Antibodies	126
4.5.2.1	Boron Clusters Directly Linked to mAb	126
4.5.2.2	Attachment of Boronated Dendrimers to mAb	129
4.5.3	Boronated Dendrimers Delivered by Receptor Ligands	127
4.5.3.1	Epidermal Growth Factors (EGF)	127
4.5.3.2	Folate Receptor Targeting Agents	129
4.5.3.3	Vascular Endothelial Growth Factor (VEGF)	129
4.5.4	Other Boronated Dendrimers	130
4.6	Liposomes as Boron Delivery Agents	130
4.6.1	Overview of Liposomes	130
4.6.2	Liposomal Encapsulation of Sodium Borocaptate and Boronophenylalanine	133
4.6.2.1	Boron Delivery by Non-targeted Liposomes	133
4.6.2.2	Liposomal Encapsulation of other Boranes and Carboranes	134

VIII | Contents

4.6.3	Boron Delivery by Targeted Liposomes	137
4.6.3.1	Immunoliposomes	137
4.6.3.2	Folate Receptor-targeted Liposomes	138
4.6.3.3	EGFR Targeted Liposomes	138
4.7	Boron Delivery by Dextrans	139
4.8	Other Macromolecules used for Delivering Boron Compounds	141
4.9	Delivery of Boron-containing Macromolecules to Brain Tumors	142
4.9.1	General Considerations	142
4.9.2	Drug-transport Vectors	142
4.9.3	Direct Intracerebral Delivery	142
4.9.4	Convection-enhanced Delivery (CED)	143
4.10	Clinical Considerations and Conclusions	144

**6 Nanomaterials for Controlled Release of Anticancer Agents 168**

*Do Kyung Kim, Yun Suk Jo, Jon Dobson, Alicia El Haj, and Mamoun Muhammed*

6.1	Introduction	168
6.2	Nanoparticles for Biomedical Applications	170
6.2.1	First Generation Nanoparticles	171
6.2.2	Second Generation Nanoparticles	171
6.2.3	Advanced Generation Nanoparticles	172
6.3	Polymer Materials for Drug Delivery Systems	174
6.4	Design of Drug Delivery Vectors and Their Prerequisites	175
6.4.1	Polymeric Nanoparticles	175
6.4.2	Inorganic Nanoparticles	180
6.4.3	Metallic Nanoparticles	181
6.5	Kinetics of the Controlled Release of Anticancer Agents	181
6.5.1	Diffusion Model	182
6.5.2	Dissolution Model	183
6.5.3	Kinetics of the Indomethacin (IMC, 1-[ <i>p</i> -chlorobenzoyl]-2-methyl-5-methoxy-3-indoleacetic acid) Release	183
6.6	Controlled Release of Anticancer Agents	186

6.6.1	Alkylating Agents	186
6.6.1.1	Chlorambucil	187
6.6.1.2	Cyclophosphamide	187
6.6.1.3	Carmustine	188
6.6.2	Antimetabolic Agent	188
6.6.2.1	Cytarabine	188
6.6.2.2	Fluorouracil (FU)	189
6.6.2.3	Methotrexate	189
6.6.3	Anticancer Antibiotics	190
6.6.3.1	Actinomycin D	190
6.6.3.2	Bleomycin	190
6.6.3.3	Daunorubicin	191
6.7	Future Directions	191
	References	192
<b>7</b>	<b>Critical Analysis of Cancer Therapy using Nanomaterials</b>	<b>199</b>

## Preface

Even five years into the new millennium, cancer continues to torment humanity as the second leading cause of death with 10.9 million newly diagnosed cases worldwide in the year 2005 alone. Despite new discoveries of drugs and treatment combinations as evidenced by reports of close to 200,000 experimental studies on mice, two million scientific publications and an annual spending of around 15 billion US dollars world wide, the mortality rate due to cancer did not change in the past five to six decades. Therefore, there is still a strong need for a paradigm shift in the approach to cancer diagnosis and therapy. The advent of nanotechnological revolution offers an opportunity to achieve this paradigm shift. Since the biological processes in general and those that lead to cancer in particular occur at the nanoscale, there is a great opportunity for nanotechnologists to treat cancer at an as early stage as possible. Several innovative nanoscale constructs have been demonstrated to radically change cancer therapy with capabilities to deliver large doses of chemotherapeutic agents or therapeutic genes into malignant cells while sparing healthy cells. They have also shown great promise in enabling rapid and sensitive detection of single cancer cells and cancer-related molecules. Reports of these investigations are being published in a very broad range of journals spanning several traditional disciplines. It is becoming difficult for researchers to gather all the available information on 'Cancer Nanotechnology'. I am, therefore, pleased to share with you, again on behalf of dedicated team of researchers in cancer nanotechnology, two volumes of the ten volume series on nanotechnologies for the life sciences specifically dedicated to cancer. The first of these two volumes, sixth in the series, that is being presented to you here is dedicated to cancer therapy and is aptly titled as "*Nanomaterials for Cancer Therapy*."

The book is divided into eleven chapters encompassing a number of therapeutic approaches in cancer treatment through use of a variety of nanomaterials. It begins with a chapter reviewing the progress that has been made to date in utilization of conventional chemotherapeutic drug nanoparticles for cancer treatment. The chapter *Conventional Chemotherapeutic Drug Nanoparticles for Cancer Treatment* contributed by Loredanna Serpa from the University of Turin, Italy, is an up to date review of literature on advances being made in cancer treatment through use of nanoparticle formulations containing conventional chemotherapeutic drugs such as doxorubicin, cisplatin, paclitaxel and other drugs. Moving from conventional anticancer

drugs to conventional therapies that are being affected by nanotechnological tools, the second chapter starts with fundamental aspects of Photo Dynamic Therapy (PDT) that has been found to be promising in selectively treating tumors as well as metastasis without affecting the surrounding healthy tissue. The chapter *Nanoparticles for Photodynamic Therapy of Cancer*, written by Florence Delie and her team from the Laboratory of Pharmaceutical Technology and Biopharmaceutics, University of Geneva, Switzerland, provides an in-depth analysis of how nanoparticles, with special emphasis on polymeric biodegradable ones, are being developed to improve the conventional approaches to PDT. Continuing on a similar theme of improving conventional therapies, Yoshinobu Fukumori and co-workers from Kobe Gakuin University in Japan provide a general background on neutron capture therapy (NCT), a new radiotherapy that differs from the conventional radiotherapies, in the third chapter. This is followed by the authors reviewing more specifically both gadolinium neutron capture therapy (GdNCT) and boron neutron capture therapy (BNCT) with reference to use of nanomaterials. The remainder of the chapter *Nanoparticles for Neutron Capture Therapy of Cancer* provides a detailed account of the authors' experiences in developing Gd-containing lipid nanoemulsions and chitosan nanoparticles to demonstrate the usefulness of nanoparticle technology in NCT. Addressing a different facet of NCT, the fourth chapter entitled *Nanovehicles and High Molecular Weight Delivery Agents for Boron Neutron Capture Therapy* focuses on various high molecular weight (HMW) agents consisting of macromolecules and nanovehicles such as monoclonal antibodies, dendrimers, liposomes, dextrans, polylysine, avidin and folic acid, epidermal and vascular endothelial growth factors (EGF and VEGF) as delivery vehicles for introducing boron atoms. In it, Gong Wu, Rolf F. Barth, Weilian Yang, Robert Lee, Werner Tjarks, Marina V. Backer and Joseph M. Backer from the Department of Pathology at Ohio State University in Columbus, USA, have done a remarkable job in describing procedures for introducing boron atoms into HMW agents in addition to providing information on their chemical properties, bio-distribution based on in vivo studies, delivery across the blood brain barrier and various routes of their administration. Overall, the work reported in chapters three & four is very valuable and exciting not only from the scientific point of view, but also from the commercial point of view as recently clinical BNCT trials mainly for brain tumors were carried out in Japan.

Switching gears from earlier parts of the book where applications of nanotechnology to already well established treatments for cancer are presented, the rest of the chapters describe 'non-traditional' and innovative approaches completely based on nanotechnology that are being investigated for cancer therapy. Christoph Alexiou and Roland Jurgons from the Policlinic for otorhinolaryngological Illnesses of Friedrich-Alexander University, Erlangen-Nuremberg, Germany, contributed the fifth chapter, *Local Cancer Therapy with Magnetic Drug Targeting using Magnetic Nanoparticles*, in which they review current literature on the use of magnetic nanoparticles in biomedicine in general and local chemotherapies, focusing especially on regional cancer therapy, in particular. In the sixth chapter, *Nanomaterials for Controlled Release of Anticancer Agents*, the team lead by Do Kyung Kim at the

Massachusetts Institute of Technology, Cambridge, USA, has done a remarkable job in capturing nuances of nanotechnologies, particularly those based on polymeric nanomaterials, being developed for controlled release of anticancer agents. In this chapter, the authors discuss various design aspects, theoretical models and kinetics of controlled release of anticancer drugs. The seventh chapter on the other hand provides a much broader perspective to cancer therapy using nanomaterials by providing a critical analysis of various approaches. While the chapter starts with a description of the tools of nanoparticle technology that can be used to treat cancer, it goes a step further in critically reviewing and discussing the advantages and drawbacks of nanoparticles for the targeted delivery of anticancer agents to defined cells of human cancers. The chapter entitled *Critical Analysis of Cancer Therapy using Nanomaterials* contributed by Lucienne Juillerat-Jeanneret from the University Institute of Pathology in Lausanne, Switzerland, concludes the section with a final section that describes the author's own design of how an ideal nanoparticulate system should be for the targeted treatment of human cancers.

Treating cancer using heat has been known for a long time as cells are known to undergo apoptosis when exposed to temperatures around 40 °C. Thermotherapy, as it is called, as performed using conventional approaches has several drawbacks. In the eighth chapter, *Nanoparticles for Thermotherapy*, a team of cancer specialists lead by Andreas Jordan describe, based on their own experience, how some of these drawbacks are being overcome using magnetic nanoparticles. The chapter is particularly valuable as the team from the Center of Biomedical Nanotechnology (CBN), Berlin, Germany, share their experience in conducting the first ever clinical trials with thermotherapy using magnetic nanoparticles. Moving conceptually to a more elegant approach, the ninth chapter entitled *Ferromagnetic Filled Carbon Nanotubes as Novel and Potential Containers for Anticancer Treatment Strategies* explores the feasibility of different applications using magnetic multi-walled CNTs (MWCNTs) more specifically as heat mediators for hyperthermia of solid tumors. While authors Ingolf Mönch et al. from the Leibniz Institute for Solid State and Materials Research in Dresden, Germany, are upbeat about potential opportunities in the use of different types of functionalized MWCNTs, they restrict their review to only those that are novel and those that have benefits specifically in the treatment of prostate cancer.

Several types of nanomaterials are currently being investigated for targeted delivery of anticancer agents and there is a need for understanding the pros and cons of using these different types of nanomaterials. Chapter ten written by Yong Zhang and Dev K. Chatterjee from the Division of Bioengineering at the National University of Singapore provides a platform for comparing the efficacy of different types of nanomaterials for targeted delivery. The chapter, *Liposomes, Dendrimers and other Polymeric Nanoparticles for Targeted Delivery of Anticancer Agents – A Comparative Study*, provides a unique perspective on different types of nanomaterials in general and three major types in particular that are gaining importance in this field. The chapter is a must for those interested in learning about background information on mechanisms and methods of targeting cancer cells. At this point of time, liposomes seem to have an edge over the other types of nanomaterials and in the au-

thor's own words, "the most exciting news is the performance of Epeius Biotechnologies Corporation's liposomal based active targeting system that delivers genetic material to treat several cancers, including pancreatic head carcinoma, which has one of the worst prognoses among all neoplasms." In the eleventh and final chapter of the book, the team lead by Jack-Michel Renoir from University of Paris-Sud in Châtenay-Malabry, France, focuses on the benefits of encapsulating a class of anticancer drugs known as antiestrogens (AEs) to improve antitumoral activities in vivo. In addition, the authors discuss in this chapter, *Colloidal Systems for the Delivery of Anticancer Agents in Breast Cancer and Multiple Myeloma*, the use of passive targeting through long-circulating drug delivery systems in different types of xenografts. They strongly believe that the approach using colloidal systems is promising not only for the administration of antiestrogens in estrogen-dependent breast cancers and multiple myeloma (MM), but also for the delivery of much more toxic anticancer agents such as taxol, thalidomide, bortezomib, VEGF inhibitors, farnesyltransferase inhibitors, histone transferase inhibitors and hsp90 inhibitors.

I am pleased by the broad range of useful information gathered by the dedicated contributors working in the area of cancer nanotechnology, and I am hoping that the book will be a guide for all those who wish to be associated with the growing field of 'Nanomaterials for Cancer Therapy'. I am indebted to all the authors for their extraordinary efforts and as always grateful to my employer, family, friends and Wiley VCH publishers for making this book a reality. I am thankful to you, the reader, who has taken time to join the journey with fellow cancer nanotechnologists. It will be my pleasure to hear back from you and I look forward to receiving your comments, suggestions and constructive criticism in order to make further improvements in the next editions of the book.

## Conventional Chemotherapeutic Drug Nanoparticles for Cancer Treatment

*Loredana Serpe*

### 1.1 Introduction

Chemotherapy is a major therapeutic approach for the treatment of localized and metastasized cancers. The selective increase in tumor tissue uptake of anticancer agents would be of great interest in cancer chemotherapy since anticancer drugs are not specific to cancer cells. Routes of administration, biodistribution and elimination of available chemotherapeutic agents can be modified by drug delivery systems to optimize drug therapy.

This chapter focuses on progress in targeted treatment of cancer through the delivery of conventional anticancer agents via microparticulate drug carriers as nanoparticles. Briefly, nanoparticles may be defined as submicronic colloidal systems that are generally made of polymers and, according to the preparation process used, nanospheres (matrix systems) or nanocapsules (reservoir systems) can be obtained. The drug can either be directly incorporated during polymerization or by adsorption onto preformed nanoparticles [1].

The first part of this chapter pays particular attention to cancer as a drug delivery target and to the development of different types of nanoparticles as drug delivery device. The interaction of drug carrier systems with the biological environment is an important basis for designing strategies; these systems should be independent in the environment and selective at the pharmacological site. If designed appropriately, nanoparticles may act as a drug vehicle able to target tumor tissues or cells, protecting the drug from inactivation during its transport. The formulation of nanoparticles and physicochemical parameters such as pH, monomer concentration, added stabilizer and ionic strength as well as surface charge, particle size and molecular weight are important for drug delivery.

For instance, poly(acrylamide) nanocapsules, due to their polymeric nature, are stable in biological fluids and during storage, and can entrap various agents in a stable and reproducible way but, since they are not lysed by lysosomal enzymes, their clinical application is restricted [2]. The development of biodegradable polymers by the polymerization of various alkyl cyanoacrylate monomers and the association of anticancer agents with these poly(alkyl cyanoacrylate) polymers has

afforded further improvement. These colloidal drug carriers are biodegradable and can associate with various drugs in a non-specific manner. The binding capacity of these nanoparticles to dactinomycin (90%), vinblastin (36–85%) and methotrexate (15–40%) exceeds that of these drugs incorporated in liposomes [1].

Furthermore, certain types of nanoparticles are able to reverse multidrug resistance – a major problem in chemotherapy – and selectivity in drug targeting can be achieved by the attachment of certain forms of homing devices, such as a monoclonal antibody or lecithin [3].

Finally, the last part of the chapter reports some of the most significant and recently developed nanoparticle formulations for the delivery of specific anticancer agents.

## 1.2

### Cancer as Drug Delivery Target

Tumor blood vessels have several abnormalities compared with physiological vessels, such as a relatively high proportion of proliferating endothelial cells, an increased tortuosity and an aberrant basement membrane formation. The rapidly expanding tumor vasculature often has a discontinuous endothelium, with gaps between the cells that may be several hundred nanometers large [4, 5].

Macromolecular transport pathways across tumor vessels occur via open gaps (interendothelial junctions and transendothelial channels), vesicular vacuolar organelles and fenestrations. However, it remains controversial which pathways are predominantly responsible for tumor hyperpermeability and macromolecular transvascular transport [6].

Tumor interstitium is also characterized by a high interstitial pressure, leading to an outward convective interstitial fluid flow, as well as the absence of an anatomically well-defined functioning lymphatic network. Hence, the transport of an anticancer drug in the interstitium will be governed by the physiological (i.e., pressure) and physicochemical (i.e., composition, structure) properties of the interstitium and by the physicochemical properties of the molecule itself (i.e., size, configuration, charge, hydrophobicity). Physiological barriers at the tumor level (i.e., poorly vascularized tumor regions, acidic environment, high interstitial pressure and low microvascular pressure) as well as at the cellular level (i.e., altered activity of specific enzyme systems, altered apoptosis regulation and transport based mechanisms) and in the body (i.e., distribution, biotransformation and clearance of anticancer agent) must be overcome to deliver anticancer agents to tumor cells *in vivo* [1].

Colloidal nanoparticles incorporating anticancer agents can overcome such resistances to drug action, increasing the selectivity of drugs towards cancer cells and reducing their toxicity towards normal cells.

The accumulation mechanism of intravenously injected nanoparticles in cancer tissues relies on a passive diffusion or convection across the hyperpermeable tumor vasculature. Additional retention of the colloidal particles in the tumor inter-

stitium is due to the compromised clearance via lymphatics. This so-called “enhanced permeability and retention effect” results in an important intratumoral drug accumulation that is even higher than that observed in plasma and other tissues [7]. Controlled release of the drug content inside the tumoral interstitium may be achieved by controlling the nanoparticulate structure, the polymer used and the way by which the drug is associated with the carrier (adsorption or encapsulation).

However, anticancer drugs, even if they are located in the tumoral interstitium, can have limited efficacy against numerous tumor types because cancer cells are able to develop mechanisms of resistance. Simultaneous cellular resistance to multiple lipophilic drugs is one of the most important problems in chemotherapy. This drug resistance may appear clinically either as a lack of tumor size reduction or as the occurrence of clinical relapse after an initial positive response to antitumor treatment. Multidrug resistance is mainly due to overexpression of the plasma membrane P-glycoprotein, which is capable of extruding various generally positively charged xenobiotics, including some anticancer drugs, out of the cell. Multidrug resistance is always multifactorial when other mechanisms can be associated with this drug efflux pump in cancer cells, such as enzymatic function modification (topoisomerase, glutathione S-transferase) or altered intracellular drug distribution due to increased drug sequestration into cytoplasmic acidic vesicles [8]. P-glycoprotein probably recognizes the drug to be effluxed out of the cancer cell only when the drug is present in the plasma membrane, and not when it is located in the cytoplasm of lysosomes, after endocytosis. Many cancer cell types can develop resistance to doxorubicin, which is a P-glycoprotein substrate, therefore incorporation of this compound into nanoparticles to reverse multidrug resistance P-glycoprotein mediated has been extensively investigated [9]. Certain types of nanoparticles are able to overcome multidrug resistance mediated by the P-glycoprotein, such as poly(alkyl cyanoacrylate) nanoparticles [10].

The delivery of anticancer agents to a highly perfused tumoral lesion and the tumor cells response have been described through the development of a two-dimensional tumor simulator with the capability of showing tumoral lesion progression through the stages of diffusion-limited dormancy, neo-vascularization and subsequent rapid growth and tissue invasion. Two-dimensional simulations based on a self-consistent parameter estimation demonstrated fundamental convective and diffusive transport limitations in delivering anticancer drug into tumors via intravenous free drug administration or via 100 nm nanoparticles injected into the bloodstream, able to extravasate and release the drug into the tumoral tissue, or via 1–10 nm nanoparticles, able to diffuse directly and target the individual tumor cell. Even with constant drug release from the nanoparticles, homogenous drug-sensitive tumor cell type, targeted nanoparticle delivery and model parameters calibrated to ensure sufficient drug or nanoparticle blood concentration to kill all cells *in vitro*, analysis shows that fundamental transport limitations are severe and that drug levels inside the tumor are far less than *in vitro*. This leaves large parts of the tumor with inadequate drug concentration. Comparison of cell death rates predicted by simulations reveals that the *in vivo* rate of tumor reduction is

several orders of magnitude less than *in vitro* for equal chemotherapeutic carrier concentrations in the blood. Small nanoparticles equipped with active transport mechanisms would overcome the predicted limitations and result in improved tumor response [11].

### 1.3

#### Nanoparticles as Anticancer Drug Delivery System

The fate of a drug after administration *in vivo* is determined by a combination of several processes, such as distribution, metabolism and elimination when given intravenously or absorption, distribution, metabolism and elimination when an extravascular route is used. The result depends mainly on the physicochemical properties of the drug and therefore on its chemical structure. In recent decades, much work has been directed towards developing delivery systems to control the fate of drugs by modifying these processes, in particular the drug distribution within the organism. Nanoparticles loaded with anticancer agents can successfully increase drug concentration in cancer tissues and also act at cellular levels, enhancing anti-tumor efficacy. They can be endocytosed/phagocytosed by cells, with resulting cell internalization of the encapsulated drug. Nanoparticles may consist of either a polymeric matrix (nanospheres) or of a reservoir system in which an oily or aqueous core is surrounded by a thin polymeric wall (nanocapsules). Suitable polymers for nanoparticles include poly(alkyl cyanoacrylates), poly(methylidene malonate) and polyesters such as poly(lactic acid), poly(glycolic acid), poly( $\epsilon$ -caprolactone) and their copolymers [3].

Nanoparticles of biodegradable polymers can provide controlled and targeted delivery of the drug with better efficacy and fewer side-effects. Lipophilic drugs, which have some solubility either in the polymer matrix or in the oily core of nanocapsules, are more readily incorporated than hydrophilic compounds, although the latter may be adsorbed onto the particle surface. Nanospheres can also be formed from natural macromolecules such as proteins and polysaccharides, from non polar lipids, and from inorganic materials such as metal oxides and silica [3].

As cancer chemotherapeutic agents are often administered systemically, numerous biological factors, associated with the tumor, influence the delivery of the drugs to the tumors. Consequently, drug delivery systems to solid tumors have been redesigned and, subsequently, injectable delivery systems (i.e., solid lipid nanoparticles) have been developed as an alternative to polymeric nanoparticles for adequate drug delivery to solid tumors [12].

The introduction of synthetic material into the body always affects different body systems, including the defense system. Synthetic polymers are usually thymus-independent antigens with only a limited ability to elicit antibody formation or to induce a cellular immune response against them. However, they influence, or can be used to influence, the immune system of the host in many other ways. Low-immunogenic water-soluble synthetic polymers sometimes exhibit significant immunomodulating activity, mainly concerning the activation/suppression of NK

cells, LAK cells and macrophages. Some of them, such as poly(ethylene glycol) and poly[N-(2-hydroxypropyl)methacrylamide], can be used as effective protein carriers, as they can reduce the immunogenicity of conjugated proteins and/or reduce non-specific uptake of nanoparticle-entrapped drugs and other therapeutic agents [13].

### 1.3.1

#### Conventional Nanoparticles

Association of a cytostatic drug to colloidal carriers modifies the drug biodistribution profile, as it is mainly delivered to the mononuclear phagocytes system (liver, spleen, lungs and bone marrow). Once in the bloodstream, surface non-modified nanoparticles, (conventional nanoparticles), are rapidly opsonized and massively cleared by the fixed macrophages of the mononuclear phagocytes system organs.

The size of the colloidal carriers as well as their surface characteristics greatly influence the drug distribution pattern in the reticuloendothelial organs, since these parameters can prevent their uptake by macrophages. The exact underlying mechanism was not fully understood, but it was rapid and compatible with endocytosis. A high curvature (resulting in size < 100 nm) and/or a hydrophilic surface (as opposed to the hydrophobic surface of conventional nanoparticles) are needed to reduce opsonization reactions and subsequent clearance by macrophages [14]. Since conventional nanoparticles are naturally concentrated within macrophages, they can be used to deliver drugs to these cells. The muramyl dipeptide, a low-molecular-weight, soluble, synthetic compound based on the structure of peptidoglycan from mucobacteria, stimulates the antitumoral activity of macrophages. Although it acts on intracellular receptors, it penetrates poorly into macrophages. Furthermore, it is eliminated rapidly after intravenous administration. These problems can be overcome by encapsulation within nanocapsules, and lipophilic derivatives such as muramyl tripeptide-cholesterol have been developed to increase encapsulation efficiency. *In vitro* studies have shown increased intracellular penetration of muramyl peptides into macrophages when they are associated with nanoparticles, increasing macrophage effector functions (i.e., nitric oxide, cytokine and prostaglandin production) and cytostatic activity against tumor cells [3].

The contribution of conventional nanoparticles to enhance anticancer drugs efficacy is limited to targeting tumors at the organs of the mononuclear phagocytes system organ. Owing to their very short circulation time (the mean half-life of conventional nanoparticles is 3–5 min after intravenous administration) addressing anticancer drug-loaded nanoparticles to other tumoral tissues is not reasonable. Moreover, penetration of such a carrier system across the tumoral endothelium would be minimum, leading to subtherapeutic concentrations of the drug near the cancer cells. This biodistribution can be of benefit for the chemotherapeutic treatment of mononuclear phagocytes system localized tumors (i.e., hepatocarcinoma, hepatic metastasis, bronchopulmonary tumors, myeloma and leukemia). Activity against hepatic metastases has been observed in mouse models, although this treatment is only therapeutic when the tumor load is low [15].

Both the polymeric composition of the nanoparticles and the associated drug greatly influence the drug distribution pattern in the mononuclear phagocytic system. Conventional nanoparticles, likely, have a better safety profile than free anticancer agents when acting on normal tissue. For example, a reduction of the cardiac accumulation of drugs [16] and of the genotoxicity of mitomycin [17] have been reported. Moreover, encapsulation of doxorubicin within nanoparticles reduces its cardiotoxicity by reducing the amount of drug that reaches the myocardium with a significant increase of drug concentrations in the liver. In one study this was not associated with any overall toxicity [18] while another study, using unloaded nanoparticles, observed a reversible decline in the phagocytic capacity of the liver after prolonged dosing, as well as a slight inflammatory response [19]. Accumulation of drug nanoparticles in the liver may also influence its elimination, since this organ is the site of metabolism and biliary excretion. Biliary clearance of indomethacin was increased three-fold by inclusion in nanocapsules [20]. Nanoparticle-associated doxorubicin accumulated in bone marrow and led to a myelosuppressive effect in one study [21]. Thus, altered distribution may generate new types of toxicity. When conventional nanoparticles are used as carriers in chemotherapy, some cytotoxicity against the Kupffer cells or other targeted macrophages can be expected, as the class of drugs being used is able to induce apoptosis in these cells. Treatments featuring frequent administrations (with intervals shorter than two weeks – the restoration period of Kupffer cells) could result in a deficiency of Kupffer cells, which in turn could lead to decreased liver uptake and a subsequent decreased therapeutic efficacy for hepatic tumors. In addition, a risk for bacteremia can not to be excluded [22]. Moreover, conventional carriers also target the bone marrow, hence chemotherapy with such carriers may increase myelosuppressive effects. However, this tropism of carriers can also be used to deliver myelostimulating compounds such as granulocyte-colony-stimulating factor [23].

Certain types of nanoparticles were also found to be able to overcome multidrug resistance mediated by the P-glycoprotein efflux system localized at the cancerous cell membrane. This simultaneous cellular resistance to multiple lipophilic drugs represents a major problem in cancer chemotherapy. Such drug resistance may appear clinically either as a lack of tumor size reduction or as the occurrence of clinical relapse after an initial positive response to antitumor treatment. The resistance mechanism can have different origins, either directly linked to specific mechanisms developed by the tumor tissue or connected to the more general problem of distribution of a drug towards its targeted tissue. Poly(alkyl cyanoacrylate) nanoparticles have been developed to overcome multidrug resistance [10]. Despite encouraging results with conventional carrier systems, much research has been dedicated to designing carriers with modified distribution and new therapeutic applications.

### 1.3.2

#### **Sterically Stabilized Nanoparticles**

Since the usefulness of conventional nanoparticles is limited by their massive capture by the macrophages of the mononuclear phagocytes system after intravenous

administration, systems with modified surface properties to reduce the disposition of plasma proteins and the recognition by phagocytes have been developed [14]. These are known as sterically stabilized carriers or “stealth carriers” and may remain in the blood compartment for a considerable time. The hydrophilic polymers poly(ethylene glycol), poloxamines, poloxamers, polysaccharides have been used to coat efficiently conventional nanoparticles’ surface [24]. These coating provide a dynamic cloud of hydrophilic and neutral chains at the particle surface that keep away plasma proteins [25]. Poly(ethylene glycol) (PEG) has been introduced at the surface either by adsorption of surfactants [24] or by using block or branched copolymers, usually with poly(lactide) [26, 27]. These Stealth™ nanoparticles are characterized by a prolonged half-life in the blood compartment and by extravasation into sites where the endothelium is more permeable, such as solid tumors, regions of inflammation and infection. Consequently, such long-circulating nanoparticles are supposed to be able to target directly most tumors located outside the mononuclear phagocytes system [22]. A higher tumor uptake, thanks to the small size and the hydrophilicity of the carrier device, as well as a sustained release of the drug could improve the efficacy of anticancer chemotherapy. The complement-rejecting properties of nanocapsules are superior to those of nanospheres at equivalent surface area [28].

Coating conventional nanoparticles with surfactants to obtain a long-circulating carrier, the first strategy used to direct tumor targeting *in vivo*, has been demonstrated using photosensitizers like phthalocyanines in PEG-coated nanoparticles [29] and *meta*-tetra(hydroxyphenyl)chlorin in poly(lactide)-PEG nanocapsules [30].

PEG chains have been attached covalently to poly(alkyl cyanoacrylate) polymers by two chemical strategies; both types of particle have shown long-circulating properties *in vivo* [31]. Such particles have been loaded with tamoxifen with a view to their use in treating hormone-dependent tumors [32]. Poly(alkyl cyanoacrylate) nanoparticles allow the delivery of several drugs, including doxorubicin, across the blood–brain barrier after coating with surfactants. However, only the surfactants polysorbate (Tween 20, 40, 60 and 80) and some poloxamers (Pluronic F68) can induce this uptake. A therapeutic effect with this sterically stabilized carrier system has been noted in rats bearing intracranial glioblastoma [33]. The delivery mechanism across the blood–brain barrier is most likely endocytosis via the LDL receptor by the endothelial cells lining the brain blood capillaries after injection of the nanoparticles into the blood stream. This endocytotic uptake seems to be mediated by the adsorption of apolipoprotein B and/or E adsorption from the blood. The drug, then, may be released either within these cells followed by passive diffusion into the brain or be transported into the brain by transcytosis [34]. Long-circulating nanoparticles have also been used in tumor targeting followed by irradiation of tumor site in the case of photodynamic therapy. To improve anticancer efficacy and avoid systemic phototoxicity this combination was evaluated in a EMT-6 tumor-bearing mice model. Unfortunately, poly(lactic acid) nanospheres covered by PEG did not allow a higher intratumoral accumulation of its incorporated photosensitizer (hexadecafluoro zinc phthalocyanine). The fragility of the adsorbed coating and the large size (>900 nm) could be responsible for this failure. How-

ever, formulation of the photosensitizer in the biodegradable nanospheres improved photodynamic therapy response, probably by influencing the intratumoral distribution pattern of the photosensitizer [35]. The biodistribution of non-biodegradable poly(methyl methacrylate) nanospheres coated or not with different surfactants (Polysorbate 80, Poloxamer 407 and Polaxamine 908) have been investigated in several mice bearing tumor models, including a murine B16-melanoma (inoculated intramuscularly), a human breast cancer MaTu (engrafted subcutaneously) and an U-373 glioblastoma (implanted intracerebrally). The coated poly(methyl methacrylate) nanospheres in circulation showed a prolonged half-life, especially with the Poloxamer 407 and Poloxamine 908 coatings. Moreover, an accumulation and retention of the coated nanospheres in the B-16 and MaTu tumors were observed, depending on the particle surface hydrophilicity and the specific growth difference of the tumor [36].

Although interesting results have been obtained with adsorbed surfactant, a covalent linkage of amphiphilic copolymers is generally preferred to obtain a protective hydrophilic cloud on nanoparticles that avoids the possibility of rapid coating desorption upon either dilution or after contact with blood components. This approach has been employed with poly(lactic acid), poly(caprolactone) and poly(cyanoacrylate) polymers, which were chemically coupled to PEG [27, 31, 37].

The surface characteristics of nanospheres prepared from poly(lactide-co-glycolide) copolymers have been optimized to reduce their interactions with plasma proteins and to increase their circulating half-life [26, 27, 38]. Biodegradable nanospheres prepared from poly(lactide-co-glycolide) coated with poly(lactide)-PEG diblock copolymers showed a significant increase in blood circulation time and reduced liver uptake in a rat model compared with non-coated poly(lactide-co-glycolide) nanospheres [39]. Nanocapsules containing poly(lactide)-PEG showed reduced association with a macrophage-like cell line (J774 A1) irrespective of dilution and incubation time up to 24 h [40]. This formulation, which showed a lower capture by macrophages *in vitro*, also gave good results *in vivo*, yielding a plasma area under the curve 15-fold higher than that obtained with nanocapsules stabilized by adsorbed Poloxamer F68. Persistence in the blood compartment was accompanied by delayed liver and spleen uptake [41].

### 1.3.3

#### **Actively Targetable Nanoparticles**

Nanoparticles can be targeted to the particulate region of capillary endothelium, to concentrate the drug within a particular organ and allow it to diffuse from the carrier to the target tissue. The folate receptor is overexpressed on many tumor cells. Folic acid has some advantages over transferrin or antibodies as a ligand for long-circulating carriers because it is a much smaller molecule that is unlikely to interact with opsonines and can be coupled easily to a poly(ethylene glycol) (PEG) chain without loss of receptor-binding activity. This targeting strategy has also been applied to long-circulating nanoparticles prepared from a cyanoacrylate-based polymer. Folate grafted to PEG cyanoacrylate nanoparticles has a ten-fold higher appar-

ent affinity for the folate-binding protein than the free folate. Indeed, the particles represent a multivalent form of the ligand folic acid and folate receptors are often disposed in clusters. Thus conjugated nanoparticles could display a stronger interaction with the surface of malignant cells [42]. Bovine serum albumin nanoparticles have been reacted with the activated folic acid to conjugate folate via amino groups of the nanoparticle to improve their intracellular uptake to target cells. The nanoparticles were taken up to SKOV3 cells (human ovarian cancer cell line) and levels of binding and uptake were increased with the time of incubation until 4 h. The levels of folate-conjugated bovine serum albumin nanoparticles were higher than those of non-conjugated nanoparticles and saturable. Association of folate conjugated bovine serum albumin nanoparticles to SKOV3 cells was inhibited by an excess amount of folic acid, suggestive of binding and/or uptake mediated by the folate receptor [43].

Folate-linked microemulsions of the antitumor antibiotic aclacinomycin have been developed and investigated both *in vitro* and *in vivo*. Three kinds of folate-linked microemulsions with different PEG chain lengths loading aclacinomycin were formulated. *In vitro* studies were performed in a human nasopharyngeal cell line, KB, which overexpresses the folate receptor and in a human hepatoblastoma cell line, folate receptor (-), HepG2. *In vivo* experiments were carried out in a KB xenograft by systemic administration of folate-linked microemulsions loading aclacinomycin. This afforded selective folate receptor mediated cytotoxicity in KB but not in HepG2 cells. Association of the folate-PEG 5000 linked and folate-PEG 2000 linked microemulsions with the cells was 200- and 4-fold higher, respectively, whereas their cytotoxicity was 90- and 3.5-fold higher than those of non-folate microemulsion. The folate-PEG 5000 linked microemulsions showed a 2.6-fold higher accumulation in solid tumors 24 h after intravenous injection and greater tumor growth inhibition than free aclacinomycin. This study showed how folate modification with a sufficiently long PEG-chain on emulsions can be an effective way of targeting emulsion to tumor cells [44].

Transferrin is another well-studied ligand for tumor targeting due to upregulation of transferrin receptors in numerous cancer cell types. A transferrin-modified, cyclodextrin polymer-based gene delivery system has been developed. The nanoparticle is surface-modified to display PEG for increasing stability in biological fluids and transferrin for targeting of cancer cells that express transferrin receptor. At low transferrin modification, the particles remain stable in physiologic salt concentrations and transfect K562 leukemia cells with increased efficiency over untargeted particles. The transferrin-modified nanoparticles are appropriate for use in the systemic delivery of nucleic acid therapeutics for metastatic cancer applications [45].

Nanoparticles conjugated with an antibody against a specific tumor antigen have been developed to obtain selective drug delivery systems for the treatment of tumors expressing a specific tumor antigen. For instance, biodegradable nanoparticles based on gelatin and human serum albumin have been developed. The surface of the nanoparticles was modified by covalent attachment of the biotin-binding protein NeutrAvidin, enabling the binding of biotinylated drug targeting ligands by

avidin–biotin complex formation. Using the HER2 receptor specific antibody trastuzumab (Herceptin) conjugated to the surface of these nanoparticles, a specific targeting to HER2-overexpressing cells could be shown. Confocal laser scanning microscopy demonstrated an effective internalization of the nanoparticles by HER2-overexpressing cells via receptor-mediated endocytosis [46].

There is a tremendous effort to develop and test gene delivery vectors that are efficient, non-immunogenic, and applicable for cancer gene systemic therapy. Since internalization of colloidal carriers usually leads to the lysosomal compartment, in which hydrolytic enzymes will degrade both the carrier and its content, the intracellular distribution of the carrier must be modified when the encapsulated drug is a nucleic acid. Thus, systems have been developed that either fuse with the plasma membrane or have a pH-sensitive configuration that changes conformation in the lysosomes and allows the encapsulated material to escape into the cytoplasm [3]. Rapid endo-lysosomal escape of biodegradable nanoparticles formulated from the copolymers of poly(D,L-lactide-co-glycolide) has been reported. This occurred by selective reversal of the surface charge of nanoparticles (from anionic to cationic) in the acidic endo-lysosomal compartment, which causes the nanoparticles to interact with the endo-lysosomal membrane and escape into the cytosol. These nanoparticles can deliver various therapeutic agents, including macromolecules such as DNA at a slow rate, resulting in a sustained therapeutic effect. Thermo-responsive, pH-responsive and biodegradable nanoparticles have been developed by grafting biodegradable poly(D,L-lactide) onto N-isopropyl acrylamide and methacrylic acid. It may be sufficient for a carrier system to concentrate the drug in the tissue of interest. However, for hydrophilic molecules such as nucleic acid, which cross the plasma membrane with difficulty, intracellular delivery is required. Clinical trials for deadly pancreatic cancer have recently begun on two continents. The aim is to evaluate the safety and efficacy of engineered nanoparticles guided by a targeted delivery system to overcome dilution, filtration and inactivation encountered in the human circulatory system to deliver a killing designer gene to metastatic tumors that are refractory to conventional chemotherapy. The first patients receiving multiple intravenous infusions of the targeted delivery system-encapsulated genetic bullets have all responded favorably [47].

#### 1.3.4

#### **Routes of Drug Nanoparticles Administration**

The most convenient route of drug administration is the oral one but this presents several barriers to the use of colloidal carrier owing to conditions within the gastrointestinal tract. Duodenal enzymes and bile salts destroy the lipid bilayers of most types of liposome, releasing the drug. Polymeric nanoparticles are more stable, although there is some evidence that polyesters can be degraded by pancreatic lipases [48]. They may be able to improve bioavailability, particularly for highly insoluble drugs, by increasing the surface area for dissolution and as a result of bioadhesion. However, nanoparticles can be used to protect a labile drug from degradation in the gastrointestinal tract or to protect it from toxicity due to the drug.

Polymeric nanoparticles, due to their bioadhesive properties, may be immobilized within the mucus or, when in contact with the epithelial cells, show a slower clearance from the gastrointestinal tract [49]. Nanoparticles of biodegradable polymers containing alpha-tocopheryl PEG 1000 succinate (vitamin E TPGS) have been proposed to replace the current method of clinical administration and to provide an innovative solution for oral chemotherapy. Vitamin E TPGS could be a novel surfactant as well as a matrix material when blended with other biodegradable polymers – it has great advantages for the manufacture of polymeric nanoparticles for controlled release of paclitaxel and other anticancer drugs [50].

Potential applications of colloidal drug carriers by the intravenous route can be summarized as concentrating drugs in accessible sites, rerouting drugs away from sites of toxicity and increasing the circulation time of labile or rapidly eliminated drugs.

After subcutaneous or intraperitoneal administration, nanoparticles are taken up by regional lymph nodes [51].

Subcutaneously or locally injected (in the peri-tumoral region) nanoparticles can be used for lymphatic targeting as a tool for chemotherapy against lymphatic tumors or metastases since they penetrate the interstitial space around the injection site and are gradually absorbed by the lymphatic capillaries into the lymphatic system. Aclarubicin adsorbed onto activated carbon particles has been tested after subcutaneous injection in mice, against a murine model (P288 leukemia cells) of lymph node metastases [52]. The same system has also been used as a locoregional chemotherapy adjuvant for breast cancer in patients after intratumoral and peritumoral injections [53]. In both cases, this carrier system distributed selectively high levels of free aclarubicin to the regional lymphatic system and low levels to the rest of the body. However, this carrier system is not biodegradable and it is rather big (>100 nm), impeding drainage from the injection site. In addition, the drug is associated to the particles by adsorption, leading to a rapid release with possible systemic absorption. Biodegradable systems coated by adsorption of the surfactant Poloxamine 904 or poly(isobutyl cyanoacrylate) nanocapsules [51, 54] have been developed to improve lymphatic targeting. Poloxamine 904 caused an increased sequestration of the particles in lymph nodes, reducing the systemic absorption of any encapsulated drug [54]. Poly(isobutyl cyanoacrylate) nanocapsules were also able to retain the lipophilic indicator 12-(9-anthroxy)stearic acid in the regional lymph nodes for 168 h after intramuscular administration [51]. A study combining intratumoral administration of gadolinium-loaded chitosan nanoparticles and neutron-capture therapy has been performed on the B16F10 melanoma model subcutaneously implanted in mice. Gadolinium retention in tumor tissue increased when it was encapsulated with respect to the free drug. Tumor irradiation 8 h after the last intratumoral injection of gadolinium nanoparticles prevented further tumor growth in the animals treated, thereby increasing their life expectancy [55].

Retention of carriers instilled into the eye also occurs, leading to important therapeutic potential in this area. As well as a bioadhesive effect, some evidence has been presented to show that nanoparticles can penetrate through the corneal epithelium [56].

## 1.4

### Anticancer Drug Nanoparticles

#### 1.4.1

##### Anthracyclines

One of the most powerful and widely used anticancer drugs is doxorubicin, an anthracyclenic antibiotic that inhibits the synthesis of nucleic acids. This drug has a very narrow therapeutic index as its clinical use is hampered by several undesirable side-effects like cardiotoxicity and myelosuppression [57]. Thus, much effort has been made to target doxorubicin to cancer tissues, improving its efficacy and safety.

Poly(isohexyl cyanoacrylate) nanospheres incorporating doxorubicin have been developed. On an hepatic metastases model in mice (M5076 reticulum cell sarcoma) such doxorubicin nanospheres afforded a greater reduction in the number of metastases than when free doxorubicin was used and it appeared to increase the life span of the metastasis-bearing mice [58]. Another study found higher concentrations of doxorubicin in mice liver, spleen and lungs with doxorubicin incorporated into poly(isohexyl cyanoacrylate) than in mice treated with free doxorubicin. At the same time, the concentration of doxorubicin in heart and kidneys of the mice were lower than when free doxorubicin was used [18]. Tissue pharmacokinetic studies showed that the underlying mechanism responsible for the increased therapeutic efficacy of the nanoparticle formulation was a transfer of doxorubicin from the healthy hepatic tissue, acting as a drug reservoir, to the malignant cells. Kupffer cells, after a massive uptake of nanoparticles by phagocytosis, were able to induce the release of doxorubicin, leading to a gradient concentration, favorable for a prolonged diffusion of the free and still active drug towards the neighboring metastatic cells [59]. Thus, this biodistribution profile can be of benefit for chemotherapeutic treatment of tumors localized in the mononuclear phagocytic system.

Clinical pharmacokinetics after a single intravenous administration of doxorubicin adsorbed onto poly(methacrylate) nanospheres has been investigated in hepatoma patients. This type of conventional carrier, although of limited use *in vivo* because not biodegradable, allowed a reduction in both the volume of distribution and the elimination half-life of doxorubicin [60]. Another phase I clinical investigation has been carried out on 21 cancer patients with doxorubicin associated to biodegradable poly(isohexyl cyanoacrylate) nanospheres. Pharmacokinetic studies conducted in 3/21 patients revealed important interindividual variation for doxorubicin (encapsulated or not) plasma levels. Clinical toxicity of encapsulated doxorubicin consisted of dose-dependent myelosuppression of different grades in all patients, in pseudo-allergic reactions in 3/21 patients and in diffuse bone pain in 3/21 patients. However, neither cardiac toxicity nor hepatotoxicity were encountered among 18 patients treated with the nanoparticles formulation. According to WHO criteria, there were only 2/21 stable diseases lasting 4–6 months. All the other patients had progressive disease after the first course of doxorubicin-loaded poly(isohexyl cyanoacrylate) nanospheres. This could be due to tumor localization, as

they were rarely located at sites of the mononuclear phagocytic system, resulting in subtherapeutic anticancer drug concentration exposure [61].

As doxorubicin-loaded poly(isobutyl cyanoacrylate) nanoparticles are more efficient than free drug in mice bearing hepatic metastasis of the M5076 tumor, and Kupffer cells could have acted as a drug reservoir after nanoparticle phagocytosis, the role of macrophages in mediating the cytotoxicity of doxorubicin-loaded nanoparticles on M5076 cells was studied. After direct contact, free doxorubicin and doxorubicin-loaded nanoparticles had the same efficacy against M5076 cell growth. Co-culture experiments with macrophages J774.A1 led to a five-fold increase in the IC<sub>50</sub> for both doxorubicin and doxorubicin-loaded nanoparticles. The activation of macrophages by IFN- $\gamma$  in co-culture significantly decreased the IC<sub>50</sub>s. After phagocytosis of doxorubicin-loaded nanoparticles, J774.A1 cells were able to release active drug, allowing it to exert its cytotoxicity against M5076 cells. Drug efficacy was potentiated by the activation of macrophages releasing cytotoxic factors such as NO, which resulted in increased tumor cell death [62]. Similarly, the use in a murine tumor model (implanted subcutaneously J774.A1 macrophages) of a dextran-doxorubicin conjugate incorporated into small chitosan nanospheres was reported to outperform the free conjugate, especially in relation to life expectancy [63].

The body distribution of nanoparticle incorporating doxorubicin injected into the hepatic artery of hepatoma bearing rats was investigated. The nanoparticle formulation and free doxorubicin were injected into the hepatic artery of Walker-256 hepatoma bearing rats on the seventh day after tumor implantation. Survival time, tumor enlargement ratio and tumor necrosis degree were compared. Nanoparticles containing doxorubicin substantially increased the drug concentrations in liver, spleen, and tumor of rats compared to free drug, whereas the concentrations in plasma, heart and lungs were significantly decreased. The nanoparticulate formulation brought on a more significant tumor inhibition and more extensive tumor necrosis. The prolonged life span ratio was 109.22% as compared with rats that accepted normal saline [64, 65].

The nanoparticle modified biodistribution may generate new types of toxicity, as has been observed with doxorubicin incorporated in poly(isobutyl cyanoacrylate) and poly(isohexyl cyanoacrylate) nanospheres, whose hematopoietic toxicity was generally more pronounced and long-lasting than that of free doxorubicin [21]. Acute renal toxicity was another murine-reported doxorubicin toxicity, which was amplified by the association of the drug to poly(isobutyl cyanoacrylate) nanospheres. Proteinuria was probably the result of a modified biodistribution of the associated drug, which resulted in glomerular damage [66]. In another instance, doxorubicin was incorporated into gelatin nanospheres by a covalent bond on its amino group via glutaraldehyde [67]. Unfortunately, no or only marginal antitumor activity against a C26 tumor (mouse colon adenocarcinoma) *in vivo* was showed, and in certain cases there was even an increased doxorubicin cardiotoxicity. Once again this lack of antitumor activity may due to slow dissociation of the complex due to the covalent linkage or to the slow diffusion of the complex across the cellular membrane.

Polysorbate 80-coated poly(isobutyl cyanoacrylate) nanospheres provided no ma-

for changes in doxorubicin biodistribution and pharmacokinetic parameters in rats when compared to those of conventional poly(isobutyl cyanoacrylate) nanospheres. However, the coated nanospheres did transport a significant amount of incorporated doxorubicin to the brain of healthy rats, reaching the highest drug levels in this organ 2–4 h after intravenous administration. Consequently, an active transport from the blood to the brain was suspected since cerebral accumulation occurred against a concentration gradient. A mechanism involving an endocytosis by brain endothelial cells was hypothesized, as the brain uptake was inhibited at 4 °C and after a pretreatment with cytochalasin B [68]. Then, polysorbate 80-coated poly(isobutyl cyanoacrylate) nanoparticles were shown to enable the transport of doxorubicin across the blood–brain barrier to the brain after intravenous administration and to considerably reduce the growth of brain tumors in rats. The acute toxicity of doxorubicin associated with polysorbate 80-coated nanoparticles in healthy rats was studied and a therapeutic dose range for this formulation in rats with intracranially implanted 101/8 glioblastoma was established. Single intravenous administration of empty poly(isobutyl cyanoacrylate) nanoparticles in the dose range 100–400 mg kg<sup>-1</sup> did not cause mortality within the period of observation. Association of doxorubicin with poly(isobutyl cyanoacrylate) nanoparticles did not produce significant changes of quantitative parameters of acute toxicity of the antitumor agent. Likewise, the presence of polysorbate 80 in the formulations was not associated with changes in toxicity compared with free or nanoparticulate drug. The results in tumor-bearing rats were similar to those in healthy rats. The toxicity of doxorubicin bound to nanoparticles was similar or even lower than that of free doxorubicin [69]. As doxorubicin bound to polysorbate-coated nanoparticles crossed the intact blood–brain barrier, reaching therapeutic concentrations in the brain, the therapeutic potential of this formulation *in vivo* was studied using an animal model created by implantation of 101/8 glioblastoma tumor in rat brains. Rats treated with doxorubicin bound to polysorbate-coated nanoparticles had significantly higher survival times than with free doxorubicin; over 20% of the animals showed a long-term remission (Fig. 1.1). All animals treated with polysorbate-containing formulation also had a slight inflammatory reaction to the tumor. There was no indication of neurotoxicity [70].

Doxorubicin has also been conjugated chemically to a terminal end group of poly(D,L-lactic-co-glycolic acid) by an ester linkage and then formulated into nanoparticles. The conjugated doxorubicin nanoparticles showed increased uptake within a HepG2 cell line. They exhibited a slightly lower IC<sub>50</sub> against the HepG2 cell line than did free doxorubicin. An *in vivo* antitumor activity assay also showed that a single injection of the nanoparticles had comparable activity to that of free doxorubicin administered by daily injection [71]. Doxorubicin-loaded poly(butyl cyanoacrylate) nanoparticles have been used to enhance the delivery of the drug to Dalton's lymphoma solid tumor. <sup>99m</sup>Tc-labeled complexes of doxorubicin and doxorubicin-loaded poly(butyl cyanoacrylate) nanoparticles were administered subcutaneously below the Dalton's lymphoma tumor. The distribution of doxorubicin-loaded poly(butyl cyanoacrylate) nanoparticles to the blood, heart and organs of the

**Fig. 1.1.** Kaplan–Meier survival curves. Percentage of survival of the rats with intracranially transplanted glioblastoma after intravenous injection of  $2.5 \text{ mg kg}^{-1}$  doxorubicin each on day 2, 5 and 8 using one of the following formulations: DOX, doxorubicin in saline; DOX+Ps, doxorubicin

in saline plus polysorbate 80; DOX-NP, doxorubicin bound to poly(butyl cyanoacrylate) nanoparticles; DOX-NP+Ps, doxorubicin bound to poly(butyl cyanoacrylate) nanoparticles coated with polysorbate 80. (Reproduced with permission from Ref. [70].)

reticuloendothelial system was biphasic with a rapid initial distribution, followed by a significant decrease later at 6 h post-injection. The distribution of doxorubicin to tissues was very low initially and increased significantly at 6 h post-injection, indicating its accumulation at the injection site for a longer time. The concentration of doxorubicin-loaded poly(butyl cyanoacrylate) nanoparticles was also high in tissues at 6 h post-injection, indicating their accumulation at the subcutaneous site and consequent disposition to tissues with time. A significantly high tumor uptake of doxorubicin-loaded poly(butyl cyanoacrylate) nanoparticles (approx. 13-fold higher at 48 h post-injection) was found compared to free doxorubicin. Tumor concentrations of both doxorubicin and doxorubicin-loaded poly(butyl cyanoacrylate) nanoparticles increased with time, indicating their slow penetration from the injection site into tumor [72].

Poly(ethylene glycol)-coated poly(hexadecyl cyanoacrylate) nanospheres also displayed a significant accumulation within an orthotopic 9L gliosarcoma model, after intravenous administration to rats. Hence, in the same model, the pre-clinical efficacy of this carrier when loaded with doxorubicin was evaluated. The cumulative maximum tolerated dose of nanoparticulate doxorubicin was 1.5-fold higher than that of free doxorubicin. Nevertheless, encapsulated doxorubicin was unable to elicit a better therapeutic response in the 9L gliosarcoma. A biodistribution study revealed that the doxorubicin-loaded nanospheres accumulated to a 2.5-fold lesser extent in the 9L tumor than did the unloaded nanospheres and that they were mainly

localized in the lungs and the spleen. Such a typical profile indicated aggregation with plasma proteins as a consequence of the positive surface charge of these loaded particles; this ionic interaction resulting from drug encapsulation was mainly responsible for 9L treatment failure [73].

The ability of doxorubicin-loaded solid lipid nanoparticles to achieve prolonged drug plasma levels was also investigated. One study observed a low uptake of solid lipid nanoparticles by the liver and spleen macrophages. This might be explained by a low surface hydrophobicity of the nanoparticles avoiding the adsorption of any blood proteins mediating the uptake by liver and spleen macrophages [74]. Moreover, uptake of the solid lipid nanoparticles (SLNs) by the brain might be explained by adsorption of a blood protein mediating adherence to the endothelial cells of the blood–brain barrier [75]. Pharmacokinetic studies of doxorubicin incorporated into SLNs showed higher blood levels in comparison to a commercial drug solution after intravenous injection in rats. Concerning the body distribution, doxorubicin-loaded SLNs caused higher drug concentrations in lung, spleen and brain, while the solution led to a distribution more into liver and kidneys [76]. Furthermore, incorporation of doxorubicin into SLNs strongly enhanced its cytotoxicity in several cell lines [77, 78]. In particular, in the human colorectal cancer cell line HT-29, the intracellular doxorubicin content was double after 24 h exposure to loaded SLNs versus the conventional drug formulation [78]. Pharmacokinetics and tissue distribution of doxorubicin incorporated in non-sterically stabilized SLNs and in sterically stabilized SLNs at increasing concentration of stearic acid-PEG 2000 as stabilizing agent after intravenous administration to rabbits have been studied. The doxorubicin area under the concentration–time curve increased as a function of the amount of sterically stabilizing agent present in the SLNs. Doxorubicin was present in the brain only after doxorubicin-loaded SLNs administration and the increase in the stabilizing agent affected the doxorubicin transported into the brain. There was always less doxorubicin in the liver, lungs, spleen, heart and kidneys after injection of any of the types of SLNs than after the doxorubicin solution. In particular, all SLNs formulations significantly decreased heart and liver concentrations of doxorubicin [79]. Interestingly, both non-coated and coated SLNs showed a similar low uptake by liver and spleen macrophages [80]. The bioavailability of idarubicin can be also improved by administering idarubicin-loaded SLNs duodenally to rats. The pharmacokinetic parameters of idarubicin found after duodenal administration of idarubicin solution and idarubicin-loaded SLNs were different. The area under the concentration–time curve and the elimination half-life were 2- and 30-fold higher after administration of idarubicin-loaded SLNs than after solution administration, respectively. Tissue distribution also differed: idarubicin and its main metabolite idarubicinol concentrations were lower in heart, lung, spleen and kidneys after idarubicin-loaded SLNs administration than after solution administration. Furthermore, the drug and its metabolite were detected in the brain only after idarubicin-loaded SLNs administration, indicating that SLNs were able to cross the blood–brain barrier. After intravenous idarubicin-loaded SLNs administration, the area under the time–concentration curve of idarubicin was lower than after duodenal administration of the same formulation [81].

#### 1.4.1.1 Reverse of P-glycoprotein Mediated Multidrug Resistance of Cancer Cells to Doxorubicin

Different types of nanoparticles have been developed to reverse the P-glycoprotein mediated multidrug resistance of cancer cells to doxorubicin, an important problem in its clinical use.

Conventional poly(cyanoacrylate) nanoparticles allow doxorubicin P-glycoprotein mediated multidrug resistance to be overcome *in vitro* only when the nanoparticles and the resistant cancer cell line are in close contact [82]. The nanoparticle-associated drug accumulated within the cells and appeared to avoid P-glycoprotein dependent efflux. This reversal was only observed with poly(alkyl cyanoacrylate) nanoparticles and was not due to particle endocytosis. The formation of a complex between positively charged doxorubicin and negatively charged polymer degradation products seemed to favor diffusion across the plasma membrane [82].

When doxorubicin was coupled via an ionic interaction to non-biodegradable poly(methacrylate) nanospheres, the P-glycoprotein mediated multidrug resistance reversal differed from that of doxorubicin incorporated into biodegradable poly(cyanoacrylate) nanoparticles.

When adsorbed onto the surface of poly(methacrylate) nanospheres, doxorubicin was demonstrated to be cell internalized by an endocytic process in cultured rat hepatocytes and in a human monocyte-like cancer cell line expressing P-glycoprotein (U-937). Once internalized, poly(methacrylate) nanospheres generated an intracellular sustained release of doxorubicin in U-937 cells. A higher intracellular accumulation, related to a more important cytotoxicity on U-937 cells, was noted for encapsulated doxorubicin than for free doxorubicin. However, such a carrier, despite its ability to mask the positive charge of doxorubicin, is of limited use *in vivo* since it is not biodegradable [83].

When doxorubicin was incorporated into rapidly biodegraded poly(isobutyl cyanoacrylate) nanospheres and tested in a resistant murine leukemia sub-line over-expressing P-glycoprotein (P388/ADR), a higher cellular uptake was observed. Furthermore, the cell uptake kinetics of doxorubicin nanoparticles were unchanged in the presence of cytochalasin B, an endocytosis inhibitor. Efflux studies showed a similar profile for doxorubicin in nanoparticulate or free form. This suggests that poly(isobutyl cyanoacrylate) nanospheres did not enter the cells. In an *in vitro* model of doxorubicin-resistant rat glioblastoma (C6 cells sub-lines), doxorubicin incorporated into poly(isobutyl cyanoacrylate) nanospheres was always more cytotoxic, and also had a lower intracellular concentration, than the free drug. The polymer constituting the nanospheres did not inhibit the P-glycoprotein by direct interaction with the protein. It was also observed that on C6 cell sub-lines with different expression of P-glycoprotein that doxorubicin nanospheres were only efficient on pure P-glycoprotein mediated multidrug resistance phenotype cells and not on the additional mechanisms of resistance to doxorubicin [84]. Thus, the mechanism of P-gp reversion by nanoparticles could only be explained by a local delivery of the drug in high concentration close to the cell membrane, after degradation of the polymeric carrier. Such local microconcentration of doxorubicin was supposed to be able to saturate P-glycoprotein [85]. P-glycoprotein mediated multidrug resis-

tance is overcome with poly(isobutyl cyanoacrylate) and poly(isobutyl cyanoacrylate) doxorubicin-loaded nanospheres not only due to the adsorption of nanoparticles to the cell surface but also due to an increased diffusion of doxorubicin across the plasma membrane, thanks to the formation of an ion pair between negatively charged cyanoacrylic acid (a nanoparticle degradation product) and the positively charged doxorubicin. Such ion-pair formation has been evidenced by Raman spectroscopy and by ion-pair reversed-phase HPLC [86]. Masking the positive charge of the amino sugar of doxorubicin appears to be key to overcoming P-gp mediated multidrug resistance. At the same time, the cytotoxic activity of doxorubicin was only slowly compromised after chemical modifications of the amino sugar. Consequently, some studies focused on developing systems featuring covalent linkage between the polymers and the amino sugar of doxorubicin [87]. Such a complex mechanism for overcoming P-glycoprotein mediated multidrug resistance was only observed with cyanoacrylate nanoparticles.

The failure to overcome P-glycoprotein mediated multidrug resistance with nanoparticles designed with other polymers could be explained by an appropriate release mechanism of drug (diffusion could lead to the release of the active compound without the polymeric counter ion), by degradation kinetics of the polymer that are too slow, or by the size of the polymeric counter ion, which could be the limiting factor for diffusion across the cell membrane.

Interestingly, the association of doxorubicin with poly(alkyl cyanoacrylate) nanoparticles also reversed the resistance to doxorubicin in numerous multidrug-resistant cell lines [88].

Furthermore, doxorubicin encapsulated in poly(isohexyl cyanoacrylate) nanospheres can circumvent P-glycoprotein mediated multidrug resistance. K562 and MCF7 cell lines were more resistant to free doxorubicin than to doxorubicin poly(isohexyl cyanoacrylate) nanospheres. The MCF7 sub-lines selected with doxorubicin poly(isohexyl cyanoacrylate) nanospheres exhibited a higher level of resistance to both doxorubicin formulations than those selected with free doxorubicin. Different levels of overexpression of several genes involved in drug resistance occurred in the resistant variants. MDR1 gene overexpression was consistently higher in free doxorubicin selected cells than in doxorubicin poly(isohexyl cyanoacrylate) nanosphere selected cells, while this was the reverse for the BCRP gene. Overexpression of the MRP1 and TOP2 alpha genes was also observed in the selected variants. Thus, drug encapsulation markedly alters or delays the several mechanisms involved in the acquisition of drug resistance [89].

Other strategies to bypass doxorubicin multidrug resistance, such as the use of Stealth™ poly(cyanoacrylate) nanoparticles, could be considered, as well as the co-administration of doxorubicin with chemo-sensitizing agents, generally acting as P-glycoprotein inhibitors. Co-encapsulation of the reversing agent cyclosporin and doxorubicin into poly(isobutyl cyanoacrylate) nanospheres was investigated to reduce the side-effects of both drugs while enhancing their efficacy. This formulation, compared to incubation of cyclosporin and doxorubicin, or doxorubicin nanoparticles and cyclosporin, elicited the most effective growth rate inhibition on

P388/ADR cells. Such a high efficacy was supposed to result from the synergistic effect of the rapid release of both doxorubicin and cyclosporin at the surface of cancer cells, allowing a better internalization of doxorubicin, while inhibiting its efflux by blocking the P-gp with the cyclosporin [90].

#### 1.4.2

##### **Antiestrogens**

Nanospheres and nanocapsules made of biodegradable copolymers and coated with poly(ethylene glycol) (PEG) chains have been developed as parenteral delivery system for the administration of the anti-estrogen 4-hydroxytamoxifen RU 58668 (RU). Coating with PEG chains lengthened the anti-estrogen activity of RU, with prolonged antiuterotrophic activity of the encapsulated drug into PEG-poly(D,L-lactic acid) nanospheres as compared with non-coated nanospheres. In mice bearing MCF-7 estrogen-dependent tumors, free RU injected by the intravenous route slightly decreased estradiol-promoted tumor growth while RU-loaded PEG-poly(D,L-lactic acid) nanospheres injected at the same dose strongly reduced it. The antitumoral activity of RU encapsulated within PEGylated nanocapsules was stronger than that of RU entrapped with PEGylated nanospheres loaded at an equivalent dose. The PEGylated nanocapsules decreased the tumor size in nude mice transplanted with estrogen receptor-positive but estrogen-independent MCF-7/Ras breast cancer cells at a concentration 2.5-fold lower than that of the PEGylated nanospheres [91, 92].

To increase the local concentration of tamoxifen in estrogen receptor-positive breast cancer cells poly( $\epsilon$ -caprolactone) nanoparticle formulation has been developed. Poly( $\epsilon$ -caprolactone) nanoparticles labeled with rhodamine123 were incubated with MCF-7 estrogen receptor-positive breast cancer cells. A significant fraction of the administered rhodamine123-loaded poly( $\epsilon$ -caprolactone) nanoparticles was found in the perinuclear region of the MCF-7 cells, where estrogen receptors are also localized, after 1 h of incubation. These nanoparticles were rapidly internalized in MCF-7 cells and intracellular tamoxifen concentrations followed a saturable process [93]. In another study, the biodistribution profile of tamoxifen encapsulated in polymeric nanoparticulate formulations after intravenous administration was evaluated, with or without surface-stabilizing agents. *In vivo* biodistribution studies of tamoxifen-loaded poly(ethylene oxide)-modified poly( $\epsilon$ -caprolactone) nanoparticles were carried out in Nu/Nu athymic mice bearing a human breast carcinoma xenograft, MDA-MB-231, using tritiated [ $^3\text{H}$ ]tamoxifen as radio-marker for quantification. After intravenous administration the drug-loaded nanoparticles accumulated primarily in the liver, though up to 26% of the total activity could be recovered in tumor at 6 h post-injection for poly(ethylene oxide)-modified poly( $\epsilon$ -caprolactone) nanoparticles. In comparison with free drug and uncoated nanoparticles, the modified nanoparticles exhibited a significantly increased level of accumulation of the drug within the tumor with time as well as prolonged drug presence in the systemic circulation [94].

## 1.4.3

**Anti-metabolites**

Poly(amidoamine) dendritic polymers coated with poly(ethylene glycol) have been developed to deliver 5-fluorouracil. In rats after intravenous administration this nanoparticle formulation showed a lower drug clearance than after the free drug administration [95]. In addition, poly(D,L-lactide)-*g*-poly(*N*-isopropyl acrylamide-co-methacrylic acid) nanoparticles have been studied as drug carrier for intracellular delivery of 5-fluorouracil [96].

Methotrexate has been incorporated in modified poly(amidoamine) dendritic polymers conjugated to folic acid as a targeting agent. These conjugates were injected intravenously into immunodeficient mice bearing human KB tumors that overexpress the folic acid receptor. Targeting methotrexate increased its antitumor activity and markedly decreased its toxicity, allowing therapeutic responses not possible with the free drug [97].

## 1.4.4

**Camptothecins**

Solid lipid nanoparticles (SLNs) are a promising sustained release system for camptothecin after oral administration. The pharmacokinetics and body distribution of camptothecin after intravenous injection in mice have been studied. Two plasma peaks were observed after administration of camptothecin-loaded SLNs. The first was attributed to the presence of free drug, the second peak can be attributed to controlled release or potential gut uptake of the SLNs. In comparison to the drug solution, SLNs lead to a much higher area under the concentration–time curve/dose and mean residence times, especially in brain, heart and organs containing reticuloendothelial cells. The highest area under the concentration time curve ratio of SLNs to drug solution among the tested organs was found in the brain. Incorporation of camptothecin into SLNs also prevented its hydrolysis [98].

The *in vitro* and *in vivo* antitumor characteristics of methoxy poly(ethylene glycol)-poly(D,L-lactic acid) nanoparticles containing camptothecin have been examined. After intravenous administration in rats, camptothecin-loaded nanoparticles showed a longer plasma retention than camptothecin solution and high and long tumor localization. In both single and double administration to mice bearing sarcoma 180 solid tumor, camptothecin-loaded nanoparticles were much more effective than camptothecin solution, in particular the tumor disappeared completely in three of the four mice after double administration of camptothecin-loaded nanoparticles [99].

Irinotecan-containing nanoparticles have been prepared by co-precipitation with addition of water to an acetone solution of poly(D,L-lactic acid), PEG-*block*-poly(propylene glycol)-*block*-PEG and irinotecan. When the antitumor effect was examined using mice bearing sarcoma 180 subcutaneously, only nanoparticles suppressed tumor growth significantly. After intravenous injection in rats, nanopar-

ticles maintained irinotecan plasma concentration longer than irinotecan aqueous solution [100].

Lipid based nanoparticles incorporating the irinotecan analog SN-38 have been developed and studied *in vitro* and *in vivo*. Interestingly, incorporation of SN-38 into nanoparticles improved the stability of the active drug, the lactone form, in serum-containing medium. Furthermore, studies in nude mice showed a prolonged half-life of the active drug in whole blood and increased efficacy compared to irinotecan in a mouse xenograft tumor model [101].

#### 1.4.5

##### **Cisplatin**

Nanoparticles prepared from poly(lactide-co-glycolide) copolymers increase the circulating half-life of cisplatin [102]. A system for the local delivery of chemotherapy to malignant solid tumors has been developed based on calcium phosphate nanoparticles containing cisplatin. Cytotoxicity was investigated in a K8 clonal murine osteosarcoma cell line. Drug activity was retained after adsorption onto the apatite crystals and the apatite/cisplatin formulation exhibited cytotoxic effects with a dose-dependent decrease of cell viability [103].

#### 1.4.6

##### **Paclitaxel**

Paclitaxel, a microtubule-stabilizing agent that promotes polymerization of tubulin causing cell death by disrupting the dynamics necessary for cell division, is effective against a wide spectrum of cancers, including ovarian cancer, breast cancer, small and non-small cell lung cancer, colon cancer, head and neck cancer, multiple myeloma, melanoma and Kaposi's sarcoma. In clinical practice high incidences of adverse reactions of the drug such as neurotoxicity, myelosuppression and allergic reactions have been reported. Since its clinical administration is hampered by its poor solubility in water, excipients such as Cremophor EL (polyethoxylated castor oil) and ethanol are used in the pharmaceutical drug formulation of the current clinical administration [104].

Cremophor EL and polysorbate 80 (Tween 80) are widely used as drug formulation vehicles for the taxane anticancer agents paclitaxel and docetaxel. Both solubilizers are biologically and pharmacologically active compounds, and their use as drug formulation vehicles has been implicated in clinically important adverse effects, including acute hypersensitivity reactions and peripheral neuropathy. Cremophor EL and Tween 80 have also been demonstrated to influence the disposition of solubilized drugs that are administered intravenously. The overall resulting effect is a highly increased systemic drug exposure and a simultaneously decreased clearance, leading to alteration in the pharmacodynamic characteristics of the solubilized drug. Kinetic experiments revealed that this effect is caused primarily by reduced cellular uptake of the drug from large spherical micellar-like structures with a highly hydrophobic interior, which act as the principal carrier of circulating drug.

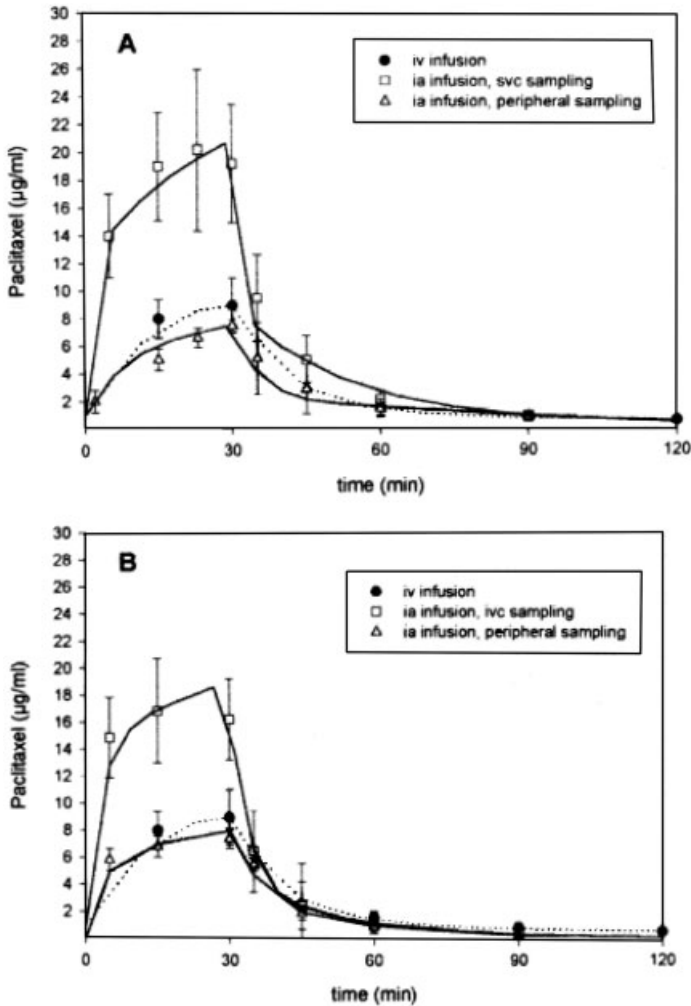

The existence of Cremophor EL and Tween 80 in blood as large polar micelles has also raised additional complexities in the case of combination chemotherapy regimens with taxanes, such that the disposition of several co-administered drugs, including anthracyclines and epipodophyllotoxins, is significantly altered. In contrast to the enhancing effects of Tween 80, addition of Cremophor EL to the formulation of oral drug preparations seems to result in significantly diminished drug uptake and reduced circulating concentrations [105]. Nanoparticles of biodegradable polymers can provide an ideal solution to such an adjuvant problem and realize a controlled and targeted delivery of paclitaxel with better efficacy and less side-effects. With further development, such as particle size optimization and surface coating, nanoparticle formulation of paclitaxel can promote full paclitaxel efficacy, thereby improving the quality of life of the patients.

Paclitaxel incorporated into poly(vinylpyrrolidone) nanospheres has been assayed on a B16F10 murine melanoma transplanted subcutaneously in C57B1/6 mice. Mice treated with repeated intravenous injections of paclitaxel-loaded nanospheres showed a significant tumor regression and higher survival rates than mice treated with free paclitaxel [106]. Sterically stabilized SLNs were also prepared to prolong the blood circulation time following intravenous administration [107]. Incorporation of paclitaxel into SLNs enhanced paclitaxel cytotoxicity on the human breast adenocarcinoma cell line MCF-7, but not on the human promyelocytic leukemia cell line HL-60 [77].

In a phase I study, ABI-007 – a novel formulation prepared by high-pressure homogenization of paclitaxel in the presence of human serum albumin, which results in a nanoparticle colloidal suspension – was found to offer several clinical advantages, including a rapid infusion rate and a high maximum tolerated dose. Furthermore, the absence of Cremophor EL allowed ABI-007 to be administered to patients without a need for premedication that is routinely used to prevent the hypersensitivity reactions associated with the conventional formulation of paclitaxel. Hematologic toxicities were mild throughout treatment, while most non-hematologic toxicities were grade 1 or 2 [108].

The feasibility, maximum tolerated dose, and toxicities of intraarterial administration of ABI-007 were studied in patients with advanced head and neck and recurrent anal canal squamous cell carcinoma in 43 patients (31 with advanced head and neck and 12 with recurrent anal canal squamous cell carcinoma). Patients were treated intraarterially with paclitaxel-albumin nanoparticles every four weeks for three cycles. Paclitaxel albumin nanoparticles were compared preliminarily with paclitaxel for *in vitro* cytostatic activity. Significantly, pharmacokinetic profiles after intraarterial administration were obtained (Fig. 1.2). The dose-limiting toxicity of the nanoparticles formulation was myelosuppression consisting of neutropenia in three patients. Non-hematologic toxicities included total alopecia, gastrointestinal toxicity, skin toxicity, neurologic toxicity, ocular toxicity, flu-like. The maximum tolerated dose in a single administration was  $270 \text{ mg m}^{-2}$ . Most dose levels showed considerable antitumor activity (80.9% complete response and partial response) [109].

The effectiveness of intraarterial infusion of paclitaxel incorporated into human

**Fig. 1.2.** Concentration–time curves. Mean paclitaxel concentration versus time profiles in patients with head and neck (A) or anal canal (B) carcinomas during and after 30 min

constant infusion of ABI-007 ( $250 \text{ mg m}^{-2}$  of paclitaxel); iv, intravenous; ia, intraarterial; svc, superior vena cava; ivc, inferior vena cava. (Reproduced with permission from Ref. [109].)

albumin nanoparticles for use as induction chemotherapy before definitive treatment of advanced squamous cell carcinoma of the tongue was also evaluated on 23 untreated patients who had carcinoma of the tongue. Each patient received two to four infusions, with a three-week interval between infusions. Sixteen patients underwent surgery, and of the remaining seven patients one received chemotherapy alone, four received radiotherapy alone, one received chemotherapy plus radio-

therapy and one refused any further treatment. Eighteen patients (78%) had a clinical and radiologic objective response (complete, 26%; partial, 52%). Three patients (13%) showed stable disease and two (9%) showed disease progression. The toxicities encountered were hematologic in two patients (8.6%) and neurologic in two patients (8.6%) [110].

Furthermore, a recent phase III trial in patients with metastatic breast cancer compared ABI-007 with paclitaxel. ABI-007 resulted in significantly higher response rates and time to tumor progression than paclitaxel. Toxicity data showed that ABI-007 resulted in less grade 4 neutropenia than paclitaxel, and although the incidence of grade 3 sensory neuropathy was higher with ABI-007, the time until the neuropathy decreased to grade 2 was significantly less with ABI-007 compared with paclitaxel [111].

A cholesterol-rich microemulsion or nanoparticle termed LDE has been developed and its cytotoxicity, pharmacokinetics, toxicity to animals and therapeutic action has been compared with those of the commercial paclitaxel. The cytostatic activity of the drug in the complex was diminished compared with commercial paclitaxel due to the cytotoxicity of the vehicle Cremophor EL used in the commercial formulation. Competition experiments in neoplastic cultured cells showed that paclitaxel oleate and LDE were internalized together by the LDL receptor pathway. LDE-paclitaxel oleate arrested the G<sub>2</sub>/M phase of cell cycle, similarly to commercial paclitaxel. Tolerability to mice was remarkable, such that the lethal dose (LD<sub>50</sub>) was nine-fold greater than that of the commercial formulation. Furthermore, LDE concentrated paclitaxel oleate in the tumor four-fold relative to the normal adjacent tissues. At equimolar doses, the association of paclitaxel oleate with LDE resulted in remarkable changes in the drug pharmacokinetic parameters when compared to commercial paclitaxel, with increasing half-life, area under the time–concentration curve and diminishing clearance [112].

The *in vitro* antitumoral activity of a developed poly(lactic-co-glycolic acid) nanoparticle formulation incorporating paclitaxel-loaded has been assessed on a human small cell lung cancer cell line (NCI-H69 SCLC) and compared to the *in vitro* antitumoral activity of the commercial formulation. The release behavior of paclitaxel from the nanoparticles exhibited a biphasic pattern characterized by an initial fast release during the first 24 h, followed by a slower and continuous release. Incorporation of paclitaxel in these nanoparticles strongly enhanced the cytotoxic effect of the drug as compared to free drug, this effect being more relevant for prolonged incubation times [113]. In addition, nanoparticles of poly(lactic-co-glycolic acid) have been developed by a modified solvent extraction/evaporation technique, in which natural emulsifiers, such as phospholipids, cholesterol and vitamin E TPGS were applied. These natural emulsifiers showed great advantages for nanoparticle formulation of paclitaxel over the traditional macromolecular emulsifiers such as poly(vinyl alcohol). In the human adenocarcinoma cell line HT-29 the cytotoxicity caused by the drug administered after 24 h incubation was 13-fold higher than that caused by the free drug [114].

To improve paclitaxel use in intravesical therapy of superficial bladder cancer, paclitaxel-loaded gelatine nanoparticles have been developed. The excipient Cremo-

phor EL contained in the commercial formulation of paclitaxel forms micelles that entrap the drug, reducing its partition across the urothelium. The paclitaxel-loaded nanoparticles were active against human RT4 bladder transitional cancer cells with  $IC_{50}$ s nearly identical to those of the commercial solution of paclitaxel. In dogs given an intravesical dose of paclitaxel-loaded particles, drug concentrations in the urothelium and lamina propria tissue layers, where Ta and T1 tumors would be located, were 2.6-fold greater than those reported for dogs treated with the Cremophor EL formulation [115].

The *in vitro* cytotoxicity, *in vivo* antitumor activity, pharmacokinetics, pharmacodynamics, and neurotoxicity of a micellar nanoparticle formulation of paclitaxel, NK105, has been compared with those of free paclitaxel. NK105 showed significantly potent antitumor activity on a human colorectal cancer cell line (HT-29) xenograft as compared with paclitaxel. The area under the time–concentration curve was approximately 90-fold higher for NK105 than for free paclitaxel. Leakage of paclitaxel from normal blood vessels was minimal and its capture by the reticulo-endothelial system minimized. Thus, the tumor area under the time–concentration curve was 25-fold higher for NK105 than for free paclitaxel. Neurotoxicity was significantly weaker with NK105 than with free paclitaxel [116].

Paclitaxel-loaded biodegradable nanoparticles following conjugation to transferrin ligand have been developed to enhance the therapeutic efficacy of the encapsulated drug in the treatment of prostate cancer. The antiproliferative activity of nanoparticles was determined in a human prostate cancer cell line (PC3) and the effect on tumor inhibition in a murine model of prostate cancer. The  $IC_{50}$  of the drug with transferrin ligand conjugated nanoparticles was about five-fold lower than that with unconjugated nanoparticles or drug in solution. Animals that received an intratumoral injection of paclitaxel loaded transferrin ligand conjugated nanoparticles demonstrated complete tumor regression and greater survival rate than those that received either unconjugated nanoparticles or paclitaxel Cremophor EL formulation [117].

Poly(ethylene glycol)-coated biodegradable poly(cyanoacrylate) nanoparticles were also conjugated to transferrin for paclitaxel delivery. This nanoparticle formulation exhibited a markedly delayed blood clearance in mice and the paclitaxel level remained much higher at 24 h compared with that of free drug after paclitaxel intravenous injection. In S-180 solid tumor-bearing mice, tumor regression was significant with the actively targetable nanoparticles, and complete tumor regression occurred for five out of nine mice. In addition, the life span of tumor-bearing mice was significantly increased when they were treated with the nanoparticle formulation [118].

Paclitaxel is active against gliomas and various brain metastases, though its use in treating brain tumors is limited due to low blood–brain barrier permeability. The lack of paclitaxel brain uptake is thought to be associated with the P-glycoprotein efflux transporter. To improve paclitaxel brain uptake, paclitaxel was entrapped in ethyl alcohol/polysorbate nanoparticles. The paclitaxel nanoparticles cytotoxicity profile was monitored in two different cell lines, U-118 and HCT-15. Brain uptake of paclitaxel nanoparticles was evaluated using an *in situ* rat brain

perfusion model. The results suggest that entrapment of paclitaxel in nanoparticles significantly increases the drug brain uptake and its toxicity toward P-glycoprotein-expressing tumor cells. It was hypothesized that paclitaxel nanoparticles could mask paclitaxel characteristics and thus limit its binding to P-glycoprotein, which consequently would lead to higher brain and tumor cell uptake of the otherwise effluxed drug [119].

#### 1.4.7

#### Miscellaneous Agents

##### 1.4.7.1 Arsenic Trioxide

Arsenic trioxide was considered as a novel antitumor agent. However, it also showed a severe toxicity effect on normal tissue. To improve its therapeutic efficacy and decrease its toxicity, arsenic trioxide-loaded albuminates immuno-nanospheres targeted with monoclonal antibody (McAb) BDI-1 have been developed and its specific killing effect against bladder cancer cells (BIU-87) investigated. The albuminates immuno-nanospheres were tightly junctioned with the BIU-87 cells and specific killing activity of bladder tumor cells was observed [120].

##### 1.4.7.2 Butyric Acid

Butyric acid, a short-chain fatty acid naturally present in the human colon, regulates cell proliferation. It specifically modulates the expression of oncogenes such as c-myc, c-fos and H-ras, and various genes involved in the activation of apoptosis like p53 and bcl-2. The clinical applicability of the sodium salt of butyric acid is limited because of its short half-life of approximately 5 min. To improve its efficacy the pro-drug cholesterylbutyrate has been used as a lipid matrix to develop SLNs. The *in vitro* antiproliferative effect of cholesterylbutyrate SLNs was stronger than that of sodium butyrate in several human cell lines [121–123].

##### 1.4.7.3 Cystatins

Cystatins can inhibit the tumor-associated activity of intracellular cysteine proteases cathepsins B and L and have been suggested as potential anticancer drugs. Chicken cystatin, a model protein inhibitor of cysteine proteases, in poly(lactide-co-glycolide) nanoparticles has been developed to improve its bioavailability and delivery into tumor cells. Poly(lactide-co-glycolide) nanoparticles and cystatin-loaded poly(lactic-co-glycolic acid) (PLGA) nanoparticles were cytotoxic towards mammary MCF-10A neoT cells, but free cystatin at the same concentrations was not. Poly(lactide-co-glycolide) nanoparticles were rapidly internalized into MCF-10A neoT cells, whereas the uptake of free cystatin was very slow. These nanoparticles are a useful carrier system. Delivery of the protein inhibitor into tumor cells was rapid and useful to inhibit intracellular proteolysis [124].

##### 1.4.7.4 Diethylenetriaminepentaacetic Acid

Since chelating agents exhibit anticancer effects, the cytotoxicity of the extracellular chelator diethylenetriaminepentaacetic acid (DTPA) has been evaluated in breast

cancer cells, MCF-7, and neuroblastoma cells, UKF-NB-3. DTPA inhibited cancer cell growth in three-fold lower concentrations compared to human foreskin fibroblasts. The anticancer activity of chelating agents is caused by intracellular complexation of metal ions. DTPA was covalently coupled to human serum albumin nanoparticles and gelatin type B (GelB) nanoparticles to increase its cellular uptake. Coupling of DTPA to this drug carrier system increased its cytotoxic activity by five-fold [125].

#### 1.4.7.5 Mitoxantrone

Mitoxantrone-loaded poly(butyl cyanoacrylate) nanoparticles have been tested in leukemia- or melanoma-bearing mice after intravenous injection. Efficacy and toxicity of mitoxantrone nanoparticles were compared with a drug solution and with a mitoxantrone-liposome formulation. The poly(butyl cyanoacrylate) nanoparticles and liposomes influenced the efficacy of mitoxantrone in cancer therapy in different ways. Liposomes prolonged survival time in P388 leukemia, whereas nanoparticles led to a significant tumor volume reduction in B16 melanoma. Neither nanoparticles nor liposomes were able to reduce the toxic side-effects caused by mitoxantrone, specifically leucocytopenia [126].

In a different study, mitoxantrone adsorbed onto poly(isobutyl cyanoacrylate) nanospheres, coated or not with poloxamine 1508, was administered by intravenous injection in B16 melanoma-bearing mice. In both cases, the observed tumor concentrations of mitoxantrone were high. However, the influence of the hydrophilic coating of the nanoparticles on the biodistribution and pharmacokinetics was minor. Moreover, the non-adsorbed drug was not removed from the nanoparticle preparation and the hydrophilic coating was rapidly desorbed *in vivo* [127].

#### 1.4.8

#### Gene Therapy

Delivery systems are necessary for molecules such as antisense oligonucleotides since they are susceptible to nuclease-mediated degradation in the circulation and penetrate poorly through the membranes. They are also susceptible to nuclease attack within the lysosomes and their site of action is either in the cytoplasm in the case of an antisense strategy or in the nucleus for gene replacement or antigene therapy.

Antisense oligonucleotides are molecules that can inhibit gene expression being potentially active for the treatment of cancer. Short nucleic acid sequences specific to oncogene targets such as bcl-2, bcr-abl and c-myc have been shown to exhibit specific anticancer activity *in vitro* through antigene or antisense activity. However, their negative charge seriously hinders the intracellular penetration of these short fragments of nucleic acid. Efficient *in vivo* delivery of oligonucleotides remains a major limitation for their therapeutic application.

To prevent the degradation of oligonucleotides and improve their intracellular capture, it was proposed to associate them with nanoparticles. Oligonucleotides associated to nanoparticles were shown to be protected against degradation and to

penetrate more easily into different types of cells. Poly(alkyl cyanoacrylate) nanoparticles mainly release their drug content by biodegradation, thus rendering the release profile of an entrapped compound independent of its physicochemical characteristics. After intratumoral injection, the bioavailability of oligonucleotides is seriously reduced due to their fast degradation by ubiquitous exo- and endonucleases [128].

For instance, a carrier system consisting of a cationic hydrophobic detergent (cetyltrimethylammonium bromide, CTAB), which interacted with the oligonucleotides by ion-pairing, was developed. *In vivo*, HBL100ras1 cells implanted in nude mice were treated intratumorally with several formulations of oligonucleotides targeted against Has-ras oncogene. Tumor growth inhibition was achieved at concentrations 100-fold lower than those needed with free oligonucleotides, when the oligonucleotides-CTAB complex was adsorbed onto the surface of the poly(isohexyl cyanoacrylate) nanospheres. Interestingly, the oligonucleotides-CTAB complex alone exerted no effect on HBL100ras1 cell proliferation. Analysis of the amount of intact intracellular oligonucleotides, in cell culture experiments, revealed concentrations 100-fold higher in cells treated with oligonucleotides-CTAB adsorbed onto nanospheres [129].

The nanospheres were able to enhance oligonucleotides cell internalization and to protect oligonucleotides from both rapid cell internalization and rapid intracellular breakdown, which led to a considerably higher intracellular concentration of intact oligonucleotides and to a more efficient antisense activity. However, the oligonucleotides release was followed by the release of the detergent CTAB, which, at high intracellular concentrations, could induce cell toxicity.

Cholesterol-modified oligonucleotides, capable of direct adsorption onto poly(alkyl cyanoacrylate) nanospheres without the need for potentially toxic intermediates, have also been tested, but they proved less able to inhibit T24 human bladder carcinoma cells proliferation in culture than the system previously described [130].

To circumvent CTAB toxicity while maintaining an efficient biological activity, another approach was developed. Functional nanospheres were obtained by free radical emulsion polymerization of methyl methacrylate using the quaternary ammonium salt of 2-(dimethylamino)ethyl methacrylate as the reactive emulsifier [131].

The cationic dextran derivative diethylaminoethyl-dextran, by formation of an ion pair at the oligonucleotides surface, was developed to replace CTAB and was associated with poly(isohexyl cyanoacrylate) nanospheres. Poly(isohexyl cyanoacrylate) nanoparticles, with an aqueous core containing oligonucleotides, were prepared by interfacial polymerization of isobutyl cyanoacrylate in water/oil emulsion. Further studies also demonstrated that nanoencapsulation was able to protect oligonucleotides against degradation by serum nucleases contained in the cell culture medium [132].

For *in vivo* studies, phosphorothioate oligonucleotides against EWS Fli-1 chimeric RNA were encapsulated into cyanoacrylate nanocapsules and their efficacy was tested on experimental Ewing sarcoma, after intratumoral administration. Oligo-

nucleotides nanocapsules led to more efficient tumor growth inhibition. The encapsulation of oligonucleotides provided enhanced protection against *in vivo* degradation, resulting in a higher number of oligonucleotides available. Cyanoacrylate nanocapsules yielded a higher ratio of oligonucleotides targeting the tumor cells [133].

*In vivo*, poly(alkyl cyanoacrylate) nanoparticles were able to efficiently distribute the oligonucleotides to the liver and to improve, in mice, the treatment of RAS cells expressing the point mutated Ha-ras gene. As all the oligonucleotides studied had a specific therapeutic efficacy, this means that the oligonucleotides delivered by nanoparticles escape from the lysosome compartment before degradation [134].

Preclinical studies have shown that DOTAP:cholesterol nanoparticles are effective systemic gene delivery vectors that efficiently deliver tumor suppressor genes to disseminated lung tumors. A phase-I trial for systemic treatment of lung cancer using a novel tumor suppressor gene, FUS1, has been initiated. Although DOTAP:cholesterol nanoparticles complexed to DNA are efficient vectors for systemic therapy, induction of an inflammatory response in a dose-dependent manner has also been observed, thus limiting its use. Systemic administration of DNA nanoparticles induced multiple signaling molecules both *in vitro* and *in vivo* that are associated with inflammation. Use of small molecule inhibitors against the signaling molecules resulted in their suppression and thereby reduced inflammation without affecting transgene expression [135]. Nanoparticles coated with ligands such as transferrin and epidermal growth factor (EGF) have also been developed in gene delivery to target selectively the tumor cells [136]. Complexes for DNA delivery composed of polyethylenimine (polyplexes) linked to poly(ethylene glycol) and coated with transferrin or EGF were prepared with fixed nanoparticle diameters. Intravenous injection of the transferrin-coated polyplexes resulted in gene transfer to subcutaneous neuroblastoma tumors in syngenic mice, and intravenous injection of the EGF-coated polyplexes targeted human hepatocellular carcinoma xenografts in SCID mice. In these models, luciferase marker gene expression levels in tumor tissues were 10- to 100-fold higher than in other organ tissues. Repeated systemic application of the transferrin polyplexes encoding tumor necrosis factor alpha (TNF- $\alpha$ ) into tumor-bearing mice induced tumor necrosis and inhibition of tumor growth in different murine tumor models [137].

Transferrin-modified nanoparticles containing DNazymes (short catalytic single-stranded DNA molecules) for tumor targeting have been developed. Linear,  $\beta$ -cyclodextrin-based polymers were complexed with DNazyme molecules to form sub-50 nm particles termed "polyplexes". Adamantane forms inclusion complexes with the surface cyclodextrins of the polyplexes, allowing a sterically stabilizing layer of poly(ethylene glycol) to be added. The stabilized polyplexes were also modified with transferrin to increase the targeting to tumor cells expressing transferrin receptors. Administration by intraperitoneal bolus, infusion, intravenous bolus and subcutaneous injection were studied in tumor-bearing nude mice. DNazymes packaged in polyplex formulations were concentrated and retained in tumor tissue and other organs, whereas unformulated DNazyme was eliminated from the body

within 24 h post-injection. Tumor cell uptake was observed with intravenous bolus injection only and intracellular delivery requires transferrin targeting [138].

Potent sequence selective gene inhibition by siRNA is also hindered by poor intracellular uptake, limited blood stability and non-specific immune stimulation. Thus, ligand-targeted, sterically stabilized nanoparticles have been developed for siRNA. Self-assembling nanoparticles with siRNA were constructed with poly(ethyleneimine) that is PEGylated with an Arg-Gly-Asp peptide ligand, as a means to target tumor neovasculature expressing integrins, and used to deliver siRNA inhibiting vascular endothelial growth factor receptor-2 (VEGF R2) expression and thereby tumor angiogenesis. Intravenous administration into tumor-bearing mice gave selective tumor uptake, siRNA sequence-specific inhibition of protein expression within the tumor and inhibition of both tumor angiogenesis and growth rate [139].

## 2 Nanoparticles for Photodynamic Therapy of Cancer

*Magali Zeisser-Labouèbe, Angelica Vargas, and Florence Delie*

### 2.1 Introduction

Currently, the limiting factor in cancer chemotherapy is still the lack of selectivity of anticancer drugs towards neoplastic cells. Photosensitizers (PS), the active compounds used for photodynamic therapy (PDT), have the intrinsic advantage of distributing primarily in highly regenerative tissues after intravenous or topical administration. Therefore, they will accumulate preferentially in tumor tissue when present. In addition, these molecules are inactive as such; indeed, the anticancer effect is only attained after irradiation with light at the right wavelength. Compared to other current cancer therapies such as surgery, radiotherapy or chemotherapy, PDT is an effective and selective means of suppressing diseased tissues without altering the surrounding healthy tissue. It also offers a unique opportunity to reach unseen metastasis. As fluorescent molecules, PS may also be used as a tool, namely photodetection (PD), to reveal tumor tissues that remain unseen by other conventional methods.

Interestingly, PD and PDT are mutually beneficial. Ideally, a PS could be used to detect tumors and then to treat them. Quantification of PS fluorescence allows us to follow PS uptake and pharmacokinetics [1–3]. Finally, after treatment, the tissue can be examined by PD to evaluate disease control or possible recurrence [4, 5].

The first compound on the market was Photofrin<sup>®</sup>, a synthetic haematoporphyrin derivative characterized by a pronounced skin photosensitivity. Second-generation PS have since been designed with less pronounced adverse effects. There are, currently, about ten molecules marketed worldwide. The most potent PS currently under development are hydrophobic molecules with a high tendency to localize in cancer tissue. However, water-insoluble products are difficult to administer to patients, especially when the intravenous route is considered. Therefore several strategies have developed, among which polymeric nanoparticles offer multiple advantages.

This chapter briefly presents the basis of PDT and the most used PS and then reviews the interest in developing nanoparticles (NPs) to improve current PDT, with special interest on polymeric biodegradable NPs. First, the main preparation

methods used to load nanoparticles with PS will be introduced. The major achievements obtained both *in vitro* and *in vivo* with encapsulated PS are then critically appraised, especially with regards to methodologies. The primary outcomes are discussed, highlighting the interest in polymeric nanoparticles as delivery systems for PS. To our knowledge, this is the first published review on the use of polymeric nanoparticles for the delivery of PS in the framework of cancer therapy or detection.

## 2.2

### Concept and Basis of Photodynamic Therapy and Photodetection

Photodynamic therapy, an innovative alternative to conventional therapies, is based on the systemic or topical administration of a photosensitizing drug, also known as a photosensitizer. After biodistribution of the drug, the diseased tissue is illuminated with light at an appropriate wavelength. Light will activate the PS and, in the presence of molecular oxygen, will generate cytotoxic species. In turn, those highly oxidizing species will damage cellular constituents, leading to tumor destruction. Fluorescence PD of cancer is also based on the administration of a PS, and takes advantage of the fluorescence emission of these substances. Cancer diagnosis is of major importance, as early detection of malignancies and metastasis can improve the chance of success for anticancer therapies. In addition, PD is a valuable tool to help guide biopsy and resection to minimize the removal of non-cancerous tissue. Although PS are usually administered systemically, the therapeutic effect of PDT is local rather than systemic. The selectivity of the treatment is not only due to the preferential biodistribution of the PS in cancer tissues but also to the precise activation of the drug by a light beam, usually from a laser source directed to the target tissue.

#### 2.2.1

##### Mechanisms of Photodynamic Therapy and Photodiagnosis

The phototoxic effects on which PDT is based and the fluorescence used for PD are both initiated by the absorption of light by a PS, leading to its excitation from the ground state to the singlet state (Fig. 2.1). The singlet state lifetime, which is on the nanosecond time scale, is too short to allow significant interaction with surrounding molecules [6]. The singlet state can be deactivated via three pathways. The first, fluorescence, results in the emission of photons of a wavelength longer than the excitation light (Fig. 2.1A), and thus allows fluorescence photodetection. The use of highly sensitive imaging devices in PD permits visualization of diseased tissues over normal tissues due to the preferential accumulation of PS in the former [7]. The singlet state can also be deactivated by the release of heat (Fig. 2.1B) or by undergoing intersystem crossing to generate the triplet state (Fig. 2.1C). Since the lifetime of the triplet state is in the micro- to millisecond range, the transfer energy to surrounding molecules is possible [6]. The triplet state is the

**Fig. 2.1.** Schematic representation of the photophysical and photochemical mechanisms associated with photodiagnosis and photodynamic therapy. After light irradiation, photosensitizer in its ground state ( $^0\text{PS}$ ) is excited to the singlet state ( $^1\text{PS}$ ). This state can be deactivated by (A) emitting fluorescence, (B) releasing heat or (C)

undergoing intersystem crossing, which results in the generation of PS in its triplet state ( $^3\text{PS}$ ). The PS triplet state induces phototoxicity via type I and type II reactions, generating free radical species and singlet oxygen, respectively. These entities are toxic in biological systems, inducing cellular death and vascular occlusion.

key to initiating the photochemical process that induces phototoxicity, and it occurs via two main mechanisms [8, 9]. The type I mechanism involves hydrogen-atom abstraction or electron-transfer between the triplet state and neighboring molecules, generating free radicals. These radicals react with oxygen and generate a mixture of highly reactive oxygen intermediates, such as  $\cdot\text{O}_2^-$ ,  $\text{H}_2\text{O}_2$  and  $\cdot\text{OH}$ , which are highly oxidizing [10, 11]. In the type II mechanism, energy is transferred from the PS in its triplet state to molecular oxygen to form highly reactive singlet oxygen ( $^1\text{O}_2$ ), which is presumed to be the most reactive species in PDT. Reactive intermediate oxygen species, including both radicals and non-radicals, are called reactive oxygen species (ROS). Type I and type II pathways are not mutually exclusive and both ultimately lead to the formation of oxidized products and radical chain reactions, which can trigger cascades of biochemical, immunological, and physiological reactions, finally resulting in the destruction of the irradiated tissue [7, 12–14].

At a cellular level, PDT induces cytotoxic effects through photodamage to subcellular organelles and biomolecules. Various cellular components can react with sin-

glet oxygen, such as amino acid residues (especially cysteine, methionine, tyrosine, histidine and tryptophan), nucleosides (mainly guanine) and unsaturated lipids [12]. PS can localize in lysosomes, mitochondria, plasma membrane, Golgi apparatus and endoplasmic reticulum of tumor cells, as well as in tumor vasculature. Interestingly, most PS do not accumulate in cell nuclei; thus PDT has a low potential for causing DNA damage, mutation and carcinogenesis [15]. Two distinct types of cell death may be induced by PDT. First, PDT can trigger apoptosis, a form of programmed cell death that involves the activity of proteolytic caspases, whose action dismantles the cell and results in cell death. Apoptosis begins internally with condensation and subsequent fragmentation of the cell nucleus while the plasma membrane remains intact. Afterwards, apoptotic cells are ultimately fragmented into multiple membrane-enclosed spherical vesicles, which are scavenged by phagocytes [16, 17]. The second mode of cell death induced by PDT is necrosis, characterized by cytoplasm swelling, destruction of organelles and disruption of plasma membrane, leading to the release of intracellular content and inflammatory factors. The cell type, PS subcellular localization and applied light dose determine the type of cell death. PS with tropism for mitochondria are more likely to induce apoptosis, whereas PS localized in the plasma membrane are expected to cause necrosis [15].

There are three main mechanisms for suppressing malignant tissue when using PDT:

1. Direct cellular damage by necrotic and/or apoptotic mechanisms [16, 17].
2. Alteration of tumor vascularization such as occlusion, stasis and/or increase in vascular permeability, thereby depriving cancer tissue of oxygen and nutrients [18–20].
3. Stimulation of inflammatory and immune responses against the tumor [21–23].

The impact of these pathways in the therapeutic effects of PDT depends on the PS and its formulation, the route of administration, and the time interval between administration and light irradiation.

### 2.2.2

#### **Selective Tumor Uptake of Photosensitizers**

One of the key aspects of PDT is the preferential accumulation of PS into tissues with a high rate of regeneration such as cancer tissue and neovasculature [15, 24, 25]. Although the exact underlying mechanisms that drive this tropism have not been completely elucidated, the abnormal physiology of tumors is the main contributor to the selectivity of PS. The affinity of PS for tumors and their surrounding stroma has been related to some of the unique characteristics of hyperproliferative tissues listed in Table 2.1. Of great importance is the increased vascular permeability of tumors, which facilitates the crossing of PS, or their carriers to the interstitial space. This effect, called the enhanced permeability and retention (EPR) effect, is potentiated by an impaired lymphatic drainage reducing macromolecule clearance

**Tab. 2.1.** Characteristics of tumor tissues.

- 
- Decreased pH of interstitial fluid, due to an increased glycolysis and a decreased supply of oxygen.
  - Increased number of low-density lipoprotein receptors at the cell surface.
  - Abundance of macrophages.
  - Abnormal stromal composition, due to the newly formed collagen.
  - Leaky vasculature.
  - High rate of angiogenesis (neovasculature development).
  - Poor lymphatic drainage.
- 

from the tumors [26]. Indeed, macromolecules can be entrapped and retained in solid tumors at high concentration for an extended period (>100 h) whereas low-molecular weight substances return to circulating blood by diffusion. Consequently, entrapping PS in macromolecular drug carriers, such as nanoparticles, is thought to increase PS concentration within tumors.

The physicochemical characteristics of PS molecules, such as molecular weight, hydrophile–lipophile balance value [1, 27–29], ionic charge [30], and protein binding characteristics, also influence their biodistribution. In a literature review, Boyle and Dolphin have attempted to correlate PS structure with its biodistribution and pharmacokinetics [31]. Evaluation of this relationship was, however, made impossible by the disparity between delivery vehicles, animals and tumor types used in the different studies. The PS hydrophile–lipophile balance value appears to be a key factor that is able to regulate pharmacokinetic profiles. Indeed, hydrophobic PS induce preferential damage to tumor cells, whereas hydrophilic PS mainly cause damage to the tumor vasculature. This selectivity will be determined by the nature of the binding between the PS and plasma proteins. Hydrophobic PS are bound to the lipid moiety of lipoproteins [32–36] whereas hydrophilic PS are bound to albumin and globulins [37]. Hydrophobic PS bound to low-density lipoproteins (LDL) can be endocytosed via LDL receptors [34, 38], which are over-expressed in tumor cells. Thus, they accumulate in the lipophilic compartment of tumor cells, including plasma, mitochondrial, endoplasmic reticulum, nuclear and lysosomal membranes. In this case, photodamage of tumor cells occurs preferentially. Conversely, hydrophilic PS will be preferentially localized within the interstitial space and the vascular stroma of the tumor tissue. Owing to their hydrophilic character, diffusion across the plasma membrane into the cytoplasm is limited. Subsequently, these PS cause extensive impairment of the vascular system, promoting tumor ischemia and hypoxia [15, 39].

Since ROS have a short life-time and act close to their site of generation, the sites of initial cell and tissue damage induced by PDT are closely related to both the lo-

calization of the PS within cells and the site of illumination. As a strategy to improve photosensitizer efficiency regardless of the properties of the PS itself, several pharmaceutical formulations have emerged. Indeed, PS delivery systems influence the pharmacokinetic profiles and tissue distribution of PS [40–45].

### 2.2.3

#### Photosensitizers

A photosensitizer is defined as a chemical entity that, upon absorption of light, induces a chemical or physical alteration of another chemical entity [14]. Photosensitizers used against cancer must be able to absorb light and then to transfer the absorbed energy to molecular oxygen in order to cause biological effects. Several publications have described the characteristics of the ideal PS [7, 12, 14, 46, 47]. Since the triplet state of the PS initiates the photochemical process, a good PS requires a long-lived triplet state with a high quantum yield to allow enough time to interact with neighboring target molecules [8]. Ideally, a PS should absorb photons efficiently in the red part of the spectrum because light with long wavelengths have an increased penetration depth in tissues. High chemical purity, good solubility in pharmaceutical acceptable formulations and low aggregation tendency are also mandatory. PS used for photodetection should be photostable, have a high fluorescence quantum yield with low interference with tissue autofluorescence and induce minimal photodamage. Allison et al. have reviewed the clinically relevant properties of PS intended for PDT of cancer [48]. PS should not induce dark toxicity, which is defined as toxicity in the absence of light. Furthermore, PS should have a preferential biodistribution in the tumor as selectively as possible and be eliminated quickly enough to avoid generalized skin photosensitization and systemic toxicity.

##### 2.2.3.1 Conventional Photosensitizers

Originally, PDT was based on the topical application of dyes such as eosin, methylene blue (MB) and rose bengal with remarkable success [46]. Most compounds able to reach triplet states and to produce ROS have either tricyclic, heterocyclic or porphyrin-like ring structures with conjugated double bonds ( $\pi$ -electron system) [14]. Figure 2.2 shows examples of these structures. PS used in clinics have been classified as first, second and third-generation PS. Haematoporphyrin derivative (HpD) or Photofrin<sup>®</sup>, a first-generation PS, is a very complex mixture of monomers and oligomers. It was the first PS approved by the U.S. Food and Drug Administration (FDA), in 1995. Photofrin<sup>®</sup> has been used widely in clinics to treat esophageal, papillary bladder and endobronchial cancers. It is also indicated for ablation of high-grade dysplasia associated with Barrett's esophagus, which is a precancerous condition, thus reducing the risk of progression to esophageal cancer [49]. However, HpD and its analogues not only have poor tumor selectivity, resulting in long-lasting skin photosensitivity [50, 51], but also lack strong absorption bands in the red region of the spectrum [52]. Furthermore, they are complex mixtures and their synthesis and biological activity are difficult to reproduce [12, 48,

CORE

Porphin

Chlorin

## EXAMPLE

Meso-tetra(p-hydroxyphenyl)  
porphyrin or pTHPPMeta-tetra(m-hydroxyphenyl)  
chlorin or mTHPC

**Fig. 2.2.** Structure of some photosensitizers. Porphins consist of four pyrrole subunits linked together by four methylene bridges. Derivatives of porphin are named porphyrins. Reduction of one of the pyrrole units on the porphin ring leads to a class of porphyrin derivatives called chlorins.

53]. Therefore, considerable effort has been devoted to developing new second-generation photosensitizers, characterized by greater selectivity for tumor tissue, rapid excretion from the body, and improved purity, stability, solubility and photophysical properties. Owing to the high oxygen quantum yield of the porphyrin skeleton, most second-generation PS belong to this family. The porphyrin structure provides 12 positions that can potentially be substituted. Furthermore, the porphyrin cycle can be oxidized, extended and/or a central ion may be introduced to modulate the pharmacological, as well as the photophysical, properties of the molecule [7, 52]. Porphyrins, chlorins, texaphyrins, purpurins and phthalocyanines have been most actively investigated [24, 47].

Recently, considerable interest in the use of 5-aminolevulinic acid (5-ALA) in PDT has risen. 5-ALA itself is not a photosensitizer, but it can induce the formation of protoporphyrin IX (PpIX), a potent PS. 5-ALA is a substrate in the biosynthetic pathway of heme, the iron(II) complex of PpIX. In contrast to heme, PpIX is

a fluorescent molecule and a potent PS. When 5-ALA is administered, its biosynthesis leads to the selective transient accumulation of PpIX in neoplastic cells [7, 54]. If tissues containing the 5-ALA-induced PpIX are irradiated, photochemical processes are triggered, resulting in tissue destruction. Although the underlying mechanisms of the preferential accumulation of 5-ALA-induced PpIX in tumors and other proliferating tissues are not fully understood, the 5-ALA approach is one of the most selective modalities currently available in anticancer therapy. Collaud et al. have recently reviewed the mechanisms of the selective formation of PpIX in neoplastic tissue after 5-ALA administration [55]. Topical administration (e.g., skin and bladder) of 5-ALA and 5-ALA ester derivatives induced no skin photosensitivity and had short half-life in the treated area [56–59]. 5-ALA and its derivatives can also be used for photodiagnosis [60–62], because PpIX emits red fluorescence upon irradiation with blue light.

Recently, the third generation of PS has emerged. These are second-generation photosensitizers with fine tuned properties that allow selective delivery to tumor tissue. Different strategies have been proposed, such as conjugation to biomolecules like monoclonal antibodies [63].

Although the clinical potential of PDT has been recognized for over 25 years, it is only now starting to be used clinically [24]. Table 2.2 summarizes clinically relevant PS for PDT and the PD of cancer. There are few PS intended for PD, only 5-ALA-hexyl ester has been recently approved for detection of bladder cancer in Europe and has been submitted to the FDA ([www.photocure.com](http://www.photocure.com)). Local administration of hypericin has also shown promising results for the PD of bladder carcinoma [64]. Other PS evaluated for PD such as haematoporphyrin derivative and meta-tetra(hydroxyphenyl)chlorin induced prolonged skin and eye photosensitivity [50, 51, 65, 66] and are not yet approved for photodiagnosis.

### 2.2.3.2 New Entities

New systems such as semiconductors, fullerenes and transition metal complexes are promising photosensitizers, as shown by several studies measuring singlet oxygen production and *in vitro* phototoxicity against tumor cells. However, since little is known about their biocompatibility, their use in clinical PDT of cancer is still unexplored.

Semiconductors, such as titanium dioxide ( $\text{TiO}_2$ ), can sensitize the photogeneration of ROS, thus inducing damage similar to that found in traditional PDT [67]. Particles of  $\text{TiO}_2$  have shown phototoxicity against HeLa cells *in vitro* and were not toxic when administered orally or parenterally to nude mice. After UV irradiation,  $\text{TiO}_2$  particles significantly suppressed the growth of HeLa [68] and T-24 cells [69] implanted in nude mice. However, this approach is limited because UV light, used to irradiate  $\text{TiO}_2$  particles, does not penetrate deep in the skin [70].

When the size of a semiconductor particle is decreased to the nanometric scale, these materials are called quantum dots (QDs). QDs are single crystals of semiconductor material, a few nanometers in diameter. Their size and shape can be controlled precisely [71]. A quantum dot can have anything from a single electron to a collection of several thousands. Therefore, light absorption of QDs can be precisely

Tab. 2.2. Relevant photosensitizers under clinical trials or approved for PDT and PD of cancer [5, 15, 24, 48, 163, 164].

Photosensitizer/ Generic name	Commercial name	Formulation/ Administration	Approved oncological indications	Clinical trials for different types of cancer	Drug-light interval <sup>[a]</sup>	Skin photosensitivity <sup>[b]</sup>
Haematoporphyrin derivative (HpD)/ Porfimer sodium	Photofrin <sup>®</sup>	Powder for solution/ i.v. or topical	Esophageal adenocarcinoma and high-grade dysplasia in Barrett's esophagus. Cervical, superficial gastric, bronchial, bladder, and advanced and early lung cancer	Intraperitoneal, hilar bile-duct, head and neck, intestinal, lung, larynx, skin, bladder and metastatic breast	40–50 h	1–3 months
Meta- tetra(hydroxyphenyl) chlorin (mTHPC)/ Temoporfin	Foscan <sup>®</sup>	Solution in ethanol and propylene glycol/i.v.	Palliative advanced head and neck cancer. Squamous cell carcinoma	Brain, gastric, prostate and oral cavity, Mesothelioma	24–96 h	Up to 6 weeks
5-Aminolevulinic acid (5-ALA) <sup>[c]</sup>	Levulan <sup>®</sup>	Powder for solution/ Topical. Oral and i.v. have been also evaluated	Actinic keratosis	Basal-cell carcinoma, esophageal, gastrointestinal and non-melanoma skin	2 h	1–2 days
5-ALA-methyl ester <sup>[c]</sup>	Metvix <sup>®</sup>	Cream/Topical	Actinic keratosis, superficial basal-cell carcinoma and basal cell-carcinoma. Bowen's disease		3 h	Uncommon

5-ALA-hexyl ester <sup>c</sup>	Hexix <sup>®</sup>	Powder for solution/ Intravesical injection	Bladder cancer diagnosis. Surgeons can easily define bladder lesions and ablate them	1–2 h	Uncommon
Benzoporphyrin- derivative monoacid ring A (BPD-MA)/ Verteporfin	Visudyne <sup>®</sup>	Liposomes/i.v.	None. It is approved for choroidal neovascularization associated to age-related macular degeneration (CNV-AMD), a non- malignant disease	30–150 min	3–5 days
Tin-ethyl etiopurpurin (SnET2)	Purlytin <sup>™</sup>	Lipid emulsion		24 h	2–3 weeks
Lutetium texaphyrin/Lutex	Lutrin <sup>™</sup>	Powder for solution			1–2 days

<sup>a</sup> Interval between drug administration and light irradiation.

<sup>b</sup> Skin photosensitivity reactions include erythema, edema, blistering, hyperpigmentation and sunburn. Ultraviolet sunscreens provide no protection. Patients must avoid exposure of eyes and skin to direct sunlight and wear protective clothing and dark sunglasses when outdoors.

<sup>c</sup> Prodrug of protoporphyrin IX.

tuned from the UV to the infrared (IR) region of the spectrum by changing their size and composition. At the same time, QDs have narrow emission spectra that can be tuned to emit in the near-IR region, in contrast to the visible emission of most conventional PS [72–74]. QDs are highly resistant to degradation and their fluorescence is remarkably stable. Most work on semiconductor QDs has focused on fluorescence imaging and diagnosis applications [71, 74–76]. However, they are seen as suitable candidates for PDT because of their capacity to generate ROS after light irradiation [72, 73, 77]. Interestingly, QDs can enhance the effect of conventional photosensitizers if light-mediated energy transfer between both molecules is possible. Consequently, in addition to their intrinsic efficacy as photosensitizers, QDs have been used to potentiate conventional PS. Semiconductor QDs of cadmium selenide (CdSe) conjugated to anti-CD90 antibodies potentiate the activity of the PS trifluoperazine against leukemia cells [77]. Moreover, CdSe QDs linked to silicon phthalocyanine have enabled the use of an excitation wavelength where the PS alone does not absorb [72]. Unwanted potential toxicity of QDs is a key issue inhibiting their development as a therapeutic tool. Since the primary site of acute injury within the body after exposure to Cd is the liver, the cytotoxicity of CdSe QDs was investigated *in vitro* on primary hepatocytes isolated from rats [78]. QDs were cytotoxic due to the slow release of Cd. Surface oxidation of QDs after air and UV light exposure leads to the formation of reduced Cd on the QDs surfaces. Surface coating of QDs with either zinc sulfide or bovine serum albumin decreased the oxidation and consequently the cytotoxicity of the nanoparticles [78]. However, even when QDs are coated, there is still the risk of Cd release into the body after *in vivo* oxidation of these particles.

Before considering the use of QDs in clinics, some concerns regarding the propensity of QDs to aggregate, their toxicity profile and potential to release heavy metals should be addressed.

Fullerenes are a class of spherically-shaped molecules made exclusively of carbon atoms. Fullerene C<sub>60</sub> and C<sub>70</sub> efficiently generate singlet oxygen when irradiated with light. However, fullerenes are practically insoluble in both aqueous and most polar media – not to mention their poor absorption in the red region of the visible spectrum [79, 80]. These properties hamper the development of fullerene-based agents for PDT. Furthermore, the mechanism of action of photoexcited fullerenes in biological systems is not at all understood [81]. Nevertheless, intense research has been devoted to evaluate the potential applications of fullerenes in medicine and biology [79, 80].

Some inorganic complexes are also efficient photosensitizers, among them transition metal complexes of ruthenium(II), osmium(II), iridium(III), chromium(III), platinum(II) and palladium(II) have been investigated [46].

As described above, the selectivity of PDT can be increased using a PS that preferentially accumulates in cancer tissues. The affinity of PS for neoplastic cells is in part governed by the lipoprotein transport of PS and subsequent cellular uptake of these protein-PS complexes [34, 38]. However, little is known about the interaction of semiconductors, fullerenes and transition metal complexes with serum proteins. Besides the ability of such PS to photogenerate singlet oxygen, their toxicity, bio-

distribution and selectivity towards cancer tissues should be addressed before clinical application.

#### 2.2.4

#### **Photodynamic Therapy: Advantages and Limitations**

PDT is effective, minimally invasive and offers several advantages over other cancer therapies, such as surgery, radiation therapy and chemotherapy. Generation of cytotoxic species after PDT is only due to the combination of PS, light and oxygen; therefore, great selectivity towards diseased tissues is achieved. Indeed, singlet oxygen has a short lifetime in the biological environment ( $<40$  ns) [82] and cannot diffuse far from its point of origin (radius of action  $\leq 70$  nm) [83]. Differences in PS clearance between tissues enable optimization of the interval between PS administration and light irradiation, which should be performed when the drug has reached the maximum concentration in the tumor. Additionally, the ability of cells to recover from photodynamic damage also contributes to the selectivity of PDT. Indeed, healthy tissues are able to recover better than tumor tissues after PDT. For example, in the treatment of skin cancers, even if healthy tissue is damaged during PDT, the cosmetic results are usually excellent with little or no scarring, as has been demonstrated with topically applied 5-ALA [59] and intravenously administered verteporfin (benzoporphyrin derivative monoacid ring A) [84]. Additionally, PDT is a photochemical process without tissue heating, thus connective tissues such as collagen and elastin stay largely unaffected [53]. PDT can be repeated if necessary, and performed after surgery, chemotherapy or radiotherapy. Last but not least, PDT can be used to treat different types of cancers, including tumor resistant to other treatments [85].

Even though PS are expected to be retained preferentially by neoplastic tissues and their activity is triggered by light activation at a specific wavelength, the drug is still distributed throughout the whole body [53]. Therefore, PS administration can induce side effects in tissues exposed to daylight such as skin and eyes. Skin photosensitivity reactions are characterized by erythema, edema, blistering, hyperpigmentation and sunburn. Some precautions are strongly recommended during the period in which the PDT patient remains photosensitive. Physical barriers, particularly protective clothing and sun glasses, provide some protection against UV and visible light, but by far the optimum safety for these patients is complete sun avoidance. The period during which these safety measures have to be applied depends specifically on the nature of the photosensitizer [86]. Depending on the molecule, it ranges from a few days to up to three months. PDT can induce also occasional systemic and metabolic disturbances, and excessive tissue destruction at the treated site [12]. Adverse effects of PDT depend mainly on the nature of the PS, the route of administration and the type and localization of the malignancy. Table 2.3 summarizes the main adverse effects induced by PS used in PDT and PD of cancer. Intravenously administered PS, such as temoporfin (Foscan<sup>®</sup>) and HpD (Photofrin<sup>®</sup>), induce prolonged skin and eye photosensitivity [50, 51, 65, 66]. Conversely, 5-ALA (Levulan<sup>®</sup>) and 5-ALA-hexyl ester (Hexvix<sup>®</sup>), which are topically ap-

plied on either skin or bladder, induce no skin photosensitivity and have a short residence time at the application site [56–59].

The therapeutic outcome of PDT is limited by the penetration of light in tissues. Light is either scattered or absorbed when it enters tissues and the extent of both processes depends on the tissue type and the light wavelength. Between 600 and 1000 nm, however, light is scattered to a relatively small extent and is poorly absorbed by important endogenous chromophores such as melanin and hemoglobin [87]. As a consequence, red light possesses a high penetration power into human tissues. Ochsner has compared the penetration of light as a function of the wavelength. At an equal incident light intensity, the penetration depth in human skin is of 6.8 mm at 800 nm, whereas it is only 0.4 mm at 400 nm [88]. The deeper penetration of longer wavelengths is a major incentive for the development of PS absorbing at these wavelengths. Additionally, to improve the outcome of PDT, new light delivery devices have been developed for this particular application. The traditional argon-dye and copper-dye lasers can be replaced by diode lasers, which are cheaper, very stable, reliable and easily transportable [89]. However, they are not tunable and may only be used at fixed wavelengths [90]. Optical fibers can be used to deliver light to the target tissue. They facilitate the illumination in various directions using either cylindrical or spherical diffusers. Furthermore, the versatility of optical fibers enables illumination of the skin or inside a body cavity [91]. PDT is usually performed with external illumination of the target site; however, deeply localized tumors should be treated with special light delivery devices that are inserted percutaneously. This technique, namely interstitial PDT, uses multiple laser fibers that are inserted directly into tumors through needles positioned under image guidance. Therefore, it is possible to use PDT for the treatment of internal tumors [92, 93].

The dependence of PDT on the oxygenation of the irradiated tissue represents a limitation of this treatment. Indeed, the efficacy of PDT depends on the amount of singlet oxygen produced within the tumor, which in turn depends on the concentration of oxygen in the tissue [94, 95]. Consequently, hypoxic tumor cells are generally more resistant to PDT, and may contribute to treatment failures.

Finally, most PS are hydrophobic, which is a key factor contributing to their selectivity for cancer tissues. However, PS lipophilicity makes formulation difficult due to the lack of physiologically acceptable solvents, especially when intravenous administration is considered. Furthermore, hydrophobic PS can aggregate in aqueous media, leading to quenching; thus in their aggregated form PS are less efficient than in their monomeric form [96–98]. Additionally, some PS lack selectivity for accumulating in cancerous tissues. Therefore, the design of adequate PS delivery systems is critical to improving the outcome and acceptability of PDT and PD in a clinical context.

### 2.2.5

#### **Photosensitizer Formulations**

Different formulation approaches have been proposed, such as the incorporation of PS into liposomes, micelles, polymeric particles, and LDL, as well as the develop-

ment of hydrophilic polymer–drug complexes, as reviewed by Konan et al. [99]. The delivery carrier can influence the PS biodistribution and hence the mechanisms and kinetics of PS transport to tissues, as well as PS subcellular distribution [15]. Among the different approaches, nanoparticles (NPs) offer numerous advantages, including high drug loading, controlled release, and a large variety of carrier materials and manufacturing processes. Nanoparticles are defined as particles in the nanometer scale, typically  $<1 \mu\text{m}$ . NPs appear to be suitable delivery systems for PS because encapsulation of PS into NPs would make it possible to disperse hydrophobic PS in aqueous media. Moreover, NPs have large surface areas, and their surface can be modified with functional groups to modulate their biochemical and physicochemical properties. Owing to their size, direct targeting of tumor tissues is also possible by taking advantage of the tumor vasculature enhanced permeability [100, 101]. Biodegradable and non-biodegradable materials can be used to produce NPs. The use of biodegradable materials enables the controlled release of the encapsulated drug. Conversely, non-biodegradable materials offer the advantage of enhancing the direct interaction of PS with molecular oxygen, either within the nanoparticles or at their surface. The use of non-biodegradable NPs made of metals, ceramics and non-biodegradable polymers are discussed in the next section. The final section is devoted to biodegradable polymeric NPs used for photodynamic activity. The biodegradability and biocompatibility of polymeric NPs bring them closer to clinical application than non-biodegradable carriers.

## 2.3

### Non-biodegradable Nanoparticles for Photodynamic Therapy

#### 2.3.1

##### Metallic Nanoparticles

This approach involves the coating of metallic nanoparticles, mainly made of gold or magnetic materials, with photosensitizers. The design of PS-coated metallic NPs for PDT has been primarily developed in two directions. First, the adhesion of hydrophobic PS to gold NPs enables an aqueous PS suspension, where the PS photophysical properties are enhanced. This concept has been demonstrated with phthalocyanine derivative-coated NPs that were able to generate singlet oxygen with higher quantum yield than the free PS [102]. In the second approach, the development of magnetic nanoparticles coated with PS allowed either the targeting of the pathological tissue by directing the NPs by an external magnetic field or cancer diagnosis by using the NPs as magnetic resonance (MR) contrast agents. For instance, magnetic NPs made of  $\text{Fe}_3\text{O}_4$  have been coated with haematoporphyrin [103]. Likewise, pheophorbide-a has been complexed to  $\text{Fe}_3\text{O}_4$  NPs and the spectroscopic and photophysical properties of this complex characterized [104]. The authors hypothesized that these NPs might be used to combine the action of hyperthermia therapy (HT) and PDT synergistically. Similarly, Gu et al. have conjugated porphyrin to  $\text{Fe}_3\text{O}_4$  NPs for the same combination of anticancer therapies [105]. The conjugation of porphyrin to the NPs induced a blue-shift in the fluorescence

emission spectrum of the PS. No dark toxicity on HeLa cells was seen 5 h after incubation with NPs at 37 °C. Fluorescence microscopy observations showed that NPs were taken up and localized intracellularly. Irradiation of HeLa cells, incubated with the PS-conjugated NPs for 10 min, induced changes in cell morphology. Although the authors interpreted this data as a qualitative sign of phototoxicity, further experiments should be performed to assess the potential of such NPs.

So far, the efficacy of metallic nanoparticles in photodynamic experiments with cancer animal models has not been yet evaluated, although the biocompatibility of metallic nanoparticles has been tested. Neither gold nor magnetic nanoparticles made of iron oxides were toxic *in vivo*. Indeed, 2-nm-gold NPs were administered intravenously to Balb/C mice (2.7 g-Au kg<sup>-1</sup>) and no lethality was observed [106]. It was also shown that gold NPs were largely cleared from the body through the kidneys. Furthermore, blood analysis two weeks after injection from mice treated with 0.8 g-Au kg<sup>-1</sup> demonstrated no signs of toxicity as far as haematocrits and plasmatic enzymes are concerned. Similarly, iron oxides particles seem to be generally well tolerated [107, 108] and are intended for several medical applications, as recently reviewed by Ito et al. [109]. The safety of colloidal dispersions of magnetic nanoparticles made of iron oxides has been also demonstrated [110, 111]. In fact, magnetic resonance agents, such as Feridex I.V.<sup>TM</sup> (Advanced Magnetic, Cambridge, MA, USA) and Resovist<sup>®</sup> (Schering, AG, Germany), have already been approved for the detection of focal hepatic lesions by MR imaging.

### 2.3.2

#### Ceramic Nanoparticles

Ceramic NPs made of silica have been developed as an alternative to polymeric NPs. Ceramic NPs are resistant to microbial attack [112] and their particle size, shape, and porosity can be easily controlled during the preparation process [113]. Ceramic NPs do not release encapsulated compounds even at extreme pH conditions and temperature [114]. This feature represents a limitation for the delivery of common drugs, but can be suitably used in PDT. Since ceramic matrices are generally porous, molecular oxygen can diffuse through the pores and interact with the PS entrapped within the NPs [115]. The photogenerated singlet oxygen can diffuse out of the particle to generate the cytotoxic effect. This approach has been evaluated by entrapping 2-devinyl-2-(1-hexyloxyethyl) pyropheophorbide (HPPH) into 30 nm silica NPs; unfortunately, the percentage of PS loaded into the NPs was not reported. *In vitro* studies with HeLa and UCI-107 cells demonstrated that HPPH-loaded silica NPs were taken up by tumor cells and induced significant cell death, similarly to Tween-80 micelles, which were used as a control [113]. *m*-tetra(Hydroxyphenyl)chlorin (mTHPC) has been embedded in amine-functionalized silica NPs of 180 nm to deliver singlet oxygen instead of releasing PS molecules [116]. The results showed that singlet oxygen production from mTHPC embedded in silica NPs exceeds that of free mTHPC. However, the tests were run in a mixture of water and ethanol in which mTHPC is soluble. Thus, it is possible that mTHPC could be released from the core of the NPs during oxygen

sensitization. As a result, more molecules of mTHPC would be soluble and the amount of singlet oxygen would be higher than if mTHPC would have been a solid dispersion inside the NP core. Ideally, singlet oxygen production should be evaluated in aqueous media simulating biological environments. These experiments are far from physiological conditions and may not reflect what would be observed in the cellular environment. Methylene blue, a water-soluble PS of low molecular weight, was encapsulated into three types of sub-200 nm NPs, achieving different MB loadings: polyacrylamide (20–30 nm; loading 0.1%), sol–gel silica (190 nm; loading 3.0%) and organically modified silicate (160 nm; loading 0.4%) [117]. Polyacrylamide NPs were, *in vitro*, the most efficient delivery of singlet oxygen per MB molecule. Moreover, these particles gave the most stable aqueous suspension and therefore were used for *in vitro* photodynamic experiments on rat C6 glioma tumor cells. MB-loaded polyacrylamide NPs were more active than free MB. Notably, concerning silica NPs, the potential toxicity of ceramic nanoparticles is controversial. Toxicological data from studies investigating silica NPs as DNA delivery systems suggest that these carriers have little toxicity [118]. Likewise, organically modified silica NPs have been used for *in vivo* gene delivery in mice and no toxicity was reported up to four weeks after transfection [119]. Conversely, Chen and von Mikecz showed that the uptake of silica NPs (40–70 nm) by the cell nucleus of HEp-2 and RPMI 2650 cells induced nuclear damages close to those seen in neurodegenerative disorders [120]. The nuclear architecture was altered, probably as a result of the formation of nucleoplasmic protein aggregates. Furthermore, silica NPs (4–40 nm) induced inflammatory reactions in cultured human endothelial cells, as shown by the overexpression of interleukin-8 [121].

### 2.3.3

#### **Nanoparticles Made of Non-biodegradable Polymers**

Polyacrylamide (PAA) and amine-functionalized PAA have been used to encapsulate the disulfonated PS 4,7-diphenyl-1,10-phenanthroline ruthenium into nanoparticles of 40–50 nm [122]. Incorporation of the PS into the polyacrylamide matrix did not affect the singlet oxygen production, allowing it to be released into the aqueous media in which the NPs were suspended. PS delivery from amine-functionalized PAA was slower than from PAA NPs. Furthermore, less singlet oxygen was produced than with both free PS and PAA nanoparticles [122]. Recently, the same group developed polyacrylamide NPs to perform simultaneously magnetic resonance imaging and PDT of a rat brain cancer model, providing a real-time tumor death measurement [123]. In this approach, Photofrin<sup>®</sup> and a magnetic resonance contrast agent were encapsulated together within a polyacrylamide core, resulting in 30–60 nm NPs. The NPs were surface-coated with poly(ethylene glycol) (PEG) to increase the plasma half-life of the carrier. Singlet oxygen production and *in vitro* photoactivity against 9L rat gliosarcoma cells were evaluated. Although the PS was not released from the NPs, as demonstrated by *in vitro* degradation studies in phosphate buffer at 37 °C, the photoactivity of the encapsulated PS was retained. The photoactivity and magnetic resonance contrast ability of this formulation have

been evaluated after intravenous administration in intracerebral 9L tumor bearing rats, but the dose of Photofrin<sup>®</sup> is not mentioned. The activity of the free compound was not tested; however, rats receiving no treatment and treated only with laser were used as controls. The evolution of tumor volume was followed by magnetic resonance imaging. Photofrin<sup>®</sup>-loaded NPs induced tumor shrinkage, whereas tumors not treated or treated only with laser continued to grow. However, tumor re-growth was observed 12 days post-PDT treatment with Photofrin<sup>®</sup>-loaded NPs. Polyacrylamide NPs showed no toxicity, in terms of alterations in histopathology or clinical chemistry values, after administration of doses up to 500 mg of NPs per kg over four weeks. The authors suggest that these NPs, namely a multifunctional nanoparticle platform, might enable simultaneous cancer detection, therapy and monitoring. Additionally, particles coated with an integrin ligand for the recognition of the tumor neovasculature were prepared. The specific binding of these NPs was demonstrated *in vitro* with MDA 435 cells expressing integrins. The authors hypothesized that these multifunctional nanoparticles stay in the extracellular compartment and do not release the PS; only singlet oxygen would be delivered after light irradiation [123]. However, the intracellular localization of these NPs after *in vivo* administration should be further studied to confirm the advantages of such a system.

Most research on non-biodegradable materials for the administration of PS has focused on the development of carriers delivering singlet oxygen without releasing the PS. Additionally, non-biodegradable NPs are thought to protect the entrapped PS from the biological environment. The internalization of such NPs into target cells is thought to be unnecessary. In this context, only the external contact of NPs with the cell membrane is required. However, none of these systems have undoubtedly demonstrated the absence of internalization of such NPs. Despite the promising results encountered with these materials, their use in PS delivery has not yet been fully explored, probably due to toxicity concerns in the administration of non-biodegradable materials, particularly if chronic or repeated administrations are needed. Degradation is desired to prevent accumulation of extraneous material and possible subsequent toxicity. Indeed, recent histopathological studies of human biopsies indicate that the development of kidney and liver pathologies, such as chronic inflammation and granulomas, was associated with the presence of non-biodegradable micro- and nanoparticles in these organs [124]. These particles probably originated from debris of implants and prostheses. Certainly, studies of the long-term toxicity non-biodegradable nanoparticles should be undertaken before clinical investigations can be launched.

## 2.4

### Biodegradable Polymeric Nanoparticles for Photodynamic Therapy

Polymeric nanoparticles, as drug delivery systems, have been investigated for over three decades. Several polymers and preparation methods have been developed and the choice of both depends on the physicochemical nature of the drug, as well as

**Fig. 2.3.** Different types of drug-loaded nanoparticles: drugs may be either adsorbed at the surface of the polymer (●) or encapsulated within the particle (○).

on the type of controlled release kinetic being sought, and the desired target site. Polymeric nanoparticles used for drug delivery are defined as submicron (<1000 nm) colloidal systems made of solid polymers that may be classified according to their preparation processes and internal structure (Fig. 2.3). Nanocapsules (NCs) are composed of a polymeric wall containing a liquid inner core, while nanospheres (NS) are made of a polymeric matrix in which the drug can be dispersed. Active substances may be either adsorbed at the surface of the polymer or encapsulated in the particle. After administration, the drug is released by diffusion from the particles to the surrounding medium or after particle erosion resulting from polymer degradation. Ester or amide functions can be hydrolyzed, and the rate of this process depends on the nature of the polymer (chemical composition and molecular weight), and is triggered by water or the presence of enzymes.

#### 2.4.1

##### **Preparation of Biodegradable Polymeric Nanoparticles**

Particles may be produced by polymerization of synthetic monomers, or dispersion of synthetic polymers or natural macromolecules. The preparation methods have been extensively reviewed in the literature [125–127] and will be described only briefly here.

Nanoencapsulation of PS has been considered primarily for hydrophobic molecules that are difficult to formulate in aqueous media, which are mostly used for parenteral administration. The development of a solid suspension offers an interesting alternative. Owing to their hydrophobicity, organosoluble polymers have been mainly used as encapsulating material.

##### **2.4.1.1 *In situ* Polymerization**

*In situ* polymerization of monomers has been used mainly with poly(alkyl cyanoacrylates) (PACA) to prepare either nanoparticles or nanocapsules. The different

methods of preparation as well as medical application of these polymers have been reviewed recently [128].

The preparation of nanoparticles is based on an emulsion-polymerization process in which the cyanoacrylic monomer is dissolved in an organic solvent and dispersed in an aqueous phase containing a surfactant. Anionic polymerization is then induced by hydroxide ions present in water. The polymerization rate is mainly determined by the surrounding pH or the presence of inhibitors. PS can be encapsulated directly during the reaction [129, 130] or adsorbed on the particle surface by incubation with the nanoparticles after neutralization of the aqueous medium [131, 132]. For PACA, the major degradation pathway is based on enzymatic hydrolysis, the rate of degradation being governed by the length of the side chain.

Nanocapsules are usually prepared by interfacial polymerization, where an organic phase containing the monomer and the PS is emulsified in an aqueous phase [129, 130]. Concomitantly, solvent diffusion and anionic polymerization will occur, creating a polymeric wall around the oil core. These particles are especially well adapted for the encapsulation of lipophilic material.

One of the critical concerns with these techniques is the purification step to remove all the residual monomers and the surfactant which may induce undesirable effects.

#### 2.4.1.2 Dispersion of a Preformed Polymer

To reduce toxicity related to the presence of monomer residues or traces of polymerization initiators, preparation methods based on the use of preformed polymers have been developed. These are based on the formation of an emulsion in which the polymer is solubilized in an organic solvent immiscible with the external phase. Polymer precipitation is initiated by the removal of the organic solvent. Another approach, called nanoprecipitation, is based on direct precipitation of the solubilized polymer when in contact with a non-solvent. However, to our knowledge, this method has not been yet reported in the literature for PS.

Polymers used for nanoparticle preparation may be of natural origin. For instance, Zhao et al. have used gelatine to encapsulate hypocrellin B [133]. Particles were made by a modified salting-out coagulation process. An organic solution of the photosensitizer is added to an aqueous solution of the polymer and a surfactant. After nanoparticle formation, glutaraldehyde, a crosslinking agent, is added to the NP suspension. The suspension is then dialyzed to eliminate the glutaraldehyde. However, for hydrophobic photosensitizers, using water-soluble polymers might not be the best choice for their encapsulation. Indeed, no encapsulation rate was reported; therefore, it is not possible to assess how much drug was actually entrapped in the particles. The fluorescence quantum yields decreased as compared to the free drug, but this may also be the result of quenching due to the high number of molecules in the particles. Furthermore, the use of gelatine is warranted due to the potential allergenic reactions induced by this protein; thus, biocompatibility may be a concern at least with certain patients prone to allergies.

To promote entrapment of hydrophobic compounds into polymeric particles, synthetic hydrophobic polymers are frequently used. Polyesters such as poly(lactic

acid) (PLA) and copolymers such as poly(lactic-co-glycolic acid) (PLGA) are widely used due to their good biocompatibility and because they are accepted by the authorities (FDA) as suture threads. Several methods have been described for PLA and PLGA particle preparation. They are based on the formation of an emulsion of an organic solvent containing the polymer (and the drug) solubilized in an aqueous phase containing a surfactant. The solvent is then removed to induce polymer precipitation and particle formation. The size of the particles is governed by the size of the emulsion and the rate of solvent removal. Several methods have been developed to eliminate the solvent, including evaporation, diffusion [134–138] and dilution after salting-out [138–141]. These methods allow high encapsulation rates since usually more than 80% of the compound is entrapped in the polymeric matrix.

Encapsulation of sensitizers has also been reported in PLA nanocapsules [142, 143]; they were obtained by a solvent-displacement process. The polymer was dissolved in acetone while the hydrophobic photosensitizer was dissolved in Miglyol® (caprylic/capric diglyceryl myristate) and added to the polymer solution. The organic solution was then poured into a water solution containing surfactants. Solvent removal leads to precipitation of the polymer around the oil core containing the active compound.

The emulsion-diffusion method has also been used to prepare particles from a complex made of poly(sebacic anhydride) and phthalocyanine, where the drug was conjugated with the polymer before particle formation [144]. Different complexes were made with various amounts of phthalocyanine, and were characterized by UV/visible spectra. Depending on the degree of aggregation of the photosensitizer in the copolymers, different spectra were found.

Complexation of a photosensitizer and a polymer has been further studied by associating poly( $\epsilon$ -caprolactone) and silicon phthalocyanine [145]. Particles 30–90 nm in diameter were prepared by an emulsion-diffusion process.

#### 2.4.1.3 “Stealth” Particles

When administered *in vivo*, polymeric nanoparticles are rapidly taken up by the reticuloendothelial system (RES) due to the adsorption of proteins at their surface [146–148]. Thus, the biodistribution of particles is mainly directed towards liver and spleen where they are sequestered and made unavailable to other target tissues. This propensity to localize in RES has been related to the hydrophobicity of the particle surface. Therefore, “stealth” particles have been designed to limit this drawback. The principle is based on “hydrophilization” of the surface. The first approach reported was the coating of the particles with polymers such as poloxamer [130, 142] or PEG [139, 142]. Another approach is to use a directly modified polymer such PLA-PEG [142, 143] or PLGA-PEG.

#### 2.4.1.4 Targeted Nanoparticles

Even though biodistribution of PS is characterized by a preferential accumulation into target tissues such as cancer cells and neovasculature, their distribution in normal tissues induces adverse side effects. Therefore, a more specific distribution

may be sought by using active targeting. One way to increase the biodistribution of colloidal carriers to the target site is to covalently bind a recognition molecule to their surface that will drive the carrier to the target site. This approach was used by Kopelman et al. with non-biodegradable particles [123], but to our knowledge it has not yet been developed with PS-loaded biodegradable nanoparticles. Several methods are available to covalently bind ligands to the surface of colloidal systems [149] and numerous recognition molecules are available to target either cancer cells or neovasculature surrounding tumor sites. This aspect of active targeting strategies will be further developed in chapter 10.

#### 2.4.2

#### ***In Vitro* Relevance of Polymeric Nanoparticles in PDT on Cell Models**

*In vitro* studies with cultured cells are usually an easy way to evaluate the efficacy of new drug delivery systems. Two main issues are evaluated with *in vitro* studies: either the activity of the drug-loaded carriers on cancer cells or the cellular uptake and trafficking of the photosensitizers encapsulated into nanoparticles.

##### 2.4.2.1 Photodynamic Activity of PS-loaded Nanoparticles

First, the potential activity of encapsulated photosensitizers has to be verified on the targeted cancer cells. For this purpose, several *in vitro* models are used, corresponding to different cancer cell lines, but the principle is generally similar. The activity of PS formulations is evaluated by measuring the inhibition of cell growth. Cells are incubated with either the free drug or the drug-loaded carriers, PDT is applied to the cells by illumination at the right wavelength, and the damage, namely cell death, is evaluated by a simple viability test, such as the colorimetric 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay (Fig. 2.4).

Nanoencapsulation does not affect the activity of photosensitizers. Indeed, the phototoxicity of loaded nanoparticles, when compared to free drug under the same experimental conditions, was similar or even better.

The effect of mTHPC in different formulations: in solution, PLA NCs, poloxamer-coated NCs, PEG-grafted PLA (PLA-PEG) NCs, and oil/water nanoemulsion (NE) has been compared by Bourdon et al. [142]. HT29 human adenocarcinoma cells were treated with increasing concentrations of PS (0.125 to 1.25  $\mu\text{g mL}^{-1}$ ). A long incubation time (300 min) and high light dose (25  $\text{J cm}^{-2}$ ) were used, as fluences of 5 or 10  $\text{J cm}^{-2}$  seemed to be inefficient. Phototoxicity increased when PS concentrations increased, regardless of formulation. In their experimental setting, all formulations showed similar photoactivity, except PLA-PEG NCs, which yielded a lower phototoxicity.

The activity of loaded nanocarriers was demonstrated with mTHPC on HT29 tumor cells, but the same concentration-dependent profile was obtained for other nanocarriers or photosensitizers such as meso-tetra(*p*-hydroxyphenyl)porphyrin (pTHPP) used by Konan et al. [136]. In this case, the influence of drug concentration on cellular toxicity with pTHPP-loaded nanoparticles (PLA or PLGA) was compared to free pTHPP. For this purpose, EMT-6 mammary tumor cells were used

**Fig. 2.4.** Schematic representation of *in vitro* efficacy assay on cell culture. Cells are incubated with NPs; after washing, the plate is irradiated with light at the right wavelength.

The light dose depends on the power of the light and time of exposure. Photodamage is assessed by cell viability assay after incubation in fresh medium.

under the following conditions: 1 h of incubation with increasing concentrations of PS (3 to 10  $\mu\text{g mL}^{-1}$ ) and a light exposure of 6  $\text{J cm}^{-2}$ . For all delivery systems tested, the phototoxicity increased with PS concentration. The most important difference between formulations was observed at 3  $\mu\text{g mL}^{-1}$ , where loaded NPs exhibited a two-fold higher activity than free pTHPP. In contrast, at 6  $\mu\text{g mL}^{-1}$  all formulations reached a plateau of cell death (90% dead cells). Thus, encapsulation of a photosensitizer is an advantage, as the same photodynamic effect could be obtained with a lower concentration, thereby minimizing possible side effects.

Before analyzing the phototoxicity of photosensitizers, the following controls have to be performed: dark toxicity of photosensitizers, effect of irradiation on untreated cells and finally toxicity of unloaded nanoparticles. With this intention, Bourdon et al. [142] related no dark toxicity with mTHPC-loaded NCs in human colorectal adenocarcinoma (HT29) cells after incubation times of up to 18 h. Light or photosensitizer alone did not lead to a significant decrease in survival fraction according to Konan et al. [136] on EMT-6 mammary tumor cells. Moreover, unloaded nanoparticles, after a 24 h-incubation and an irradiation at 9  $\text{J cm}^{-2}$ , induced no phototoxicity in concentrations up to 20  $\mu\text{g mL}^{-1}$ . Thus, the observed phototoxic effects were only triggered by the combination of a specific photosensitizer and its activation by light.

The research by Bourdon et al. and Konan et al. have validated the proof of con-

cept of using polymeric NPs for PDT [136, 142]. It is, however, difficult to compare the ability of two different photosensitizers when the carriers and the experimental conditions are different. Indeed, several parameters can influence the photoactivity of a drug: experimental conditions (incubation time, light dose), nature of drugs and delivery systems (free or encapsulated), size of carriers, mechanisms of uptake (diffusion, endocytosis), subcellular localization and mechanism of cells destruction.

**Influence of Experimental Settings** The survival rate is determined by a viability assay, which is generally done one day after irradiation. Konan et al. have studied the influence of the time delay between irradiation and viability assay [136]. For this purpose, the cell viability was determined either immediately or 18 h after irradiation. The effect of the photosensitizer (pTHPP) was undervalued when the MTT assay was carried out immediately after irradiation: in this case the drug dose needed to kill 50% of cells ( $IC_{50}$ ) was doubled. Cell damage resulting from photochemical reactions may not be immediately lethal. Indeed, cell death implicates several cascades of reactions such as activation of enzymatic processes. Therefore, cell death can not be observed immediately after illumination. This study on the time delay is the only one in the literature on PDT with loaded-nanoparticles. However, a study carried out on 5-ALA in solution by Betz et al. [150], evaluating cell viability 18 or 24 h after irradiation, seemed to be reasonable to compare different carriers or experimental conditions. It is, however, difficult to deduce a general trend from these results as the needed post-irradiation incubation will depend at least on the PS and the cell line.

The incubation time of the PS with cells and irradiation parameters also have an effect on the phototoxicity of photosensitizers on cancer cells. Indeed, phototoxicity generally increases with incubation time and this correlation is intensified at higher drug concentrations. For example, for pTHPP-nanoparticles, cell viability began to show a decrease after 30 min incubation at  $3 \mu\text{g mL}^{-1}$ ; however, this was reduced to 15 min when using 6 and  $8 \mu\text{g mL}^{-1}$  [136]. At higher concentrations, more NPs are available, so cellular uptake may be improved and then the time required for a good efficiency is reduced.

If the incubation time is long enough, an increase in light dose can also play a considerable role on phototoxicity. PDT is performed at a fixed wavelength, where the photosensitizer absorbs photons, from a laser source [142] or from white light passing through an aqueous filter (e.g., rhodamine) [136]. The fluence rate is determined using a photometer and the irradiation times are adjusted accordingly to the desired light doses. The homogeneity of the light delivered to cells is very important to allow comparison between different treatments. Moreover, the temperature during irradiation has to be controlled to avoid thermal effects on cell viability. Therefore, irradiation times should not be too long. For PLA-nanoparticles, an increase from 6 to  $9 \text{ J cm}^{-2}$  triggered a decrease in cell viability from 85 to 18% after 15 min incubation [136]. Such a fall in viability was observed for all polymeric systems, whereas the influence of light dose with free drug was quite low, 100 to 73%, respectively, for the same dose. Perhaps the free drug needs more time to penetrate

the cells, and thus 15 min is not long enough to obtain a reasonable phototoxicity. Moreover, encapsulation may change the intracellular distribution into the different compartments of the cell, bringing the PS closer to the targets.

**Influence of Incubation Medium** Photoactivity of loaded NPs is generally affected by the presence of serum proteins. When cells are incubated with a photosensitizer in the presence of proteins from fetal calf serum (FCS) or fetal bovine serum (FBS), phototoxicity is improved [135, 141]. This trend was observed for all nanoparticle formulations, whereas free drug did not seem to be influenced by serum. For example, pTHPP-loaded nanoparticles [135] were two-fold more efficient in the presence of 10% FBS regardless of the polymer (PLA, 50:50 and 75:25 PLGA). The serum may enhance the intracellular accumulation of photosensitizer but also favor the monomeric form of the photosensitizer. Indeed, as hydrophobic entities, photosensitizer molecules tend to aggregate in aqueous solution or within the nanoparticles. In this aggregated state, the photosensitizer exhibits a low photodynamic activity and has to be first dispersed to become efficient [151]. Proteins could enhance this dispersion process mainly by lipoprotein association with PS. Improvements in phototoxicity were observed according to the formulations by Konan et al. with pTHPP and verteporfin [135, 141] and Bourdon et al. with mTHPC [142]. Indeed, when compared to nanoparticle formulations, free drug and drug formulated in oil/water NE were not affected by the presence of proteins. The association of PS molecules and proteins can be studied by fluorescence. When aggregated, PS emits very little fluorescence, so the state of dispersion can be observed by following the increase in fluorescence after adding serum. A rapid transfer of verteporfin seems to occur from the nanoparticles to the serum proteins, as Konan-Kouakou et al. observed a rapid increase in fluorescence immediately after the injection of 5% FBS in the suspension medium [141]. In contrast, verteporfin was slightly transferred from DMSO/PBS formulation, which correlates well with the results observed for *in vitro* phototoxicity.

**Influence of Carrier Characteristics** Different types of polymers are available for NP manufacture. The characteristics of the surface can also be changed either by using block copolymers or by coating particles with different excipients. Finally, managing the preparation processes parameters allows control of NP size. It is therefore possible to design customized particles that exhibit very different characteristics in terms of physicochemical properties as well as delivery features. Several studies have evaluated the influence of these parameters.

**Polymer and Surface Modifications** The carrier nature can modulate the photoactivity. The nature of the polymer influences the phototoxicity of drug-loaded nanoparticles. Nanoparticles having the same characteristics (size, drug loading and polymer molecular weight) can exhibit different *in vitro* toxicities that depend on the polymer they are made of. Konan et al. have shown that PLGA-nanoparticles are more efficient than PLA-nanoparticles [136]. Even the lactic/glycolic ratio played a role, since 50:50 PLGA induced a drop in viability at lower doses than 75:25

**Fig. 2.5.** Influence of drug concentration on photocytotoxicity of free pTHPP (■) or pTHPP-loaded nanoparticles (▲, 50:50 PLGA; □, 75:25 PLGA; ●, PLA). The EMT-6 tumor cells were incubated for 1 h, at equivalent drug concentrations, ranging from 3 to 10  $\mu\text{g mL}^{-1}$ , for 1 h and irradiated at a light dose of 6  $\text{J cm}^{-2}$  (655 nm). The MTT assay was performed 18 h after light exposure. Each data point represents the mean ( $\pm$ S.D.) of six values. (Redrawn from [136].)

PLGA (Fig. 2.5). Thus, with the same photosensitizer, *in vitro* activity can be affected by the polymer hydrophile–lipophile balance value, degradation rate and drug release profile. The hydrolysis-labile ester linkages are more accessible to water in PLGA than PLA. In the same way, the higher the content of glycolide in the polymer, the more accessible it would be to water, resulting in a faster hydrolysis. Thus, a faster intracellular release of drug is expected from 50:50 PLGA nanoparticles, which explains their higher efficiency.

By coating nanoparticles with poloxamer or using PEG-grafted polymers, different efficacies can also be obtained with the same polymer (PLA). Naked PLA NCs or poloxamer NCs exhibited quite similar toxicities as determined by Bourdon et al. [142]. However, PLA-PEG NCs induced a slight decrease in phototoxicity.

**Particle Size** The influence of particle size is a key factor regarding cellular internalization [141, 152, 153]. Usually, smaller particles tend to be more readily internalized, and thus higher activity is expected. This parameter has not been yet extensively studied for PDT. The efficiency of a photosensitizer seems to be improved by encapsulating it into small nanoparticles rather than larger nanoparticles. Konan-Kouakou et al. have compared three formulations of verteporfin on EMT-6 mammary tumor cells [141]. Free verteporfin and verteporfin-loaded nanoparticles with different mean sizes (167 and 370 nm) resulted in different survival rates after 1 h-incubation when irradiated at 6  $\text{J cm}^{-2}$ . Treatment with 70  $\text{ng mL}^{-1}$  of free or entrapped verteporfin into large nanoparticles yielded only 11 and 29% cell death, respectively. At the same concentration, almost 69% of cells were killed by small nanoparticles. The small size can increase the particles capacity to be taken up by cells and allow a faster drug release into cells. Furthermore, the distri-

bution of photosensitizer in the nanoparticles can also be affected by their size. With small NPs, the PS could be absorbed on the particle's surface rather than being incorporated into the polymeric matrix. The PS is then more exposed to the external medium and available at its site of action. This influence of size has also been reported recently *in vivo* by Vargas et al. [154].

**Influence of Photosensitizer** Depending on their nature, photosensitizers could enter the cells by different mechanisms and/or rates. In solution, free PS are generally taken up by diffusion, leading to a low intracellular concentration. In contrast, nanoparticles seem to be taken up by endocytosis, leading to higher accumulation and delivery of drug.

In the same chemical family of PS, different derivatives can exhibit different phototoxic activities but these differences can be minimized by encapsulation. The free photosensitizers, depending on their physicochemical properties and, especially, on their hydrophile–lipophile balance value, can penetrate the cell membrane to different extents. However, when encapsulated, all PS derivatives could lead to similar photoactivities. For example, for free zinc-phthalocyanine derivatives, photodynamic activity increased when the degree of sulfonation decreased, according to Lenaerts et al. [130]. In V-79 Chinese hamster cells, the free disulfonated derivative ( $\text{ZnPcS}_2$ ) yielded an  $\text{IC}_{90}$  of 0.19 versus 7.5  $\mu\text{M}$  for the tetrasulfonated derivative ( $\text{ZnPcS}_4$ ). However, after encapsulation into poly(isohexyl cyanoacrylate) (PIHCA) NCs, both PS exhibited similar  $\text{IC}_{90}$  (0.19 and 0.28  $\mu\text{M}$ , respectively). One possible explanation is that amphiphilic molecules, such as  $\text{ZnPcS}_2$ , are readily taken up by cells in their free forms, and thus they are not more active after encapsulation. In contrast, hydrophilic drugs, when incorporated into carriers, can be delivered more readily to the cells and thus be more active. This hypothesis should be verified by internalization experiments and *in vivo* assays. Indeed, in contrast with these conclusions, Pegaz et al. have demonstrated on the chick chorioallantoic membrane (CAM) model that the photodynamic activity of PS is strongly influenced by their hydrophile–lipophile balance [138]. Once entrapped into NPs, the most hydrophobic PS exhibited a higher photoactivity.

Lenaerts et al. [130] have also suggested that encapsulation would reduce the degree of aggregation of the drug, aggregation that is detrimental to PS activity. This point is considered to be of key importance for the success of PDT because the susceptibility of highly hydrophobic PS to undergo aggregation in aqueous environments has a deleterious effect on the photoinduced oxidative process [151]. Indeed, due to the lack of physiological acceptable solvents for hydrophobic PS, encapsulation allows one to overcome formulation problems, especially when intravenous administration is needed.

#### 2.4.2.2 Uptake and Trafficking of Photosensitizers

PS, depending on their properties (hydrophile–lipophile balance value, charge, etc.), enter cells through different mechanisms, thereby determining their subcellular localization and ultimately their photodynamic efficacy. PS may penetrate into the cell by passive diffusion or by endocytosis [12].

Interest in using polymeric nanoparticles for PDT was first demonstrated by studies from Bachor et al. who conjugated the porphyrin derivative chlorine  $e_6$  ( $Ce_6$ ) on 1000 nm polystyrene particles [155]. Association of PS to the particles increased the cellular uptake of the drug while the free drug stayed in the membrane of MGH-U1 cells (human bladder carcinoma cell line). The intracellular concentration was  $20\times$  higher in cells treated with  $Ce_6$ -microspheres than in cells treated with unconjugated  $Ce_6$ . As a consequence, after irradiation at 659 nm, encapsulated  $Ce_6$  ( $0.43 \mu M$ ) induced total growth inhibition at a light dose of  $5 J cm^{-2}$ , whereas treatment with unconjugated  $Ce_6$  did produced no effect.

PS, free or entrapped, enters the cells in a concentration- and time-dependent manner [135, 142]. However, different uptake rates could be obtained depending on the PS or on the nature of the carrier. mTHPC has been entrapped in plain, or surface modified with PLA-PEG, NCs [142]. The cellular uptake, evaluated by the total fluorescence intensity of cells, showed that encapsulation decreased the intracellular uptake of the drug. Indeed, a higher internalization rate was obtained when the drug was solubilized in an ethanol/PEG/water (20/30/50 by volume) solution than with the encapsulated drug. Plain PLA NCs were less internalized than either poloxamer-coated nanocapsules or PLA-PEG NCs (Fig. 2.6). Nevertheless, quite similar phototoxic activity was observed for all treated groups. This strongly suggests that the PS does not follow the same cellular uptake pathway depending

**Fig. 2.6.** Uptake of mTHPC ( $0.25 \mu g mL^{-1}$ ) by HT29 cells as determined by microspectrofluorimetry. mTHPC formulations: solution ( $\blacktriangle$ ), nanoemulsion ( $\triangle$ ), poloxamer-coated PLA NCs ( $\circ$ ), PLA-PEG NCs ( $\blacksquare$ ) and PLA NCs ( $\bullet$ ). Cellular fluorescence intensities were measured at 654 nm. For each experiment, data have been averaged from intensity values determined on 30 individual living cells. Experiments were carried out in triplicate (bars represent S.E.). (Reprinted from Ref. [142] with permission.)

on whether it is encapsulated or free. This was further demonstrated in a recent publication where the degree of internalization of pTHPP-loaded nanoparticles sharply dropped when incubation was performed at +4 °C whereas no effect on the uptake of the free drug was observed [135]. Thus, an energy-dependent process is involved in the uptake of loaded-nanoparticles. Endocytosis of NPs leads to higher intracellular concentration whereas free pTHPP, owing to its hydrophobic nature, tends to diffuse passively into the cell membrane, where it is less active. Therefore, encapsulation favors the PS internalization; however, PLA nanoparticles were less likely to be taken up than PLGA NP. In this case, pTHPP is a PS able to cross the membrane by diffusion; however, other PS, which are less hydrophobic or too polar to diffuse through the plasma membrane, are taken up, similar to the NPs, by endocytosis.

ROS have a short life-time, and their activity is limited to sites close to ROS generation; thus, PS uptake by cancer cells is crucial for effective PDT. To a certain degree, the type of damage that occurs in cells depends on the subcellular localization of the PS. The localization of PS in cancer cells, studied by fluorescence microscopy, seems to be formulation-dependent. The intracellular localization of PS might differ between free PS and loaded-carriers, permitting induction of different photochemical lesions in irradiated cells. A specific subcellular localization could determine the mechanism of cell death. For example, localization in mitochondria has been associated with the tendency of PS to produce apoptosis [12].

Precise PS localization can be determined by confocal laser scanning microscopy and by using co-staining of cellular organelles using fluorescent markers or indirect immunofluorescence. Bachor et al. first showed that microspheres loaded with Ce<sub>6</sub> can be visualized in the cytoplasm and more precisely in phagolysosomes [155]. In contrast, unconjugated PS, due to their lipophilicity, seemed to stay in cellular membranes, including plasma, nuclear and mitochondrial membranes. The cellular distribution within HT29 cells reported by Bourdon et al. was also affected by encapsulation [142]. Cells treated with free drug showed a diffused distribution throughout the cytoplasm, with a non-fluorescent nuclear area. As for NCs, even if the nuclear area is still non-fluorescent, PS was localized in the Golgi system.

In contrast to these studies reporting different localization for free and encapsulated PS, Konan et al. observed, in EMT-6 cells, similar localization in early and late lysosomes for free and encapsulated pTHPP [135]. However, this discrepancy might be related to the use of different cell lines and experimental parameters. Indeed, as far as uptake is concerned, a specific behavior of EMT-6 cells has been reported compared to other cell lines [156].

The photochemical reactions induced by irradiation may damage membrane integrity and therefore cause the release of PS from their primary site of localization. The efflux of pTHPP from EMT-6 cells was studied in a comparative manner after treatment with PLGA loaded-nanoparticles and free drug at 6 µg mL<sup>-1</sup> for 15 min incubation [135]. After irradiation at 6 J cm<sup>-2</sup>, the rate of the pTHPP escape was evaluated by loss of fluorescence as a function of time. Indeed, free or loaded drug gradually escaped from cells as a function of time. This trend was faster for a treatment with NPs. This may be due to a higher uptake and thus to more severe pho-

tochemical damage, including important membrane disruption. Before total efflux from cells, redistribution inside the cells could be observed, e.g., from lysosomes to cytoplasm or nuclei [157]. This phenomenon has been demonstrated with PS, such as porphyrins or phthalocyanines derivatives [158, 159], but not yet with PS-loaded nanoparticles.

One of the limitations of nanocarriers is their rapid uptake by the reticuloendothelial system (RES), which results from the adsorption of opsonins (plasma proteins) on these carriers. Then, they are taken up by the cells of the immune system located mainly in the liver and the spleen. Thus, a strategy has been developed to avoid the adsorption of opsonins. Bourdon et al. have studied this phenomenon with macrophage-like cells (J774) [142]. For this purpose they compared different mTHPC formulations with the aim of evaluating the capability of surface-modified NCs to reduce phagocytosis. Compared with naked PLA NCs, drug uptake by macrophages is indeed decreased by poloxamer coating of particles, or by using PEGylated polymers (Fig. 2.7). This reduction in uptake is better achieved with PLA-PEG NCs. These results are a positive indication that RES clearance *in vivo* could be limited with such PEGylated carriers (as discussed below). Interaction between carriers and opsonins is of van der Waals type, and coating nanoparticles with a hydrophilic chain of poloxamer or PEG could increase the circulating time in the body.

**Fig. 2.7.** Uptake of mTHPC ( $0.25 \mu\text{g mL}^{-1}$ ) by macrophage-like J774 cells as determined by microspectrofluorimetry. mTHPP formulations: PLA NCs (●), nanoemulsion (△), solution (▲), poloxamer-coated PLA NCs (○) and PLA-PEG NCs (●). ## 2.4.3

**In Vivo Relevance of Polymeric Nanoparticles in PDT**

Encapsulation may lead to a different intracellular localization of the hydrophobic photosensitizers, favoring light activated phototoxicity. One must, however, be very careful in extrapolating previous data to an *in vivo* situation. Indeed, *in vitro* experiments are obtained on cell monolayers directly in contact with light and PS, conditions rarely encountered *in vivo*. These studies are a proof of concept as they document the ability of the NP approach to improve PDT efficacy. Encapsulation would allow one not only to reduce the PS dose administered to the patients but also to use a lower light dose, thus reducing potential collateral damage to neighboring tissues. To demonstrate these advantages of NPs, *in vivo* studies have to be carried out with several goals: first, to compare the body biodistribution of PS according to their formulations, to assess the efficacy of PS-loaded nanocarriers as far as vascular or tumor suppression effects are concerned, and finally to investigate possible side effects, such as skin photosensitization.

**2.4.3.1 Biodistribution and Pharmacokinetics of Photosensitizers Coupled to Nanoparticles**

As with therapies against cancer, one of the main challenges in photodynamic therapy is enhancement of the PS concentration ratio between tumor and other organs [7]. However, the localization of NP in specific tissues may depend on the intrinsic characteristics of the carrier (e.g., nature of the polymer, size, and surface properties). The tissue distribution and pharmacokinetics of a PS can be influenced by its incorporation into nanoparticles. Generally, following *i.v.* administration, nanoparticles are rapidly and extensively taken up by the RES [125]. Accordingly, as soon as a few minutes after intravenous injection of nanoparticles, the PS mainly accumulates in the liver and spleen. Thereafter, the RES drug level gradually decreases over several days, depending on the biodegradability of the polymer and on the drug release kinetics.

Although few *in vivo* studies have been carried out, the advantages of surface modification to decrease the accumulation of the photosensitizer in the liver have been demonstrated. The body distribution of poloxamer-coated-PIHCA NCs containing radiolabeled tetraiodinated zinc-phthalocyanine ( $\text{ZnPcI}_4$ ) were studied in healthy Balb-C mice and mice bearing the EMT-6 mammary tumor [130]. The accumulation of PS in the liver was significantly lower with poloxamer-coated NCs than with free  $\text{ZnPcI}_4$  in solution. As a consequence, the main fraction of PS was present in blood when NCs are used as a carrier. The experiments in tumor-bearing mice confirmed not only the reduced liver uptake with NCs but also showed a higher uptake by the tumor. Photodynamic therapy should be performed when PS concentrations have a maximum value in the tumor, thus, in this study, tumor-to-blood ratios  $> 200$  were obtained as early as 12 h post-injection. This high tumor selectivity achieved by surface modification of nanocarriers confirmed that NPs could be an efficient drug delivery system for cancer treatment.

PLA biodegradable nanoparticles coated with PEG-20 000 have also been suggested to enhance tumor uptake of the encapsulated compound [139]. Coating PLA NPs with PEG-20 000 substantially enhanced the blood circulation time of the photosensitizer hexadecafluoro zinc phthalocyanine (ZnPcF<sub>16</sub>), as compared to plain particles. After 24 and 168 h, the cumulated uptake of the compound in the liver and spleen represented 61% and 44% for plain NPs versus 50% and 29% for PEG-coated NPs, respectively. The reduction of the uptake of the NPs by the RES and the resulting longer blood circulation time were associated with a three-fold increase of the compound concentration in the tumor after 24 h. Such coated NPs yielded advantageous tumor-to-skin and tumor-to-muscle ratios, which is important in predicting the risk of damage to adjacent tissues during PDT.

Similar results were also observed by fluorescence with poloxamer-coated nanocapsules and PEG-grafted PLA nanocapsules loaded with mTHPC [143]. A decrease in liver distribution was observed with coated particles and was more pronounced for PLA-PEG NCs. Tumor distribution was also affected, and PLA-PEG particles seemed to better accumulate in the tumor tissue. Nonetheless, the influence of surface modification on particle biodistribution is difficult to compare between studies because results are frequently presented in arbitrary units of fluorescence, and the relative fluorescence of each formulation is not given.

#### 2.4.3.2 Vascular Effects

Vascular damage and blood flow stasis are consequences of PDT on solid tumors. The irreversible destruction of the tumor vasculature, with the subsequent ischemia, is primarily responsible for an effective PDT of solid tumors and contributes to the long-term tumor control [18, 160]. Vascular events observed after PDT include release of vasoactive molecules, enhanced leakage and platelet aggregation, followed by occlusion of the blood vessels. Apart from oncological applications, the vascular occlusion induced by PDT has been used to treat the wet form of age-related macular degeneration, characterized by choroidal neovascularization. The mechanisms underlying the vascular effects of PDT differ greatly according to the nature of the PS and have been studied in different animal models [25]. However, the effect of incorporating photosensitizers in nanoparticles on the PDT-induced vascular occlusion is still unexplored and has only been studied *in vivo* using the chick chorioallantoic (CAM) model. The chorioallantoic membrane is a highly vascularized organ of the chick embryo, which allows the evaluation of vascular occlusion induced by PDT [161]. The pharmacokinetics of intravenously injected PS in the CAM is followed by measurement of the fluorescence of the vascularized and non-vascularized tissues. The photodynamic activity of the PS can be assessed by evaluation of the vascular occlusion achieved after irradiation of the CAM. Vargas et al. have compared the vascular effects of pTHPP, either in solution or encapsulated in 120 nm PLGA NPs, on the CAM vessels [137]. Vascular occlusion was greatly enhanced by the incorporation of pTHPP into NPs (Fig. 2.8), probably because of the reduced diffusion of NPs out of vessels during irradiation. Indeed, non-encapsulated PS quickly leaked out of the vasculature, whereas PS-

## a. Evaluation of PDT induced damage on CAM vessels

Damage Scale	Criterion
0	No damage
1	Partial closure of capillaries of diameter < 10 $\mu\text{m}$
2	Closure of capillary system, partial closure of blood vessels of diameter < 30 $\mu\text{m}$ and size reduction of larger blood vessels
3	Closure of vessels of diameter < 30 $\mu\text{m}$ and partial closure of higher order vessels

5	Total occlusion of vessels in the irradiated area

**Fig. 2.8.** Top. (a) Evaluation criteria of vascular occlusion induced in CAM vessels. Bottom: Comparison of the vascular damage induced by (b) pTHPP-loaded nanoparticles

and (c) pTHPP dissolved in a mixture of ethanol, poly(ethylene glycol) and water. CAM was irradiated with various light doses. Mean ( $n = 3$ ). (Adapted from [137].)

loaded NPs remained longer intravascularly during the 25 min observation time. Using the CAM model, Pegaz et al. have evaluated the influence of the encapsulation of PS with different degrees of lipophilicity on the vascular effects of PDT [138]. Porphyrin derivatives, such as meso-tetraphenylporphyrin (TPP) and meso-tetra(4-carboxyphenyl)porphyrin (TCPP), and chlorin derivatives, such as pheophorbide-a (phéo-a) and  $\text{Ce}_6$ , were encapsulated in PLA nanoparticles of around 200 nm. The PS loading increased with the lipophilicity of the encapsulated PS, ranging from 0.5% for  $\text{Ce}_6$  to 4.6% for TPP. The more hydrophobic PS, TPP for porphyrins and phéo-a for chlorins, extravasated to a lesser extent than the more hydrophilic derivatives. At 1 mg per kg of chick embryo body weight, the extent of vascular occlusion induced by the NPs decreased with decreasing lipophilicity of the PS: TPP > TCPP > phéo-a >  $\text{Ce}_6$ . The authors suggest that the hydrophile-

lipophile balance value of the PS plays an important role in the release of porphyrins and chlorins from these NPs. However, NPs with different drug loadings were compared in this study, and the loading rate may also influence the phototoxicity of NPs. Furthermore, controls using the PS in solution were not performed. Recently, the effect of the NP size on the extent of vascular occlusion has been investigated in the same model. pTHPP was incorporated into PLGA NPs of about 100, 300 and 600 nm [154]. Although the nanoparticles had similar porphyrin loading, the phototoxic effects and the pharmacokinetic profile of the drug were influenced by the size of the nanocarrier. Vascular occlusion decreased as the NPs size rose. Although *in vivo* cancer models should be used to further evaluate the vascular effects of photosensitizers loaded in NPs, observations on the CAM model suggest that the pharmacokinetic profile and the vascular effects induced by PS can be enhanced and modulated by their incorporation into NPs.

#### 2.4.3.3 *In Vivo* Efficacy on Tumor: Tumor Suppression Effects

Encapsulation of ZnPcF<sub>16</sub> into PEG-coated PLA NPs greatly improved its photodynamic activity against EMT-6 mouse mammary tumor implanted in Balb/c mice [140]. Light irradiation was performed 24, 48 and 72 h after intravenous injection of ZnPcF<sub>16</sub> in PEG-coated NPs or Cremophor® [polyoxethylated castor oil (CRM)] based emulsion. At a concentration of 1  $\mu\text{mol kg}^{-1}$ , the best tumor response was obtained when irradiation was carried out 24 h post-injection. Indeed, 63% of Balb/c mice showed no macroscopic sign of tumor progression one week after PDT, and they were completely cured three-weeks post-treatment. In contrast, treatment with CRM formulation led to only 14% tumor regression. Thus, uptake is not the only important parameter as the two formulations were taken up by tumor at a similar rate at this time point (24 h), but the distribution inside the tumor might be different, depending on the formulation. To improve early tumor response, Allémann et al. [140] increased the PS doses (2 and 5  $\mu\text{mol kg}^{-1}$ ). For both doses, early tumor response, in terms of edema, was observed for all treated mice. At 2  $\mu\text{mol kg}^{-1}$ , no effect of the time delay between NP injection and irradiation was observed. In this case, three-weeks post-PDT, 40% of the mice showed complete healing when PDT was performed either at 24, 48 or 72 h post-injection. At 5  $\mu\text{mol kg}^{-1}$ , the treatment with NPs is even more efficient as all mice were cured as compared to only 60% when treated with CRM. Unfortunately, no comparison with uncoated NPs was performed. Nonetheless, uncoated NPs appear to be efficient as well, since Konan-Kouakou et al. have shown the ability of verteporfin-loaded PLGA NPs to control rhabdomyosarcoma (M1) tumor growth implanted in DBA/2 mice [141]. At 1.4  $\mu\text{mol kg}^{-1}$ , tumor suppression was obtained with irradiation as early as 15 and 30 min after injection, with 66 and 75% tumor-free animals, respectively, on day 20. However, irradiation performed 60 min post-injection led to only 33% tumor-free animals. This suggests rapid *in vivo* clearance of the PS when administered in NPs. Moreover, the size of NPs might influence their efficacy *in vivo*, as demonstrated *in vitro* [141]. Indeed, small NPs could reach the target sites and thus be active more rapidly than large NPs. But in this part of the study, Konan-Kouakou et al. showed no control formulations, such

as free PS in solution or emulsion in order to compare the possible differences in efficacy *in vivo* [141].

#### 2.4.3.4 Adverse Effects

Despite promising results in the treatment of cancer, the use of photosensitizers is associated with undesirable side effects, such as prolonged cutaneous photosensitivity that persists for a long time (up to several months). New sensitizers have thus been developed to combine acceptably low rates of skin phototoxicity and clinically useful tumor tissue specificity.

Konan-Kouakou et al. have evaluated the skin photosensitivity caused by verteporfin when administered in NPs to SKH1 hairless mice [141]. Mice were exposed to  $60 \text{ J cm}^{-2}$  of light 15 or 60 min after PS injection. Photosensitivity was assessed 1 and 3 days later using a scoring system for erythema/eschar and edema formation (Table 2.4). The total skin photosensitivity score was calculated as the sum of scores from injury observations. The highest skin photosensitivity scores were observed one day after light exposure when mice were exposed to light 15 min after injection. The average score was then  $1.7 \pm 0.6$ , and 3 days after exposure the value came back to the normal. No skin photosensitivity was observed when mice were irradiated 60 min after injection. Thus, the animals are photosensitive for only a short period, which is very important in limiting the risk of adverse side effects. However, this might be limited to verteporfin, for which a rapid clearance has been described [162]. Although NPs appear to prevent adverse effects, this aspect has only been evaluated in one report – confirmation requires more experimental data.

**Tab. 2.4.** Skin photosensitivity scoring system<sup>[a]</sup>.

---

#### Erythema plus eschar

- 0 No observable reaction
- 1 Minimally detectable erythema
- 2 Slightly visible pale pink erythema, no vessels broken, no red spots
- 3 Blanching, few broken vessels, no eschar formation
- 4 Definite erythema, more broken vessels leading to yellow eschar formation
- 5 Severe reaction, many broken vessels, eschar formation – but less than 50% of site
- 6 Very severe rosette, eschar formation on more than 50% of site

#### Edema

- 0 No observable reaction
  - 1 Slight edema within exposure site
  - 2 Mild edema within exposure site (skin fold measurement < 1 mm)
  - 3 Moderate edema (skin fold measurement 1–2 mm thick)
  - 4 Severe edema extending beyond exposure site (skin fold measurement > 2 mm thick)
- 

<sup>a</sup>Total skin photosensitivity score is the sum of scores from erythema plus eschar and edema observations (minimum = 0, maximum = 10).

## 2.5

### Conclusions

Photodynamic therapy and photodetection are innovative and newly developed approaches for the treatment and detection of cancer. It implies the photoactivation of photosensitizers to induce cellular damage in the target tissue. This approach to cancer chemotherapy, due to the nature of the drug itself, is characterized by better targeting of the treatment, thus limiting side effects usually encountered with conventional therapies. The development of this therapy is somehow limited by the fact that the more potent molecules are hydrophobic, thus requiring potentially harmful solvents to have injectable formulations. The use of biodegradable or non-biodegradable particles as a photosensitizer formulation allows injectable suspensions to be obtained. Encapsulation of different types of photosensitizers does not reduce their photoactivity and in most cases leads to a better activity than shown by the free compounds.

Promising results have been found with non-biodegradable materials. However, non-biodegradable nanoparticles do not offer the possibility of drug release patterns achieved with biodegradable polymers. Further, toxicological aspects have not been yet fully addressed.

*In vivo* and *in vitro* literature data have reported interest in the encapsulation of PS into polymeric nanoparticles, a system offering long-term stable shelf life. The main strength of polymeric nanoparticles for PS delivery is that they are well tolerated both *in vivo* and *in vitro*. Furthermore, encapsulation of PS preserves their pharmacological activity and may decrease the occurrence of adverse effects. Currently, the mechanistic approach behind pharmacological efficiency has not yet been explored and it would be interesting to better understand how photosensitizers can be still active when incorporated into a polymeric shell. Indeed, is the release of the PS necessary for the PDT effect to happen? Since PDT is a two-step process with, first, drug administration and, second, light activation, release kinetics from the polymeric matrix may have a determining influence on treatment dose and schedule. Another unevaluated aspect is the possibility of using particles to actively target cancer or neovascularized tissues. Active targeting with nanoparticles is still at an early stage and its development in the field of PDT will increase tremendously the interest in this type of carrier.

Photodetection with PS loaded NPs has not yet been evaluated. However, there are many opportunities to develop delivery systems explicitly for PD. For instance, PD is mostly used to detect superficial cancers, but the detection of deeper localized tumor, using optic fibers, could take advantage of the tumor localizing properties of NPs.

### Acknowledgments

The authors are very grateful to Dr. Marino Campo for interesting discussions and for critical reading of the manuscript.

**Abbreviations**

5-ALA	5-Aminolevulinic acid
BPD-MA	Benzoporphyrin derivative monoacid ring A
CAM	Chick chorioallantoic membrane
Ce <sub>6</sub>	Chlorine e <sub>6</sub>

## Nanoparticles for Neutron Capture Therapy of Cancer

*Hideki Ichikawa, Hiroyuki Tokumitsu, Masahito Miyamoto, and Yoshinobu Fukumori*

### 3.1

#### Introduction

Conventional radiotherapy using X-rays or  $\gamma$ -rays has been applied to cancer treatment due to its non-invasive methodology. However, some types of tumor are radioresistive; even if radiosensitive, the radiation dose that can be delivered to the tumor is limited by the tolerance of surrounding normal tissues within the treatment volume. In addition, some special techniques are required to treat tumors in deeper parts of the body or in organs because the radiation dose is in general highest on the surface of the body. In particle radiotherapy using beams of accelerated protons or carbon nuclei, the dose has the Brag peak, i.e., becomes maximal at the depth depending on the energy of the particles. Despite this benefit of particle radiotherapy, the dose is also limited by the tolerance of surrounding normal tissues within the treatment volume. Targeting radiotherapy uses radioactive isotopes that can be selectively targeted to tumor after injection, but special attention has to be paid to handling of the radioactive isotopes.

This chapter describes neutron capture therapy (NCT), a new radiotherapy that differs from the conventional radiotherapies described above. Coderre and Morris have reviewed the radiation biology of boron neutron capture therapy (BNCT), including the biodistribution of currently used boron compounds, in detail, but they limited the coverage to BNCT [1]. Consequently, the present chapter also covers gadolinium neutron capture therapy (GdNCT), and drug delivery issues in BNCT and GdNCT are discussed with special focus on the roles of nanoparticle technology. Section 3.2 explains the principle of NCT, and Section 3.3 reviews the present status of BNCT, including two boron compounds clinically used at present and past investigations on their nanoparticulate delivery systems. Section 3.4 deals with the approaches to GdNCT carried out so far, including a detailed account of the present authors' experiences in developing Gd-containing lipid nanoemulsions and chitosan nanoparticles to demonstrate the usefulness of nanoparticle technology in NCT.

**Tab. 3.1.** Neutron capture cross section of typical atoms.

Atom	Cross section (barn)	Reaction
$^{16}\text{O}$	0.00019	
$^{12}\text{C}$	0.0035	
$^1\text{H}$	0.333	$^1\text{H}(\text{n}, \gamma)^2\text{H}$
$^{14}\text{N}$	1.83	$^{14}\text{N}(\text{n}, \text{p})^{14}\text{C}$
$^{10}\text{B}$	3840	$^{10}\text{B}(\text{n}, \alpha)^7\text{Li}$
$^{157}\text{Gd}$	254000	$^{157}\text{Gd}(\text{n}, \gamma)^{158}\text{Gd}$

### 3.2

#### Principle of Neutron Capture Therapy of Cancer

NCT is a cancer therapy that utilizes the radiations emitted *in vivo* as a result of the nuclear neutron capture reaction (NCR) between radiation-producing agents administered in the body and thermal or epithermal neutrons irradiated from outside of the body. NCT is a binary treatment system, consisting of dosing the radiation-producing agents and neutrons. Neutrons have in general been classified according to their energies,  $E$ , as thermal neutrons ( $E < 0.4$  eV), epithermal neutrons ( $0.4$  eV  $< E < 10$  keV), and fast neutrons ( $E > 10$  keV) [1]. Table 3.1 shows the NCRs and neutron capture cross sections of typical elements [1]. Commonly existing O, C, H and N in the body or tissues have small cross sections, but boron ( $^{10}\text{B}$ ) and gadolinium ( $^{157}\text{Gd}$ ) have extremely large cross sections.

The most common radiation-producing element for NCT is  $^{10}\text{B}$  at present [2]. In clinical experiences, NCT with  $^{10}\text{B}$  (BNCT) has achieved encouraging results using the mercaptoundecahydro-*closo*-dodecaborate dianion ( $[\text{B}(12)\text{H}(11)\text{SH}]^{2-}$ , BSH) in patients with grades III–IV glioma and using the boronophenylalanine (BPA) in patients with malignant melanoma (Fig. 3.1). In BNCT, the  $^{10}\text{B}$  compounds administered have to be delivered to tumor intracellularly to obtain an antitumor effect, because  $^{10}\text{B}$  emits  $\alpha$ -particles whose range is nearly equal (9  $\mu\text{m}$ ) to a cell diameter or shorter [3]: success in clinical BNCT trials depends on the selective accumulation of  $^{10}\text{B}$  compounds into individual tumor cells.

$^{157}\text{Gd}$  causes the following neutron capture reaction by thermal neutron irradiation [4]:

$^{157}\text{Gd}$  NCR (Gd-NCR) results in emission of long-range prompt  $\gamma$ -rays, internal conversion electrons, X-rays and Auger electrons with a large total kinetic energy (7.94 MeV) [4]. The  $\gamma$ -rays and the electrons thus generated provide a tumor-killing

Fig. 3.1. Compounds in clinical use for BNCT.

effect [5, 6]. GdNCT has the following theoretical and possible advantages over typical BNCT: (a)  $^{157}\text{Gd}$  has the highest thermal neutron capture cross section (254 000 barns) among naturally occurring isotopes,  $66\times$  larger than that of  $^{10}\text{B}$  [7]; (b) the  $\gamma$ -rays released by Gd-NCR have a long range ( $>100\ \mu\text{m}$ ) in contrast with the  $\alpha$ -particles, so that they may extensively affect tumors even if Gd exists extracellularly in tumor tissue [8]; (c) Auger electrons with a short-range and high linear energy transfer may lead to a local and intensive execution of DNA in neoplastic cells [9]; (d) since Gd has been used as a magnetic resonance imaging (MRI) diagnostic agent [10, 11], it will be possible in future to integrate GdNCT with MRI diagnosis by using Gd-loaded dosage forms.

NCT has certain advantages over traditional cancer chemotherapy. Unlike chemotherapy that uses antitumor drugs, NCT does not need to use pharmacologically active substances in a traditional sense, since it is the neutron capture element itself that contributes to tumor inactivation. Therefore, a large amount of the radiosensitizer can be administered, provided the elements are modified so as to be non-toxic compounds. Thus, severe side effects, which are often experienced in cancer chemotherapy, are not a major concern in NCT.

### 3.3

#### Boron Neutron Capture Therapy

##### 3.3.1

##### Boron Compounds

NCT was first postulated by Locher in 1936 [12]. The earliest clinical treatments of malignant glioma were carried out at the Brookhaven National Laboratory in 1951–1961, and the Massachusetts Institute of Technology in 1959–1961, but no success-

ful result could be obtained, possibly because of the poor tumor-selectivity of the compounds used. Thereafter, many boron compounds have been synthesized for this purpose and their potential to accumulate boron in tumors has been evaluated. However, most compounds could not be used clinically due to chemical instability and toxicity even if they would exhibit a high tumor accumulation. Nonetheless, two compounds, i.e., BSH and BPA (Fig. 3.1), were found to be applicable to clinical treatment.

Hatanaka et al. at Teikyo University, Japan, started clinical trials on brain tumors by using BSH in 1968 [13–15]. They reported one case where a brain tumor seemed to be completely treated. Thereafter, they have employed BNCT for over 200 patients to date. In 1987 Mishima et al. at Kobe University, Japan, also began BNCT of malignant melanoma, subsequently reporting 18 excellent, almost completely treated, results in the treatment of 22 patients [16, 17].

BSH and BPA are the only boron compounds that can be applied to clinical trials at present. They are intravenously (i.v.) administered only as solutions; however, the selectivity in tumor accumulation has to be increased to gain a more efficient treatment outcome. Consequently, new compounds having a high potential for selective tumor-accumulation are still actively sought [18].

BNCT of melanoma has been carried out clinically as follows. Fukuda et al. in Mishima's group have analyzed the neutron dose in 22 melanoma patients with primary or metastatic melanomas who received BPA and subsequently underwent BNCT [19]. The blood concentration in nine patients receiving  $179.7 \pm 14.9$  mg-BPA per kg body weight (BW) increased with time during i.v. infusion, peaked at the end of administration and decreased thereafter. The peak values at the end of administration were  $9.4 \pm 2.6$   $\mu\text{g}^{-10}\text{B}$  per gram of blood, and half-lives for the initial and second components of the blood clearance were 2.8 and 9.2 h, respectively. Skin concentrations in ten patients varied from case to case; however, skin-to-blood (Sk/B) ratios were relatively constant at  $1.31 \pm 0.22$  during the 6 h after the end of administration. Boron concentrations in the tumors resected from the seven patients who were operated on decreased in parallel with the blood values, the tumor-to-blood (T/B) ratio being relatively constant at  $3.40 \pm 0.83$ . Based on these analytical data of BPA pharmacokinetics, they optimized the timing of irradiation and the setting of the neutron flux large enough for tumor eradication but still tolerable for normal skin.

### 3.3.2

#### **Delivery of Boron Using Nanoparticles**

Drug delivery system (DDS) is most often associated with fine particulate carriers, such as emulsion, liposomes and nanoparticles, which are designed to localize drugs in the target site. They have actively been studied as injectable devices that may enhance therapeutic potency and reduce side effects. From a clinical viewpoint, they might have to be biodegradable and/or highly biocompatible. In addition, high drug content is desirable, because in many cases actual drug-loading efficiency is often too low to secure an effective dose at the target site. Biodegradable

liposomes have received considerable attention as potent vehicles for targeting a site and controlled release of a drug.

The successful treatment of cancer by BNCT requires the selective, very high concentration of  $^{10}\text{B}$  within malignant tumors. To achieve this, many approaches relating to the liposomal delivery of boron have been carried out [20–51]. The results from typical studies are described in the following.

Shelly et al. [40] have carried out model studies on  $^{10}\text{B}$  delivery to murine tumors with small unilamellar liposomes of 70 nm or less in tumor-bearing mice. The liposomes were composed of a pure synthetic phospholipid (distearoyl phosphatidylcholine) and cholesterol, encapsulating high concentrations of water-soluble ionic boron-rich compounds, with hydrolytically stable borane anions such as  $[\text{B}(20)\text{H}(18)]^{2-}$ . Unlike the boron compounds themselves, which exhibited no affinity for tumors and are normally rapidly cleared, liposomes selectively delivered the borane anions to tumors. The highest tumor concentrations after i.v. injection of the two isomers of  $[\text{B}(20)\text{H}(18)]^{2-}$  reached the therapeutic range ( $>15\ \mu\text{g-B}$  per g tumor) while maintaining high T/B ratios ( $>3$ ). The authors suggested that these boron compounds might have the capability to react with intracellular components after they had been deposited within tumor cells by the liposome, thereby preventing the borane ion from being released into blood.

Feakes et al. [41] in the same group have investigated the newly synthesized  $[\text{B}(20)\text{H}(17)\text{NH}(3)]^{3-}$  as a water-soluble boron-delivery agent. The  $[\text{ae-B}(20)\text{H}(17)\text{NH}(3)]^{3-}$  anion was encapsulated in liposomes prepared with 5% poly(ethylene glycol) (PEG)-2000–distearoyl phosphatidylethanolamine in the liposome membrane. As expected, these liposomes exhibited a longer circulation lifetime in the biodistribution experiment, resulting in the continued accumulation of boron in the tumor over the entire 48 h experiment, reaching a maximum of 47  $\mu\text{g-B}$  per g tumor.

Subsequently, these authors have synthesized the acylated nido-carborane species  $\text{K}[\text{nido-7-CH}_3(\text{CH}_2)_{15}\text{-7,8-C2B(9)H(11)}]$  for use as an addend for the bilayer membrane of liposomes [42]. Low injected doses of approximately 5–10 mg-B per kg BW afforded a peak tumor boron concentration of approximately 35  $\mu\text{g-B}$  per g tumor and a T/B boron ratio of approximately 8. These values are sufficiently high for the successful application of BNCT. Further, the incorporation of both hydrophilic and hydrophobic species within the same liposomes demonstrated significantly enhanced biodistribution characteristics, as exemplified by the maximum tumor boron concentration of approximately 50  $\mu\text{g-B}$  per g tumor and a T/B ratio of approximately 6. The same authors have also synthesized the thiol derivative [43]. At low i.v. injected doses, the tumor boron concentration increased throughout the time-course experiment, resulting in a maximum observed boron concentration of 46.7  $\mu\text{g-B}$  per g tumor at 48 h and a T/B boron ratio of 7.7. They also reported that the most favorable results were obtained with the polyhedral borane  $\text{Na}_3[\text{a2-B}(20)\text{H}(17)\text{NH}_2\text{CH}_2\text{CH}_2\text{NH}_2]$  [44]. Liposomes encapsulating this species produced a tumor boron concentration of 45  $\mu\text{g-B}$  per g tumor at 30 h post-injection, at which time the T/B ratio was 9.3.

Watson-Clark et al. have reported model studies directed toward the application

of BNCT to rheumatoid arthritis using the above liposomes incorporating K[nido-7-CH<sub>3</sub>(CH<sub>2</sub>)<sub>15-7,8</sub>-C<sub>2</sub>B(9)H(11)] as an addend in the lipid bilayer and encapsulated Na<sub>3</sub>[a<sub>2</sub>-B(20)H(17)NH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH<sub>2</sub>] in the aqueous core [45]. With low i.v. injected doses of 13–18 mg-B per kg BW, the peak boron concentration observed in arthritic synovium was 29 µg-B per g tumor. The highest synovium/B ratio observed was 3.0, when the synovial boron concentration was 22 µg-B per g tumor.

Yanagie et al. have reported BNCT using <sup>10</sup>B entrapped anti-CEA (carcinoembryonic antigen) immunoliposome. A new murine monoclonal antibody (2C-8) was prepared by immunizing mice i.p. with a CEA-producing human pancreatic cancer cell line, AsPC-1 [46]. This anti-CEA monoclonal antibody was conjugated with large multilamellar liposomes incorporating BSH. AsPC-1 cells were incubated with the <sup>10</sup>B-Lip-MoAb (CEA) for 8 h. After irradiation with thermal neutrons (10<sup>11</sup>–10<sup>13</sup> neutrons cm<sup>-2</sup>), AsPC-1 cells showed decreasing uptake of <sup>3</sup>H-TdR compared with control group, indicating that the immunoliposomes could exert cytotoxic effect by thermal neutrons. Further, the boronated anti-CEA immunoliposome was applied to tumor cell growth inhibition in an *in vitro* BNCT model [47]. The liposomes were shown to bind selectively to cells bearing CEA on their surface. The immunoliposomes attached to tumor cells suppressed growth *in vitro* upon thermal neutron irradiation, and suppression was dependent upon the concentration of the <sup>10</sup>B compound in the liposomes and on the density of antibody conjugated to the liposomes. The cytotoxic effects of locally injected <sup>10</sup>B compound, multilamellar liposomes containing <sup>10</sup>B compound or <sup>10</sup>B immunoliposomes (anti-CEA) on human pancreatic carcinoma xenografts in nude mice have been evaluated with thermal neutron irradiation [48]. Injection of <sup>10</sup>B immunoliposomes caused the greatest tumor suppression with thermal neutron irradiation *in vivo*. Histopathologically, hyalinization and necrosis were found in boron-treated tumors, while tumor tissue injected with saline or saline-containing immunoliposomes showed neither destruction nor necrosis, suggesting that BNCT with intratumoral (i.t.) injection of immunoliposomes was able to destroy malignant cells in the marginal portion between normal tissues and cancer tissues.

Yanagie et al. have also extended the use of BNCT assisted by liposomal boron delivery to breast cancer [49]. In addition, they have employed neutron capture autoradiography (NCAR) of the sliced whole-body samples of tumor-bearing mice [50]. They obtained NCAR images for mice i.v. injected by <sup>10</sup>B-PEG liposome, <sup>10</sup>B-transferrin (TF)-PEG liposome, or <sup>10</sup>B-bare liposome. This study demonstrated the increased accumulation of <sup>10</sup>B atoms in the tumor tissues by binding PEG-chains to the surface of liposome, which increased retention in the blood flow and escaped phagocytosis by the reticuloendothelial system (RES).

Maruyama et al. have prepared unilamellar TF-PEG liposomes less than 200 nm in diameter for intracellular targeting of BSH to solid tumors [51]. When TF-PEG liposomes were injected at 35 mg-<sup>10</sup>B per kg BW, a prolonged residence time in the circulation and a low uptake by RES in Colon 26 tumor-bearing mice were observed. TF-PEG liposomes maintained a high <sup>10</sup>B level in the tumor with concentrations above 30 µg g<sup>-1</sup> for at least 72 h after injection, indicating that binding and

concomitant cellular uptake of the extravasated TF-PEG liposomes occurred by TF receptor and receptor-mediated endocytosis, respectively. On the other hand, the plasma level of  $^{10}\text{B}$  decreased, resulting in a tumor/plasma ratio of 6.0 at 72 h after injection. Administration of BSH encapsulated in TF-PEG liposomes at a dose of 5 or 20 mg- $^{10}\text{B}$  per kg BW and irradiation with  $2 \times 10^{12}$  neutrons  $\text{cm}^{-2}$  produced tumor growth suppression and improved long-term survival compared with controls. Thus, intravenous injection of TF-PEG liposomes could increase the tumor retention of  $^{10}\text{B}$  atoms, which were introduced by receptor-mediated endocytosis of liposomes after binding, causing tumor growth suppression *in vivo* upon thermal neutron irradiation.

Koning et al. have tried to target  $^{10}\text{B}$  to the tumor vasculature for NCT [24]. Alpha ( $\nu$ )-integrin specific RGD-peptides were coupled to liposomes that encapsulated BSH. These RGD-liposomes strongly associated with human umbilical vein endothelial cells (HUVEC) expressing this integrin and were internalized. Irradiation of RGD- $^{10}\text{B}$ -liposome-incubated HUVEC with neutrons strongly inhibited endothelial cell viability.

Low-density lipoproteins (LDLs) are internalized by the cell through receptor-mediated mechanisms. A boronated analogue of LDL has been synthesized for possible application in BNCT by Laster et al. [52]. The analogue was tested in cell culture for uptake and biological efficacy in the thermal neutron beam. The boron concentration found was  $10\times$  higher than that required in tumors for BNCT, 240  $\mu\text{g}\text{-}^{10}\text{B}$  per gram of cells.

### 3.4

#### Approaches to GdNCT

Therapeutic potential in GdNCT has been explored theoretically and experimentally [53–69]. Magnevist<sup>®</sup> (gadopentetate dimeglumine aqueous solution), an MRI contrast agent, has been most used as gadolinium source in GdNCT studies. Because of the lack of its targeting ability, however, an adequate amount of gadolinium required for an efficient therapeutic index could not be delivered through the i.v. route. In addition, even i.t. injection did not give rise to significantly prolonged retention of gadolinium in tumor tissues. Thus, a key for success in current GdNCT trails is the use of a device by which gadolinium can be delivered efficiently and retained in a high level inside tumor tissues and/or cells during thermal neutron irradiation. In addition, this may extend NCT to wider types of tumors. From these perspectives, the present authors have prepared delayed-release type ethyl cellulose-coated microcapsules containing gadopentetate dimeglumine for preliminary GdNCT trials [61]. GdNCT using the microcapsules demonstrated a significant effectiveness in survival time of the murine Ehrlich ascites tumor model [62]. This result, which first demonstrated the potential of GdNCT *in vivo*, led us develop a more elaborate gadolinium-loaded particulate system and to establish its potential application to GdNCT, as described below.

## 3.4.1

**Typical Research on GdNCT**

Hofmann et al. have reported GdNCT of melanoma cells and solid tumors with a neutral macrocyclic gadolinium complex (Gadobutrol), a magnetic resonance imaging contrast agent [53]. In mice, i.t. administration of 1.2 mmol-Gd per kg BW of the Gd complex, corresponding to about 23 000  $\mu\text{g-Gd}$  per mL of tumor, before neutron irradiation ( $3.6 \times 10^{12}$  neutrons  $\text{cm}^{-2}$ ) resulted in a significant delay in tumor growth with respect to control groups.

Kobayashi et al. have developed avidin-dendrimer-(1B4M-Gd)(254) (Av-G6Gd) as a tumor-targeting therapeutic agent for GdNCT of intraperitoneal disseminated tumor that can be monitored by MRI in order to deliver large quantities of Gd atoms into tumor cells [63]. An *in vitro* internalization study showed that Av-G6Gd accumulated and was internalized into SHIN3 cells, a human ovarian cancer, 50- and 3.5-fold greater than gadolinium diethylenetriaminepentaacetic acid (Gd-DTPA, Magnevist<sup>®</sup>) and G6Gd. The accumulation of Gd in the cells was also detected by the increased signal on T1-weighted MRI. Av-G6Gd showed specific accumulation in the SHIN3 tumor 366- and 3.4-fold greater than Gd-DTPA and G6Gd one day after intraperitoneal (i.p.) injection. Thus, a sufficient amount of Av-G6Gd (162 ppm of Gd) was accumulated and internalized into the SHIN3 cells *in vivo*.

De Stasio et al. have observed directly the microdistribution of Gd in cultured human glioblastoma cells exposed at 1–25 mg of Gd-DTPA per mL, corresponding to 300–7100  $\mu\text{g-Gd mL}^{-1}$  [64]. They demonstrated that Gd-DTPA penetrated the plasma membrane, and observed no deleterious effect on cell survival and a higher Gd accumulation in cell nuclei compared with cytoplasm. They also exposed Gd-containing cells to thermal neutrons ( $3.6 \times 10^{12}$  neutrons  $\text{cm}^{-2}$ ) and demonstrated the effectiveness of Gd-NCR in inducing cell death. However, the efficacy of Gd-DTPA and Gd-DOTA as GdNCT agents *in vivo* was predicted to be low due to the insufficient number of tumor cell nuclei incorporating Gd [65]. The authors then suggested that although multiple administration schedules *in vivo* might induce Gd penetration into more tumor cell nuclei, a search for new Gd compounds with higher nuclear affinity would be warranted before planning GdNCT in animal models or clinical trials.

Oyewumi and Mumper have used microemulsions (oil-in-water) as templates to engineer stable emulsifying wax or Brij 72 (polyoxyl 2 stearyl ether) nanoparticles [66]. The technique was simple, reproducible, and amenable to large-scale production of stable nanoparticles having diameters below 100 nm. The emulsifying wax and Brij 72 nanoparticles ( $2 \text{ mg mL}^{-1}$ ) made together with polyoxyl-20 stearyl ether and polysorbate 80, respectively, were the most stable based on retention of nanoparticle size over time. Gadolinium acetylacetonate (GdAcAc), a potential anti-cancer agent for NCT, was entrapped in the nanoparticles. Challenges of these cured nanoparticles in biologically relevant media at 37 °C for 60 min demonstrated that these nanoparticles were stable. The results showed the ease of preparation of these very small, stable nanoparticles and the ability to entrap lipophilic drugs such as GdAcAc with high efficiency.

Oyewumi's group further synthesized gadolinium hexanedione (GdH) by complexation of  $Gd^{3+}$  with hexane-2,4-dione as NCT agent, and a folate ligand by chemically linking folic acid to distearoylphosphatidylethanolamine (DSPE) through a PEG (MW 3350) spacer [67]. To obtain folate-coated nanoparticles, the folate ligand (0.75 to 15% w/w) was added either to the microemulsion templates at 60 °C or to nanoparticle suspensions at 25 °C. Cell uptake studies were carried out in KB cells (human nasopharyngeal epidermal carcinoma cell line), which are known to overexpress folate receptors. The uptake of folate-coated nanoparticles was about ten-fold higher than uncoated nanoparticles after 30 min at 37 °C. The uptake of folate-coated nanoparticles at 4 °C was 20-fold lower than the uptake at 37 °C and comparable to that of uncoated nanoparticles at 37 °C. Folate-mediated endocytosis was further verified by the inhibition of the uptake of folate-coated nanoparticles by free folic acid. Folate-coated nanoparticle uptake decreased to approximately 2% of its initial value with the co-incubation of 0.001 mM of free folic acid. The authors suggested that these tumor-targeted nanoparticles containing high concentrations of Gd may have potential for NCT. Thiamine was also effective as a tumor-specific ligand for gadolinium nanoparticles in a methotrexate-resistant breast cancer cell line, MTX(R)ZR75, transfected with thiamine transporter genes (THTR1 and THTR2) [68].

Using the folate-coated and PEG-coated gadolinium (Gd) nanoparticles, Oyewumi et al. carried out *in vivo* studies in KB tumor-bearing athymic mice [69]. Gd nanoparticles did not aggregate platelets or activate neutrophils. The retention of nanoparticles in the blood 8, 16 and 24 h post-injection of nanoparticles (1.6 mg-Gd per kg BW) was 60, 13 and 11% of the injected dose (ID), respectively. The maximum Gd tumor localization was  $33 \pm 7 \mu\text{g-Gd g}^{-1}$ . Both folate-coated and PEG-coated nanoparticles had comparable tumor accumulation. However, the cell uptake and tumor retention of folate-coated nanoparticles was significantly enhanced over PEG-coated nanoparticles. Thus, the folate-ligand coating shows beneficial facilitation of tumor cell internalization and retention of Gd-nanoparticles in the tumor tissue.

### 3.4.2

#### Delivery of Gadolinium using Lipid Emulsion (Gd-nanoLE)

##### 3.4.2.1 Preparation of Gd-nanoLE

Oil-in-water (o/w) emulsions stabilized with emulsifiers such as phospholipids have attracted much attention as drug carriers because they are biodegradable and biocompatible and, unlike liposomes, they can be prepared on an industrial scale and are relatively stable below 25 °C for long periods [70]. One problem with using emulsion particles as drug carriers is how they can leave the vascular space and reach their site of action. The extravascular transfer of particulate carriers largely depends on their size. A diameter of approximately 100 nm is the cut-off value for drug carriers able to pass through the discontinuous capillary endothelium of tumors [71]. In addition, drug carriers <100 nm are expected to more easily avoid uptake by RES and to circulate for longer periods in blood, as estimated from the

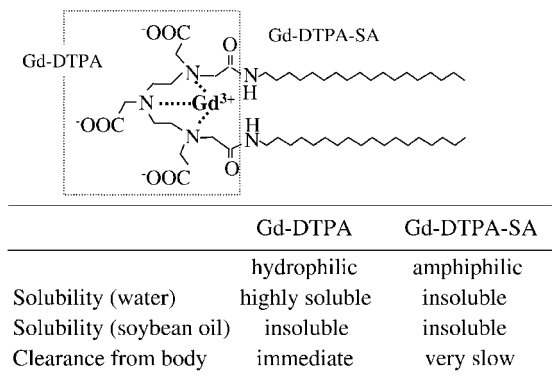

Fig. 3.2. Chemical structure and properties of Gd-DTPA-SA.

finding that small unilamellar liposomes of about 70–100 nm are cleared more slowly from the circulation than larger ones of the same composition [72].

The authors' first study on developing nanoparticulate systems for GdNCT was to prepare Gd-containing emulsions with reduced particle size, surface properties exhibiting prolonged blood retention, and a high gadolinium content [73]. As a Gd-source, a water-insoluble and oil-insoluble Gd-DTPA derivative, distearylamine (Gd-DTPA-SA) (Fig. 3.2), was synthesized. Gd-DTPA-SA has two hydrophobic tails (side-chains) consisting of stearyl amines that are connected to the Gd-DTPA moiety through amide linkages. It can be incorporated into the membrane of liposomal vesicles as a component of the liposomal lamella [74].

The particle structure is schematically shown in Fig. 3.3. Emulsions containing soybean oil, water, Gd-DTPA-SA, as an amphiphilic drug, and hydrogenated egg yolk phosphatidylcholine (HEPC), as an emulsifier, in a weight ratio of 7.36:92:1:2 were prepared by the thin-layer hydration method using a bath-type sonicator (Table 3.2). The mean particle size of the emulsions was 250 nm.

Particle size (nm)	250	78	84

<sup>a</sup>L-Phosphatidylcholine hydrogenated from egg yolk.

<sup>b</sup>HCO-60.

<sup>c</sup>Theoretical Gd content.

To prepare o/w emulsions, oils other than the commonly used soybean oil have been employed. The particle size of triolein-emulsion (240 nm) was almost the same as that of soybean oil-emulsion. Lipiodol Ultra-Fluide<sup>®</sup> (Guerbert Laboratories, France) produced a mean droplet size of 195 nm. When castor oil (448 mPa s/25 °C; 262 mPa s/37 °C [75a]) with a higher viscosity was selected as an oil component, no emulsion could be prepared by the procedure used here, while stable emulsions could be prepared using oils with a lower viscosity such as soybean oil (49 mPa s/25 °C, 29 mPa s/37 °C [75a]), Lipiodol (37 mPa s/25 °C, 25 mPa s/37 °C [75a]) and ethyl oleate (4 mPa s/37 °C [75b]). The mean particle size of the emulsions seemed to be closely correlated to the viscosity of the oils: the particle size of the emulsions fell on reducing the viscosity of the oil. This indicated that oil viscosity is an important factor, influencing the particle size of the Gd-DTPA-SA emulsions. Despite this, soybean oil was used in this study because of its widespread application. To make the droplet size of the emulsions smaller than 100 nm, as well as to modify the emulsion surfaces, a co-surfactant, Tween<sup>®</sup> 80, HCO<sup>®</sup>-60, Pluronic<sup>®</sup> F68, polyoxyethylene alkyl ether (Brij<sup>®</sup>) or polyoxyethylene alkyl ester (Myrj<sup>®</sup>), was introduced into the standard system. Figure 3.4 shows the chemical structures of typical co-surfactants. Tween 80, HCO-60, Brij 76, 78 and 700 were effective in reducing the particle size to below 100 nm when the co-surfactant weight ratio (CWR), defined as co-surfactant/(HEPC+Gd-DTPA-SA) (w/w), was larger than 0.67. The particle size with Tween 80 and HCO-60 was reduced to 53 and 78 nm, respectively, at a CWR of 1.0 (w/w) (Table 3.2). To increase the gadoli-

Fig. 3.4. Chemical structure of co-surfactants.

nium content, the weight ratio of Gd-DTPA-SA to HEPC was increased from 1:2 of the standard-Gd formulation to 2:1 of the high-Gd formulation (Table 3.2). The measured particle size of the HCO-60 high-Gd emulsions was 84 nm when the CWR was 1.0 (w/w). In this case, the calculated gadolinium content reached 3.0 mg-Gd mL<sup>-1</sup>. These results indicate that HCO-60 is an effective co-surfactant not only in terms of particle size reduction but also with respect to gadolinium enrichment.

#### 3.4.2.2 Biodistribution of Gadolinium after Intraperitoneal Administration of Gd-nanoLE

Tokuuye et al. have reported the effect of <sup>157</sup>Gd concentration on tumor inactivation in GdNCT [76]. The neutron fluence required for 10% survival of the Chinese hamster cells (V79) decreased rapidly between 0 and 100 μg-<sup>157</sup>Gd mL<sup>-1</sup>, but leveled off above that. This result indicates that the optimal tumor inactivation effect would be achieved around 100 μg-<sup>157</sup>Gd mL<sup>-1</sup>. To achieve this level *in vivo*, Gd-nanoLEs were i.p. administrated in Greene's melanotic melanoma (D<sub>1</sub>-179)-bearing hamsters as a model system and the biodistribution of gadolinium was investigated [77].

The inferior surface of the diaphragm is very rich in lymphatic capillaries. The lymphatic lumen is separated from the abdominal cavity by its own endothelium, a fenestrated basement membrane and the peritoneal mesothelium. Hirano and Hunt have reported that, at least in rats, most compounds of molecular weight smaller than 20 000 were exclusively absorbed via splenic or intestinal blood capillaries into the portal vein [78]. In contrast, the lymphatic system was a major absorption route for compounds with a molecular weight larger than 70 000 that were impermeable to blood capillary membranes. Klein et al. have reported that even particles administered through the abdominal cavity were transported through pores in the diaphragm directly to lymphatic and then to the venous system [79]. Thus, lymphatic capillaries could accommodate and transport large materials such

as erythrocytes of about 10  $\mu\text{m}$  in diameter [80] and particles with a diameter of up to 22  $\mu\text{m}$  [81]. Hirano and Hunt also reported that the use of liposomes 50–720 nm in diameter gave no size effect on absorption from the abdominal cavity [78]. These results suggested that almost all the emulsion particles so-prepared might have the potential to be absorbed through the lymphatic system.

For our *in vivo* experiments, a Greene's melanotic melanoma (D<sub>1</sub>-179) [82] fragment ( $2 \times 2 \times 2$  mm) was subcutaneously inoculated on the left thigh of Syrian hamster. The experiments were performed at 10 d after inoculation, when the diameter of the tumor mass became about 10 mm ( $0.81 \pm 0.60$  g) and the body weight was  $99.7 \pm 10.6$  g. Gd-DTPA derivative-containing lipid emulsion (Table 3.2) was i.p. injected at a dose of 2.0 mL per hamster (30 mg-Gd/kg BW for the standard-Gd formulation and 60 mg-Gd/kg BW for the high-Gd formulation). Tissue concentration was measured by inductively coupled plasma atomic emission spectroscopy (ICP-AES) at 355.047 nm.

**Effect of Co-surfactant** In addition to HCO-60, polyoxyethylene (POE) stearyl ether (Brij, C18POEm) and POE stearyl ester (Myrj, C18POEm') were also selected as co-surfactant to build up the steric hindrance on the emulsion particle surface. Figure 3.5 shows time-courses of gadolinium levels in blood and tumor after i.p. injection of Gd-DTPA-SA-containing plain, HCO-60, Myrj 53 (C18POE50) and Brij 700 (C18POE100) emulsions prepared in the standard-Gd formulation (Table 3.2). The Gd levels in blood (Fig. 3.5A) with the co-surfactant-containing emulsions were significantly higher than those with the plain emulsion. The gadolinium level in blood with the Brij 700 emulsion was prolonged during 12–48 h at the highest level. The high blood gadolinium level with Brij 700 emulsion is related to the stable nature of its ether linkage, in contrast to the ester linkage of the Myrj family (Fig. 3.4).

The Gd concentration in tumor with all emulsions leveled off 24 h after i.p. injection (Fig. 3.5B). Although the gadolinium level in tumor with the Myrj 53 emul-

Fig. 3.5. Effect of co-surfactant on Gd distribution after i.p. injection of the standard Gd-nanoLE at 3 mg/2 mL. Data are represented as the mean  $\pm$  SD ( $n = 3-9$ ).

sion was 31  $\mu\text{g-Gd}$  per g tumor (wet) at 24 h, those with the HCO-60 and Brij 700 emulsions were 59  $\mu\text{g-Gd}$  per g tumor (wet) and 53  $\mu\text{g-Gd}$  per g tumor (wet) at 24 h, respectively. Although gadolinium retention in blood with the Brij 700 emulsion was prolonged at a higher level (Fig. 3.5A), the gadolinium level in tumor increased more slowly, and the final level was not higher than that with the HCO-60 emulsion (Fig. 3.5B). HCO-60 was the most effective co-surfactant for gadolinium accumulation in tumor.

The T/B ratio at 48 h was  $>2.8$  in every emulsion, reaching 21.4 with the HCO-60 emulsion. T/B with the Brij 700 emulsion was as low as that with the plain emulsion. This was related to the prolonged and higher blood gadolinium level. The T/Sk values with the Brij 700 and HCO-60 emulsions were larger than 6.0. Conversely, the Sk/B ratios at 24 h were low (0.05–0.5).

In NCT, thermal neutrons are irradiated from outside the body. As a result, the T/Sk ratio, T/B ratio and/or Sk/B ratio of radiation sensitizer (gadolinium or boron) concentration are important factors influencing in the therapeutic effects. For BNCT, Mishima [83a] and Honda et al. [83b] have reported that when  $^{10}\text{B}$ -BPA fructose complex was administered by the drip infusion method, the average T/B ratio of  $^{10}\text{B}$  concentration was 3–4, T/Sk was 3–6 and Sk/B was around 1.2 [19]. The T/B ratio at 48 h in the present study using the high-Gd-DTPA-SA was far higher (13.2), with the sensitizer concentration in tumor being kept very high (Fig. 3.5), whereas the T/Sk and Sk/B ratios were comparable with the corresponding values in BNCT. These results indicate that the methodology developed here can be used efficiently when a high and long retention of sensitizer in tumor and a high T/B ratio are required.

**Effect of Gadolinium Content in Emulsion and Derivative Type** The Gd content in the HCO-60 emulsion could be increased while the particle size was kept small (Table 3.2). Gadolinium levels in tumor, blood, liver and spleen with the high-Gd emulsion were almost twice as high as those with the standard-Gd emulsion. At 48 h after i.p. injection, the Gd level in tumor with the high-Gd-DTPA-SA HCO-60 emulsion reached 107  $\mu\text{g-Gd}$  per g tumor (wet).

The amide linkages of Gd-DTPA-SA were not expected to degrade *in vivo*. Thus, the stearyl ester derivative of Gd-DTPA (Gd-DTPA-SE) was synthesized. The Gd levels in tumor and blood with the high-Gd-DTPA-SE HCO-60 emulsion were far lower than those with the high-Gd-DTPA-SA HCO-60 emulsion. Conversely, gadolinium levels in liver and spleen in the early period (2–6 h) with the high-Gd-DTPA-SE HCO-60 emulsion were higher than those with the high-Gd-DTPA-SA HCO-60 emulsion. However, both liver and spleen gadolinium levels decreased to levels lower than those with the high-Gd-DTPA-SA HCO-60 emulsion thereafter. Gd-DTPA-SA was very stable in serum: no transfer to serum proteins and no metabolism to small-molecular-weight compounds occurred up to 24 h at 37 °C [74b, 84]. However, the Gd-DTPA-SE complex was not stable, showing both the transfer and metabolism in a time-dependent manner [74b, 84]. The more rapid elimination of gadolinium from liver and spleen with the Gd-DTPA-SE emulsion could be well explained by the faster degradation of Gd-DTPA-SE.

The pharmacokinetic parameters of MRT, Vdss and Cltot with the standard- and the high-Gd-DTPA-SA HCO-60 emulsion were similar. In addition, the AUC with the high-Gd-DTPA-SA HCO-60 emulsion was twice that with the standard-Gd-DTPA-SA HCO-60 emulsion. Since the gadolinium content in the high-Gd-DTPA-SA HCO-60 emulsion was just twice that with the standard-Gd-DTPA-SA HCO-60 emulsion (Table 3.2), these results indicated that particles of both types of emulsion, with different gadolinium content, behaved similarly *in vivo*. This led to the high level in tumor reaching 107  $\mu\text{g-Gd}$  per g tumor (wet) at 48 h, which was the level reported by Tokuyue et al. [76] as an optimal level for tumor inactivation when  $^{157}\text{Gd}$  would be used.

#### 3.4.2.3 Biodistribution of Gadolinium after Intravenous Administration of Gd-nanoLE

The administration route is one of the most important factors in the biodistribution and pharmacokinetics of drug carriers such as liposomes and lipid-emulsions. Previously, the i.p. route was adopted as an administration route of Gd-nanoLE because it allows the injection of a relatively large amount and, consequently, delivers a large amount of Gd to the tumor via the systemic circulation [85]; as a result, the Gd concentration in the tumor reached 107  $\mu\text{g-Gd}$  per g wet tumor at a dose of 60 mg-Gd per kg BW (2 mL as an administration volume of the Gd-nanoLE). However, even with i.p. injection, many factors affect the biodistribution and pharmacokinetics of the drug carriers, including the absorption of these carriers from the abdominal cavity and their localization in the lymph nodes, making estimation of the *in vivo* fate of the drug carriers difficult. In contrast, i.v. injection delivers drugs more simply and, therefore, has been widely employed instead of i.p. injection in clinical treatments. Consequently, our next study aimed to evaluate i.v. as an alternative to i.p. injection with respect to tumor accumulation of Gd incorporated in Gd-nanoLE.

**Comparison of I.V. with I.P. Injection of Gd-nanoLE** The biodistribution of Gd after i.v. or i.p. injection of the standard-Gd-nanoLE with HCO-60 (particle size, 78 nm) was determined at a dose of 15 mg-Gd/kg BW, half that of the previous case [85]. Table 3.3 summarizes the calculated pharmacokinetic parameters. The Gd concentration in the blood after i.v. injection of the Gd-nanoLE consistently decreased from the initial high concentration of 136  $\mu\text{g-Gd}$  per mL blood at the first sampling time, whereas i.p. injection showed a peak concentration of 50  $\mu\text{g-Gd}$  per mL blood at 4 h after administration (Table 3.3).

The AUC of Gd after i.p. injection was only 57% of that after i.v. injection (Table 3.3). It was reported earlier that the blood concentration of a marker incorporated into liposomes containing sphingomyelin and cholesterol after i.p. injection peaked at several hours after administration and subsequently declined [86]. In addition, some reports have shown that the absorption route of the conventional liposomes from the peritoneal cavity to the bloodstream is mediated by the lymphatic system [87, 88], and part of the i.p. injected liposomes are localized in the lymphatic system over 24 h [88]. These findings can probably be extended to interpret the behavior of the lipid-nanoemulsions in the peritoneal cavity. Accordingly, the

**Tab. 3.3.** Pharmacokinetic parameters after i.p. or i.v. administration of the standard-Gd-nanoLE with HCO-60 at a dose of 1.5 mg Gd in 1 mL.

Route	$C_{\max}^{[a]}$ ( $\mu\text{g mL}^{-1}$ )	$T_{\max}^{[a]}$ (h)	AUC <sup>[b]</sup> ( $\mu\text{g h mL}^{-1}$ )	MRI <sup>[b]</sup> (h)
i.p.	50.0	4.0	612	9.2
i.v.	(135.9)	(0.5)	1071	6.3

<sup>a</sup>The maximum blood concentration,  $C_{\max}$ , and the time of maximum blood concentration,  $T_{\max}$ , were derived directly from the mean blood concentration–time curve.

<sup>b</sup>Area under the blood concentration time curve. Each value was calculated from the mean values of blood concentration up to infinite time ( $n = 3-5$ ).

delayed increase of Gd concentration in the blood after i.p. injection might be ascribed to the transport time of the Gd-nanoLE from the peritoneal cavity to the bloodstream through the lymphatic system. In addition, the lower AUC of Gd after i.p. injection, compared with i.v. injection might be explained by the partial localization of Gd-nanoLE in the lymphatic system, since the Gd-nanoLE remaining in the peritoneal cavity, as determined by visual observation, was negligible at 12 h after administration.

In terms of the tumor accumulation of Gd, i.v. injection of the Gd-nanoLE had an advantage over i.p. injection, namely, faster accumulation. The Gd concentration in the tumor after i.v. injection rapidly increased for 6 h after administration, and thereafter it almost leveled off. In contrast, the Gd concentration after i.p. injection remained at a low level for the first 6 h. The maximum Gd tumor concentrations after i.v. and i.p. injections of the Gd-nanoLE were 30  $\mu\text{g-Gd per g wet tumor}$  at 24 h and 22  $\mu\text{g-Gd per g wet tumor}$  at 12 h, respectively.

**Effect of Repeated Dosing and Gd Content of Gd-nanoLE** To achieve a higher Gd accumulation in the tumor, two i.v. injections at a 24 h interval were made at a dose of 15 and 30 mg-Gd/kg BW per injection by using the standard- and high-Gd-nanoLE, respectively. Biodistribution was determined at 12 h after administration, because the tumor accumulation almost leveled off thereafter with Gd-nanoLEs prepared with HCO-60 (Fig. 3.5) [77]. Two i.v. injections of the standard-Gd-nanoLE made the Gd concentration in the tumor higher, reaching a level of 50  $\mu\text{g-Gd per g wet tumor}$  at 12 h after the second injection. Unfortunately, Gd concentrations in the liver and spleen concurrently increased to almost twice those observed after a single i.v. injection.

In certain cases of the repeated administration of liposomes, an accelerated blood clearance and altered biodistribution of the liposomes were observed at the second or later administration for a certain period after the administration, resulting from the induction of an immunoreaction [89]. Oussoren and Storm, though,

**Tab. 3.4.** Effect of dosing frequency and Gd content of the Gd-nanoLE with HCO-60 on blood and tumor concentrations of Gd ( $\mu\text{g}$ -Gd wet tissue) at 12 h after the final i.v. administration at a dose of 1.5 mg Gd per injection for the standard- or 3.0 mg Gd per injection for the high-Gd formulation.

Tissue	Standard-Gd-nanoLE		High-Gd-nanoLE
	Single (1.5) <sup>[a]</sup>	Double (3.0) <sup>[a]</sup>	Double (6.0) <sup>[a]</sup>
Blood	29.7 $\pm$ 2.8	25.3 $\pm$ 5.7	45.1 $\pm$ 11.4*
Tumor	26.9 $\pm$ 1.4	49.7 $\pm$ 30.9	100.7 $\pm$ 35.9**

<sup>a</sup> Values in parentheses are total dose of Gd (mg). Each value represents the mean  $\pm$  S.D. ( $n = 3-5$ ). \* $p < 0.05$  and \*\* $p < 0.01$ , significantly different from the Gd concentration of the standard-Gd-nanoLE injected twice.

demonstrated that the kinetic profiles of the first and second injections of the PEG-liposomes with a 24 h interval were virtually identical [90]. In our case, the Gd concentrations in tissues after two administrations of the standard-Gd-nanoLE seemed to be almost twice as high as those after a single administration (Table 3.4). This implied that, by employing the same schedule as Oussoren and Storm, the repeated administration had no significant effect on the biodistribution mechanisms of the Gd-nanoLE.

With the administration of two i.v. injections of the high-Gd-nanoLE, the Gd concentration in the tumor reached 101  $\mu\text{g}$  per g wet tissue (Table 3.4). This was comparable to the level achieved by a single i.p. injection of 2 mL of the high-Gd-nanoLE at a dose of 60 mg-Gd per kg body weight per injection [85]. These results indicated that even i.v. injection of the Gd-nanoLE whose tolerable volume was only 1 mL could result in the accumulation of Gd in the tumor at a high concentration when an appropriate dosing schedule was employed.

Many researchers have demonstrated that the charge and fluidity of the liposomal membrane affect the biodistribution even in conventional liposomes [91, 92]. For instance, Nagayasu et al. [92] reported that the tumor-to-bone marrow accumulation ratio of the HEPC-containing liposomes increased remarkably with a decrease in cholesterol content. In the present study, it was anticipated that the membrane property of the high-Gd-nanoLE would differ from that of the standard-Gd-nanoLE. However, the biodistribution of Gd-nanoLE after i.v. injection of each formulation was likely to be almost identical, as it had been after i.p. injection [85]. Thus, the biodistribution of the Gd-nanoLE was hardly affected by the membrane property. In concurrence, it was also observed that the Gd tumor concentration was proportional to the Gd content of the lipid particles in the Gd-nanoLE. According to this finding, a higher Gd tumor concentration could be

achieved by loading a highly lipophilic Gd compound into the core component, though the further introduction of the Gd-DTPA-SA into the membrane of the Gd-nanoLE led to instability of the emulsion.

### 3.4.3

#### Delivery of Gadolinium using Chitosan Nanoparticles (Gd-nanoCPs)

A major problem with previous GdNCT trials using an MRI contrast agent such as Magnevist<sup>®</sup> was that a sufficient quantity of gadolinium could not be retained in the tumor tissue during neutron irradiation [53, 54]. The commercially available gadolinium agent does not exhibit such a selective accumulation in the tumor after i.v. injection as BPA in BNCT [17] and is eliminated rapidly from the tumor tissue after i.t. injection. Therefore, gadolinium compounds that can be efficiently accumulated in the tumor have been sought [93]. We have developed novel Gd-nanoCPs in order to retain gadolinium in the tumor tissue during a GdNCT trial.

As is well-known, chitosan (poly[ $\beta$ -(1  $\rightarrow$  4)-2-amino-2-deoxy-D-glucopyranose]) is a hydrophilic, cationic polysaccharide derived by the deacetylation of chitin (Fig. 3.6), which is the second most abundant polysaccharide, next to cellulose, in the world and a promising resource, originating from crustaceans shells and insects [94]. Chitosan has some interesting properties such as bioadhesive (cationic), biocompatible (nontoxic) and biodegradable (bioerodible) capabilities. Therefore, it has been investigated in depth and used in various industrial and medical applications [95]. Furthermore, these interesting properties make it one of the most promising biopolymers for drug delivery [96–107]. Indeed, chitosan has been studied as a drug carrier in various forms, such as tablets, beads, granules, microparticles and nanoparticles. In particular, micro- and nano-particles are being most widely studied as a drug carrier for the purpose of protein, peptide, vaccine and DNA delivery. A wide variety of preparation methods of chitosan particles have been investigated, such as solvent evaporation techniques, multiple emulsion methods, spray drying methods, electrostatic complex-formation with anionic materials (ionotropic gelation) and block copolymerization. These methods often require a crosslinking agent, such as glutaraldehyde. While such crosslinking agents afford hardened par-

Fig. 3.6. Chemical structures of chitin and chitosan (100% deacetylated).

ticles as well as the possibility of controlling the drug-release rate through the degree of crosslinking, the toxicity of the crosslinking agent would become a major concern. In addition, it leads to low loading of anionic drugs because amino groups in chitosan responsible for electrostatic interaction with anionic drugs become unavailable due to the crosslinking reaction between the amino groups in chitosan and aldehyde groups in crosslinking agents. As an alternative approach, a novel emulsion-droplet coalescence technique has been developed in our laboratory to prepare non-crosslinked chitosan nanoparticles. In fact, this technique offered a useful methodology for the preparation of Gd-nanoCPs specially designed for GdNCT as an i.t. injectable device.

#### 3.4.3.1 Preparation of Gd-nanoCPs

Figure 3.7 shows the preparation of Gd-nanoCPs [108, 109]. Chitosan (2.5% w/v) was dissolved in a Gd-DTPA aqueous solution (5–15% w/v) and an aliquot (1 mL) was added to 10 mL of liquid paraffin containing 5% v/v sorbitan sesquioleate (Arlacel C). The mixture was then stirred to form a water-in-oil (w/o) emulsion A using a high-speed homogenizer. Similarly, a w/o emulsion B was prepared by adding 3 M sodium hydroxide solution (1.5 mL) to liquid paraffin (10 mL) containing 5% v/v Arlacel C. As emulsion B was added to emulsion A, they were mixed and stirred vigorously. As a result of coalescence of droplets, chitosan was deposited as nanoparticles. Gd-nanoCPs in the mixed emulsion were washed and separated by centrifugation at 3000 rpm for 60 min using toluene, ethanol and water

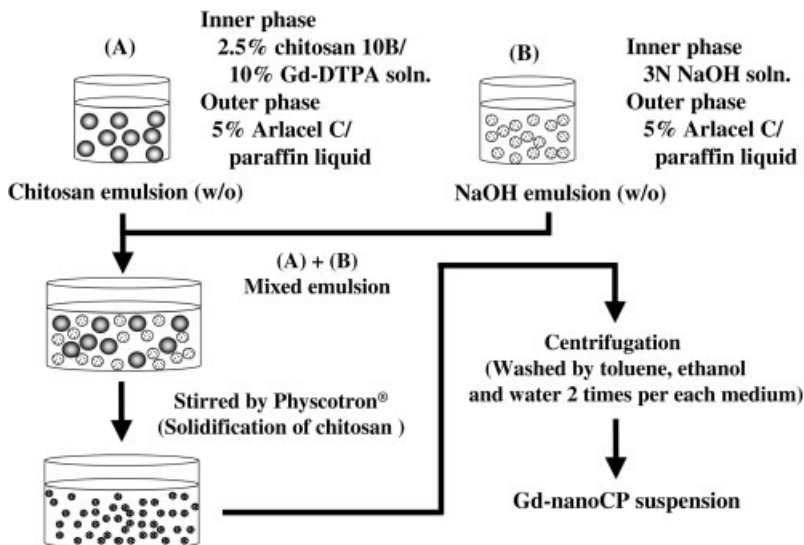

Fig. 3.7. Preparation process of Gd-nanoCPs using an emulsion droplet coalescence technique.

**Tab. 3.5.** Mean particle size and Gd content of Gd-nanoCP.

	No. of batch	Mean particle size (nm) <sup>[a]</sup>	Gd content (% w/w) <sup>[a]</sup> [Gd-DTPA content (%)]
Chitosan 10B			
5% Gd-DTPA soln	3	461 ± 15	7.7 ± 1.7 [26.9 ± 5.9]
10% Gd-DTPA soln	6	426 ± 28	9.3 ± 3.2 [32.4 ± 11.0]
15% Gd-DTPA soln	3	452 ± 25	13.0 ± 1.8 [45.3 ± 6.2]
Chitosan 9B			
10% Gd-DTPA soln	3	594 ± 96	4.1 ± 1.0 [14.2 ± 3.4]
Chitosan 8B

<sup>a</sup> Value shows average ± S.D. of 3–6 batches.

successively. Finally, the Gd-nanoCPs were obtained as water suspensions or powders lyophilized after suspending in isotonic mannitol solution.

This technique utilized the fact that, when two emulsions of the same type with the same continuous phase are mixed and stirred vigorously, droplets of each emulsion collide at random, coalesce and split, and all of the droplets finally become uniform in content. Thus, Gd-nanoCP generation was triggered by neutralization of the acidic chitosan-dissolving droplets of emulsion A with sodium hydroxide in the droplets of emulsion B. Nanoparticle generation consequently occurred within the emulsion droplets. The size of nanoparticles did not reflect the droplet size.

Chitosans of grade 10B (100% deacetylated), 9B (91.4% deacetylated) and 8B (84.9% deacetylated) (Katokichi Bio, Japan) were used. Table 3.5 shows the mean particle diameter and gadolinium content in Gd-nanoCPs for each chitosan grade. When chitosan 9B and 8B were used, the mean particle diameters were 594 and 750 nm, respectively, and the gadolinium contents were 4.1% and 3.3% (corresponding to 14.2% and 11.6% as Gd-DTPA), respectively. Namely, as the deacetylation degree of chitosan decreased, the particle size increased gradually and, in contrast, the Gd content decreased markedly. With chitosan 10B, Gd-nanoCPs prepared using 5% and 15% Gd-DTPA solution had mean particle diameters of 461 and 452 nm, respectively, and the gadolinium contents were 7.7% and 13.0% (corresponding to 27% and 45% as Gd-DTPA), respectively. Thus, as the Gd-DTPA concentration in the solution of chitosan 10B increased, the gadolinium content increased, but the particle size was not significantly influenced.

The crosslinking [110–115] and electrostatic interaction by anionic materials such as alginate [116, 117] have been generally used to prepare solid chitosan particles, since it is difficult to form microparticles using only chitosan and drug. In addition, the precipitation technique [118, 119] and block copolymerization [119] have been studied to produce chitosan nanoparticulate carriers in recent years. A major problem with the clinical application of nanoparticles is that the drug load is too low to deliver an effective dose; the performance of the above chitosan particles in past studies was also unexceptional. In the present emulsion-droplet coalescence technique, the Gd-DTPA appears to strongly interact electrostatically with the amino groups of chitosan in the deposition of Gd-nanoCPs. This would contribute to the extraordinarily high Gd-DTPA content (45.3%) and their small particle size, which was reduced to i.t. injectable size (452 nm), in Gd-nanoCPs prepared using chitosan 10B and 15% Gd-DTPA solution.

#### 3.4.3.2 Gd-DTPA Release Property of Gd-nanoCPs

Gd-DTPA release from Gd-nanoCPs that were prepared using chitosan 10B and 10% Gd-DTPA solution has been examined *in vitro* [109]. As test media, an isotonic phosphate-buffered saline solution (PBS) of pH 7.4 and human plasma, as a biological medium, were used, and the method was based on a dynamic dialysis. The gadolinium release behavior was significantly different between Gd-nanoCPs in PBS and those in the human plasma. Gd-nanoCPs released only 1.8% up to 7 d in PBS, whereas 67.9 and 91.5% of gadolinium were eluted from Gd-nanoCPs in human plasma for 6 and 24 h, respectively. This again suggested strong complex formation of Gd-DTPA with chitosan in a simple aqueous medium, because highly water-soluble Gd-DTPA was hardly eluted for a long time in PBS. This releasing property might be advantageous to GdNCT trial by i.t. injection into a solid tumor. The mechanism of fast release of gadolinium from Gd-nanoCPs in human plasma was not clear.

#### 3.4.3.3 Gd-DTPA Retention in Tumor Tissue after Intratumoral Injection

The quantity of gadolinium in the melanoma tissue on mice after i.t. injection of each Gd-DTPA dosage form containing 1200  $\mu\text{g}$  as gadolinium has been determined [109]. In an *in vivo* experiment, the B16F10 malignant melanoma cell suspension (0.1 mL) in an isotonic PBS containing  $3 \times 10^6$  cells was carefully inoculated subcutaneously (s.c.) into the posterior flank of a six-week-old C57BL/6 mouse. At 10 d after tumor implantation by the above procedure, 200  $\mu\text{L}$  of the Gd-nanoCP (prepared with chitosan 10B and 10% Gd-DTPA solution) suspension in isotonic mannitol solution (Gd 6000 ppm) was injected gently into a block of grown tumor that was about 10 mm in diameter (Gd dose, 1200  $\mu\text{g}$  per mouse). In parallel, the dilute Magnevist<sup>®</sup> solution (Gd 6000 ppm) was injected in the same manner. At 5 min or 24 h after i.t. injection, mice were sacrificed and tumoral blocks were excised. The amount of gadolinium in the tumor tissue was analyzed by ICP-AES after incineration.

When a dilute solution of Magnevist<sup>®</sup> was administered, the quantities of gadolinium in a tumor block were 452  $\mu\text{g}$  (37.6% of dose) and 5.3  $\mu\text{g}$  (0.4%) 5 min and

24 h after injection, respectively. In contrast, 892  $\mu\text{g}$  (74.3% of dose) and 821  $\mu\text{g}$  (68.4%) of gadolinium remained in the tumor block 5 min and 24 h after administration of Gd-nanoCP suspension, respectively. Thus, since the gadolinium hardly leaked to the surrounding normal tissues, in particular to the subcutaneous space on tumor tissue, over 24 h, damage beyond the tumor part by GdNCT would be kept to a minimum. No Gd-DTPA release from Gd-nanoCPs in the aqueous medium might contribute to prolonged retention in the tumor tissue. This extended retention was thought to lead to greater enhancement of the antitumor effect as compared with past GdNCT trials using Magnevist<sup>®</sup> [52].

#### 3.4.3.4 *In vivo* Growth Suppression of Experimental Melanoma Solid Tumor

A GdNCT trial has been carried out *in vivo* by i.t. injection using Gd-nanoCPs prepared with chitosan 10B and 10% Gd-DTPA solution [120]. The Gd-nanoCPs were 430 nm in mean particle diameter and the content of the natural form of gadolinium was 9.3 w/w %. Therefore, the content of <sup>157</sup>Gd, 15.6% of the natural form, corresponded to 1.45 w/w %. The radioresistive B16F10 malignant melanoma was selected as tumor model [121, 122] to demonstrate a potential for GdNCT.

When the s.c. B16F10 melanoma tumor in the five-week-old male C57BL/6 mice (body weight, 21–27 g) grew to about 10 mm in diameter 10 d after tumor implantation by the above procedure, i.t. administration of the Gd-nanoCP suspension in isotonic mannitol solution or Magnevist<sup>®</sup> solution as a control was started. Each gadolinium dosage form (corresponding to natural Gd 6000  $\mu\text{g mL}$ ), 200  $\mu\text{L}$ , was injected twice into the block of tumor, 24 and 8 h before neutron irradiation (total natural Gd dose, 2400  $\mu\text{g}$  per mouse). The source of the thermal neutron beams was obtained from the Kyoto University Research Reactor Institute, Japan (the Heavy Water Facility; operating power, 5 MW; irradiation time, 60 min; operating mode, OO-0011-F) [123, 124]. The measured average fluence on the tumor surface was  $6.32 \times 10^{12}$  neutrons  $\text{cm}^{-2}$ . Neutron irradiation was performed only once.

In the gadolinium-loaded nanoparticle-administered and neutron-irradiated (Gd-P, N+) group, the tumor growth was significantly suppressed despite the radioresistance of melanoma model [121, 122] and the long interval (8 h) until neutron irradiation after second gadolinium administration. Its mean tumor volume was less than 15%, compared with that in the non-gadolinium-administered and neutron-irradiated (Gd–, N+) group, 14 d after neutron irradiation. The mean time taken to reach a tumor volume ratio of 10 in the [Gd-P, N+] group was prolonged to 23.2 d, which was 227% and 374% of that in the [Gd–, N+] group and the non-gadolinium-administered and non-neutron-irradiated (Gd–, N–) group, respectively. In addition, the survival time of mice in the [Gd-P, N+] group was also significantly prolonged, to 22.2 d as the mean time. Three of the six mice in the [Gd-P, N+] group were alive at 28 d after neutron irradiation, while all mice in the other groups were dead by 21 d.

Conversely, no GdNCT effect was observed in the Magnevist<sup>®</sup> solution-administered and neutron-irradiated (Gd-S, N+) group, since the change in the tumor volume ratio and the survival time of mice did not differ from those in the [Gd–, N+] group. When the gadolinium nanoparticle or solution was adminis-

tered and there was no neutron irradiation (Gd-P or Gd-S, N-), tumor growth was not inhibited at all: the mean time to reaching a tumor volume ratio of 10 was about 6–7 d, which is no different from that in the [Gd-, N-] group.

The content of gadolinium in the tumor just at the starting point of neutron irradiation was estimated to explain the GdNCT effect enhanced by Gd-nanoCPs. When Gd-nanoCPs were administered in the same manner as that in the GdNCT trial, the gadolinium content in melanoma tissue in mice was  $1766 \pm 96 \mu\text{g}$ , corresponding to 74% of dose. However, following the administration of Magnevist<sup>®</sup> solution, the gadolinium content in the tumoral block was  $16 \pm 7 \mu\text{g}$ , corresponding to only 0.7% of dose. Clearly, the strong suppression of tumor growth observed in the present GdNCT trial with Gd-nanoCPs resulted from the excellent Gd-DTPA retention in the tumor tissue of chitosan nanoparticles after i.t. injection.

No skin damage over the tumor was apparent in [Gd-, N+] and [Gd-S, N+] groups. However, the skin over the tumor in the [Gd-P, N+] group became red for a few days after neutron irradiation and, later, ulcer formation was observed. This severe side effect demonstrated that the photons and/or electrons emitted by the frequent Gd-NCR would have a sufficient destructive effect for the tumor if selective gadolinium distribution in the tumor tissue and neutron fluence were controlled as optimally as possible in GdNCT.

In one report on a GdNCT trial, a neutral macrocyclic gadolinium complex (Gadobutrol, Gadovist<sup>®</sup>) was used as the gadolinium source and excellent results were obtained by i.t. injection [53]. The biological half-life of the wash-out from the tumor tissue after i.t. injection of Gadobutrol was estimated to be 50–151 min (average, 115 min) and might contribute to the assured antitumor effect, because it was longer than that of Magnevist<sup>®</sup> [53, 54]. In the present study, the outstanding gadolinium retention in the tumor tissue following i.t. injection of Gd-nanoCPs clearly led to the potent GdNCT effect even though the tumors were irradiated at an exceptionally longer interval after gadolinium administration compared with the usual GdNCTs with Magnevist<sup>®</sup> and Gadovist<sup>®</sup>. This property will also contribute to flexible adaptation in duration and frequency of neutron irradiation in future GdNCT trials.

In the present GdNCT trial, the dose of natural gadolinium per a tumor block with the nanoparticle formulation (2400  $\mu\text{g-Gd}$  per tumor) was considerably smaller than that in past trials [53, 54]. This gadolinium dose indicated that if gadolinium enriched to 100% of <sup>157</sup>Gd was used the corresponding level of growth inhibition could be gained by about 16% of gadolinium dose (460  $\mu\text{g}$ ) against B16F10 melanoma block about 10 mm in diameter [53].

#### 3.4.3.5 Bioadhesion and Uptake of Gd-nanoCP in Three Different Cell Lines

The extracellular matrix is composed of sulfated glycosaminoglycans and polysaccharide acids, which form hydrophilic, negatively charged gels over the cell membrane. Membrane glycoproteins, most often bearing sialic acid residues, also contribute to the negative charge of the cell surface. Chitosan, however, has the characteristics of a cationic polyelectrolyte, thereby providing a strong electrostatic interaction with negatively charged cell surfaces. Therefore, the use of cationic

polymers, such as chitosan, in preparing particulate carriers would give rise to higher drug retention in cells and tissues because of the electrostatic interaction between particle surfaces and cell surfaces. Indeed, many workers have reported that the bioadhesive properties of chitosan originate from electrostatic interaction between positively charged amino groups in chitosan and negatively charged sialic acid residues on the cell surface [125–127]. In addition, Chatelet et al. have demonstrated the role of deacetylation degree of chitosan on bioadhesive properties using chitosan film [128]. They showed that the adhesion of chitosan on fibroblasts isolated from foreskins of children was increased as the deacetylation degree of chitosan was increased. Therefore, the use of 100% deacetylated chitosan in the present Gd-nanoCPs was expected to lead to such a bioadhesive property.

L929 mouse fibroblast cells, B16F10 melanoma cells and SCC-VII squamous cell carcinoma were employed to evaluate the bioadhesion and uptake of Gd-nanoCPs in cultured cells in order to clarify the mechanism of high tumor-killing effects observed in our GdNCT trials [129]. Gd-DTPA incorporated in Gd-nanoCPs was hardly released in culture medium during the experiments.

**Transmission Electron Microscopy** Using a transmission electron microscope (TEM), L929 cells after exposure to Gd-nanoCPs were observed. Following exposure to the autoclaved Gd-nanoCP suspension in the culture medium at 37 °C for 12 h, L929 cells were washed with phosphate-buffered saline solution (PBS) to remove the free Gd-nanoCPs not adhered on and not endocytosed into the cells. The cells were then fixed with formaldehyde solution and epoxy resin, thinly sliced with a microtome, and observed by TEM.

Transmission electron micrographs of L929 cells incubated with Gd-nanoCPs for 12 h at 37 °C indicated that Gd-nanoCPs were not so stably dispersed in the culture medium because they loosely aggregated (Fig. 3.8). However, a considerable number of Gd-nanoCPs adhered to L929 cells and some of these were being endocytosed or incorporated in the cells in the form of particles.

**Effect of Gd Concentration, Incubation Time and Temperature** The amount of Gd in and on the cells after 12 h incubation was increased with increasing feed concentration of Gd (ranging from 0 to 20 ppm). At 20 ppm of applied Gd concentration, the amount of Gd reached 18  $\mu\text{g-Gd per } 10^6$  cells and this value was unchanged up to 40 ppm. However, it was experimentally confirmed that no further increase in cellular uptake and adhesion was observed beyond 40 ppm. Cationic macromolecules such as polylysine affect, in general, cell viability [130]. However, the cytotoxicity of Gd-nanoCPs against L929 cells was negligible in the range 20–40 ppm. Therefore, the following studies were performed at a Gd feed concentration of 40 ppm.

The Gd accumulation in L929 cells, B16F10 melanoma cells and SCC-VII squamous cell carcinoma incubated with Gd-nanoCPs at 37 and 4 °C was determined as a function of incubation time. The accumulation at 37 °C seemed to level off after 12 h. When incubated with Gd-nanoCPs for 12 h at 37 °C, the total Gd amounts were 18, 27 and 60  $\mu\text{g Gd per } 10^6$  cells with L929 fibroblast cells,

**Fig. 3.8.** Transmission electron micrograph of L929 fibroblast cells after exposure to Gd-nanoCPs for 12 h.

B16F10 cells and SCC-VII cells, respectively (Fig. 3.9). In contrast, the Gd accumulation at 4 °C where endocytic activity would not exist rapidly leveled off and was far lower, about 5 or less  $\mu\text{g Gd}$  per  $10^6$  cells in all three cell lines. Thus, this significantly higher cellular-accumulation at 37 °C, which would be attributed to endocytosis that was active at 37 °C but suppressed at 4 °C, indicated that endocytic

**Fig. 3.9.** Uptake and adhesion of Gd-nanoCPs or Magnevist at Gd-dose of 40 ppm in three different cell lines 12 h after exposure to the cells under a 5% CO<sub>2</sub> atmosphere at 37 °C.

uptake of Gd-nanoCPs made a major contribution to the total accumulation. The notably varied accumulation behavior of Gd in these three cell lines is attributed to their differing endocytic activity.

The size and bioadhesive property of Gd-nanoCPs is related to the endocytic uptake by the cells. Indeed, Green et al. have examined the particle size dependence of endocytosis of polyethylene particles in C3H murine peritoneal macrophages [131]. They found that polyethylene particles in the range 0.3–10  $\mu\text{m}$  in diameter were endocytosable. The size of the present Gd-nanoCPs, 430 nm, is included in this range. In addition, Lee et al. have demonstrated that a high level uptake of liposomes in J774 cells, a murine macrophage-like cell line, could be obtained by altering the lipid formulation to provide an adhesive property on their surfaces, as might be achieved by the present Gd-nanoCPs [132]. These results support the idea that the adhesion of optimally sized Gd-nanoCPs on the cell surface might be an important step in the subsequent uptake by endocytosis.

The cellular accumulation behavior observed *in vitro* may also be related to the tumor-killing effects *in vivo*. B16F10 cell-bearing mice were employed in our GdNCT trials *in vivo* as described earlier [120]. The tumor-killing effects observed in SCC-VII cell-bearing mice [133] were nearly identical to those achieved with B16F10 cell-bearing mice [120] at the same i.t. Gd dose of 2400  $\mu\text{g}$  per tumor even though the thermal neutron fluence in the GdNCT trials using SCC-VII cell-bearing mice ( $3.31 \times 10^{12}$  neutrons  $\text{cm}^{-2}$ ) was only a half of that in the cases of B16F10 cell-bearing mice ( $6.32 \times 10^{12}$  neutrons  $\text{cm}^{-2}$ ). From these results, at least one reason for the relatively higher tumor-killing effects obtained with SCC-VII cell-bearing mice *in vivo* would be their higher endocytic activity. Further, since the accumulation was almost saturated at 40 ppm of Gd in the *in vitro* studies described here, which was far lower than the Gd level in the previous GdNCT trials at a dose of 2400  $\mu\text{g}$  per tumor, it was suggested that most of Gd i.t. administered as Gd-nanoCPs might exist in tumor tissue extracellularly, as might be estimated from the TEM photograph given in Fig. 3.8, which shows the presence of agglomerates in the cultured cells.

**Comparative Studies with Magnevist<sup>®</sup>** In a comparative study using the solution system, the most important point to be emphasized again was that Gd accumulation in all cell lines utilized in the present study was mostly achieved in the form of particles by cell-surface adhesion and endocytosis of Gd-nanoCPs, though the activity more or less varied. In fact, Magnevist<sup>®</sup> solution scarcely showed intra- and extracellular Gd accumulation in any of the cell lines (Fig. 3.9). The Gd amount detected in the Magnevist<sup>®</sup> group after 12 h at 37 °C was less than 1% of that in Gd-nanoCP group (Fig. 3.9), which is probably related to the well-known fact that Magnevist<sup>®</sup> was eliminated from the tumor tissue immediately after i.t. injection [120]. Conversely, bioadhesion, endocytosis and strong Gd-DTPA-binding of optimally sized Gd-nanoCPs would significantly extend the elimination half-life of Gd i.t. administered [120]. The present results evidenced that Gd-nanoCPs have great potential to accumulate Gd into tumor tissue and/or cells, consequently leading to improved therapeutic efficiency in our GdNCT trials [120].

A major concern in past GdNCT trials using cultured cells and solution systems had been the necessity of a large amount of Gd for cell-growth suppression. Akine et al. reported that 10% survival level of the cultured Chinese hamster cells was obtained with a fluence of  $1.55 \times 10^{12}$  neutrons  $\text{cm}^{-2}$  in the presence of Gd of 5000 ppm [58]. Tokuyue et al. have evaluated the effect of radiation released during neutron capture reaction by  $^{157}\text{Gd}$  of 800 ppm,  $^{10}\text{B}$  of 51 ppm or their combination, using Magnevist<sup>®</sup> and BSH, on cell survival [134] – fluences of 1.13, 1.69 and  $0.95 \times 10^{12}$  neutrons  $\text{cm}^{-2}$  were required for 10% survival levels, respectively. Further, Hofmann et al. have demonstrated, using the Gadovist<sup>®</sup>, that at a fluence of  $3.6 \times 10^{12}$  neutrons  $\text{cm}^{-2}$  a Gd concentration of 10 mmol-Gd  $\text{L}^{-1}$ , equivalent to 1570 ppm, was required to obtain about a 52% survival level of Sk-Mel-28 cells, a melanoma cell line of human origin [53]. A possible problem of these studies was that they had to apply high Gd concentrations, because only Gd-agents that show no affinity to the tumor cells, possibly including Gadovist<sup>®</sup>, were available. As a result, cells were unable to suffer sufficient neutron-irradiation because of obstruction by the presence of excess neutron capture elements in the medium. Unlike such a solution-based formulation, Gd would be concentrated on and in cells when using the present Gd-nanoCPs. This situation is clearly favorable for obtaining effective cell-growth suppression.

It has been believed that a contact between the cells and Gd is not always necessary for the tumor cell inactivation in GdNCT, because of the long-range  $\gamma$ -rays emitted as a result of Gd-NCR. Akine and coworkers, however, have proposed that the electrons might also play an important role in the tumor-killing effect in GdNCT [58]. Therefore, the presence of Gd in the intracellular space may be rather desirable for GdNCT, since the electrons, especially Auger electrons, have a short-range and a high linear energy transfer. As shown in the present study, Gd-nanoCPs could bind to the cell surfaces, owing to their cationic nature, and subsequently be endocytosed. These intra- and extracellular accumulation behaviors would provide a compatible way to accomplish the high suppression of tumor growth in GdNCT.

### 3.5

#### Conclusions

Recently, clinical BNCT trials have often been carried out, mainly for brain tumors in Japan. It is hopeful that BNCT has been extended to other types of cancer such as head-neck and tongue cancers, with excellent treatment results being reported. In the near future, lung cancer and hepatoma are to be treated by BNCT. Proton accelerators as a source of neutron beams are also going to become a reality, instead of the nuclear reactors currently used. Success in NCT, essentially, depends on the selective tumor-accumulation of boron or gadolinium. Only BPA and BSH are now used clinically as solutions, but their selectivity in the accumulation is not necessarily high. We believe that applications of nanoparticulate “atom” delivery technologies can contribute to NCT.

## 4.1

### Introduction

## 4.1.1

#### Overview

Boron neutron capture therapy (BNCT) is based on the nuclear capture and fission reactions that occur when non-radioactive boron-10 is irradiated with low energy thermal neutrons to yield high linear energy transfer (LET) alpha particles ( $^4\text{He}$ ) and recoiling lithium-7 ( $^7\text{Li}$ ) nuclei. For BNCT to be successful, a sufficient number of  $^{10}\text{B}$  atoms ( $\sim 10^9$  atoms per cell) must be selectively delivered to the tumor and enough thermal neutrons must be absorbed by them to sustain a lethal  $^{10}\text{B}(n, \alpha) ^7\text{Li}$  capture reaction. BNCT primarily has been used to treat patients with brain tumors, and more recently those with head and neck cancer. Two low molecular weight (LMW) boron delivery agents are currently used clinically, sodium borocaptate and boronophenylalanine. However, various high molecular weight (HMW) agents consisting of macromolecules and nanovehicles have been developed. This chapter focuses on the latter, which include monoclonal antibodies, dendrimers, liposomes, dextrans, polylysine, folate receptor targeting agents, epidermal and vascular endothelial growth factors (EGF and VEGF). Procedures for introducing boron atoms into these HMW agents and their chemical properties will be discussed. *In vivo* studies on their biodistribution will be described, and the efficacy of a subset of them, which have been used for BNCT of tumors in experimental animals, will be discussed. Since brain tumors currently are the primary candidates for treatment by BNCT, delivery of these HMW agents across the blood-brain barrier presents a special challenge. Various routes of administration will be discussed, including receptor-facilitated transcytosis following intravenous admin-

istration, direct intratumoral injection and convection-enhanced delivery by which a pump is used to apply a pressure gradient to establish bulk flow of the HMW agent during interstitial infusion. Finally, we conclude with a discussion relating to issues that must be addressed if these HMW agents are to be used clinically.

#### 4.1.2

### General Background

After decades of intensive research, high grade gliomas, and specifically glioblastoma multiforme (GBM), are still extremely resistant to all current forms of therapy, including surgery, chemotherapy, radiotherapy, immunotherapy and gene therapy [1–5]. The five-year survival rate of patients diagnosed with GBM in the United States is less than a few percent [6, 7] despite aggressive treatment using combinations of therapeutic modalities. This is due to the infiltration of malignant cells beyond the margins of resection and their spread into both gray and white matter by the time of surgical resection [8, 9]. High grade gliomas are histologically complex and heterogeneous in their cellular composition. Recent molecular genetic studies of gliomas have shown how complex the development of these tumors is [10]. Glioma cells and their neoplastic precursors have biologic properties that allow them to evade a tumor-associated host immune response [11], and biochemical properties that allow them to invade the unique extracellular environment of the brain [12, 13]. Consequently, high grade supratentorial gliomas must be regarded as a whole brain disease [14]. The inability of chemo- and radiotherapy to cure patients with high grade gliomas is due to their failure to eradicate micro-invasive tumor cells within the brain. To successfully treat these tumors, therefore, strategies must be developed that can selectively target malignant cells with little or no effect on normal cells and tissues adjacent to the tumor.

BNCT is based on nuclear capture and fission reactions that occur when non-radioactive  $^{10}\text{B}$  is irradiated with low energy thermal neutrons to yield high LET alpha particles ( $^4\text{He}$ ) and recoiling  $^7\text{Li}$  nuclei. In order to be successful BNCT, sufficient  $^{10}\text{B}$  atoms ( $\sim 10^9$  atoms per cell) must be delivered selectively to the tumor and enough thermal neutrons must be absorbed by them to sustain a lethal  $^{10}\text{B}(n,\alpha)^7\text{Li}$  capture reaction. The destructive effects of these high-energy particles are limited to boron-containing cells. BNCT primarily has been used to treat high grade gliomas [15, 16], and either cutaneous primaries [17] or cerebral metastases of melanoma [18]. More recently, it also has been used to treat patients with head and neck [19, 20] and metastatic liver cancer [21, 22]. BNCT is a biologically rather than physically targeted type of radiation treatment. If sufficient amounts of  $^{10}\text{B}$  and thermal neutrons can be delivered to the target volume, the potential exists to destroy tumor cells dispersed in the normal tissue parenchyma. Readers interested in more in-depth coverage of other topics related to BNCT are referred to several recent reviews and monographs [15, 23–25]. The present chapter focuses on boron-containing macromolecules and nanovehicles as boron delivery agents.

## 4.2

## General Requirements for Boron Delivery Agents

A successful boron delivery agent should have (1) no or minimal systemic toxicity with rapid clearance from blood and normal tissues; (2) high tumor ( $\sim 20 \mu\text{g}^{-10}\text{B g}^{-1}$ ) and low normal tissue uptake; (3) high tumor:brain (T:Br) and tumor:blood (T:Bl) concentration ratios ( $>3\text{--}4:1$ ); and (4) persistence in the tumor for a sufficient period of time to carry out BNCT. At this time *no* single boron delivery agent fulfills all these criteria. However, as a result of new synthetic techniques and increased knowledge of the biological and biochemical requirements for an effective agent, several promising new boron agents have emerged, and these are described in a special issue of *Anti-Cancer Agents in Medicinal Chemistry* (6, 2, 2006). The major challenge in their development has been the requirement for specific tumor targeting to achieve boron concentrations sufficient to deliver therapeutic doses of radiation to the tumor with minimal normal tissue toxicity. The selective destruction of GBM cells in the presence of normal cells represents an even greater challenge than malignancies at other anatomic sites.

## 4.3

## Low Molecular Weight Delivery Agents

In the 1950s and early 1960s clinical trials of BNCT were carried out using boric acid and some of its derivatives as delivery agents. These simple chemical compounds had poor tumor retention, attained low T:Br ratios and were non-selective [26, 27]. Among the hundreds of low-molecular weight boron-containing compounds that were synthesized, two appeared to be promising. One, based on aryl-boronic acids [28], was L-4-dihydroxyborylphenylalanine, referred to as boronophenylalanine or BPA (Fig. 4.1, 1). The second, a polyhedral borane anion, was

**Fig. 4.1.** Structure of two compounds used clinically for BNCT, dihydroxyborylphenylalanine or boronophenylalanine (BPA, 1) and disodium borocaptate (BSH, 2), and the isocyanato polyhedral borane (3), which has been used to heavily boronate dendrimers.

sodium mercaptoundecahydro-*closo*-dodecaborate [29], more commonly known as sodium borocaptate or BSH (2). These two compounds persisted longer in animal tumors than did related molecules, attained T:Br and T:Bi boron ratios > 1 and had low toxicity.  $^{10}\text{B}$ -enriched BPA, complexed with fructose to improve its water solubility, and BSH have been used clinically for BNCT of brain, as well as extracranial tumors. Although their selective accumulation in tumors is not ideal, the safety of these two drugs following i.v. administration has been well established [30, 31].

#### 4.4

#### High Molecular Weight Boron Delivery Agents

High molecular weight (HMW) delivery agents usually contain a stable boron group or cluster linked via a hydrolytically stable bond to a tumor-targeting moiety, such as monoclonal antibodies (mAbs) or low molecular weight receptor targeting ligands. Examples of these include epidermal growth factor (EGF) or the mAb cetuximab (IMC-C225) to target the EGF receptor or its mutant isoform EGFRvIII, which are overexpressed in various malignant tumors, including gliomas and squamous cell carcinomas of the head and neck [32]. Agents that are to be administered systemically should be water soluble, but lipophilicity is important in order to cross the blood–brain barrier (BBB) and diffuse within the brain and the tumor. There should be a favorable differential in boron concentrations between tumor and normal brain, thereby enhancing their tumor specificity. Their amphiphilic character is not as crucial for LMW agents that target specific biological transport systems and/or are incorporated into nanovehicles such as liposomes. Molecular weight also is an important factor, since it determines the rate of diffusion both within the brain and the tumor. Detailed reviews of the state-of-the-art of compound development for BNCT have been published [33, 34]. The present chapter focuses on boron-containing macromolecules and liposomes as delivery agents for BNCT, and how they can be most effectively administered.

#### 4.5

#### Dendrimer-related Delivery Agents

##### 4.5.1

##### Properties of Dendrimers

Dendrimers are synthetic polymers with a well-defined globular structure. They are composed of a core molecule, repeat units that have three or more functionalities, and reactive surface groups (Fig. 4.2) [35, 36]. Two techniques have been used to synthesize these macromolecules: divergent growth outwards from the core [37], or convergent growth from the terminal groups inwards towards the core [36, 38]. Regular and repeated branching at each monomer group gives rise to a symmetric structure and pattern to the entire globular dendrimer. Dendrimers are an attrac-

**Fig. 4.2.** Structure of a boronated PAMAM dendrimer that has been linked to targeting moieties. PAMAM dendrimers consist of a core, repeating polyamido amino units, and reactive terminal groups. Each successfully higher generation of PAMAM dendrimer has a

geometrically incremental number of terminal groups. Dendrimers have been boronated by reaction with water-soluble isocyanato polyhedral boranes and subsequently attached to targeting moieties by means of heterobifunctional linkers.

tive platform for macromolecular imaging and gene delivery because of their low cytotoxicity and their multiple types of reactive terminal groups [36, 39–44].

#### 4.5.2

#### Boronated Dendrimers Linked to Monoclonal Antibodies

##### 4.5.2.1 Boron Clusters Directly Linked to mAb

Monoclonal antibodies have been attractive targeting agents for delivering radio-nuclides [45], drugs [46–50], toxins [51] and boron to tumors [52–55]. Before the introduction of dendrimers as boron carriers, boron compounds were directly attached to mAbs [53, 54]. Approximately  $\sim 10^9$   $^{10}\text{B}$  atoms per cell ( $\sim 20 \mu\text{g g}^{-1}$  tumor) must be delivered to kill tumor cells [55, 56]. Based on the assumption of  $10^6$  antigenic receptor sites per cell,  $\sim 50$ – $100$  boron cage structures of carboranes, or polyhedral borane anions and their derivatives must be linked to each mAb molecule to deliver the required amount of boron for NCT. The attachment of such a large number of boron cages to a mAb may result in precipitation of the bioconjugate or a loss of its immunological activity. Solubility can be improved by inserting a water-soluble gluconamide group into the protein-binding boron cage compounds, thereby enhancing their water solubility [57]. This modification makes it possible to incorporate up to 1100 boron atoms into a human gamma globulin (HGG) molecule without any precipitation. Other approaches to enhance solubility include the use of negatively charged carboranes [58] or polyhedral borane anions [59], as well as the insertion of carbohydrate groups [60, 61]. A major limitation of using an agent containing a single boron cage is that many sites must be modified to deliver  $10^3$  boron atoms per molecule of antibody and this can reduce its immunoreactivity activity. Alam et al. have shown that attachment of an average of

1300 boron atoms to mAb 17-1A, which is directed against human colorectal carcinoma cells, resulted in a 90% loss of immunoreactivity [62].

#### 4.5.2.2 Attachment of Boronated Dendrimers to mAb

Dendrimers are one of the most attractive polymers that have been used as boron carriers due to their well-defined structure and multiple reactive terminal groups. Depending on the antigen site density, ~1000 boron atoms need to be attached per molecule of dendrimer and subsequently linked to the mAb. In our first study, second- and fourth-generation polyamido amino (PAMAM or “starburst”) dendrimers, which have 12 and 48 reactive terminal amino groups, respectively, were reacted with the water-soluble isocyanato polyhedral borane [Na(CH<sub>3</sub>)<sub>3</sub>NB<sub>10</sub>H<sub>8</sub>NCO] (3, Fig. 4.1) [63, 64]. The boronated dendrimer then was linked to the mAb IB16-6, which is directed against the murine B16 melanoma, by means of two heterobifunctional linkers, *m*-maleimidobenzoyl-*N*-hydroxysulfosuccinimide ester (sulfo-MBS) and *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) [63, 65]. However, following intravenous (i.v.) administration, large amounts of the bioconjugate accumulated in the liver and spleen and it was concluded that random conjugation of boronated dendrimers to a mAb could alter its binding affinity and biodistribution. To minimize the loss of mAb reactivity, a 5<sup>th</sup> generation PAMAM dendrimer was boronated with the same polyhedral borane anion, and more recently it was site-specifically linked to the anti-EGFR mAb cetuximab (or IMC-C225) or the EGFRvIII specific mAb L8A4 (Fig. 4.3). Cetuximab was linked via glycosidic moieties in the Fc region by means of two heterobifunctional reagents, SPDP and *N*-( $\kappa$ -maleimidoundecanoic acid) hydrazide (KMUH) [66, 67]. The resulting bioconjugate, designated C225-G5-B<sub>1100</sub>, contained ~1100 boron atoms per molecule of cetuximab and retained its aqueous solubility in 10% DMSO and its *in vitro* and *in vivo* immunoreactivity. As determined by a competitive binding assay, there was a <1 log unit decrease in affinity for EGFR(+) glioma cell line F98<sub>EGFR</sub>, compared to that of unmodified cetuximab [66]. *In vivo* biodistribution studies, carried out 24 h after intratumoral (i.t.) administration of the bioconjugate, demonstrated that 92.3  $\mu\text{g g}^{-1}$  of boron was retained in rats bearing F98<sub>EGFR</sub> gliomas compared to 36.5  $\mu\text{g g}^{-1}$  in EGFR(-) F98 parental tumors and 6.7  $\mu\text{g g}^{-1}$  in normal brain [67] thereby indicating specific molecular targeting of the receptor.

### 4.5.3

#### Boronated Dendrimers Delivered by Receptor Ligands

##### 4.5.3.1 Epidermal Growth Factors (EGF)

Due to its increased expression in various human tumors, including high grade gliomas, and its low or undetectable expression in normal brain, EGFR is an attractive target for cancer therapy [68–70]. As described above, targeting of EGFR has been carried out using either mAbs or alternatively, as described in this section, EGF, which is a single-chain, 53-mer heat- and acid-stable polypeptide. It binds to a transmembrane glycoprotein with tyrosine kinase activity, which triggers dimeri-

**Fig. 4.3.** Conjugation scheme for linking a boron-containing dendrimer to the monoclonal antibody C225 (cetuximab), which is directed against EGFR [66, 69].

zation and internalization [71, 72]. Since the EGF boron bioconjugates have a much smaller MW than mAb conjugates, they should be capable of more rapid and effective tumor targeting than mAbs [69, 73].

The procedure used to conjugate EGF to a boronated dendrimer was slightly different from that used to boronate mAbs. A fourth-generation PAMAM dendrimer was reacted with the isocyanato polyhedral borane  $\text{Na}(\text{CH}_3)_3\text{NB}_{10}\text{H}_8\text{NCO}$ . Next, reactive thiol groups were introduced into the boronated dendrimer using SPDP, and EGF was derivatized with *m*-maleimidobenzoyl-*N*-hydroxysulfosuccinimide ester (MBS). Reaction of the thiol groups of the derivatized, boronated dendrimer with maleimide groups produced stable BSD-EGF bioconjugates, which contained ~960 atoms of boron per molecule of EGF [74]. The BSD-EGF initially was bound to the cell surface membrane and then was endocytosed, which resulted in accumulation of boron in lysosomes [74]. Subsequently, *in vitro* and *in vivo* studies were carried out to evaluate the potential efficacy of the bioconjugate as a boron delivery agent for BNCT [73]. As will be described in more detail later below (Section 4.9.3), therapy studies demonstrated that F98<sub>EGFR</sub> glioma bearing rats that received either boronated EGF or mAb by either direct i.t. injection or convection-enhanced delivery into the brain had a longer mean survival time than animals bearing F98 parental tumors following BNCT [75–77].

#### 4.5.3.2 Folate Receptor Targeting Agents

Folate receptor (FR) is overexpressed on various human cancers, including those originating in ovary, lung, breast, endometrium and kidney [78–80]. Folic acid (FA) is a vitamin that is transported into cells via FR-mediated endocytosis. The attachment of FA via its  $\gamma$ -carboxylic function to other molecules does not alter its endocytosis by FR-expressing cells [81]. FR targeting has been used successfully to deliver protein toxins, chemotherapeutic, radio-imaging, therapeutic and MRI contrast agents [82], liposomes [83], gene transfer vectors [84], antisense oligonucleotides [85], ribozymes and immunotherapeutic agents to FR-positive cancers [86]. To deliver boron compounds, FA was conjugated to heavily boronated 3<sup>rd</sup> generation PAMAM dendrimers containing poly(ethylene glycol) (PEG) [87]. PEG was introduced into the bioconjugate to reduce its uptake by the reticuloendothelial system (RES) and, more specifically, the liver and spleen. Folate linked to 3<sup>rd</sup> generation PAMAM dendrimers containing 12–15 decaborate clusters and 1–1.5 PEG<sub>2000</sub> units had the lowest hepatic uptake in C57Bl/6 mice (7.2–7.7% injected dose [ID] per gram of liver). *In vitro* studies using FR (+) KB cells have demonstrated receptor-dependent uptake of the bioconjugate. Biodistribution studies with this conjugate, carried out in C57Bl/6 mice bearing subcutaneous (s.c.) implants of the FR (+) murine sarcoma 24JK-FBP, demonstrated selective tumor uptake (6.0% ID per g tumor), but there was high hepatic (38.8% ID per g) and renal (62.8% ID per g) uptake [87].

#### 4.5.3.3 Vascular Endothelial Growth Factor (VEGF)

There is preclinical and clinical evidence indicating that angiogenesis plays a major role in the growth and dissemination of malignant tumors [88, 89]. Inhibition of angiogenesis has yielded promising results in several experimental animal tumor

models [90, 91]. The most important molecular targets have been vascular endothelial growth factor (VEGF) and its receptor (VEGFR) [92, 93]. We recently have constructed a targeting vehicle consisting of a human VEGF<sub>121</sub> isoform fused to a novel 15-aa cysteine-containing tag designed for site-specific conjugation of therapeutic and diagnostic agents [94] (Fig. 4.4). A boronated 5<sup>th</sup> generation PAMAM dendrimer (BD), tagged with a near-infrared (IR) fluorescent dye Cy5, was conjugated using the heterobifunctional reagent sulfo-LC-SPDP to BD/Cy5 via reactive SH-groups, which was generated in the VEGF fusion protein by mild dithiothreitol (DTT) treatment. The bioconjugate, designated VEGF-BD/Cy5, contained 1050–1100 boron atoms per dimeric VEGF molecule. VEGF-BD/Cy5 retained the *in vitro* functional activity of VEGF<sub>121</sub>, which was similar to that of native VEGF. Tagging the bioconjugate with Cy5 dye permitted near-IR fluorescence imaging of its *in vitro* and *in vivo* uptake. *In vitro* uptake was determined by incubating VEGF-BD/Cy5 with VEGFR-2 overexpressing PAE/KDR cells and *in vivo* uptake was evaluated in mice bearing s.c. tumor implants. *In vitro*, the bioconjugate localized in the perinuclear region and *in vivo* it primarily localized in regions of active angiogenesis. Furthermore, depletion of VEGFR-2 overexpressing cells from the tumor vasculature with VEGF-toxin fusion protein significantly decreased bioconjugate uptake, indicating that these cells were the primary targets of VEGF-BD/Cy5. These studies demonstrated that VEGF-BD/Cy5 potentially could be used as a diagnostic agent [94]. Further studies are planned to evaluate its therapeutic efficacy using the F98 rat glioma model, which we have used extensively to evaluate both low and high MW boron delivery agents [95].

#### 4.5.4

##### Other Boronated Dendrimers

An alternative method to deliver boron compounds by means of dendrimers is to incorporate carborane cages within the dendrimer (Fig. 4.5). Parrott et al. have reported that 4, 8 or 16 carboranes could be inserted into an aliphatic polyester dendrimer by means of a highly effective synthon, a bifunctional carborane derivative with an acid group and a benzyl ether protected alcohol [96]. The procedure employed a divergent synthesis with high yield. The resulting polyhydroxylated dendrimer was water soluble with a minimum ratio of eight hydroxyl groups per carborane cage. Carborane-containing dendrimers potentially could be used as boron delivery agents for BNCT, since it is possible to control the number of carborane moieties and overall solubility.

#### 4.6

##### Liposomes as Boron Delivery Agents

#### 4.6.1

##### Overview of Liposomes

Liposomes are biodegradable, non-toxic vesicles that have been used to deliver both hydrophilic and hydrophobic agents (Fig. 4.6) [97]. Both classical and PEGylated

**Fig. 4.4.** Preparation of a vascular endothelial growth factor (VEGF) receptor targeting nanovehicle (VEGF-BD/Cy5). (A) A fifth-generation (G5) PAMAM dendrimer is initially reacted with SPDP and the near-infrared dye Cy5-NHS dissolved in a dimethylformamide-methanol mixture for 1 h. (B) Reaction with the polyisocyanato polyhedral borane  $\text{Na}(\text{CH}_3)_3\text{-NB}_{10}\text{H}_8\text{NCO}$  in a carbonate buffer

(pH 9.0)/9% acetone mixture for 24 h. (C) A 1.5-fold molar excess of DTT is added to the VEGF monomer in a solution containing  $20 \text{ mmol L}^{-1}$  NaOAc (pH 6.5),  $0.5 \text{ mol L}^{-1}$  urea and  $0.5 \text{ mol L}^{-1}$  NDSB-221 and incubated at  $4^\circ\text{C}$  for 16 h. (D) The boronated dendrimer is incubated with the targeting vehicle for 15 min to produce the VEGF-BD/Cy5 [94].

**Fig. 4.5.** Structure of a carborane-containing aliphatic polyester dendrimer. Carborane cages were incorporated into the interior of the dendrimer structure and the peripheral hydrophilic groups improved water solubility and were available for modification.

**Fig. 4.6.** Schematic structure of a liposome that has an aqueous core and a lipid bilayer membrane. The latter is composed of polar head groups with hydrocarbon tails. The

liposomal surface can be modified by PEGylation to prolong its circulation time and can be linked to either a mAb or a ligand for targeting.

(“stealth”) liposomes can increase the amounts of anticancer drugs that can be delivered to solid tumors by passive targeting. Rapidly growing solid tumors have increased permeability to nanoparticles due to increased capillary pore size. These can range from 100 to 800 nm compared to 60–80 nm for those in normal tissues, which are impermeable to liposomes. In addition, tumors lack efficient lymphatic drainage, and, consequently, clearance of extravasated liposomes is slow [98]. Modification of the liposomal surface by PEGylation or attachment of antibodies or receptor ligands will improve their selective targeting and increase their circulation time [98].

#### 4.6.2

### Liposomal Encapsulation of Sodium Borocaptate and Boronophenylalanine

#### 4.6.2.1 Boron Delivery by Non-targeted Liposomes

Liposomes have been extensively evaluated as nanovehicles for the delivery of boron compounds for NCT [99, 100]. *In vitro* and *in vivo* studies have demonstrated that they can effectively and selectively deliver large quantities of boron to tumors and that the compounds delivered by liposomes have a longer tumor retention time. BPA is an amino acid analogue that is preferentially taken up by cells with increased metabolic activity, such as tumor cells of varying histopathologic types, including melanomas [31, 101], gliomas [102] and squamous cell carcinomas [103, 104]. Because of its low aqueous solubility, BPA has been used as a fructose complex, which has permitted it to be administered i.v. rather than orally [105, 106]. Following i.v. administration of BPA, which had been incorporated into conventional liposomes, there was rapid elimination by the reticuloendothelial system (RES) with very low blood and liver boron concentrations at 3 h. In contrast, if BPA was incorporated into liposomes composed of DSPE-PEG, therapeutically useful tumor boron concentrations ( $>20 \mu\text{g g}^{-1}$ ) were seen at 3 and at 6 h, indicating that PEG-liposomes had evaded the RES [107]. In addition, BPA has been incorporated into the lipid bilayer of liposomes, composed of either the positively charged lipid 1,2-dioleoyl-3-trimethylammonium propane (DOTAP) or the zwitterionic lipid, 1,2-dioleoyl-*sn*-glycerol-3-phosphoethanolamine (DOPE) [108]. Cationic liposomes have been widely used as carriers of biomolecules that specifically target the cell nucleus [109], which would be advantageous for BNCT. Another clinically used drug, sodium borocaptate (BSH), has been incorporated into liposomes composed of DPPC/Chol in a 1:1 molar ratio with or without PEG stabilization [110]. The average diameter of liposomes containing BSH was in the range 100–110 nm. Both types of liposomes resulted in a significant improvement in their circulation time compared with that of free BSH. At 24 h following i.v. injection of PEG-liposomes, 19% of the injected dose of boron was in the blood compared with 7% following formulation of BSH in conventional liposomes. The mean percent uptake by the liver and spleen was not significantly different for the two types of liposomes. However, the blood:RES ratios were higher for PEG-liposomes at all time points, indicating that a higher fraction of the injected dose of BSH was still in the blood. Ji et al. have reported that there were no significant differences in the *in vitro* up-

take by 9L gliosarcoma cells of free BSH versus a liposomal formulation after 16 h incubation. However, cellular persistence was increased at 12 and 24 h for BSH-loaded liposomes [111]. BSH has also been incorporated into transferrin (TF) conjugated PEG liposomes (TF-PEG liposomes) [112], which then were taken up by cells via transferrin receptor-mediated endocytosis. Intravenous administration of this formulation increased boron retention at the tumor site compared with PEG liposomes, bare liposomes or free BSH, and suppressed tumor growth following BNCT. These results suggest that TF-targeted liposomes might be a useful intracellular targeting vehicle.

#### 4.6.2.2 Liposomal Encapsulation of other Boranes and Carboranes

Polyhedral boranes [34] and carboranes [113, 114] are another class of boron compounds that have been used for NCT. They contain multiple boron atoms per molecule, are resistant to metabolic degradation, and are lipophilic, thereby permitting easier penetration of the tumor cell membrane [113]. In addition to BSH, carboranylpropylamine (CPA, Fig. 4.7, 4) [115] has been incorporated into conventional and PEGylated liposomes by active loading, using a transmembrane pH gradient [115, 116]. Although as many as 13 000 molecules of CPA were loaded into liposomes having a mean average diameter of 100 nm, there was *in vitro* toxicity to both the glioblastoma cell line SK-MG-1 and normal human peripheral blood lymphocytes. Borane anions, such as  $B_{10}H_{10}^{2-}$ ,  $B_{12}H_{11}SH^{2-}$ ,  $B_{20}H_{17}OH^{4-}$  and  $B_{20}H_{19}^{3-}$ , and the normal form and photoisomer of  $B_{20}H_{18}^{2-}$ , also have been encapsulated into small unilamellar vesicles with mean diameters of 70 nm or less [117–120]. These were composed of the pure synthetic phospholipids, distearoyl phosphatidylcholine and cholesterol [117]. Although encapsulation efficiencies were only 2–3%, following *i.v.* injection these liposomes were selectively delivered to tumors in mice bearing the EMT6 mammary carcinoma and had attained boron concentrations of  $>15 \mu\text{g-B g}^{-1}$ , with a T:Bl ratio of  $>3$ . Two isomers of  $B_{20}H_{18}^{2-}$  attained boron concentrations of 13.6 and  $13.9 \mu\text{g g}^{-1}$  with T:Bl ratios of 3.3 and 12, respectively, at 48 h following administration. The high boron retention and prolongation of their circulation time was due to interaction with intracellular components after it had been released from liposomes within tumor cells [117].

To examine the effect of charge and substitution on the retention of boranes the two isomers  $[B_{20}H_{17}NH_3]^{3-}$  and  $[1-(2'-B_{10}H_9)-2-NH_3B_{10}H_8]^{3-}$  (5) have been prepared from the polyhedral borane anion  $[n-B_{20}H_{18}]^{2-}$  (6) [118, 119]. The sodium salts of these two isomers had been encapsulated within small unilamellar liposomes, composed of distearoyl phosphatidylcholine/cholesterol at a 1:1 ratio. Both isomers of  $[B_{20}H_{17}NH_3]^{3-}$  had excellent tumor uptake and selectivity in EMT 6 tumor bearing mice, even at very low injected doses, and this resulted in peak tumor boron concentrations of  $30\text{--}40 \mu\text{g-B g}^{-1}$  and a T:Bl ratio of  $\sim 5$ . Owing to low boron retention of liposomal  $Na_3[B_{20}H_{19}]$  and  $Na_4[e^2-B_{20}H_{17}OH]$  and rapid clearance of liposomal  $[2-NH_3B_{10}H_9]^-$ , the enhanced retention of liposomal  $Na_3[ae-B_{20}H_{17}NH_3]$  was not due to the anionic charge or substitution in the borane cage. Rather, it could be attributed to facile intracellular oxidation to an extremely re-

**Fig. 4.7.** Structures of hydrophilic and lipophilic boron-containing compounds incorporated into liposomes. Carboranylpropylamine (CPA, **4**), [1-(2'-B<sub>10</sub>H<sub>9</sub>)-2-NH<sub>3</sub>B<sub>10</sub>H<sub>8</sub>]<sup>3-</sup> (**5**), [n-B<sub>20</sub>H<sub>18</sub>]<sup>2-</sup> (**6**), [B<sub>20</sub>H<sub>17</sub>SH]<sup>4-</sup> (**7**), Na<sub>3</sub>[α2-B<sub>20</sub>H<sub>17</sub>NH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NH<sub>2</sub>] (**9**) and boronated

water-soluble acridine (WSA, **11**) have been encapsulated into the aqueous core. K[nido-7-CH<sub>3</sub>(CH<sub>2</sub>)<sub>15</sub>-7,8-C<sub>2</sub>B<sub>9</sub>H<sub>11</sub>] (**8**) and cholesteryl 1,12-dicarba-*closo*-dodecaborane-1-carboxylate (**10**) have been incorporated into the lipid bilayer of liposomes.

active  $\text{NH}_3^{3-}$  substituted  $[\text{n-B}_{20}\text{H}_{18}]^{2-}$  electrophilic anion,  $[\text{B}_{20}\text{H}_{17}\text{NH}_3]^-$ . Another anion,  $[\text{ae-B}_{20}\text{H}_{17}\text{NH}_3]^{3-}$ , also was encapsulated into liposomes prepared with 5% PEG-2000-distearoyl phosphatidylethanolamine as a constituent of the membrane. These liposomes had longer *in vivo* circulation times, which resulted in continued accumulation of boron in the tumor over the entire 48 h, and reached a maximum concentration of 47  $\mu\text{g-B}$  per g tumor.

$[\text{B}_{20}\text{H}_{17}\text{SH}]^{4-}$  (7), a thiol derivative of  $[\text{B}_{20}\text{H}_{18}]^{4-}$ , possesses a reactive thiol substituent that can be oxidized to give the more reactive  $[\text{B}_{20}\text{H}_{17}\text{S}]^{2-}$  anion. Both species were considered to be essential for high tumor boron retention [120] and they have been encapsulated into small, unilamellar liposomes. Biodistribution was determined after i.v. injection into BALB/c mice bearing EMT6 tumors. At low injected doses, tumor boron concentrations increased throughout the experiment, resulting in a maximum concentration of 47  $\mu\text{g-B}$  per g tumor at 48 h, which corresponded to 22.2% ID  $\text{g}^{-1}$  and a T:Bl ratio of 7.7. This was the most promising of the polyhedral borane anions that had been investigated for liposomal delivery. Although they were able to deliver adequate amounts of boron to tumor cells, their application to BNCT has been limited due to their low incorporation efficiency ( $\sim 3\%$ ).

Lipophilic boron compounds incorporated into the lipid bilayer would be an alternative approach. Small unilamellar vesicles composed of a 3:3:1 ratio of distearoylphosphatidylcholine, cholesterol and  $\text{K}[\text{nido-7-CH}_3(\text{CH}_2)_{15}\text{-7,8-C}_2\text{B}_9\text{H}_{11}]$  (8) in the lipid bilayer and  $\text{Na}_3[\text{a2-B}_{20}\text{H}_{17}\text{NH}_2\text{CH}_2\text{CH}_2\text{NH}_2]$  (9) in the aqueous core were produced as a delivery agents for NCT-mediated synovectomy [121]. Biodistribution studies were carried out in Louvain rats that had a collagen-induced arthritis. The maximum synovial boron concentration was 29  $\mu\text{g}$  per gram of tissue at 30 h and this had only decreased to 22  $\mu\text{g g}^{-1}$  at 96 h following i.v. administration. The prolonged retention by synovium provided sufficient time for extensive clearance of boron from other tissues so that at 96 h the synovium: blood (Syn:Bl) ratio was 3.0. To accelerate blood clearance, serum stability of the liposomes was lowered by increasing the proportion of compound 8 embedded in the lipid bilayer. Liposomes were formulated with a 3:3:2 ratio DSPE:Ch:8 in the lipid bilayer and 9 was encapsulated in the aqueous core. The boron concentration in the synovium reached a maximum of 26  $\mu\text{g g}^{-1}$  at 48 h with a Syn:Bl ratio of 2, following which it slowly decreased to 14  $\mu\text{g g}^{-1}$  at 96 h, at which time the Syn:Bl ratio was 7.5 [121].

Another method to deliver hydrophilic boron-containing compounds would be to incorporate them into cholesterol to target tumor cells expressing amplified low density lipoprotein (LDL) receptors [122–124]. Glioma cells, which absorb more cholesterol, have been reported to take up more LDL than the corresponding normal tissue cells [125–127]. The cellular uptake of liposomal cholesteryl 1,12-dicarba-*closo*-dodecaborane-1-carboxylate (10) by two fast-growing human glioma cell lines, SF-763 and SF-767, was mediated via the LDL receptor and was much higher than that of human neurons. The cellular boron concentration was  $\sim 10\text{--}11\times$  greater than that required for BNCT [128].

## 4.6.3

**Boron Delivery by Targeted Liposomes**

To improve the specificity of liposomally encapsulated drugs and to increase the amount of boron delivered, targeting moieties have been attached to the surface of liposomes. These could be any molecules that selectively recognized and bound to target antigens or receptors that were overexpressed on neoplastic cells or tumor-associated neovasculature. These have included either intact mAb molecules or fragments, and low molecular weight, naturally occurring or synthetic ligands such as peptides or receptor-binding ligands such as EGF. To date, liposomes linked to mAbs or their fragments [129], EGF [130], folate [131] and transferrin [112] have been the most extensively studied as targeting moieties (Fig. 4.8).

**4.6.3.1 Immunoliposomes**

The murine anti-carcinoembryonic antigen (CEA) mAb 2C-8 has been conjugated to large multilamellar liposomes containing  $^{10}\text{B}$  compounds [132, 133]. The maximum number of  $^{10}\text{B}$  atoms attached per molecule of mAb was  $\sim 1.2 \times 10^4$ . These immunoliposomes bound selectively to the human pancreatic carcinoma cell line, AsPC-1, that overexpressed CEA. Incubating the immunoliposomes with either MRKnu/nu-1 or AsPC-1 tumor cells suppressed *in vitro* tumor cell growth follow-

**Fig. 4.8.** Proposed mechanism of intracellular boron delivery based on receptor-mediated tumor cell targeting. Liposomes loaded with a boron compound (A) are conjugated to a targeting ligand (e.g., folate, transferrin, or anti-EGFR antibody). These bind to receptors on the cell surface (B), and are then

internalized by receptor-mediated endocytosis (C) into the acidified endosomal/lysosomal compartment. The boron compound is then released (D) into the cytosol by liposomal degradation, endosome/lysosome disruption or liposome-endosome/lysosome membrane fusion.

ing thermal neutron irradiation [134]. This was dependent upon the liposomal concentration of the  $^{10}\text{B}$ -compound and on the number of molecules of mAb conjugated to the liposomes. Immunoliposomes containing either  $(\text{Et}_4\text{N})_2\text{B}_{10}\text{H}_{10}$  and linked to the mAb MAb 2, directed against human gastric cancer [135, 136] or water-soluble boronated acridine (WSA, 11; Fig. 4.7) linked to trastuzumab, directed against HER-2, have been prepared and evaluated *in vitro* [129]. There was specific binding and high uptake of these immunoliposomes, which delivered a sufficient amount of  $^{10}\text{B}$  to produce a tumoricidal effect following thermal neutron irradiation.

#### 4.6.3.2 Folate Receptor-targeted Liposomes

A highly ionized boron compound,  $\text{Na}_3\text{B}_{20}\text{H}_{17}\text{NH}_3$ , has been incorporated into liposomes by passive loading [131, 137, 138]. This showed high *in vitro* uptake by the FR-expressing human cell line KB (American Type Culture Collection CCL 17), which originally was thought to be derived from a squamous cell carcinoma of the mouth, and subsequently was shown to be identical to HeLa cells, as determined by isoenzyme markers, DNA fingerprinting and karyotypic analysis. KB-tumor-bearing mice that received either FR-targeted or non-targeted control liposomes had equivalent tumor boron values ( $\sim 85 \mu\text{g g}^{-1}$ ), which attained a maximum at 24 h, while the T:Bl ratio reached a maximum at 72 h. Additional studies were carried out with the lipophilic boron compound  $\text{K}[\text{nido-7-CH}_3(\text{CH}_2)_{15}\text{-7,8-C}_2\text{B}_9\text{H}_{11}]$  (8). This was incorporated into large unilamellar vesicles,  $\sim 200$  nm in diameter, composed of egg PC/chol/8 in a 2:2:1 mol/mol ratio, and an additional 0.5 mol% of folate-PEG-DSPE or PEG-DSPE for the FR-targeted or non-targeted liposomal formulations [139]. Boron uptake by FR-overexpressing KB cells, treated with these targeted liposomes, was  $\sim 10\times$  greater compared with those treated with control liposomes. In addition, BSH and five weakly basic boronated polyamines were evaluated (Fig. 4.9). Two of these were the spermidine derivatives  $N^5$ -(4-carboranylbutyl)spermidine  $\cdot 3\text{HCl}$  (12) and  $N^5$ -[4-(2-aminoethyl-*o*-carboranyl)butyl]spermidine  $\cdot 4\text{HCl}$  (13). Three were the spermine derivatives  $N^5$ -(4-*o*-carboranylbutyl)spermine  $\cdot 4\text{HCl}$  (14),  $N^5$ -[4-(2-aminoethyl-*o*-carboranyl)butyl]spermine  $\cdot 5\text{HCl}$  (15), and  $N^5, N^{10}$ -bis(4-*o*-carboranylbutyl)spermine  $\cdot 4\text{HCl}$  (16). These were incorporated into liposomes by a pH-gradient-driven remote-loading method with varying loading efficiencies, which were influenced by the specific trapping agent and the structure of the boron compound. Greater loading efficiencies were obtained with lower molecular weight boron derivatives, using ammonium sulfate as the trapping agent, compared with those obtained with sodium citrate.

#### 4.6.3.3 EGFR Targeted Liposomes

Acridine is a water-soluble (WS) DNA-intercalator. Its boronated derivative WSA has been incorporated into liposomes composed of EGF-conjugated lipids. Their surface contained  $\sim 5$  mol% PEG and 10–15 molecules of EGF, and  $10^4$ – $10^5$  of the WSA molecules were encapsulated. These liposomes had EGFR-specific cellular binding to cultured human glioma cells [130, 140] and were internalized following specific binding to the receptor. Following internalization, WSA, primarily, was

**Fig. 4.9.** Structures of five weakly basic boronated polyamines encapsulated in FR targeting liposomes. The two spermidine (**12**, **13**) and three spermine derivatives (**14**–**16**), which contain hydrophilic amine groups and lipophilic carboranyl cages, had DNA-binding properties.

localized in the cytoplasm, and had high cellular retention, with 80% of the boron remaining cell-associated after 48 h [141].

#### 4.7 Boron Delivery by Dextrans

Dextrans are glucose polymers that consist mainly of a linear  $\alpha$ -1,6-glucosidic linkage with some degree of branching via a 1,3-linkage [142, 143]. Dextrans have been

used extensively as drug and protein carriers to increase drug circulation time [144, 145]. In addition, native or chemically-modified dextrans have been used for passive targeting to tumors, the RES or active receptor-specific cellular targeting. To link boron compounds to dextrans [146],  $\beta$ -decachloro-*o*-carborane derivatives, in which one of the carbon atoms is substituted by  $-\text{CH}_2\text{CHOHCH}_2\text{-O-CH}_2\text{CH=CH}_2$ , have been epoxidized and subsequently bound to dextran, with a resulting boron content of 4.3% (w/w) [147]. The modified dextran could then be attached to tumor-specific antibodies [147–150]. BSH has been covalently coupled to dextran derivatives by two methods [151]. In the first, dextran was activated with 1-cyano-4-(dimethylamino)pyridine (CDAP) and subsequently coupled with 2-aminoethyl pyridyl disulfide. Then, thiolated dextran was linked to BSH in a disulfide exchange reaction. A total of 10–20 boron cages were attached to each dextran chain. In the second method, dextran was derivatized to a multiallyl derivative (Fig. 4.10, 17), which was reacted with BSH in a free-radical-initiated addition reaction. Using this method, 100–125 boron cages could be attached per dextran chain, suggesting

**Fig. 4.10.** Preparation of EGF-targeted, boronated dextrans. The bioconjugate was prepared by a free-radical-initiated addition reaction between multiallyl dextran derivatives and BSH or thiolated EGF at 50 °C using  $\text{K}_2\text{S}_2\text{O}_8$  as an initiator.

that this derivative might be a promising template for the development of other HMW delivery agents. By the second method, designed to target EGFR over-expressing cells, EGF and BSH have been covalently linked to a 70 kDa dextran (18) [152–154]. Bioconjugates having a few BSH molecules attained maximum *in vitro* binding at 4 h with the human glioma cell line U-343 MGaC12:6. In contrast, there was a slow increase of binding over 24 h for those having many BSH molecules. Although most of the bioconjugates were internalized, *in vitro* retention was low, as was *in vivo* uptake following i.v. injection into nude mice bearing s.c. implants of Chinese hamster ovary (CHO) cells transfected with the human gene encoding EGFR (designated CHO-EGFR). However, following i.t. injection, boron uptake was higher with CHO-EGFR(+) tumors compared to wild-type EGFR(–) CHO tumors [155].

#### 4.8

#### Other Macromolecules used for Delivering Boron Compounds

Polylysine is another polymer having multiple reactive amino groups that has been used as a platform for the delivery of boron compounds [53, 156]. The protein-binding polyhedral boron derivative isocyanatoundecahydro-*closo*-dodecaborate ( $B_{12}H_{11}NCO^{2-}$ ) has been linked to polylysine and subsequently to the anti-B16 melanoma mAb IB16-6 using two heterobifunctional linkers, SPDP and sulfo-MBS. The bioconjugate had an average of 2700 boron atoms per molecule and retained 58% of the immunoreactivity of the native antibody, as determined by a semiquantitative immunofluorescent assay or by ELISA. Other bioconjugates prepared by this method had >1000 boron atoms per molecule of antibody and retained 40–90% of the immunoreactivity of the native antibody [53]. Using another approach, site-specific linkage of boronated polylysine to the carbohydrate moieties of anti-TSH antibody resulted in a bioconjugate that had  $\sim 6 \times 10^3$  boron atoms with retention of its immunoreactivity [156].

A streptavidin–biotin system has also been developed to specifically deliver boron to tumors. Biotin was linked to a mAb and streptavidin was attached to the boron-containing moiety. The indirect linking of boron to the mAb minimized loss of its immunoreactivity. BSH was attached to poly-(D-glutamate D-lysine) (poly-GL) via a heterobifunctional agent [157]. This boronated poly-GL then was activated by a carbodiimide reagent and in turn reacted with streptavidin. Another approach employed a streptavidin mutant that had 20 cysteine residues per molecule. BSH was conjugated via sulfhydryl-specific bifunctional reagents to incorporate  $\sim 230$  boron atoms per molecule [158]. A closomer species with an icosahedral dodecaborate core and twelve pendant anionic *nido*-7,8-carborane groups has been developed as a new class of unimolecular nanovehicles for evaluation as a delivery agent for BNCT [159].

## 4.9

### Delivery of Boron-containing Macromolecules to Brain Tumors

#### 4.9.1

##### General Considerations

Drug delivery to brain tumors is dependent upon (1) the plasma concentration profile of the drug, which depends upon the amount and route of administration, (2) the ability of the agent to traverse the blood brain barrier (BBB), (3) blood flow within the tumor, and (4) the lipophilicity of the drug. In general, a high steady-state blood concentration will maximize brain uptake, while rapid clearance will reduce it, except in the case of intra-arterial (i.a.) drug administration. Although the i.v. route is currently being used clinically to administer both BSH and BPA, this may not be ideal for boron-containing macromolecules, and other strategies must be employed to improve their delivery.

#### 4.9.2

##### Drug-transport Vectors

One approach to improve brain tumor uptake of boron compounds has been to conjugate them to a drug-transport vector by means of receptor-specific transport systems [160, 161]. Proteins such as insulin, insulin-like growth factor (IGF), transferrin (TF) [162], and leptin can traverse the BBB. BSH encapsulated in TF-PEG-liposomes had a prolonged residence time in the circulation and low RES uptake in tumor-bearing mice, resulting in enhanced extravasation of the liposomes into the tumor and concomitant internalization by receptor-mediated endocytosis [163, 164]. Mice that received BSH-containing TF-liposomes followed by BNCT had significantly longer survival times than those that received PEG-liposomes, bare liposomes and free BSH, thereby establishing *proof-of-principle* for transcytosis of a boron-containing nanovehicle [112].

#### 4.9.3

##### Direct Intracerebral Delivery

Studies carried out by us have clearly demonstrated that the i.v. route of administration is not suitable for delivery of boronated EGF or mAbs to glioma bearing rats [75, 165]. Intravenous injection of technetium-99m labeled EGF to rats bearing intracerebral implants of the C6 rat glioma, which had been genetically engineered to express the human EGFR gene, resulted in 0.14% ID localizing in the tumor. Intracarotid (i.c.) injection with or without BBB disruption increased the tumor uptake to 0.34 to 0.45% ID  $g^{-1}$ , but based even on the most optimistic assumptions the amount of boron that could be delivered to the tumor by i.v. injection would be inadequate for BNCT [165]. Direct i.t. injection of boronated EGF (BSD-EGF), however, resulted in tumor boron concentrations of 22  $\mu g g^{-1}$  compared to 0.01  $\mu g g^{-1}$  following i.v. injection and almost identical boron uptake values were ob-

tained using the F98<sub>EGFR</sub> glioma model [77]. This was produced by transfecting F98 glioma cells with the gene encoding human EGFR. Based on our biodistribution results, therapy studies were initiated with the F98<sub>EGFR</sub> glioma in syngeneic Fischer rats. F98<sub>EGFR</sub> glioma bearing rats that received BSD-EGF i.t. had a mean survival time (MST) of  $45 \pm 1$  d compared to  $33 \pm 2$  d in animals that had EGFR(-) wild-type F98 gliomas. Since it is unlikely that any single boron delivery agent will be able to target all tumor cells, the combination of i.t. administration of BSD-EGF with i.v. injection of BPA was evaluated. This furthered increased the MST to  $57 \pm 8$  d compared to  $39 \pm 2$  d for i.v. BPA alone [73]. These data provide *proof-of-principle* for the idea of using a combination of low and HMW boron delivery agents.

#### 4.9.4

#### Convection-enhanced Delivery (CED)

CED, by which therapeutic agents are directly infused into the brain, is an innovative method to increase their uptake and distribution [166–168]. Under normal physiological conditions, interstitial fluids move through the brain by both convection and diffusion. Diffusion of a drug in tissue depends upon its molecular weight, ionic charge and its concentration gradient within normal tissue and the tumor. The higher the molecular weight of the drug and the more positively charged the ionic species, the lower its concentration, then the slower its diffusion. For example, diffusion of antibody into a tumor requires three days to diffuse 1 mm from the point of origin. Unlike diffusion, however, convection or “bulk” flow results from a pressure gradient that is independent of the molecular weight of the substance. CED, potentially, can improve the targeting of both low and HMW molecules, as well as liposomes, to the CNS by applying a pressure gradient to establish bulk flow during interstitial infusion. The volume of distribution ( $V_d$ ) is a linear function of the volume of the infusate ( $V_i$ ). CED has been used to efficiently deliver drugs and HMW agents such as mAbs and toxin fusion proteins to brain tumors [168–170]. CED can provide a more homogenous dispersion of the agent and at higher concentrations than otherwise would be attainable by i.v. injection [165]. For example, in our own studies, CED of <sup>125</sup>I-labeled EGF to F98<sub>EGFR</sub> glioma bearing rats resulted in 47% ID  $g^{-1}$  of the bioconjugate localizing in the tumor compared to 10% ID  $g^{-1}$  in normal brain at 24 h following administration. The corresponding boron values were 22 and 2.9–4.9  $\mu g g^{-1}$ , respectively [76]. Based on these results, therapy studies were initiated. F98<sub>EGFR</sub>-glioma-bearing rats that received BD-EGF by CED had a MST of  $53 \pm 13$  d compared to  $40 \pm 5$  d for animals that received BPA i.v. [73]. Similar studies have been carried out using either boronated cetuximab (IMC-C225) or the mAb L8A4 [171, 172], which is specifically directed against the tumor-specific mutant isoform EGFRvIII; comparable results were obtained [173]. Direct intracerebral administration of these and other HMW agents by CED has opened up the possibility that they actually could be used clinically, since CED is being used to administer radiolabeled antibodies, toxin fusion proteins and gene vectors to patients with GBM [168–170, 175–179].

It is only a matter of time before this approach is also used to deliver both low and HMW boron-containing agents for NCT.

#### 4.10

#### Clinical Considerations and Conclusions

In this chapter we have focused on HMW boron delivery agents and nanovehicles that potentially could be used clinically for targeting intra- and extracranial tumors. Animal studies, carried out in glioma-bearing rats, have demonstrated that boronated EGF and the mAb cetuximab, both of which bind to EGFR, selectively target receptor (+) tumors following direct i.c. delivery. Furthermore, following BNCT, a significant increase in MST was observed, and this was further enhanced if BPA was administered in combination with the HMW agents. These studies provide *proof-of-principle* first for the potential utility of HMW agents and, second, the therapeutic gain associated with combining them with LMW boron delivery agents. A major question is whether any of these agents will ever be used clinically? There are several critical issues that must be addressed if BNCT is to ever become a useful modality for the treatment of cancer. *First*, large clinical trials, preferably randomized, must be carried out to convincingly demonstrate the efficacy of the two drugs that currently are being used, BPA and BSH. Once this has been established, studies with HMW EGFR targeting agents could move forward. Both direct i.t. injection [174, 175] and CED [170, 176–179] have been used clinically to deliver mAbs and toxin fusion proteins to patients who have had surgical resection of their brain tumors. These studies provide a strong clinical rationale for the direct intracerebral delivery of HMW agents. Initially, the primary focus should be on determining the safety of administering them to patients prior to surgical resection of their brain tumors. Once this has been established, then biodistribution studies could be carried out in patients who were going to have surgical resection of their brain tumors. Tumor and normal tissues would be analyzed for their boron content, and if there was evidence of preferential tumor localization with boron concentrations in the range 10–20  $\mu\text{g g}^{-1}$  and normal brain concentrations of  $<5 \mu\text{g g}^{-1}$  then therapy studies could be undertaken. Since there is considerable variability in EGFR expression in gliomas, it is highly unlikely that any single agent will be able to deliver the requisite amount of boron to all tumor cells, and they would be used in combination with BPA/BSH. This general plan would also be applicable to the other HMW delivery agents and nanovehicles that have been discussed here. The joining together of chemistry and nanotechnology [180, 181] represents a major step towards the development of effective boron delivery agents for NCT. Nanovehicles offer the possibility of tumor targeting with enhanced boron payloads. Potentially, this could solve the central problem of how to selectively deliver a large number of boron atoms to individual cancer cells.

The preceding discussion shows that the development of HMW boron delivery agents must proceed in step with strategies to optimize their delivery and an appre-

ciation as to how they would be used clinically. Intracerebral delivery has been used in clinically advanced settings, but nuclear reactors, which currently are the only source of neutrons for BNCT, would not be conducive to this. Therefore, the development of accelerator neutron sources [24], which could be easily sited in hospitals, is especially important. This would also facilitate the initiation of large-scale clinical trials at selected centers that treat large numbers of patients with brain tumors and would permit evaluation of new boron delivery agents. In conclusion, as should be apparent from this review, a plethora of HMW boron delivery agents have been designed and synthesized. The challenge is to move from experimental animal studies to clinical biodistribution studies, a step that has yet to be taken.

### Acknowledgments

## 5

# Local Cancer Therapy with Magnetic Drug Targeting using Magnetic Nanoparticles

*Christoph Alexiou and Roland Jurgons*

### 5.1

#### Introduction

A continual problem in cancer therapy is the fact that applied drugs do not have a selective site of action. To achieve a therapeutic concentration in the region of interest using systemic administration it is necessary to administer high doses of drugs. Frequently, the dose of therapeutic agents is limited by their body distribution and subsequently their negative side effects and toxicity. During the last three decades many approaches and techniques have been developed in medicine for diagnosis and therapy both *in vivo* and *in vitro* to obtain a more site-specific transport of therapeutic agents, especially anticancer drugs in *local chemotherapy*, so as to increase the agent's local concentration in specific body compartments without harming healthy tissue [1–5]. Targeted drug delivery systems for accumulating pharmaceuticals in specific areas can be passive, based on specific properties of pathological tissues or specific characteristics of targeted organs [6], or active, often magnetically directed as *magnetic targeting* or *magnetic drug delivery*, based on various carrier systems [7]. Inflamed tissues or tumors, for example, differ from healthy tissue concerning pH, temperature or permeability of the vascular endothelium [8]. This enables the use of drug loaded pH-sensitive or thermosensitive liposomes to achieve a high amount of the therapeutic agent in the respective tissue [9–11]. Among liposomes, various substances such as peptides or proteins can be used for targeted drug delivery. Drug-containing monoclonal antibodies can be used for thrombolysis [12] or tumor-specific antibodies can be employed in cancer treatment [13, 14]. In addition to reviewing magnetic nanoparticles in biomedicine, this chapter overviews local chemotherapies, focusing especially on regional cancer therapy with magnetic nanoparticles.

### 5.2

#### Local Chemotherapy

The therapeutic effectiveness of drugs, especially of chemotherapeutic agents, is connected with their cell toxic properties [15]. This cell toxicity can cause a cell-

  6. Chemoembolization
- 

depression of bone marrow or the gastrointestinal tract. Furthermore, it may have serious consequences such as mutagenic, teratogenic or cancerogenic effects. The occurrence of secondary tumors induced by chemotherapy is evaluated at about 3% [16]. Targeted drug delivery may increase the therapeutic effects, reduce the costs of therapies and, especially for patients, would mean less negative side effects.

The easiest way of drug targeting involves local injection directly in the region of interest, which in cancer therapy is the tumor region (Table 5.1) [17, 18].

Another possibility of local chemotherapy is the intracavitary application of cytostatics. After systemic administration, chemotherapeutic agents reach the tumor by the vascular system; given intracavitally the site of action is penetration of the tumor tissue. The effectiveness of such local chemotherapy depends on a high plasma clearance and a small cavital clearance of the chemotherapeutic agent [19], on a good penetration of the tumor tissue and on the tumor size. With tumors larger than 2 cm in diameter, penetration is less and there is no advantage over systemic administration [20]. Application can be performed intraperitoneally [21], intrapleurally [22] or intravesically [23].

Secondary liver tumors can be treated by the injection of cytostatics in the portal vein [24] or in most cases in the hepatic artery [25].

Actually, regional perfusion with chemotherapeutic agents in an isolated circulation is used in treating liver tumors. Furthermore, isolated perfusion is performed in malignant melanoma of extremities [26].

A very effective palliative treatment of non-resectable hepatocellular carcinomas is chemoembolization. The combination of embolization and application of chemotherapeutics induces a high accumulation and a long residence time of the drug in the tumor [27].

Intraarterial infusion of chemotherapeutics bypasses a possible so-called first-pass-effect through liver and spleen before reaching the tumor. This results in a higher concentration of the drug compared with systemic administration. This effect can be increased by diminishing the arterial flow rate, which can be accomplished by the use of balloon-catheters [28], by administration of vasoconstrictive drugs [29, 30] or embolization [31, 32].

### 5.3

#### Magnetic Drug Delivery

Drug targeting with magnetic carrier systems enables an active transport of drugs into the respective region. Therefore, therapeutic agents such as drugs [33, 34] or radioisotopes [35] bound to a magnetic carrier will be injected in the vascular system. Under the influence of an external magnetic field this compound will be held in the targeted area and concentrated in the region of interest. Magnetic particles have been used in medicine for about 40 years and different sophisticated biomedical applications have been developed. Magnetic particles are frequently used *in vitro* and *in vivo*, depending on their size, surface and coating.

##### 5.3.1

#### *In Vitro* Applications

For *in vitro* applications several biotechnological approaches have been developed. A molecular-biological diagnostic procedure that has become increasingly important is biomagnetic separation. Magnetic nanoparticles are bound to a ligand (i.e., antibodies) that can be used to target cells, DNA or bacteria. After binding of the ligands to the targets they can be separated by the use of an external magnetic field. Magnetic cell separation is a medical approach of this biomagnetic separation technique that has become standard for *in vitro* diagnosis in cancer patients [36, 37]. By the use of superparamagnetic nanospheres (Fig. 5.1) and an automated magnetic cell separation (MACS®, Miltenyi Biotech®) this system allows the detection of disseminated tumor cells in the peripheral blood of cancer patients.

Another approach for *in vitro* application of magnetic nanoparticles is Magnetofection™. Gene vectors bound to starch-coated magnetic nanoparticles are attracted by an external magnetic field and used to transfect cells *in vitro*. The respective cells show greater transfection than without the influence of an external magnetic field [38].

**Fig. 5.1.** Magnetic particles with homogenous size for the magnetic cell separation system (Dynabeads®).

## 5.3.2

**In Vivo Applications**

For *in vivo* applications the magnetic particles have to be biocompatible. They can be incorporated in, or coated with, different biological materials. Therefore, different carriers have been used, such as magnetic microparticles, magnetoliposomes or magnetic iron oxide nanoparticles and also ferromagnetic substances. Alksne et al. (1966) have used carbonated iron and the influence of an external magnetic field to occlude intracranial aneurysms [39].

McNeil et al. (1995) have described a magnetic guidance system for a promising use in neurosurgery. Six external electromagnetic coils are able to guide magnetic neodymium-iron-bor capsules in the brain [40].

Another drug delivery system that can target chemotherapeutic agents is magnetic microspheres [41, 42]. Widder et al. have used magnetic albumin microspheres to increase the concentration of drugs in the tumor-region after applying an external magnetic field to this region [43–46]. Tumor remissions in rats could be shown [45]. These particles were about 1–7  $\mu\text{m}$  in size. Because of enzymatic breakdown of the albumin, a controlled release of the incorporated drug could not be achieved.

Another approach is the use of activated carbonated iron [47, 48]. Allen et al. (1997) have formulated Magnetically Targetable Carriers (MTC<sup>TM</sup>) made of iron and activated carbon bound to the chemotherapeutic agent paclitaxel for targeted drug delivery [49].

A magnetically targeted carrier bound to doxorubicin (MTC-Dox, FerX<sup>®</sup>, CA, USA) has been used to treat hepatocellular carcinomas. In human patients, MTC-Dox was administered in the hepatic artery while an external magnetic field was focused to the tumor region. In one case, reduction of tumor size could be shown [50]. However, another study has described a necrosis of the liver corresponding to embolization after treatment with these particles [51]. Recently, a global multicenter phase II/III study using MTC-Dox in human patients had to be stopped because “the clinical endpoints of the trial could not be met with statistical significance with the product as currently manufactured” (FerX<sup>®</sup>, San Diego, April 30, 2004).

Magnetoliposomes are also used for magnetically targeted drug delivery. These colloidal particles are composed of a lipid layer and qualified as drug carriers [52]. The chemotherapeutic agent Methotrexat encapsulated in thermosensitive liposomes can be accumulated in the tumor region after intravenous administration and local hyperthermia [53]. The use of magnetic thermosensitive liposomes and the influence of an external magnetic field placed over the tumor-region may increase the concentration of the encapsulated drug [54]. Furthermore, thermosensitive magnetoliposomes can also be used for local hyperthermia in cancer treatment [55]. Whole body hyperthermia in combination with chemotherapy is a very common approach in cancer treatment. A possibility to achieve local hyperthermia with magnetic particles is the use of magnetic iron oxide particles, which can be heated to over 40 °C by an alternating magnetic field after intralesional injection [56].

The size of albumin-microspheres or magnetoliposomes is in the range of  $\mu\text{m}$ s. As a consequence there is a risk of embolization in the capillary system because of these particles. Also useful for magnetically targeted drug delivery and smaller in size are magnetic nanoparticles. On nanoparticles, the surface-to-volume ratio is much higher than on larger particles. Therefore, nanomaterials show completely new characteristics and can be used for various new approaches. After application in an organism, different components such as material, size, charge and coating of the nanoparticles and the bound chemotherapeutic agent have an influence on biocompatibility and the biodistribution as well as the applied magnetic field and the respective gradient [57–68]. Nanoparticles have to be small enough not to occlude the capillary system and cause embolization, but they have to be large enough to be attractable by an external magnetic field. Furthermore, nanoparticles over 100 nm in diameter are more readily cleared by cells of the MPS (mononuclear phagocyte system) than smaller particles [57]. Research on biocompatible magnetic nanoparticles has focused on superparamagnetic iron oxide nanoparticles ( $\text{Fe}_3\text{O}_4$ ). These particles have been used as a contrast agent in magnetic resonance imaging for lymphography [69] (Fig. 5.2).

A first clinical trial with superparamagnetic iron oxide nanoparticles bound to a chemotherapeutic agent was performed in 1996 by Lübke et al. [33]. For experimental studies on rats and in a clinical trial on 14 human patients they used

**Fig. 5.2.** MR-Imaging of iliac lymph nodes in tumor-bearing rabbits. MRI before (A) and after (B) administration of superparamagnetic iron oxide particles. There is a homogeneous signal in healthy lymph nodes (curved arrows) and an inhomogeneous signal in metastatic lymph nodes [69].

**Fig. 5.3.** Histological cross section of a rabbit's VX2-squamous cell carcinoma after treatment with intraarterial magnetic drug targeting (MDT). Arrows show the ferrofluids in tumor vessels. Staining: Prussian blue; magnification: 200× [72].

**Fig. 5.4.** Typical multidomain-particle in the intracellular space of tumor cells. Single particles (marked with arrows) are surrounded by starch polymers (not visible in the electron-microscopic picture) [73].

**Fig. 5.5.** Concentration of mitoxantrone in different body compartments 60 min after the respective injection in percent of the applied dose. Experiments were performed on tumor-bearing rabbits (i.a. = intraarterial, i.v. = intravenous).

1 ■ i.a. application of  $5 \text{ mg m}^{-2}$  ferrofluid-bound mitoxantrone with an external magnetic field [ $n = 1$ , magnetic drug targeting (MDT)].  
 2 ▨ i.a. application of  $2 \text{ mg m}^{-2}$  ferrofluid-bound mitoxantrone with an external magnetic field ( $n = 1$ , MDT).

3 ▩ i.v. application of  $10 \text{ mg m}^{-2}$  mitoxantrone without an external magnetic field ( $n = 1$ , application of the regular systemic dose).

4 ▤ i.a. application of  $5 \text{ mg m}^{-2}$  ferrofluid-bound mitoxantrone without an external magnetic field ( $n = 1$ ).

5 ▥ i.a. application of  $10 \text{ mg m}^{-2}$  mitoxantrone without an external magnetic field ( $n = 1$ ).

ts. = tumor side; opp. = opposite; tumor region = tumor and surrounding area (<1 cm) [72].

starch-coated magnetic nanoparticles ionically bound to epidoxorubicin. It could be demonstrated that these particles are biocompatible. In another preclinical study, intraarterial Magnetic Drug Targeting (MDT) on tumor-bearing rabbits was performed using a powerful external magnetic field (1.7 Tesla) placed over the tumor region. Starch-coated superparamagnetic iron oxide nanoparticles (about 100–150 nm in diameter) ionically bound to the chemotherapeutic agent mitoxantrone were injected in the tumor supplying artery.

Through this intraarterial MDT, complete tumor remissions could be shown only by the use of 50% and 20% of the regular systemic chemotherapeutic dose

without any negative side effects [34, 70, 71]. It could be demonstrated histologically that the nanoparticles were enriched in the tumor tissue (Figs. 5.3 and 5.4). Radioactive  $^{59}\text{Fe}$ -nanoparticles showed  $114\times$  more activity in the tumor region after MDT than the control without magnetic field [72]. Furthermore, with this system a high and specific enrichment of the bound chemotherapeutic agent in a desired body compartment (i.e. the tumor) is possible. HPLC-analysis of the chemotherapeutic agent after MDT revealed a  $75\times$  higher concentration of the administered chemotherapeutic agent in the tumor region compared with the regular systemic administration (Fig. 5.5) [72, 73]. These encouraging data will lead to further studies on cancer patients.

## 6 Nanomaterials for Controlled Release of Anticancer Agents

*Do Kyung Kim, Yun Suk Jo, Jon Dobson, Alicia El Haj, and  
Mamoun Muhammed*

### 6.1 Introduction

The enormous advances made in basic cancer research have not been paralleled by similar improvements in treatment results. Metastatic breast cancer, late-stage colon cancer, malignant melanoma and other forms of cancer are still essentially incurable in most cases. Enormous efforts have been made in recent years to develop “smart drugs” that are directed to tumor cell-specific enzymes and surface receptors. Almost without exception, these drugs have encountered problems in clinical trials. Today’s cancer treatment is therefore primarily based on the use of conventional cytotoxic drugs that have adverse side effects and only limited effectiveness. The gains in health that would be achieved by efficient tumor treatment with fewer side effects (owing to specific targeting to tumor tissue) are therefore enormous. Cancer is a group of diseases characterized by uncontrolled growth and spread of abnormal cells. If the growth and spread of cancer cells is not controlled, the disease is fatal. Though in many cases the specific cause of cancer is unknown, in general it can be caused by several external factors (tobacco, chemicals, radiation, and infectious organisms) and internal factors (inherited mutations, hormones, immune conditions and mutations that occur from metabolism). These factors may act together or in sequence to initiate or promote carcinogenesis. Generally, cancer is treated by surgery, radiation, chemotherapy, hormones and immunotherapy [1]. Cancer therapy can be successful in treating solid tumors/cancers in lesions that can be removed by surgery or treated by radiotherapy/chemotherapy, the major treatment modalities for primary cancer/tumor and metastases. Each of these cancer treatments has advantages and disadvantages, thus the combination with other treatments is recommended to achieve the optimum outcome.

Chemotherapy for cancer is a whole body treatment that is administered either orally or intravenously. This results in systemic distribution of cytotoxic chemotherapeutic compounds that can be more effective for the treatment of micro-

metastases. However, the systemic distribution of cytotoxic compounds results in more severe side effects (some of which can be life-threatening) compared to surgery or radiotherapy. The major goal of targeted therapies is to reduce the side effects of cytotoxic drugs, resulting in more effective control of cell growth or tumor angiogenesis.

Presently, numerous anticancer agents are available in the clinic. These anticancer agent/drugs have an elimination half-life that results in a decrease of therapeutic potential and side effects such as bone marrow depression and gastrointestinal damage [2]. For example, poly(alkyl cyanoacrylate) nanoparticles as drug delivery systems (DDSs) play an important role in the incorporation of anticancer drugs as they can enhance the drug's concentration in the tumor and reduce drug levels in the heart, thus avoiding some side effects [3]. Targeting toxic therapeutics to tumors through binding to receptors overexpressed on the surface of cancer cells can also reduce systemic toxicity and increase the effectiveness of the targeted compounds. Small molecule-targeted therapeutics have several advantages over toxic immunoconjugates, including better tumor penetration, lack of neutralizing host immune response and superior flexibility in the selection of drug components with optimal specificity, potency and stability in circulation [4].

Novel strategies have been developed to decrease the toxicity of active molecules by targeting the specific tumor site, where the drug can selectively bind to the targeted tissue at cellular and/or sub-cellular level to influence its therapeutic effects. The chemotherapeutic activity can be enhanced by using macromolecules as a vector to control the release rate of anticancer agents. The use of polymeric nanoparticles is mainly focused on controlling the loaded anticancer agent/drug at the targeted lesion. Polymeric nanoparticles are a form of core-shell structure/nanocapsule that can be loaded with therapeutic agents. Several kinds of inorganic or metallic nanoparticles can be used due to their intrinsic physical properties even without a core-shell structure. Superparamagnetic iron oxide nanoparticles (SPION) in particular can be used as a transducer for active targeting by responding to both external ac and dc magnetic fields [5].

Despite major advances in the development of small-scale devices, however, most DDSs still use small molecules administered orally, transdermally, parenterally, or through the nose or lung. The emergence of novel, biologically targeted anticancer agents such as gefitinib ("Iressa", ZD1839) has raised the question of how the dose for later-stage clinical development and clinical use is best determined. For cytotoxic drugs, because toxic effects and antitumor activity often fall within the same dose range and are dose dependent, the clinically used dose will depend on the therapeutic window [6]. Cytostatic drug handling in hospitals is not unproblematic. Large doses are given of compounds that are highly mutagenic. Administration of the drugs and also disposal of patient urine etc. is therefore potentially hazardous. Target-oriented, controlled drug delivery will lead to decreases in the quantities of drugs used and will, therefore, help to reduce these problems. The development of novel smart biomaterials is already having an enormous effect on nanomedicine [7].

## 6.2 Nanoparticles for Biomedical Applications

Modern technological realizations are concerned with the development of advanced, multifunctional, and even more “smart” materials for specific applications in highly integrated biomedical approaches (Table 6.1). These novel interdisciplinary concepts are recently emerging at the intersection of material science and molecular biotechnology. They are closely associated with surface chemistry and the physical properties of inorganic nanoparticles, the topics of bioorganic and bioinorganic chemistry, and various aspects of molecular biology, recombinant DNA technology and protein expression, and immunology.

**Tab. 6.1.** Examples of nano-sized inorganic components in biomedical applications.

Particle composition	Particle size (nm)	Applications	Ref.
Metals			
Au	2–150	Drug and gene delivery	8
Ag	1–80	Antibody tagged marker	9
Pt	1–20	Sensors and electrodes	10
Co	1–50	Magnetic separation, drug targeting	11
Semiconductors			
CdX (X = S, Se, Te)	1–20	Fluorescent labeling	12
ZnX (X = S, Se, Te)	1–20	Fluorescent labeling	13
PbS	2–18	Photoluminescence	14
TiO <sub>2</sub>	3–50	Biomedical devices for nerve tissue monitoring	15
ZnO	1–30	Photoluminescence	16
CaAs, InP	1–15	Nonlinear optics	17
Ge	6–30	Photoluminescence	18
Magnetic			
Fe-O	6–40	MR contrast agent, drug delivery	[19]
Fe-Pt	2–10	MR contrast agent, drug delivery	[20]

### 6.2.1

#### First Generation Nanoparticles

First generation nanoparticles have been available for several years. Colloids are representative of nanoparticles stabilized in solution to prevent uncontrolled growth, aggregation, and flocculation of the nanoparticles. Utilization of colloidal processing leads to attractive new concepts for the fabrication of advanced nanostructured materials. For this reason, many investigations have focused on colloidal processing of inorganic materials through chemical methods.

### 6.2.2

#### Second Generation Nanoparticles

As a result of an increasing degree of complexity and sophistication needed for the engineering of nanostructures for advanced applications, second generation nanoparticles have emerged. A key aspect here is the need for multifunctionality of these materials in which several properties are combined to achieve a specific function. For example, certain properties could be achieved through the reduction of building blocks to the nanometer regime, e.g., magnetite ( $\text{Fe}_3\text{O}_4$ )/maghemite ( $\gamma\text{Fe}_2\text{O}_3$ ) nanoparticles become superparamagnetic at sizes below about 30 nm. Ferrofluids – which have the fluid properties of a liquid but are strongly magnetized in applied fields – can be produced by suspending these sub-30 nm nanoparticles in a suitable media. Ferrofluids are useful as active components for enhancing the performance of many devices, e.g., mechanical (seals, bearings and dampers) or electromechanical (loudspeakers, stepper motors and sensors, etc.). However, by combining the superparamagnetic properties of ferrofluids with functional chemical groups on the particles' surface there are opportunities for advanced applications in magnetically targeted drug delivery.

For second generation nanoparticles, the surface layer (a few or several monolayers) is distinctly different from that of the core material (composition or structure). Again, such particles are categorized as core-shell structures. The surface layer may be thin or thick, depending on the functionality required. Figure 6.1 shows a schematic representation of different types of second generation nanoparticles with surface modifications and nanoparticles with a core-shell structure. Broadly speaking, these particles can also be considered as composite nanoparticles. However, the term nanocomposite generally refers to materials consisting of a dispersion of nanoparticles within a suitable matrix. The most common example of nanocomposites is the precipitation of inorganic (often metal) nanoparticles within a nanoporous polymer structure. Interestingly, the fundamental properties of the polymeric materials can be dramatically altered as a result of the dispersion of few percent of inorganic nanoparticles – particularly with the addition of magnetic iron oxides.

**Fig. 6.1.** Evolution of second generation nanoparticles: (a) Nanoparticle coated with surfactant to form a stable suspension, (b) nanoparticle coated with a thin metallic layer,

(c) small nanoparticle coated with a porous ceramic layer and (d) dispersion of core-shell combination of (a) and (c) for stable suspension.

### 6.2.3

#### Advanced Generation Nanoparticles

Recently, advanced generation nanoparticles have emerged to meet the need for the fabrication of more complex nanoparticles. Further to the core-shell structure, nanoparticles with structures similar to nanocomposites have been fabricated (nanobeads). In these nanobeads, a single bead consists of a nanocomposite core, where one or more smaller nanoparticles are dispersed into the matrix. Several possible combinations of organic and inorganic particles can be dispersed within the matrix of the core structure. Each dispersed component can be selected to achieve a specific function or properties of the particle. The surface layer can combine both physical (e.g., diffusion control) and chemical (e.g., allowing certain conjugation chemistries) functionality to the particles. In this way, it is possible to “program” the nanobeads with multiple functionalities, suitable for performing certain tasks, that can be triggered under specific conditions. For example, it is possible to fabricate such nanobeads that can be magnetically moved or localized for controlled drug release. The release of the drug can be controlled by diffusion control of the matrix of the bead or through the control of the porosity of a suitable shell layer on the surface of the bead. Nanobeads can be programmed to be responsive to the environment, e.g., small variations in temperature or pH. Fabrication of these advanced generation nanoparticles requires the use of comprehensive and detailed procedures.

The design and fabrication of biochemically functionalized superparamagnetic iron oxide nanoparticles and near-infrared light absorbing nanoparticles is of particular interest for cancer targeting and therapy applications. Figure 6.2 illustrates a strategy to construct magnetic drug carriers in combination with thermosensitive polymeric materials. Target-oriented release of drugs encapsulated in polymeric nanocapsules is presently the most active research area in this field. Processing of

**Fig. 6.2.** Functional nanoparticles: (A) Coronary plaque removal by nanofluid of magnetic nanoparticles under RF magnetic field and (b) multipurpose nanovectors for target oriented controlled drug release.

nanoparticles with controlled properties, such as chemical properties (composition of the bulk, interaction between the particles, and surface charge) and structural properties (crystalline or amorphous structure, size, and morphology), is the main feature in designing the nanoprecursors (nanoparticles/nanotube/nanolayer). The development of supramolecular, biomolecular, and dendrimer chemistries for engineering substances of ångström and nanoscale dimensions has been encouraged for requirements in nanotechnology. The emerging disciplines of nanoengineering, nanoelectronics, and nanobioelectronics require suitably sized and functional building blocks to construct their architecture and devices [21].

Nanoparticles are in the solid phase and may be either amorphous or crystalline. They can be constructed to absorb, conjugate and encapsulate therapeutic agents inside or outside. Several parameters of colloidal systems developed have been considered, such as the temperature, osmolality and pH of the polymerization medium, that could influence the characteristics (morphology and morphometry, drug content, melting point transition or the enthalpy of transition) and stability of nanospheres. On the other hand, based on their unique mesoscopic physical, chemical, thermal and mechanical properties, nanoparticles offer great potential for many biomedical applications, including bioanalysis and biosepara-

tion, tissue-specific drug therapeutic applications, gene and radionuclide delivery [5, 22].

To be used effectively in fighting disease, the specific surface chemistry of the nanoparticles must be tailored for the desired biomedical applications. Magnetic nanoparticles are also of particular interest as inhomogeneous external magnetic fields exert a force on them, and thus they can be manipulated or transported to a specific diseased tissue by a magnetic field gradient. They also have controllable sizes, so that their dimensions can match either that of a virus (20–500 nm), a protein (5–50 nm) or a gene (2 nm wide and 10–100 nm long). In addition, superparamagnetic particles are of interest because they do not retain any magnetism after removal of the magnetic field.

### 6.3

#### Polymer Materials for Drug Delivery Systems

The past few decades has seen considerable interest in developing biodegradable nanoparticles as effective drug delivery devices [23]. Biodegradable polymers are polymers that can be degraded and/or catabolized, eventually to carbon dioxide and water, by microorganisms (bacteria, fungi, etc.) under natural environments [24]. However, due to the development of a wide variety of synthetic biocompatible polymers, the definition has been altered to include many artificially synthesized polymeric materials. Needless to say, degraded components of the polymers should not be toxic and should not promote the generation of harmful substances. Biodegradable polymers can be classified into three major categories:

1. Polyesters produced by microorganisms.
2. Natural polysaccharides (i.e., chitosan [25–29], dextran [30]).
3. Artificially synthesized polymers, especially aliphatic polyesters, {i.e., polylactide (PLA) [31, 32], poly(lactide-*r*-glycolide) (PLGA) [33], and poly(*ε*-caprolactone) (PCL) [34]}, polyamide (i.e., poly L-lysine [35]), and others such as poly(methyl methacrylate) (PMMA) [36] and poly(ethyl-2-cyanoacrylate) (PECA) [37], which have also been developed as nanoparticles for the same purpose.

Biodegradable polymers are not only limited to medical devices and wound dressing, but are also used for the fabrication of scaffolds in tissue engineering [38], and as DDSs for controlled release of 5-fluorouracil [39], cisplatin [40], lidocaine [41–43], indomethacin [32, 34], taxol [44], 4-nitroanisole [45], dexamethasone [46], radioactive compound [47], peptides [48], and proteins [49–54] at characteristic rates and specific target sites. For DDS, interest has focused on the use of particle formations prepared from aliphatic polyesters due to their biocompatibility and resorbability. In terms of these required characteristics, numerous workers use polyesters produced from glycolic acid and lactic acid polymers, which are approved by the FDA. These polymers do not require surgical removal after the completion of drug release [55].

## 6.4

### Design of Drug Delivery Vectors and Their Prerequisites

The development of micro/nanospheres for novel drug delivery systems has become an important area of research as such systems enable the controlled release of toxic drugs into the target organs. They also make it possible to deliver useful drugs into sites of inflammation or tumor cells. One of the most important characteristics required by these materials to be suitable for biomedical applications is their biocompatibility, especially with respect to their surface chemistry.

Biocompatibility of nanospheres can be further improved by modifying the terminal groups located on the polymer surface as well as its structure. Obviously, it is important to stabilize the nanospheres sterically by a coating process or chemical modification so as to minimize recognition by phagocytic cells in the reticuloendothelial system (RES). The most promising materials for this purpose are polymeric drug carriers. In general, a polymer that tends to lose mass over time within a living organism is called an absorbable, resorbable, or bioabsorbable, as well as a biodegradable polymer. In comparison with the strict definition, biodegradable polymers require enzymes of microorganisms for natural hydrolytic or oxidative degradation. Regardless of its degradation behavior, this terminology applies to both enzymatic and non-enzymatic hydrolysis.

The physiochemical properties of the materials should be considered to develop nanoparticles as vectors for controlled DDS. Toxins must be removed from the drugs in the patient's body as quickly as possible. Engineered nanoparticles are strong candidates for drug detoxification because the particle size is the key to preventing further damage to the patient's healthy organs [33].

#### 6.4.1

##### Polymeric Nanoparticles

Numerous factors should be considered when designing a DDS. The first generation of polymeric vectors is simple core-shell structures/capsules within which the therapeutic agents are loaded. The second generation of polymeric vectors aims to enhance degradation rates by synthesizing block copolymers with more than two different species and by varying the molecular weight of the polymer components. Obviously, the release time of the therapeutic agents can be effectively improved in this way by understanding the physiochemical properties of the human body. Even though the drugs are effectively incorporated into the vectors, the nanoparticles can be easily agglomerated after dosing via various routes of administration (i.e., oral, intravenous, intramuscular, subcutaneous, etc.).

A particular consideration to take into account when designing nanoparticles for these applications is that the body's fluids are composed of quite complex compositions such as water, hormones, plasma (e.g., erythrocytes, leukocytes, platelets), fats, protein (e.g., albumin, globulin, fibrinogen), and numerous ions etc. For example, stable colloidal suspensions of DDS can be prepared simply in water-based solvent. However, the nanoparticles, once administrated into the blood stream, typ-

ically create a serious blockage of blood flow due to their agglomeration and particle growth through interactions with compounds in the blood. Moreover, many kinds of biological substances are hydrophilic and water soluble, and cannot therefore pass through the hydrophobic lipid bilayer membranes. For example, MPEG has uncharged hydrophilic residues and a very high surface mobility, leading to high steric exclusion. Therefore, it is expected to effectively improve the biocompatibility of nanoparticles and to possibly avoid accumulation in the RES or the mononuclear phagocyte system. Obviously, it is important to stabilize the nanospheres sterically by a coating process or chemical modification so as to minimize recognition by phagocyte cells in the RES.

The most advanced generation of polymeric DDSs has been developed to resolve the above-mentioned problems for multifunctional applications. This can be achieved via the use of nano-biotechnology to fabricate nanovectors with a higher degree of complexity based on the design and fabrication of bio-active and biocompatible, functionalized nanofluids using nanoparticles with several chemistries relevant to specific biological/medical activities.

Surface functionalization of nanovectors is designed to perform the following tasks:

1. Carrier for certain functional compound, e.g., drug(s) and other materials.
2. Formation of stable suspension in physiologically compatible solutions.
3. Controlled targeting to an organ or tissue within the body of a living animal or human subject.
4. Keeping the particles in a given location for a desired period.
5. Controlled release of drugs or chemicals through the pores of the shell according to defined conditions.

As one of the stimuli-sensitive polymers (SSPs), PNIPAAm is well known as a thermosensitive polymer due to its distinct phase transition at a specific lower critical solution temperature (LCST) of 32 °C in water [56–60]. PNIPAAm is hydrophilic below the LCST but becomes hydrophobic when it is heated up above the LCST. PNIPAAm has been consistently investigated as it has “smart” characteristics and is being developed for biomedical applications in the form of micelles [56], tablets [59], and hydrogels.

A new class of temperature-programmed “shell-in-shell” structures with two different copolymers synthesized by a modified-double-emulsion method (MDEM) has been reported as an advanced generation nanovector [31]. In this approach, thermosensitive inner shells composed of poly(N-isopropylacrylamide-co-D,L-lactide) (PNIPAAm-PDLA) with a lower critical solution temperature (LCST) can be fabricated. This novel concept can effectively load any hydrophilic proteins into a polymeric DDS and construct an adequate vector together with the programmable release rate. The release rates are governed by several key parameters, which only involve the PLLA-PEG outer shell, such as the volumetric ratio between the organic phase and aqueous phase, the interaction parameter between the therapeutic agents and the core domain, tacticity of the copolymer, the encapsulation efficiency, etc. Figure 6.3 shows a schematic representation of “shell-in-shell”

**Fig. 6.3.** Schematic of the fabrication of Au@PLLA-PEG@PNIPAAm-PDLA: (I) Formation of the hydrophilic protein-loaded PNIPAAm-PDLA sphere; (II) construction of PLLA-PEG@PNIPAAm-PDLA dual-shell structure via a MDEM; (III) functionalization of PLLA-PEG@PNIPAAm-PDLA dual-shell structure with 3-aminopropyltrimethoxysilane (APTMS); (IV) *in situ* reduction of Au<sup>3+</sup> for the self-assembly of Au nanoparticles on the surface of PLLA-PEG@PNIPAAm-PDLA; (V) completion to load a protein in Au@PLLA-PEG@PNIPAAm-PDLA by elimination of the PNIPAAm-PDLA inner shell.

structures produced by a MDEM. Generally, a hydrophilic protein such as bovine serum albumin (BSA) can be encapsulated in the polymeric spheres using a double-emulsion method (DEM), a so-called “water-in-oil-in-water” (w/o/w) emulsion method [51, 60, 61]. However, the DEM has a disadvantage with respect to the stability of amphiphilic polymer spheres because both the inner shells and the outer shells are composed of the same species of copolymer. Instead, as for the MDEM, two different kinds of copolymers are sequentially incorporated in the organic phase to promote enhanced stability of the spheres. In this way, the inner shells can be prepared with PNIPAAm-PDLA diblock copolymers and the outer shells can be prepared with PLLA-PEG diblock copolymers.

For another class of thermosensitive nanocarriers, poly[(NIPAAm-*r*-AAm)-co-lactic acid] (PNAL) has been reported [62]. As schematically illustrated in Fig. 6.4(b), Au nanoparticles can be directly self-assembled on the surface of PNAL nanospheres by virtue of primary amino groups coming from acrylamide (AAm) molecules of the PNAL diblock terpolymer. The primary amino groups can be strongly bound to noble metals such as gold or silver. Therefore, the “shell” domain of Au@PNAL becomes an affinity site for biomolecules to be conjugated. Furthermore, the LCST of poly(*N*-isopropylacrylamide-*r*-acrylamide) (PNA) was modulated from 32 up to approximately 36 °C through the manipulation of the ratio between *N*-isopropylacrylamide (NIPAAm) and AAm units. This nanostructure is expected to serve as a synchronous delivery system by virtue of its Au-modified surface and hydrophobic inner core site (Fig. 6.4).

Figure 6.5 shows TEM images of the “shell-in-shell” spherical structures of PLLA-PEG@PNIPAAm-PDLA (parts a and b) and Au@PLLA-PEG@PNIPAAm-PDLA (c and d). The well-defined PLLA-PEG@PNIPAAm-PDLA can be prepared by MDEM and the Au nanoparticles are further deposited by self-assembly, resulting in hybrid nanosphere, i.e., Au@PLLA-PEG@PNIPAAm-PDLA. The bright contrast in the TEM images shown in Fig. 6.5(b) can be identified by a distinct difference in gray scale, which infers the “shell-in-shell” structures are properly fabricated. By increasing the temperature above the LCST, the inner shell of

**Fig. 6.4.** Strategy to fabricate Au@PNAL spheres: (a) Synthetic pathway to PNAL diblock terpolymer: (1) NIPAAm; (2) AAm; (3) PNA; (4) hydroxyl-terminated PNA; (5) L,L-lactide; (6) PNAL. (b) Schematic of direct self-assembly of Au nanoparticles on PNAL

nanospheres: step (I) PNAL nanospheres; (II) direct self-assembly of Au nanoparticles to the primary amide groups of AAm; (III and IV) completion of the self-assembly of Au nanoparticles.

PLLA-PEG@PNIPAAm-PDLA undergoes the phase transition, resulting in elimination of the inner shell. Finally, PLLA-PEG@PNIPAAm-PDLA dual-shell structures are changed to the simple core-shell structure.

Hydrolyzable diblock copolymers of poly(ethylene glycol)-poly(L-lactic acid) (PEG-PLA) or poly(ethylene glycol)-poly(caprolactone) (PEG-PCL) have been prepared and loaded with doxorubicin for controlled release of the anticancer agent. The release rates of doxorubicin from the hydrolyzable vector can be modulated by increasing the amount of PEG in the polymeric systems, and also increased linearly with the molar ratio of degradable copolymer blended into the non-degradable membranes. In both nano- (100 nm) and micro-size vectors, the average release time reflects a highly quantized process in which any given vector is either intact or retains its encapsulant. Poration occurs as the hydrophobic PLA or PCL block is hydrolytically scissioned, progressively generating an increasing number of pore-preferring copolymers in the membrane. The kinetics of this evolving detergent mechanism underlies the phase behavior of amphiphiles, with transitions from membranes to micelles allowing controlled release [63].

**Fig. 6.5.** TEM images of PLLA-PEG@PNIPAAm-PDLA (negatively stained with 2 wt.% ammonium molybdate aqueous solution for 2 min) (a and b) and Au@PLLA-PEG@PNIPAAm-PDLA (without staining) (c and d).

Chitosan is a polysaccharide obtained by alkaline deacetylation of the naturally occurring abundant polysaccharide chitin. It is biodegradable, biocompatible, non-immunogenic, and non-carcinogenic, making it suitable for pharmaceutical applications [64]. Chitosan tripolyphosphate (TPP) microspheres have been prepared by spray-drying methods using acetaminophen as a model drug substance. Such

ionically crosslinked chitosan-TPP microspheres afforded slower release rates. The vectors can be prepared using a higher concentration of chitosan, higher volume of TPP solution, a higher molecular weight chitosan and/or higher drug loading. In this study, acetaminophen release rates were mainly controlled by the chitosan-TPP matrix density and by the degree of swelling of the hydrogel matrix. The overall release trend of acetaminophen from spray-dried chitosan-TPP microspheres is a two-step biphasic process, with an initial burst followed by subsequent slower release [65]. A complex composite of proteins glycoproteins and proteoglycans has provided an important model for the design of biomaterials [66, 67]. Recent progress in the development of methods for incorporating non-natural amino acids into recombinant proteins using DNA technology points the way to an alternative strategy for preparing new types of drug deliver systems (DDS).

#### 6.4.2

##### **Inorganic Nanoparticles**

Inorganic porous materials are emerging as novel host systems. Owing to some interesting features, such as their biological stability and their drug-releasing properties, there is a significant and increasing interest in these potential vectors. Several porous materials have been used, including synthetic zeolites and silica xerogel materials. MCM 41 is typical mesoporous, templated silica that has been widely investigated. This material presents nanosized pores that allow the incorporation of therapeutic agents. The release properties of ibuprofen-loaded MCM 41 show the feasibility of such systems as vectors for DDS [68].

Porous calcium hydroxyapatite is also used as a vector for anticancer drugs (cis-platinum). The slow release of cis-platinum from the inorganic vector has been confirmed by *in vitro* experiments [69]. When the drug-loaded vector was implanted into normal back muscle, or the tibia, sustained release of cis-platinum was observed during the subsequent 12 weeks. The diffusion rate of cis-platinum into the blood and other organs (liver, kidney, brain) was <10% of that at the implanted site. The vector administered into tumors of mice also showed a steady release of cis-platinum for more than three months. Inhibition of tumor growth was more obvious after local implantation of the cis-platinum-loaded inorganic vector than after intraperitoneal administration of cis-platinum. Based on these results, this novel mesoporous vector shows great potential as controlled DDS of anticancer agents. It is more attractive in bone tumors because the mechanical strength of calcium hydroxyapatite permits partial surgical excision and replacement of the bone defect at the same time.

Porous CuX zeolite has been synthesized as an inorganic vector to incorporate cyclophosphamide (CP). Biochemical and anatomopathological evaluations of antitumoral effects by oral administration of the CP-loaded CuX zeolite show that the intensity of the antitumoral effects is similar to that with normal administration of CP. An advantage of the CP-loaded CuX zeolite is the maintenance of a CP concentration ranging between 100 and 1000 ng per mL of plasma in the blood [70].

### 6.4.3

#### Metallic Nanoparticles

Recently, the immobilization of biomolecules, ligands and therapeutic agents onto the surface of metallic nanoparticles has been the focus of intense activity in biological engineering and biotechnology [71–77]. Especially, amine groups and cysteine residues in the proteins can be bound onto the surface of Au nanoparticles and can be stabilized electrostatically [71, 75]. In parallel with this work, several groups have focused on the fabrication of Au nanoparticles-organic/inorganic hybrid structures with polyurethane (PU) [71], silica [78–80], polystyrene (PS) [81], and stimuli-sensitive polymers (SSPs) [31, 62, 82].

Colloidal Au can be used as a vector for therapeutic agents as well as an indicator for immunodiagnosics. However, the use of these Au nanoparticles for *in vivo* DDS was not well established. A colloidal gold (cAu) nanoparticle vector has been used to target the delivery of tumor necrosis factor (TNF) to a solid tumor growing in mice [83]. The optimal vector, designated PT-cAu-TNF, consists of molecules of thiol-derivatized PEG (PT) and recombinant human TNF that can be directly bound onto the surface of the Au nanoparticles. Following intravenous administration, PT-cAu-TNF rapidly accumulates in MC-38 colon carcinoma tumors and shows little to no accumulation in the liver, spleen (i.e., the RES) or other healthy organs of animals. PT-cAu-TNF was less toxic and more effective in reducing tumor burden than native TNF since maximal antitumor responses were achieved at lower drug doses. Svarovsky et al. have described the synthesis of Au nanoshells encapsulated with up to 90 units of the Thomsen-Friedenreich (TF) tumor-associated carbohydrate antigen (TACA) disaccharide (Galbeta1-3GalNAc-alpha-O-Ser/Thr) as well as the assembly of a suitably linked designer glycopeptide as a precursor to similar multivalent presentations on Au. The TF-coated Au nanoparticles are highly stable, water soluble, and easily handled. Improvements in the linker technology used to attach the disaccharide to the Au nanoparticles led to a robust multivalent platform. The antigen retains all recognition characteristics while displayed on this template, as shown by several *in vitro* assays. This approach can be used to develop novel therapeutic agents that inhibit protein–carbohydrate interactions [84].

## 6.5

### Kinetics of the Controlled Release of Anticancer Agents

*In vivo* treatment requires the release of therapeutic agents into the body; this is followed by absorption, metabolism, distribution, and elimination of the therapeutic agents that are administered, and subsequent target organ effects, both therapeutic and toxic. The process of release followed by absorption, distribution, metabolism, and elimination is referred to as “pharmacokinetics” – a process commonly represented by a mathematical description of the behavior of a drug, and possibly its metabolites, in the system. Pharmacokinetics are frequently

described as what the body does to the drug. A major goal of clinical pharmacology is to integrate pharmacokinetics and pharmacodynamics so that their relationships can be understood, and so that drug treatment can be optimized based upon such an understanding [85].

The release rate of DDS predicted by the diffusion- and the dissolution-based release systems can be applicable for the controlled-release of drugs during circulation in the blood stream or localization at the target site. Diffusion models are defined literally as a mass transfer process of the individual substance, brought about by random molecular motion and associated with a concentration gradient. In monolithic devices, the drug is uniformly mixed within a polymeric matrix and is present either in a dissolved or dispersed structure.

Generally, the release model of the devices where the drug is dissolved follows Fickian kinetics. When the drug is dispersed in a polymeric matrix, the rate of release follows the square root of time kinetics until the concentration of the drug decreases below the saturation value. In addition, the preferred release profiles of the drug in bulk degrading systems can be manipulated by adjusting the molecular weight of the polymer, copolymer composition, crystallinity, loading amounts of the drug, and interactions between polymer and drug, etc. Generally, drug release may be diffusion controlled or dissolution controlled, depending on parameters such as the permeability of the polymer to water, the solubility of the drug in the polymer and in the water phase, the molecular weight of the drug, etc. With methotrexate-loaded gelatin nanoparticles, the drug release follows a diffusion-controlled mechanism [86].

Polakovič et al. have made a significant contribution to the investigation of the release profiles of model drugs for spherical shapes of DDS [42]. They suggested that two main models, consisting of the diffusion and the dissolution, should be considered to determine the release rate of the drug from polymeric spheres. Generally, drug release mechanisms from micro/nanoparticles should be assumed based on (a) surface desorption, (b) diffusion through particle pores, (c) diffusion through intact polymers, (d) diffusion through water swollen polymers and (e) surface or bulk erosion of polymeric matrix [87]. The last phenomenon partly represents a mechanism of drug-release. However, other factors will change the morphologies of the platforms, resulting in changes to the rate of diffusion for drug release [42].

### 6.5.1

#### Diffusion Model

The release of a drug from a polymeric matrix generally follows Fick's second law. The concentration gradient of the spherical particles follows the form given by Eq. (1).

$$\frac{\partial c}{\partial t} = D \left( \frac{\partial^2 c}{\partial r^2} + \frac{2}{r} \frac{\partial c}{\partial r} \right) \quad (1)$$

where  $c$  is the local drug concentration at time  $t$  and the distance  $r$  from the center

of the particle and  $D$  is the diffusion coefficient of the drug in the polymeric matrix.

Therefore,

$$\frac{c_1}{c_{1\infty}} = 1 - \sum_{n=1}^{\infty} \frac{6(\alpha + 1)\alpha}{(9 + 3\alpha + q_n^2\alpha^2)} e^{-(q_n^2/R^2)Dt} \quad (2)$$

$\alpha = V/(V_s K_p)$ , where  $V$  is the bulk liquid volume of the surrounding medium,  $V_s$  is the total volume of the particles  $q_n = \lambda R$  where  $\lambda$  is eigen value and  $R$  is radius of particles.

### 6.5.2

#### Dissolution Model

The dissolution model can be expected when a solid drug is dissolved in media. The dissolution rate of a drug can often be the rate-determining step when the absorption rates are faster than the dissolution rates (e.g., as with steroids). If the drugs are not dissolved before they are removed from the intestinal absorption site, the proper effects can not be expected due to a limited residence time at the absorption site. Therefore, the rate of the dissolution should be considered rather than the diffusion model for drugs that are poorly soluble. For this reason, the dissolution rate of drugs in solid dosage forms is an important parameter in the design of proper DDSs.

Drug release by the dissolution model can be defined by Eq. (3).

$$r_d = -\frac{dc}{dt} = k(c - K_p c_1) \quad (3)$$

where  $r_d$  is the rate of drug dissolution and  $k$  is the dissolution coefficient. The drug concentration is eliminated after introducing the mass balance and its derivative in Eq. (3). Integration of the rearranged equation provides the relationship of  $c_1$  with time given in Eq. (4).

$$c_1 = \frac{c_0}{K_p(\alpha + 1)} \left[ 1 - \exp\left(-\frac{\alpha + 1}{\alpha} kt\right) \right] \quad (4)$$

$K_p = c_{\infty}/c_{1\infty}$  is the partition coefficient characterized by the concentration ratio of the concentration inside the particles to the bulk liquid drug concentration in thermodynamic equilibrium.

### 6.5.3

#### Kinetics of the Indomethacin (IMC, 1-[*p*-chlorobenzoyl]-2-methyl-5-methoxy-3-indoleacetic acid) Release

The release kinetics of IMC as a model drug have been examined with parameters obtained by comparing the diffusion and dissolution kinetic models. Table 6.2

Tab. 6.2. Different series of IMC-loaded PLA-PEO spheres.

Code	Ratio (o/w)	Ratio (drug/ polymer)	Water phase (mL)	Organic phase	
				PLA soln (mL)	IMC soln (mL)
LL <sub>1</sub>	0.11	1	3	0.165	0.165
LL <sub>2</sub>	0.22	1	3	0.330	0.330
LL <sub>3</sub>	0.33	1	3	0.660	0.660
DL <sub>1</sub>	0.11	1	3	0.165	0.165

summarizes the codes of IMC-loaded PLA-PEO spheres for *in vitro* experiments on the controlled-release of IMC. Figure 6.6(a–d), representing LL<sub>1</sub>, LL<sub>2</sub>, LL<sub>3</sub>, and DL<sub>1</sub> respectively, shows four different kinetic behaviors. The results of LL<sub>1</sub> and DL<sub>1</sub> are in a good agreement with the diffusion model only. However, the release profiles gradually shift from the diffusion model towards the dissolution model as  $c_{1\infty} V_r/c_0$  decreases. Figure 6.6(b) shows the release profile of LL<sub>2</sub>, which is more dissolution-dependent than that of LL<sub>1</sub>.

A similar phenomenon can be observed in LL<sub>3</sub>, which shows the greatest dissolution-dependent characteristics with the lowest  $c_{1\infty} V_r/c_0$ . Consequently, LL<sub>2</sub> has intermediate behavior between the two different models, showing that the *in vitro* release profile is located between the diffusion and the dissolution profiles. This demonstrates that the kinetic models are strongly dependent upon  $c_{1\infty} V_r/c_0$ . A high  $c_{1\infty} V_r/c_0$  can directly affect the diffusion kinetics. Therefore, a high apparent efficiency ( $\zeta$ ) can result in an intermediate characteristic between the diffusion- and dissolution-dependent mechanisms. In addition to the parameters mentioned above, other parameters should be considered during the fabrication of nanospheres for DDS. Yang et al. have reported a correlation between the release behavior and surface porosity of microspheres [61]. They also reported that the organic phase used for the fabrication of the nanospheres by emulsion/evaporation techniques plays a critical role in determining the overall release characteristics of the drugs. The fabrication temperature also becomes a critical factor because the shell of the nanospheres is vulnerable to evaporating solvents with a low-boiling point such as chlorine-based solvents (i.e., methylene chloride and/or chloroform). The release rate is increased owing to a larger pore size on the surface of the spheres when the DDS has a lower  $V_r$ . The release profiles of LL<sub>1</sub> and DL<sub>1</sub> show initial fast release rates. In contrast, the initial “bursting” behaviors of LL<sub>2</sub> and LL<sub>3</sub> are less pronounced. This phenomenon explains that  $V_r$  can affect the release rates at the initial stage, especially within a short period, i.e., as soon as exposed to the surrounding medium. From the mathematical modeling and *in vitro* experiments, we should not use only one model to predict the release behavior of therapeutic agents because the releasing environments are usually more complicated than ex-

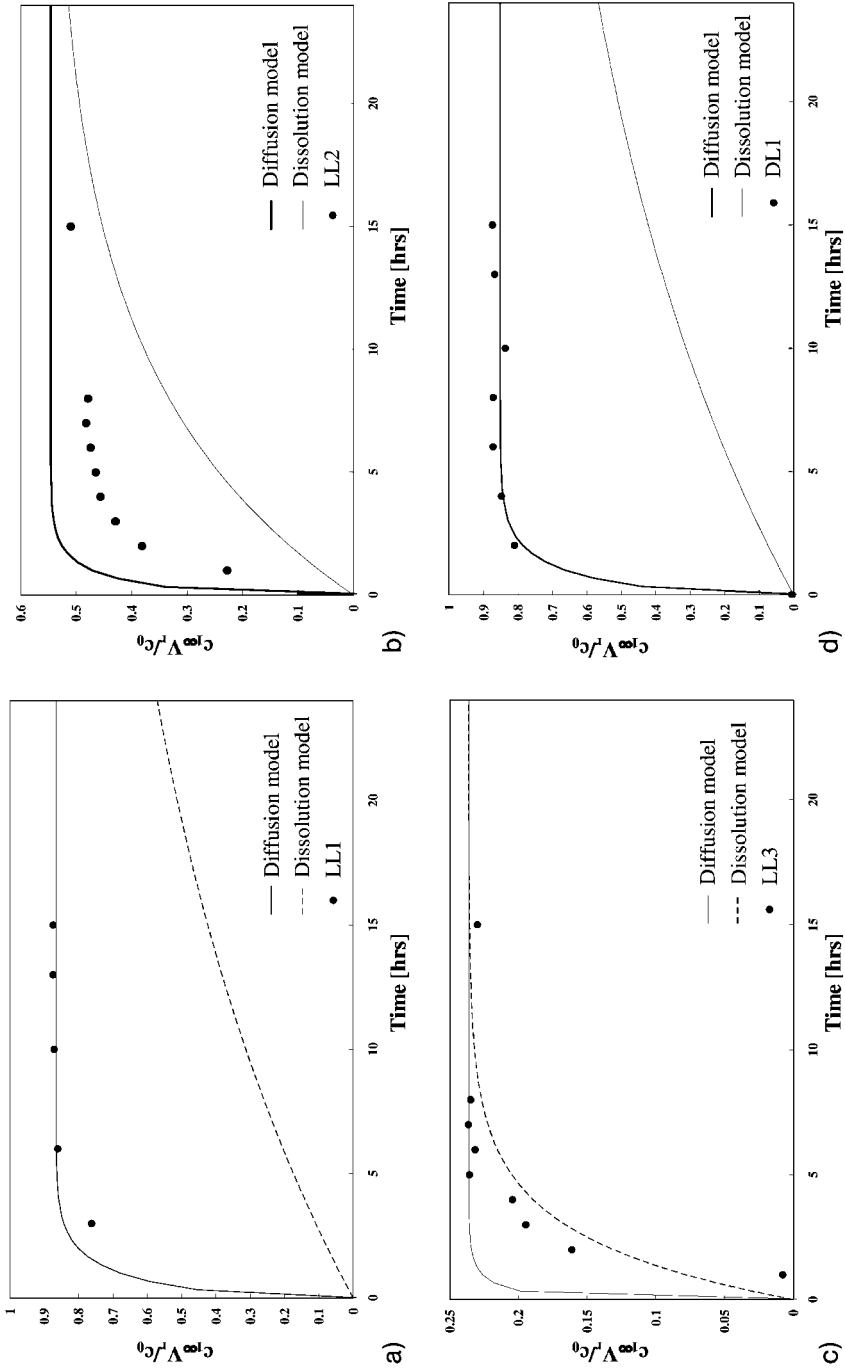

Fig. 6.6. Drug-releasing profiles in comparison with diffusion and dissolution models: (a) LL<sub>1</sub>, (b) LL<sub>2</sub>, (c) LL<sub>3</sub>, and (d) DL<sub>1</sub>.

pected. Thus, proper assumptions and possible variables should be considered for both theoretical and practical applications.

## 6.6

### Controlled Release of Anticancer Agents

Although biomaterials (biologically derived components) are useful for new medical treatments, critical problems in biocompatibility, mechanical properties, degradation and numerous other issues remain. Stealth properties and responsiveness to factors such as pH, temperature, specificity and other critical problems have to be resolved. The possibility of delivering cytotoxic agents directly into tumor cells has several advantages: drug losses in the bloodstream and upon liposome–cell interaction are minimized and the preparation of drug-loaded nanoparticles becomes simpler. To be effective, a material must possess several attributes, including the ability to condense therapeutic molecules to a size of less than 150 nm so that it can be taken up by receptor-mediated endocytosis, the ability to be taken up by endosomes in the cell and to allow therapeutic molecules to be released in active form, and to enable it to travel to cell's nucleus. Moreover, gene therapy is gaining in popularity as a medical treatment for cancer, tumors, Alzheimer's diseases, diabetes etc.; however, the clinical efficacy is lower than expected due to the detergent effect. When administered directly into the blood vessel or lesion, the therapeutic molecules are taken up by other healthy organs/cells and the residual time in biological systems is less than 2 h, and thus the pharmacological action is diminished. In addition, it has been reported that therapeutic molecules taken up by healthy organs/cells undergo mutation and may cause other, more serious diseases, including cancer. Also, most antitumor agents are hydrophilic compounds and, therefore, cannot be retained within the membrane. Thus, the use of prodrug forms of anticancer agents to alter the phase behavior of the chemicals is becoming more popular.

#### 6.6.1

##### Alkylating Agents

Alkylating reagents are chemical reagents that have an alkyl group such as propyl in place of a nucleophilic group. They include several cytotoxic drugs, some of which react specifically with N7 of the purine ring, resulting in depurination of DNA. These alkylating drugs interact with DNA and prevent the division of the cells.

The alkylation of DNA bases can disrupt the replication mechanism of the cell. The nitrogen bases in DNA molecules are nucleophilic and can be easily alkylated. If the N–H groups are replaced by N–R groups then the DNA base pairing is disrupted and can lead to cellular dysfunction. This should have an effect on the replication of cancerous cells, thus leading to a slow-down or stoppage of growth of the cancer.

### 6.6.1.1 Chlorambucil

Chlorambucil (pronounced “klor-AM-byoo-sil”) is a well-known anticancer agent for blood cancers and acts to reduce the number of blood cells. It is also used to treat other cancers such as lymphomas. Chlorambucil is an aromatic derivative of mechlorethamine and is closely related in structure to melphalan. The therapeutic effects are the slowest acting and generally least toxic among the alkylating agents. Alkylation of DNA results in breaks in the DNA molecule as well as crosslinking of the twin strands, thus interfering with DNA replication and transcription of RNA. Like other alkylators, chlorambucil is cell cycle phase-nonspecific [88, 89].

Leroux et al. have demonstrated that polymeric nanoparticles can be loaded with chlorambucil (8.52% m/m) with an entrapment efficiency of 60%. Polymeric nanospheres have been prepared by emulsification of a benzyl alcohol solution of a polymer in a hydrocolloid-stabilized aqueous solution followed by dilution of the emulsion with water. Nanoparticles as small as 70 nm in diameter can be produced by increasing the percentage of poly(vinyl alcohol) to 27.5% in the external phase. The particle size can be controlled by using gelatin instead of poly(vinyl alcohol) and the smallest nanoparticles, with an average size of 70 nm, can be obtained [90].

Chitin-based biodegradable microspheres have also been investigated for their ability to encapsulate chlorambucil as a model drug. The polymer sphere can be prepared by directly blending chitin with different contents of poly(D,L-lactide-co-glycolide 50:50) (PLGA 50/50) in dimethylacetamide–lithium chloride solution, followed by coagulating in water via wet phase inversion. Chlorambucil-loaded chitin/PLGA (50/50) has a two-step release mechanism. In the initial stage, the drug release rate increases with increased chitin content due to hydration and surface erosion of the hydrophilic chitin phase; however, the subsequent slow release is sustained for several days, mainly due to bulk hydrolysis of the hydrophobic PLGA phase [91].

### 6.6.1.2 Cyclophosphamide

Cyclophosphamide is a cyclic phosphamide ester of mechlorethamine. It is transformed via hepatic and intracellular enzymes into active alkylating metabolites, acrolein and phosphoramidate mustard. Cyclophosphamide prevents cell division primarily by crosslinking DNA strands. This anticancer agent is applicable to breast cancer, lung cancer, multiple myeloma, mycosis fungoides, neuroblastoma and retinoblastoma etc. It must be handled carefully as it is considered to be highly carcinogenic in humans. Cyclophosphamide-loaded poly(butyl cyanoacrylate) nanospheres have been investigated to obtain a suitable and tolerated ocular delivery device for therapeutic applications, involving treatment of severe ocular inflammatory processes that localize in the anterior chamber of the eye [92, 93].

Local delivery of 4-hydroperoxycyclophosphamide (4HC derived from cyclophosphamide) has been carried out via a controlled-release biodegradable polymer to determine whether the use of a polymer vector can enhance efficacy. Ninety Fischer 344 rats implanted with 9L or F98 gliomas were treated with an intracranial polymer implant containing 0–50% loaded 4HC in the polymer. The 20%

4HC-loaded polymers caused minimum local brain toxicity and maximum survival. These polymers were then used to compare the *in vivo* efficacy of 4HC to BCNU in rats implanted with 9L glioma. Animals with brain tumors treated with 4HC had a median survival of 77 days compared to that of 21 days in BCNU-treated animals and 14 days in untreated animals. Long-term survival for more than 80 days was 40% in the 4HC-treated rats versus 30% in the BCNU-treated rats.

In conclusion, 4HC-impregnated polymers provide an effective, safe local treatment for rat glioma [94].

### 6.6.1.3 Carmustine

Carmustine [BCNU, 1,3-bis(2-chloroethyl)-1-nitrosourea] is a highly lipophilic nitrosourea compound that undergoes hydrolysis *in vivo* to form reactive metabolites. These metabolites cause alkylation and crosslinking of DNA. Nitrosoureas generally lack cross-resistance with other alkylating agents [88, 89]. The US Food and Drug Administration (FDA) approval of Gliadel® in 1996 represented the first new treatment approved for brain tumors in over 20 years. It has also been approved by numerous regulatory agencies worldwide.

Gliadel® is a polymer–drug combination that delivers the chemotherapeutic agent carmustine directly to the site of a brain tumor via controlled release from a biodegradable matrix [95]. To compare the effectiveness of lipid microspheres with Gliadel®, Takenaga has incorporated a BCNU into lipid microspheres by homogenizing a soybean oil solution of BCNU with egg yolk lecithin. Compared with the corresponding conventional dose of BCNU, the lipid microsphere-encapsulated BCNU significantly enhanced antitumor activity with reduced toxicity in mice with L1210 leukemia. Lipid nanospheres with an average size of 50 nm also showed a similar level of *in vivo* antitumor activity. In this report, [<sup>14</sup>C]triolein uptake by L1210 leukemia cells was increased by incorporation into microspheres. The nanospheres showed a longer *in vivo* half-life due to the avoidance of cellular uptake by the RES, resulting in higher accumulation at the tumor sites [96].

## 6.6.2

### Antimetabolic Agent

#### 6.6.2.1 Cytarabine

Cytarabine is metabolized intracellularly into its active triphosphate form (cytosine arabinoside triphosphate). This metabolite then damages DNA by multiple mechanisms, including the inhibition of  $\alpha$ -DNA polymerase, inhibition of DNA repair through an effect on  $\beta$ -DNA polymerase, and incorporation into the DNA. The latter mechanism is probably the most important. Cytotoxicity is highly specific for the S phase of the cell cycle [88, 89]. Ellena et al. have investigated the distribution of phospholipid and triglyceride molecules in the membranes forming the nonconcentric vesicular network within a multivesicular lipid particle (MLP). MLP formulations exhibited controlled release of encapsulated pharmaceuticals on time scales of a few days to a few weeks. The MLP can be synthesized by a double emul-

sification process with a neutral lipid such as a triglyceride. MLP formulations with the antineoplastic agent cytarabine encapsulated in the aqueous compartments have been prepared that further contained [ $^{13}\text{C}$ ]carbonyl-enriched triolein. This rational approach can be used to develop MLP formulations with variable rates of sustained release, modulated by changes in the distribution of various phospholipids and triglycerides [97].

#### 6.6.2.2 Fluorouracil (FU)

Fluorouracil was developed in 1957 based on the observation that tumor cells utilized the base pair uracil for DNA synthesis more efficiently than did normal cells of the intestinal mucosa. It is a fluorinated pyrimidine that is metabolized intracellularly to its active form, fluorodeoxyuridine monophosphate (FdUMP). The active form inhibits DNA synthesis by inhibiting the normal production of thymidine. Fluorouracil is cell cycle phase-specific (S phase) [88]. 5-Fluorouracil (5-FU)-loaded poly(L-lactide) (PLLA) or its carbonate copolymer microspheres have been prepared by a modified oil-in-oil (o/o) emulsion solvent evaporation technique. The dispersed phase was a solvent mixture of *N,N*-dimethylformamide (DMF) and acetonitrile, and the continuous phase was liquid paraffin containing 1–10% (w/v) Span 80(R). Using this modified process, microspheres with various particle sizes can be prepared with high 5-FU entrapment efficiency (~80%). *In vitro* drug release experiments showed a burst release of 5-FU from PLLA microspheres, followed by a sustained release over 50 days. With other vectors, poly(L-lactide-co-1,3-trimethylene carbonate) (PLTMC) and poly(L-lactide-co-2,2-dimethyl-1,3-trimethylene carbonate) (PLDTMC), the drug release rate can be prolonged to over 60 days [98].

Roullin et al. have developed 5-FU-loaded poly(L-lactide-co-glycolide) (PLGA) microspheres to deliver therapeutic agents into the CNS for stereotactic intracerebral implantation [39]. *In vivo* experiments with C6 glioma-bearing rats showed promising results – the median survival time was doubled [99]. A phase I–II pilot study was conducted on eight patients with high-grade glioma who underwent surgical removal before 5-FU-loaded microspheres were implanted. After 18 months the patients' survival rate and welfare was improved [100]. Microsphere fate and the 5-FU diffusion area from these particles in the brain was also investigated, depending on the inserted locations of the drug-loaded microspheres. [ $^3\text{H}$ ]5-FU microspheres were used to evaluate diffusion areas from the implantation site [39].

Another approach for controlled DDSs into the brain has also been developed using implantable, biodegradable microspheres. The strategy was evaluated initially to provide localized and sustained delivery of the radiosensitizer 5-FU after patients underwent surgical resection of malignant glioma [101].

#### 6.6.2.3 Methotrexate

Methotrexate and its active metabolites compete for folate-binding sites of the enzyme dihydrofolate reductase. Folic acid must be reduced to tetrahydrofolic acid by this enzyme for DNA synthesis and cellular replication to occur. Competitive inhibition of the enzyme leads to blockage of tetrahydrofolate synthesis, depletion of

nucleotide precursors, and inhibition of DNA, RNA and protein synthesis. Methotrexate is cell cycle phase-specific (S phase) [88, 102]. Methotrexate can be widely employed for breast cancer, bladder cancer and head and neck cancer, etc.

ABA-type triblock copolymers of poly(trimethylene carbonate)-poly(ethylene glycol)-poly(trimethylene carbonate) were synthesized by ring-opening polymerization. The anticancer drug methotrexate was loaded into a core-shell structure of polymeric nanoparticles 50–160 nm in diameter. Generally, the release rate of methotrexate from the nanoparticles was comparatively faster than that of microsphere systems due the higher surface area and smaller particle size [103].

Hydrophilic gelatin nanoparticles have also been prepared that incorporated the methotrexate by solvent evaporation techniques based on a single water-in-oil (w/o) emulsion with glutaraldehyde as a crosslinking agent. The mean diameter of the methotrexate-loaded gelatin particles was 100–200 nm [86].

### 6.6.3

#### Anticancer Antibiotics

##### 6.6.3.1 Actinomycin D

At low concentrations actinomycin D inhibits DNA-directed RNA synthesis and at higher concentrations DNA synthesis is also inhibited. All types of RNA are affected, but ribosomal RNA is more sensitive. Actinomycin D binds to double-stranded DNA, permitting RNA chain initiation but blocking chain elongation. Binding to the DNA depends on the presence of guanine. It is applicable to the treatment of testicular, ovarian, and germ cell cancers. Isobutyl cyanoacrylate nanoparticles loaded with actinomycin D were shown to concentrate preferentially in rat mesangial cells and to increase the drug's uptake in these cells *in vitro* and *in vivo*, as compared to the free drug. Drug targeting by nanoparticles to renal cells and macrophages may be possible, resulting in a lowering of the critical level of drug dosage in tubular cells and a reduction of tubular toxicity [104].

The effects of actinomycin D-loaded poly(methyl cyanoacrylate) nanoparticles on the growth of a transplantable soft tissue sarcoma has also been investigated in a rat model. Actinomycin D-loaded poly(methyl cyanoacrylate) nanoparticles showed a greater inhibitory action than the free drug on the growth of the S250 sarcoma but the nanoparticles alone did not demonstrate any significant antitumor effect [105]. This study demonstrated that, 24 h after injection, adsorbed actinomycin D is 5.6-, 44- and 64-fold more concentrated than the free drug in muscle, spleen and liver, respectively [106].

##### 6.6.3.2 Bleomycin

Bleomycin is an antineoplastic antibiotic. It is used to treat several types of cancer, including cervical and uterine cancer, head and neck cancer, testicular and penile cancer, and certain types of lymphoma. Bleomycin causes DNA strand scission through formation of an intermediate metal complex requiring a metal ion cofactor such as copper or iron. This action results in inhibition of DNA synthesis and, to a lesser degree, in inhibition of RNA and protein synthesis. The drug is cell

cycle-specific for G phase, M-phase and S phase [107]. Manipulation of the physicochemistry of water-soluble polymers such as glycolchitosan can be used to create hybrid materials for drug delivery and gene delivery with biocompatibility. Glycolchitosan modified by the attachment of a strategic number of fatty acid pendant groups (11–16 mol%) assembles into unilamellar, polymeric vesicles in the presence of cholesterol. An ammonium sulfate gradient bleomycin (MW 1400), for example, can be efficiently loaded onto these polymeric vesicles to yield a bleomycin-to-polymer ratio of 0.5 units  $\text{mg}^{-1}$  [108].

Bleomycin has been conjugated to carbon nanoparticles as a new DDS for the treatment of digestive cancer. In this way, higher levels of anticancer drug can be localized to the regional lymph nodes and at the injection site compared with distribution of the drug in aqueous solution. In 12 patients with histologically proven carcinoma, bleomycin-conjugated carbon nanoparticles were injected endoscopically into the primary lesions. Endoscopic injection of this dosage formulation shows that it can control these digestive cancers in patients in whom operation is contraindicated [109].

Formulations of ultra-deformable liposomes containing bleomycin (Bleosome™) also have been reported and proposed for topical treatment of skin cancer [110]. Bleosome™ exerted a lethal effect on human keratinocytes cell lines and a cell line derived from a primary carcinoma *in vitro* when loaded with sufficient bleomycin. The cell line, derived from squamous cell carcinoma, seemed to be more susceptible to Bleosome™ than HPV-immortalized keratinocytes (NEB-1) [111].

#### 6.6.3.3 Daunorubicin

Daunorubicin is an anthracycline antibiotic that damages DNA by intercalating between base pairs, resulting in uncoiling of the helix, ultimately inhibiting DNA synthesis and DNA-dependent RNA synthesis [112]. DaunoXome®, a tumor-targeting daunorubicin liposome, is commercially available and its beneficial effects are well reported. It is a formulation of daunorubicin in small unilamellar vesicles (SUVs) composed of highly pure distearoylphosphatidylcholine (DSPC) and cholesterol in a 2:1 mole ratio. Several countries have approved DaunoXome® for use in for treating Kaposi's sarcoma (KS) in HIV-positive patients. Preclinical investigations indicate that DaunoXome® increases *in vivo* daunorubicin tumor delivery by about ten-fold over conventional drugs, yielding a comparable increase in therapeutic efficacy [113].

## 6.7

### Future Directions

Although many trials on different types of DDS have been reported, these laboratory experiments still remain far from clinical application due to matters of their reproducibility and production. New strategies for the design of DDS vectors should be developed to move these systems into the clinic by decreasing the toxicity of anticancer agents and targeting them to malignant tissues. Furthermore,

novel techniques for the effective loading of active molecules and surface activation (i.e., antibodies and functional groups) for active targeting are essential to improve the therapeutic effectiveness by reducing both the dose and the side effects. Several functions should be considered, such as effective targeting, maximum uptake and retention at the target sites, and rapid clearance after finishing the mission. For this reason, the generation of intelligent smart biomaterials (ISB) based on nanotechnology is being intensively investigated for controlled DDS of anticancer agents and is already having an enormous effect on nanomedicine as a new research field.

While many of nanoparticle synthesis techniques have focused on the empirical basis for controlled release of anticancer agents, increasing demand for multifunctional vectors represents a major fabrication challenge. These vectors should be designed to integrate several aspects: (a) theoretical and practical considerations of the evolution of novel phenomena coming from their composition and size, (b) design of complex or composite structures with given morphology required for multifunctionality, (c) generation and assembly of new molecular and macromolecular structures using suitable processing routes, (d) incorporation of drugs to be delivered to the target cells, and (e) modification of the nanoparticulate surfaces and interfaces, rendering them suitable for interaction with the target.

To develop artificial synthetic biomaterials based on nanotechnology for cancer-oriented drug delivery systems (CoDDS), we should consider the extracellular matrix biology, cell receptors and immunology, and how the body responds to specific materials. These novel vectors should incorporate hydrophobic/hydrophilic drugs with active surface modifications by the attachment of active functional ligands for passive targeting at specific target organs, receptors, etc.

Moreover, novel concepts of ISB for CoDDS can be developed based on core-shell, mesoporous nanotechnology. These vectors can be programmed to respond to external environmental conditions, e.g., pH, ionic strength, temperature, ultrasound, radiation, magnetic fields, UV-light, etc. The development of suitable nanostructures, methodologies for drug incorporation, methodologies for controlling releasing rates, and acceptable biological activity should be considered in the design process.

Targeting is also an important concept for CoDDS. Passive and active targeting to specific lesions, degradation/release rates, and surface activation/functionalization should be considered for optimization of these systems. Toxicology and pharmacological evaluation are also important factors. Thus, the therapeutic compounds, loading methods, quantity and efficacy, etc. should all be carefully considered during the design proper vectors.

# Critical Analysis of Cancer Therapy using Nanomaterials

*Lucienne Juillerat-Jeanneret*

### 7.1

#### Introduction

The treatment of diseases such as cancer is challenging because these pathologies involve dysregulation of endogenous and often essential cellular processes. Cancer cells replicate faster than most non-tumoral cells, and the vast majority of presently used therapies capitalize on these differences. More selective therapies, such as anti-angiogenic therapies, are under development and/or clinical evaluation, whereas a few targeted therapies are in clinical use, such as antiestrogen therapies in estrogen receptor-positive breast cancer. With targeted approaches, not only patient survival will increase due to improved treatment efficiency, but also the quality of life of patients will improve by decreasing side effects to normal cells. Most solid tumors possess unique features, such as extensive angiogenesis, defective vascular architecture, increased vascular permeability, impaired lymphatic drainage, which can also be used as therapeutic targets. Nanoparticles can take advantage of these features and act as a vehicle to selectively and specifically deliver anti-cancer drugs to tumors, either by using passive mechanisms such as increased vascular permeability or acting as drug reservoir in a defined location, or by using active targeting. These combined approaches would result not only in increased efficacy but also in decreased collateral side effects. However, targeting strategies and chemical synthesis routes need to be improved, and the mechanisms of interactions of these functionalized nanostructures with living materials need to be better understood.

This chapter describes not only the tools of nanoparticle technology that can be used to treat cancer, as many excellent reviews (indicated below the section headings) have been published, but rather critically reviews and discusses the advantages and drawbacks of nanoparticles for the *targeted* delivery of anticancer agents to defined cells of human cancers. Approaches that have been developed or are under development to achieve improved cancer therapy using nanoparticles as targeting delivery agents for anticancer drugs are reviewed, and the problems and issues that need to be answered to validate these approaches are summarized. Section 7.2 reviews the characteristics of human tumors that can be used to develop anticancer

treatments. Section 7.3 covers the characteristics of already developed nanoparticles, considering the chemical, biophysical and biological demands of such devices. Information from the previous two sections is combined in Section 7.4 to review the characteristics of already developed, or under development, nanoparticles for anticancer treatments using drugs employed in clinics or under development, photodynamic and gene therapy approaches, or magnetically controlled delivery. Section 7.5 describes the defects and characteristics of human tumors that can be used to develop targeted anticancer treatments using nanoparticles, via cancer-associated cells, cancer cell molecules, or by achieving intracellular delivery, and also describes the chemical challenges involved in preparing these nanovectors. Section 7.6 hypothesizes how nanoparticles may result in the delivery of anticancer drugs in drug-resistant human cancers. Issues not yet resolved issues concerning the potential toxicity of nanoparticulate vectors to patients and the general population are covered in Section 7.7. Finally, Section 7.8 describes what might be the ideal nanoparticle in the context of targeted treatment of human cancer using nanodevices.

## 7.2

### Anticancer Therapies

For a more extensive review see Ref. [1] and references herein. Effective therapies of cancer capitalize on differences between diseased and healthy tissues that can be targeted with drugs. Cancer drugs used in patients target the cell cycle, DNA replication, and cytoskeletal assembly. The general toxicity to the whole body of current anticancer chemotherapeutic treatments, resulting in important side effects such as sterility, loss of digestive capacities and appetite, loss of hair, defects in immune functions, etc., is a challenge facing the development of new modalities of cancer treatment. In addition, combination therapies or scheduled therapies improved patient response to chemotherapy regimen. One of the main challenges in cancer treatment is no longer the development of efficient drugs but the improvement of drug selectivity. More recently, the targeting of growth receptors and cellular signaling pathways, “targeted therapeutics”, has become a new approach in cancer treatment. However, even targeted and combined therapies suffer from side effects that result from imperfect selectivity for diseased tissue. The availability of novel molecular targets and drug delivery systems that distinguish diseased from healthy cells could vastly amplify therapeutic opportunities. The identification of new disease-associated changes in cellular biology, and the development of associated tools, that may be used to improve selectivity in diagnosis, treatment and evaluation of response to treatment will be the next challenges in cancer therapy. Most cancer-related deaths occur as a consequence of metastasis, and the major problem facing oncologists treating cancer is metastatic disease. Metastasis of tumor cells to organs distant from the original primary tumor site involves about half of all cancers and is generally detected only at an advanced stage of metastatic disease. Successful eradication of metastatic lesions still depends on the early detection of

metastases, which only rarely happens. Therefore, devising new means to detect metastatic tumor lesions at the earliest possible stage, and at the same time to be able to treat them, would be an important breakthrough in cancer treatment. Magnetic nanoparticles can be used for this purpose. Therefore, one goal in the field of cancer is to develop chemically derivatized nanoparticles able to target tumor cells and tumor-associated stromal cells via specific recognition mechanisms, and dual cancer detection such as magnetic resonance imaging and cancer therapy using cell-directed drugs.

Neoplastic tissue can be divided into three compartments, vascular, interstitial and cellular, and cancers are constituted of several cell types:

- Endothelial cells and pericytes, either overnumbered or undernumbered;
- immune/inflammatory cells, including macrophages and lymphocytes, and fibroblasts and myofibroblasts;
- normal cells and tumor cells derived from these normal cells;
- and by the absence of a well-defined lymphatic network.

Tumor vasculature is highly abnormal, proliferating, activated, tortuous, and presenting increased permeability and gaps, with pores between 350 and 800 nm, and a cutoff around 400 nm. Tumor vascularization is generally poorly perfused. Tumor interstitium is predominantly constituted of a protein network, including collagens, elastin, proteoglycans and glycoproteins, forming a hydrophilic gel and producing high interstitial osmotic pressure, leading to an outward convective fluid flow. The tumor environment is oxidative and acidic, and thus ionization of basic drugs may decrease their interstitial transport and oxidation destroy their anti-cancer properties. The transport of drugs in the interstitium will thus be governed by interstitial osmotic pressure and the relative chemical composition and characteristics of drugs and the interstitium.

Therefore, the delivery of a therapeutic agent to tumor must:

1. Resist hydrostatic, hydrophilic/hydrophobic and biophysical/biochemical barriers;
2. resist cellular resistance to treatment;
3. resist biotransformation, degradation and clearance mechanisms;
4. reach its treatment target: extracellular or intracellular compartments, tumor cells or vascular cells, etc.;
5. achieve distribution in all tumor areas even with low vascularization, or poor perfusion;
6. and be active in tumors at efficient concentrations, without unacceptable side effects to non-tumoral cells.

Both tissue- and cell-distribution of anticancer drugs can be controlled and improved by their entrapment in colloidal nanoparticles, increasing anti-tumor efficacy, reversing resistance mechanisms and decreasing side effects. Active tumor targeting with long-circulating nanoparticles decorated with targeting agents is the

main development required to achieve these goals. The association of drugs with colloidal nanoparticles may be a way to overcome many of these resistance mechanisms of tumors to treatment and increase selectivity. In this context, nanoparticles are defined as submicroscopic colloidal systems, which may act as a drug vehicle either as nanospheres (a matrix system in which the drug is dispersed) or nanocapsules, which are reservoirs in which the drug is confined in a hydrophobic or hydrophilic core surrounded by a single polymeric membrane. The structure of the polymer and the method of trapping the drugs in the nanoparticles will define the drug release kinetics and characteristics. The necessary characteristics to be useful in cancer treatment, and the drug–nanoparticle systems that have reached clinical use, are under clinical evaluation or are under development will be reviewed.

### 7.3

#### Characteristics of Nanoparticles for Cancer Therapy

For more extensive reviews see Refs. [2–6] and references herein. The treatment of cancer is limited by the inability to deliver therapeutic agents in such a way that most drug molecules will selectively reach the desired targets, with only marginal collateral damage. To achieve such efficient treatments, two main goals must be met:

- Increasing targeting selectivity for defined organ, tissue or cells.
- Devising a therapeutic formulation able to overcome the biological barriers that prevent drugs efficiently reaching their targets.

However, the realization of such a system faces formidable challenges, which include:

- Identification of neoplastic biomarkers as biological targets, and their evolution over time.
- Development of biotechnologies to develop biomarker-targeted delivery of multiple therapeutic agents, coupled to the possibility to avoid biological barriers and various resistance mechanisms.

Nanoparticles are interesting for medical application since they present a large surface for functionalization with drugs compared to larger particles made of the same materials, and hopefully achieve targeted drug delivery. They can pass epithelial and vascular barriers. Thus, nanoparticles have the potential to provide opportunities to meet the challenges of cancer therapy, and also of therapeutic approaches for other disorders.

The dawning era of polymer therapeutics started with improved knowledge of polymer characteristics and the development of polymer chemistry (reviewed in Ref. [3]). Initially, polymer–drugs, polymer–proteins, and, in particular, PEGylated derivatives and HPMA [*N*-(hydroxypropyl)-methacrylamide] copolymers have been

used in the context of anticancer therapy [7], and are the precursors of nanoparticulate systems. Self-assembling block-copolymers were then evaluated to deliver drugs to cancer. A pluronic block copolymer-doxorubicin was able to circumvent Pgp [8, 9], and PEG-polyAsp-doxorubicin accumulated preferentially in tumors due to vascular leakage [10, 11], while the increased size prevented back-diffusion and renal clearance when evaluated in clinical trials. These approaches opened the way to nanotechnology for drug delivery.

### 7.3.1

#### Nanovectors

Nanotechnology implies that the drug delivery device is man-made, and of dimensions in the nm range (sub-cellular size), which includes nanovectors such as liposomes or monomeric or block copolymeric nanoparticles for the (targeted) delivery of anticancer drugs, imaging contrast agents such as gadolinium or iron-oxide nanosized magnetic resonance imaging contrast agents (cf., for example, Chapters 3 and 5), or quantum dots. First, basic definitions for the various nanoparticulate systems in the context of cancer are given as they will be developed in this chapter. Nanoparticles are non-viral solid nanovectors made of one or several different materials, including water-soluble polymers, whose upper size limit is  $<1 \mu\text{m}$ , generally  $<100 \text{ nm}$ . These nanostructures have unique properties, such as modification of the properties, spacing and arrangement of surface atoms, and physics and chemistry compared to larger particles of the same material, and they also have a large surface area to volume ratio. Nanoparticles may be built of polymeric drugs (nanosuspensions), polymer–drug conjugates, polymer–protein conjugates, polymeric drug-micelles, etc. Micelles are self-assembling colloidal aggregates of amphipathic molecules–polymeric block copolymers to give polymeric micelles, which occurs when the concentration reaches the crucial micelle concentration (c.m.c.). Polyplexes are polyelectrolyte complexes formed by a polycation and an anionic molecule, generally an oligonucleotide. Dendrimers are macromolecule that contain symmetrically arranged branches arising from a multifunctional core, to which a precise number of terminal groups are added stepwise. Drug nanosuspensions are insoluble nanocrystals of drugs, generally coated with a surfactant.

Rational approaches in design and surface engineering for site-specific delivery of drugs, genetic material and diagnostic agents, to tissues, cells and intracellular cell compartments, after intravascular, parenteral, intraperitoneal, etc., administration, include:

- Liposomes: closed vesicles formed by hydration of phospholipids above their transition temperature. Nanoliposomes are bilayer structures of less than 100 nm, surrounding the drug entrapped in the aqueous space. Drugs can also be contained in the lipid space between bilayers. Surface modification is possible, and nucleic acids are adsorbed on cationic liposomes by ion-pairing. These structures have been the first to reach clinical use.
- Micelles: amphiphilic aggregates,  $<50 \text{ nm}$ , made of hydrophilic (A) and hydro-

phobic (B) block copolymers (AB or ABA), in which hydrophobic or hydrophilic drugs are physically trapped or covalently bound. Drugs may include nucleic acids for transfection and gene therapy.

- Nanospheres: made of polymer (synthetic or natural) aggregates (tens to hundreds nm size) in which the drug is either dissolved, entrapped, encapsulated or covalently attached. Surface modification is possible.
- Superparamagnetic iron oxide crystals: made of an iron oxide core (5–10 nm) obtained by coprecipitation of  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$ , and coated with a polymer [dextran, poly(ethylene glycol), poly(vinyl alcohol), etc.]. Surface modification is possible by covalent links or adsorption (drug, antibodies, nucleic acid, targeting agents). These nanostructures have mainly been used for cancer detection, and are now developed to couple detection with drug delivery.
- Carbohydrates-ceramic nanoparticles: core composed of calcium phosphate or ceramic, surrounded by a polyhydroxyl oligomeric film, on which drugs are adsorbed.
- Dendrimers: highly branched three-dimensional macromolecules that grow by outward-controlled polymerization; drugs are covalently bound at the surface.

Therapeutic agents (chemically synthesized therapeutic small or large drugs, therapeutic peptides or proteins, nucleic acids for gene therapy) can be entrapped, encapsulated, adsorbed, covalently bound either to the surface or at the interior of biodegradable polymeric nanoparticles (Table 7.1). These approaches can improve drug solubility, and also achieve better drug selectivity. Drugs can be made to form small aggregates, surrounded by a water- and bio-compatible, biodegradable poly-

**Tab. 7.1.** Biological characteristics of the polymers.

Polymer	Efficient for
PEG	Increases biocompatibility, increases circulating time, decreases uptake by macrophages
Dextrans	Increases circulating time, decreases aggregation and opsonization, decreases uptake by macrophages
Poly(vinylpyrrolidone)	Increases circulating time, decreases aggregation and opsonization, decreases uptake by macrophages
PVA	Decreased aggregation/coagulation
Polyacrylates	Biostabilization, biocompatibility, increases bioadhesion
Polypeptides	Targeting
Poly(DL-lactide)	Increases biocompatibility, decreases cytotoxicity
Chitosan	Increases biocompatibility, increases hydrophilicity

meric thin layer, improving the biodistribution and bioavailability of drugs. Surface or polymers functionalization with appropriate ligands can allow the targeting of these nanostructures to defined cells, tissues or body locations, depending on the chosen specificity and selectivity of the ligand, improving the therapeutic effectiveness and decreasing side effects of drugs. Finally, the polymer properties may also be defined to respond to changes in pH or redox state, chemical environment, heat (either internal or external), or an external physical stimulus, therefore allowing choice for the rate and location of drug release, e.g., acidic intracellular organelles such as the lysosomes.

The development of nanovectors has given birth to what has been called “nanomedicine”: the applications of nanotechnology for the rational delivery and targeting of pharmaceuticals, therapeutics and diagnostic agents. The next challenges include:

- Identification of precise targets for selective delivery.
- Choice of appropriate nano-carriers.
- Avoidance of mononuclear phagocytes and the reticuloendothelial system, to selectively target either angiogenic cancer-associated endothelial cells or cancer cells, which are key targets in cancer.

### 7.3.2

#### **Biological Issues**

Injection in the blood and lymphatic vessels, but also inhalation or intraperitoneal injection, etc., are possible routes of administration for the delivery of therapeutic nanoparticles. The stability, extracellular or cellular distribution of nanoparticles depend on their surface properties, chemical composition, morphology and size. The main challenges for intravenously injected nanoparticles are rapid opsonization and clearance by the reticuloendothelial system (RES) of the liver and the spleen or excretion by the kidneys (Fig. 7.1). Opsonization by complement proteins, vitronectin, fibronectin, immunoglobulins, lipoproteins, etc. renders nanoparticles recognizable by the major defense systems of the body, the RES and the mononuclear phagocyte system, depending on the surface properties of nanoparticles, their size (< or >200 nm) and surface characteristics. Nanoparticles with a largely hydrophobic surface are efficiently coated with plasma components, trapped in the liver and rapidly removed from circulation, while smaller particles can stay in circulation. More hydrophilic nanoparticles can resist coating process to a variable extent and are more slowly cleared from the blood stream [2]. Therefore, clearance kinetics depend on the chemical and physical properties of the nanoparticles: surface charges and charge density, lipophilic/hydrophilic area ratio, presence of functional and chemically reactive groups. Consequently, successful drug delivery requires careful control of the physicochemical properties (size and surface) of nanovectors. Suppression of opsonization will increase the retention of nanoparticles in locations other than macrophages and so afford a longer circulatory time. In addition, macrophages are heterogeneous, in different tissues and within a tis-

**Fig. 7.1.** Fate and distribution in the body of intravenously injected nanoparticles – their uptake by different organs, according to the particles' size and surface.

sue. PEGylation [the coating of the surface by poly(ethylene glycols)] of nanoparticles has been the main approach up to now to solve opsonization problems and short circulation times. PEG coating decreases liver, spleen, lung, or kidney clearance. A large surface area is also an issue in the aggregation of nanoparticles in a biological environment, determining the effective clearance rates and mechanisms.

### 7.3.3

#### **Nanoparticle Targeting: Passive or Active**

Long circulation times are efficient in both treating circulatory disorders and vascular imaging. Passive targeting depends on vascular leakage and passive diffusion [enhanced permeability and retention (EPR) effect] of nanovectors to achieve drug delivery. Nanoparticles escape from the vasculature compared with virus behavior and is restricted to endothelial fenestration (between 150 and 300 nm) of leaky areas in inflammation or tumors, or splenic filtration for non-deformable nanoparticles (200–250 nm). Initially, targeting was passively achieved at the organ/tissue level by virtue of particle size, 50–200 nm carriers restricting the distribution volume to the blood compartment.

Active (ligand-targeting, cationic lipids or polymers cytotoxic and low circulating times) delivery using selective recognition mechanisms can be achieved with more recent nanoparticles, and is presently under development and evaluation. Therefore, the surface engineering of nanoparticles is a crucial determinant of their biological behavior, and much effort is presently undertaken to improve these modifications (see below). A thorough understanding of the elaborate cell transport ma-

chinery as well as an understanding and the finding of targets to achieve selective delivery will be necessary to fulfill the potential of nanobiotechnologies in cancer.

Many drugs are agonists and antagonists of chemicals inappropriately produced by diseased cells. Intelligent systems should respond to differences in concentration of these chemicals or changes in external biological conditions, e.g., by modification of the polymer lattices, allowing increased or decreased release of drugs, dependent on a biosensor to achieve “intelligent therapeutics”. Delivery of therapeutic agents precisely where and when they are needed in the human body is becoming realistic due to rapid, tremendous progress in physiology, nanoparticle and nanobiotechnology. Nanoparticles can improve the targeting of cytotoxic drugs to cancer only if they can be directed to cancer areas and maintained there for long time periods with their drug cargo for selective and local release of drugs such as alkylating agents, 5-fluorouracyl, platinum derivatives, taxol derivatives, and more selective kinase inhibitors. Chemical bonding, ionic or hydrophobic adsorption or embedding of drugs into nanoparticles have been devised to be sensitive to cancer tissue properties, including high proteolytic or glycolytic activity, high metabolism, low pH, and high oxidative environments in tumors, to further ensure selective release of the drug in the tumor area. The discovery and design of intelligent material will be the next drug-delivery system generation for chronic diseases. These approaches will now be reviewed.

#### 7.4

#### **Nanovectors in Biomedical Applications: Drug Delivery Systems (DDS) for Cancer**

For general reviews see Refs. [6, 12] and references herein. Present treatments for cancer include various unique or combined approaches, encompassing total or partial surgical excision of tumor tissue, chemotherapy and radiotherapy. Anticancer chemotherapeutic drugs are generally administered intravenously, leading to general systemic distribution. As drugs used in cancer chemotherapy are mostly non-selective for tumor or tumor-associated cells, important and deleterious side effects result from their use [2, 13, 14]. These secondary effects in patients result in loss of quality of life and necessitate drugs to alleviate them. Therefore, means are needed to deliver drugs to specific areas of the body, maximizing drug action (exclusively in diseased cells), together with minimizing side effects, and consequently increasing treatment efficiency. Selective or targeted DDS, and in particular nanoparticles, have the potential to achieve the goals of drug-targeted delivery:

- Delivery to a particular organ;
- to a specific cell type (differentiation from tumor and normal cells);
- to a structure within a cell (such as the nucleus in gene therapy, where targeting to the nucleus is a prerequisite of gene expression).

They use (a) physicochemical, (b) biological or (c) chemical methods to control the distribution of drugs to improve the outcome of chemotherapy.

## 7.4.1

**Physicochemical Drug Delivery**

Polymers and colloidal nanocarriers (nanoparticles) can be used for passive or active drug delivery. Passive targeting implies a physiological uptake mechanism (filtration or macrophage sequestration), while active methods involve the use of a recognition ligand.

## 7.4.2

**Biological Drug Delivery**

With biological targeting a specific marker (a target) is selectively expressed on diseased cells and not, or at a much lower level, in normal cells. The targeting agent, such as antibodies, a ligand for a receptor or a lectin, is covalently conjugated via an appropriate spacer to the nanoparticle. It can be directed towards an antigen or receptor residing on or within the target tissue.

## 7.4.3

**Chemical Drug Delivery**

Chemical methods involve the use of modified forms of active drugs, e.g., prodrugs, by exploiting differences in pathophysiological conditions within target tissues (e.g., pH, redox state, enzyme content) and normal tissues.

The efficiency of drug delivery depends strongly on the nanovector size and surface characteristics, controlling the fate of a drug in the organism, and the selective delivery of drugs. The size, zeta potential (surface charge, coating), release characteristics (polymers and linkers), biodegradability and cytotoxicity and encapsulation efficiency are the main factors determining efficient drug delivery. Expression at the surface of nanovectors of cell-specific ligands can further increase selectivity. Control of the release of a drug, in a defined localization in an organism, organ, tissue, at the cell surface or intracellularly, and the kinetics of drug release must also be characterized. Finally, the stability, cytotoxicity, mechanisms of cell uptake and the biodegradation of the nanovectors are also important. Passive (EPR effect) versus active (ligand-targeting, cationic lipids or polymer cytotoxicity and poor circulating times) delivery is also a choice to consider for efficient delivery, and must be dictated by the characteristics of the cancer to be treated, whether a marked angiogenesis is present or not.

Various nanovectors are available to achieve drug delivery, such as liposomes, micro/nanospheres, nanoemulsions and micro/nanocapsules. They can be used to deliver hydrophilic drugs, hydrophobic drugs, proteins, nucleic acids, vaccines, biological macromolecules, etc. Nanovectors, such as liposomes, protect drugs from degradation and biological metabolism; however, liposomes have a low encapsulation efficiency, poor storage stability, and rapid leakage of water-soluble drugs in the blood. As such, their ability to control the release of many drugs is not optimal. Nanoparticles made of colloidal suspensions and biodegradable poly-

mers offer better stability than liposomes and allow controlled release. Finally, the efficiency of drug delivery is increased by using magnetic vectors, which can be targeted with an external gradient magnetic field; such vectors also have the potential to record the drug delivery sites as contrast agents in magnetic resonance imaging (MRI) for diagnostics (see below). The characteristics, composition, etc. of nanoparticles (which are in clinical use, in clinical trials or under development) necessary to achieve targeted delivery of anticancer agents to treat human cancers will be reviewed as a function of their physicochemical properties and the chemical and biological properties of the drug, or the cancer type characteristics. However, this chapter is not an extensive review of all the published information available.

#### 7.4.4

#### **Nanoparticles for Anticancer Drug Delivery**

For more extensive reviews see Refs. [6, 12, 15]. What has been attempted and what are the next challenges of the nanoparticulate approach to drug delivery in cancer?

##### 7.4.4.1 Existing Systems

**Colloidal Delivery Systems** Encapsulation of therapeutic agents in colloidal carriers, including liposomes, emulsion, solid lipid nanoparticles, polymeric particle and polymeric micelles, form colloidal delivery systems.

**Liposome Nanoparticles** These nanoparticles are biodegradable and flexible, have an aqueous core containing the drug, and are bilayer amphipathic lipids. Drugs encapsulated in liposomes under evaluation or in clinics include paclitaxel, lurtotecan, platinum derivatives, vincristine, doxorubicin (see below).

**Emulsion/Solid Lipid Nanoparticles** Here an oily core, either liquid or solid lipids at body temperature, or a monolayer of amphipathic lipids contains the drug. Drugs under evaluation include protoporphyrin IX, for photodynamic therapy, and taxol (see below).

**Polymeric Nanospheres** Polymers [such as poly(lactide-co-glycolide), poly(vinylpyrrolidone), poly( $\epsilon$ -caprolactone)] and entrapped drugs allow controlled drug release from the polymer.

**Polymeric Micelles** Biodegradable polymeric micelles with the drug in the core have been prepared from di-block copolymers (one core-forming segment, one shell-forming segment).

**Drug-conjugated Delivery Systems** In these systems drugs are covalently bound to the polymer and are either active when coupled to the polymer or after release (acid-sensitive, enzyme-sensitive bonds) or polymer degradation.

Lipid-based or polymer–drug conjugate-based nanoparticles (<200 nm) can im-

prove the pharmacological properties, pharmacokinetics and biodistribution, and sustained release of free drugs. But they also present new challenges and issues [12] that need to be taken into account for the DDS to reach clinical use, including potency (the fewer the carrier can carry, the more potent the drug must be), the stability of the drug carrier (either shelf or biological stability), solubility of the drug, size of the carrier and the cargo (e.g., proteins and small carriers), charge, carrier biocompatibility, cytotoxicity, degradation products, drug survival to chemical procedures and coupling routes, rates and efficacy of drug release in the tumor space (e.g., for schedule-dependent anticancer drug therapies drugs must stay above minimal efficacy levels for several hours or days, for schedule-independent drugs a large burst is more important than constant release), hypersensitivity reaction to the carrier–drug conjugates. A drug linked to a carrier may have the same activity as the free drug or, alternatively, its pharmacological properties may be modified, e.g., the toxicity of liposomal vincristine is similar to that of the free drug, but its potency is augmented, liposomal topotecan is protected from biodegradation, and doxorubicin-linked *N*-2-hydroxypropyl methacrylamide copolymer displays a slow release and an increased maximal tolerated dose.

#### 7.4.4.2 Systems under Development and Challenges

**Targeted Drug Delivery Nanoparticulate Systems** These are the most recent development, presently only at the initial stages. Drugs are conjugated to ligands/antibodies or incorporated in carriers bearing ligands/antibodies for recognition by cell surface receptors expressed by target cells, e.g., doxorubicin-nanoparticles targeting HerB2/neu for breast cancer. Major obstacles for the delivery of anti-cancer drugs include the definition of selective cell-specific targets and physiological barriers, in particular the epithelial and blood–brain barriers. For example, approaches using LDL-mimic nanoparticles targeting the LDL receptors on brain endothelial cells [16] or galactose-HPMA copolymer bearing doxorubicin for the asialoglycoprotein receptors in liver tumors, which is under clinical trial [17], have been attempted. One major problem in these approaches is to identify relevant targeting entities in cancers compared with normal cells of the whole body. A few have been identified and evaluated in preliminary trials, e.g., folate receptors and PSA-doxorubicin conjugates for PSA-positive prostate cancer.

**Intracellular Delivery** For maximal efficacy, cancer drugs must reach their appropriate targets, in the appropriate location within cells, which are mainly located either in the cytosol, the nucleus, and more recently in cell organelles such as mitochondria. Therefore, either drug-loaded carriers must be transported intact inside cells, then carriers must release their cargo, or carriers must release their cargo at the targeted-cell surface, and free drug must be transported inside cells. Colloids and nanoparticles are mostly taken up by endocytosis in cancer cells, via the endosome/lysosome pathway. Therefore, the drug must be released intact from the lysosomal compartment. Most approaches have used the acidic characteristics of this compartment to dissociate the drug from its carrier, e.g., HPMA copolymer,

liposomes, polymeric micelles, cationic lipids and photosensitizers [18–22], and release into the cytosol; more recently, the presence of lysosomal enzymes have been used to release covalently bound drug from a carrier system. Nuclear delivery is also necessary for many drugs, mainly nucleic acid or protein drugs. In this case tagging with a nuclear location signal is necessary.

**Avoiding Drug Resistance Mechanisms** Resistance of tumor cells to chemotherapeutic agents is a major cause of treatment failure in cancer therapy, mainly mediated by families of energy-dependent ATP-driven efflux pumps (MDR, Pgp). Liposomes, polymer conjugates, polymeric micelles have the potential to overcome resistance mechanisms, and positive results in this direction have been obtained (reviewed in Ref. [23], and see below).

Methods of delivery and tumor targeting are key areas for the future of nanotechnology in anticancer therapy. For this, innovative nanotechnological methodologies have been initiated, are under active development and will be further improved, to achieve better, more efficient and less aggressive therapies of cancer for the whole organism.

#### 7.4.5

#### **Nanoparticles for Drug Delivery in Clinical Use or under Clinical Evaluation**

More extensive reviews are given in Refs. [6, 12, 24]. Several polymer–drug conjugates are in clinical use or under clinical evaluation as anticancer agents (Table 7.2).

Hydrophilic drugs can be easily entrapped with high efficiency in the aqueous core of liposomes whereas hydrophobic weak bases, such as doxorubicin or vincristine, are loaded by pH and chemical gradients across the liposome bilayer. Consequently, as many of the agents active against cancer are hydrophobic molecules, most presently used DDSs in clinics are liposomes, and many have been decorated with PEG to increase their bioavailability (decreased opsonization, decreased clearance by the RES, increased circulation time), e.g., PEGylated doxorubicin-liposomes.

##### 7.4.5.1 **Doxorubicin Family**

Liposomes encapsulating doxorubicin are the archetypal, simplest and first form of nanoparticles used for cancer therapy. Doxorubicin-liposomes were the first to be used clinically and ameliorated versions, such as PEGylated doxorubicin liposomes, have been in clinical use for breast and other cancers for several years.

Doxorubicin belongs to the anthracyclines and is used to treat breast, ovarian, bronchial cancers by inhibiting the synthesis of nucleic acids in cancer cells, but at the price of cardiotoxicity and myelosuppression and a very narrow therapeutic index. Doxorubicin-liposomes of phosphatidylcholinum-carbamoyl-cholesterol coated (glycosylated) with methoxypoly(ethylene glycol) (MPEG) (100 nm particles) to form an hydrophilic layer that protects against phagocytosis by macrophages and increases the circulation half-life, extravasation via defective tumor vessels and release of doxorubicin chlorhydrate selectively in tumor vicinity are in clinical use.

**Tab. 7.2.** Some nanoparticulate drugs under clinical use or evaluation. (Adapted from Ref. [12] with modifications.)

Nanoparticulate drug	Clinical use or evaluation
Doxorubicin-liposome/PEG	Breast and ovarian carcinoma
Zinostatin-styrene	Hepatocellular carcinoma
Liposomal-vincristine	non-Hodgkin's lymphoma
Liposomal all-trans-retinoic acid	non-Hodgkin's lymphoma
Polyglutamate-paclitaxel	non-Small cell lung carcinoma
Liposomal paclitaxel	Advanced solid tumors
Liposomal oxaliplatin	Colorectal cancer
Liposomal lurtotecan or irinotecan	Solid tumors, ovarian, small cell lung cancer
N-(2-Hydroxypropyl)methacrylamide copolymer doxorubicin	Breast, colon, lung cancer
N-(2-Hydroxypropyl)methacrylamide copolymer doxorubicin-galactosamine	Liver cancer

Conjugates of doxorubicin and dextran have been encapsulated with chitosan (100 nm size particles) or conjugated to PLGA, PCAA or poly( $\gamma$ -benzyl-L-glutamate)/poly(ethylene oxide) nanoparticles (200–250 nm), resulting in long-term *in vitro* release of the drug [25] and *in vivo* suppression of tumor growth in *in vivo* experimental models [26], proving efficacy. Efficacy was also suggested to be macrophage-mediated [27]. Brain delivery of doxorubicin has also been obtained by biodegradable poly(butyl cyanoacrylate)-polysorbate 80-coated nanoparticles [28]. Recent developments of nanoparticles for doxorubicin include the development of lecithin lipid core-drug/pluronic [poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide) triblock copolymer]-shell nanoparticles, obtained by a freeze-drying procedure [29]. In addition, solid lipid nanoparticles of cholesteryl butyrate of doxorubicine with paclitaxel, which had additive effects [30], and nanoparticles of poly(isohexyl cyanoacrylate) able to overcome MDR and increase sensitivity to doxorubicin [31], have also been developed recently.

#### 7.4.5.2 Paclitaxel (Taxol)

Paclitaxel (taxol) is a microtubule-stabilizing agent that causes polymerization of tubulin and cell death. Paclitaxel is used in ovarian, breast, colon, non-small cell lung carcinomas. Paclitaxel is poorly aqueous soluble, but soluble in organic solvents, and is presently formulated in Cremophor EL (polyoxyethyleneglycerol triiricinoleate 35) or polysorbate (Tween) 80 (polyoxyethylenene-sorbitan-20-monooleate), which have important side effects and drawbacks. Strategies have

been developed to formulate taxanes in Cremophor and Tween 80 based on pharmaceuticals such as albumin nanoparticles, emulsions, liposomes, polyglutamates, and prodrugs strategies [32]. New formulations that have been developed include biodegradable nanoparticle formulations (140 nm mean diameter) using poly(lactic-co-glycolic) and nanoprecipitation in acetone, showing efficiency and high incorporation loading [33, 34], poly(ethylene glycol)-poly(lactide) (PLGA) nanoparticles (<100 nm) [35–38] and d- $\alpha$ -tocopheryl PEG as an emulsifier. In addition, the use of methoxy poly(ethylene glycol)-poly(lactide) (MPEG-PLA) results in a slow and long-lasting release after an initial burst [39]. More recently, entrapment of paclitaxel by hydrophobic forces in micelles of block copolymers (NK105) led to increased blood stability, bioavailability and anticancer drug efficacy, extended *in vivo* antitumor activity and reduced the neurotoxicity of paclitaxel [40].

#### 7.4.5.3 5-Fluorouracil

5-Fluorouracil is used in the treatment of rectum, colon, breast, stomach, pancreas, liver, uterus, ovarian and bladder cancers. Intravenous injection of an aqueous solution of 5-fluorouracil inhibits cell growth by blocking thymine (5-methyluracile) formation, and DNA synthesis, and the formation of aberrant RNA; however, the drug is very short-lived under this route of application. For clinical formulation, 5-fluorouracil has been incorporated in dendrimers of poly(amidoamine) modified with mPEG-500 by simple incubation due to the hydrophilicity of the drug, achieving longer-lasting release than the free drug. The *in vivo* half-life of 5-fluorouracil, a clinical problem necessitating continuous infusion for several hours, has been increased by drug formulation by a diafiltration procedure in biodegradable amphiphilic PEG-poly( $\gamma$ -benzyl-L-Glu) micelles (180–250 nm) and an hydrophilic shell of 30 nm [41].

#### 7.4.5.4 Tamoxifen

Tamoxifen is a non-steroid inhibitor of estrogen receptors mainly used to treat breast cancer. For clinical use, tamoxifen is encapsulated within PEG-coated nanospheres and located at the nanosphere surface, resulting in immediate drug release [23]. More recently, tamoxifen was encapsulated in poly(ethylene oxide)-modified poly( $\epsilon$ -caprolactone) nanoparticles of an average diameter of 150–250 nm, for targeted delivery of tamoxifen to breast cancer. The primary site of accumulation *in vivo* was the liver; however, 26% of the total drug-loaded nanoparticles were recovered in the tumor at 6 h post-injection, increasing further with time. Extended presence in the circulation was also observed. Therefore, these nanoparticles achieved preferential tumor-targeting and a circulating drug reservoir [42]. Anti-estrogens were also incorporated at high amounts in nanocapsules [polymers with an oily core and coupling with PEG] displaying enhanced anti-tumoral activity toward breast cancer cells [43].

#### 7.4.5.5 Cisplatin

Platinum derivatives (cisplatin and carboplatin) are inorganic metallic complexes of the Pt<sup>2+</sup> cation and pairs of chloride and amino ligands in the cis position for

cisplatin. Their mechanism of action resembles that of alkylating agents active on DNA, independently of the cell cycle. Cisplatin, alone or in combination with other drugs, is used to treat testicular, ovarian, bladder, prostate, respiratory carcinomas, and lymphoma, sarcomas and melanoma. Platinum derivatives have a short half-life in the biological environment and are frequently associated with drug resistance in many cancers and, therefore, their entrapment in liposomes has been attempted to enhance efficacy – these formulations are presently under clinical evaluation [44–47].

#### 7.4.5.6 Camptothecins

Camptothecins (irinotecan and topotecan) are cytostatic drugs that act as specific inhibitors of DNA topoisomerase I, active in S phase and on P-glycoprotein (MDR)-positive cells, with activity that depends on exposure time; they induce single-strand lesions in DNA and inhibition of replication. They are in clinical use mainly for advanced colorectal cancer in conjunction with 5-fluorouracil, but are extremely hydrophobic. Lipid-based nanoparticles (100–375 nm) of irinotecan have been prepared and their activity was size-dependent: 375 nm irinotecan-nanoparticles > irinotecan > 100 nm irinotecan-nanoparticles > no treatment [24].

#### 7.4.5.7 Methotrexate

Methotrexate is a cytotoxic antagonist (antimetabolite) of folic acid during the S phase of the cell cycle of actively proliferating cells, acting by competitive inhibition of dihydrofolate reductase and blocking the reduction of dihydrofolic acid (FH<sub>2</sub>) into tetrahydrofolic acid (FH<sub>4</sub>), and hence the synthesis of pyrimidine and purine bases and amino acids, and of DNA, RNA and protein synthesis. Methotrexate has been entrapped in triblock poly(trimethylene carbonate)-PEG-poly(trimethylene carbonate) copolymer core-shell type nanoparticles (50–160 nm) by ring-opening polymerization [48]. Very recently, in a very elegant approach, polyamidoamine (PAMAM) dendrimers (<5 nm size), conjugated to folic acid for tumor targeting and methotrexate as anticancer agent for tumor treatment, injected i.v. into folate receptor-positive human KB tumor-bearing immunodeficient mice displayed increased anti-tumor activity of methotrexate and markedly decreased toxicity, allowing a tumor drug dosage not possible with the free drug [49].

### 7.4.6

#### New Experimental Drugs and Therapies

##### 7.4.6.1 Proteins, Peptides, their Inhibitors and Antagonists

- The cysteine protease cathepsin B inhibitor cystatin, potentially active as an anticancer drug, has been incorporated in poly(lactide-co-glycolide) nanoparticles (300–350 nm size), preserving its cathepsin B inhibitory activity; it was internalized and was cytotoxic for tumor cells whereas free cystatin was not [50, 51].
- Conjugation of an anti-EGF receptor monoclonal antibody to colloidal gold nano-

particles increased their selectivity toward cancer cells versus non-cancer cells, suggesting their utility in both detection and targeted delivery [52].

- Magnetic nanoparticle-loaded anti-Her2 immunoliposomes have been developed for a combination of antibody therapy with hyperthermia [53].
- Increased transmembrane transport has been observed using positively charged, membrane translocation-inducing poly-D-Arg and Tat-peptide crosslinked to dextran nanoparticles (30 nm) [54].

#### 7.4.6.2 New Drugs

- All-trans retinoic acid incorporated in solid lipid nanoparticle powder displayed increased stability, decreased hemolytic toxicity, and efficacy was maintained against human cell lines [55].
- Clinical application of cucurbitacin in poly(lactic acid) nanoparticles (85 nm diameter), as anticancer targeting against metastasis foci of cervical lymph nodes in patients with oral carcinoma, displayed enhanced efficacy, decreased side effects and a long-lasting high concentration of the drug in lymph nodes [56].

#### 7.4.6.3 New Therapeutic Approaches: Photodynamic Therapy (PDT)

Ceramic-based nanoparticles entrapping water-insoluble photosensitizing anti-cancer drugs have been developed as a novel drug-carrier system for the PDT of tumor cells [57]. Methylene blue, as a photosensitizer and a source of singlet oxygen in PDT, has been encapsulated in polyacrylamide, sol-gel silica or organically modified silicate sub-200 nm nanoparticles. Of these three matrices, polyacrylamide was the most efficient delivery system but its content in methylene blue was low, whereas the opposite was true for the sol-gel nanoparticles. PDT treatment of cells was demonstrated to be efficient [58]. PDT protocols have also been developed using photosensitizers incorporated in PLA-PEG nanospheres and tumor irradiation (EMT-6 cells). However, the large (>900 nm) particle size did not allow high enough intra-tumoral accumulation [59]. Therefore, the nanoplatform represents a functional system for decreasing the side effects in detection and therapy of cancer in PDT protocols.

#### 7.4.7

#### Gene Therapy

Viral vectors are very efficient but present the inherent risk that the inactivated virus reverts to wild-type and that viruses induce immunogenic reaction. Therefore, attempts have been made to replace viruses by synthetic vectors with improved safety, greater flexibility and easier manufacturing. Synthetic polymers (mainly cyclodextrin-modified, branched polyethyleneimine) are generally cationic molecules to which negatively charged DNA or RNA molecules electrostatically bind, forming polyplexes of a few tens to hundreds of nm in diameter, but with excess cationic charges maintained to favor cell uptake. Serum stability, aggregation, and clearance of polyplexes depend on the packaging polymer and surface

modification. Surface modification with a hydrophilic polymer, such as PEG, N-2(hydroxypropyl)methacrylamide, oligosaccharides and sugars or proteins, can increase serum compatibility and provides a basis for chemically grafting target addresses, which include membrane receptors, lectins, transferrin, antibodies, lectins. Targeting efficacy depends on the conjugation chemistry, the length and chemical composition of the spacer between the polyplex and the ligand, the kinetics characteristics and the number of interactions between the ligand and receptor. Intracellular trafficking and endosomal escape are also important factors for targeting approaches.

Polymers used for gene delivery include polylysine, branched polyethyleneimine, poly(amidoamine) dendrimers, membrane-disrupting pH-responsive or pH-degradable acrylate-based polymers, allowing lysosomal escape, peptides, cyclodextrins and non-cytotoxic biodegradable polymers of L-glycolic acid (for a discussion of the advantages/disadvantages of the various polymers see the reviews in Refs. [60–62]). However, whereas substantial progress has been made *in vitro*, their utilization in clinics remains to be evaluated. Moreover, the much lower efficacy of all synthetic vectors than that of viruses makes them generally considered as unacceptable for clinical applications.

#### 7.4.7.1 Nanoparticle for Gene Delivery: Non-chitosan and Chitosan-type Polymers

Progress in gene therapy has relied on the emergence of polymeric and non-polymeric nanoparticles that have been investigated for their ability to deliver genes, mainly encompassing two families: chitosan-related and chitosan-unrelated materials.

##### Non-chitosan Polymers

- Polyethyleneimine-DNA complexes (39–1200 nm) linked to PEG coated with transferrin or EGF have achieved 10–100× higher tumor selectivity over other organs in mice [24].
- Dextran-SPION plasmid as a model for gene carrier (59 nm effective diameter) has achieved efficient transfer in a human bladder cancer cells line [63].
- Positively charged calcium phosphate nanoparticles (30 nm) were able to transfer foreign DNA with high transfection efficiency and were less cytotoxic than DNA liposomes [64].

**Chitosan-type Polymers** The inclusion of poly(propyl acrylic acid), which disrupts lipid bilayer membranes at defined pH incorporated in chitosan-DNA plasmid, increased delivery from the endosomal to cytoplasmic compartment for non-viral gene delivery [65].

#### 7.4.8

##### New Approaches

Recent, new and innovative approaches have been aimed mainly at (a) improving existing systems, by enhancing biocompatibility, biodegradability and biological

characteristics of existing systems, and (b) developing novel nanotechnological approaches for drug–nanoparticle preparation as anticancer agents (for more detailed reviews see Refs. [6, 23]).

#### 7.4.8.1 Improvement of Biological Characteristics

**Conventional Drug-loaded Nanoparticles** These nanoparticles are rapidly opsonized in the circulation and cleared by the RES, mainly macrophages, in the liver, spleen, lungs, bone marrow where drug accumulates. Conventional nanoparticles induce some cytotoxic effects against phagocytes, and drugs accumulate in bone marrow and result in myelosuppression, an unfavorable event. Nephrotoxicity has also been observed. However, the drug–nanoparticle toxicity profile is more favorable than the free drug toxicity profile, in particular for the cardiotoxicity of doxorubicin. The accumulation of nanoparticle–doxorubicin in the lysosomes of Kupffer cells in the liver, but not in tumor cells, acts as a long-term active drug delivery system [66]. For example, in mice treated with doxorubicin–poly(isohexyl cyanoacrylate) (PIHCA) nanospheres [67] the drug accumulates in the liver, spleen and lungs, but a reduction of hepatic metastasis and a longer life span were also observed [68] compared with free doxorubicin. The same was seen for actinomycin D adsorbed on poly(methyl cyanoacrylate) (PMCA) and lung accumulation [69], and for actinomycin D adsorbed on the more slowly degradable poly(ethyl cyanoacrylate) (PECA) and small intestine accumulation [70] or vinblastine incorporated into PECA and accumulation in the spleen [70]. Therefore, as both the polymer composition and the drug chemical characteristics, as well as the location in the nanoparticle (adsorbed or incorporated), are important for tissue localization these factors have been modified.

An ideal drug carrier should be a system that can reside *in vivo* for long periods, targeting particular cell types, compartmentalizing a large set of molecules and releasing them in the appropriate environment at the appropriate rate and dose. Creating a toolbox of molecules that hierarchically assemble in ordered structures, spatially and chemically controlled, is requisite to making them attractive and efficient for encapsulating and delivering drugs. The chemistry used to achieve biomimetic assemblies, which consist of the polymer, a linker and a bioactive molecule, has been reviewed [71]. Di- or tri-block copolymers with low polydispersity can be obtained via anionic polymerization. Subsequent manipulation involves self-assembly at concentrations favoring spherical micelles, controlled crosslinking using radical chemistry to obtain a hydrogel shell and polymer micelle architecture, followed by conjugation with a biological molecule to achieve targeting, such as peptides via a carboxyl end group on the polymer. The most commonly incorporated polymer is PEG [poly(ethylene glycol)], a flexible water-soluble molecule that can be end-functionalized to obtain aldehyde, methacryloyl, hydroxyl, primary amine, acetal, mercapto groups, and copolymerization with other polymers [72–74]. The chemical procedures available have been outlined [71].

Factors controlling the rate of drug release are not well understood but depend on the assembly morphology, drug molecular weight, chemical composition, etc. These factors have also been addressed. Biodegradable polymers are preferred for

controlled drug delivery systems, and are made of natural or synthetic polymers, which have the advantage over natural polymers in that they can be tailored to obtain defined properties. They must match the mechanical properties and degradation rates required for the application. Commonly used biodegradable polymers for biomedical applications include polyglycolic acid, L-, D-, DL-poly(lactic acid), poly( $\epsilon$ -caprolactone), poly(DL-lactide-co-glycolide), and poly(vinyl alcohol). These polymers have features such as controllable mechanical properties, controllable degradation rates, minimal toxicity and immune responses [75].

**Long-circulating Biocompatible and Biodegradable Drug-loaded Nanoparticles** To escape the RES, stealth nanoparticles that are “invisible” to macrophages, and which are long-lasting in the blood compartment, need to be designed. For this, modification of the surface (hydrophilic/hydrophobic) and a small size (<100 nm) of the colloidal carrier are essential [23]. The hydrophilicity of the carrier and sustained drug release are also important. A previous breakthrough was the use of PEG or polysaccharides to coat the nanoparticle surface and, thereby, repel plasma proteins. Hydrophilic polymers are either adsorbed at the surface of nanoparticles or are block copolymers. Finally, covalent linkage of amphiphilic copolymers is the preferred way to obtain a protective hydrophilic coat, using poly(lactic) (PLA), poly( $\epsilon$ -caprolactone), or poly(cyanoacrylate) copolymers chemically coupled to PEG. Controlled drug-delivery systems are generally based on either diffusion or degradation of the polymer. The choice of polymer depends on potential interactions with the drugs, surface characteristics, the hydrophilic–hydrophobic balance, surface charges, and the biological properties of the target. Novel approaches to solve the drug release problems have been addressed.

The preparation and characterization of biodegradable/bioerodible polymers for the controlled targeted release of proteic drugs (interferon or growth factors for tissue engineering) have been described. *Bioerodible polymeric matrices* are hemiesters of alternating copolymers of maleic anhydride with alkyl vinyl ethers of oligo(ethylene glycol). Hydrophilic shell coating to minimize opsonization was achieved with grafted  $\beta$ -cyclodextrins. Coprecipitation was used for formulation, based on dropwise addition of synthetic polymer in water-miscible organic solvent to aqueous protein solution under stirring, followed by the addition of the glycolipid. Particles 130–150 nm diameter were obtained, with  $\beta$ -galactose residues exposed at the surface. *Biodegradable polymer matrices* solve the issue of removal of the device after drug delivery. Among them, poly(malolactonates) are biocompatible, degrading to malic acid, and contain reactive side-chain carboxyl groups that can be esterified [76] for adjustment of the hydrophilic–hydrophobic balance [76–81]. The starting components are commercially available and nanoparticles of 100–150 nm can be obtained by coprecipitation (reviewed in Ref. [82]).

The effects of the following surface modifications have also been evaluated:

- Poly(lactic-co-glycolic acid) nanoparticles coated with vitamin E TPGS [82, 83], or polysaccharide-decorated nanoparticles [84].
- Poly(alkyl cyanoacrylate) nanoparticles [85].
- Amphiphilic poly(lactic)-pluronic block copolymers, which can release either hy-

drophobic anthracene and hydrophilic procaine drugs due to slow hydrolytic degradation of poly(lactic acid) [86].

- Poly(ethylene oxide)- $\beta$ -poly(N-isopropylacrylamide) nanoparticles with crosslinked cores as hydrophobic drug carriers [87].

#### 7.4.8.2 New Technological Approaches
