The effect of proteins on membrane asymmetry has been taken into account in the mechanism of active translocation, in the kinetic approach and in the mechanism of facilitated lipid transport. However, possible effects of the mechanical properties of the membrane proteins have not been analyzed in detail. It may be an oversimplification that a rather high proportion of the membrane surface (around 50% for erythrocytes) is occupied by proteins. It would be straightforward to extend the mechanical energy of the monolayers by incorporating compressible protein components. Thus, the net effect of proteins on the mechanical force constants is taken into account, at least qualitatively. In addition to mechanical forces, transmembrane electric potential gradients may also affect the translocation kinetics of lipids, depending on their ionization states under physiological conditions. The present model neglects the effects of lateral organization of cell membranes that could result from specific lipid–lipid interactions, e.g. the pronounced interaction of cholesterol and SM and the protein–lipid interactions. These interactions would give rise to a more general expression for the free energy of mixing. Prelim-

inary results, based on the Bragg–Williams approximation, indicate that no qualitative changes regarding the simulation of the overall transversal lipid distributions occur, at least in the limits of that approximation [21].

### 12.3

#### Problems of Drugs Crossing through Biological Membranes

##### 12.3.1

##### Through the Skin

The skin is an extremely efficient barrier that minimizes water loss from the body. Drug absorption across the skin is potentially more limiting, and the relationship between drug physiochemical properties and epidermal permeability is less ambiguous than for the mucosal barriers. The body skin surface area in humans is approximately  $1.5 \text{ m}^2$  and represents a readily accessible surface for the application of drug delivery systems. The skin is structured in three layers: the epidermis, the dermis and the subcutaneous layer. The outer layer of the epidermis and the stratum corneum cover the entire outside of the body, and contain dead cells only, those that are strongly keratinized. For most chemicals, the stratum corneum is the rate-limiting barrier to percutaneous absorption. The skin of mammalian species is, on most parts of the body, covered with hair. At the sites where hair follicles grow, the barrier capacity of the skin differs slightly from the “normal” stratified epidermis. Most studies concerning penetration of materials into the skin have focused on whether or not drugs penetrate through the skin using different formulations containing chemicals and particulate materials as a vehicle.

The main types of particulate materials commonly used are: liposomes, inorganic compounds such as zinc and  $\text{TiO}_2$ , polymer particulates and solid lipid nanoparticles (SLN).  $\text{TiO}_2$  particles are often used in sunscreens to absorb UV light and therefore protect skin against sunburn or genetic damage. The micrometer-sized particles of  $\text{TiO}_2$  penetrate through the human stratum corneum and even into some hair follicles (including their deeper parts) [22]. The observation of penetration into living layers of the skin is not considered, since this part of the follicular channel (the acroinfundibulum) is covered with a horny barrier layer. In a recent review, Kreilgaard argued that “very small  $\text{TiO}_2$  particles (e.g. 5–20 nm) penetrate into the skin and can interact with the immune system”. Particles of  $0.5\text{--}1.0 \text{ }\mu\text{m}$ , in conjunction with motion, penetrate the stratum corneum of human skin, and reach the epidermis and, occasionally, the dermis. The lipid layers within the cells of the stratum corneum form a pathway through which the particles can move into the skin and be phagocytosed by the Langerhans cells [23]. The penetration of particles is limited to particle diameter of  $1 \text{ }\mu\text{m}$  or less.

Penetration of nonmetallic solid materials such as biodegradable poly(D,L-lactic-co-glycolic acid) (PLGA) microparticles,  $1\text{--}10 \text{ }\mu\text{m}$  with a mean diameter of  $4.61 \pm 0.8 \text{ }\mu\text{m}$ , was studied after application on to porcine skin. The number of microparticles in the skin decreased with the depth (measured from the airside

towards the subcutaneous layer). At 120  $\mu\text{m}$  depth (where the viable dermis is present), a relatively high number of particles was found. At 400  $\mu\text{m}$  depth (dermis), some microparticles were still seen. At 500  $\mu\text{m}$  depth, no microparticles were found. Soil microparticles frequently of 0.4–0.5  $\mu\text{m}$  and some large particles 25  $\mu\text{m}$  diameter were found in the dermis of the foot in a patient with endemic elephantiasis. The particles are seen to be in the phagosomes of macrophages or in the cytoplasm of other cells. The failure to conduct lymph to the nodes produces a permanent deposit of silica in the dermal tissues (a parallel is drawn with similar deposits in the lung in pneumoconiosis). This indicates that soil particles penetrate through (damaged) skin, most probably in every individual, and are normally removed through the lymphatic system [24]. Liposomes penetrate through the skin in a size-dependent manner. Micron-sized, and even submicron-sized, liposomes do not easily penetrate into the viable epidermis, whereas liposomes with an average diameter of 272 nm can reach into the viable epidermis and some are found in the dermis. Smaller-sized liposomes of 116 and 71 nm were found in higher concentration in the dermis. Submicron emulsion particles such as liposomes and nonionic surfactant vesicles (niosomes), with a diameter of 50 nm to 1  $\mu\text{m}$ , were detected in the epidermis in association with the cell membranes after application to human skin. The single molecules that make up the particles penetrate the intercellular spaces at certain regions in the stratum corneum, and are able to accumulate and reform into microspheres. The formulation used allowed the penetration of the spheres into melanoma cells, even to the nucleus [25]. The uptake of metals through the skin is difficult because of both exogenous factors (e.g. dose, vehicle, protein reactivity, valence) and endogenous factors (e.g. age of skin, anatomical site, homeostatic control). Penetration of metals through the skin still needs to be determined separately for each of metal species, either by *in vitro* or *in vivo* assays.

#### 12.3.1.1 Mechanical Irritation of Skin

Glass and rockwool fibers are widely distributed manmade mineral fibers, and have many applications, mainly as insulation materials. They are used as a substitute for asbestos fibers. In contact with the skin, these fibers can induce dermatitis through mechanical irritation. These fibers are strong irritants and thus were not examined in detail. In occlusion with irritant patch tests in humans, rockwool fibers with a diameter of  $4.20 \pm 1.96 \mu\text{m}$  were more irritating than those with a mean diameter of  $3.20 \pm 1.50 \mu\text{m}$ . The fact that “small” fibers can cause strong skin irritation has been known for a long time. It is also commonly accepted that some types of manmade fibers can easily induce nonallergic dermatitis. It is not clear what makes these fibers irritants. No information is available on skin irritation caused by fibers with a diameter of less than 100 nm, indicating that more research is needed on this problem [26].

#### 12.3.1.2 Low-voltage Electroporation of the Skin

The skin is an effective barrier against toxic chemicals and pathogens. The uppermost layer of skin, the stratum corneum, is impermeable to almost all water-

soluble substances. It also constitutes a formidable obstacle to transdermal delivery of drugs and genetic material. The transdermal route, if available, provides an alternative, convenient and noninvasive pathway for local and systemic delivery of drugs, especially with respect to time release and the avoidance of degradation or metabolism in the GI tract or liver. The stratum corneum is crossed by many appendages like hair follicles and sweat glands. The lining of these appendage ducts, consisting of two layers of epithelial cells, is much less resistant than the stratum corneum for drug transport.

Many biophysical approaches have been suggested to facilitate the transport of selected chemicals across the skin barrier. The most well-known method used is iontophoresis. In this approach, a low DC voltage (normally below 5 V) is applied across the skin. Charged molecules to be delivered are placed under an appropriate electrode, and driven through the skin barrier by electrophoresis and electroosmosis [27, 28]. The electrical impedance spectra of the skin are well characterized and transport by iontophoresis has been analyzed by macroscopic theory [29].

About 20 years ago, reversible electroporation of biological membranes was recognized to deliver materials into living cells [30]. This method is based on the resilience of the cell membrane to resealing after a temporary electrical breakdown. Due to the low electric conductivity across the membrane, as compared with that of the cytoplasm and the external media, the major potential drop across the cell is concentrated across the plasma membrane “poles” facing the electric field direction. This leads to the electroporation of the membrane, whereas the rest of the cell experiences a much lower potential gradient. The same advantage applies to the electroporation of the skin barrier in which the major potential drop develops across the highly resistive stratum corneum – the target for electroporation. This was recognized recently and the technique has been applied, although sometimes in an irreversible sense, to permeabilize the skin for drug delivery.

A paradox is realized that if electroporation occurs when a potential of 1 V is applied across a cell membrane, the membranes of the epithelial cell layers lining the skin appendages are porated, as soon as the low iontophoretic voltage (above 4 V) is applied to the skin. Molecular transport by iontophoresis is considered, as there is consequence of electroporation of the epithelial layers of the skin appendages. This alternative interpretation is complicated because the potential drop along narrow hair follicles or sweat glands is taken into account in calculating the net potential drop across the epithelial cell layers at different depths from the skin surface. Furthermore, the response and resealing times of the membrane to the applied electric field are unknown. The difficulties arise in modeling the low field electroporation if a pulse or AC voltage is applied in the traditional iontophoretic setting [31].

The analysis and the experimental support given provide a broad picture of what happens when a low electric voltage is applied to the skin with appendages. The initial event, characterized by the charging of the skin capacitor and the subsequent poration of the appendage lining, is clearly depicted. It bridges the gap between the theories of iontophoresis and electroporation. This work paves the way for the future development of combined high- and low-voltage protocols

designed to enhance transdermal transport that will play an increasingly important role in drug and gene delivery [32].

### 12.3.2

#### Through the BBB

Despite enormous advances in brain research, brain and CNS disorders remain the world's leading cause of disability. More hospitalization and prolonged care is necessary in CNS disorders than almost all other diseases. The major problem in drug delivery to the brain is the presence of the BBB. Effective drugs against the CNS disease reach the brain via the blood compartment, which must pass through the BBB. It is important to understand the mechanisms involved in uptake into and efflux from the brain. Various cells present at the level of the BBB dynamically regulate the function of the BBB. This realization implies a better understanding of the relationship of transport at the BBB to drug structure and physicochemical properties. Despite successful drug delivery to the CNS, only some drugs have reached the phase where they can provide safe and effective human applications. As pharmacological strategies improve, there will be less need for invasive procedures for treating CNS diseases. Considerable advances are being made in intravascular delivery and neurosurgical invasive procedures to deliver therapeutic substances into the brain. The failure of systemically delivered drugs to effectively treat many CNS diseases can be rationalized by considering a number of barriers that inhibit drug delivery to the CNS.

The CNS consists of blood capillaries which are structurally different from the blood capillaries in other tissues. These structural differences result in a permeability barrier between the blood within brain capillaries and the extracellular fluid in brain tissue. Blood capillaries of the vertebrate brain and spinal cord lack small pores and allow rapid movement of solutes from the circulation into other organs. These capillaries are lined with a layer of special endothelial cells that lack fenestrations and are sealed with tight junctions. Tight epithelium, similar in nature to this barrier, is also found in other organs (skin, bladder, colon and lung) [33].

Ependymal cells lining the cerebral ventricles and glial cells are of three types. Astrocytes form the structural framework for the neurons and control their biochemical environment. Astrocyte foot processes or limbs spread out and meet one other, encapsulate the capillaries to form the BBB. Oligodendrocytes are responsible for the formation and maintenance of the myelin sheath, which surrounds axons and is essential for fast transmission by salutatory conduction. The tight junctions between endothelial cells result in a very high transendothelial electrical resistance of 1500–2000  $\Omega \text{ cm}^2$  compared to 3–33  $\Omega \text{ cm}^2$  of other tissues, which reduces the aqueous based paracellular diffusion observed in other organs [34, 35].

Microvessels cover an estimated 95% of the total surface area of the BBB and represent the principal route through which chemicals enter the brain. Vessels in the brain are found to have a somewhat smaller diameter and thinner wall than vessels in other organs. The mitochondrial density in brain microvessels was also

found to be higher than in other capillaries, not because of more numerous or larger mitochondria, but because of the small dimensions of the brain microvessels and, consequently, the smaller cytoplasmic area. In brain capillaries, intercellular cleft, pinocytosis and fenestrae are virtually nonexistent; transcellular exchange is preferred. Lipid-soluble solutes can only freely diffuse through the capillary endothelial membrane and may cross the BBB. In capillaries of other parts of the body, such exchange is overshadowed by other nonspecific exchanges. Despite the estimated total length of 650 km and total surface area of 12 m<sup>2</sup> of capillaries in human brain, this barrier is very efficient and makes the brain practically inaccessible for lipid-insoluble compounds such as polar molecules and small ions.

Therefore, the therapeutic value of many promising drugs is diminished and cerebral diseases have proved to be most refractory to therapeutic interventions. All drugs used for disorders of the brain are lipid soluble and readily cross the BBB following oral administration. Although antimicrobial  $\beta$ -lactam antibiotics, when administered intracerebroventricularly, cause severe convulsion, these antibiotics do not cause such CNS side-effects when administered intravenously or orally, due to their limited transport across the BBB. Further, in spite of being well distributed into various tissues, a lipophilic new quinolone antimicrobial agent, grepafloxacin, cannot enter the brain. It results in CNS side-effects such as headache and dizziness due to the displacement of  $\gamma$ -aminobutyric acid (GABA) from the GABA receptor binding sites. Benzodiazepines such as diazepam are used as sedative hypnotic agents because these lipophilic drugs readily cross the BBB. However, the BBB transport of an immunosuppressive agent, cyclosporin A, that is more lipophilic than diazepam is highly restricted. Similarly, almost all of the lipophilic anticancer agents such as doxorubicin, epipodophylotoxin and Vinca alkaloids (e.g. vincristine and vinblastine) hardly enter the brain, causing difficulty in the treatment of brain tumors. L-DOPA, used for the treatment of Parkinson's disease, is very hydrophilic and it can readily penetrate the BBB. What mechanisms underlie these diverse BBB transport characteristics of drugs that are apparently structurally and pharmacologically unrelated? Drug transport across the BBB of small-molecular drugs by carrier-mediated transport and of peptide drugs through adsorptive-mediated transcytosis is possible. The regions adjacent to the ventricles of the brain are termed circumventricular organs (CVOs). The CVOs include the choroid plexus, median eminence, neurohypophysis, pineal gland, organum vasculosum of the lamina terminalis, subfornical organ, subcommissural organ and area postrema. Although the capillaries in the CVO brain regions are more permeable to solutes, the epithelial cells of the choroid plexus and the tanycytes of other regions form tight junctions to prevent transport from the abluminal extracellular fluid (ECF) to the brain ECF. The choroid plexus is very important for the transport of peptide drugs. Although it is the major site of cerebrospinal-fluid (CSF) production, both the CSF and brain ECF are freely exchanged with each other [36]. BBB enzymes are well known and recognized for rapid degradation of almost all peptides, including naturally occurring neuropeptides. Solutes crossing the cell mem-

branes are subsequently exposed for enzyme degradation present in large numbers inside endothelial cells. These contain large densities of mitochondria and metabolically highly active organelles. The BBB is further reinforced by a high concentration of P-glycoprotein, an active drug-efflux transporter protein in the luminal membranes of the cerebral capillary endothelium. This efflux transporter actively removes a broad range of drug molecules from the endothelial cell cytoplasm before they cross into the brain parenchyma [37].

### 12.3.2.1 Small Drugs

The majority of drugs do not cross the brain capillary wall which forms the BBB *in vivo*. Only small molecules with high lipid solubility and a low molecular mass ( $M_r$ ) below 400–500 Da cross the BBB [38]. However, only few diseases of the brain consistently respond to this category of small-molecule drugs [39, 40]. These include depression, affective disorders, chronic pain and epilepsy. In contrast, many other serious disorders of the brain do not respond to conventional lipid-soluble molecular therapeutics. These include Alzheimer's disease, stroke/neuroprotection, brain and spinal cord injury, brain cancer, HIV infection of the brain, various ataxia-producing disorders, amyotrophic lateral sclerosis, Huntington's disease, Parkinson's disease, multiple sclerosis and childhood inborn genetic errors affecting the brain. Although L-DOPA therapy has been available for decades to treat Parkinson's disease, there has been no neuroprotective drug available for Parkinson's disease that halts the inexorable neurodegeneration of this disorder. Patients with multiple sclerosis have benefited from cytokine drug therapy that acts on the peripheral immune system. However, no drug is available to stop the inevitable demyelination within the CNS caused by multiple sclerosis. Many of the CNS disorders that are refractory to small-molecule drug therapy might be treated with large-molecule drugs including recombinant proteins and gene-based medicines; however, several obstacles, both biochemical and economic, are inhibiting their development.

#### 12.3.2.1.1 Limitations of Small Drugs

Only 12% of drugs are active in the CNS and only 1% of the total number of drugs are active in the CNS for diseases other than affective disorders [41]. The rate-limiting role of the BBB is illustrated by the small molecule histamine. Histamine, however, does not cross the BBB, but the inability of histamine to penetrate the brain is illustrated [42]. Histamine has too many hydrogen-bond-forming functional groups and the BBB penetration is inversely related to the number of hydrogen bonds that a drug forms with solvent water. Large-molecule drugs are not suitable for brain treatment because of the BBB problem. Indeed, if a large-molecule drug is found to be effective for the brain, the molecule is generally abandoned for a small-molecule peptidomimetic. However, with the exception of where the endogenous ligand itself is a small molecule, no small-molecule peptidomimetics have been discovered to date that are capable of transport across the BBB. There-

fore, the small-molecule peptidomimetics still have to be reformulated for BBB transport. The development of a small-molecule drug targeting the BBB is challenging and requires more work in this field.

#### 12.3.2.2 Peptide Drug Delivery via SynB Vectors

Cells poorly take up a large number of hydrophilic molecules such as peptides, proteins and oligonucleotides, since they do not efficiently cross the lipid bilayer of the plasma membrane. Peptide neuromodulators failed to affect their target cells within the brain when administered peripherally. This is due to the existence of the BBB. The most important factors determining the extent to which a molecule is delivered from the blood into the CNS are lipid solubility, molecular mass and charge. Simply based on lipid solubility and molecular mass, peptide- or oligonucleotide-based neuropharmaceuticals are impeded by the BBB. To overcome the limitation in accessing the drugs to the brain, some strategies need to be developed to achieve BBB penetration [43, 44]. In the past decade, several peptides have been described such as penetratin [45, 46], a basic segment of the transcription-activating factor (Tat), and SynB vectors [44] that allow the intracellular delivery of polar, biologically active compounds *in vitro* and *in vivo*. Since the peptides penetrate into the cells by a receptor-independent nonendocytotic process, the interaction of some of them with the lipid matrix of the plasma membrane could play a key role in their cell uptake [43].

#### 12.3.3

##### GI Barrier

The GI barrier plays an important role in the organism – protecting against toxic substances, and transferring nutrients and xenobiotics from the lumen to the blood. Since the oral route of administration is the most common route, the absorption and metabolism of a chemical in the intestinal mucosa is particularly important. These processes affect the bioavailability of a chemical, i.e. the fraction of an oral dose that reaches the systemic circulation [47]. Absorption across the intestinal lining includes passive diffusion across the cell membrane and cytoplasm (transcellular transport). The uptake transporters includes the sodium-dependent bile transporter, peptide transporters, the glucose transporter and organic anion transporters. Some of the export transporters includes ATP-dependent P-glycoprotein, and multi drug resistance (MDR) proteins 1 and 2 (MRP1 and MRP2). These represent well-characterized transporters in the apical membrane of the intestinal mucosal epithelium, which actively pump substrates back into the intestinal lumen after absorption into the intestinal epithelial cells [48, 49]. The current *in vitro* models of the intestinal barrier have been recently made available for investigating the principal mechanisms of absorption [50, 51]. The advantage of *in vivo* models is that they integrate all the factors that can influence chemical partitioning. The disadvantage is that it is very difficult to separate these variables during absorption. The advantage of *in vitro* models over *in vivo* models is that

it is possible to study the mechanisms of absorption *per se*, and to bypass stomach and liver metabolism. The rate and extent of drug absorption from the small intestine depends on the release of the active ingredient from a dosage form, its solubility in the liquid phase of the GI contents, and the transport of the dissolved compound or the intact dosage form from the stomach into the duodenum. In dynamic systems such as dosing to the GI tract, drug absorption is dependent on the residence time of the drug in solution at an absorption site. As such, gastric emptying and intestinal motility can be critical determinants of drug absorption.

The oral route of administration for protein and nucleic acid drugs is quite problematic because in addition to proteolysis in the stomach, the high acidity of the stomach destroys them before they can reach the intestine for absorption. Polypeptides and protein fragments, produced by the action of gastric and pancreatic enzyme, are further cleaved by exo- and endopeptidases in the intestinal brush border membrane to yield di- and tripeptides, even if proteolysis by pancreatic enzymes is avoided. Polypeptides are mostly degraded by brush border peptidases. Any peptide that survives and passes through the stomach is further metabolized in the intestinal mucosa, where the penetration barrier prevents entry into cells [52].

#### 12.3.3.1 Intestinal Translocation and Disease

Crohn's disease is characterized by transmural inflammation of the GI tract. It is of unknown etiology, and it has been suggested that a combination of genetic predisposition and environmental factors plays a role. Particles (0.1–1.0  $\mu\text{m}$ ) are associated with the disease and indicated as potent adjuvants in model antigen-mediated immune responses. In a double-blind randomized study, a low particle diet (low in calcium and exogenous microparticles) alleviated the symptoms of Crohn's disease [53]. However, there is a clear association between particle exposure, their uptake and Crohn's disease. The exact role of the phagocytosis cells in the intestinal epithelium is not known. The disruption of the epithelial barrier function by apoptosis of enterocytes is a possible trigger mechanism for mucosal inflammation. Diseases other than of gut origin also have marked effects on the ability of the GI tract to translocate particles. The absorption of 2- $\mu\text{m}$  polystyrene particles from the PP of rats with experimentally induced diabetes is increased up to 100-fold (10% of the administered dose) compared to normal rats [54]. However, the diabetic rat displayed a 30% decrease in the systemic distribution of the particles. The possible explanation for this discrepancy is the increased density of the basal lamina underlying the GI mucosa of diabetic rats that may impede particle translocation into deeper villous regions. This uncoupling between enhanced intestinal absorption and reduced systemic dissemination has been observed in dexamethasone-treated rats [55].

From the literature it is clear that engineered nanoparticles are taken up via the GI tract. In general, the intestinal uptake of particles is better understood and has been studied in more detail than pulmonary and skin uptake. Because of this advantage, it is possible to predict the behavior of some particles in the intestines,

with some precautions. Nanoparticles designed for food or to drug delivery via intestinal uptake needs to follow strict rules before marketing.

## 12.4

### Nanoparticulate Drug Delivery

Drug delivery at a simplistic level has been dominated by the theme of noninjected peptide delivery. Efforts to combine peptides with novel mucoadhesive polymers and to encapsulate them in nanoparticles are being renewed. This is done by increasing intestinal permeability and increasing solubility. In last 10 years, scientists have discovered nanoparticles that favor uptake by immune surveillance systems in the intestine and in the dermis of the skin. This led to an increase in vaccine delivery research with novel antigens and adjuvants. The nanoparticles and liposomes discovered can access the brain, which has potential for targeting them to the BBB. It is worth noting that 95% of all drugs discovered for Alzheimer's disease, Parkinson's disease and stroke have poor brain-penetrating capability. There are a number of advanced transdermal systems in the research phase, including iontophoresis, sonophoresis and patches with probes. Peptide delivery via the skin is back in vogue, although the devices are simpler and cheaper. A complete range of new bioadhesive and mucoadhesive polymers is being produced, and they have unique properties to increase organ retention. Such polymers, of which the glucosamine-based chitosan was a pioneer, can lead to increased localization and retention of a conjugated drug.

Several types of nanomaterials created by nanotechnology research range are used in drug delivery, ranging in size from 1 to 100 nm:

- Fullerenes are pure carbon molecules composed of at least 60 atoms of carbon. Fullerene has a shape similar to a soccer ball or a geodesic dome (also known as a "buckyball").
- Nanotubes are a sequence of nanoscale  $C_{60}$  atoms arranged in a long, thin cylindrical structure. They are related to two other carbon crystal forms – graphite and diamonds. They often look like rolls of graphite chicken wire. However, as member of the fullerene family, they are buckyballs expanded from the center into cylinders.
- Quantum dots are nanoscale crystalline structures made up of cadmium selenide that absorb white light and then reemit it within a couple of nanoseconds later in a specific color.
- Dendrimers are synthetic, three-dimensional macromolecules formed using a nanoscale fabrication process. A dendrimer is formed from monomers, with new branches added in steps until form a tree-like structure.
- Nanoshells are concentric sphere nanoparticles consisting of a dielectric (typically gold sulfide or silica) core and a metal (gold) shell. They are a very special kind of nanoparticle because they combine IR optical activity with the uniquely biocompatible properties of gold colloids. In simple words, they are spheri-

cal glass particles with an outer shell of gold. Their size is about 100 nm in diameter.

#### 12.4.1

##### **Skin**

Mammalian skin is a complex transport barrier with an anatomical organization and chemical structure. The important region of skin is the stratum corneum, which comprises columns of tightly packed corneocytes organized into clusters of up to a dozen cells. Mammalian stratum corneum consists of 15 corneocyte layers, with a total thickness of 0.3–0.8  $\mu\text{m}$ . The corneocytes merge together with desmosomes and are sealed tightly with intercellular lipids, attached to plasma membranes. The quality and crystallinity of lipids in the stratum corneum determine the skin barrier characteristics. The fine structure of the skin and epidermal refractivity to molecular diffusion differ at different body sites [56–58].

##### **12.4.1.1 Skin as Semipermeable Nanoporous Barrier**

The skin behaves as a mechanical nanoporous barrier perforated by a large number of probably gap-like or quasi-semicircular pathways. The reported estimates for such passage widths range from 0.4 to 36 nm. Detailed information on the distribution of hydrophilic transcutaneous path widths in the skin is unavailable to date. Arguably, pore size distribution is nonsymmetrical, with a peak around 20 nm and decline on the low size side. Only one hydrophilic (circular) pathway exists between two corneocytes in the stratum corneum. The maximum number of passages through the barrier is calculated to be between  $10^{10} \text{ cm}^{-2}$  (in the case of 0.4-nm pores) and  $4.5\text{--}10^8 \text{ cm}^{-2}$  (for 20-nm pores). The most likely, realistic “open pore” density in the skin is  $10^8\text{--}10^9 \text{ cm}^{-2}$ . Pore density of a comparable order of magnitude was determined by analyzing the results of transcutaneous electrical current (iontophoresis) and water flux (streaming potential) measurements. The funnel-like pathway shape close to the skin surface minimizes the impact of such geometrical factors. Experiments accordingly reveal that a much higher proportion of the epicutaneously applied material is transported through the skin, at least under suitable conditions [59, 60].

##### **12.4.1.2 Hydrophilic Pathway through the Skin Barrier**

The hydration and stress-dependent pathways within each cluster of cells have relatively high transport resistance, and typically lead between intercellular lipid (multi) lamellae and/or such lamellae and the proximal corneocyte envelope. In contrast, the hydrophilic pathways between clusters of corneocytes in the stratum corneum have a lower transport resistance and are sparser. The hydrophilic path between the skin cells clusters acts as a transcutaneous shunt, which is typically wider than 30 nm and permanently open. Transepidermal shunts thus cover a broad spectrum of widths, encompassing anything between a relatively wide inter-cluster gap (width greater than 5  $\mu\text{m}$ ), a hair follicle (width greater than 5  $\mu\text{m}$ ) and a cutaneous gland (width greater than 50  $\mu\text{m}$ ) [61].

## 12.4.2

**Solid-Lipid Nanoparticles (SLN) Skin Delivery**

The liposomal and emulsion solid particles possess several advantages like protection of incorporated active compounds from chemical degradation and flexibility in modulating the release of the compound. Liposomes and emulsions are composed of well-tolerated excipients and are used as a carrier for drug delivery. Solid-Lipid Nanoparticles (SLN) were realized simply by exchanging the liquid lipid (oil) of the emulsion by a solid lipid at room temperature. Solid-Lipid Nanoparticles (SLN) focused exclusively on pharmaceutical applications mainly for nondermal administration routes, e.g. oral and parenteral administration. In the last few years Solid-Lipid Nanoparticles (SLN) have been used in topical formulations for pharmaceutical and cosmetic products [62, 63]. In addition, generally recognized as safe (“GRAS”) substances were also used, which provide a broad variety of lipids and surfactants/polymers for the formulation of Solid-Lipid Nanoparticles (SLN) dispersions. The production of Solid-Lipid Nanoparticles (SLN) is done using hot or cold homogenization techniques. The cold homogenization technique is commonly used for extremely temperature-sensitive and hydrophilic compounds [64].

**12.4.2.1 Chemical Stability of SLN**

With regard to polymeric nanoparticles, the active compounds were incorporated into the solid matrix of SLN to protect them from degradation. The coenzyme Q10 incorporated in SLN composed of cetyl palmitate is stabilized with 1.2% Tego Care 450 as a surfactant [65]. Similarly, under the influence of light and oxygen, the sensitive cosmetic molecule retinol is decomposed to different epoxyretinoids. The stabilization effect of SLN on retinol was investigated using different lipids as matrix and different surfactants. The study of the stabilization effect between lipids indicates the lipids have to be selected carefully for sensitive molecules. The smallest particles with a large interface area had the most pronounced stabilization effect. Obviously, retinol located in the surface layer and an optimal surfactant showed highest stability. This indicates that the smallest particles provided the largest interfacial area for retinol and led to the highest stabilization.

The homogeneous matrix with dispersed drug molecules is present in amorphous clusters when the cold homogenization method is applied and when the lipophilic drug molecules are incorporated in SLN by the hot homogenization method. In the cold homogenization method, the bulk lipid contains the dissolved drug in dispersed form, which breaks up under high pressure and leads to nanoparticles having a homogeneous matrix structure [66]. Fast release is attained if the application of SLN to the skin should increase the drug penetration, using the occlusive effect of SLN. A core with an active compound is formed when the active compound starts precipitating and the shell has fewer drugs. This leads to a membrane-controlled release governed by the law of diffusion. It indicates that the structure of the SLN formed depends on the chemical nature of the active compounds and excipients. The release profile of SLN is often biphasic. The initial burst release is followed by a prolonged release. The burst release is high when produced at high temperature by hot homogenization.

#### 12.4.2.2 *In Vitro* Occlusion of SLN

An adhesive effect is claimed for small-sized liposomes, forming a film on the skin after application. The occlusivity of SLN in the form of the occlusion factor has been investigated using the de Vringer model of a water beaker covered by a filter paper [67]. In this study, the particle size should be small-sized nanoparticles. Admixing of the SLN increased the occlusivity to maintain the light characters of day cream, avoiding the glossiness of occlusive night cream. Highly occlusive night cream was composed of lipid nanoparticles of high lipid concentration.

#### 12.4.2.3 *In Vivo* SLN: Occlusion, Elasticity and Wrinkles

A study on the effect of *in vivo* SLN on skin hydration and elasticity has been performed. Using several volunteers, the cosmetic formulation was applied to one arm and the same formulation with 4% SLN was applied to other arm twice a day for 4 weeks. The addition of SLN with the commercial formulation increased the skin hydration by 32%, while in pure formulation the skin hydration increased by 24% [68]. Little or no increase in elasticity was observed in young volunteers. The effect on wrinkle depth was found effective in wrinkle treatment using established formulations with SLN. Detection of adhesive SLN on human skin was done by the Tesa strip test. The SLN were found to stick to the skin surface, forming a film and increasing the skin hydration.

#### 12.4.2.4 Active Compound Penetration into the Skin

The penetration of active compounds into human skin involves coenzyme Q10 and retinol. SLN are found to be more efficient in promoting penetration into the stratum corneum. In cosmetic products the active compounds should stay in the skin, penetrating sufficiently deep, but not too deep so as to affect systemic availability. Penetration study with drugs in pharmaceutical dermal formulations revealed that the degree of penetration depends on the chemical composition of the formulation. The film formation, skin hydration, SLN lipids interaction and surfactants with the skin lipids are considered the factors affecting the degree of penetration [65].

Depending on the composition of SLN, different penetration profiles were obtained [69]. In the optimized formulation, a therapeutically desired enrichment in the upper layer of the skin was obtained with systemic uptake minimization.

#### 12.4.2.5 Controlled Release of Cosmetic Compounds

Perfume was incorporated in SLN and the release study compared to a nanoemulsion of the same lipid and surfactant composition. Initially the release was same due to the presence of perfume in the outer shell of the SLN. During the follow-up period to 8 h the release from SLN was delayed. This technique is used for developing longer-lasting perfume formulations based on the prolonged release of the perfume from the solid lipid matrix [70].

Prolonged release is also desired for insect repellents, while the carrier should be also released from the adhesive SLN carrier system to stick firmly to the skin. The insect repellent DEET (*N,N*-diethyl-4methyl Benzamide) was incorporated in different SLN formulations. A loading of 10% was achieved in stearic acid SLN stabi-

lized with Tween 80 as a surfactant. The particles were physically stable for a long period when incorporated into a gel [71, 72].

#### 12.4.2.6 Novel UV Sunscreen System Using SLN

The reduction of the ozone layer has increased the need for effective UV protection systems with minimum side-effects. The main UV protection systems are molecular UV blockers (sunscreens) and particulate compounds like  $\text{TiO}_2$ . The molecular blockers showed side-effects such as photoallergies and phototoxic effects; therefore, the particulate blockers systems are now used. The mechanism of the protection is simply the scattering of UV rays. However, the very small  $\text{TiO}_2$  particles penetrate into the skin and interact with the immune system [73]. The crystalline solid lipid nanoparticles also act as particulate UV blockers by scattering the light efficiently. To enhance the UV protection further, a molecular sunscreen was incorporated into the solid lipid matrix. The fixation of the molecular sunscreen inside the solid matrix minimized the side-effects due to penetration of the molecular sunscreen into the skin. Incorporation of the molecular sunscreen into the SLN matrix led to a synergetic protective effect. This means that the total amount of molecular sunscreen in the formulation was reduced with a minimization of the side-effects.

The release of the sunscreen from oil-in-water nanoemulsions and SLN dispersions was studied. A membrane-free release model used an oil phase above the aqueous nanoemulsion or aqueous SLN dispersion in a test tube. After 4 h, 6.5% of the sunscreen was released from the nanoemulsion; however, only 3.1% of the sunscreen was released from the SLN dispersion [74].

#### 12.4.3

##### Polymer-based Nanoparticulate Delivery to the Skin

Poly(alkyl cyanoacrylate) (PACA) nanoparticles have been used as controlled release devices for peptide delivery after subcutaneous administration. Radiolabeled poly(isobutyl cyanoacrylate) (PIBCA) nanospheres injected subcutaneously revealed a progressive reduction of staining in muscular tissue suggesting that the nanospheres were progressively biodegraded [75a]. These nanospheres were used to release growth releasing factor in a sustained manner and to improve its bioavailability. After association with the nanospheres, the peptide was partially protected from enzymatic degradation, whereas it was very rapidly metabolized at the injection site when administered with the free drug.

A proposed mechanism for the reversion of MDR by means of doxorubicin-loaded PACA nanospheres is shown in Fig. 12.2.

#### 12.4.4

##### Subcutaneous Nanoparticulate Antiepileptic Drug Delivery

Antiepileptic drugs are rarely administered subcutaneously due to their slowness and unreliability. In extraordinary circumstances such as end of life palliative

**Fig. 12.2.** Proposed mechanism for the reversion of MDR by means of doxorubicin-loaded PACA nanospheres. Given as free drug, doxorubicin is pumped out of the cell by P-glycoprotein (A). When given as PACA nanospheres, doxorubicin and degradation

products such as poly(cyanoacrylic acid) are released locally from the nanospheres adsorbed on the cell membrane. Together they can form ion pairs, which facilitate the penetration of doxorubicin into resistant cells [75b].

care, subcutaneous administration is advocated. Subcutaneous delivery of insulin by programmable infusion or on-demand linked to a glucose sensor has proved promising [76]. The idea of a subcutaneous antiepileptic drug implant is attractive. The low solubility, high alkaline pH in solution and low potency of most antiepileptic drugs make such implants bulky and impractical. Benzodiazepines have high potency, but exhibit tachyphylaxis with continuous use. All most all antiepileptic drugs have a relatively narrow therapeutic/toxic range, allowing for little variations in release rates from the implant. Transdermal patches are used to deliver many medications like nitroglycerine, antiemetics and nicotine. Significant transdermal penetration through the stratum corneum by medicines usually requires chemical enhancers like oxazolidinones, propylene glycol and epidermal enzymes [77]. Despite the limits of solubility and potency, antiepileptic drug patches remain an attractive option.

#### 12.4.5

#### Nanoparticulate Anticancer Drug Delivery

Cancer therapy usually involves intrusive processes including application of catheters to allow chemotherapy to shrink any cancer present, surgery to then remove

the tumor followed by more chemotherapy and radiation. The purpose of the chemotherapy and radiation is to kill the tumor cells, which are more susceptible to the action of the drugs and methodologies, due to their faster growth rate than healthy cells. Current research areas include development of carriers to allow alternative dosing routes, new therapeutic targets such as blood vessels fueling tumor growth (angiogenesis) and targeted therapeutics that are more specific in their activity. The effectiveness of the treatment is directly related to the treatment's ability to target and kill the cancer cells while affecting as few healthy cells as possible. Currently, cancer patients' selectivity in their treatment is related to the inherent nature of the chemotherapeutic drugs to work on a particular type of cancer cell more intensely than on healthy cells. However, by administering bolus doses of these intense drugs systematically some side-effects will always occur and sometimes these are so intense that the patient must discontinue therapy before the drugs have a chance to eradicate the cancer [78]. Advances in the treatment of cancer are progressing quickly both in terms of new agents against cancer, and new ways of delivering both old and new agents. Some new methods for delivering therapies, both old and new, with a focus on nanoparticle formulations and ones that specifically target tumors are discussed in the following subsections.

#### 12.4.5.1 Paclitaxel

Paclitaxel is a microtubule-stabilizing agent that promotes polymerization of tubulin causing cell death by disrupting the dynamics necessary for cell division. It has neoplastic activity against primary epithelial ovarian carcinoma, breast, colon and non-small cell lung cancers. Paclitaxel is poorly soluble in aqueous solutions, but soluble in many organic solvents such as alcohols. The currently available formulation includes Cremophor EL (polyethoxylated castor oil) and ethanol for solubilization; however, Cremophor EL is a toxic substance which shows side-effects such as hypersensitivity reactions, nephrotoxicity and neurotoxicity [79]. Biodegradable nanoparticle formulations of PLGA have been used. Paclitaxel is incorporated at very high loading efficiencies, about 100%, by a nanoprecipitation method using acetone and PLGA [80]. These nanoparticles, 117–160 nm diameter, released over half of their drug *in vitro* in the first 24 h.

#### 12.4.5.2 Doxorubicin

It is the most potent and widely used anticancer drug and works by inhibiting the synthesis of nucleic acids within cancer cells [81]. Doxorubicin has a number of undesirable side-effects like cardiotoxicity and myelosuppression, which leads to a very narrow therapeutic index. Various researchers have studied different ways to target doxorubicin delivery to cancer tissues with minimum side-effects. Conjugates of dextran and doxorubicin have been encapsulated in chitosan nanoparticles of around 100 nm diameter. Mice injected intravenously with both dextran-doxorubicin conjugates and the conjugates encapsulated in chitosan nanoparticles showed a decrease in tumor volume. Treatment with doxorubicin alone did not decrease the tumor volume. Another method used for cancer treatment is neutron capture therapy using gadolinium [82]. *In vitro* cellular studies of chitosan-

encapsulated gadopentetic acid in nanoparticles has shown that the nanoparticles will be taken up by L929 fibroblast cells, B16F10 melanoma cells and SCC-VII squamous cell carcinoma cells through endocytosis. Doxorubicin was also conjugated with PLGA and formed nanoparticles from these conjugates [81]. Nanoparticles of 200–250 nm diameter were prepared, with *in vitro* release for up to 1 month. *In vivo* analysis of injected nanoparticles as compared with daily doxorubicin injections shows a single injection of doxorubicin–PLGA conjugate nanoparticles could suppress tumor growth for up to 12 days.

#### 12.4.5.3 5-Fluorouracil (5-FU)

Incorporation of 5-FU is achieved using dendrimers of poly(amidoamine) modified with mPEG-500. The hydrophilicity of the 5-FU is allowed to complex with the dendrimers. Simply incubate the polymer with the drug. In *in vitro* studies, pegylated formulations showed release over 144 h (6 days), while non-pegylated formulations had completed their release within 1 day. Intravenously administered formulations in rats showed that free 5-FU was cleared from the bloodstream within 1.75 h. Those given dendrimer formulations, however, showed 5-FU clearance only after 7 h for non-pegylated systems and 13 h for pegylated systems. This confirms the formulation ability to control the 5-FU release *in vivo* and the extension of release by pegylation of the polymers in the formulation [83].

#### 12.4.5.4 Antineoplastic Agents

Camptothecin-based drugs, specifically irinotecan (Camptosar) and topotecan (Hycamptin), have been approved by the FDA, and are used most often either in conjunction with 5-FU as first-line therapy or sometimes used alone after 5-FU has failed. Analogs of these molecules have shown up to 1000-fold higher activity, but the great challenge to their delivery is their extreme hydrophobicity [84]. Lipid-based nanoparticles of 100–375 nm diameter were prepared with the SN-38 analog of irinotecan. The weight of tumors was followed for mice injected twice weekly for 2 weeks (four doses) or daily for 10 days (10 doses) with Camptosar as compared with encapsulated SN-38 twice weekly for 2 weeks (four doses) at two different particle sizes. The longest tumor regression and survival was seen for mice injected with nanoparticles around 375 nm in diameter (65 days survival, 1.98 mg SN-38 per mouse), followed by those injected daily with Camptosar (51 days survival, 9 mg irinotecan per mouse) and those injected with nanoparticles around 100 nm diameter (48 days survival, 1.51 mg SN-38 per mouse). The control mice survival was 22 days.

#### 12.4.5.5 Gene Delivery

Other ligands which show a selective targeting to cancer cells are transferrin (Tf) and epidermal growth factor (EGF) [85, 86]. Complexes for DNA delivery composed of poly(ethyleneimine) linked to PEG coated with either Tf or EGF were prepared with nanoparticle diameters ranging from 49 to 1200 nm. The plasmid pCMV-Luc which codes for luciferase production was incorporated into these nanoparticles and *in vivo* studies in mice showed the gene expression from admin-

istration of targeted systems was 10–100 higher in tumors than in other organs [87].

A new class of biosensors has been developed which recognizes and detects specific DNA sequences and genetic mutations in laboratory experiments. The technology could lead to a new method of cancer detection or drug development. The nanosensors, called “smart nanoparticle probes”, work by attaching short pieces of DNA (oligonucleotides) to 2.5-nm gold nanocrystals, which serve both as scaffolds and as “quenchers” for fluorescence. The oligonucleotide molecule forms into an arch-like shape labeled with a fluorescent dye at one end and a sulfur atom at the other end. The new nanoparticle probes will be more effective than conventional molecular beacons because their unique shape is better suited to binding with target molecules and their fluorescence changes very little with changes in temperature.

Nanoparticles are used to trace specific proteins in cells for early cancer diagnosis and to monitor the effectiveness of drug therapy. The nanoparticles are also used to quantify and identify gene sequences, proteins, infectious organisms and genetic disorders. The particles might be able to profile a large number of genes and proteins simultaneously, allowing physicians to individualize cancer treatments based on the molecular differences in the cancers of various patients. Because of their novel structural and optical properties, these nanobeacons open new opportunities in biomolecular sensing and bioengineering [88].

#### 12.4.5.6 Breast Cancer

A research study used Doxil (a commercial liposomal doxorubicin formulation from Alza) in which a modified PEG conjugated to antibody F5 had been incubated to form a coupled liposome system. Comparison *in vivo* in mice treated with Doxil or F5-coupled Doxil showed a faster and greater regression in tumor volume for F5-containing Doxil over unmodified Doxil [89].

#### 12.4.6

#### Nanofibers Composed of Nonbiodegradable Polymer

The incorporation of a drug into water-insoluble nonbiodegradable polyurethane has been performed to make the drug amorphous. To achieve this goal, electrostatic spinning was applied [90, 91] resulting in the formation of nanodimension fibers. The application of this technology to drug-based delivery systems has been examined only to a limited extent [92–95]. To generate drug delivery systems based on this approach, a drug is incorporated along with the polymer in the solution to be electrospun. In this process, three general variable types determine the diameter and morphology of the filaments – solution parameters, equipment-controlled parameters and environmental parameters [96, 97]. Such treatments form fibers ranging in diameter from 100 nm to several Ångstroms, which are cylindrical and uniform ranging to beaded fibers of homogeneous size. The large surface area associated with nanospun fabrics allows fast and efficient solvent evaporation, giving

limited time to recrystallize the incorporated drug for the formation of amorphous dispersions or solid solutions [92]. The electrostatic spinning of poorly water-soluble drugs in a water-insoluble nonbiodegradable polymer may generate useful delivery forms. Two drug models, itraconazole and ketanserin, were evaluated using a polyurethane carrier. Oral itraconazole is widely used for the treatment of tinea pedis and other superficial fungal infections. The compound is highly water insoluble and does not penetrate into the dermis to any significant extent after topical application to explant human skin in traditional vehicles [98, 99]. Ketanserin is a selective 5<sub>2</sub>-serotonin antagonist which accelerates wound healing in the treatment of diabetic foot ulcers [100, 101].

#### 12.4.6.1 Electrostatic Spinning

A high voltage Spellman DC current supply was used for the experiments in an electrostatic spinner. The voltage applied was set to 16 kV. All the experiments were done at ambient temperature and humidity. The solutions were prepared by dissolving the drug and polymer in a suitable organic solvent. The solution was fed to the glass spinneret and a high voltage was applied to the solution. On completion of the spinning nonwoven spun fabric was removed and characterized.

#### 12.4.6.2 Scanning Electron Microscopy

The electrostatic spun fibers surface was analyzed using a scanning electron microscope. In the method of analysis the spun fibers were placed in a center of an aluminium stud. A very thin layer of gold was applied to the fibers and placed in the microscope chamber connected to a high vacuum. Surface morphology study was done at 5–10 kV mode.

#### 12.4.6.3 Differential Scanning Calorimetry (DSC)

The Differential Scanning Calorimetry (DSC) study was done using a DSC instrument connected with a thermal analysis controller. The samples were analyzed in covered aluminum pans under dry nitrogen. Approximately 5 mg of crystalline compound was heated from 25 to 200 °C and then cooled at room temperature.

A second heating cycle was applied on the sample starting at room temperature upto 200 °C. For the electrospun materials, approximately 5 mg was weighed in the DSC pan.

## 12.5

### Nanoparticulate Delivery to the BBB

Nanoparticles represent a tool to transport essential drugs across the BBB that are normally unable to cross this barrier. Drugs that have successfully been transported into the brain using nanoparticles include the hexapeptide dalargin, the dipeptide kytorphin, loperamide, tubocurarine, the NMDA receptor antagonist MRZ 2/576 and doxorubicin. Nanoparticles may be especially helpful for the treatment

of disseminated and very aggressive brain tumors. The first promising result in this direction was obtained in rats. The mechanism of nanoparticle-mediated transport of drugs across the BBB needs further elucidation. The most likely mechanism seems to be receptor-mediated endocytosis by the endothelial cells lining the brain blood capillaries [35], following adsorption of apolipoprotein (apo) B and E from the blood after intravenous injection.

By increasing bioavailability, nanoparticles can increase the drug development and help to treat previously untreatable conditions. Because of the BBB, many new chemical entities aimed at treating brain disorders have not proved clinically useful. In contrast, nanoparticles have been used to cross the BBB with little difficulty. Several systems have been developed, capable of reaching the brain for anesthesia (Dalargin, an analgesic), cancer drugs and other different therapeutics. There are several advantages over existing systems, including (a) no requirement to open the BBB, (b) the ability to use hydrophilic or hydrophobic drugs, and (3) the drug does not need to be modified. Researchers at the University of Texas at Austin have also described means of using nanospheres for oral drug delivery. These nanosphere carriers are derived from hydrogels – highly stable organic compounds that swell when their environment becomes more acidic. These are successfully formulated into controlled release tablets and capsules, which release active drug compounds.

#### 12.5.1

##### **Peptide Delivery to the BBB**

Nanoparticles are used as transport vectors for peptide drugs. The nanoparticles are colloidal polymer particles of poly(butyl cyanoacrylate) with the desired peptide absorbed onto the surface and then coated with polysorbate 80. Nanoparticles are also used as a vector for delivering the hexapeptide dalargin (an enkephalin analog). Intravenous injections of the vector-dalargin produce analgesia, while dalargin alone does not [102]. Drugs successfully transported across the BBB with nanoparticles include loperamide, tubocerin and doxorubicin [103, 104]. The mechanism of nanoparticulate transport was not completely elucidated. The most probable transport pathway seems to be endocytosis by the blood capillary endothelial cells following adsorption of blood plasma components, most likely apoE after intravenous injection. These particles interact with the low-density lipoproteins (LDL) receptors on the endothelial cells and are then internalized. After internalization by the brain capillary endothelial cells, the drug is released by desorption or degradation of the nanoparticles and diffuses into the residual brain. Alternatively, transport may occur by transcytosis of the nanoparticles with the drug across the endothelial cells. The coating of nanoparticles with polysorbate led to adsorption of apoE and possibly other plasma components. This interacts with the LDL receptors of the brain endothelial cells, which could lead to their endocytosis [105]. In addition to these processes, polysorbates are capable of inhibiting the efflux pump. This inhibition could contribute to the brain transport properties of

the nanoparticles. However, the possibility of a general toxic effect is also a serious impediment.

#### 12.5.1.1 Peptide Conjugation through a Disulfide Bond

Short peptide sequences, known as protein transduction domains (also known as cell-penetrating peptides), have become important tools to internalize impermeant molecules into cells. The transduction domain from the HIV TAT protein has been the most widely used and characterized. The ability of the TAT protein to cross the plasma membrane has since been shown to reside primarily in a highly basic region composed of nine amino acid residues.

A microanalytical instrument is used to provide quantitative data on cargo transported into the cytoplasm of living. Fluorescently labeled peptides, kinases, were conjugated to a TAT-derived peptide. Two strategies were employed to introduce a cleavage site between the TAT and the substrate cargo – a disulfide bond and a photolabile moiety. Cytosolic concentrations of the released substrates were detectable at approximate concentrations of less than  $10^{-20}$  moles. These substrate peptides were used as probes of cytoplasmic kinase activity in single cells, with their phosphorylation providing a measure of their accessibility to cytoplasmic kinases. The percentage of phosphorylation of a TAT-loaded substrate peptide was compared to determine whether the free peptide released from the TAT conjugate was efficiently phosphorylated. The conjugated peptides were also used to determine the kinetics and temperature dependence of TAT-mediated delivery of kinase-accessible peptide to the cytosol [106].

#### 12.5.2

#### Biodegradable Polymer Based Nanoparticulate Delivery to BBB

Polymeric lipid-based devices that can deliver drug molecules at defined rates for specific periods are making a tremendous impact in clinical medicine. Drug delivery to the brain interstitium using polyanhydride can circumvent the BBB. The drug is released directly to an intracranial target in a sustained fashion for an extended period of time. The fate of a drug delivered to the brain interstitium from the biodegradable polymer was predicted by a mathematical model based on (a) rates of drug transport via diffusion and fluid convection, (b) rates of elimination from the brain via degradation, metabolism and permeation through capillary networks, and (c) rates of local binding and internalization [107]. Such models are used to predict the intracranial drug concentrations, results from 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU)-loaded pCPP:SA (1,3-bis-para-carboxyphenoxypropane:sebacic acid) as well as other drug–polymer combinations, paving the way for the rational design of drugs specifically for intracranial polymeric delivery.

Conjugation of a polymerically delivered chemotherapeutic agent to a water-soluble macromolecule increases drug penetration into the brain by increasing the period of drug retention. Recently, interleukin-2-loaded biodegradable polymer microspheres were developed for local cytokine delivery to improve the immuno-

therapeutic approach to brain tumor treatment [108]. Polymeric cytokine delivery has several advantages over delivery from transduced cells, including obviating need for transecting cytokine genes, producing longer periods of cytokine release *in vivo*, yielding more reproducible cytokine release profiles and total cytokine dose. Microparticles are easily implanted by stereotaxy in discrete, precise and functional areas of the brain without damaging the surrounding tissue. This type of implantation avoids the inconvenient insertion of large implants by open surgery, which may lead to repeat operations [109]. The feasibility of polymer-mediated drug delivery by the standard chemotherapeutic agent BCNU showed local treatment of gliomas. This method is effective in animal models of intracranial tumors. Obviously, such an invasive approach is only useful in a limited number of patients; however, it does prolong survival of patients with recurrent glioblastoma multiform brain tumors. Nevertheless, because of diffusion problems the therapeutic agent is likely to reach only nearby sites.

Polymeric nanoparticles are interesting colloidal systems to enhance the therapeutic efficacy and reduces the toxicity of a large variety of drugs [110]. Nanoparticles are helpful for the treatment of the disseminated and aggressive brain tumors. Intravenously injected doxorubicin-loaded polysorbate 80-coated nanoparticles produced 40% cure in rats with intracranially transplanted glioblastomas [103]. Another study shows that pegylated PHDCA (*n*-hexadecylcyanoacrylate) nanoparticles made by pegylated amphiphilic copolymer penetrate into the brain better than all the other tested nanoparticle formulations, without inducing any modification of BBB permeability [111]. Two important requirements are necessary in design of adequate brain delivery systems – long-circulating properties of the carrier and appropriate surface characteristics to permit interactions with endothelial cells. Valproic acid-loaded nanoparticles showed reduced toxic side-effects of valproate therapy, not by reducing the therapeutically necessary dosage, but by inhibiting the formation of toxic metabolites [112]. In conclusion, the capacity of biodegradable polymer delivery methodology to deliver drugs directly to the brain interstitium is extensive.

### 12.5.3

#### **Nanoparticulate Gene Delivery to the BBB**

Another strategy to achieve interstitial drug delivery involves releasing drugs from biological tissues. The simplest approach to this technique is to implant into the brain a tissue which naturally secretes a desired therapeutic agent. This approach is useful in the treatment of Parkinson's disease. Transplanted tissue often did not survive due to a lack of neovascular innervation. Recently, enhanced vascularization and microvascular permeability in cell-suspension embryonic neural grafts related to solid grafts has been demonstrated [113]. An alternative for this method is to use gene therapy to develop optimized biological tissue for interstitial drug delivery. Before implantation, cells are modified genetically to synthesize and release specific therapeutic agents. The therapeutic potential of this technique in the treatment of brain tumors has been demonstrated [114]. The use of nonneuronal cells

for therapeutic protein delivery to the CNS has been recently reviewed. The survival of foreign tissue grafts may be improved by advancements in techniques for culturing distinct cell types. Co-grafted cells engineered to release neurotropic factors with cells engineered to release therapeutic proteins may enhance the survival and development of foreign tissue [115].

It is possible to perform *in vivo* genetic engineering to cause specific endogenous brain tissue to express a desired protein, circumventing the ischemic and immunogenic complications encountered with the implantation of foreign tissue grafts. One such technique that has been successfully used for the treatment of CNS malignancies involves *in vivo* tumor transduction with the herpes simplex virus thymidine kinase (HSV-tk) gene followed by the treatment with anti-herpes drug ganciclovir. It was achieved by intratumoral injection of retroviral vector-producing cells containing the HSV-tk gene, rendering the transfected tumor cells susceptible to treatment with ganciclovir [116]. Other vector systems used in CNS gene transfer studies include retroviruses, adenoviruses, adeno-associated viruses, encapsulation of plasmid DNA into cationic liposomes, and neutral and oligodendrial stem cells. Although this approach holds remarkable therapeutic potential in the treatment of CNS diseases, several obstacles hinder its efficacy – restriction to the delivery of vector systems across the BBB, inefficient transfection of host cells, nonselective expression of the transgene and deleterious regulation of the transgene by the host [117].

#### 12.5.4

#### **Mechanism of Nanoparticulate Drug Delivery to the BBB**

The mechanism of drug delivery across the BBB has not been completely elucidated, even several possibilities are existing to explain it [103, 118]:

- (a) An increased retention of the nanoparticles in the brain blood capillaries is combined with adsorption to the capillary walls. A higher concentration gradient is responsible for enhancing the transport across the endothelial cell layer and it results in delivery to the brain.
- (b) A general surfactant effect characterized by a solubilization of the endothelial cell membrane lipids leads to membrane fluidization and enhanced drug permeability through the BBB.
- (c) The nanoparticles could lead to an opening of the tight junctions between the endothelial cells. The drug permeates through the tight junctions in free form or together with the nanoparticles.
- (d) The nanoparticles may be endocytosed by the endothelial cells followed by the release of the drugs within these cells and delivery to the brain.
- (e) The nanoparticles bound with drugs are transcytosed through the endothelial cell layer.
- (f) The polysorbate 80 used as the coating agent could inhibit the efflux system, especially P-glycoprotein.

## 12.5.5

**Nanoparticulate Thiamine-coated Delivery to the BBB**

Thiamine is a water-soluble micronutrient essential for normal cell function, growth and development. The consideration of thiamine as a cell-specific ligand for targeted delivery is rationalized since all eukaryotic cells have a specified transport mechanism for thiamine. The effectiveness of using the thiamine ligand in tumor targeting has been studied. Thiamine-coated gadolinium nanoparticles had specific association with human breast cancer cells, which expressed the thiamine transporters THTR1 and THTR2 [119]. The thiamine ligands bind to the BBB thiamine transporter and subsequently increase the number of nanoparticles at the BBB interface. Based upon BBB thiamine transport capacity and kinetics, it is referred to as a brain drug delivery vector [120]. The thiamine-coated nanoparticles (thiamine nanoparticles) specifically favor the brain uptake either by facilitating transport mechanisms or by increased passive diffusion, secondary to an increased concentration gradient of the nanoparticles located at the BBB interface due to association with the thiamine transporter. The thiamine-coated nanoparticles are engineered directly from microemulsion precursors. Brain uptake and distribution of nanoparticles with and without thiamine as a brain targeting ligand were investigated.

## 12.5.6

**Nanoparticle Optics and Living Cell Imaging**

Optical properties of silver nanoparticles depend on their size and shape and on the dielectric constant of the embedded medium [121–123]. The surface plasmon resonance of nanoparticles is excited by propagating light waves leading to the selective absorption and scattering of light. Therefore, the colors [localized SPRs (LSPRs)] of silver nanoparticles are correlated with the sizes of nanoparticles, while the shape of nanoparticles and their embedded medium remain unchanged [124, 125]. Unique size-dependent optical properties allow us to use the color index of nanoparticles (violet, blue, green, red) as nanometer-size index probes for real-time sizing of the change of living cellular membrane permeability and porosity at the nanometer scale. Individual silver nanoparticles are extremely bright under dark-field optical microscope and directly imaged by a digital or CCD camera through the dark-field microscope.

These nanoparticles do not photo-decompose and are used as probes to continuously monitor dynamics and kinetics of membrane transport in living cells for an extended time (hours). In addition, these nanoparticles are used to determine the sizes of substrates transported in and out of the living cellular membrane in real time. The scattering intensity of the nanoparticles decreases as nanoparticles enter the cell membrane and move into the cytoplasmic space. The cellular membrane and matrix absorbs the light of the microscope illuminator and reduces its intensity. The intracellular nanoparticles are surrounded by a cellular matrix (e.g. proteins, lipids) inside the cells and hence the reflection coefficient of intracellular

silver nanoparticles is smaller than the extracellular silver nanoparticles [121, 123]. The imaging system is sufficiently sensitive to detect single fluorescence dye molecules [126], and intracellular and extracellular single silver nanoparticles with diameters of 20–100 nm. Since the size of the nanoparticles and the thickness of the cellular membrane are under the optical diffraction limit (200 nm), the intracellular nanoparticles are accumulated on the membrane. However, these nanoparticles appear blurry and dimmer than extracellular nanoparticles, indicating that the blurry nanoparticles are inside the cells.

Transmission electron microscopy (TEM) is used to confirm the intracellular nanoparticles inside the cells. TEM images of ultrathin cross-sections of cells with nanoparticles unambiguously illustrate that nanoparticles up to 80 nm in diameter are observed inside the cells in the absence of chloramphenicol. The majority of nanoparticles (20–80 nm) are in the cytoplasmic space of the cells, whereas some of nanoparticles are right underneath the cellular membrane. It suggests that the outer and inner membrane of *Pseudomonas aeruginosa* permeate substrates with sizes up to 80 nm, which are 50 times larger than conventional antibiotics and detergents. Bulk cells are monitored simultaneously at single-cell resolution using single-living-cell imaging. Accumulation kinetics of nanoparticles in living cells is measured in real time using single nanoparticle optics. Even though these nanoparticles look larger than their actual sizes due to the optical diffraction limit, the sizes of nanoparticles are determined using their colors (LSPRS). As chloramphenicol concentration increases to 25 and 250  $\mu\text{g mL}^{-1}$ , more nanoparticles are observed in the cells, suggesting that the membrane permeability and porosity increase. The sizes of individual intracellular nanoparticles are distinguished using their colors (LSPRS) even in the presence of 250  $\mu\text{g mL}^{-1}$  of chloramphenicol, suggesting the chloramphenicol increases membrane permeability, but does not completely disrupt the cell walls. Chloramphenicol's primary target is ribosomal peptidyl transferase, where it acts competitively to inhibit normal substrate binding and protein synthesis [127]. These new insights further demonstrate the unique advantages of using single nanoparticle as probes for the study of function of antibiotics and membrane transport.

The MexAB–OprM has a wide spectrum of substrates, such as antibiotics, dyes, detergents and chemotoxic materials, and works by using proton motive force as the energy source [128]. Therefore, it is plausible to suggest that the transport mechanism of nanoparticles through the living cellular membrane is that nanoparticles enter the cells through passive diffusion and are extruded out of the cells by the extrusion mechanism of bacteria. Even though the sizes of silver nanoparticles seem 50 times larger than the pore sizes of membrane pumps (MexAB–OprM), the substrate (nanoparticles) can induce the assembly of the pumps in real time and define the pore sizes of the pumps. Currently, the crystal structure of the membrane pump is unavailable and the extrusion mechanism of the pump is still unknown [129]. Silver nanoparticles may enter the cells and be extruded out of the cells through unidentified pathways.

Ethidium bromide (EtBr) has been widely used as a fluorescence probe for the study of membrane permeability and extrusion machinery of bacterial cells [130,

131]. EtBr emits weaker fluorescence in an aqueous environment (outside the cells), and becomes 10 times more strongly fluorescent as it enters the cells and intercalates with DNA in the cells [132]. EtBr enters the cells through passive diffusion and is extruded out of cells by efflux pumps of *P. aeruginosa* using proton motive force as an energy source. The fluorescence spectra of EtBr indicate that the emission peak at 590 nm remains unchanged after a 2-h incubation of EtBr with the living cells. The time-dependent fluorescence intensity transients also show the mutant dependence. It indicates the mutant devoid of MexAB–OprM ( $\Delta$ ABM) accumulates EtBr most rapidly, whereas the mutant with overexpression of MexAB–OprM (nalB-1) accumulates EtBr most slowly. MexAB–OprM plays an important role in the accumulation of substrate (EtBr) in the cells. Taken together, accumulation kinetics measured using EtBr is consistent with those observed using single nanoparticles, eliminating the concern of the possible steric and size effects. The minimum inhibitory concentrations (MICs) of chloramphenicol in the presence of 10  $\mu$ M EtBr or 1.3 pM silver nanoparticles show mutant dependence, indicating a MIC of 12.5, 25 and 250  $\mu$ g mL<sup>-1</sup> for  $\Delta$ ABM, wild-type and nalB-1, respectively [133]. See Fig. 12.3.

## 12.6

### Oral Nanoparticulate Delivery

The oral route is the preferred route for drug delivery. However, numerous drugs remain poorly absorbed after oral administration. This can be due to (a) low mucosal permeability of a drug, (b) permeability restricted to a region of the GI tract, (c) low solubility of the compound results in low dissolution in the mucosal fluids and (d) lack of stability in the GI environment, resulting in degradation of the compound prior to its absorption (e.g. peptides, oligonucleotides). Drug delivery associated with nanoparticle systems has been investigated to overcome these problems. Several oral administration experiments are known which help to improve the pharmacokinetics of the drugs [134, 135]. See Fig. 12.4.

Orally administered drugs with nano- and microparticles follow different pathways and undergo: (a) direct transit and fecal elimination, (b) bioadhesion, and (c) oral absorption. Those pathways are important to determine an efficient drug delivery strategy. Some techniques are used for macroscopic controlled-release dosage forms for the accurate control of the drug delivery successfully transported via nanoparticles [136]. Micro- or nanoparticles orally administered in the form of a suspension diffuse into the liquid media and rapidly encounter the mucosal surface. The particles are immobilized at the intestinal surface by an adhesion mechanism referred as to as “bioadhesion”. More specifically, when adhesion is restricted to the mucus layer lining the mucosal surface, the term “mucoadhesion” is employed. The direct contact of particles with intestinal cells through a bioadhesion phase is the first step before particle absorption. The oral absorption pathway is investigated in the work of Volkheimer [137].

**Fig. 12.3.** Characterization of color index and size index of silver nanoparticles. (A) The representative full-frame optical image of silver nanoparticles taken from a 0.4-nM silver nanoparticle solution in a microchannel by a digital color camera through the dark-field optical microscope. Optical images of single silver nanoparticles selected from the full

frame image show the color index of silver nanoparticles. The optical images of nanoparticles look larger than their actual sizes because of the optical diffraction limit (200 nm). (B) Representative TEM images of silver nanoparticles from the solutions in (A) show the sizes and shapes of nanoparticles. The scale bar represents 40 nm [133].

### 12.6.1

#### Lectin-conjugated Nanoparticulate Oral Delivery

The association of ligands (i.e. lectins) with particulate systems is achieved by different procedures, including covalent linkage and adsorption processes. The ligand

Fig. 12.4. Problems inherent in developing peptides as drugs [134b].

should be bound to particles through a covalent linkage, which is more stable than simple adsorption. It is difficult to control the amount of ligand associated, which is not sufficient to assure its efficacy [138]. Most of the conjugates have been prepared from polystyrene nanoparticles. Polystyrene latexes are interesting models from an experimental point of view, because polystyrene particles are not degradable in biological media and are easily detected by turbidimetry [139] or fluorescent labeling. However, it is probably unacceptable as a drug carrier because of the non-degradability of the polymer after a probable translocation of a fraction of the particles after administration. For conjugates based on polystyrene nanoparticles (latex), the binding procedure is by covalent attachment. Depending on the chemical nature of the functional groups located on the carrier surface, glutaraldehyde and carbodiimide, are used for lectin coupling. Recently, some lectin conjugates based on a biodegradable particulate system were described. The carbodiimide technique was successfully used for the covalent attachment of lectins to vicilin (feed vegetal protein from *Pisum sativum*) and gliadin (protein fraction from wheat gluten) nanoparticles [140]. The procedure used for the preparation of the lectin–vicilin nanoparticle conjugates is illustrated elsewhere [141, 142].

#### 12.6.2

#### Oral Peptide Nanoparticulate-based Delivery

Nanospheres have a matrix-type structure, where active compounds (e.g. peptides) are adsorbed at their surface entrapped or dissolved in the matrix. The development of oral therapeutic peptide formulations with these substances is a challenging opportunity for researchers. The GI tract is designed to degrade dietary proteins and facilitate absorption of single amino acids or oligopeptides. For therapeutic compounds, however, the molecules have to remain intact when they reach the systemic circulation. Due to the presence of an acidic environment, pepsins, peptides and proteins are hydrolyzed in the stomach. In the intestine, peptides are confronted with pancreatic proteases, such as trypsin, chymotrypsin, elastase and carboxypeptidase A [143]. Furthermore, the peptides are exposed to brush border proteases and finally have to cross the epithelium. Degradation by enzymes is also possible during the absorption step. Several approaches, such as site-specific delivery systems, chemical modification of peptides (e.g. lipophilic derivatives, synthesis

of peptidomimetics), bioadhesive systems and concomitant administration of penetration enhancers or protease inhibitors, have been investigated to improve the oral delivery of peptides [143]. The use of particulate systems aims to improve the delivery of peptides by the oral route. Incorporating or encapsulating peptides in polymeric particles should have at least one effect. Depending on the nature of the particles used (type of polymer, size, adjuvant substances added), these systems enhance oral peptide absorption by other mechanisms. How the drug-loaded particulate systems are translocated from the intestinal mucosa to the systemic circulation after oral administration is still unknown [144, 145]. Many studies mention that not more than 5% of the ingested dose of submicron particles can be absorbed.

### 12.6.3

#### **Polymer-Based Oral Peptide Nanoparticulate Delivery**

Calcitonin is a peptide comprising 32 amino acids with high species-to-species sequence variations. It is soluble in water (1:5) and methanol (1:10), and is almost insoluble in acetone, alcohol, chloroform and ether. Calcitonin-loaded polyacrylamide nanospheres have been prepared by a reported method [146]. Particles containing hydrophilic peptide have also been prepared by interfacial polymerization, leading to the formation of nanocapsules [147, 148].

##### **12.6.3.1 Polyacrylamide Nanospheres**

Calcitonin-loaded nanospheres are prepared by the method of Birrenbach and Speiser [149]. This method involves polymerization in an inverse microemulsion (water-in-oil) method. It requires a large amount of solvent (e.g. hexane). The particles are isolated by several washings with ethanol and finally are freeze-dried. The nanospheres obtained with this technique had a size below 50 nm, but their loading efficiency remained low (5%). The peptide was immediately released from the particles after rehydration, thus impeding the protection against protease degradation.

##### **12.6.3.2 Poly(alkyl cyanoacrylate) PACA Nanocapsules**

The interfacial polymerization technique was used to encapsulate calcitonin in poly(isobutyl cyanoacrylate) PICBA nanocapsules [146]. The isobutyl cyanoacrylate (IBCA) monomers and calcitonin were dissolved in ethanol solution containing an oil (Mygliol 812). This phase was added dropwise into stirred water containing poloxamer 188. Anionic polymerization took place at the surface of the Mygliol droplets as soon as IBCA reached the oil/water interface, thus forming nanocapsules of a mean size ranging from 100 to 300 nm. Preparation additives were subsequently removed by diafiltration. Surprisingly, the calcitonin incorporated with an efficiency of 90%. The hydrophilic peptide has marked hydrophobic regions in its structure. This probably enables calcitonin to interact with the Mygliol oil. When incorporated into PIBCA nanocapsules, calcitonin was significantly more resistant to protease degradation than the free peptide [146]. However, in the pres-

ence of bile salts, the protection was significantly reduced, but still higher than a solution of free peptide. The authors suggested that calcitonin molecules diffused at the oil/water interface, together with IBCA and the poloxamer. This localization would then render the peptide susceptible to enzymes. Taking into account that peptides are highly water soluble it leads to the formation of nanocapsules with a complete inner aqueous core facilitates the incorporation of hydrophilic compounds [147, 148].

#### 12.6.3.3 Derivatized Amino Acid Microspheres

The releasing of the peptide at a specific site of the GI tract is done using dissolved nanoparticles of substrate. Microparticles sensitive to pH were prepared by using derivatized amino acids [150, 151]. Benzoylated and phenylsulfonylated single amino acids are novel, low-molecular-weight and self-assembling molecules. At low pH, these molecules aggregate to form microspheres that dissolved readily under neutral conditions. For example, modified soybean amino acids, dissolved in water, form microparticles when poured into a 1.7 N citric acid solution containing salmon calcitonin. This technique is used for the entrapment of nearly 60% of the dissolved peptide.

#### 12.6.4

#### Lymphatic Oral Nanoparticulate Delivery

The lymphatic pathway has not been investigated in many studies, possibly due to the difficulty, complexity and expense encountered in cannulating the major lymph ducts in laboratory animals. The evaluation of 80-nm solid lipid nanoparticles administered intraduodenally shows primarily their presence in the thoracic lymph duct [152]. Incorporation of the highly lipophilic drug cyclosporin in solid lipid microspheres increases lymphatic absorption 46-fold compared to conventional formulations. In another study, cyclosporin A formulated in stearic acid nanoparticles (300 nm) had a relative bioavailability of nearly 80% over the cyclosporin reference solution; however, it was unclear whether this was primarily lymphatic absorption [153]. Bioactive peptides such as insulin, calcitonin, luteinizing hormone-releasing hormone [154] and cyclosporin have been the typical peptides delivered as GI tract-labile drugs using nanoparticulate systems. Further, alteration in the physiology and metabolism of an animal is found in diseased states. In insulin-deficient streptozotocin-treated rats, the intestine is hypertrophic, and the synthesis and transport of cholesterol are increased. The increased load of cholesterol is transported through the mesenteric lymph in chylomicrons to developed oral formulations for insulin using steroidal lipids [155]. Liposome compositions of soybean sterols showed higher uptake than cholesterol, but this has been attributed to the increased stability of vesicles prepared by forming rigid liposomes [156]. All these attempts to deliver insulin orally using nanoparticles have been successful. In the oral administration of a very similar system, but dispersed in an oily phase, a 50% decrease of fasted glycemia was achieved from 2 h up to 10–13 days in rats [157]. This effect was shorter (2 days) or absent when nanospheres were dispersed in wa-

**Fig. 12.5.** Electron photomicrograph of semi-thin sections of rat Peyer's patch of a ligated intestinal segment after exposure to liposomes. Gold particles are indicated by the arrow. Notice the relatively small area of the M-cell apical surface sandwiched between the regular villi of the enterocytes. The presence of a large intraepithelial lymphocyte that approaches the apical surface is a conspicuous feature of the M-cell [158].

ter with and without surfactants. The results suggest primarily a lymphatic route of absorption with the nanoparticles being lodged in some way in the intestinal mucosa. A similar result has been reported for recombinant human erythro protein administered in liposomes composed of soyabean sterols. See Fig. 12.5.

#### 12.6.5

#### Oral Nanosuspension Delivery

The problems to find a suitable formulation are even greater in the case of drugs that are poorly soluble in aqueous media and in organic media.

Simple examples reflecting this problem of poor solubility combined with low absorption are the experimental compound bupravaquone and the recently approved drug atovaquone (Wellvone), used for the treatment of opportunistic *Pneumocystis carinii* infections in HIV patients. Oral administration of nanosuspensions can overcome the problem of the poor solubility of drug. This is because of the high adhesiveness of drug particles, sticking on biological surfaces of the epithelial gut wall. When atovaquone formulated as a nanosuspension is given orally to *Leishmania*-infected mice, the parameter for increased absorption is related to the infectivity score of each animal or it is related to the reduction of the parasite load in the liver. In comparison to Wellvone-treated mice, containing a micronized drug, nanosuspensions of atovaquone at equivalent doses reduced infectivity from 40 to 15% at a reduced concentration of only  $7.5 \text{ mg kg}^{-1}$  [158, 159]. Another example of the effectiveness of nanosuspensions for improving bioavailability is the application of amphotericin B. When amphotericin B is given orally in approved drugs for the treatment of GI tract mycosis, the drug is not, or only to a minor ex-

**Fig. 12.6.** Transmission electron micrographs of a atovaquone nanosuspension (size: 468 nm) [161].

tent, absorbed. Formulating this antimycotic and leishmanicidal drug as a nanosuspension and administering it orally, the number of *L. donovani* parasites *in vivo* was reduced significantly, indicating a high uptake of the drug in the GI tract. When given amphotericin B nanosuspensions orally, the infectivity score was determined at 25% (control = 100% parasite growth) [160]. See Fig. 12.6.

#### 12.6.6

##### **Mucoadhesion of Nanoparticles after Oral Administration**

Considering the different phenomena occurring after oral administration of a suspension of colloidal particles via the oral route, the following general dynamic description is given. First, a suspension of particles is administered and immediately contacts the oral mucosa. From this moment on, the concentrated suspension acts as a reservoir of particles and, very rapidly, an adsorption process takes place, leading to the adsorption of a fraction of the available particles. Adsorption occurring with the mucous layer is an irreversible process. However, the luminal particle suspension transits through the intestine, progressively sweeping the whole mucosa. The simultaneous adsorption process results in a progressive covering of the intestinal mucosa by adhering particles. Finally, detachment of the particles from the mucosa begins to occur in the proximal region and is progressively extended to the distal region. Nonadhering particles from the lumen pool are detached from the mucoadherent pool and are finally eliminated in the feces. Quantitatively, particle translocation through the intestinal mucosa remains a secondary phenomenon [161].

#### 12.6.7

##### **Protein Nanoparticulate Oral Delivery**

Protein nanoparticles are incorporated into biodegradable polymer microspheres/nanospheres as a controlled release depot or for oral delivery. In proteinaceous

therapeutics, the generation of nanoparticles is problematic. Existing practices have difficulties in achieving the desired particle size for distribution. Protein nanoparticles technology avoids most of these difficulties. The process exploits the ability of superfluids to penetrate the protein aggregates and then utilizes the expansive energy of superfluids to disaggregate protein crystals into monodisperse nanoparticles. Superfluid protein nanoparticles technology is not constrained by limited solubility in benign solvents such as ethanol [162].

## Fluorescence Imaging in Biology using Nanoprobes

*Daniele Gerion*

### 1.1 Introduction and Outlook

#### 1.1.1 A New Era in Cell Biology

Fluorescence is ubiquitous in biology. Indeed, any biology textbook contains a multitude of colorful images, most of which would not disfigure an art gallery [1]. For decades, biologists have mastered the use of fluorescently labeled molecules to stain cells in cultures or tissues. They developed the tools to target different compartments inside the cells, such as the nucleus and mitochondria, and subcompartment structures, such as chromosomes and the telomeres using light-emitting organic markers. These traditional approaches permitted the unraveling of a wealth of information on organs and tissues and, to a smaller scale, on the cell organization and its functioning. Images of cellular division captured by fluorescence microscopy are breathtaking, particularly the movement of the duplicated chromosomes along the spindle apparatus towards the two poles of the parent cell. Similar examples abound in the scientific literature and in fluorescent dye catalogs to the point that biology may convey a false sense of completeness. Indeed, an engineer or a physicist like myself may have the impression that everything interesting in biology has been already discovered and that only a few blanks remain to be filled.

Yet, in recent years, biology has witnessed an extraordinary revolution. Modern biology looks beyond responses to stimuli or the morphological description of structures. Modern biology does not satisfy itself with the successful sequencing of the human genome because a list of four repeating letters does not reveal a biological function. Modern biology is much more ambitious. It seeks to understand how biological and chemical processes work together to make cells and living organisms [2]. The journey towards this “Holy Grail” of biology depends on our ability to decipher interconnected cellular networks, mainly by observing molecular pathways of proteins and other metabolites in living organisms. The ultimate goal is to know where and when proteins and metabolites are expressed, how and at

which level they are distributed in time and space and how are signals generated and transmitted to maintain cell vitality [3].

### 1.1.2

#### **Nanotechnology and its Perspectives for Fluorescence Imaging in Cell Biology**

It is instructive to describe a problem of primary interest for biologists that illustrates the importance of knowing the entire pathway of a biological process and exemplifies how nanotechnology may enter the game. The example concerns double-stranded silencing RNA (siRNA [4–6]), a potent agent able to temporarily knockdown selected genes in mysterious fashion. Elucidation of this process is of considerable importance because it may reveal new routes that regulate the expression of genes and lead to the development of drugs with the ability to selectively keep the “good” genes on and turn the “bad” ones off. To study the mechanism by which siRNA works, a simple strategy would be to follow its path when it travels through the cell. This can be done by labeling it with a fluorescent chromophore and following its path with a fluorescence microscope. The double strand nature of the duplex raises the possibility that siRNA opens up at some point and that only one of the strands becomes the active agent that knocks down the gene expression. Where and when does it happen? A partial answer can be gained by labeling each strand of the siRNA duplex with a different fluorophore and following each of them separately. However, the colocalization of both strands with a resolution of a few nanometers far exceeds the diffraction limit of conventional microscopes, and therefore the very idea of observing the siRNA denaturation needs a different strategy. An elegant approach would be to use fluorescence resonance energy transfer or FRET [7] between two fluorophores, each located on a different strand of the siRNA duplex. When the duplex is intact, the fluorescence of the donor is resonantly transferred to the acceptor. Therefore, the donor fluoresce is “low” and the acceptor emission is “high”. The opening up of the molecule manifests itself by the switching off of the FRET mechanism with the consequence that the donor fluorescence becomes “high” while the acceptor fluorescence goes to “low”. Such a plan to study siRNA cannot rely on organic dyes. They bleach too rapidly under continuous illumination, especially at the single molecule level where the time window to observe them is limited to a few seconds. In addition, the photobleaching is generally associated with the formation of reactive oxygen radicals, which are a major cause of DNA damage and may result in the poisoning and death of the cell [8].

Enter nanotechnology. Over the past ten years, chemists have learned how to make fluorescent colloidal nanocrystals [9], also called quantum dots, and how to solubilize them in water, and to functionalize them with biomolecules [10, 11]. What makes these quantum dots interesting is their remarkable optical properties [12] and the fact that live cells seem to tolerate them quite well [13–15]. Quantum dots could represent an ideal solution to the shortcomings of organic dyes for labeling siRNA in live cells. The fate of siRNA is only one of a handful of problems where quantum dots can play a decisive role in biology or medicine. Other exam-

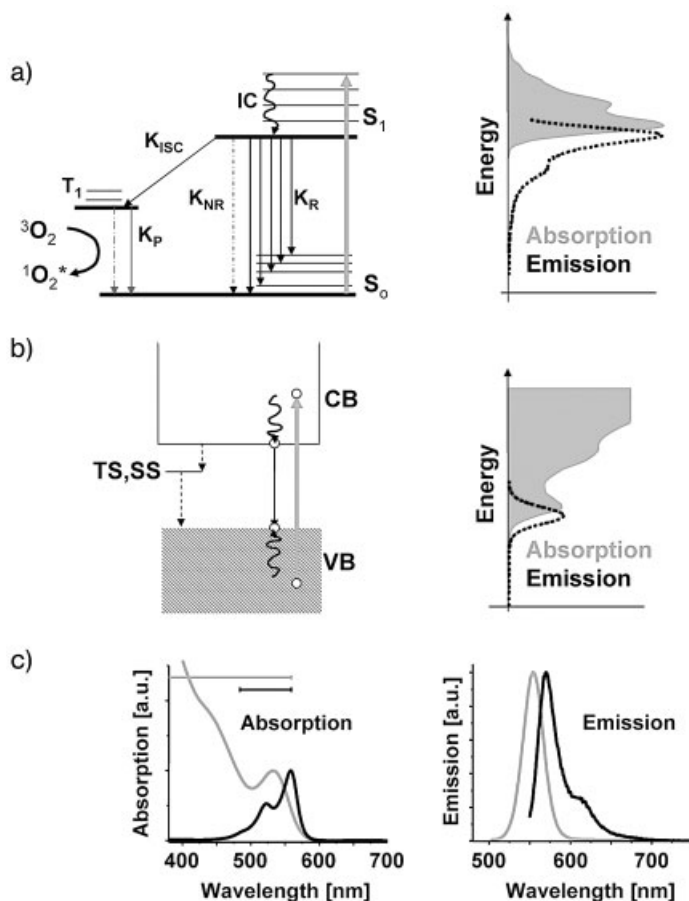

ples are described below. In fact, nanotechnology could represent a platform that would feed biologist's requests for more sophisticated tools to see smaller and smaller units with faster and better resolution. Whether chemists' dreams of using quantum dots to label live cells and solve important problems will come true is an open issue; but as the number of scientists working in nanoscience grows, new horizons open and the role of nanotechnology in biology is likely to expand in directions not yet been foreseen.

This chapter presents one area in which nanotechnology is rapidly establishing itself, namely fluorescence imaging. It seeks to describe different imaging techniques, and how new types of fluorescent probes, i.e., quantum dots, can be used in the context of biolabeling. In Section 1.2, I review some fundamentals of fluorescence by summarily describing the properties of several types of fluorescent probes. A brief section describes a few ways to excite the fluorescent probes and some principles of detection that will illustrate the potential of qdots for bioimaging. Section 1.3 considers how sources and detectors can be assembled to allow the observation of fluorescent signals in live organisms. Then I will take a brief tour and describe different strategies to make images, insisting on the advantages that nanoparticles may offer (Section 1.4). Section 1.5 then presents some example applications where quantum dots may indeed be the probes that biologists have been looking for.

## 1.2 Fundamentals of Fluorescence

### 1.2.1 Basic Principles

Fluorescence is the result of molecules emitting photons after an excitation. The fluorescence process is generally illustrated by the Jablonski diagram [16] (Fig. 1.1), a schematic based on the energy levels of the molecules. The molecule can be excited from a ground electronic state to a higher energy electronic state by the absorption of a photon whose energy is in resonance with the transition energy. Very rapidly, internal conversion takes place. During this process the molecule dissipates some excess energy into the vibrational states and falls to the bottom of the electronic excited state. There, the molecule still needs to dissipate some of its excess of energy, which is too large to go only through the vibrational modes. The return to the ground state can use different channels, which are described in details in the caption of Fig. 1.1. One possible relaxation channel proceeds through the emission of a photon (black arrows  $K_R$ ) and constitutes what is called "fluorescence". The emission energy is always lower than the excitation energy, which translates into the fact that the wavelength of the emission is always red-shifted compared with that of the excitation. This difference in wavelength is called the Stokes shift. The Stokes shift depends on the nature of the molecules and on their environment (i.e., the solvent), but it is in the order of 10–20 nm. A large Stokes

**Fig. 1.1.** Optical properties of organic dyes and qdots. (A) Jablonski diagram for organic dyes. Upon absorption of a photon of appropriate energy (light gray arrow), a molecule in a vibrational sublevel of the electronic ground state ( $S_0$ ) is promoted to a vibrational sublevel of the first excited electronic state ( $S_1$ ). This excess energy supplied by the photon is relaxed partially into vibrational modes by internal conversion (IC). IC is a radiation-less process that brings the molecule to the lowest  $S_1$  sublevel within picoseconds. The remaining excess energy is too large to be dissipated only into vibrational modes. Thus, the dye emits one photon to reach one sublevel of  $S_0$  (black arrows,  $K_R$ ). Emission takes place a few nanoseconds after excitation. This is the fluorescence mechanism of an organic dye. The energy can also be dissipated through collisions with other molecules in solution and,

in this case, there is no need to emit a photon (black dotted arrow,  $K_{NR}$ ). A third route is possible in organic molecules: intersystem crossing to the first triplet state ( $T_1$ ,  $K_{ISC}$ ). The electronic transition from  $T_1$  to  $S_0$  is spin-forbidden and, therefore, requires the assistance of phonons or external collisions. Consequently, relaxation to the ground state is in the microsecond to the millisecond range. It can take place through emission of a photon (phosphorescence) or through a nonradiative process. Note also that oxygen reacts readily with the triplet state ( $T_1$ ) of the dye, producing quenching of the emission. In this reaction, the ground state oxygen molecule,  $^3O_2$  (a triplet), is excited into a singlet state,  $^1O_2^*$ . This singlet state can initiate chemical reactions that lead to bleaching of the dye and its phototoxicity. The right-hand panel shows the absorption band of an organic dye (Cy3B) as a

shift is desirable for imaging because it facilitates separation between the excitation light and the emission (Section 1.3).

The precedent emission properties are shared by all organic dyes because their electronic structure is composed of discrete electronic states with vibrational envelopes. Nanotechnology has brought along new types of fluorescent systems that differ markedly from dyes. These systems are nanometer-size crystals made of semiconductor materials [12, 17]. In bulk semiconductors, the electronic states merge into bands, a valence band and a conduction band, separated by a bandgap [18]. In the ground state, the valence band is fully occupied and the conduction band is empty. Any photon of energy superior to the bandgap can excite the semiconductor by forming an exciton, i.e., by bringing one electron in the conduction band and leaving a hole in the valence band. Both electrons and holes release part of their energy by relaxing to the bottom of the conduction band and the top of the valence band, respectively. Once there, one possible energy relaxation mechanism is a recombination process where the electron recombines with the hole and the excess of energy is released as a photon. The photon energy corresponds to the value of the bandgap. In confined systems of nanometer size dimension, the same overall picture applies except that the bandgap varies with the diameter of the nanoparticles: the smaller the particle, the larger the bandgap [17, 19]. Therefore, the fluorescence of a quantum dot is size tunable. Similarly to the fluorescence process in organic molecules, the energy of the emitted photon is lower

function of photon energy along with the associated fluorescence emission. Note the limited extension of the absorption band, the redshift of the emission maximum compared to the maximum of absorption and the tail in the fluorescence emission extending towards low energies. The tail represents the contribution of photons relaxing into vibrational levels of  $S_0$ .

(B) A diagram similar to the Jablonski plot can be drawn for quantum dots. In a qdot, the electronic energy levels merge into two bands called valence and conduction bands. They are separated by an energy gap. In the ground state, the valence band is full and the conduction band is empty. Upon absorption of a photon with energy larger than the bandgap, an electron is promoted to the conduction band, leaving a hole in the valence band. Both electrons and holes can easily relieve energy by relaxing to the bottom of the conduction band or the top of the valence band, a process analogous to internal conversion in organic dyes (although involving electronic states of qdots and not vibrations). At this stage, there are no more electronic states available and the

excess energy would be too large to be dissipated through vibrations of the qdot. Therefore, qdots emit a photon, whose energy corresponds to the bandgap. As in organic dyes, qdots also undergo nonradiative processes. For instance, a nonradiative channel is induced by surface/trap states (defect at the surface of the dots) that create discrete energy levels within the bandgap. The right-hand panel shows the absorption spectrum of qdots along with its emission spectra. Unlike dyes, the absorption is a continuous band not limited to a specific energy range. The fluorescence emission is also redshifted compared with the absorption band. Remarkably, the position of the emission is independent of the excitation energy, although its amplitude depends on it.

(C) Absorption spectra of a qdots solution (light gray) and the organic dye Cy3B (in black). Horizontal lines at the top of the figure represent the range of wavelengths that can effectively excite the chromophores. In the emission spectra, notice the symmetry of the qdot emission and the tail in that of dyes at higher wavelengths.

than that of the absorbed photon and, therefore, the fluorescence light has a longer wavelength than the excitation.

A marked difference between a quantum dot and an organic dye is in their absorption spectra. For a dye, the absorption is centered around bands, conveying the discrete nature of the electronic states. In quantum dots, the absorption is a continuum from the band-edge up, mapping the continuous nature of the conduction band of the material. A continuous excitation spectrum represents clear advantages for imaging purposes. First, a main issue concerns the filtering out of the excitation source. When the excitation and emission are close in wavelength, as with organic dyes, the excitation light can be filtered out but a fair amount of the emission is also blocked. The possibility to excite quantum dots far from their emission greatly improves fluorescent detection. Second, it becomes possible to excite all sizes of quantum dots with just one single wavelength and therefore obtained all colors of emission with one excitation. Similarly, the emission of organic dyes exhibits a red tail resulting from transitions from the bottom of the excited state into the various vibrational levels of the ground state (black arrows  $K_R$  in Fig. 1.1). In contrast, quantum dots have symmetric and narrower emission patterns, because the energies of the radiated photons are determined solely by the size of the bandgap. Those properties represent distinct advantages for multicolor labeling, as the rest of this chapter will show.

### 1.2.2

#### A Few Types of Fluorescent Probes

Now that the mechanism of fluorescence has been described in general terms, it is worth looking in more detail into the nature of fluorescent molecules encountered in biology.

##### 1.2.2.1 Small Luminescent Units and Autofluorescence of Living Organisms

Fluorescence in organic molecules comes from delocalized  $\pi$  orbital states of conjugated double bonds [16, 20]. Thus, most aromatic molecules exhibit a natural emission. This is the case of tryptophan, an amino acid, NADH (nicotinamide adenine dinucleotide), an important coenzymes found in cells used extensively in glycolysis and in the citric acid cycle of cellular respiration, and other coenzymes such as flavins and some forms of pyridoxyl. Because these fluorophores are natural, cells and tissues fluoresce when excited with a UV source; this is the source of autofluorescence. The dominant autofluorescence from biological samples usually occurs below 500 nm.

Autofluorescence represents a fair amount of light. Unfortunately, these natural fluorophores do not possess properties that are useful for biolabeling. Most proteins contain a few tryptophan amino acids and therefore all proteins emit to a certain extent. Because autofluorescence may easily overshadow other unnatural fluorescent labels, it must be removed by an appropriate combination of filters, or by the implementation of detection techniques that selectively eliminate autofluorescence (Section 1.4.3).

**Fig. 1.2.** Structure of commonly used organic dyes, fluorescent proteins, qdots and bio-molecules, and the comparative sizes of common fluorophores, fluorescent proteins, qdots, some protein carriers and antibodies. The scale bar applies to all molecules. Organic dyes (FLAsH tetracysteine complex, DAE, DTPA-CS124-Eu, alexa, Cy3 and atto) are organic

conjugated structures 1–2 nm in size. Qdots passivated to become water-soluble are ~10 nm – comparable to proteins such as streptavidin and VFP (violet fluorescent proteins) – but are smaller than a typical IgG antibody. (Copyright 2004 Nature Publishing Group. Reproduced with permission from Ref. [7].)

#### 1.2.2.2 A few Organic Dyes and their Limitation in Live Cell Labeling

A plethora of unnatural organic dyes cover the whole range of desirable emissions and have unique optical signatures. Fluorescein, cyanine, rhodamine, alexa or atto are among the most popular. Figure 1.2 shows the structure of organic dyes and compares their size with other fluorescent probes and biological units. Organic dyes consist of aromatic conjugated structures of 2 to 10 units providing different degrees of electron delocalization, and hence colors of emission. The emission of an organic dye has a full-width at half-maximum (fwhm)  $>50$  nm and exhibits a red tail (Fig. 1.1C). The quantum yield, the ratio of the number of photons emitted to the number of photons absorbed, can be close to one, but it is quite dependent on the local environment of the dye. Alteration of the media pH, buffer components, solvent polarity, or dissolved oxygen can affect or even quench an organic probe. For instance, in an environment below pH 7, fluorescein is significantly quenched. Similarly, the solubility of the dyes depends on the solvent and not all dyes are soluble in aqueous environment. The fluorescence decay time or lifetime of most organic fluorophores falls in a narrow range of 1 to 5–10 ns, a time window shared by autofluorescence lifetime. This limits the use of time-gated detection methods to distinguish between the fluorescence of an unnatural dye and the autofluorescence (Section 1.4.3). These properties represent an inconvenience for the use of organic dyes as biolabels. But, in fairness, the dye industry has managed to downplay these issues by synthesizing alternative or new types of probes that minimize these effects.

A more serious shortcoming that has not been solved yet is photostability. Dyes bleach after the emission of  $10^6$ – $10^8$  photons [21]. The exact physical bases for bleaching are not entirely clear in all cases. The dye is not physically destroyed, but rather it is altered so that it can no longer emit. One cause of photobleaching is the oxidative reaction between atmospheric oxygen and the triplet state of the dye (Fig. 1.1 and its caption). Photobleaching of the dye produces radical oxygen species (ROS) that may poison and kill the cell in a short while [8]. One way to markedly reduce photobleaching consists in using antioxidants, an oxygen-free atmosphere or oxygen scavengers (such as the enzyme glucose oxidase along with glucose and catalase). Such approaches work well for studying conformation change of biomolecules, catalytic activity of ribosomes adsorbed on surfaces or fixed (dead) cells [22]. However, they are inadequate for the study of live organisms that need oxygen to survive.

#### 1.2.2.3 Green Fluorescent Protein and its Cousin Mutants

Green fluorescent protein (GFP) is a natural fluorescent protein produced by the jellyfish *Aequorea victoria* [23]. It has 238 amino acids and a molecular weight of 27 or 30 kDa. The gene responsible for this protein was identified in 1961 [24] and cloned in 1992 [23]. GFP has a barrel-shape enclosing a short polypeptide fluorescent unit (Fig. 1.2). The nature of the polypeptide determines the color of emission. Biologists have selectively modified this short amino acid sequence and have been able to clone mutants that emit at different wavelengths. The proteins are called YFP (yellow fluorescent protein), BFP (blue), RFP (red), or CFP (cyan).

All exhibit, however, a fairly large emission spectrum with a fwhm larger than 50 nm and the distinctive red tail common to all organic dyes. Fluorescent proteins are relatively stable in the very diverse environments of the cells, although their fluorescence properties may be affected. GFP for instance remains fully fluorescent at pH above 6, below which the fluorescence decreases dramatically.

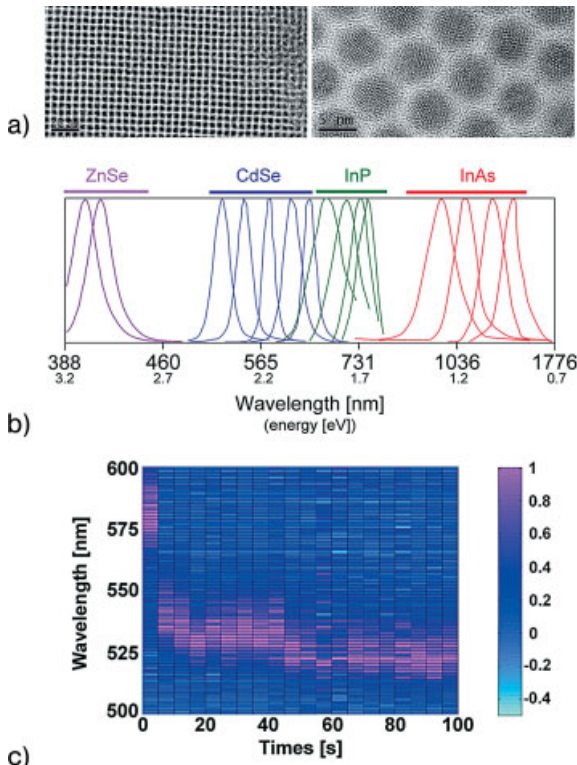

By applying the powerful methods of DNA recombinant technology it is possible to link together a specific gene of interest, for instance a therapeutic gene, with the GFP gene, and to transfect a mammalian cell or a whole organism with this engineered DNA. The cell machinery can translate this DNA into the protein of interest tagged with GFP. The protein complex is fluorescent but, amazingly, the tagged protein maintains the same function as the natural protein. Biologists have, therefore, a fluorescent complex whose location in space and time can be monitored. This is a marked improvement over traditional antibody labeling techniques that work on fixed (dead) cells. The ability to fuse the GFP gene to any protein brings biologists very close to what we called the promised land in the introduction.

Yet GFP and its cousin mutants are still cumbersome to construct. GFP fluorescence is the final product of a long, complex pathway involving transcription, translation, and post-translational modifications. Moreover, GFP and its mutants tend to form dimeric structures, and there have been questions on the feasibility of using GFP in certain conditions, for instance for gene expression studies under tumor conditions [25]. As a result, although GFP and its cousins allowed a huge step forward for molecular imaging, there is still room and need for alternative probes.

#### 1.2.2.4 Quantum Dots

Quantum dots, often abbreviated qdots, are nanometer-size crystals made of semiconductor materials [12, 17]. The most widely used and studied quantum dots consist of a core of cadmium selenide or CdSe [9]. Colloidal chemistry allows the synthesis of nanoparticles with a very narrow size distribution (<10%) and in (milli)-gram quantities (Fig. 1.3a). The dimension of the core determines the bandgap and hence the color of emission of the nanoparticles. For instance, emission of CdSe quantum dots covers the visible spectrum from green (520 nm, ~2.3 nm dots) to red (650 nm, ~5 nm dots). It is possible to cover the near-IR and IR spectrum by synthesizing quantum dots made from other materials such as CdTe [26], InP [27], InAs [28], PdS [29], PbSe [30, 31] but most of these chemical syntheses do not allow the degree of control reached in the case of CdSe. In principle though, the emission of qdots can be coarse-tuned by the choice of the material and later fine-tuned by playing with the size of the core (Fig. 1.3b).

The emission of the qdots presents many advantages over that of organic dyes and GFP. For instance, the emission of a batch of CdSe qdots is symmetrical and its fwhm is generally around 30–35 nm, although experienced groups can reach an fwhm as low as 22–25 nm. Moreover, the position of the qdot emission does not depend on the excitation wavelength. If qdots are excited at 360, 400 or at 500 nm, the emission will occur at the same wavelength (but the intensity will vary). All together, these relatively narrow and symmetric emissions that can be excited by a single excitation wavelength are ideal candidates for multiplexing detection

**Fig. 1.3.** Overview of CdSe qdots and their optical properties. (A) Low-resolution transmission electron microscope (TEM) image of CdSe qdots, showing an ordered lattice of CdSe nanocrystals, called a superlattice. The superlattice extends over a few microns. Scale bar: 20 nm. Right-hand side: high-resolution TEM view of the superlattice, revealing the internal structure of the CdSe qdots. Scale bar: 5 nm. Note the different alignment of qdots and the homogeneous particle size. (Image courtesy of Dr Natalia Zaitseva, Lawrence Livermore National Laboratory.) (B) Fluorescence emission of qdots spans from the UV to the IR. Different materials emit in different bands. For a given material, the emission can be fine-tuned by the size of the qdots. For instance, with CdSe, the maximum emission is at 530, 550, 590, 620 and 640 nm for qdots of 2.1, 2.4, 3.1, 3.6, 4.6 nm respectively. (C) Comparison

of the photostability of an organic dye (Cy3B) and a silica-coated CdSe/ZnS qdot in phosphate buffer. The qdot–dye conjugate was synthesized as a model system to study FRET. The conjugate was illuminated continuously with a picosecond laser diode (400 nm) and its emission spectrum collected every 5 s with a CCD camera. The dye emits at 579 nm and the qdot emits at ~530 nm. In the first 5 s of illumination, the qdot is not seen because it transfers its emission energy to the dye through a FRET process (Section 1.4.4). However, after <5 s, the dye photobleaches, the FRET channel closes and the qdot shows up. The qdot emission remains strong throughout the measurement, with only a slight blue-shift. The long-lasting emission of single dots is the basis of long-term monitoring of molecular processes in live cells (Section 1.5.2).

**Fig. 1.4.** CdSe, CdSe/ZnS and water-soluble qdots. Schematic of qdot cores, core/shell and water-soluble particles used in bioapplications (drawing not to scale). Left: a core of CdSe surrounded by TOPO (tri-octylphosphine oxide). The phosphine oxide head of TOPO (red ball) sticks to the Se atoms of the qdot. Middle: a thin shell of ZnS passivates the CdSe core. The shell increases the fluorescence emission of the core. The quantum yield of core/shell qdots is 30–50%. Since TOPO

molecules are hydrophobic, core and core/shell are not soluble in water, where biology takes place. An additional shell makes the interface between the inorganic qdot and the organic/water outside (right-hand side). If the shell is made of glass, functional groups on the glass surface allow bioconjugation of the qdots to biomolecules. Note that, regardless of the solubilization method, the final size of water-soluble qdots is close to or above 10 nm, even if the active CdSe core is only 2–3 nm.

with minimal or no cross-talk between detection channels. In a proof-of principle experiment, five orthogonal channels have been simultaneously detected within the visible range using a single laser excitation [32], but under more realistic conditions, which use ligand–receptor interactions mediated by single-stranded DNA, only four qdot channels could be unambiguously sorted out [33].

In general, qdots grown by colloidal methods have surface trap states that reduce their emission to a few percents. However, these trap states can be removed by passivating the surface with a few layers of a second semiconductor material with a larger bandgap. For instance, a few monolayers of zinc sulfide (ZnS) can be grown on top of a CdSe core (Fig. 1.4) [34]. The core/shell CdSe/ZnS are about 20–50× brighter than CdSe cores and their quantum yield can reach 30–50%, although certain laboratories with more experience in the art of growing core/shell qdots can reach quantum yields above 80–90% by further doping the shell. Core/shell qdots do not bleach as fast as organic dyes. In fact, qdots in solutions can be excited continuously well over 4 h with an Ar<sup>+</sup> laser excitation and their emission remains fairly stable [35]. Eventually, over the long term, photobleaching occurs. It is easier to quantify the resistance to photobleaching at the single molecule level. With organic dyes exposed to air, photobleaching occurs in a matter of seconds, even for Cy3B, one of the most robust dyes (Fig. 1.3C). Under similar excitation conditions, qdots can emit for well over a few minutes and in some cases for over 20 min. The photostability of qdots is the major advantage that could allow the tracking of single molecules over extended periods (see Section 1.5.2).

Qdots are characterized by very high photoabsorption cross-sections. Chemists prefer to use the extinction coefficients, which measure the absorption of a 1 M

solution along a 1 cm path. Extinction coefficients scale roughly as the volume of the qdots and range from  $\sim 1.5 \times 10^5 \text{ M}^{-1} \text{ cm}^{-1}$  for CdSe qdots of 2 nm up to over  $5 \times 10^5 \text{ M}^{-1} \text{ cm}^{-1}$  for qdots of 5 nm [36]. For comparison, extinction coefficients of organic dyes vary from less than  $1 \times 10^5$  to  $1.5 \times 10^5$ . High extinction coefficients mean that a lower amount of light is needed to excite them, a particularly beneficiary thing for the study of delicate systems such as live cells. Similarly, two-photon cross sections of CdSe/ZnS qdots exceed by far the values of organic dyes. In fact, two-photon cross-sections of qdots are two to three orders of magnitude larger than those of organic dyes and one order of magnitude larger than those of molecules designed specifically for enhanced two-photon absorption [37]. These high values enable the imaging of organs and tissues at greater depth and lower power than with any other dyes. A further improvement may come from the use of IR-qdots whose emitted photons are more transparent to tissues (Section 1.5.3).

Other optical signatures that distinguish organic dyes and qdots are lifetime and polarization. Qdots have a lifetime of  $\sim 10\text{--}20$  ns, which is significantly larger than the lifetime of organic dyes (1–5 ns) or the lifetime of autofluorescence [38]. This longer lifetime provides an efficient way to reduce the autofluorescence background by time-gating the detection (Section 1.4.3). Conversely, a negative point of qdots vs. dyes is the lack of strong polarization of the emitted photons. In fact, elongated qdots, also called nanorods, do emit photons polarized along the long axis of the rod [39]. But as the ratio between the long axis and the short axis of the rod approaches one, the polarization vanishes. Since chemical procedures to solubilize nanorods are not perfected yet, the present qdot technology does not allow orientational sensing. Further developments in the post-processing of nanorods will likely lift this limitation.

Although qdots have photophysical properties that surpass organic dyes in many aspects, they have one big shortcoming: quantum dots are not water-soluble. Qdots are generally synthesized in organic solvents and are passivated with hydrophobic molecules. It is possible to modify the surface of the qdots to render them hydrophilic. Many methods have been developed and there is probably no consensus on which one works best. The most promising solubilization methods for bioapplications consist in embedding the qdots into a shell or surfactant layer that cannot be further exchanged. The reason is that the shell/layer represents a protection that masks the true hydrophobic nature of the qdots. Examples of solubilization strategies include ligand exchange by thiol-containing molecules [40], oligomeric phosphines [41], dendrons [42], or two-domain peptides [43]. Other solubilizations proceed through encapsulation of the qdots by layers of phospholipids micelles [14], amphiphilic diblock [44], or triblock copolymers [45], polymer [46] or silica shells [35] and amphiphilic polysaccharides [47]. Regardless of the solubilization strategy, the difficulty to interface these inorganic objects with the bioworld is a major concern for biolabeling applications, and is likely to require constant improvement in forthcoming years.

As with organic dyes, water-soluble qdots can be conjugated to biomolecules using standard bioconjugation approaches [48]. Biologists have developed covalent conjugation schemes based on thiol, amine, and carboxylic group chemistries (the

natural functional groups found in amino acids) to crosslink proteins together. It turns out that similar schemes can be used to link qdots to any biomolecule. Most biomolecules (DNA, oligonucleotides [14, 33, 49, 50], peptides [13, 43], antibodies [44], virus peptides [13], proteins [45]) have been linked to water-soluble qdots and, surprisingly, the binding has no effect either on the qdot optical signature or on the functionality of the biomolecules. For instance, a single strand of DNA of 24 bases long ( $\sim 7$  nm) linked to a qdot of  $\sim 10$  nm is able to find its perfect complement within a pool of competing stands. Even a single base mismatch does not produce hybridization [51]. In addition, the DNA strand does not modify the emission of the qdot. Similarly, qdots linked to antibodies for surface receptor proteins indeed find their target on the cell membranes without losing their optical properties [43]. It is remarkable that a 10 nm qdot does not perturb the function of a biomolecule and conversely that a biomolecule does not modify the emission of the qdot, although it does change the local dielectric constant around the dot. It becomes therefore possible to envision studying biomolecules in their native cellular environment (Section 1.5.2) [2].

#### 1.2.2.5 Toxicity Issues of Nanomaterials

So far, we have described the benefits of using qdots for *in vivo* labeling applications. In fact, a major issue for biologists is the toxicity of the qdots for live organisms. Because qdots are made of toxic chemicals, they have to be toxic, or so the rationale goes. This has sparked a debate that encompasses the general theme of the environmental impact of nanotechnology [52, 53]. An extreme position calls for a ban on nanoscience until its environmental impact is assessed. A wiser position may consist in taking seriously the potential toxicity of these new nanoprobe and studying in parallel benefits and shortfalls of this technology. There are no benefits in banning nanoscience all together. However, there are strong merits in warning against the potential toxicity of the nanomaterials, while we await the results of long-term cytotoxicity or genotoxicity studies.

Besides its unknown long-term effects, short-term toxicity is an important factor for live cell labeling, because the markers must not interfere with the regular cell cycle. For instance, the presence of qdots in the cell cytoplasm should not impede the cellular division, nor should it switch off vital cell–cell communication channels. So far, the toxicity of qdots towards live cells has been studied only through simple experiments where the survival rate of cells transfected with different types of foreign material was quantified [15, 54, 55]. The major result in all those studies is that surface functionalization plays the key role in nanoparticle toxicity. For instance, an apparently inert molecule like  $C_{60}$ , with a well-defined surface and no available dangling bonds, is extremely harmful to cells even at low doses because  $C_{60}$  is an excellent electron acceptor that can readily react with available oxygen and water and generate free radicals [56]. These radicals eventually cause oxidative damage to the cellular membrane.  $C_{60}$  derivatized with hydroxyl groups showed much lower toxicity because derivatized fullerenes are less efficient in producing oxygen radicals. A similar situation exists for water-soluble CdSe/ZnS. These qdots tend to release  $Cd^{2+}$  into the cellular environment, due to photooxidation, which

leads to the death of the cells by poisoning. If these qdots are solubilized by ligand exchange with a mercaptoacid [40] the particles present low solubility and a high toxicity in the cells, essentially because the bond between the qdot and the mercapto-surfactant is weak, dynamic and unable to prevent diffusion of dissolved  $\text{Cd}^{2+}$ . In contrast, qdots embedded in a cross-linked silica shell have greatly reduced toxicity [55]. However, even in such cases, the overall toxicity is a function of surface functionalization. Silica-coated qdots with negatively-charged phosphate groups at the surface cause a higher rate of cell death than silica-coated qdots with neutral PEG groups. Such experiments tell us a lot about the compatibility of the probes to live organisms, but they lack the ability to discriminate further than the simple toxic/less toxic/non-toxic conclusions. A classification of the effects of nanomaterials on the expression of genes in live cells would help clarify the potential dangers of nanomaterials. Those experiments are likely underway.

### 1.2.3

#### Sources and Detectors

With a toolkit of bioconjugated qdots in hand, the doors to biology get closer. But before going there, let us tour the world of sources and detectors that could be used for imaging qdots. There are many ways to excite fluorescent probes and similarly there are many different ways of detecting them. The selection of a particular type of source and detector is dictated by the type of experiments and the information that one wants to access. Imaging time-resolved and dynamic events puts a stronger constraint on the equipment than the imaging of a static field of fluorescent probes. In the next section, we look briefly into the different types of light sources and detectors commonly used in fluorescence microscopy.

##### 1.2.3.1 Light Sources

Light sources commonly used for fluorescent microscopy are arc lamps and lasers. Lasers are essentially used for confocal microscopy where an important aspect is to focus the excitation source (Section 1.3.2). For wide-field (Section 1.3.1) illumination, however, biologists tend to prefer arc lamps because of their lower price, relative flexibility (i.e., any wavelength may be selected – an important factor when using two different dyes) and the lack of interference fringes from reflections inside the optical system.

**Arc Lamps** These include mercury lamps or xenon lamps. Mercury lamps exhibit a compact arc, with some lines dominating the whole spectrum. They can reach very high flux densities, mainly concentrated in the wavelengths of the mercury lines. When a broader, more homogenous excitation spectrum is needed, xenon lamps are the sources of choice. They have a fairly flat spectrum with only a few lines in the blue and IR region. A main disadvantage of arc lamps is the need of optical filters to block the excitation light from the fluorescence light. Considering the broad excitation that often overlaps with the emission of the probes, complete removal of the excitation source also reduces the fluorescent signal that reaches the detector. This is a problem when one wants to detect a few labels inside a cell. In

that case, every photon counts. Arc lamps also lack coherence properties. Because of their wide spectrum, different wavelengths going through an objective are focused at different locations in the sample. This is one source of chromatic aberrations in the excitation arm of the microscope. One consequence is that two different dyes, excited by two different wavelengths, may show up at the same location on the recorded image even though they are physically far apart. As a result, high precision colocalization of two fluorophores cannot be achieved with an arc lamp. A high level of localization requires coherent light sources.

**Lasers** Lasers are coherent, monochromatic light sources. While it becomes experimentally easier to get rid of the excitation light using interference filters, lasers present the inconvenience that not all organic dyes can be excited by a single wavelength, so a second excitation wavelength is needed; and the story continues. However, qdots have a broad absorption band and therefore a single wavelength can produce the emission of all qdot colors at once. For instance, with a simple Ar<sup>+</sup> laser emitting at 488 nm and a shortpass filter with cutoff below 500 nm, it is easy to observe the glowing of five different colors of CdSe qdots simultaneously and record it with a color consumer-grade CCD camera. A decided advantage of monochromatic excitation is that chromatic aberrations in the excitation path are suppressed altogether. This opens up the possibility of colocalizing multiple qdots with nanometer precision (Section 1.5.1). A disadvantage of a laser source over an arc lamp is the smaller area that can be illuminated. A Xe lamp can cover an area of a few cm<sup>2</sup>. In contrast, a defocused laser beam can illuminate an area of a few tens of μm<sup>2</sup> only [33, 57].

### 1.2.3.2 Detectors

Fluorescence microscopy uses digital imaging due to the high sensitivity that such detectors can reach. The detection of fluorescence signals is often a trivial task, especially if the signals are strong. This is the case when the nucleus of a cell is stained with DAPI dyes or when the cell membrane is stained with fluorescent markers. In these cases, the fluorescence signal is easily observable even to naked eyes, and can be captured by low-tech techniques such as the traditional emulsion-based films. Most of today applications, however, look intensively to fluorescence signals coming from rare events where only a handful of probes emit. One example concerns the expression of proteins in live cells following an external stimulus. Often, these proteins are expressed at a low level (a few hundred to a thousand of copies per cells) and their localization is spread all around the cell cytoplasm. Detecting them is like finding a nail in a haystack. In addition, irreversible photobleaching imposes an additional constraint on the quality of the detector, because not only there are a few emitting probes, but the time window to detect them is limited. The detection of weak signals becomes therefore a central piece in biomedical applications. Fortunately, the field of optics has developed ultrasensitive detection devices for all sorts of single-molecule applications that encompass the field of materials science, chemistry, physics and biology. Broadly defined, there are two classes of detectors: point detectors and two-dimensional arrays. The next two sections discuss their properties.

**Point Detectors** These detectors include photomultiplier tubes (PMT) and photodiodes (PD). Both devices employ a photosensitive surface that captures the impinging photons and generates electronic charges that are amplified and sensed. Therefore, a common feature of these single-elements detectors is the lack of spatial resolution.

In a PMT, the impinging photon strikes a photocathode that releases secondary electrons that get amplified by a series of dynodes. PMT sensitivity depends on the composition of the photocathode [58]. Photocathodes made of gallium-arsenide-phosphide (GaAsP) are sensitive in the range of 250–650 nm and GaAs photocathodes are sensitive to 300–800 nm. InGaAs photocathodes extend the sensitivity from 900 to 1700 nm in the IR range, but they are less common or available in regular laboratories. The output signal from a dynode is proportional to the number of impinging photons and a gain of up to  $10^6$  can be obtained. Because PMTs do not store charge, and respond to changes in photon fluxes within a few nanoseconds, they can be used to monitor extremely fast events such as photon bursts. A limiting factor of PMTs is their low quantum efficiency (QE), i.e., the ability to generate a signal from the percentage of incident photons. It ranges from 20% for GaAs up to 40% for GaAsP photocathodes. In contrast, PMTs have a large detection area, on the order of  $1 \times 1$  cm. Such a large area is a great experimental advantage because it does not require tedious alignment of the microscope on a daily basis.

Avalanche photodiodes (APDs) are an alternative to PMTs with greater efficiencies. They consist for instance in p-n junctions or heterojunctions operated at reverse biases close to avalanche breakdown voltage to enable the multiplication of photogenerated carriers [58]. APDs have generally higher QEs (up to 95% for silicon APDs) and a relatively flat response over the entire visible range (400–850 nm). APDs have been fabricated in many semiconductor materials. While Si APDs have a 90% QE up to  $\sim 850$  nm, their efficiency is greatly diminished in the 1000–1600 nm range. For this wavelength range, APDs made of Ge or other III–V compounds are used. The temporal response of APDs is comparable to PMTs but the sensing surface area is much smaller (a few hundreds of microns in diameter). Although PMTs offer higher gain, APDs feature better quantum efficiency, lower noise, higher linearity, and compact packaging.

**Two-dimensional Array Detectors** Two-dimensional detectors consist of a dense array of photodiodes that collect simultaneously the light coming from an area several microns or millimeters in size. These detectors are used for imaging a wide field in a single shot. There are several variations on the same principle, but the most popular 2D detector used in fluorescence microscopy is the CCD (charge couple device). A photosensor called a pixel is coupled to a charge storage region that is connected to an amplifier. The amplifier reads out the quantity of accumulated charge.

The spectral sensitivity of CCD camera is usually lower than that of a simple photodiode, because the CCD surface has channels used for charge transfer that are shielded by polysilicon electrodes. These structures do absorb in the blue region. This reduces the quantum efficiency of the device down to  $\sim 40\%$  in the

case of a Si chip. A marked improvement consists in using a back-illuminated CCD. In this configuration, the light impinges on the back of the CCD on a surface that has been thin-etched to the point of being transparent ( $\sim 10\text{--}15\ \mu\text{m}$ ). This results in quantum efficiencies of  $\sim 90\%$  over the entire visible spectrum. In addition, when CCD cameras are cooled to liquid nitrogen temperature, the background noise can be reduced to a few counts per second, making it possible to detect single emitters spread on a surface in a heartbeat.

The limiting factor of CCD cameras, beside their cost, is the transfer rate, i.e., the speed at which the collected frames are read out and transferred to the computer. CCD cameras are often termed slow-scan cameras because their standard frame rate is usually less than that of a video camera. This is because the data readout is performed pixel row by pixel row. The fastest full resolution readout time reaches a few hundreds of milliseconds or about 10 frames per second in the case of frame-transfer cameras. As a result, CCD cameras are not appropriate to monitor time-dependent events occurring on a timescale of millisecond or below. For instance, the dynamics of proteins folding, the lifetime emission of fluorophores and time-correlated events are too fast for CCD detection, but can be caught quite easily with a PMT/APD.

### 1.3 Microscope Configurations

So far, we have discussed how to excite a fluorescent probe and how to detect its emission. Let us now look at how to assemble these devices into a custom-made microscope to acquire images. The next few sections discuss the advantages and disadvantages of each configuration (Fig. 1.5).

#### 1.3.1

#### Wide-field Methods: Epi-, and Total Internal Reflection (TIR)

Most fluorescence detection techniques in biology use a wide-field illumination. As the name indicates, a laser or an arc lamp illuminates a large area of interest and the fluorescence from the whole field of view is collected.

##### 1.3.1.1 Epifluorescence Illumination

By far the simplest microscope uses an epifluorescence configuration in which the excitation and the emission pass through the same objective (Fig. 1.5). The excitation light, usually a mercury or xenon source, or in rarer cases a defocused laser beam [33, 57], is directed through an objective by a dichroic mirror and illuminates the sample. The fluorescence emission is captured back through the same objective, and passes through an appropriate long pass filter that further removes any residual excitation light scattered back from the surface. The fluorescent light is then detected. The simplicity of such a setup has made it the most commonly used fluorescent imaging technique.

Epifluorescence microscopy has certain limitations. For instance, the samples are illuminated along the whole path of the excitation light and therefore probes

**Fig. 1.5.** A qdot sample can be illuminated in many ways. Excitation light is represented by the black line. The most popular illumination is *epifluorescence*, where the excitation source (arc lamp or laser) and the fluorescence emission go through the same objective. A dichroic mirror (DM) is used to direct the excitation in the back of the objective. The back-scattered excitation light is further blocked by a bandpass filter (F) that is transparent to the fluorescence emission that is directed to the detector. Total internal reflection (TIR) uses an evanescent wave at the interface of two phases of different refractive indexes to excite the probes. It is, therefore, used to study structures close to interfaces. TIR illumination can use either a prism or a special objective configuration. In both cases, excitation and emission paths

are disconnected. The detection arm of a TIR microscope is similar to that of an epifluorescence microscope. In a scanning *confocal* microscope, a focused light source, i.e., a laser, is scanned over the surface at a fixed height. Although all probes crossing the laser beam will emit, emissions from outside the focal plane of the objective are blocked by a pinhole (P). By varying the focal depth, sections of the samples can be isolated and imaged. In a stage-scanning confocal microscope, the stage is scanned while the objective is kept fixed. This configuration allows the removal of chromatic aberration in the excitation arm. Finally, in a near-field scanning optical microscope (NSOM), the tip of a fiber is brought in close to the sample and is scanned over it.

that are slightly out of the objective focal plane emit light that can reach the detector. This results in images that contain a fair amount of background signal. As a consequence, epifluorescence imaging lacks the sectioning ability and has a limited spatial resolution. It does not allow discrimination between a probe on the membrane of the cell or a probe engulfed in the cytoplasm.

### 1.3.1.2 Total Internal Reflection (TIR) Illumination

One strategy to decrease the background and increase the spatial resolution is to eliminate fluorescence from outside the focal plane. Various strategies are employed to restrict the excitation and detection of fluorophores to a thin region of the specimen. Among them, total internal reflection (TIR) is one way to reduce the background signal while maintaining the wide-field illumination. Confocal microscopy is a second option, which will be discussed in Section 1.3.2.1.

The principle of TIR is simple and illustrated in Fig. 1.5. A light beam, incident on an interface with different refractive indexes for the two phases, is totally reflected if the incident angle exceeds a critical angle. While the light is totally reflected, a portion of the radiation exists in the distal phase called the evanescent wave. The evanescent wave will continue to travel into the medium of higher refractive index, but its strength will decay exponentially. The TIR illumination system takes advantage of the evanescent wave to specifically illuminate only a range of 100–200 nm from the coverslip. The result is that only probes located within such distance from the surface are excited. This provides an optical sectioning capability of a few hundreds of nanometers, at least  $5\times$  thinner than any existing confocal microscope (Section 1.3.2).

In general, TIR illumination has potential benefits in any applications requiring imaging of minute structures or single molecules in specimens having large numbers of fluorophores located outside the optical plane of interest. Since the excitation light is completely reflected away from the detection, one can easily discriminate the fluorescence signal from the excitation light and achieve very high sensitivities and detection limits. This capability is particularly useful in many types of applications. For instance, TIR fluorescence is very helpful in monitoring the interaction between an intracellular protein and the substrate, especially in cases where the intracellular protein is of very high abundance in the cytoplasm, which will inevitably generate very high internal noise using a conventional epillumination. Another important application of TIR is in the characterization of forces exerted on the substrate during cell motility. For instance, the observation of points of contacts or focal adhesions between the cell and the substrate holds information on how the traction forces are transmitted [59]. Finally, by varying the illumination incidence angle, and consequently the penetration depth of the evanescent wave, fluorophores can be distinguished by depth on a nanometric scale. If one were able to vary rapidly the evanescent field depth, target vesicles or other structures can be tracked at different depths and their positions accurately determined.

The main limitation of TIR, however, resides in the small penetration depth of the evanescent field. Imaging chromophores inside cells becomes exponentially difficult and requires a different strategy.

### 1.3.2

#### Scanning Methods for Microscopy

##### 1.3.2.1 Laser-scanning or Stage-scanning Confocal Microscopy

Traditionally, biologists have physically sliced through specimens to look at internal structures with a conventional light or electron microscope. The *laser-scanning* confocal microscope allows optical sectioning through a whole intact sample. Its principle is illustrated in Fig. 1.5. A computer-controlled laser beam is tightly focused and scanned over the surface at a fixed depth (in fact the objective is scanned). For each position of the light beam, the emission light is collected back through the same objective. By using a pinhole in the path to the detector, the fluorescence

light coming from outside the objective focal plane is rejected, thus providing a high-resolution image at that depth. By progressively changing the plane of focus, one can section the entire specimen optically, producing a sharp image of the fluorescently marked components for many different depths. A confocal reconstruction is produced when all these layers are put together to provide a two-dimensional representation of the three-dimensional information. The slicing resolution of a confocal microscope is of the order of  $\sim 1 \mu\text{m}$ , i.e., about  $5\times$  the  $z$ -resolution achievable by TIR illumination (Section 1.3.1.2). However, the ability to probe entire cells or organisms instead of only their contact point with the surface makes confocal microscopy the method of choice for many applications. One inconvenience of a confocal microscope is the time needed to acquire an image. Considering an integration time of a few tens of milliseconds per pixel, it takes a few minutes to capture a high resolution image.

In a laser-scanning confocal microscope, the spatial resolution is limited by the optics and by the size of the focused laser beam. In particular, diffraction limits its size so that a tightly focus beam of wavelength  $\lambda$  still has a spot with extension of roughly  $\lambda/2$ . Considering that excitation wavelengths are in the 400–500 nm range, the spot of a focused laser beam is at least 200 nm wide. Two point-like sources closer than this distance will be excited simultaneously by the focused beam, and one will not be able to distinguish them. There are two strategies to reduce the resolution limit of a confocal microscope. First, the excitation volume can be narrowed. This can be achieved through interference methods [60] or by stimulated emission depletion [61]. Resolutions beyond the Rayleigh limit have been achieved, although these methods are cumbersome to implement. The second strategy is useful when one is interested in the relative distance between two point-like sources with different emissions rather than the exact location of each object separately [32]. In this case, one can acquire the diffraction-limited shape of each point-like source in separate channels, also called point spread function or PSF, and determine the position of the center of each PSF [62]. This requires a signal strong enough to accurately fit the PSFs. An additional critical point here is to make sure that both objects are excited identically. Usually, wavelength-dependent properties of the objective produce different  $z$ -focuses for different wavelengths. In addition, spherical aberrations and uneven flatness of the back of the objective will produce distortions in beams scanned off-axis. Finding the exact positions of the PSFs in these conditions requires an impractical characterization of the whole system. One way to circumvent these problems is to use a monochromatic excitation and move the stage instead of the laser beam. This constitutes the principle of the *stage-scanning confocal* microscope. By keeping the laser beam fixed with respect to the optical setup, chromatic aberrations in the excitation path are removed. With such a setup, colocalization of two chromophores with distinct emission spectra in the nanometer range has been reported [32, 62, 63].

### 1.3.2.2 Near-field Scanning Optical Microscopy (NSOM)

An alternative way to beat the Rayleigh diffraction limit is to use near-field methods [21, 64]. Near-field optics uses laser spots and tiny fibers with an aperture di-

ameter smaller than the diffraction limit. If the light that leaks through the fiber tip is captured in close proximity of the aperture, the excitation spot size is on the order of the aperture size, i.e., it has a subwavelength dimension. Transmitted and fluorescence light are collected in the far-field through conventional optics and detectors. To make an image, the tip is scanned over the surface and an image is built pixel by pixel.

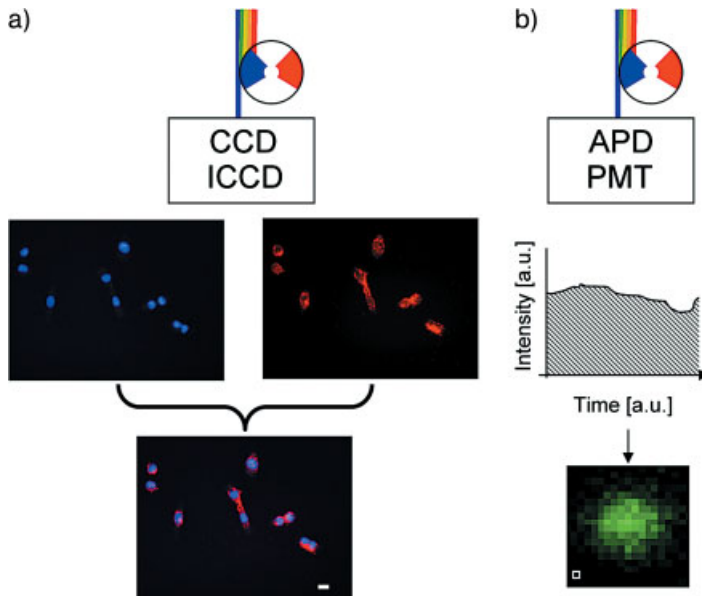

To obtain a high-resolution image of a specimen, the tip has to be positioned within a few nanometers of the sample surface all along the scanning process. This requires a feedback mechanism, usually based on shear force. Although NSOM has been successful in imaging biological specimens on surfaces, it still presents a tremendous challenge to image unfixed cells under buffered conditions. An additional limitation of NSOM comes from the delicate process of manufacturing the fiber tips. These are brittle and may break easily if in contact with rough surfaces. In addition, the near-field regime disappears quickly in the  $z$ -direction, preventing observations in the cell interior. Finally, the experimental challenges in NSOM often overcome by far its benefits over confocal microscopy.

## 1.4 Strategies for Image Acquisition

There are different strategies to collect information and form an image. Each photon encodes a wealth of information: it has a wavelength, a polarization, and an arrival time. Each of these properties can be used to create an image. It is also possible to use a combination of detectors to measure multiple properties of the photons simultaneously, i.e., the location of multiple chromophores, their spectra, their polarization and their lifetime, provided there are enough photons to generate a signal.

### 1.4.1 Intensity Imaging

The simplest method to acquire an image is to attribute to each pixel a value proportional to the intensity of light impinging on the detector. In its simplest form, such approach is color-blind since one green photon and one red photon are not discriminated by a PMT/APD or a CCD camera. However, with the appropriate use of bandpass filters, it is possible block all photons outside a spectral window and leave only a few selected photons to reach the detector. By sequentially using different filters with orthogonal spectral windows, images corresponding to each spectral window are collected and then overlaid to produce a false-color image. Figure 1.6(A) illustrates this procedure. It shows a field of HeLa cells whose nucleus is stained with DAPI, an organic dye, and whose cytoplasm is stained with qdots. Cells are observed under epifluorescence illumination using a Hg lamp. Since DAPI emission occurs at  $\sim 450\text{--}550$  nm and the qdots emission is centered around 620 nm, the two channels of emission present minimal spectral overlap. By insert-

**Fig. 1.6.** A simple option for making images – Intensity imaging. (A) The simplest method of image making is to collect the fluorescence light in a CCD or intensified CCD camera. To discriminate different colors, filters are inserted in the emission path to block undesired colors. By changing filters, the same CCD camera can record, sequentially, different emissions from the same area. A color image is created by overlaying individual images. In the example shown, HeLa cells are imaged through epifluorescence illumination with an Hg lamp. The nuclei of the cells were stained with a blue dye (DAPI) and the cytoplasm stained with red qdots. Scale bar: 5 nm. (B) If a PMT or an APD

were used, one would have measured a time-dependent signal with no encoded spatial information. The integrated intensity over a period of time may be used for imaging. If a focused laser beam is scanned over a surface, each position of the objective can be translated into a pixel. The value of the pixel is proportional to the integrated intensity. This is illustrated by measuring the spot produced by a single qdot. Note that the qdot spot is diffraction-limited even if the emitter is a point source. The white square represents a single pixel. Pixel size: 50 nm, integration time: 100 ms pixel<sup>-1</sup>.

ing the appropriate bandpass filters (for instance a short pass filter with cutoff at 520 nm and a long pass with cutoff at 580 nm), a blue image of the nuclei and a red image of the cell cytoplasm can be recorded separately and then overlaid. When multiple chromophores with closer emission wavelengths are used, a clear distinction between channels is not always possible, and spectral imaging (Section 1.4.2) can represent one way to minimize the overlaps. This is especially true for organic dyes where the emissions are broad (>50 nm) and tailed to the red; but it also applies to qdots with narrower and more symmetric emission spectra.

If the CCD camera were replaced by a PMT or APD detector, one would acquire a trace similar to that shown in Fig. 1.6(B). There is no spatial resolution in this case but a time dependence of the signal, which represents the amount of photons

emitted from all over the illuminated area that reach the detector. For imaging purposes, epifluorescence illumination using an arc lamp and PMT detection is of limited use. However, things are different if a cw or pulsed laser is used. Here, the coherence of the laser allows its focusing down to a tiny spot. The fluorescence intensity from the illuminated spot is proportional to the integrated signal reaching the PMT/APD detector. If the laser spot is scanned over the surface, and the out-of-focus light blocked by a pinhole (Section 1.3.2.1), an image of the emitters can be constructed pixel by pixel. For example, Fig. 1.6(B) shows the confocal image of a single CdSe/ZnS qdot. Although the qdot is less than 10 nm in diameter, its image is diffraction-limited because it maps the point-spread function of the excitation. With a sufficient signal-to-noise ratio, the PSF can be accurately fitted and its center determined (Sections 1.3.2.1 and 1.5.1) [32, 62]. Because of the scanning nature of the acquisition process and because typical integration times of a few tens of millisecond per pixel are needed, the acquisition of a  $256 \times 256$  pixels image necessitates a few minutes. The use of a pulsed excitation affords additional imaging modalities. It allows correlation of the arrival time of the photon onto the PMT/APD detector to an external clock (i.e., the pulse of the laser), which constitutes the basis for measuring the lifetime of a chromophore (Fig. 1.8 and Section 1.4.3 below).

#### 1.4.2

#### **Spectral Imaging**

A general problem with organic chromophores is their relatively broad emission spectra. This makes the spectral separation by bandpass filters difficult and impractical, especially when multiple chromophores with close emissions are used. It is often impossible to avoid the leaking of one color channel into another one. It is then advantageous to use spectral imaging. These methods collect all photons together and record an emission spectrum. Because fluorescence is incoherent, the total signal is simply the sum of every individual photon. The knowledge of the emission properties of each single fluorophore permits the deconvolution of the signal into diverse contributions.

Spectral imaging is illustrated in Fig. 1.7. Green-emitting qdots (emission at 540 nm) are covalently linked to several Cy3B, an organic dye with emission at about 575 nm. These conjugates are model systems for FRET imaging that will be discussed in Section 1.4.4. A tightly focused laser excites the conjugates. The fluorescence emission is spectrally resolved using a grating and collected by a CCD camera. The spectrum clearly shows two components, corresponding to qdots and dyes, respectively. Notice the narrower contribution of the qdot. A deconvolution of the spectrum into qdot and dye components allows the encoding of this pixel into several colors. If the same procedure is repeated for other pixels, a multicolor map can be constructed. In the simple case of Fig. 1.7, the deconvolution is a trivial task because the chromophores have almost non-overlapping emissions. However, spectral imaging may become quite complex as the number of chromophores increases and their spectra start to overlap. With CdSe/ZnS qdots, four colors of

**Fig. 1.7.** Another simple option for making images is spectral imaging. Instead of using filters to separate the different emissions, the entire beam can be split through a prism or a grating and detected with a CCD camera or an intensified CCD camera. Here, the wavelength of the photon is encoded into the area of the CCD chip. The spectrum on the right shows

the emission of a complex made of a single CdSe/ZnS qdot (emission  $\sim 530$  nm) linked to several Cy3B, an organic dye (emission  $\sim 580$  nm). By scanning the surface and deconvoluting the spectrum into these two components for each pixel, a multicolored map can be created with a single scan.

emission in the visible range could be specifically coded and detected by linking single-stranded DNA to each color of emission [33]. The use of qdots with emissions in the IR (Fig. 1.3B) can provide additional detection channels while preserving the simplicity of the excitation/detection schemes.

#### 1.4.3

#### Lifetime and Time-gated Imaging

Lifetime is another property of fluorophores that can be used for imaging because it allows high-sensitivity and background-free imaging (Fig. 1.8). After excitation by a laser pulse, most organic fluorophores emit one photon within a characteristic time of a few nanoseconds. Two distinct fluorophores are likely to have different

**Fig. 1.8.** Lifetime imaging is a further simple option for making images. A PMT/APD can also be used to map the lifetime of the emission. The arrival time is correlated with the firing of the laser by a time correlated single-photon counter (TCSPC). The example

shown here compares the lifetimes of Cy3B, an organic dye (blue curve,  $\sim 2$  ns), and qdots (red curve,  $\sim 10$ – $17$  ns). The large difference allows electronic gating as a way of increasing the signal-to-noise ratio.

**Fig. 1.9.** Time-gate detection. The long lifetime of qdot permits suppression of the fluorescence of short-lived species, for instance autofluorescence and emission from other organic dyes. In this example, 3T3 mouse fibroblasts were incubated with red qdots. Imaging was performed using a confocal microscope (10 ms integration per pixel, lifetime window of 0–150 ns after the laser

pulse, 5 MHz repetition rate). (A) All photons have been used to create the image. (B) Only photons arriving after the disappearance of the autofluorescence background were retained (30–65 ns after the laser pulse). Even though the total signal decreases markedly, the signal-to-noise ratio increases from 3 to 45. (Adapted with permission from Ref. [38]. Copyright 2001, Optical Society of America.)

lifetimes and a simple idea is to harness this difference to encode the image. Often, however, the difference in lifetime is too small to allow a proper discrimination between two distinct fluorophores. For instance moieties responsible for the autofluorescence background of cells and conventional organic dyes have very close lifetimes and it is difficult to isolate and remove only the background contribution. Other types of fluorophores have lifetimes of the orders of milliseconds (chelated lanthanide, metal ligand complexes), but this slow emission process results in a low turnover rate, i.e., a few photons emitted per second. Qdots combine the advantage of a high turnover rate with a long lifetime (10–20 ns) that seems more amenable for high-sensitive or background-free imaging. Lifetime imaging can be implemented by using either a time correlated single-photon counter (TCSPC) [65] or a time-gated ICCD camera [38]. In this latter case, the camera is electronically gated to detect only photons emitted after a certain time window after the laser pulse and reject all other photons.

Figure 1.9 shows an implementation of lifetime imaging of a cell using qdots to increase the signal-to-noise ratio [38]. 3T3 epithelial cells were transfected with qdots and imaged with a stage-scanning confocal microscope (Section 1.3.2). Figure 1.9(A) shows the image of the cell constructed from all photons reaching the APD detector. A major contribution comes from autofluorescence background that masks partially the qdot contribution. The electronically gated image con-

structured from photons that arrived 35–65 ns after the laser pulse is shown in Fig. 1.9(B). The autofluorescence background is suppressed but the emission of the qdots is still visible. The linescan shows that the time-gated imaging, allowed by the long lifetime of the qdots, considerably increases the signal-to-noise ratio.

#### 1.4.4

#### **Other Imaging Modalities: Polarization and FRET Imaging**

Polarization imaging can be achieved by splitting the emission according to the polarizations of the photons. This can be achieved through the use of a polarizing beam-splitter or through the use of a 50/50 beam-splitter and the insertion of polarizers in front of the detector. Similarly, imaging based on fluorescence resonance energy transfer (FRET) can also be performed [66]. In a FRET process, a fluorescent donor molecule is excited but, instead of relaxing through the emission of a photon, it transfers its energy into an acceptor molecule. Emission comes from the acceptor although excitation was provided by the donor. The FRET process efficiency is very sensitive to the distance between the donor and the acceptor and vanishes for distances larger than  $\sim 10$  nm. Therefore FRET can resolve molecular interactions, because even though both donor and acceptor probes cannot be localized below the diffraction-limit individually the fact that FRET occurs is an indication that donor and acceptor are less than 10 nm apart. The detection of FRET usually proceeds through the detection in parallel of two different channels, corresponding to the donor and acceptor probes. Several protein interactions have been demonstrated in cells by FRET microscopy [67]. In fact, FRET imaging has been performed only with pairs of organic dyes or pairs of fluorescent proteins (CFP and YFP) [68] because the use of qdots as FRET pairs has not yet been established. CdSe/ZnS qdots are excellent donors even at the single molecule level, as Fig. 1.3(C) indicated. Whether they also can act as acceptors is an open issue. It may well be that, because of their size and optical properties (Section 1.2.2.4), qdots will not be efficient probes neither as FRET pairs nor for polarization imaging.

### 1.5

#### **Qdots in Biology: A Few Selected Examples**

So far, we have focused on generic aspects of qdot fluorescence, by insisting on the properties that distinguish them from organic dyes. We have described several ways to excite and detect them, and several modalities for imaging them. It is time to consider their use in life sciences applications. In fact, qdot technology has generated a great deal of excitement in chemistry and material sciences communities for all their wonderful properties, but biologists have yet to embrace it. One reason is that the interface between the bioworld and the inorganic world is still a complex field. For example, live organisms have developed defense mechanisms to fight foreign intruders. Forcing them to tolerate unnatural inorganic probes may require tricks such as masking the surface of qdots with natural moi-

eties. This section goes through some examples that illustrate how qdots can provide unique detection signatures in biology. The examples will give an overview of the possibilities of qdots for biolabeling. We will start by describing briefly the problematic that biologists are facing and how qdot technology may help solve those issues.

### 1.5.1

#### Ultra-high Colocalization of Qdots for Genetic Mapping

An important issue in genetic disease screening and diagnostics is the ability to detect DNA abnormalities in high-throughput. Many diseases result from deletions, additions or rearrangements of short segments of DNA, some of them only a few bases long. Although single nucleotide polymorphisms can be detected by DNA microarray methods using either dyes [69] or qdots [51], when the length of the abnormalities gets bigger, so do the challenges to detect and map them. A new approach was proposed in the mid-1990s by combining a technique to stretch the full genome on a glass slide with a technique to hybridize short fluorescently labeled oligonucleotides along the DNA backbone at selected locations [70]. This new approach was named dynamic molecular combing, or DMC. It features a homogenous stretching of the DNA (2  $\mu\text{m}$  per kilobase) that allows the conversion of physical distances into genetic units. DMC measures the gap between loci labeled with two different dyes. Loci can be chosen to be contiguous of a specific gene and, therefore, the measured gap between loci holds information on the length of the gene. By comparing the gap measured on the normal allele with the gap measured on the abnormal allele, the size of the deletion/addition can be determined. DMC proved to be successful in observing kilobase deletions in *tuberous sclerosis 2* gene on patients' DNA [70].

Detection of smaller abnormalities using DMC requires a method that can localize two distinct sets of probes distance of 10 to 200 nm. This range of distances lies between the range of FRET detection (1–10 nm) and the Rayleigh resolution limit of conventional optical microscopes. Two recent methods promised to reach this goal. In the first approach, resolutions down to the 5–10 nm range have been reported using organic dyes, TIR illumination and a CCD camera [60]. The method makes use of the photobleaching behavior of one of the two probes. By fitting images collected both before and after photobleaching of one of the dyes, it is possible to localize both dyes separately and compute their distance. The method has been validated by using two identical Cy3 dyes linked by a double stranded DNA [60] or multicolor dyes that are more amenable for DNA mapping [71]. Colocalization by photobleaching requires that all random and individual photobleaching events are resolved. Besides, the numerical methods used to compute the relative distances may affect the precision of the localization.

The second approach does not rely on such constraints but builds on the strengths of fluorescent probes: it uses the photostability of qdots. The approach is based on stage-scanning confocal microscopy with a single excitation source that allows the imaging of qdots free of chromatic aberrations (Section 1.3.2.1)

[32]. A laser beam is focused onto a sample sitting on a stage that can be positioned and moved with nanometer precision. For each position of the stage, the intensity of fluorescence is collected, directed into an APD, and converted into a pixel value. Pixel by pixel, an image of the emitting object is constructed as illustrated in Fig. 1.6(B). By using two APDs/PMTs, each recording the light in an orthogonal fashion, it is possible to image simultaneously two point sources emitting at different wavelengths. Because the excitation arm is fixed, it does not produce chromatic aberrations. Comparison of the positions of the two PSFs allows the determination of their relative distances. Using such a stage-scanning confocal setup and qdots, two qdots have been localized with better than 10 nm resolution. Advances in nanometer-localization imaging are likely to open new doors for DNA mapping. It may be envisioned that such fluorescence techniques would yield physical maps of single nucleotide polymorphisms of the whole genome adsorbed on a surface a few inches wide.

### 1.5.2

#### **Dynamics of Biomolecules in a Cellular Environment**

The ability to track molecules directly in live cells is an important issue in biology that may lead to an integrative view of cellular function [2, 3]. Indeed, seeing the whole pathway of a molecule in its native environment, seeing how it works, where it goes and what it does may reveal precious information on its function and its communication with the rest of the interconnected cellular network. One way to study the motion of a biomolecule is to label it with a chromophore and acquire a succession of fluorescence images that are recombined in a movie. The first experiments of fluorescence tracking of lipids on cell surfaces were reported in 2000, using TIR fluorescence microscopy [72]. Since then, ion channels, cell-adhesion proteins [73], virus infection pathways [74] and other biological processes have been visualized at the single molecule level in live cells. Most of the measurements provide a low contrast and, above all, a time window for observation limited to a few seconds before the dye or GFP bleaches out [3, 57, 75].

The photostability of qdots provides a bright and long-lasting photon source that can be used to monitor biomolecular motion either on cell membranes [11, 76, 77] or directly inside cells [13] with a high signal-to-noise ratio for many minutes. The use of an epifluorescence illumination with a CCD detector is a good compromise between the necessity to monitor an area of a few tens/hundreds of micron square, a reasonable signal-to-noise ratio, and the time resolution of  $\sim 100$  ms required to monitor moving molecules. In fact, the monitoring of molecular motion through fluorescence only reveals changes in the location of a fluorescent spot. It is then necessary to analyze its position as a function of time and relate it to a physical or biological process. Traditionally, this has been analyzed in terms of diffusion constants. An example of a physical process is Brownian motion, which is characterized by a single diffusion coefficient and a mean square travel distance that depends linearly on time. If linearity is not observed, it may be a sign that an underlying biological process is at play.

### 1.5.2.1 Trafficking of Glycine Receptors in Neural Membranes of Live Cells

The first example of molecule tracking using qdots concerns the study of the membrane structure of spinal neurons. This is achieved by tracking the dynamics of qdot-labeled glycine receptors (GlyR) for long periods [76, 77]. In general, membrane neurotransmitter receptors, such as GlyR, are free to diffuse in the membrane. However, they can accumulate at synaptic sites by interacting with sub-synaptic scaffold proteins. The number of neurotransmitter receptors at synaptic sites is an important parameter because it determines synapse plasticity and the strength of synaptic transmission. For example, removal of glutamate receptors from synapses is involved in long-term depression while their insertion contributes to long-standing synaptic efficiency. Generally, immunocytochemistry methods used to study variations in receptors distribution provide a static view of the neurotransmitter receptors and give no information on their dynamics. To study the dynamics of neurotransmitter receptors, a simple strategy consists in labeling them with fluorescent latex beads and tracking their motions with a simple epifluorescence illumination and a CCD detector. The size of the latex beads ( $\sim 500$  nm) prevented them from accessing the synaptic cleft. Things change by replacing beads with qdots. Because of their much smaller size ( $\sim 10$ – $20$  nm), qdots can be used to study the lateral movement of individual GlyR in great detail.

Figure 1.10 shows an example of QD-GlyR motion over the neural surface. Synaptic buttons are labeled in red using an organic dye (FM4-64) while GlyR are labeled with green qdots using a bridge of biotinylated antibodies and streptavidin coated qdots. The sequence of images shows one QD-GlyR (in the white circle) moving from one synaptic button to another one about  $4 \mu\text{m}$  away. In the first 30 s (top row), QD-GlyR diffuses freely in the synaptic membrane, it then docks at the synaptic button (bottom row). Further quantitative information is obtained by analysis of QD-GlyR motions over more than 20 min. The diffusion coefficients reveal three types of behavior: some receptors diffuse freely and cover large areas

**Fig. 1.10.** Dynamics of glycine receptors revealed by qdots tracking: The example here shows the movement of a single membrane glycine receptor (circle). The receptor is labeled by a single green qdot moving from one synaptic button, labeled b1, to another

labeled b2. The synaptic buttons are labeled with a red dye. Images on the panel are selected snapshots from a 20 min sequence. (Reproduced with permission from Ref. [76]. Copyright 2003, The American Association for the Advancement of Science.)

on the membrane, other receptors remain at the synapse, whereas a final pool of receptors move in a confined space around the synapse. This leads to the classification of the neural membrane in three domains (extrasynaptic, synaptic and perisynaptic, respectively) with distinct diffusion properties. This beautiful work of Dahan and co-workers underlies the advantages of using robust qdot probes for tracking small biomolecules and illustrates the potential of qdots for the study of membrane dynamics.

#### 1.5.2.2 Dynamics of Labeled Nuclear Localization Sequences Inside Living Cells

The observation of dynamical events directly inside live cells adds one layer of complexity because the cytoplasmic environment is vastly different from conditions found outside the cell. Live cells have various kinds of inner membranes that maintain compartmental organization and they have developed various defense mechanisms to protect themselves against foreign intruders [1]. Whether exogenous qdot labels are compatible with the cell cytoplasm environment is largely unknown.

Only a handful of preliminary targeting studies using qdots in live cells have been performed. Perhaps, the simplest approach is to target the largest and most distinctive organelle of a cell: its nucleus. Nature provides the drive on how to do that. For example, viruses are hollow particles containing infectious RNA. Their

**Fig. 1.11.** Dynamics of labeled biomolecules inside live cells. HeLa cells were transfected with qdots linked to a nuclear localization signal (NLS). The NLS–qdots localize around the nucleus of the cell, and attempt to penetrate the nuclear envelope. The nucleus of a single cell is visible in the image. The image is an overlay of two frames taken 10 s apart that show how the qdots move during these 10 s (green is at time  $t$ , red at  $t + 10$  s, yellow

is the overlay, 700 ms integration time). Scale bar: 5 nm. The motions of the two NLS–qdots indicated by the arrows are shown on the right of the image. Positions at the beginning of the imaging process are indicated by stars. The nuclear membrane is shown as a dashed line. The NLS–qdot conjugates jiggle around the membrane and eventually cross it. Scale bar: 5 nm.

envelope contains peptide sequences, called nuclear localization signals (NLSs), that are recognized by the cell machinery and ferried towards the nucleus by motor proteins. It is possible to link a NLS sequence derived from a virus SV40 [78] to a silanized qdot [13]. Figure 1.11 shows the end stage of the infection process where NLS-qdots attempt to penetrate through the nuclear pores of a live cell. In a movie sequence that lasts well over 15 min, the somewhat chaotic jiggling of qdots can be observed. Some qdots get stuck at the nuclear membrane, while others manage to cross the nuclear membrane. Two examples of such NLS-qdots are highlighted on the right of the figure.

Although fluorescence imaging shows qdots concentrated around the nucleus, the fate of the NLS peptide is not known. The presence of the qdot exogenous agent is likely to activate the defense mechanisms of the cells. This may result in the cleavage of the qdot from the NLS peptide with the obvious consequence that the tracking of the fluorescent probe does not mimic the molecular pathway of the biomolecule. This is an obvious concern that needs to be addressed in forthcoming years when, no doubt, people will start tracking biomolecules inside live cells using qdots.

### 1.5.3

#### ***In Vivo* and Non-invasive Detection Using Qdot Reporters**

A final example concerns the observation of fluorescent qdots inside small animals through non-invasive imaging. In general, biomedical imaging in living tissues requires the use of exogenous contrast agents. These include MRI contrast agents, radioactive PET reporters, or infrared photons that can penetrate deeper into tissues than visible photons. In particular, the use of IR or near-IR probes would provide submicron spatial resolution and high sensitivity with simple and cost-effective detector technologies. Unfortunately, the requirements of absorption cross section, quantum yield and stability are not met by conventional organic fluorophores emitting in the IR. However, infra-red qdots may be efficient alternatives.

The fact that IR core/shell CdTe/CdSe qdots may be useful probes for non-invasive detection was demonstrated in early 2004 by mapping the sentinel lymph nodes in mice [79]. This allowed a major cancer surgery to be performed in an animal under complete image guidance. A subsequent step forward was achieved when near-IR CdSe/ZnS dots functionalized with a cancer targeting antibody were used to detect non-invasively the location of cancerous metastasis in live mice [45]. These two preliminary reports open new windows of opportunities for nanotechnology in medicine. The area of non-invasive imaging using qdots is likely to grow, as chemists get better at synthesizing IR probes.

## 1.6

### **Outlook: Is there a Role for Nanoscience in Cellular Biology and in Medicine?**

In this chapter we have focused on fluorescence detection, a central diagnostics in biology and medicine. Fluorescence imaging has reached an incredible level of

sensitivity, mainly fueled by the desire of some pioneers to watch single molecules. Today, researchers want to see more than single molecules, they want to see them rock'n roll (as beautifully phrased by Xavier Michalet [80]), and possibly in an *in vivo* environment. Moreover, as other examples discussed in this chapter have shown, biology and medicine have very ambitious plans to observe molecular events directly in their native environment. What limits such experiments today is the availability of appropriate probes, probes that are non-toxic, probes that do not bleach, probes that can be functionalized. Organic dyes, and to a lesser extent engineered fluorescent proteins, have certain limitations. Their shortcomings will likely not be compensated by an upgrade of current technologies. Future breakthroughs will rely on the development of advanced technologies based on a radically different platform. Nanotechnology can provide this platform.

Biology and nanoscience have come to a crossroads after a long courtship. Driven by the intellectual challenge of addressing the properties of particles with a finite size (first enounced by Feynman [81] and later addressed theoretically by Ryogo Kubo [82] and Terrell L. Hill [83] in the early 1960s), experimentalists started working on the production of small particles in the late 1960s and early 1970s. Over the course of two decades, synthetic methods have been perfected and the range of material synthesized has been expanded. In the 1990s, the use of chemical routes permitted the synthesis of semiconductor, metallic and oxide nanoparticles with excellent crystallinity, and with controlled size and shape [17]. In particular, semiconductor nanocrystals, whose flag carrier is cadmium selenide, exhibited remarkable optical properties, described in an earlier section, that attracted the interest of biologists as possible biolabels. Eight years after the first two reports [40, 84], the use of fluorescent nanocrystals in biology is still limited. This is largely due to the difficulty of interfacing inorganic nanoobjects with the bioworld. Yet, chemists and physicists are learning how to do it at a fast pace, and it is likely that fluorescent particles will emerge as useful tools for biology.

We can dream that qdot technology will provide highly integrated probes that can be customized to perform many tasks at once. For instance, qdots would be synthesized to carry diagnostics (they fluoresce), functional (they may be programmed to recognize tumoral cells), and therapeutics properties (they may kill tumoral cells). Qdots could be linked to MRI or PET active compounds to allow non-invasive imaging. Because qdots are made of heavy elements they are easily observable in electron microscopy and through synchrotron radiation, which will provide access to high-resolution cellular localization. We may imagine that further developments will allow the tagging of stem cells with qdots, their transplantation in live animal models, and the remote detection of their differentiation *in vivo*. One may argue that the view expressed here is much too optimistic, and even wonder whether nanotechnology will have a real impact in biology and medicine. Only time can tell.

### Acknowledgments

I would like to thank Fanqing Chen (Lawrence Berkeley Laboratory), Balaji Kannan (UC Berkeley) and Xavier Michalet (UCLA) for many discussions and collabora-

tions over the years. I want to thank Natalia Zaitseva, Giulia Galli and Sirine Fakra for their support and Maxime Dahan, Thomas Jobin and Elizabeth Jares-Erijman for permission to reproduce their figures. This work was performed under the auspices of the US Department of Energy by the University of California at the LLNL under contract no W-7405-Eng-48.

## 2 Characterization of Nanoscale Systems in Biology using Scanning Probe Microscopy Techniques

*Anthony W. Coleman, Adina N. Lazar, Cecile F. Rousseau,  
Sebastien Cecillon, and Patrick Shahgaldian*

### 2.1 Introduction

The numerous variants of Scanning Probe Microscopies (SPM) that have appeared since the invention of Scanning Tunneling Microscopy (STM) in 1982 [1] have opened up a new world for the visualization and characterization of surfaces. Their application to the biological sciences has allowed imaging of a vast range of systems hitherto unseen and the spin-offs of SPM have allowed biologists to probe the forces [2], mechanical properties of biological entities [3] and, with the use of SPM derived cantilever arrays, develop novel bio-sensors [4–8].

However, this meeting of physics, biology, chemistry and micro-technology was and still remains, in my opinion, not quite the universal solution to the imaging of the nano-world of biology. The problems would appear to stem from the near immiscibility of the scientific rigor of biology and physics, and this chapter has been approached from the point of view of a tool user not a tool maker, but one who has been over the last ten years confronted by the need to characterize and understand complex structures interacting with biological systems while using physical methods. As a sideline, I have also spent the last ten years translating between the scientific languages and habits of biologists, physicists, chemists and microsystems scientists.

Thus this chapter is oriented not to the theory of Scanning Probe Microscopies but rather to how to obtain, using SPM, useful and valid information about biological systems at all levels. The physics of SPM has been widely treated in several excellent texts and readers are referred to the list of books given in Appendix 1. Similarly, an extensive body of reviews exists on the imaging of biological systems (Appendix 2).

With regard to the use of SPM on biological samples, the questions to ask are really: what information can one obtain from SPM; how can one best set up the bio-SPM experiment to maximize the chances of success; how can one avoid obtaining skewed information from a bio-SPM experiment and finally, and most importantly, does the information obtained have a real biological sense?

**Tab. 2.1.** The various microscopies available to the bio-sciences, and their characteristics.

	<i>Optical microscope</i>	<i>SEM</i>	<i>SPM</i>	<i>SNOM-NSOM</i>	<i>Confocal microscopy [9, 10]</i>	<i>Environmental electron microscopy</i>
Sample operating environment	Air, liquid or vacuum	Vacuum	Gas, liquid or vacuum	Gas, liquid or vacuum	Gas, liquid or vacuum	Gas <sup>[a]</sup> (up to 10 Torr)
Depth of field	Small	Large	Medium	Medium	Small	Large
Depth of focus	Medium	Large	Small	Small	Medium	Large
Resolution: $x, y$ (nm)	1000	5	1–10 AFM; atomic for STM	20–80	200	5–7
Resolution: $z$ (nm)	N/A	N/A	0.1 AFM 0.01 STM	1	200	N/A
Magnification	$1-2 \times 10^3 X$	$10-10^8 X$	$5 \times 10^2-10^8$			$15-5 \times 10^5 X$
Sample preparation requirement	Little	Little to substantial	Little or none	Little to substantial	Little to substantial	Little
Characteristics required for sample	Sample opaque to light	Sample must be vacuum compatible	Local variations in surface height $< 10 \mu\text{m}$		Incorporation of a fluorescent dye	–

<sup>a</sup> Possible in wet environments; suitable for hydrated specimens (cells, plant samples, tissue, etc.).

In view of these questions we will treat the various SPM methods in terms of the information they generate and also their limitations, some general thoughts on sample preparation and how this may affect the experiment, the pitfalls that may arise from various artifacts, before looking at selected examples of imaging, probing and analyzing biological systems. [Evidently, rarely are artifacts published but I know that the image files of anyone involved in the field are full of various types of artifacts, but with biological samples sometimes the seeming artifact may in fact be real and just seem to be an artifact.] There remains one final question; why carry out a bio-SPM experiment? To start to answer that question, Table 2.1 presents various microscopy methods with their experimental conditions, sample treatments, resolutions, etc.

## 2.2 The Scanning Probe Microscopy Experiment

The basis of all SPM experiments is simple: a probe is scanned across a surface to generate an image of some type. To obtain the image there must exist a localized interaction between the probe and the surface, in this way the signal obtained will be dominated only by the small part of the probe closest to the surface. Hence it is implicit that there is a strong distance dependence of the interaction so that

Fig. 2.1. Principle of probe–sample interaction in SPM. (Courtesy of JPK GmbH.)

only those nearest parts of the probe can contribute to the measured signal (Fig. 2.1).

Thus the SPM experiment can be defined as requiring:

$$\text{Signal} = f(d)^n$$

and effectively the resolution will be governed both by the size of the probe and the distance dependence, allowing, for example in STM where both tip size is very small and the distance dependence very strong, imaging at the atomic level.

While the physical basis of the family of Scanning Probe Microscopies is relatively straightforward, and indeed the basis of Scanning Near-Field Optical Microscopy was proposed by Syngge in 1926 in a letter to Einstein [11], the technical problems involved in the construction of a working high-resolution SPM system were the real challenge. It was thus only in the 1980s, with the development of working piezoelectric materials [12] and the computing power to implement control over the system, that working systems became available. Even then, their application to biological materials was at first hesitant.

In the following sections the basic modes of imaging, use of force–distance measurements and other SPM derived methods will be discussed with particular emphasis on the information that may be obtained and on the limitations of the various techniques towards imaging biological systems.

### 2.3

#### Scanning Tunneling Microscopy Imaging

Scanning Tunneling Microscopy is based on the principle of “tunneling current” flowing between a metallic tip and a conducting material (when the distance is small enough, typically around 1 nm) (Fig. 2.2). This current is the result of the overlapping wave functions between the tip atom and surface atom – electrons can tunnel across the vacuum barrier separating the tip and sample in the presence of a small bias voltage. This current is amplified (7 to 10 orders of magnitude) and allows the distance between the tip and the sample to be kept constant. It is mandatory to do this amplification as close as possible to the tip because any noise incorporated before the amplifier would be amplified with the relevant signal. If the tunneling current goes over its set-point the distance between tip and sample is increased, if it falls below this value then the distance is decreased.

Fig. 2.2. Principle of scanning tunneling microscopy (STM) imaging.

Tunneling current originates from the wavelike properties of particles (electrons, in this case) in quantum mechanics. When a small voltage,  $V$ , is applied between the tip and the sample, the overlapped electron wave function permits quantum mechanical tunneling and a current flows across the vacuum gap (Fig. 2.3).

## 2.4

### Atomic Force Microscopy

#### 2.4.1

##### Generalities

Atomic Force Microscopy (AFM) and its various imaging modes is the most widely used member of the SPM family in the study of biological systems (Fig. 2.4). The interactions used in AFM are the local attractive and repulsive forces occurring between a tip attached to a flexible cantilever and the sample surface. A typical curve of tip-sample interaction is given below (Fig. 2.5) along with one of the more generally used scanning conformations. As the tip approaches the surface from an infinite distance, firstly attractive forces are present and due to the flexible nature of the cantilever it deflects toward the surface; at close ranges repulsive forces will dominate and the cantilever will deflect away from the surface. By use of a laser beam reflected from the surface of the cantilever (where the tip is mounted) onto a four quadrant Position Sensitive Device (PSD) the deflection of the cantilever can be measured and a feedback loop can be activated to position the cantilever with regard to the surface (Fig. 2.4). Obviously, the choice of the deflection at a set point to set in place the feedback loop along with the spring constant of the cantilever allows the forces applied to the surface to be determined.

Fig. 2.3. Metal–vacuum–metal tunneling junction.

The schematic shown in Fig. 2.4 is one of two possible configurations of the microscope set up; here the piezo-ceramic scanners used to move in the  $x$ ,  $y$  and  $z$  dimensions are positioned to move the sample with the cantilever and the tip is held in a constant position. The second configuration has the piezo-ceramic scanners positioned above the sample to move the cantilever and the tip. Evidently both configurations present advantages and disadvantages; for a moving sample stage the rigidity and, hence, stability of the tip positioning can be maximized (however, access from below to the sample is blocked); this configuration also requires sealed fluid cells to prevent leakage into the piezo-ceramics when scanning in liquid systems. The use of a moving cantilever assembly above the sample will be less rigid and so more prone to “noise” in the images; however, for biological samples the advantage of being able to couple the AFM to a conventional optical microscope far outweighs the possible noise problem. There is also in this configuration much more experimental flexibility with regard to working in liquids.

Fig. 2.4. Schematic of the atomic force microscope measurement system using the light deflection mode.

The most used imaging modes in AFM are the contact, force modulation, non-contact and intermittent contact modes. They may be best defined with regard to their positioning along the tip-sample interaction curve (Fig. 2.5).

For both contact and force modulation modes the interactions remain entirely in the repulsive zone of the curve and hence there is no part of the experiment in

Fig. 2.5. Force curve as function of the distance between the tip and the surface. (Courtesy of JPK GmbH.)

which the tip is not touching the surface. In non-contact mode the interactions remain entirely in the attractive part of the curve, while for intermittent contact (often termed the “tapping” mode) the point will oscillate between attractive and repulsive parts of the curve.

At this point it is necessary to consider the hydration of a surface in air. Effectively, all surfaces, even highly hydrophobic ones, have a thin “contamination” layer of water associated with them, which is generally of the order of 1–5 nm high. Hence, experimentally, contact and force modulation modes of SPM imaging will be with the tip within the aqueous layer, while intermittent contact will involve the tip moving in and out of the water layer. However, for the non-contact mode it is possible to position the tip either within the water layer or when there is high cohesion of this layer to come into feedback at the surface of the aqueous layer; such positioning can modify the images obtained.

The water layer has a second effect. By capillarity, water will move up the tip to form a meniscus, and hence generate secondary drag effects when the tip scans the surface. These capillary forces may often be greater than the applied tip–sample forces and are often a cause of sample distortion or damage (cf. Section 2.6 on artifacts).

#### 2.4.2

##### Tips and Cantilevers

The SPM experiment is, in reality, simply a mean to position, move and observe the probe across a surface – hence the key to the experiment is the probe or tip.

SPM probes generally consist of a sharp (or ultra-sharp) tip mounted on the end of small flexible cantilevers [13]. Obviously, the shape and the geometry (and also the quality) of the tip will determine the resolution of the SPM image. They are generally produced from Si or  $\text{Si}_3\text{N}_4$  by micro-fabrication techniques.

Two basic shapes of cantilevers are commercially available, the V-shaped and the beam cantilever (Fig. 2.6). Because of higher mechanical stability, V-shaped cantilevers are generally preferred for contact-mode imaging (Fig. 2.7). When mechanical properties (torsion or friction forces) are studied, beam cantilevers would be preferred. For each type of cantilever, a force (spring) constant could be determined and depends on its geometry, dimensions and the material from which it is fabricated.

Fig. 2.6. V-shaped and beam SPM cantilevers.

Fig. 2.7. SEM images of V-shaped pyramidal cantilevers. (Courtesy of Dr A. Wirth.)

Table 2.2 summarizes typical physical data for various commercially available cantilevers for contact and dynamic modes of SPM.

AFM tips are usually made of the same material as the cantilever as both are usually fabricated in the same time. The geometry of the tip depends on the micro-fabrication technique [14]; two main tip geometries exist: pyramidal and cone-shaped (Fig. 2.8). These tips may be submitted to additional treatments to sharpen [15] or chemically modify them [16].

Very high aspect ratios may be obtained with electron beam deposited (EBD) tips, which are AFM tips modified to grow a narrow tip-on-the-tip (Fig. 2.9). Normally, shaped silicon intermittent-contact cantilevers are modified in scanning electron microscopes. The electron beam focused on top of the tip deposits a small column of carbon, leading to a tip with narrow radius and high aspect ratio. The

Tab. 2.2. Physical characteristics of commercial cantilevers used in different modes of operation in SPM.

<b>Contact mode cantilevers</b>		
<b>Technical data</b>	<b>Typical value</b>	<b>Range</b>
Thickness ( $\mu\text{m}$ )	2	1.5–2.5
Mean width ( $\mu\text{m}$ )	50	45–55
Length ( $\mu\text{m}$ )	450	445–455
Force constant ( $\text{N m}^{-1}$ )	0.2	0.07–0.4
Resonant frequency (kHz)	13	9–17
<b>Non-contact and intermittent contact mode cantilevers</b>		
<b>Technical data</b>	<b>Typical value</b>	<b>Range</b>
Thickness ( $\mu\text{m}$ )	4	3.5–4.5
Mean width ( $\mu\text{m}$ )	30	25–35
Length ( $\mu\text{m}$ )	125	120–130
Force constant ( $\text{N m}^{-1}$ )	42	21–78
Resonant frequency (kHz)	320	250–390

Fig. 2.8. SEM images of pyramidal and cone-shaped SPM tips. (Courtesy of JPK GmbH.)

carbon arises from hydrocarbon contamination in the vacuum chamber of the SEM. The high aspect ratio of the tip allows imaging of structures such as grooves or troughs, which are not properly imaged by tips with conventional shapes and aspect ratios [17].

#### 2.4.3

##### Contact Mode AFM

In the contact mode the tip is in continuous contact with the surface (Fig. 2.10); consequently, very high resolution imaging becomes possible. On crystalline surfaces atomic level resolution is routine for mineral systems. With well-organized two-dimensional crystals molecular imaging of proteins with sufficient resolution to show sub-units can be achieved (see Section 2.7.2 on protein imaging).

The force exerted by the tip on the sample can readily be controlled by modification of the set point value; given that this is generated by the deflection of the cantilever a lower value will evidently lead to lower interaction forces.

Fig. 2.9. Electron beam deposited (EBD) modified tip. (Courtesy of JPK GmbH.)

**Fig. 2.10.** Contact mode imaging; physical contact between the tip and the sample. (Courtesy of JPK GmbH.)

However, lateral forces will also be present as the tip is effectively dragged across the surface and these will, for imaging in air, be combined with effects from the capillary forces of the water contamination layer. This may generate, in systems having low adhesion to the surface on which the sample is placed, movement of all or parts of the sample; similarly, samples having low cohesion may be moved. The problem of capillary forces may be removed by carrying out the imaging in water.

Cantilevers used in contact mode imaging have, in general, low spring constants with resonance frequencies of about 10 kHz.

In nanolithography this effect is taken to its extreme and in fact becomes a useful tool, as by increasing the set point and hence the forces applied to the surface material may be voluntarily removed from the surface. This has been used to measure the heights of Langmuir–Blodgett films and also to remove self-assembled monolayers to allow deposition of other molecular layers.

#### 2.4.4

#### Dynamic Modes

##### 2.4.4.1 Generalities

In the various non-contact or dynamic modes the cantilever vibrates and it is this oscillation of the cantilever that is measured to generate the image rather than direct tip deflection. Various methods can be used to cause oscillation of the cantilever, for imaging in air these are usually mechanical, magnetic or piezoelectric, but in liquid imaging the cantilever is driven acoustically.

The resonant frequency  $f$  of the cantilever is defined by Eq. (1).

$$\text{Res. Freq. } f = \frac{1}{2\pi} \sqrt{\frac{k}{m}} \quad (1)$$

where  $k$  is the spring constant of the cantilever and  $m$  is the mass. Evidently, as the frequency passes through a resonant condition the amplitude of the oscillation increases to a maximum value before decreasing. This peak in the oscillation of the amplitude is accompanied by a switch in phase of the detected oscillation. Hence two modes of detection are possible: either via the amplitude directly or via measurement of the phase shift of the signal.

**Fig. 2.11.** First resonance frequency of a cantilever measured with optical detection. (Courtesy of JPK GmbH.)

Experimentally the situation is seldom as clear as presented in Fig. 2.11 and, often, several resonance peaks are available for use. It is also often not clear which of the resonances will generate the best image!

As the tip approaches the surface the effective mass of the cantilever will change due to the attractive forces acting on the point and hence the resonant frequency will vary. By setting the signal acquisition close to the resonant frequency and defining the set point in terms of the signal amplitude the feedback loop is engaged.

#### 2.4.4.2 Non-contact Mode

In non-contact mode (Fig. 2.12) the tip remains at all times in the attractive part of the interaction curve and the tip is scanned at a small distance (a few nanometers) above the surface with a relatively small amplitude. A clear problem with this mode is that the tip may jump into contact with the surface if the attractive forces exerted are greater than the spring constant of the cantilever, and thus much stiffer cantilevers are required. Generally, cantilevers with resonance frequencies in the range 150–300 kHz are used. True non-contact mode is almost unusable in liquid systems as the damping of the small cantilever oscillations by water or other liquids is too large and the signal disappears.

Resolution is also reduced in non-contact imaging, with a minimum value of around 1 nm. However, this may be compensated in the case of very soft samples by the lack of any contact between the tip and the sample, which may allow more accurate information in the z-axis, i.e., on the height.

#### Non-contact mode

**Fig. 2.12.** Non-contact mode imaging based on oscillation of the cantilever due to interaction of the tip with the surface. (Courtesy of JPK GmbH.)

### Intermittent contact

**Fig. 2.13.** Intermittent contact mode imaging characterized by oscillation with high amplitudes. (Courtesy of JPK GmbH.)

#### 2.4.4.3 Intermittent Contact Mode

In intermittent contact mode, or as it is often termed the tapping mode, the cantilever moves rapidly with a large oscillation between the repulsive and attractive regimes of the interaction curve (Fig. 2.13). Here the maximum orthogonal forces applied to the surface may be lower or higher than those experienced in the contact mode but such forces are not applied constantly, thus lowering drag forces on the sample and reducing to some extent the possibility of sample damage. However, care must be taken with regard to very soft samples in terms of compression and possible distortion of height information.

Again stiff cantilevers, generally with resonant frequencies in the range 200–400 kHz, are used to allow the tip to break free of the water contamination layer. With regard to imaging using intermittent contact mode in water the problem of capillary forces is removed and much softer cantilevers, often contact mode, are generally used. However, again severe damping will occur. Technically this problem is overcome by driving the cantilever at the resonant frequency of the liquid cell or of the acoustic cell used.

As noted above, there will be a shift between the phase of the drive signal and that observed by the lock-in amplifier of the detector. This phase signal is highly sensitive to the tip–sample interaction and can generate information on the mechanical properties of the sample. Such phase shifting may occur via adhesion between the tip and the sample or by a viscoelastic response of the sample. This can be particularly useful to analyze samples in which a phase separation has occurred between two components of a sample having the same height.

#### 2.4.4.4 Force Modulation Mode

This mode combines the oscillation of the cantilever with scanning in the contact mode (Fig. 2.14). The cantilever is now oscillated at very low frequencies, normally between 1 and 5 kHz, and thus much below the resonant frequency of even the cantilevers used in contact mode imaging.

The information extracted concerns the mechanical and viscoelastic properties of the sample, and again is useful for extracting information on samples containing composite materials but which have no topographical differentiation between the components.

However, the forces applied to the sample can be very high and this mode is often damaging to both sample and tip.

**Force modulation mode**

**Fig. 2.14.** Force modulation mode imaging based on the vertical motion of the scanner undergoing a “feeling out” of the surface by the cantilever. (Courtesy of JPK GmbH.)

## 2.4.5

**Friction Force Mode or Lateral Force Mode**

As noted in Section 2.4.1, the experimental setup of the AFM experiment uses a four quadrant detector. Thus information is not only available about the topography of the sample via the cantilever deflection in the vertical axis but also concerning twisting of the cantilever in the horizontal axis. This information concerns the friction forces occurring between the tip and the surface.

Gel surfaces that do not contribute to topographical information can be observed in the lateral mode image.

## 2.4.6

**Force–Distance Analysis**

If, in place of scanning, the tip is placed at a fixed point on the sample and now moved in the vertical direction to the surface and then retracted from the surface the deflection of the cantilever as it moves can be measured as shown in Fig. 2.15. The deflection of the cantilever will provide information on the mechanical properties of the material during the part of the approach and the retraction when it is in the repulsive, contact region of the cycle, and also on the adhesion interactions between the tip and the surface as it tries to disengage from the sample. This is termed force–distance measurement.

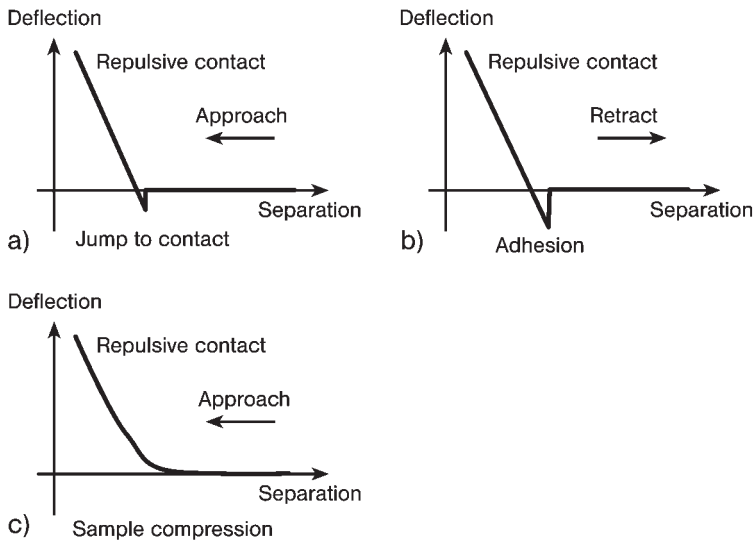

When the sample is hard and incompressible, as would be seen with glass, ceramics or metallic surfaces (Fig. 2.16a and b), the tip will simply approach the surface, jump into contact and then bend; the retraction curve will be the same, although scanning in air will induce adhesion of the tip to the sample by the water layer. To remove these water adhesion effects, which can be of the order of several to hundreds of nano-Newtons, force–distance measurements are normally carried out in a fluid system.

For more compressible samples the curve will be expected to resemble that in Fig. 2.16(c) and information on the mechanical properties of the sample may be extracted. However, care must be taken as effects of the sample substrate may also be observed. Often, during retraction hysteresis will be seen, particularly if the sample is not perfectly elastic.

However, now suppose that a molecule has been coupled to the tip and a recep-

**Fig. 2.15.** Schematic diagram of vertical tip movement during the approach and retract parts of a force spectroscopy experiment. (Courtesy of JPK GmbH.)

**Fig. 2.16.** Typical force–distance curves, showing, left to right, no adhesion on a hard surface, adhesion on a hard surface and non-adhesion on a soft surface in a liquid. (Courtesy of JPK GmbH.)

**Fig. 2.17.** Force–distance measurement in water between a ligand fixed to a coated AFM tip and the receptor present on the sample. (Courtesy of JPK GmbH.)

tor is present on the sample. When the tip is in contact with the surface there will be ligand–receptor coupling; as the tip is retracted, force will be applied to the complex until, eventually, the applied force is greater than the interaction force. At this point the tip will snap off. As the area of the tip is considerably greater than that of a single molecule one cannot be certain that the rupture of the complex is due to a single molecular event, and so multiple analysis and deconvolution of the force–distance curves (Fig. 2.17) are required to calculate a single molecule interaction force. However, where knowledge of the forces involved in single molecular complexes is not required, assuming that a set of tips are roughly the same size and using receptors of the same size, e.g., antibodies, the experiment may be used to analyze whether there is recognition between a ligand and a biomolecule [18].

Interaction forces have been calculated for a wide range of molecular interactions, varying from the streptavidin–biotin complex, which has the strongest non-covalent interaction known for biological systems at  $340 \pm 120$  pN [26], down to carboxylic acid–carboxylic acid interactions where forces are in the range of 17 pN [20]. Table 2.3 gives typical values of molecular interactions forces for biological molecules and interaction forces for cells.

AFM has also been used to evaluate the strength of a covalent bond (Si–C) under an external load [36].

For biological molecules other events may be associated with force–distance curves, including unraveling of the molecule, as has been observed for polysaccharides [37, 38], DNA [39–42] and proteins [43–49].

#### 2.4.7

#### Chemical Force Imaging

In Chemical Force Microscopy the tip is modified chemically, either directly by using organo-silane chemistry or by alkylthiol chemistry after first coating the tips with a thin layer of gold. In this way charged (ammonium or carboxylate), hydrogen bonding (hydroxyl) or non-interacting hydrophobic (alkane) surfaces may be grafted onto the tips, Fig. 2.18 [50].

Tab. 2.3. Intermolecular forces derived from force spectroscopy.

Receptor	Ligand	Force (pN)	Ref.
Thymine	Adenine	54	19
Carboxylic acid	Carboxylic acid	16.6	20
Biotin	Avidin	160	21
Iminobiotin	Avidin	85	21
Adhesion glycoprotein CsA	Adhesion glycoprotein CsA	23	22
Concavalin-A (lectin)	Mannose	47 ± 9	23
Meromyosin	Actin	15–25	24
Biotin	Streptavidin	200–257	25, 26
		340 ± 120	
20 Base pairs DNA	Complementary strand	1520	27
16		1110	
12		830	
Cell-adhesion proteoglycans	Cell-adhesion proteoglycans	40–125	28
Biotin	Antibiotin antibody	60	29
Anti-HAS, other antibody	HAS, other antigen	49–244	30, 31
P-selectin	Glycoprotein ligand-1	165	32
Cell receptor	RGD	35–120	33
Uterine epithelium	Trophoblast	1000–16000	34
Uncoated surface	Cell-adhesion proteoglycans	19000–100000	35
Coated surface	Cell	100000–220000	35

Obviously, in the case of gold-coated tips the resolution of the experiment will reduce convolution effects due to the tip.

Scanning in the lateral force mode allows chemical imaging of structures present on the surface due to differences in interactions between the tip and the sample. Figure 2.19 shows the results of scanning with alkyl carboxylic acid or alkane

SAM, and (C) friction force using a tip modified with a CH<sub>3</sub>-terminated SAM. (Reprinted with permission from Ref. [50]. Copyright (1997) Annual Review of Materials Science.)

modified points on patterned surfaces in which a square pattern of an alkylcarboxylic acid has been deposited. The topographic image in Fig. 2.19(A) clearly shows that there are no variations in layer heights. Figure 2.19(B) presents a friction force image using a tip modified with a COOH-terminated SAM, and Fig. 2.19(C) a friction force image using a tip modified with a CH<sub>3</sub>-terminated SAM. Light regions in Figs. 2.19(B) and (C) indicate high friction, and dark regions indicate low friction [50].

#### 2.4.8

##### **Dip-pen Lithography**

In a further extension of SPM derived techniques, the use of AFM tips to directly “write” structures on surfaces has been demonstrated [51–53]. Based on the soft lithography of Whitesides [54] a suitable molecule is adsorbed by capillary forces onto the AFM tip. This is then used in the contact-mode to scan pre-determined patterns on a given surface (Fig. 2.20). The use of suitable programming allows features of any shape and form to transfer to the surface with a resolution of 30 to 100 nm [53]. The choice of molecular ink to be transferred depends on the particular surface chemistry of the substrate, the application of alkane thiols onto gold surfaces being the most generally used chemistry.

#### 2.4.9

##### **Cantilever Array Sensors**

In contrast to all SPM derived methods, cantilever sensors [8] are based not on probe–sample interactions but rather on direct interaction of the sample with tip-less cantilevers. Signal detection is based on measurement of the mechanical response of the thin Si beams, arranged in a micro-fabricated array (Fig. 2.21).

**Fig. 2.20.** Schematic of the principle of dip-pen lithography. (Reprinted with permission from Ref. [53]. Copyright (1999) Science.)

**Fig. 2.21.** Microfabricated Si cantilever array. (Reprinted with permission from Ref. [8]. Copyright (2000) Elsevier.)

Cantilever sensor arrays experiments can be performed in either static or dynamic mode. In the static mode, only one side of the cantilever is chemically modified (with a receptor molecule); contact with the analyte is responsible for surface stress that causes a bending of the cantilever. In dynamic mode, both sides of the cantilever may be modified and detection is based on mass-dependant resonance frequency (or phase) shifts of the cantilever.

Detection is either by deflection of the laser on the standard AFM photo-detector or by resonance shifts as detected with dynamic AFM modes (Fig. 2.22).

Fig. 2.23. Schematic of far-field and near-field microscopies, and probe positioning.

## 2.5

### Near-field Scanning Optical Microscopy

Near-field illumination of a sample with visible light can resolve features well beyond the resolution of conventional, far-field microscopes [55–58]. Near-field Scanning Optical Microscopy (NSOM) thus has the potential of extending the resolution of techniques such as fluorescent labeling, yielding images of cell structures and molecules on the nanoscale (Fig. 2.23).

The spatial resolution of ordinary light microscopes is limited to about 250 nm, the objective lens or equivalent, at a distance from the object observed that is several times the wavelength,  $\lambda$ , of the illuminating light. At this distance the high spatial frequencies in the image components giving information about the smallest features of the object are not collected by the imaging optics and do not contribute to image formation. It is this phenomenon, rather than the physics of light itself, that sets the  $\lambda/2$  diffraction limit. If the collecting or the illuminating optics can be brought closer to the object, to a distance less  $\ll \lambda$  from its surface (Figure 23, right-hand side), then the high spatial frequencies can be resolved, at the price of reconstructing the image from the scan of the optics across the sample. The most efficient way to do this is to bring an aperture with diameter  $\ll \lambda$  to within a few nm of the object surface. Positioning at this distance allows collection of light from the sample that otherwise would be lost to far-field collection. Conversely, illuminating through the aperture means that the incident light reaches the sample and interacts with it before it can be diffracted and lost. Thus, NSOM, like scanning confocal microscopy or AFM, builds an image by registering intensity for each point of the scan. Like confocal microscopy, NSOM uses visible light. Like AFM, it achieves super-resolution by means of a very small probe. All of the

**Fig. 2.24.** The two forms of NSOM tips: (a) a pulled optical fiber with aluminum cladding and (b) an etched aperture in a standard AFM cantilever.

problems and the promise of NSOM then turn on the problems of fabricating the aperture, and scanning across the sample surface while keeping it within near-field distance of the surface.

Two main forms of NSOM tips exist (Fig. 2.24): pulled optical fibers covered with an aluminum layer and AFM tips into which the aperture is etched. Fiber tips have a better theoretical resolution, below 20 nm, while that for etched AFM tips is higher, around 50 nm; however, such resolution is not generally achieved.

In practice, fiber tips are much more fragile than AFM cantilever based tips. With regard to scanning in liquids, often a condition for biological samples, feedback control is easily obtained for the AFM tips in either contact or dynamic modes; however, fiber tips use either shear-force or an attached tuning fork for feedback, and damping of the signal is generally very high, making the experiment difficult.

## 2.6 Artifacts

### 2.6.1 Artifacts Related to Tip Size and Geometry

The shape of an AFM tip can modify considerably, with both the geometry and the radius of the tip causing artifacts. Figure 2.25 shows the effects of tip geometry on the form of the observed image of a vertical step.

None of these tip geometries can accurately give a true image of the step, indeed only a truly two-dimensional tip could image correctly such a feature. The image will always contain elements arising from a combination of tip shape and the true topography of the surface. While long thin tips will clearly best reproduce the

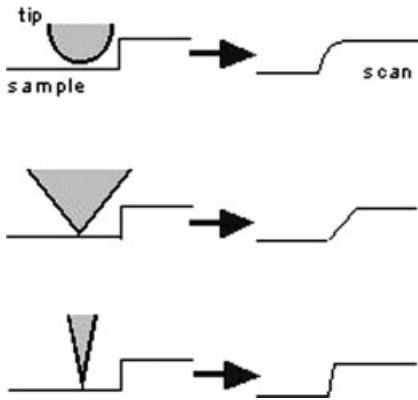

Fig. 2.25. Tip geometry effects on the image of a sharply stepped surface.

topography, there is a trade-off between the mechanical strength of the tip and the quality of the image, with sharp narrow tips being much more fragile and apt to break, which can then lead to other artifacts (see below).

Tip artifacts arising from the geometry can be modeled in terms of the cone angle of the main pyramid forming the tip and the radius of the tip end. Thus images of small sharp objects will be dominated by the tip radius, leading to sizes in the  $x$  and  $y$  dimensions that effectively measure the tip size. However, the information in the  $z$ -axis is correct and may be used to obtain the correct size of spherical or cylindrical objects. For larger objects the artifacts will be dominated by the cone angle, as noted above.

The relationship between the observed width  $W$  of a feature and the diameter of the probe tip can be calculated for an idealized tip shape, such as the one shown in Fig. 2.26, where  $x^2 = R^2 - (R - d)^2$ . For  $R \gg d$ ,  $W = \sqrt{8dR}$  and  $d = (W^2/8R)$ . For  $R = 10$  nm and  $d = 5$  nm, the observed width  $W$  would be 20 nm.

Fig. 2.26. Geometries used in investigating tip deconvolution effects.

**Fig. 2.27.** Artifacts arising from (a) a blunt tip with triangular geometry and (b) a broken tip with at least double tips.

### 2.6.2

#### Artifacts from Damaged Tips

Sometimes the tip will be damaged during use or during the fabrication process, leading to the occurrence of double or multiple tips. Such tips will generate images in which features will be present as pairs or larger multiples. These are normally relatively easy to identify (Fig. 2.27). Other damaged tips may simply have non-pyramidal shapes – again these can be identified by the presence of repeating geometries of all the features.

### 2.6.3

#### Artifacts from Tip–Sample Interactions

Artifacts may also occur when tip–sample interactions are greater than the mechanical strength of the sample being imaged. This is often encountered in the contact mode imaging of soft surfaces, or when the response times of the feedback loop are incorrectly set. This often occurs when there are rapid changes in the height of the sample in certain areas of the sample and the feedback loop values have been set on a flat part of the surface.

### 2.6.4

#### Sample Artifacts

Biological samples scanned in air are prone to sample artifacts arising from the presence of buffers in the solution used to prepare the sample. On drying, the buffer may crystallize, yielding dendritic patterns (Fig. 2.28a). By careful washing the buffer can often be selectively removed. However, some care may be taken to determine whether the patterns observed arise from the buffer, the sample or from highly complex structures arising from self-assembly (Fig. 2.28b). Here the

**Fig. 2.28.** (a) Artifact caused by phosphate buffer; dendritic crystallization is evident in the upper left of the image, (b) Non-artifactual patterns in a bovine serum albumin–sodium chloride mesocomposite.

apparently dendritic patterns are not “true artifacts” but arise from the protein, in this case bovine serum albumin, controlling crystallization of composite structures containing salt–protein complexes [59]. A similar problem was observed in the self-assembly of cowpea mosaic virus particles into highly ordered comb-structures with a spacing of 6  $\mu\text{m}$  [60].

## 2.7

### Using the Tools

In this section we attempt to illustrate how the various methods of SPM can be applied to the study of biological systems, using selected examples for each type of system. Evidently, due to space requirements, the presentations will not be exhaustive, but rather represent my personal choice (A.W.C.). So, in advance, I apologize to any author who feels left out in the examples presented.

#### 2.7.1

##### DNA

DNA has been imaged with a wide range of SPMs since the very debut of such experiments, firstly by STM [61] and then by AFM [62]. Subsequent experiments have involved various types of manipulation of DNA and determination of the recognition properties [63] and the mechanical unraveling of DNA strands [64]. Application of SPM to DNA has been widely reviewed (see Appendix 2).

##### 2.7.1.1 Topographic Imaging of DNA

In a series of single molecule experiments with different methods of AFM, Anselmetti et al. [65] observed topographically various DNA topologies (Fig. 2.29). Linear

**Fig. 2.29.** Topographic images of various DNA topologies. (a) Linear  $\lambda$ -DNA (48.5 kbp), (b) non-twisted circular DNA plasmids (vector 3.2 kbp) and (c) circular supercoiled DNA with twists and writches due to internal supercoiling (supercoiled DNA ladder 2–16 kbp). Intermittent contact mode, vertical scale 3 nm. (Reprinted with permission from Ref. [65]. Copyright (2000) Wiley.)

**Fig. 2.30.** Topographic images of  $\lambda$ -DNA: (a) Before and (b) after cutting a dsDNA strand. Intermittent contact mode, vertical scale 3 nm. (Reprinted with permission from Ref. [65]. Copyright (2000) Wiley.)

double strand DNA, circular plasmids and supercoiled DNA were observed. The measured widths of the strands were in the range 3–7 nm, which can be compared to the known radius of 2 nm [66]; thus the size of the imaged DNA is controlled by the tip convolution effects cited in Section 2.6.1. In comparison the observed height was 1 nm.

The experiments were further expanded to use the AFM tip as a cutting tool to locally cut the DNA strands. By using much higher tip-surface forces than normally used for scanning of soft material and repeatedly scanning at a predefined point on the DNA strand, the authors were able to use the AFM tip as a mechanical restriction endonuclease (Fig. 2.30).

As discussed above in Section 3.4.4.3, both topographic and phase difference information are available from the intermittent contact imaging AFM mode. By using carefully controlled humidity conditions Lee et al. [67] were able to image very short oligonucleotide strands (a biotinylated 21 mer 5'-biotinGAGGAGTTGGGG-GAGCACATT-3') attached to streptavidin on a gold surface. Under normal conditions such short strands of DNA-oligonucleotides are impossible to image and even here at low humidity little information is obtained. However, as shown in Fig. 6.31, localized signals arising from higher hydration of the oligonucleotide were observed. Normal phase differences are of the order of  $10^\circ$ ; however, phase differences in the range of  $70$ – $100^\circ$  were obtained (Fig. 2.31c). These show a typical adsorption curve as a function of concentration, implying saturation of available streptavidin–biotin binding sites.

#### 2.7.1.2 Imaging DNA Translocation

Atomic force microscopy imaging in liquids allows observation in almost real time (scan speeds are now such that an image can be acquired in about 1 min) of biological processes. This recognition was applied by Firman et al. [68] to translocation of DNA by Type 1 restriction-modification enzymes. Here large DNA fragments (2364 and 724 bp) both containing a single recognition site at 175 bp were used. Figure 2.32 shows the images obtained after fixed incubation times. Both DNA and the protein are clearly present. By using a large body of images the amount of translocated DNA associated with loop formation was analyzed. Single loops observed for the R1–DNA complex were determined. Evidently, the size of the loop increased with time. The authors were able to determine the velocity of the translocation process, which proved to be much lower than that previously measured [69, 70]. Prudently, the authors note that this may be due to sample surface interactions leading to an artificially slow translocation process. With the R2–DNA complex, two loops were formed (Fig. 2.32) – the difference in size between the loops was postulated to arise from the switch from the recognition to translocation process occurring independently in the two sub-units of the enzyme.

#### 2.7.1.3 DNA Interactions and Stretching

The double stranded DNA may interact with drugs, specific pharmacological functions being strongly dependent on the nature of the binding of the two systems.

Single-molecule force spectroscopy can discriminate between different interaction modes that modulate the binding of the small molecules to the DNA, by measuring the mechanical properties of DNA [71]. Several structure transitions are characterized upon stretching of double stranded DNA; it was observed, at a level of a single molecule, that the binding of a small molecule on to the DNA strongly affects these transitions (Fig. 2.33).

DNA occurs in solution as an entropic coil. When a DNA molecule attached between an AFM-tip and a surface is stretched it exerts a restoring force (see black curve in the Fig. 2.33). Up to a certain limit, these force–extension characteristics may be described by the worm-like chain model. On further increasing the applied force, the molecule undergoes an important structural transition (corresponding to a plateau in the force–extension profile). Initially, this transition plateau was thought to correspond to a structural modification of B-DNA to an overstretched S-DNA structure. One study [72] explains the plateau in the force–extension curves by a mere melting of the double helix, implying also the breakage of hydrogen bonds in the overstretching transition. After stretching beyond this melting transition the double stranded molecule is finally separated into two single strands, one of which remains tethered between tip and surface. The relaxation trace does not resemble the extension trace and single stranded DNA mechanical properties prevail. At lower forces ( $<150$  pN), partial melting of the DNA molecule can occur and is observable as a deviation of the relaxation trace from the stretching traces (melting hysteresis). This model, however, predicts that the overstretching force should be related to the thermal melting temperature and that the force range over which overstretching occurs should be related to the width of the thermal melting transition.

Ethidium bromide is a well-characterized dye that intercalates into DNA without sequence specificity. Insertion of a single dye molecule increases the base pair rise by  $3.4 \text{ \AA}$  and unwinds the double helix by  $26^\circ$ . Typical force–extension traces obtained on DNA in the presence of ethidium bromide show that low concentrations ( $0.44 \mu\text{g mL}^{-1}$  or ca. 1 molecule of ethidium per 10 bp) (Fig. 2.33 curve b) markedly affect the overstretching plateau. The increased slope of the transition regime is indicative of a reduction in cooperativity as compared to the curve obtained on the very same molecule before ethidium was added (Fig. 2.33 curve a). The force is reduced in the beginning of the transition while at the end it rises above 110 pN, almost twice the force at the end of the overstretching transition in non-complexed molecules. The melting transition, however, is still observed and hysteresis between stretching and relaxation remains. At elevated concentrations (Fig. 2.33 curve c), the plateau vanishes and a steadily rising force is observed that begins at larger extensions. Furthermore, the sharpness of the end of the overstretching plateau is lost, and it is difficult to precisely identify the beginning or end of the overstretching transition. The mechanical energy that can be deposited in the DNA double helix before force-induced melting occurs was found to decrease with increasing temperature. This energy correlates with the base-pairing free enthalpy  $\Delta G(\text{bp})(T)$  of DNA. Experiments with pure poly(dG-dC) and poly(dA-dT) DNA

**Fig. 2.31.** (a) Topographic image of oligonucleotide complex, (b) phase shift image, (c) phase shift variation as a function of oligonucleotide concentration. Image size  $250 \times 250$  nm. (Reprinted with permission from Ref. [67]. Copyright (2004) Elsevier.)

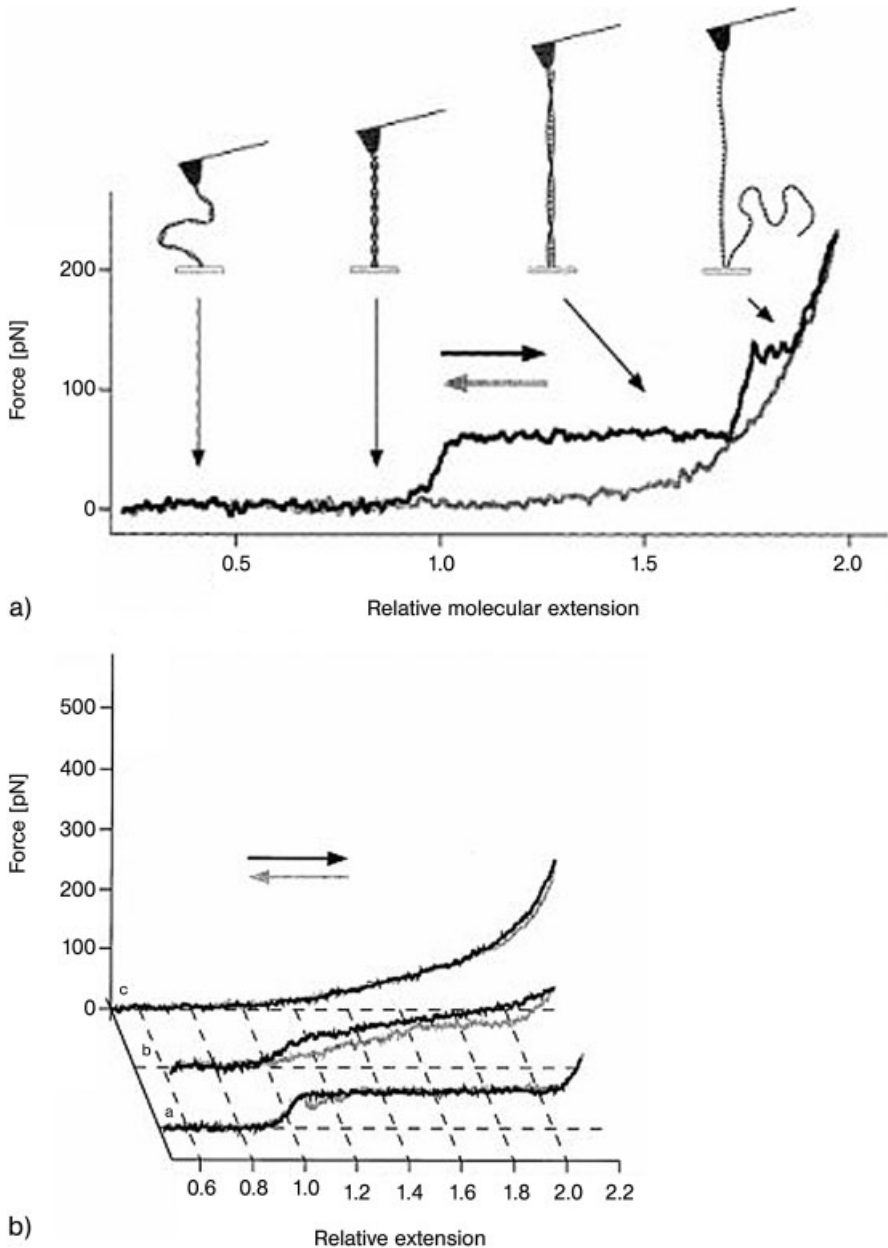

sequences again revealed a close correlation between the mechanical energies at which these sequences melt with base pairing free enthalpies  $\Delta G(\text{bp})(\text{sequence})$  (Fig. 2.34): while the melting transition occurs between 65 and 200 pN in  $\lambda$ -phage DNA, depending on the loading rate, the melting transition is shifted to  $\sim 300$  pN for poly(dG-dC) DNA, whereas poly(dA-dT) DNA melts at a force of 35 pN [73].

The force at which the melting transition occurs depends on the pulling velocity, ranging from 68 pN at  $0.15 \mu\text{m s}^{-1}$  to 300 pN at  $3 \mu\text{m s}^{-1}$ .

**Fig. 2.32.** AFM images of DNA translocation. (a)–(c) Scans taken after 10, 30 and 60 s incubation, respectively, with  $R_1$ -complex. Scan  $250 \times 250$  nm, height scale 3 nm. (d) Loop

size distribution for images taken after 10 s. (e, f) Double loops of DNA translocated by  $R_2$ -complexes. (Reprinted with permission from Ref. [68]. Copyright (2004) Oxford Journals.)

**Fig. 2.33.** Schematic of the force–extension characteristics of DNA (A): at 65 pN the molecule is overstretched to about  $1.7\times$  its contour length; at 150 pN the double strand separates into two single strands, one of which remains attached between tip and surface. (B) Force vs. extension curve of a single molecule of DNA in pure buffer (a) and in the presence of (b) 0.44 and (c)  $2.2 \mu\text{g mL}^{-1}$  ethidium

bromide. With increasing ethidium bromide concentration the overstretching plateau shortens while the force at the end of the transition increases to 110 pN. At high concentrations, hysteresis between stretching and relaxation is drastically reduced. (Reprinted with permission from Ref. [71]. Copyright (2002) Elsevier.)

**Fig. 2.34.** Superposition of four extension traces of the same piece of  $\lambda$ -BstE II digest at different pulling velocities: 3, 1.5, 0.7 and  $0.15 \mu\text{m s}^{-1}$ . (Reprinted with permission from Ref. [73]. Copyright (2002) Biophysical Society.)

Apparently the flexibility of DNA and RNA molecules depends on the D+C content. More than that, it was observed [74] that the stacking forces are stronger in RNA than in DNA, as an increased transition force is noted for RNA molecules.

## 2.7.2

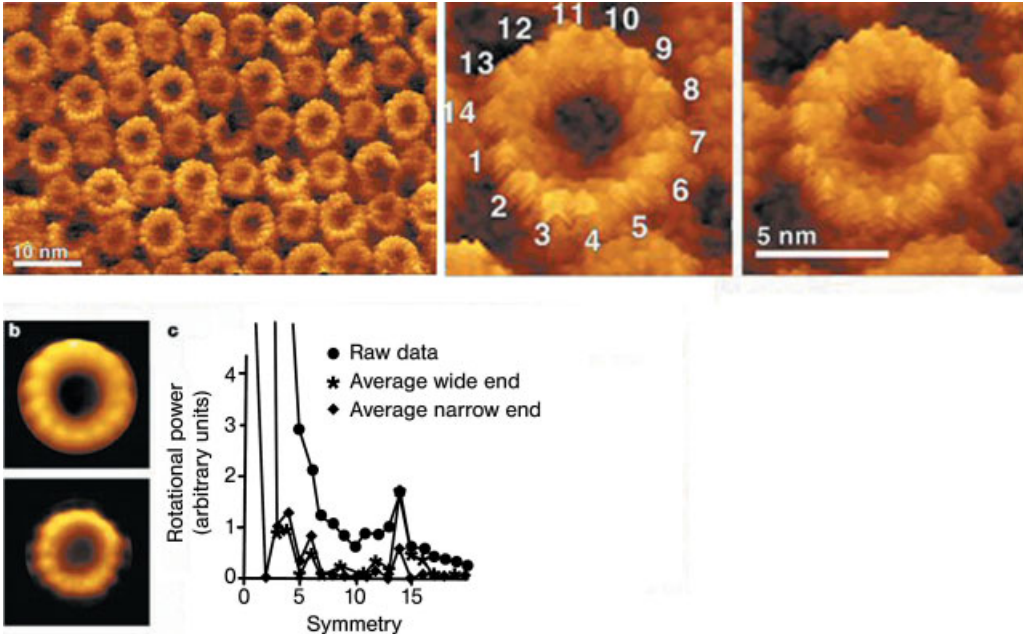

### Proteins

#### 2.7.2.1 Topographic Imaging of Proteins

Collagen presents the archetypal protein for AFM imaging first observed by Lees et al. in 1994 [75]; the bands of collagen spaced at 67 nm is often the first experiment encountered on entering the field of bio-AFM.

AFM high resolution imaging of membrane, reconstituted in high concentrations in lipid domains, is proving to be one of the major tools for obtaining structural information on these proteins, which represent a major difficulty for classical methods, such as X-ray diffraction, of structural analysis.

Contact mode AFM in liquids allows resolution at a level of individual sub-units of assembled arrays of proteins (Fig. 2.35) for the case of chloroplast ATP-synthase [76]. The image shows the protein to be formed of 14 sub-units arranged cylindrically. There are alternating cylinder diameters of  $5.9 \pm 0.3$  and  $7.4 \pm 0.3$  nm, with both having the same internal diameter of  $3.5 \pm 0.3$  nm. Given that SDS-PAGE reveals only a single sharp band at 100 kDa, the authors propose that there is alternating presentation of the extra- and intra-cellular faces of the protein. Furthermore the sub-units project by differing amounts from the lipid bilayer,  $1.7 \pm 0.3$  nm for the wider face and  $1.5 \pm 0.3$  nm for the narrower face.

**Fig. 2.35.** (a) High-resolution AFM contact-mode images of images of chloroplast ATP-synthase, showing the fourteen-fold symmetry; (b) wide and narrow faces; (c) power spectrum

analysis, showing the peak for fourteen-fold symmetry. (Reprinted with permission from Ref. [76]. Copyright (2000) Nature.)

Combining AFM with cryo-electron crystallography provides a means to enhance the structural data that may be obtained from molecular resolution AFM topographic imaging of proteins.

The lens major intrinsic protein (MIP) has been studied by Engel et al. [77], using reconstituted purified ovine lens MIP and exogenous lipids to obtain crystalline sheets. The sheets show two surfaces, one smooth and the other rough, Fig. 2.36(A) and (B). From the high level of organization, Fourier transform analysis allowed determination of the unit cell and the presence of a tetrameric structure. The rough surface was imaged by mechanical removal of the smooth part using high tip-surface forces.

Careful analysis of the geometry of the protrusions present on the surfaces of the rough and smooth faces, along with analysis of carboxypeptidase Y digestion, which permitted identification of the smooth face as being cytoplasmic, allowed the authors to propose a tongue and groove fit between the two surfaces, showing MIP assembles as a two-layer system (Fig. 2.36). Use of cryo-electron microscopy projection maps allowed confirmation of a two-layer structure of the crystalline sheets.

**Fig. 2.36.** Treated images of MIP from lens fiber cells. (A) Both rough and smooth surfaces are visible after using the point to remove the upper layer. (B) Model of the tongue and groove fit of the two layers. (Reprinted with permission from Ref. [77]. Copyright (2000) Elsevier.)

### 2.7.2.2 Dip-pen Nanolithography Patterning of Proteins

The use of Dip-pen nanolithography to allow deposition of various geometries of protein arrays on negatively charged  $\text{SiO}_2$  surfaces has been demonstrated by Mirkin (Fig. 2.37) [78].

Arrays of 450 nm spots of anti-rabbit IgG with 350 nm spacing were generated in under 5 min, using a deposition time of 3 s. While not as rapid as conventional robotic systems, the spatial resolution is much higher. However, this is counter-balanced by the maximum standard AFM displacement of about  $100 \times 100 \mu\text{m}$ . Individual spots of size as low as 55 nm can be generated by using shorter contact times (0.5 s) with low contact forces (0.5 nN). Such arrays were used to validate immuno-recognition with suitably labeled fluorescent antibodies.

### 2.7.2.3 Protein–Protein and Protein–Ligand Interactions

In the classical first experiment on force–distance measurement between a ligand and a protein, avidin was coupled to a bovine serum albumin coated tip and reacted with biotin or iminobiotin attached to agarose beads. The force required to separate a single avidin–biotin interaction was 160 pN, and 85 pN was required for a single avidin–iminobiotin complex (Figs. 2.38 and 2.39) [79].

The function of a protein derives from the specific folding of the polypeptide chain. In the case of muscles or cytoskeletal proteins, the folding is designed to maintain a certain structure under varying load conditions. Thus, single-molecule force spectroscopy, in which one end of the protein is attached to the AFM tip and

**Fig. 2.37.** Various arrays produced from IgG deposition on negatively charged Si surfaces. (Reprinted with permission from Ref. [78]. Copyright (2003) Wiley.)

the other end to the surface, provides a unique method of studying single molecular unfolding and folding under controlled loading.

The study by Gaub of reversible unfolding of titin immunoglobulin domains is a textbook example [80]. Titin was first chemisorbed onto a gold surface that was then adsorbed by contact onto the AFM tip. Retraction of the tip from the surface produced, as shown in Fig. 2.40, force–distance curves that show a saw tooth form extending to over 1  $\mu\text{m}$  from the surface.

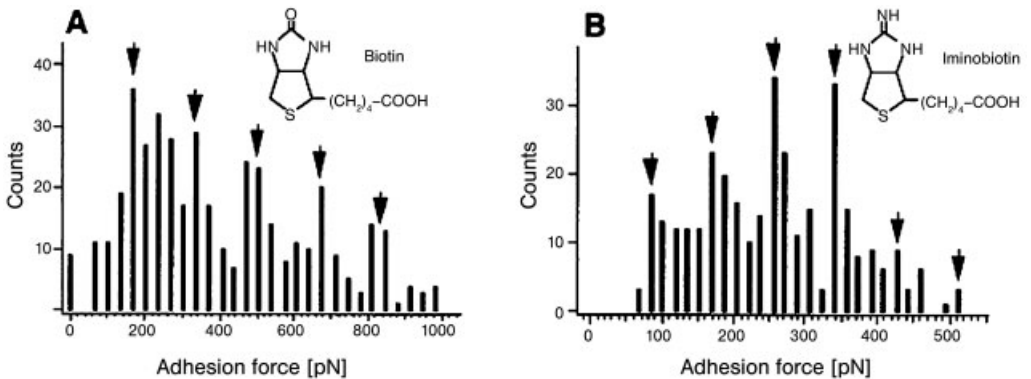

The initial high force peak may arise from tip–gold interactions. Periodicity between the peaks is between 25 and 28 nm. Using a retraction velocity of 1  $\mu\text{m s}^{-1}$ , maximum forces observed in the saw tooth curves are between 100 and 300 pN. The periodicity is close to the 31 nm expected for unraveling of an Ig domain.

**Fig. 2.38.** Force–distance curves for avidin–biotin interaction. (Reprinted with permission from Ref. [79]. Copyright (1999) Elsevier.)

This was confirmed using constructs of four or eight Ig domains (Fig. 2.41), which exhibited a strict 25 nm periodicity measured at 100 pN.

Interestingly, the slope of the rising half of the curves, representing the stiffness of the protein, decreases from peak to peak. This implies that the stiffness of the stretched protein decreases, and that the stiffness is dominated by a spring that softens on unfolding of the Ig domains. The data fits to a worm-like chain model. Repeated stretching–relaxation cycles showed that refolding occurs when the construct is allowed to fully retract (Fig. 2.42).

**Fig. 2.39.** Histograms of (A) biotin–avidin and (B) iminobiotin–avidin rupture forces. The arrows point to the locations of peaks in the histograms as determined by autocorrelation analysis. (Reprinted with permission from Ref. [79]. Copyright (1999) Elsevier.)

**Fig. 2.40.** Force–extension curves obtained by stretching titin proteins; three typical approach and retract cycles are shown: the AFM tip approaches the surface covered with the protein (lower trace), and segments of the adsorbed titin are picked up at random by an AFM tip and then stretched (upper trace). ##### 2.7.3.1 Proteoglycan Topographic Imaging

AFM topographic imaging at the molecular level can be used as a structural tool for the study of biological molecules that prove resistant to methods such as X-ray crystallography and NMR.

Ortiz et al. have achieved molecular resolution imaging of individual aggrecan proteoglycans [81]. The non-glycosylated N-terminal region was identified, along

**Fig. 2.42.** Stretching–relaxation cycles of titin in the force extension experiment. Upper trace: full relaxation yields the same saw tooth pattern. Lower trace: after half relaxation the sawtooth pattern disappears. (Reprinted with permission from Ref. [80]. Copyright (1997) Science.)

**Fig. 2.43.** (a) Schematic of the structure of aggrecan, showing the protein core and keratin sulfate (KS) and chondroitin sulfate (CS) chains. (b and c) Molecular resolution images of aggrecan, where N is the N-terminus of the

protein and C the C-terminus. Image sizes are  $1 \times 1 \mu\text{m}$  (B) and  $325 \times 325 \text{ nm}$  (C). (Reprinted with permission from Ref. [81]. Copyright (2003) Elsevier.)

with nanometer resolution of the keratin sulfate and chondroitin sulfate chains, and their spacing. Figure 2.43(a) shows a schematic of the structure of aggrecan. Figure 2.43(b) shows an image of the individual aggrecan molecules and Fig. 2.43(c) shows the GAG side chains. For fetal aggrecan, both the protein core ( $400 \pm 60$  nm) and the GAG side chains ( $41 \pm 7$  nm) were significantly longer than in mature aggrecan [protein core ( $350 \pm 90$  nm) and GA chain length ( $32 \pm 5$  nm)]. The high quality of the imaging showed that the GAG spacing increased from  $3.2 \pm 0.8$  to  $4.4 \pm 1.2$  nm on going from fetal to mature aggrecan.

#### 2.7.4

#### Lipid Systems

Scanning probe microscopies have become key methodologies in the study of the various types of lipid assemblies, including liposomes [82], solid lipid nanoparticles (SLNs) [83] and supported lipid bilayers (SLBs), and also of functioning membrane proteins contained in these assemblies. Such assemblies are highly fragile and often contain water, which hinders their study by conventional electron microscopies. Their structures are generally perturbed by insertion of fluorescent probes, effectively eliminating confocal microscopy for their study.

##### 2.7.4.1 Liposomes

A series of articles [84a,b] by Paquet and Morel on the assembly of the NADPH oxidase complex in liposomes demonstrates the utility of AFM to investigate highly complex assembly processes involving membrane proteins in their native lipid environment (Fig. 2.44). The use of functioning proteins allowed the authors to combine information from the AFM experiments with biological activity data and hence, as with the work of Firman on DNA-restriction enzymes, to determine the underlying mechanisms.

The system is particularly complicated as the NADPH oxidase complex involves assembly of different proteins: the cytochrome  $b_{558}$  an integral membrane protein composed by two sub-units p22-phox and gp91-phox; three cytosolic activating proteins p67-phox, p47-phox and p40-phox; three monomeric G proteins Rac1 or 2 participating in activation, and Rap1A a regulation factor.

Initial experiments involved simple imaging of the liposomes containing the  $b_{558}$  complex, where gp91-phox was native or enzymatically deglycosylated. Interestingly, while oxidase turnover rates and liposome heights were identical for both systems, the liposome diameter decreased from 150 nm for the native system to 68 nm for the deglycosylated system, thus showing the glycosylation is associated not just with recognition processes but also with structural properties.

As the proteins remained active in the liposomes, activation with arachidonic acid to generate the NADPH complex was achieved (Fig. 2.44), and, using height measurement, the size of the active complex was proposed to be 4 nm.

Correlating the height information and the biological activity allowed the authors to probe the role of the cytosolic proteins in the assembly and functioning of the

**Fig. 2.44.** Topographic images showing NADPH oxidase containing liposomes before (left) and after (right) activation. (Reprinted with permission from Ref. [84]. Copyright (2000) American Chemical Society.)

NADPH complex (Table 2.4). The data demonstrated that rp67-phox alone is able to mediate both assembly (change in liposome height, 6 nm) and activation. The role of p40-phox was determined; it acts to decrease the turnover rate, and with p67-phox and p47-phox alone leads to assembly (giving height changes of 6 and 4 nm, respectively, prior to activation). In the full set of cytosolic proteins this pre-activation assembly is absent.

The study was extended in a second paper to conformational changes in the cytochrome  $b_{558}$  complex, mediated by the proteins MRP8 and MRP14.

In the final paper, the use of force–distance measurements was applied to antibody recognition. The authors chose to use a “global” force–distance measurement; here it is assumed that tip size variation is not greater than experimental error, and thus associated with the use of molecules of the same size (antibodies) to assume that the total number of interaction events will be roughly constant. Hence the use of distribution curves (Fig. 2.45A) allows determination of whether the antibody–antigen recognition process occurs. The observed histograms show

**Tab. 2.4.** Correlation of assembly and activation steps of the NADPH-oxidase complex.

System	Liposome height (nm)		Oxidase turnover [[mol of O <sub>2</sub> s <sup>-1</sup> (mol of heme b) <sup>-1</sup> ]
	Before activation	After activation

Systems	Liposome height (nm)	
	-AA	+AA
Cyt $b_{558}$ PMN	$5 \pm 2$	$6 \pm 2$
Cyt $b_{558}$ EBV-BL	$7 \pm 2$	$6 \pm 4$
Cyt $b_{558}$ PMN + MRP8/MRP14 ( $\text{Ca}^{2+}$ )	$3 \pm 2$	$5 \pm 2$
Cyt $b_{558}$ PMN + MRP8/MRP14 ( $\pm\text{AA}$ )	$8 \pm 3$	$10 \pm 2$
Cyt $b_{558}$ EBV-BL + MRP8/MRP14 ( $\text{Ca}^{2+}$ )	$5 \pm 1$	$15 \pm 5$

a bimodal form with an interval control, as imprecision in the positioning often generates an antibody–mica contact (Fig. 2.45B). Again work was carried out using native and deglycosylated cytochrome  $b_{558}$ .

The results present several interesting points (Table 2.6). Firstly, interaction between the antibody Ab54.1 and the protein are significant even though the epitope is on the intracellular surface of the protein; this implies that orientation of the protein with regard to the membrane is statistical on reconstruction. Secondly, in the case of the mAb11C12 antibody, directed against neutrophil associated cyt- $b_{558}$  recognition occurs for both native and deglycosylated protein, while for EBV-BL–cyt  $b_{558}$  for the native protein no recognition is observed; deglycosylation leads to a strong recognition event, implying that here the epitope is present but hidden by the carbohydrate chains. The glycosylation is also related to the biological activity of the complex in the EBV-BL cell lines.

AFM is widely used to investigate the mode of liposomes formation, their size, the transition of attached liposomes to bilayers patches, and the complexes they form with biological molecules such as DNA or proteins. The following is the

work of Vermette et al. [85] on interaction forces between a silica particle and immobilized liposomes layers. The experiments were performed according to the colloid probe method developed by Ducker et al. [86]. Thus, a spherical colloidal particle of pure silica (diameter 4–5  $\mu\text{m}$ ) is attached to the microfabricated, gold-coated AFM cantilever spring via an epoxy adhesive. The liposomes had biotinylated PEG lipids. The resultant biotin moieties on the outer surface of the liposomes were capable of docking onto NeutrAvidin molecules immobilized onto the hydrogel interlayers. The intention was to provide a platform for binding NeutrAvidin molecules, at the same time minimizing nonspecific adsorption events as well as the disruption of liposomes upon contact with the surface. Compression of liposome layers by an approaching silica colloid sphere, mounted on the AFM cantilever, can be quantified by comparing the force vs. distance curves measured with a spherical silica particle approaching NeutrAvidin (on hydrogel interlayers) surfaces and putative immobilized liposome surfaces. Comparison of the release characteristics of fluorescent dye from liposomes in solution and liposomes bound to the three different hydrogel interlayers showed that the release characteristics were little affected, indicating that there was minimal disruption of the liposomes upon surface binding. By blocking surface-immobilized NeutrAvidin it was shown that there exists a physicochemical attractive force of non-negligible magnitude between PEGylated liposomes and hydrogel surfaces decorated with NeutrAvidin, and this physicochemical binding mechanism can surface-attach liposomes when the biologically specific biotin–avidin mechanism is absent.

The utility of AFM for measuring the mechanical properties of adsorbed small liposomes and stability changes in liposomes has been demonstrated by Liang et al. [87]. They investigated the effects of cholesterol concentration on the micro-mechanical properties of the small unilamellar EggPC liposomes adsorbed to mica. These liposomes are stable and maintain their vesicular form without fusion when deposited on a mica surface. The elastic properties are revealed by force curves between an AFM tip and an adsorbed vesicle obtained in the contact mode. Figure 2.46 presents the types of tip–sample interactions.

AFM analyses quantified the Young's modulus ( $E$ ) and bending modulus ( $K_c$ )

**Fig. 2.46.** Deflection versus  $z$  position approaching curve. Zero separation is not defined as described previously. The force curve was obtained on the EggPC/cholesterol. Zone I is non-contact. Zones II–IV illustrate different on-contact stages of tip and sample interaction. Region II illustrates elastic deformation of the vesicle under tip

compression. Region III corresponds to further tip compression after the tip penetrates the top bilayer. Region IV: tip at the top of the mica substrate; the steep slope (0.9946) indicates mica is an infinitely hard surface without deformation. (Reprinted with permission from Ref. [87]. Copyright (2004) Elsevier.)

for those unilamellar vesicles (Table 2.7). The analyses showed an increase in both  $E$  and  $K_c$  with increasing quantity of cholesterol incorporation into pure EggPC. This may be explained by the fact that the presence of cholesterol molecules enhances the rigidity of the EggPC vesicles.

#### 2.7.4.2 Solid Lipid Nanoparticles (SLNs)

Atomic force microscopy is the most used technique for the size characterization of nanoparticles, generally in conjunction with Dynamic Light Scattering (DLS).

Atomic force microscopy (FMM and LFM) has been shown to be a key tool for imaging nanoparticles incorporated in gels of biological interest [88]. It was seen that SLNs do not aggregate in gels and the use of lateral force and force modulation modes in addition to the classical topographic mode provides additional information on the gel structuring (Figure 2.47).

**Tab. 2.7.** Comparison of Young's modulus ( $E$ ) and bending modulus ( $K_c$ ) of liposome with different cholesterol and lipid ratios.

	<i>Cholesterol:lipid ratio</i>				
	<i>Pure eggPC</i>	<i>85:15</i>	<i>80:20</i>	<i>70:30</i>	<i>50:50</i>
$E \times 10^6$ Pa	$1.97 \pm 0.75$	$12.07 \pm 1.53$	$10.77 \pm 0.64$	$10.4 \pm 4.06$	$13.0 \pm 2.97$
$K_c \times 10^6$ Pa	$0.27 \pm 0.10$	$1.68 \pm 0.21$	$1.49 \pm 0.09$	$1.44 \pm 0.56$	$1.81 \pm 0.41$

**Fig. 2.47.** Images of carbopol 2020 containing nanoparticles in topographic (a), lateral force (b) and force modulation (c) modes; average particle diameter is 150 nm and the average height is 120 nm. (Reprinted with permission from Ref. [88]. Copyright (2003) Elsevier.)

To proceed to the use of SLNs in intravenous administration, it is important to verify that they do not aggregate in the presence of albumins. Gualbert et al. performed AFM studies on the interaction of SLNs based on amphiphilic calix[4]arene with one of the major circulatory proteins, serum albumin (Fig. 2.48) [89].

The results show that no aggregation occurs between the SLNs and the serum albumin. The difference in diameter and height of the particles (155 and 15 nm, respectively) with respect to the size of nanoparticles without protein (250 nm in diameter and 55 nm in height) may be explained by the fact that the nanoparticles are included in the protein gel (only the protruding parts being measured). The more circular shape proves a protective action of BSA, i.e., capping the particles, preventing their flattening.

AFM and SEM (Scanning Electron Microscopy) analyses were performed by Dubes et al. [83] on SLNs derived from  $\beta$ -CD21C6 (Fig. 2.49). Comparison of the

**Fig. 2.48.** Non-contact mode AFM images of *para*-decanoyl-calix[4]arene-based solid lipid nanoparticles without (a) and with BSA ( $20 \text{ g L}^{-1}$ ) (b) on a mica surface. (Reprinted with permission from Ref. [89]. Copyright (2003) Elsevier.)

results shows that the vacuum drying technique used in sample preparation for SEM causes shrinkage in the size of the SLNs, whereas the deposition method used for AFM causes the nanoparticles to form small clusters.

Both techniques confirm that the SLNs are circular. With images obtained from AFM, the SLNs tend to be organized as clusters of 15–30 nanoparticles. This is probably due to the sample preparation method, where the colloidal suspension is slowly dried. At the same time, shrinkage of the nanoparticles analyzed by SEM

**Fig. 2.49.** Non-contact mode AFM images of  $\beta$ -CD21C6-derived solid lipid nanoparticles (SLNs) at a scan range of 5  $\mu\text{m}$  (a). SEM images of the  $\beta$ -CD21C6-derived SLNs, scale 0.2  $\mu\text{m}$  (b). (Reprinted with permission from Ref. [83]. Copyright (2003) Elsevier.)

**Tab. 2.8.** Measured diameters on images provided by two analysis techniques.

	<i>Diameter (nm)</i>
SEM	$212 \pm 12$
AFM	
Diameter	$359 \pm 50$
Height	$140 \pm 27$

was observed (Table 2.8). This might have been caused by the freeze-drying treatment prior to analyzing.

The advantage of AFM is the simple sample preparation as no vacuum is needed during operation and the sample does not undergo high vacuum treatment leading to dehydration and shrinkage.

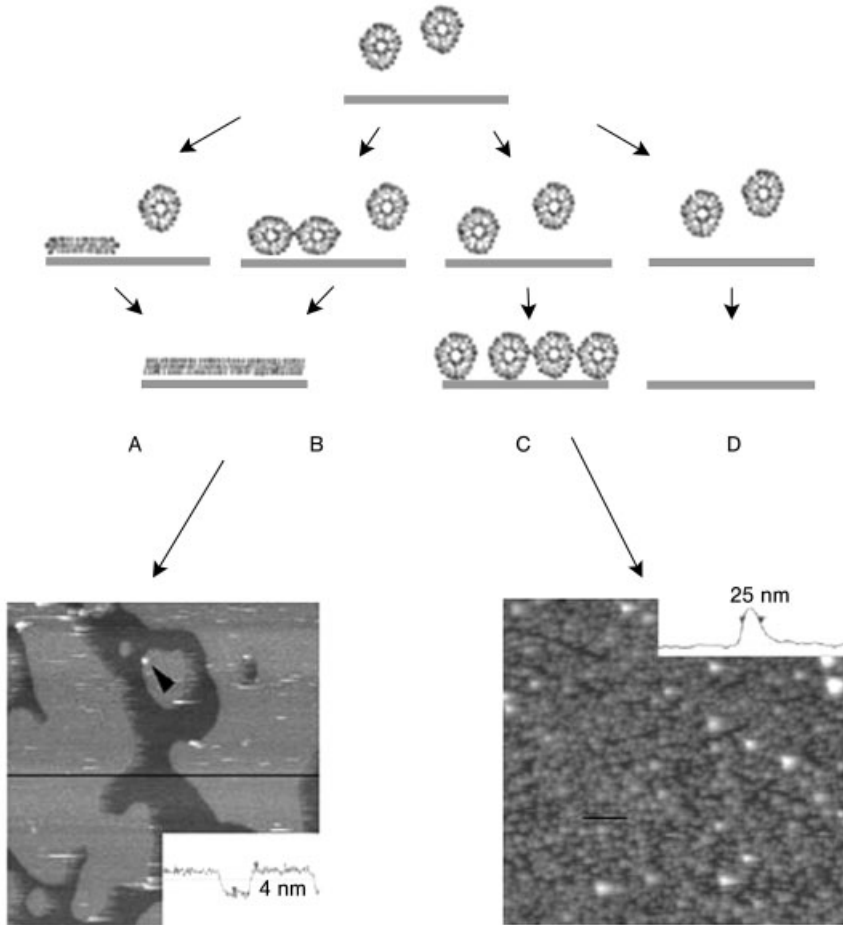

### 2.7.4.3 Supported Lipid Bilayers and Monolayers

Supported lipid bilayers (SLBs) are formed by the spreading and unfolding of liposomes on surfaces. Their formation was first demonstrated by Brian and McConnell [90] in 1984. The mechanism of their formation was proposed from AFM imaging by Jass et al. [91] (Fig. 2.50).

More recently, Richter et al. investigated the adsorption and conformational changes of unilamellar vesicles adsorbed on silica by AFM in real time studies [92]. They proved that the process of vesicle deposition onto surfaces is more complicated and depends strongly on the nature of the component lipids. Zwitterionic, negatively charged and positively charged lipids were used for this investigation.

**Fig. 2.50.** Schematic representation of supported lipid bilayer formation. (Reprinted with permission from Ref. [91]. Copyright (2000) Biophysical Society.)

**Fig. 2.51.** AFM imaging determination of supported lipid bilayer (SLB) formation; (left) image shows SLBs, (right) image of liposomes. Insets: heights of the structure. (Reprinted with permission from Ref. [92]. Copyright (2003) Biophysical Society.)

Based on AFM analysis, a schema of the pathway of vesicles deposition was proposed (Fig. 2.51).

Table 2.9 exemplifies the types of vesicle deposition, as function of the lipid ratio and composition.

The height of the SLBs did vary evidently with lipid composition. Bilayers about 4 nm high described the SLBs film.

The reported existence of microdomains in plasma membranes has prompted considerable recent interest. Microdomains of a similar composition to lipid rafts

have been shown to form in lipid bilayers, providing a model to investigate raft formation [93] (Fig. 2.52).

Many studies led to the conclusion that mixed lipid bilayers generate lipid rafts that are enriched in sphingomyelin and cholesterol. These two lipid components are thought to exist in a liquid-ordered phase or gel phase.

Fig. 2.52. Schematic of a lipid membrane with gel and fluid phase separation. The height difference due to lipid packing is such that AFM topographic imaging can distinguish the zones. (Reprinted with permission from Ref. [93]. Copyright (2003) acsmb@bmb.leeds.ac.uk.)

**Fig. 2.53.** (A) Protein film; (B) SLB containing sphingomyelin and cholesterol; (C) SLB containing sphingomyelin, cholesterol and phosphatidylcholine; (D) protein containing lipid rafts (sphingomyelin, cholesterol and phosphatidylcholine). (Reprinted with permission from Ref. [97]. Copyright (2004) Biochemical Society.)

More evidence about lipids rafts existing in biological membranes is brought by AFM studies that provide high-resolution imaging under physiological conditions [94]. Apparently, crucial cellular functions depend on preferential association of proteins with rafts [95, 96].

*Helicobacter pylori* vacuolating toxin–SLBs interaction and the preferential association of this protein with rafts [97] are presented below (Fig. 2.53).

The VacA film shows particles 7 nm high with an outer diameter of 30 nm (Fig. 2.53a). Supported lipid bilayers, formed of sphingomyelin and cholesterol, and raft formation (when phosphatidylcholine is added) are observed in Fig. 2.53(b) and (c). The film based on cholesterol and sphingomyelin is about 4 nm high. The presence of phosphatidylcholine in the lipids induces the formation of rafts. Differences of 0.8 nm in height protrude from the lipid bilayer. Analyzing the film of mixed lipids (all three components) in the presence of VacA (Fig. 2.53d), particles

**Fig. 2.54.** AFM imaging of DRM-enriched membrane bilayers. (A) 60% cholesterol depleted; (B) after repletion with cholesterol. (Reprinted with permission from Ref. [98]. Copyright (2005) Biophysical Society.)

corresponding to the protein, 2 nm higher than the SLB and of much smaller diameter (25 nm), prove that the protein is inserted and traverses the lipid bilayer. The VacA obviously associates preferentially with rafts.

Barakat et al. proved [98], in a similar study on P-glycoprotein in a DRM-enriched membrane bilayer, that the depletion of cholesterol from the rafts induces protein translocation and aggregation outside rafts (Fig. 2.54). Approximately the same height differences (about 0.7 nm) were found for the protruding rafts. Repletion of the sample with cholesterol allows the reinsertion of P-gp in the rafts, probably recovering its P-gp ATPase activity.

Thus, cholesterol appears to be an essential component of DRMs for maintaining a structure of P-gp that is compatible with its optimal activity.

### 2.7.5

#### SNOM Imaging

Scanning near-field optical microscopy is generally used complementary to AFM to enrich the structural details of supported lipid monolayers and bilayers (Fig. 2.55). The two techniques can detect the presence of domains on the submicron scale on the supported lipid bilayers. The initial supposition was that a defect in the lipid layer occurred. Further analysis of these structures simultaneously by high-resolution fluorescence and topography measurements confirmed that they arise from coexisting liquid condensed and liquid expanded lipid phases. NSOM is the only reliable technique able to observe the lipid domains. Hollars et al., using NSOM fluorescence measurements, showed that lipid domains are quantitatively similar when formed in lipid bilayers or monolayers [99].

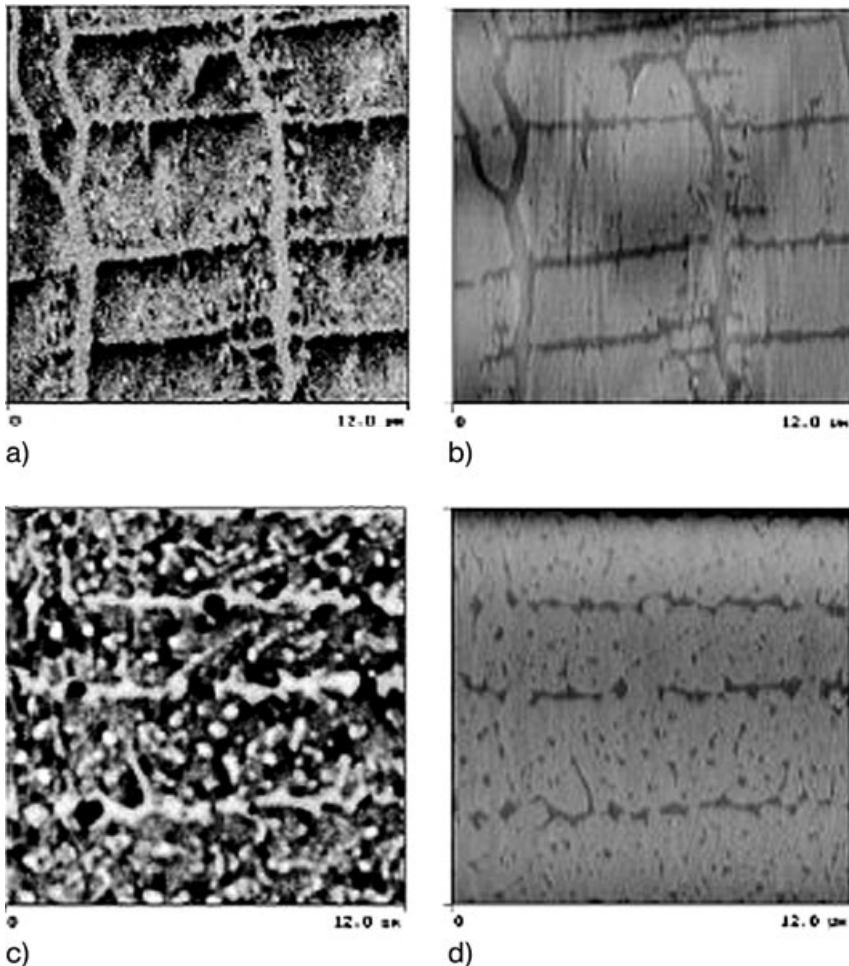

**Fig. 2.55.** (A) NSOM images and (B) AFM topographic images of monolayers, showing phase separation. The fluorescence is situated in the liquid expanded zones, as shown by the correlation with lower height in the AFM image. (Reprinted with permission from Ref. [99]. Copyright (1998) Biophysical Society.)

Apparently these domains are common features of the sample, regardless of the nature of the substrate.

The formation of phase domains can be influenced by the deposition conditions. As exemplified in Fig. 2.56, the surface pressure at the moment of deposition influences the distribution of the phase domains on the lipidic film [100].

Taken together, these results prove that SNOM might be a unique technique sensitive enough to observe phase structures present in lipid bilayers at the nanometer scale and may provide new clues to the existence of lipid phase domains in natural biomembranes.

**Fig. 2.56.** (A, C) NSOM fluorescence images of mixed DPPC, diC18 monolayers; (B, D) corresponding AFM topographic images. (Reprinted with permission from Ref. [100]. Copyright (1999) American Chemical Society.)

### 2.7.6

#### Viruses

Figure 2.57 presents typical images of the Moloney murine Leukemia virus emerging from the surfaces of infected NIH 3T3 cells [101]. The viral particles have an average diameter of 145 nm, but with a degree of polydispersity. The surfaces of the virions are studded with projections (tufts) of proteins, which display a range of packing densities. The tufts are generally 11–12 nm in size and often show a

**Fig. 2.57.** (a–c) Typical AFM images of the surfaces of Moloney murine leukemia virion, showing the dense packing of protein projections. (d) AFM image of a virus particle, showing a low density of protein projection. (Reprinted with permission from Ref. [101]. Copyright (2002) Blackwell.)

high density of surface packing. The authors postulated that these projections are aggregates of SU protein. In view of the varying aggregation, the variation in size and geometry can be explained. Moloney murine leukemia virus (M-MuLV) lacking the gene for the envelope glycoprotein ( $env^-$ ) was produced in NIH 3T3 cells and investigated using atomic force microscopy (AFM). The particles were compared with similarly produced wild-type virions, some of which had been exposed to a monoclonal antibody against the surface component of the envelope protein (SU protein).

## 2.7.7

### Cells

#### 2.7.7.1 Topographic Imaging

Optimized methods were realized to study the complex system *Shewanella oneidensis* (Gram negative). We exemplify here the work of Micic [102] which correlated tapping-mode AFM and confocal microscopy (FLIM) to analyze living bacterial cells. As this technique allows imaging of bacterial cells in their native environment, Gram-negative *Shewanella oneidensis* MR-1 cells were spread on poly-L-lysine coated surfaces or agarose gel coated surfaces for analyzing, confining them a wet environment, which is propitious for *in vivo* imaging conditions. Figure 2.58 depicts a topographic image ( $256 \times 256$  pixels) of MR-1 bacterial cells. To reduce image noise, the imaging was acquired in a slow mode, with a raster-scan frequency of 0.1 Hz.

Single cells images were obtained only by diluting the sample and using a poly-L-lysine coated substrate. Images of live MR-1 cells bearing flagella of high resolution were obtained. The topographic image shown in Fig. 2.59(A) demonstrates that the ends of these elongated cells are thicker than the central portion. However, more information and structural details are presented by phase imaging (Fig. 2.59B).

The utility of correlated AFM–FLIM imaging on MR-1 cells expressing the MCP–YFP fusion is presented as follows (Fig. 2.60) by AFM height image, fluorescence intensity image, and fluorescence lifetime image of single cells.

The fluorescence images show higher intensities at both ends of the cells, which suggest polar localization of the SO0584–YFP fusion protein. The same information is obtained by the AFM image on both ends of the cells, allowing correlation between the polar localization of the SO0584–YFP fusion protein and surface protuberances in MR-1 cells.

#### 2.7.7.2 Interactions and Mechanical Properties

Essential for multicellular development are cell–cell adhesions mediated by specific cell-surface molecules. By combining single-molecule force spectroscopy with genetic manipulation and by controlling the interactions between single cells it is possible to quantify de-adhesion forces at the resolution of an individual cell.

Presented here as a prototype of cell-adhesion properties are the measurements of Benoit et al. [22] on a glycoprotein, contact site A (csA), expressed in aggregating cells of *Dictyostelium discoideum*, which are engaged in development of a multicellular organism proteins. A simple mechanism of cell addition is used (Fig. 2.61): a cantilever-mounted cell is positioned on a target cell deposited on a Petri dish. The two elements were brought in contact until a certain repulsive force is detected and were then held in this position for a certain time, allowing the establishment of cell addition.

When retracting the cantilever, force vs. distance measurements were recorded, until the rupture of the contact between cells.

**Fig. 2.58.** Low magnification, tapping-mode image of an *S. oneidensis* colony in agarose. (Reprinted with permission from Ref. [102]. Copyright (2004) Elsevier.)

Force spectra of  $\text{Ca}^{2+}$ -dependent adhesion between cells in the growth phase were realized. In this particular case, cell–cell contacts were maintained for  $20\text{ s}$  at  $150 \pm 20\text{ pN}$  and the rupture was induced at a speed of  $1.5\text{ mm s}^{-1}$ . Strong de-adhesion forces and stepwise separation of cells in the  $\text{Ca}^{2+}$  trace are notable. When replacing  $\text{Ca}^{2+}$  by EDTA, adhesion forces are markedly reduced (Fig. 2.62a). Thus it was proved that, in the case of *Dictyostelium discoideum* cells, cell–

**Fig. 2.59.** AFM tapping-mode images of a pair of *S. oneidensis* on a poly-L-lysine surface: (A) topographic height image and (B) phase image. (Reprinted with permission from Ref. [102]. Copyright (2004) Elsevier.)

**Fig. 2.60.** Composite correlated AFM-confocal FLIM image of *S. oneidensis* bacterial cells on poly-L-lysine surface: (A) topographic AFM image, (B) confocal fluorescence intensity, and (C) confocal fluorescence lifetime image. The differences in fluorescence intensity and lifetime are presented by the brightness and color (inset), respectively. (Reprinted with permission from Ref. [102]. Copyright (2004) Elsevier.)

cell adhesion of undeveloped cells depends on the presence of  $\text{Ca}^{2+}$ . For the de-addition process, significant de-addition occurred predominantly in a single step (Fig. 2.62b).

### 2.7.7.3 NSOM Imaging

Protein–protein interactions are difficult to elucidate by classical techniques, as it is difficult to obtain an accurate localization of proteins within the substructure of

**Fig. 2.61.** (a) Experimental procedure for cell–cell adhesion; (b) light-microscopic image of a cantilever-mounted cell before being brought into contact with another cell. (Reprinted with permission from Ref. [22]. Copyright (2000) Nature.)

**Fig. 2.62.** (a) Force spectroscopy traces for *D. discoideum* cells. Cell–cell contacts were maintained for 20 s at  $150 \pm 20$  pN and the cells were subsequently pulled apart at  $1.5$  mm s<sup>-1</sup>. (b) Force spectroscopy traces for cell–cell contacts maintained for 0.2 s at  $35 \pm 5$  pN. (Reprinted with permission from Ref. [22]. Copyright (2000) Nature.)

cells and cellular organelles. Enderle et al. have described the use of near-field scanning optical microscopy (NSOM) for mapping and detection of colocalized proteins within a cell, simultaneously and at high resolution [103]. The system of interest was that of human red blood cells invaded by the human malaria parasite *Plasmodium falciparum*. This parasite expresses proteins, during intra-erythrocytic growth, that are transported across the erythrocyte cell membrane and associate with the host skeletal proteins. Specifically, these colocalization studies of the protein pairs of mature parasite-infected erythrocyte surface antigen (MESA)(parasite)/protein 4.1 (host) and *P. falciparum* histidine-rich protein (PfHRP1)(parasite)/protein 4.1 (host) have been analyzed by dual color excitation and NSOM fluorescence detection. A thin blood smear of the trophozoite infected erythrocytes was fixed, then reacted with antibodies against PfHRP1, and labeled with tetramethylrhodamine (Fig. 2.63).

While all three cells are imaged in topography, only the one in the lower right corner was infected and is visible in the fluorescence image. The results imply that the malarial protein MESA interacts with erythrocyte protein in membranes of infected red blood cells, whereas PfHRP1 does not interact with protein 4.1.

### 2.7.8

#### Cantilever Arrays as Biosensors

The application of cantilever arrays to the detection of biomolecules may open the way to a new range of biosensors capable of detecting extremely low concentrations of the order of 10 nM of analytes. Figure 2.64 shows three sets of experiments [7].

Firstly, the effect of a base pair mismatch in oligonucleotide–oligonucleotide recognition was demonstrated (Fig. 2.64A). Here the difference between full complementarity and the single mismatch is clearly seen. The detection limit is demonstrated in Fig. 2.64(B), where decreasing concentrations of oligonucleotide were used. Given the differences between 12 mer oligonucleotides and proteins, it may be expected that even lower concentration limits can be attained with protein. Figure 2.64(C) demonstrates the use of a cantilever array for immunodetection. Here differential signals between a cantilever coated with protein A and a second one coated with BSA to allow removal of signals from non-specific binding were used. Some caution must be taken over the use of cantilever arrays as the microfabrication of such systems generally leads to arrays having different cantilever thicknesses and hence differing spring constants. Thus, much care is required to validate the reproducibility of the biosensors.

## 2.8

### Conclusion

This chapter has illustrated the various types of scanning probe microscopy available to the biological community. The examples presented in the section on using

**Fig. 2.63.** (a) Bright-field image of a blood smear; (b) result of NSOM imaging in topography (left) and fluorescence (right) ( $128 \times 128$  pixels,  $60 \text{ nm pixel}^{-1}$ ); (c) Zoom around the infected cell seen in the lower right corner of (b) ( $128 \times 128$  pixels,  $52 \text{ nm pixel}^{-1}$ ). The

fluorescence signal is superimposed as a color value (brightness scale goes from black via red to yellow) to the topography to show the distribution of PfHRP1 in the erythrocyte membrane. (Reprinted with permission from Ref. [103]. Copyright (1997) PNAS.)

the tools are there to stimulate interest in imaging biological systems, and to try and answer the question posed in the introduction. Why use scanning probe microscopies in biology?

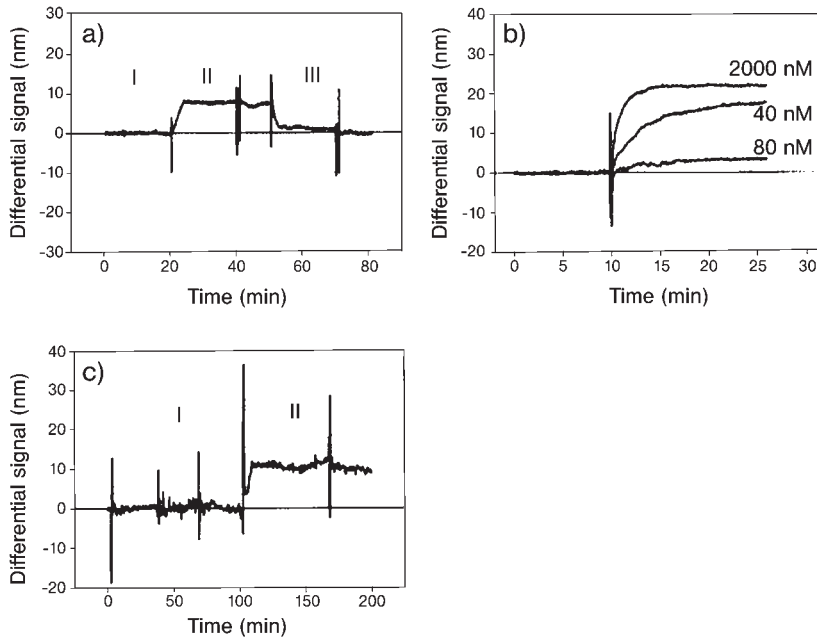

The final question is where do we go from here? The reply would seem to be towards integrated studies using SPM as one tool along with the wide panoply of other physical techniques to probe biological activity in its environment.

### Acknowledgments

We gratefully acknowledge JPK GmbH of Berlin for allowing us to use many figures from their handbook. We wish to thank the Fondation pour la Recherche Medicale for funding our AFM. S.C. thanks BioMerieux and A.N.L. thanks Delta Proteomics for financial support.

**Fig. 2.64.** (A) Differential signal of a hybridization experiment, showing detection of a single base mismatch in 12 mer oligonucleotides. Two cantilevers were functionalized with sequences differing only in one base: 59-CTATGTCAGCAC-39 (first oligonucleotide), 59-CTATGTAAGCAC-39 (second oligonucleotide). Injection of the first complementary oligonucleotide increases the differential signal (interval II); injection of the second complementary oligonucleotide decreases the differential signal (interval III). (B) Three successive hybridization experiments with different 12 mer oligonucleotide concentrations, using one array. The concen-

tration detection limit was calculated to be 10 nm, on the basis of a deflection noise of 0.5 nm. (C) Differential signal from a protein-protein interaction. One cantilever was functionalized with protein A and the other with BSA as a reference. First, as a negative control, buffer and then buffer containing goat IgG were injected. In both cases (interval I), no change of the differential signal was detected. In contrast, injection of rabbit IgG increased the differential signal by 12 nm within minutes (interval II). The signal persisted after the liquid cell was purged again with buffer. (Reprinted with permission from Ref. [7]. Copyright (2000) Science.)

## Quartz Crystal Microbalance Characterization of Nanostructure Assemblies in Biosensing

*Aren E. Gerdon, David W. Wright, and David E. Cliffler*

### 3.1

#### Introduction

The characterization of functional nanostructures is crucial in determining their efficacy for life sciences. Nanostructure design requires careful consideration of recognition units and material properties, while synthesis can be meticulous, but evaluation and characterization of the system is equally challenging and important. Nanostructure creation can not easily be deemed successful without analytical evaluation. Furthermore, it may not be used to its potential if it is not well defined and well understood. The design and development of analytical tools and techniques for nanocharacterization is, therefore, imperative. A widely-used and effective tool for structure assembly evaluation is the quartz crystal microbalance (QCM). QCM is a sensitive technique based on the propagation of evanescent acoustic waves, which are affected by adsorption processes as well as local changes in density and viscosity of the contact liquid. Real-time analyte adsorption is monitored through simultaneous measurement of the quartz crystal's resonant frequency of oscillation and the damping resistance caused by liquid loading. One of the paramount applications of QCM has been the study of adsorption of biomolecules on functionalized surfaces. It has also been used in various other applications and is particularly suited to the study of nanoscale materials [1]. This chapter addresses the principles and operational aspects of QCM (Section 3.1.1), followed by important QCM applications to the life sciences (Section 3.1.5). The importance of interfaces between biology and nanoscale materials will be discussed (Section 3.2) and will precede examples of QCM-nanoparticle sensors for chemical (Section 3.3), biological (Section 3.4), and immunological systems (Section 3.5).

#### 3.1.1

##### Principles of QCM

The quartz crystal microbalance relies on the converse-piezoelectric effect, reported by the Curie brothers in 1880. Piezoelectricity describes the electrical charge produced by pressure applied to solids having certain geometries, while the converse

**Fig. 3.1.** Top and side view of a QCM resonator (a and b) and cross sectional view of a QCM resonator in contact with a liquid (bottom). Wave propagation is relatively loss-less in the piezoelectric material, but becomes evanescent in the viscous liquid [7]. (Reprinted with permission the American Chemical Society.)

effect produces a strain on the crystal when an electric field is applied [2]. Coupling the crystal to an oscillating circuit provides crystal oscillation at a resonant frequency (Fig. 3.1).

These quartz resonators have been widely used in communication devices, commercial acoustic electronics, and sonar [2, 3]. Sauerbrey first demonstrated the usefulness of this effect for analytical chemistry by showing a linear relationship between mass deposited on the crystal and the frequency of oscillation [Eq. (1)] [1, 2].

$$\Delta f = -C_f \Delta m \tag{1}$$

Initially, QCM was used in the gas phase, where oscillator resistance is low and mass adsorption is rigid. The device was improved in 1982 by the advent of circuitry capable of crystal operation in liquids. While this advancement introduced QCM to the world of bioanalytical chemistry, it also introduced new difficulties. The first is that operation in liquid slows the mass transport of analyte to the sensor surface. The second is that many binding events in liquid, especially those biological in nature, are not static but tend to be in equilibrium. The third is resonator damping and viscous loading (Fig. 3.1). The density and viscosity of the contact solution affects crystal frequency response, convolutes mass measurements, and requires modification of the Sauerbrey equation [Eq. (1)] [2, 4]. Careful consideration of simultaneous mass and liquid loading by Kanazawa [5] and Martin [6] has shown that  $\Delta f$  relates to adsorbed mass and the density and viscosity of the contact liquid according to Eq. (2) [6].

$$\Delta f \approx C_f \Delta m - C_f (\Delta \rho \eta / 4\pi f_o)^{1/2} \quad (2)$$

It is, therefore, impossible to distinguish mass loading from liquid loading by frequency measurements alone. Fortunately, the independent term of liquid loading resistance,  $R_L$ , depends solely on density and viscosity [Eq. (3)] [6].

$$\Delta R_L \approx (\eta_q / [c_{66} C_1]) + (N\pi C_1)^{-1} (\Delta \rho \eta / \pi f_o c_{66} \rho_q)^{1/2} \quad (3)$$

Measuring both changes in frequency and resistance provides a means for decoupling mass and liquid loading effects, though different methods have been described [1, 2, 5–9]. Applying Eqs. (2) and (3) to frequency and resistance measurements to reliably calculate adsorbed mass has proven to be non-trivial. A simple approach to a reliable mass measurement has been to create a calibration curve of change in frequency as a function of change in resistance for a system in which mass loading is minimal. In one case, sucrose, a hydrophilic molecule that will not independently adsorb to the QCM electrode, was dissolved in DI water at 0, 5, 10, 20, and 40% by weight. Sequential addition of these five solutions to the QCM sensor provided simultaneous changes in frequency and resistance that were due to density and viscosity effects only (Fig. 3.2) [1]. The relationship between frequency and resistance within this range is linear and provides an accurate calibration. Above ~40% sucrose, the relationship deviates from linearity, making this approach only applicable to systems in which the resistance changes by less than 500  $\Omega$  [5, 10]. Problems also occur with this calibration, as in any QCM measurement, when coupling to the sensor is non-rigid and the analyte has its own viscous properties. Calibration allows for the calculation of  $\Delta m$  through simultaneously solving Eqs. (2) and (3) and using a sensitivity factor,  $C_f$ , of 56.6 Hz cm<sup>2</sup>  $\mu\text{g}^{-1}$ , which is known for a 5 MHz crystal [11]. Decreasing the crystal thickness increases the resonant frequency and can provide enhanced sensitivity.

Since his study of simultaneous QCM mass and liquid loading in 1991 [6], Stephen Martin from Sandia National Laboratory and collaborators at Leicester University have continued to contribute experimental and theoretical-based insight

**Fig. 3.2.** Practical QCM mass calibration using a non-mass loading system. Frequency and resistance changes mirror each other upon the addition of deionized (DI) water with (A) 0, (B) 5, (C) 10, (D) 20 and (E) 40% sucrose. Inset: linear calibration curve of change in frequency vs. change in resistance [1].

into the details of QCM measurement in liquids. Four contributions, since 1997, have covered resonator response to liquid loading [7], the modeling of resonator response under loading conditions [12], the modeling of viscoelastic film response [13], and a model for wetting characteristics of roughened surfaces [14]. This collective work has provided a better understanding of loading responses in QCM and has supported more rigorous evaluation of important systems.

Another area of QCM sensor development has been multi-channel QCM. Using arrays of resonators or micro-fluidics to partition individual resonators could provide the simultaneous measurements needed for multi-analyte detection strategies. A significant challenge in multi-channel QCM is the isolation of each electrode. Circuit shorting or resonance overlap from electrode to electrode could cause considerable problems. Two approaches to this problem have made use of electrode miniaturization [15] and the restriction of oscillation to indented areas surrounded by thicker quartz [16]. Both approaches have had success in the construction of a multi-channel QCM instrument.

### 3.1.2

#### QCM Wave Penetration Depth

QCM works well with 3D substrates and multilayer adsorptions often encountered in materials applications [1]. QCM acoustic shear waves are evanescent and decay exponentially in the contact liquid, causing a loss of sensitivity at distances from

the sensor surface (Fig. 3.1). Mass that is rigidly coupled to the sensor propagates the wave without loss, whereas viscous material causes immediate wave decay [8]. The depth at which these waves penetrate the contact liquid affects instrument sensitivity. QCM, at 5 MHz, has a calculated penetration depth of 250 nm [2], with a total decay length of 1  $\mu\text{m}$  [8], though experiments have shown no loss of sensitivity for layers as large as 400 nm [1, 8, 17, 18]. In comparison, surface plasmon resonance spectroscopy (SPR) has a calculated penetration depth of only 150 nm and has shown significant peak broadening with layers less than 200 nm [19, 20]. Examples of peak broadening in SPR come from the use of metal nanoclusters for signal amplification [21–23]. Antibody-presenting gold nanoclusters binding to immobilized anti-IgG increased the SPR shift as compared to free antibody [21, 22]. This also caused broadening of the SPR curve, which increased in width as the density or diameter of the colloidal gold was increased [23]. QCM has not suffered from this sensitivity loss, even at extensive adsorption [1].

### 3.1.3

#### QCM Sensor Specificity

A challenge in QCM, and in many biosensors, is sensor functionalization for improved specificity. While the gold QCM electrode imparts almost no specificity of its own, it provides a substrate for various functionalizations. The gold electrode is amenable to hydrophobic interactions, is well-suited for self-assembled monolayer (SAM) formation, and enables electrochemical surface reactions. Approaches to improve specificity in QCM have used SAMs [24–26], ionic interactions [27–30], electrochemical deposition [31, 32], and protein adsorption (Fig. 3.3) [33–35]. These methods allow for the immobilization of various biological species and nanostructures and permit various detection schemes. SAMs have been studied extensively [26, 36, 37] and feature a defined orientation, high aerial density, and programmability in the exposed head-group. They have recently been used for the covalent immobilization of oligosaccharides [24] and peptide epitopes [38].

Ionic layering, using polyelectrolyte [28–30] or SAMs with ionic head-groups [27], has allowed for effective immobilization and orientation of various nanoparticles. Though the interaction is generally non-specific, relying on electrostatic and van der Waals interactions, layer-by-layer growth is highly tunable according to concentration, ionic strength, and pH. This promotes high-affinity binding, reversibility, and high packing density, and has been used for single layer deposition and multilayer nanorainbow assembly [28, 30].

Electrode functionalization and nanoparticle immobilization has also been pursued with electrochemical deposition, using an electrochemical quartz crystal microbalance (EQCM). Viologens, such as *N*-methyl-*N'*-ethylamine-viologen dinitrate (MEAV), have been previously studied [32] as electroactive species and adhere to electrodes upon reversible reduction of the [viologen]<sup>2+/1+</sup> couple. Attachment of MEAV to nanoclusters allows similar adhesion to electrodes, thereby immobilizing the nanocluster on the QCM surface [31].

Another route employs Protein A for immobilization of antibodies in an accom-

**Fig. 3.3.** Examples of QCM functionalization techniques to impart specificity: (a) Self-assembled monolayers immobilize ligands in a high density, and often use poly(ethylene glycol) spacers. (b) A polyelectrolyte provides a thin layer of charge (positive or negative) for ionic interactions. (c) Viologen functionalized electroactive nanoclusters can be electrochemically deposited on the QCM surface. (d) X-ray crystal structure of a Protein A fragment commonly used in the immobilization of antibody [35].

modating conformation. Protein A is a cell wall protein that forms stable complexes with gold through van der Waals interactions ( $K_a \sim 10^8 \text{ M}^{-1}$ ) [33] and contains five tandem domains that bind the Fc region of IgG with high affinity and selectivity. These properties optimize the presentation of antibodies such that both antigen binding regions (Fab) are unobstructed (see also Figs. 3.4 and 3.6) [33–35].

#### 3.1.4

#### Calculation of Equilibrium and Kinetic Constants

An important advantage of real-time binding measurements is the ability to derive equilibrium binding constants and kinetic rate constants. These constants provide valuable information concerning the affinity or avidity of one material for another,

the rate at which they interact, and the interaction order. A molecule's affinity is defined through the equilibrium association constant ( $K_a$ ) for the interaction and is generally valid for monovalent, one-to-one interactions. Avidity is related to the same equilibrium process ( $K_v$ ), but describes multivalent processes. For example, at low ligand concentrations a multivalent ligand could bind to several monovalent receptors, increasing the affinity of the ligand for the receptor. There are also cases of multivalent receptors with monovalent ligands as well as multivalent receptors with multivalent ligands [39]. The complexity of these interactions can be daunting, especially for molecules like lectins that are designed for increased affinity through multivalency. The simplest case would be the interaction of a monovalent ligand (e.g., an antigen) with a monovalent receptor (e.g., a ScFv antibody):  $\text{Ag} + \text{Ab} \leftrightarrow \text{Ag-Ab}$ . The elementary equilibrium expression for the formation of the complex is [Eq. (4)],

$$K_a = [\text{Ag-Ab}] / ([\text{Ab}][\text{Ag}]) \quad (4)$$

where  $K_a$  is the equilibrium association constant and is generally in the range of  $10^6$  to  $10^{12} \text{ M}^{-1}$  for monoclonal antibody interactions, indicating a large equilibrium shift to product formation when antigen is in the presence of antibody. If this association and equilibrium shift occurs at a surface, where the first component adsorbs to the surface-supported second component, the equilibrium expression can be rearranged to an adsorption isotherm. The adsorption isotherm represents the connection between the amount of substance adsorbed, the concentration of the bulk solution, and the equilibrium constant,  $K_a$ . The Langmuir isotherm is commonly used and relies on three important assumptions: (1) there is no lateral interaction between adsorbed species; (2) the surface is homogeneous; (3) the maximum adsorption is saturation to a monolayer. Adsorption isotherms are sometimes written in terms of fractional coverage ( $\Theta$ ) or percent of monolayer formation. A generalized Langmuir isotherm in this form is given by Eq. (5).

$$\Theta / (1 - \Theta) = K_a C \quad (5)$$

For QCM studies, the fractional coverage is related to the change in mass ( $\Delta m$ ) and the initial concentration of surface immobilized antibody is related to the maximum change in mass ( $\Delta m_m$ ). Rearranging to solve for  $\Delta m$  provides a commonly used form of the Langmuir isotherm [Eq. (6)].

$$\Delta m = \Delta m_m [K_a C / (1 + K_a C)] \quad (6)$$

Plotting  $\Delta m$  as a function of bulk concentration ( $C$ ) shows a steep increase in adsorption that levels off with increasing concentration as a complete monolayer is achieved (Fig. 3.9d below). This line can be fit to nonlinear regressions, but does not provide a simple means for extracting the equilibrium constant. Instead a reciprocal plot can be used to obtain a straight line fit. There is more than one way to obtain a reciprocal plot by rearranging the Langmuir isotherm [Eq. (6)]. Two options are Eqs. (7) and (8).

$$\Delta m = -(K_a)^{-1}(\Delta m/C) + \Delta m_m \quad (7)$$

$$C/\Delta m = (\Delta m_m)^{-1}(C) + (\Delta m_m K_a)^{-1} \quad (8)$$

With Eq. (7),  $\Delta m$  is plotted against  $\Delta m/C$  and the inverse of the slope provides  $K_a$ . With Eq. (8)  $C/\Delta m$  is plotted against  $C$  and the  $K_a$  must be extracted from a combination of the slope and  $y$ -intercept. Both techniques have been used in the literature and provide reliable  $K_a$  [1, 24, 40–42]. Once the equilibrium association constant is known, it can be used to calculate both the fractional coverage at an infinite time point [ $\Theta_\infty$ , Eq. (9)] and the Gibbs free energy of adsorption [ $\Delta G_{\text{ads}}$ , Eq. (10)].

$$\Theta_\infty = C/(C + K_a^{-1}) \quad (9)$$

$$\Delta G_{\text{ads}} = -RT \ln K_a \quad (10)$$

This method offers a simple way to determine equilibrium constants for systems that generally follow the assumptions outlined for a Langmuir isotherm, though variations on the Langmuir isotherm can account for more complex systems.

Equilibrium association constants for antibody/antigen interactions can be determined in different ways, not necessarily involving real-time measurements. Kinetic information, however, requires time-resolved information. The rate at which an interaction takes place can be valuable in evaluating component efficacy. The time course for monolayer formation is given by Eq. (11).

$$\Theta(t) = [C/(C + K_a^{-1})]\{1 - \exp[-(k_f C + k_r)t]\} \quad (11)$$

According to Eq. (9),  $\Theta_\infty$  can be substituted in and the exponent can be simplified by calling  $(k_f C + k_r)$  equal to the time constant  $(\tau^{-1})$  [Eq. (12)],

$$\Theta(t) = \Theta_\infty[1 - \exp(-\tau^{-1}t)] \quad (12)$$

For a given concentration of the bulk solution ( $C$ ),  $\Theta(t)$  is related to  $\Delta m$  at a particular time and  $\Theta_\infty$  is related to the maximum change in mass [ $\Delta m_m$ , Eq. (13)],

$$\Delta m_t = \Delta m_m[1 - \exp(-\tau^{-1}t)] \quad (13)$$

Fitting Eq. (13) to each time point in the real-time adsorption binding curve yields the time constant. Knowing the concentration of the bulk solution allows the extraction of forward ( $k_f$ ) and reverse ( $k_r$ ) rate constants. The ratio of these kinetic constants is equal to the equilibrium constant ( $K_a = k_f/k_r$ ) and can be used for comparison with isotherm methods.

### 3.1.5

#### QCM Application to Life Sciences

The benefits of QCM and detailed functionalization strategies have allowed the study of many biological and chemical systems [2, 43]. An early and notable exam-

ple of a chemical study is the direct kinetic measurements of thiolate molecules self-assembling on two-dimensional gold surfaces [37]. This helped provide a foundation for QCM kinetic studies and was quickly followed by a kinetic study of anti-fluorescyl antibody binding to fluorescein lipids in Langmuir–Blodgett films [41]. The fluorescein hapten was coupled to lipids and mixed with unfunctionalized lipids to form a bilayer with ~5% fluorescein lipid. Through QCM measurements, monoclonal antibody was found to have an affinity ( $K_a$ ) in the range  $10^7$ – $10^8$   $M^{-1}$  and forward and reverse rate of reaction constants of approximately  $2 \times 10^5$   $M^{-1} s^{-1}$  and  $2 \times 10^{-3}$   $s^{-1}$ , respectively.

More recently, Zeng et al. conducted two immunoassay experiments using QCM [24, 44]. The first was a study of  $\alpha$ -Gal carbohydrate antigen as anti-Gal antibodies are of interest for therapeutics in xenotransplantation. Thiolated trisaccharides were immobilized on the surface of the QCM through the formation of a self-assembled monolayer and exposed to polyclonal anti-Gal antibodies, a lectin from *Griffonia simplicifolia*, and a lectin from *Marasmius oreades*. The antibody displayed the strongest binding, with a dissociation constant ( $K_d$ ) three orders of magnitude greater than either of the lectins. They concluded that this QCM approach is competitive with established label-free techniques [24]. The second immunoassay made use of single-chain fragment variable (ScFv) antibodies to increase the surface density of antigen binding sites (Fig. 3.4). The recombinant antibodies were genetically engineered to contain a linker arm and cysteine residue to ensure self-assembly in a defined orientation. Considering their size (27 kDa) and ease of engineering, they have a considerable advantage over Fab fragments or full-sized IgG for the detection of antigen. The ScFv antibodies were initially expressed and evaluated using SDS-PAGE and Western blot analysis. After immobilization on the QCM gold electrode, the monolayer assembly was verified electrochemically with cyclic voltammetry and electrochemical impedance. This confirmed surface coverage, but provided no information on antibody orientation. The ScFv rabbit anti-IgG antibody was successful in detecting rabbit IgG down to 1.1 nM, which is more than 7 times lower than that detected with an anti-IgG Fab fragment sensor. Another benefit of this system is the reversibility of IgG binding coupled with the

**Fig. 3.4.** (a) Single-chain fragment variable recombinant antibody with cysteine incorporated into the linker; (b) rabbit IgG; (c) interaction between immobilized ScFv and rabbit IgG. (Reprinted with permission from the American Chemical Society.)

stability of the ScFv monolayer to allow regeneration and reusability of the sensor [44].

A piezoelectric immunosensor has also been developed to detect aerosolized SARS-associated coronavirus [45]. Since the introduction of circuitry able to operate QCM in liquids, gas phase measurements have primarily been used in metal vapor deposition techniques, rather than biological studies. A functionalized QCM crystal could be used as a biological “nose” for the detection of aerosolized agents, such a coronavirus. In this example, polyclonal anti-SARS-CoV was presented on the gold QCM electrode through a specific Protein A intermediate. Antigen powder was then reconstituted in the saliva of a healthy volunteer and aerosolized in the presence of the sensor. The antigen bound quickly to the antibody and was detected at concentrations down to  $0.60 \text{ mg mL}^{-1}$ .

Many other interesting and pertinent biological systems have been studied, including the use of glycosphingolipids for detection of ricin [46], the use of high resonant frequency quartz crystals (39 to 110 MHz) for the detection of phages [47], and the study of annexin A1 binding to solid-support membranes [48]. A complete review of QCM applications to the life sciences is not the scope of this chapter, though other sources can be consulted for further examples [2, 43].

### 3.2

#### Interface Between Biology and Nanomaterials

Fundamental advances in chemistry and biology have allowed biotechnology and materials science to develop over the past decades. Biotechnology has attempted to emulate naturally occurring functional assemblies, from the double helix of DNA to the multi-subunit protein cage, ferritin, while material science has taken advantage of chemical methods for the miniaturization of functional devices. Further evolution of these disciplines into the emerging field of bionanotechnology depends on the successful development and evaluation of structurally well-defined interfaces that bridge biology and inorganic materials chemistry. Interdisciplinary collaboration between these fields will allow for improved biological components to generate new materials while advanced materials will be used to ameliorate biological problems [49]. The design, synthesis, and characterization of readily programmable, structurally well-defined biological interfaces for inorganic materials represent significant challenges for the realization of these goals.

Progress has been made towards the development of such interfaces, though many options have yet to be explored. Some encouraging synthetic attempts have used DNA, semiconductor-binding peptides, genetically-engineered viruses, and silica-precipitating peptides. Specifically, synthetic single-stranded oligonucleotides coordinated to nanoparticles have been shown to self-assemble with the appropriate complement to form higher ordered structures (Fig. 3.5a) [50]. Phage-display libraries have been used in the successful selection of 12-mer peptides that specifically bind to the 100 face of GaAs single crystals (Fig. 3.5b). Bivalent peptides of this nature could be used in the directed assembly of nanoscale components [51].

**Fig. 3.5.** Examples of successful interfaces between biology and inorganic materials: (a) TEM of 8 nm diameter Au nanoparticles connected to a 31 nm diameter Au nanoparticle through complementary strands of DNA [50]. (Reprinted with permission from the Royal Society of Chemistry.) (d) Electron micrograph of silica particles precipitated via a synthetic peptide [53]. (Reprinted with permission from the Royal Society of Chemistry.)

Recently, the iron-storage protein ferritin, which contains its own interface between biology and inorganic iron oxide, has been used as inspiration for the design of a genetically-engineered viral cage that can precipitate nanoclusters. The virus, cowpea chlorotic mottle virus, was engineered with HRE peptide epitopes on its surface and provided a template for the symmetry-directed synthesis of Au<sup>0</sup> nanoparticles (Fig. 3.5c) [52]. Another attempt at interfacing biology and inorganic materials has made use of a synthetic peptide based on silaffin from various eukary-

otic algae or diatoms. This peptide was shown to efficiently precipitate silica under mild conditions, mimicking diatom activity (Fig. 3.5d) [53]. These functional materials have enjoyed success in the assembly of nanoscale materials, but have not shown results for sensor applications. Still, they have succeeded at interfacing biology and inorganic materials and have served as inspiration for the subsequent design of sensor interfaces.

One biomolecular recognition method that has not been widely employed in the assembly of nanoscale materials is immunomolecular recognition. Immunoglobulin (IgG) antibodies have affinities (association constant,  $K_a$ ) on the order of  $10^6$ – $10^{12} \text{ M}^{-1}$  and have been well studied for sensor applications [54–57]. Applications of such immunoassays have had a tremendous impact on medical diagnosis and the treatment and understanding of disorders and diseases. Interfacing immunology and nanomaterials will expand these applications and provide potential for improvements on existing assays and treatments. There are several cases where immunology and inorganic materials have been successfully brought together to provide a ground work for further development.

Progress began with the non-specific immobilization of antibody on micron-sized, hydrophobic, latex beads [58–60]. Antigen binding to immunoreactive beads causes agglutination, which can be quantified by changes in solution turbidity [60]. Similarly, antibodies have been non-specifically immobilized on 11 nm diameter colloidal gold particles. These particles were used in traditional sandwich immunoassays, where the gold particle provided signal amplification when binding was detected with surface plasmon resonance spectroscopy (SPR) [21]. More recently, Nam et al. created an immunoassay using micron-diameter immuno-magnetic particles in conjunction with 13 nm diameter DNA/antibody derivatized gold clusters. Magnetization allowed for facile separation of agglutinated particle, while double stranded DNA provided an amplification avenue through polymerase chain reaction (PCR) [61]. Other strategies have used nanocluster/antibody interfaces as a means for multiplexing and amplification [62–64]. Another approach made use of a peptide epitope known to bind monoclonal antibody associated with the human malarial parasite, *Plasmodium falciparum*, and was the first example of antigen encapsulated nanoclusters assembling with antibodies through the antibody (paratope)/antigen (epitope) interface [65]. This important advancement appears to provide a robust, functional nanostructure that has the potential of successfully mimicking a biological entity. Together these interface-dependent techniques have suggested new routes for the study and detection of human IgG, prostate specific antigen, hepatitis B surface antigen, and the human malarial parasite.

### 3.2.1

#### Antibodies

Extraordinary binding affinities, ease of use, and relevance to medical disorders make antibodies attractive analytical reagents and recognition units for interfacing with nanoscale materials. The classic IgG immunoglobulin has a prototypical Y-shape made up of two heavy and light chains (Fig. 3.6). The antigen binding

**Fig. 3.6.** Cartoon structure of a typical IgG antibody, highlighting heavy and light chains joined by disulfides, a constant fragment (Fc), two fragments of antigen binding (Fab), and complementarity determining regions (CDRs).

site (paratope), within the Fab (fragment of antigen binding), is formed by the three-dimensional (3D) arrangement of the complementarity determining regions (CDR). In antibodies, this is the key region of immunorecognition and results in the proteins valency. Three different types of antibody preparations are in use for immunoassays: polyclonal, monoclonal, and single chain fragment variable (ScFv). Polyclonal antibodies (pAb) are generally collected from animals and result as a response to the injection of an antigen. They are produced by many different B lymphocytes and recognize different epitopes within the same antigen, resulting in a mixture of antibodies, with only a subset of total IgG recognizing the epitope of interest. Monoclonal antibodies (mAb), however, are produced in a colony of identical B cells. Each antibody binds to the same epitope and the mAb sample is homogeneous [54]. Single chain fragment variable (ScFv) antibodies represent the smallest functional domain of a traditional monoclonal or polyclonal antibody as they consist of one linked Fab domain [44, 66]. Phage-display recombinant antibody technology has produced high-quality, antigen-specific ScFv antibodies with affinities (binding strengths) comparable or greater than those of traditional antibodies [51]. This technique and these antibodies are particularly useful for antigens that are poorly immunogenic, readily degrade, or for which monoclonal or polyclonal antibodies are difficult to obtain. These three types of antibodies provide a range of options for interfacing immunology with nanoscale materials.

### 3.2.2

#### Nanoparticles

The interface between biology and inorganic materials has manifested in many different forms, covering the range of biological systems and the range of inorganic materials. Immunology has interfaced with many substrates, including two-dimensional (2D) surfaces [24, 38, 44], organic polymers [58, 60, 61], large metal particles [21, 65], semiconductor quantum dots [67], and small, ligand-capped

metal cores [1]. The interface of antibodies with each of these substrates has produced interesting functional materials, though ligand-capped noble-metal clusters (monolayer-protected clusters, MPC) have received attention for their unique consolidation of self-assembly techniques and metal nanoparticle chemistry [68–70]. Furthermore, their chemical, electronic, and physical properties, a lack of air and water sensitivity, and convenient characterization make them robust materials [65, 71–74]. Programmed specificity through the introduction of biologically relevant molecules is one of their most promising features and lends to the development of an immuno-interface [75, 76].

Synthesis and assembly of MPCs can occur through several routes, using various metals (Au, Ag, Cu, Pt, CdS, ZnS, Ag<sub>2</sub>S) [77], reductants (citrate, Na<sub>2</sub>S, NaBH<sub>4</sub>), and capping ligands (thiolate, disulfide, amine, imidazole, carboxylic acid, phosphine, iodine). Surfactants, templates, and physical methods (photochemistry, sonochemistry, radiolysis, thermolysis) have also been employed [78]. Conventional methods have primarily been based on the Brust–Schiffrin method, published in 1994 [79]. This was originally a two-phase synthesis with stabilization by organic soluble thiolates and reduction by NaBH<sub>4</sub> (Fig. 3.7a). This method was subsequently adjusted for the synthesis of water-soluble MPCs, which is generally a one-phase synthesis and follows a simple equation [Eq. (14)] [72].

Templeton et al. have reported the synthesis of water-soluble tiopronin [*N*-(2-mercaptopropionyl)glycine] MPCs  $1.8 \pm 0.7$  nm in diameter by this method. Characterization of these nanoclusters follows from traditional materials techniques, as previously described in depth [69, 72, 80]. Figure 3.7(b) and (c) shows examples of a transmission electron microscopy (TEM) picture and proton nuclear magnetic resonance spectroscopy (<sup>1</sup>H NMR) spectrum, respectively. Daniel et al. have recently published a more complete review of gold nanoparticle synthesis, characterization, and applications [78].

One of the most promising features of MPCs is their ability to exchange thiolate ligands with ligands in solution. This allows for the specific introduction of biologically active molecules, programmable specificity, and the synthesis of functional nanoclusters. In this way, nanoscale inorganic materials make potentially interesting solid supports for the immobilization and presentation of antibody or antigen, leading to a successful interface with an immunological system. Place exchange of free thiol onto 3D MPCs is a relatively facile process that is regulated by solvent, reaction temperature, reaction time, and properties and concentration of original and replacement thiol [75]. Investigation of the dynamics, kinetics, and mechanism of place exchange are abundant and generally support an associative, S<sub>N</sub>2 mechanism [75, 76, 81, 82]. Place exchange on MPCs has been compared to preceding studies of place exchange on 2D self-assembled monolayers. Exchange is more likely to occur on 3D surfaces (MPCs) than 2D surfaces (SAMs) due to the higher propensity for defect sites in structures with a substantial radius of curvature [36, 75, 83]. Another important feature of place exchange reactions is the

**Fig. 3.7.** Representative synthesis and characterization for a tiopronin (*N*-2-mercapto)propionylglycine)-protected cluster. (a) Synthesis conditions based on a modified Brust method and cartoon schematic of a monolayer-protected cluster (MPC). MPC ligands are connected through thiolate

moieties at one end and generally have a functional group at the opposing end (gray). (b) TEM image of MPC showing spherical shape and size dispersity. (c)  $^1\text{H}$  NMR of tiopronin MPC, showing broad  $-\text{CH}_3$  ( $\sim 1$  ppm) and  $-\text{CH}_2-/-\text{CH}-$  ( $\sim 3.5$  ppm) peaks. The water peak is at 4.8 ppm.

idea that fast-exchange sites are not static. Evidence for this has come from the exchange of several different ligands onto the same MPC [69, 76] and from an inability to completely remove ligand that had been previously exchanged on a cluster [75, 76]. A significant implication of these results is the ability of a thiolate to migrate across the monolayer of an MPC and position itself for an optimal interface [83].

There are many examples of successful place exchange and coupling reactions with organic and water-soluble MPCs, resulting in functional nanostructures. For example, Templeton et al. [76] used traditional amide coupling techniques to attach 12 different functional ligands to nanoclusters, introducing spin labels, amino acids, fluorophores, sugars, and electroactive moieties. Place exchange has also introduced fluorescein and an electroactive viologen species. Electrochemical quartz crystal microbalance of this MPC showed redox activity of the viologen as well

as deposition of the MPC upon viologen reduction [31]. Antimicrobial nanoclusters have been prepared by functionalization with vancomycin [84], glutathione-protected nanoclusters have been shown to interact with the enzyme glutathione transferase [85], and biotinylated nanoclusters bind to streptavidin [85]. This type of MPC functionalization produces nanostructures with specific activity and suggests potential for further nanocluster modulation in the design of bioreactive materials.

### 3.3

#### QCM Nanoparticle-based Chemical Sensors

The evaluation of interfaces between biology and nanotechnology has been an area of recent research interest, but originally started through the early development of chemical sensors. Originally, QCM was designed for gas-phase measurements and has been used in the control of metal vapor deposition. QCM continues to be used for gas-phase measurements, but has employed polymer and nanoparticle films for organic vapor sensing [86–88]. In 2001, dodecanethiol MPCs of 2 and 5 nm diameter were covalently assembled on a QCM substrate through dithiol linkages or non-covalently through carboxylic acid hydrogen bonding [86]. The nanoparticle thin-layers were then studied for their ability to partition toluene, hexane, methanol, ethanol, and water vapors. Vapor sorption was detected by simultaneous monitoring of frequency and resistance. Results suggested the viability of nanostructure films for vapor sensing and highlighted similarities and differences between the size of MPC used and the assembly technique.

Shortly thereafter, Zamborini et al. used electrochemical QCM to simultaneously measure conductivity and vapor partitioning in MPC films [87]. This approach used small (1.6 nm diameter) nanoclusters with mixed monolayers of alkanethiolate and  $\omega$ -carboxyalkanethiolate. The free carboxylic acid was used in conjunction with  $\text{Cu}^{2+}$  ions to assemble a network polymer of carboxylate- $\text{Cu}^{2+}$ -carboxylate bridges. These ion bridges allowed for electron transport through the polymer, though film swelling due to vapor partitioning (ethanol or dichloromethane) diminished electron flow.

Another example [88] made use of a greater variety of nanoclusters, protected with dodecanethiol, benzenethiol, 4-chlorobenzenethiol, 4-bromobenzenethiol, 4-(trifluoromethyl)benzenethiol, 4-hydroxybenzenethiol, and 4-aminobenzenethiol. Nanoparticle films were spray coated onto a QCM substrate and monitored by QCM to a final change in frequency of  $\sim 10\,000$  Hz. It was important to deposit a film with a thickness large enough to partition vapor, but small enough to rigidly couple the entire film to the sensor, maintaining an accurate sorption response. Motional resistance was monitored during film deposition to ensure rigidity as resistance is related to film viscoelastic properties. Results implied that different nanocluster films had increased sensitivity for different vapors (hexane, toluene, butanone, and butanol) and compared with vapor partitioning into organic polymers.

### 3.4

#### QCM Nanoparticle-based Biosensors

Inspired by the success of QCM bioassays (Section 3.1.5) and bionanotechnology, researchers have developed nanoparticle-based detection schemes using QCM for improved sensitivity. A popular area of analytical biochemistry involves the detection of DNA for a range of applications from gene analysis to forensic applications, where low detection limits are required. Willner et al. have developed three amplification paths for the detection of single-base mismatches in DNA with QCM detection [89–91]. Each path begins with the immobilization of ssDNA (25 bases) through SAM technology. Its complementary strand with an extra 16 bases is then introduced and allowed to base pair. In some cases a complement DNA strand with a single base-pair mismatch is purposely assembled. This allows for a single nucleotide, coupled with biotin, to bind at the mismatch site. At this point, three different approaches can be used: (1) free avidin can bind to the base-pair biotin, followed by biotin-labeled liposome binding; (2) avidin-labeled nanocluster can bind, followed by controlled nanoparticle growth for amplification; (3) avidin-labeled alkaline phosphatase can bind and catalyze the precipitation of an insoluble organic product for amplification. These methods lead to mismatch detection with detection limits ranging from  $10^{-12}$  to  $10^{-16}$  M<sup>-1</sup>. QCM gravimetry is well-suited for such precipitation/amplification schemes.

A similar approach to DNA hybridization detection and amplification also uses avidin-labeled alkaline phosphatase (as above). In this case, the enzyme catalyzes the production of the reducing agent, *p*-aminophenol, from a *p*-aminophenyl phosphate precursor. The reducing agent reduces Ag<sup>+</sup> ions in solution, which biomineralize into Ag nanoparticles on the DNA strand or on the QCM sensor surface, causing QCM signal amplification. The deposited silver can then be used in anodic stripping voltammetry to further confirm DNA binding, down to 100 aM concentrations.

Another example involves a glucose oxidase-based glucose sensor, which results from a complex nanostructure assembly. In this case, the QCM sensor was not used in the final analyte detection, but is a good example of the ability to assemble and monitor the assembly of complex nanostructures. First, polyethyleneimine (PEI) was immobilized, followed successively by 9–45 nm silica nanoparticles and PEI until several layers were assembled. This provided a roughened surface that allowed the immobilization and increased density of glucose oxidase enzyme. QCM was used to monitor these depositions and provided information for subsequent layer-by-layer construction on latex particles.

### 3.5

#### QCM Nanoparticle-based Immunosensors

The design, synthesis, and assembly of functional nanostructures are important challenges in the interface with immunology. Finding key recognition units and

presenting them in the appropriate environment and conformation are crucial to programming material specificity and affinity. A unique and creative idea for interface assembly may provide a good starting point, but redesign and optimization is difficult without a method for evaluating the proposed interface. The understanding of an interaction places interface development and application within reach. Traditional techniques have supplied qualitative information on antibody recognition for interface design and are widely used. Nanotechnology has expanded immunoassay options for the study of more diverse systems and, combined with QCM, provides a label-free, quantitative alternative. These analytical techniques can determine structural integrity of assembled nanoarchitectures, can provide equilibrium and kinetic binding constants of biological entities, and can detect analytes (antibodies, toxins, etc.) for medical diagnostic applications.

### 3.5.1

#### **Traditional Immunoassays**

Radiolabeled immunoassays were one of the first techniques used in the detection of antibody or antigen in biological systems. In this assay, radioisotopes, commonly  $^{125}\text{I}$ , were used to label the antibody or antigen, and scintillation counters measured the gamma or beta emission of the isotope. This provided the low detection limits needed for immunoassays, but regulation of radioactive isotopes made this technique inconvenient [92].

Another standard immunoassay is the enzyme-linked immunosorbent assay (ELISA). Its success comes from the ability to amplify binding through an enzyme reaction, which produces a spectroscopic signal. There are many formats for an ELISA experiment, though the indirect sandwich assay format has been widely accepted. In this format, the primary antibody is immobilized on a solid support (typically a well-plate) and antigen is allowed to bind. A second, polyclonal antibody for the antigen from a different species than that used as the primary antibody is then added and binds to the other side of the immobilized antigen, creating a "sandwich". An antibody that recognizes the second antibody (an anti-antibody) is functionalized with an enzyme (typically horseradish peroxidase) and allowed to bind. Finally, a substrate for the enzyme is introduced, which produces an enzyme product that is chromogenic. The chromophore is detected by conventional spectroscopic methods [57]. While the signal amplification from the enzyme reaction is beneficial, there are certain limitations to ELISA experiments. A lack of simple quantitation and excessive time required to assemble the complex immunomolecular biosensor, as in the case of an indirect sandwich assay, are poignant drawbacks. An example is the recent development of a quantitative ELISA assay for the detection of human IgG, which requires 19 hours from analyte immobilization to chromophore detection [93]. Other limitations include the need for labeling with a bulky enzyme, which could interfere with the antibody/antigen interaction, and the nonspecific adsorption of analyte to a hydrophobic well plate could lead to random orientation of binding sites and possible denaturation of substrate [57].

Surface plasmon resonance spectroscopy (SPR) has recently been used to detect

antibody binding. Details of SPR phenomena have been previously outlined [20, 94]. Briefly, SPR is an optical technique that takes advantage of plasmon excitation in bulk metal by wave vector matched photons. The photons induce oscillations of free electrons in the metal, which then propagate an additional field into the contacting dielectric medium. The plasmon excitation requires a transfer of energy from the photons, which can be observed through the sharp minimum of reflectivity during resonance, leading to an SPR signal [94]. Therefore, measuring the change in reflection angle provides real-time, label-free detection of antigen/antibody interaction. SPR has been used to study several different systems, an example being the characterization of FLAG peptide epitope arrays [38]. Important drawbacks of the SPR method are the complicated and expensive optics required for operation, loss of sensitivity at distances from the sensor, and interference from molecules with high molar absorptivity.

### 3.5.2

#### **Immunoassays using Nanotechnology**

Radiolabeling, ELISA, and SPR are important and effective techniques for the evaluation of traditional antibody/antigen interactions. Inorganic materials, such as nanoclusters, offer useful spectroscopic and microscopic properties that can make analysis convenient, but can also introduce added challenges. One of the first interfaces between materials and antibodies [58] was designed because radiolabel immunoassays were cumbersome and enzyme immunoassays require delicate procedures [59]. The potential of materials was harnessed to design a simpler method and successfully used antibody-functionalized latex beads and turbidity measurements to detect agglutination [58, 60]. Improvements to this method quickly followed, using electric pulses to promote antibody/antigen interaction and decrease reaction time [59].

A similar, though more recent, nanoimmunoassay also used antibody-functionalized particles. These 70 nm diameter silica particles had exterior antibody functionalization and interior fluorophore entrapment. Fluorescent-labeling techniques have enjoyed long-lived success, though low fluorescence intensity and photostability have been recurring problems. Encapsulation of  $\text{Ru}(\text{bpy})_3^{2+}$  fluorophore in silica nanoparticles yielded high intensity fluorescence and increased photostability due to exclusion of damaging oxygen [95]. These nanoparticles were compared to popular quantum dots (Qdots), which are semiconductor nanoparticles with intense intrinsic fluorescence, and were found to have similar intensity and stability. Antibody-functionalized Qdots have also been used as fluorescent tags for the imaging of live cells [67, 96].

Metal nanoparticles have been used as electrochemical labels for the simultaneous detection of four antigens,  $\beta_2$ -microglobulin, IgG, bovine serum albumin, and C-reactive protein [64]. In this experiment, a large magnetic bead was functionalized with four types of antibodies corresponding to the four different antigens. After binding antigen to the antibody on the magnetic bead, antibody with unique nanoparticle labels bound to the immobilized antigen. Collection of the

nanoparticle-labeled antibody and detection with square-wave stripping voltammetry provided four unique signals from the reduction of four unique metal nanoparticles [64].

A microscopic technique often used in nanocluster characterization, but not in immunoassay, is transmission electron microscopy (TEM). Metal nanoclusters absorb electrons, making them visible in TEM, while small carbon-based molecules do not. In a recent study, antibody-functionalized nanoparticles were incubated with pathogens *Staphylococcus saprophyticus* and *S. aureus* and examined with TEM. Functionalized nanoclusters bound to antibody binding sites and were detected. Furthermore, bacteria-bound magnetic particles were collected, thereby concentrating target pathogens [63].

Success with traditional immunoassay formats prompted SPR research in the area of nanoimmunotechnology. In 1998, Natan's group showed SPR signal amplification of antibody-nanocluster complex binding as compared to free antibody [21]. These results were confirmed with the detection of human complement factor 4 (C4) and C4 attached to colloidal Au particles [97].

These techniques, along with others, have had some success in the evaluation of interfaces between immunology and nanoscale materials. They also have their drawbacks. Many suffer from a lack of sensitivity and use large diameter particles (50–1000 nm) with relatively low surface area. Others rely on labeling to provide a detectable signal, which can interfere with recognition events and change the immunoassay dynamics. With SPR, nanoparticle labeling is used to acquire enhanced binding signals. Unfortunately, this also significantly broadens peaks, leading to a loss of sensitivity, complicated time-resolved measurements, and limited structural information [19, 20]. Efforts to develop a label-free, time-efficient, quantitative assay format that allows for 3D substrates and multilayer adsorptions have involved the quartz crystal microbalance (QCM) [1].

### 3.5.3

#### **QCM Nanoparticle-based Immunosensors**

Piezoelectric biosensors developed since 1990 have gained ground on traditional labeling experiments and on competing label-free instrumentation such as SPR [2, 98, 99]. The field of QCM immunosensors has also developed rapidly [43]. Considering the age of the new, though explosive, field of nanotechnology (the Brust nanoparticle synthesis was published in 1994), QCM immunosensors for nanotechnology applications are limited. One example used gold nanoparticle growth to amplify antibody-mediated lung carcinoma cell detection using QCM [100]. In these experiments a monoclonal antibody to cell surface antigen was immobilized on a polystyrene film and captured lung carcinoma cells. The same antibody conjugated to 10 nm diameter citrate-reduced gold nanoparticles bound to the immobilized cell in a typical sandwich scheme. Auric acid and  $\text{NH}_2\text{OH}$  were then introduced, reacted with the pre-existing gold nanoparticle, and caused the nanoparticle to grow. This growth created an increased QCM signal and allowed for the detection of cells at levels as low as  $100 \text{ cells mL}^{-1}$ . This method provided results similar to ELISA, but was less time consuming.

**Fig. 3.8.** Cartoon schematic of (a) nanocluster presenting antibody (antibody mimic) and (b) nanocluster presenting antigen (antigen mimic). Epitope antigens are generally smaller than antibodies and can be presented at a higher aerial density than antibodies.

Another example used polymer immobilized colloidal gold particles ( $\sim 15$  nm diameter) as an alternative approach to antibody immobilization [101]. Thiol-terminated Fab' antibody fragments will often denature on an unprotected hydrophobic gold QCM electrode, but retained activity when bound to the polymer/nanogold mixture. This nanoparticle-based immunosensor supplied a means for phenotyping leukemia cells for medical diagnostics with detection limits of  $6000$  cells  $\text{mL}^{-1}$ . An important technical detail of this work was the ability to detect four different phenotypes simultaneously using an array of QCM sensors. Other nanoparticle-based QCM immunosensors have made use of peptide epitope functionalized nanoclusters.

### 3.5.3.1 Antigen Mimic Design

There are two ways that functionalized nanoclusters can interface with immunology through paratope/epitope recognition: an antibody can be covalently attached to an MPC or an MPC can play the role of the antigen (Fig. 3.8). Antibody/nanocluster complexes have been previously studied as mentioned above. Briefly, immunoassays for human IgG have been developed using antibody bound latex beads [59, 60], signal amplification was observed with antibody bound gold nanoclusters in SPR immunoassays [21], and antibody bound magnetic microparticles have been used as capture agents [61]. There is further interest in using nanoparticle labeled antibodies as nanoprobables [102].

An alternative approach would be to attach an antigen to an MPC or functionalize an MPC with a peptide epitope (Fig. 3.8b). An epitope is the antigenic determinant of a protein and corresponds to the region of the protein that is specifically recognized by the antibody [103]. Accordingly, epitopes are only defined in an operational or functional sense: anything that is bound by an antibody is, by definition, an epitope. Therefore, epitope regions from proteins have been synthesized and expressed as smaller functional units and have been shown to bind antibodies. Examples of these would be the FLAG or E tags commonly used in expressed proteins [38, 44]. The current approach to this type of antigen mimetics is to synthesize the linear epitope and rely on primary structure (amino acid sequence) to

provide specificity. Combining this type of mimetics with nanoscale materials produced the first example of antigen encapsulated nanoclusters assembling with antibodies through the paratope/epitope interface. A linear peptide epitope known to bind monoclonal antibody associated with the human malarial parasite, *P. falciparum*, was used in the assembly of a robust, functional nanostructure that successfully mimicked a biological entity [65]. A more recent example used glutathione-protected nanoclusters and polyclonal anti-glutathione antibodies. This approach confirmed the ability to assemble epitope-protected nanoclusters with antibodies and provided quantitative binding information through improved analytical techniques [1].

These two examples used nanoclusters with peptide epitopes completely covering their surface and were synthesized with large amounts of the ligand, rather than specifically functionalized with small amounts of peptide. The next step in antigen mimic design was to functionalize pre-existing nanoclusters through place exchange reactions described above. This type of assembly provided a more complex nanostructure with three or more components and allowed for the use of more complicated linear and conformational epitopes. In a very recent study a linear peptide epitope, from the hemagglutinin (HA) protein related to influenza, has been synthesized and specifically presented at a controlled density on the surface of a pre-existing tiopronin-protected cluster [104]. This mimic of the HA protein was shown to interface with monoclonal anti-HA antibody and was compared to a self-assembled monolayer of the same peptide epitope.

Linear peptide epitopes used in the malaria, glutathione, and HA examples rely on primary amino acid sequence to provide antigenicity and specificity. This does not take into account the complex secondary structure (local conformation) exhibited by native proteins, which is essential to antibody recognition. Cyclization of peptides to approximate a loop structure has been used to introduce epitope conformation [105], but the development and presentation of a peptide epitope that reconstitutes a physiological conformation is an interesting alternative. This was recently achieved through the bidentate presentation of a peptide epitope from a loop region in the protective antigen (PA) of *B. anthracis* [83]. The conformational antigen mimic was able to interface with monoclonal anti-PA antibodies and showed a greater than two-fold increase in affinity over a linear antigen mimic.

This variety of antigen mimics using small molecule, linear, and conformational epitopes suggests multiple routes to interfacing inorganic nanoclusters with biological antibodies. Many other options are also available and, together, supply a “toolbox” of interfaces that can be used and studied in a multitude of systems. The three examples of GSH-MPC, HA-MPC, and PA-MPC are reviewed in further detail below.

### 3.5.3.2 Glutathione-protected Nanocluster

This research aimed to develop an immunoassay to study the test case of anti-glutathione antibody recognition of glutathione-protected nanocluster. The immunoassay was designed to be label-free, time-efficient, and quantitative and allow 3D substrates, multilayer adsorptions, and non-rigid biological recognition. QCM tech-

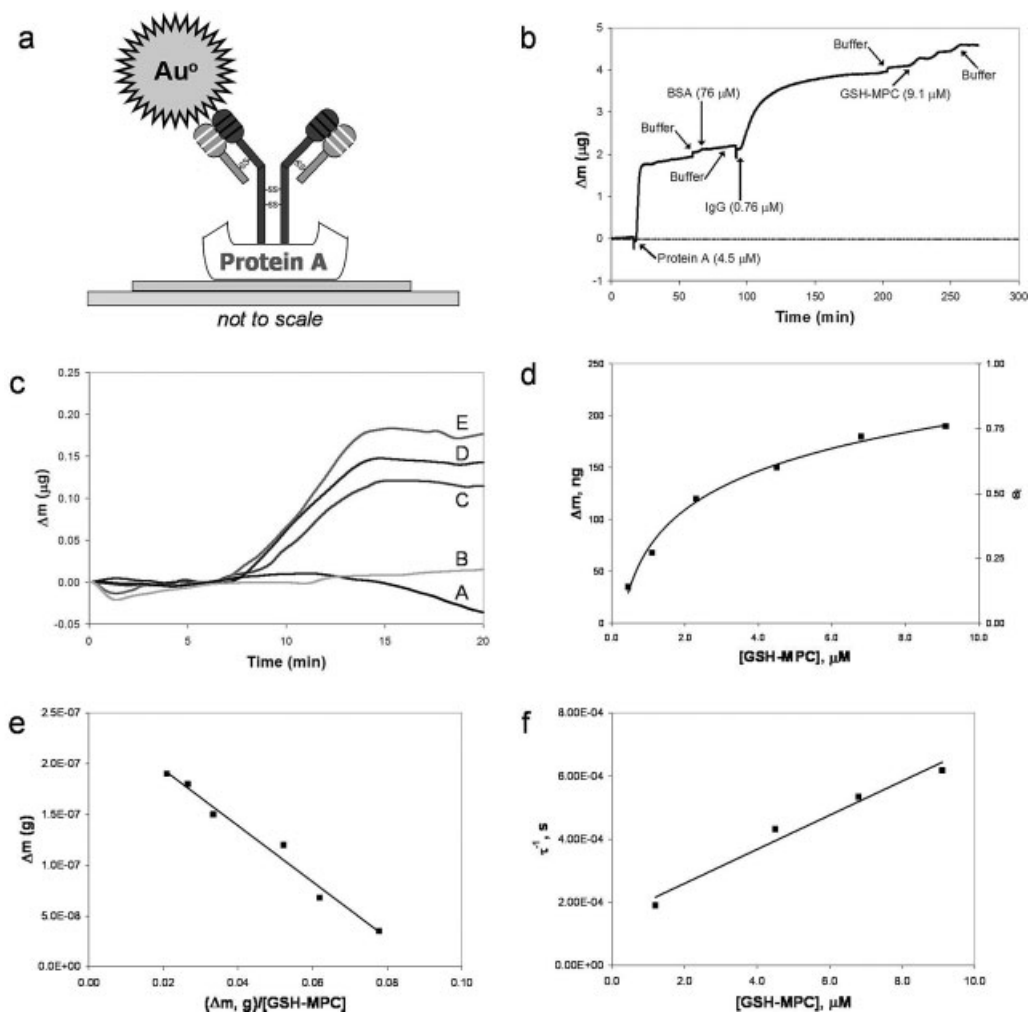

nology was used for many of the reasons previously mentioned, including high sensitivity, real-time detection, low cost, and a large wave penetration depth. Glutathione (GSH) monolayer-protected clusters (MPC) were used for their ease of synthesis, water solubility, high surface area and ligand valency, and the commercial availability of polyclonal anti-GSH antibody. Both GSH and tiopronin (Tiop), a glycine derivative and truncate of the GSH tripeptide, nanoclusters were synthesized according to a modified Brust method and characterized. The GSH-MPC had an average diameter of  $3.7 \pm 1.2$  nm, average composition of  $\text{Au}_{953}\text{GS}_{199}$ , and average molecular weight of 220 kDa.

The immunosensor consisted of the gold QCM electrode, Protein A, bovine serum albumin (BSA), and polyclonal anti-GSH antibody (Fig. 3.9a). Protein A was used to conveniently immobilize the antibody on the sensor surface in a defined orientation and BSA was used to block any exposed gold that might contribute to non-specific binding. Protein A bound to the gold electrode as a multilayer, BSA binding was minimal, and IgG bound specifically to Protein A, completing the immunosensor assembly (Fig. 3.9b). One drawback of this immunosensor design is the lack of reversibility and the need to reassemble the immunosensor structure before each experiment.

Analyte, GSH-MPC, was detected in a dose-dependent manner that was designed to limit non-specific adsorption and aggregation. Samples of different concentration were introduced to the immunosensor in short (5 min) doses and provided changes in mass that fit a logarithmic curve, revealing saturation of the immunosensor (Fig. 3.9d). This showed that the antibody was able to recognize the glutathione tripeptide epitope presented on the surface of a nanocluster. Furthermore, control experiments showed a lack of antibody binding to Tiop-MPC, suggesting antibody recognition of the  $\gamma$ -glutamic acid portion of GSH as opposed to the glycine portion (Fig. 3.9c). Equilibrium and kinetic constants for polyclonal anti-GSH antibody binding to GSH-MPC were calculated from Langmuir isotherm fits (Fig. 3.9e) and from individual binding curves (Fig. 3.9c and f). The equilibrium association constant,  $K_a$ , was found to be  $3.6 \pm 0.2 \times 10^5 \text{ M}^{-1}$ , the rate of forward reaction,  $k_f$ , was  $5.4 \pm 0.7 \times 10^1 \text{ M}^{-1} \text{ s}^{-1}$ , and the rate of reverse reaction,  $k_r$ , was  $1.5 \pm 0.4 \times 10^{-4} \text{ s}^{-1}$ . These values are reasonable, considering the use of polyclonal antibody. These results confirm the usefulness of a QCM immunosensor and suggest that epitope-presenting nanoclusters can be immunoreactive materials.

### 3.5.3.3 Hemagglutinin Mimic Nanocluster

Hemagglutinin (HA) and neuraminidase are two virus glycoproteins that are responsible for influenza infection and are targets for antibody neutralization. A peptide epitope-presenting nanocluster was designed to mimic one aspect of HA (Fig. 3.10a) and a QCM immunosensor was developed to examine the interface between monoclonal anti-HA and the HA-MPC. The peptide spanning amino acids 98–106 in the protein amino acid sequence (sequence: YPYDVPDYA) have been involved in influenza vaccine studies [106, 107]. The HA mimic was assembled by specific presentation of the synthetic peptide epitope on the surface of a pre-formed Tiop-

**Fig. 3.9.** (a) Cartoon schematic of immunosensor assembly using Protein A. (b) Representative total immunosensor assembly showing Protein A binding, BSA blocking, IgG capture, and MPC detection. (c) Binding curves (A) 1 mM free GSH, showing mass stripping; (B) 4.1  $\mu\text{M}$  tiopronin-MPC; (C) 2.3

$\mu\text{M}$  GSH-MPC; (D) 4.5  $\mu\text{M}$  GSH-MPC; (E) 9.1  $\mu\text{M}$  GSH-MPC. (d)  $\Delta m$  vs. [GSH-MPC] with logarithmic fit, showing saturation of the biosensor. (e) Linear Langmuir adsorption isotherm. (f) Adsorption kinetics. (Reprinted with permission from the American Chemical Society.)

MPC through place exchange reaction. This produced a three-component system consisting of  $3.5 \pm 1.0$  nm colloidal gold, tiopronin ligand, and HA peptide, with a final composition of  $\text{Au}_{807}\text{T}_{242}\text{HA}_4$ . A QCM immunosensor was then used in the evaluation of the interface between HA-MPC and anti-HA antibody.

In this immunoassay, a different assembly technique was used than for the

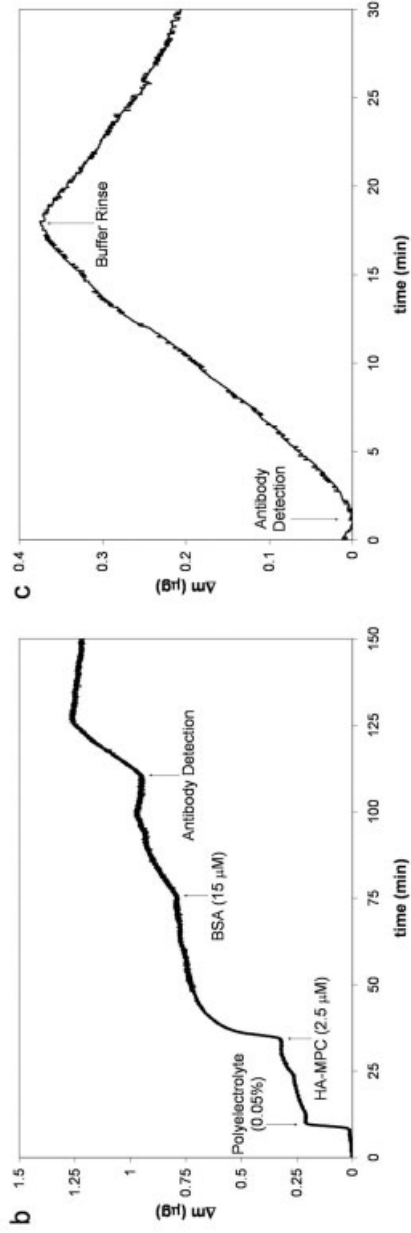

preceding GSH-MPC experiments. This approach made use of ionic interactions to immobilize the nanocluster and detect antibody binding. One reason for using this approach was the available option of analyzing complex samples containing one more antibody and various other components. The immunosensor consisted of the gold QCM electrode, a positively charged polyelectrolyte [poly(diallyldimethylammonium chloride)], nanocluster, and BSA (Fig. 3.10b). Polyelectrolyte had been previously used in the multi-layering of quantum dots and provided a thin layer of positive charge on the surface of the QCM. Negatively charged HA-MPC bound non-specifically and was immobilized for antibody binding. Before analyte was introduced, BSA was used to block non-specific polyelectrolyte binding sites (Fig. 3.10b). Again, a limitation of this immunoassay approach is the lack of reversibility and the time required to reassemble the sensor before each experiment.

This immunosensor was used for two applications, the first being an examination of antibody binding as related to the density of peptide presented on the Tiop-MPC. Three nanoclusters with 4, 11, and 33 peptides per cluster were examined and suggested that the lower density of peptide allowed the highest ratio of antibody to peptide interaction. The second application was a thorough study of the antibody interface with the HA-MPC displaying four peptides per cluster. Samples with different concentrations of antibody were introduced to the sensor in dose amounts and produced changes in mass that fit a logarithmic curve and showed saturation of the biosensor. This suggested that the antibody did recognize the peptide epitope specifically presented on the surface of a nanocluster. Control experiments using Tiop-MPC presenting no peptide showed a lack of antibody binding, signifying the specificity of the antibody for the epitope. Preliminary calculations have suggested an equilibrium binding constant ( $K_a = 1.0 \pm 0.3 \times 10^7 \text{ M}^{-1}$ ) and kinetic rate constants ( $k_f = 5.1 \pm 0.6 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$  and  $k_r = 9.4 \pm 0.7 \times 10^{-2} \text{ s}^{-1}$ ) for the association of anti-HA and HA-MPC.

These results were compared to traditionally used peptide epitope arrays. Self-assembled monolayers (SAMs) consisting of tiopronin ligand and mixed-monolayers of both peptide and tiopronin were formed on the QCM gold electrode. Antibody was introduced to the mixed-monolayer peptide array in dose amounts and bound in a manner similar to that seen with the functionalized nanocluster (Fig. 3.10c). Preliminary equilibrium association constant ( $K_a = 4.1 \pm 0.7 \times 10^6 \text{ M}^{-1}$ ) and kinetic constants ( $k_f = 1.4 \pm 0.2 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ ,  $k_r = 3.5 \pm 0.2 \times 10^{-2} \text{ s}^{-1}$ ) were calculated and compared to those for the antigen mimic HA-MPC. The  $K_a$  for the nanocluster is more than double that for the SAM, indicating a more accurate reconstitution of the peptide epitope on the surface of the MPC.

#### 3.5.3.4 Protective Antigen of *B. anthracis* Mimic Nanocluster

This study [83] made use of a QCM immunosensor, four independently functionalized nanoclusters, and monoclonal antibodies to effectively map one antibody clone to one peptide epitope. Not only did the identified antibody distinguish between three different peptide epitopes from the protective antigen (PA) of *B. anthracis*, it had an increased affinity for a conformational epitope as compared to a linear version with the same amino acid sequence. Epitopes from PA were used for

**Fig. 3.10.** (a) Schematic of a HA peptide epitope-functionalized MPC (not to scale). (b) Representative total immunosensor assembly, showing polyelectrolyte and MPC binding, BSA blocking, and antibody detection. (c) Representative antibody detection using HA/tiopronin SAM.

four reasons: (1) epitopes had been previously identified through various mapping techniques; (2) PA has been a target for immunological studies, as anti-PA antibodies confer immunity to anthrax; (3) PA has both conformational and linear epitopes; (4) anthrax has been identified as a potential bioterrorism agent. Identified PA peptide epitopes [108–111] span amino acids 680–692 (PA680), 703–722 (PA703), and 730–735 (PA730) in the intact protein, and were each synthesized for use in antigen mimic design. The functional nanostructures were assembled by specifically presenting conformational or linear epitopes on the surface of pre-existing Tiop-MPCs through place exchange reactions. Four antigen mimics had final peptide densities of 4 (PA680B, conformational), 4 (PA680M, linear), 8 (PA703B, conformational), and 10 (PA730M, linear) peptides per MPC. A cartoon schematic of PA680B-MPC and the crystal structure of PA [109] are given in Fig. 3.11(a). Labeling experiments suggested the bidentate attachment of loop epitopes to MPCs, implying the formation of conformational antigen mimics. Increased antibody affinity for the conformational over the linear epitope provided a strong case for faithful reconstitution of the loop structure.

The QCM immunoassay used ionic interactions for the immobilization of MPC, similar to that used with HA-MPC (Section 3.5.3.3). Polyelectrolyte acted as an intermediate between the gold electrode and the MPC for successful immobilization (Fig. 3.11b). Again, BSA was used to block non-specific binding sites. This immunosensor assembly was used for two different studies, the first being the screening of seven monoclonal anti-PA antibodies against the four antigen mimics. The antibodies were known to bind the full-sized 83 kDa PA protein, but had not been tested for neutralization ability [112]. Screening provided qualitative binding information and pointed to one antibody as being specific for the conformational antigen mimic, PA680B-MPC. The magnitude of antibody binding as a function of antibody concentration was the second system studied. Antibody did not bind to PA703B-MPC or PA730M-MPC, but PA680B-MPC ( $K_a = 5.9 \pm 0.7 \times 10^6 \text{ M}^{-1}$ ) and PA680M-MPC ( $K_a = 2.6 \pm 0.9 \times 10^6 \text{ M}^{-1}$ ) were evaluated to obtain equilibrium association constants. Both were also evaluated in buffer of high ionic strength. In this system, PA680B-MPC had a  $K_a$  similar to that previously reported, though PA680M-MPC showed no binding. Kinetic studies of antibody binding for PA680B-MPC yielded forward and reverse reaction rate constants of  $9 \pm 2 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$  and  $2.3 \pm 0.5 \times 10^{-3} \text{ s}^{-1}$ , respectively. Free peptide (amino acids 680–692), unencumbered or unconstrained by nanocluster or protein scaffold, showed only non-specific binding to the antibody. In this immunoassay, anti-PA antibody was immobilized using Protein A, as previously described (Section 3.5.3.2), and free peptide was introduced. This implies that the peptide epitope was presented in a more accommodating conformation on the surface of the MPC, as opposed to being free in solution.

These results point out that peptide epitopes and monolayer protected nanoclusters can be brought together in the successful assembly of an immunoreactive material and be interfaced with biological antibodies. They also show the screening and effective mapping of an antibody to a peptide epitope, as well as differentiation between conformational and linear presentation.

### 3.6 Conclusions and Future Directions

The future of bionanotechnology lies at the interface between biology and inorganic nanomaterials and relies on the ability to probe and evaluate that interface. Many analytical techniques outlined in this chapter, including AFM, TEM, NMR,

and molecular imaging, have been developed for this very purpose, for the analysis of all types of interfaces. The quartz crystal microbalance is another technique that has evolved to become a central tool in the study of both biological and nanomaterials applications. QCM has principal advantages for the investigation of bionanotechnology over existing immunological techniques: low cost and ease of operation, quantitation, real-time measurements, and large wave penetration depth, to name a few. For these reasons QCM technology has been applied to the exploration of various life science applications. QCM nanoparticle-based immunoassay is a relatively new field, but has been designed for the evaluation of several antigen mimics. Specifically, QCM has shown that antibody can recognize and interface with immunoreactive nanomaterials designed with linear and conformational peptide epitopes presented on the surface of monolayer-protected clusters. This is only one interface that QCM has successfully characterized. Given the virtues of this technique and the vast number of possible combinations between biology and nanotechnology, more systems will doubtlessly be studied.

The prospects of biotechnology and nanomaterials science are most promising at their interface, where they overlap in the emerging field of bionanotechnology. This interfacial discipline further relies on analytical techniques that can probe the boundary where they meet. The quartz crystal microbalance is certain to be an integral tool in the exploration of this frontier. Specifically, QCM can expand its applicability through the design of new immobilization strategies for repeated, reversible interactions. An improved, commercially available, multichannel detection apparatus will improve throughput and multiplexing. In the realm of medical diagnostics and defense-based toxin detection, a blood sample, water-way, or gaseous area could be largely characterized through multi-analyte detection. This is possible because of the portability, low cost, and ease of use of existing QCM instruments and potential devices. Furthermore, advances in nanotechnology and improved understanding of biology will produce smart sensors and functional devices capable of carrying out an environmental analysis or capable of modulating an environment. Continued research on advanced nanomaterials in a biological paradigm using an effective QCM transducer can make this a reality.

### Symbols

- A      area of the QCM electrode
- [C]    concentration of a bulk solution
- [C]<sub>0</sub>   initial concentration, initial concentration of surface immobilized analyte

$C_1$	motional capacitance of the unperturbed crystal
$c_{66}$	piezoelectrically stiffened quartz elastic constant
$C_f$	Sauerbrey sensitivity factor, $2f_o^2/A(c_{66}\rho_q)^{1/2}$
$f_o$	frequency of crystal in air (unperturbed) (Hz)
$k_f$	forward kinetic rate constant
$k_r$	reverse kinetic rate constant
$N$	overtone number
$R$	gas constant ( $8.3145 \text{ J K}^{-1} \text{ mol}^{-1}$ )
$R_L$	loading resistance
$T$	temperature (K)
$\Delta f$	change in frequency (Hz)
$\Delta G_{\text{ads}}$	Gibbs free energy of adsorption
$\Delta m$	change in mass (g)
$\Delta \eta$	change in viscosity
$\Delta \rho$	change in density
$\eta_q$	effective quartz viscosity
$\Theta$	fractional coverage of a surface by a species
$\Theta_\infty$	fractional coverage at infinite time
$\rho_q$	quartz mass density
$\tau^{-1}$	kinetic time constant, equal to $k_f C + k_r$

## 4 NMR Characterization Techniques – Application to Nanoscaled Pharmaceutical Carriers

*Christian Mayer*

### 4.1 Introduction

The use of nanoparticles for biomedical applications has been widely discussed in recent years. Among their wide variety, organic nanoparticles in stable aqueous dispersions are most promising candidates for pharmaceutical carrier systems. Controlled release and drug targeting are the main issues motivating their development [1–6]. In many cases, the preparation of these dispersions is quite straightforward, even on a technical scale. However, the analysis and detailed characterization of nanoparticle systems still represent a considerable challenge for common analytical methods. Most problems are connected to the fact that the particle structures are evidently nanoscopic, sensitive to many types of sample preparation techniques and often represent inhomogeneous and quite complex systems. Different approaches of transmission and electron microscopy can be applied successfully, but are often complicated by the necessity of tedious sample preparation. Atomic force microscopy is an important tool for studies on the particle assembly, but, as for electron microscopy, this method asks for isolated particles on a surface, a condition that may easily induce the formation of artifacts and destroy sensitive structures.

With the desire to analyze the particles in their “natural habitat”, the liquid dispersion, researchers are left to choose from a selection of spectroscopic methods. While most spectroscopic measurements do not differentiate between solid and liquid components, i.e., the particles and the surrounding or encapsulated liquid, nuclear magnetic resonance spectroscopy is a notable exception. Its unique ability to simultaneously detect chemical structure together with the lateral and rotational molecular mobility of every single system component makes it perfectly suitable for the study of particle dispersions [7–15]. This particular advantage of NMR spectroscopy is especially helpful in studying pharmaceutical carrier systems [16–22]. As most NMR methods are run under extremely mild physical conditions, measurements on nanoparticle dispersions may be extended over long periods under a wide variety of chemical and thermal influences. This allows for long-term time-resolved observations and opens up the possibility for continuous monitoring of

slow release and degradation processes. In most cases, the influence of the NMR measurement on the particle system can be completely neglected. The main disadvantage of NMR spectroscopy, its significant lack of sensitivity, is compensated by increasing the particle concentrations or sample volumes.

Clearly, NMR is not a routine technique for process or quality control and will always require special equipment and experimental skills. However, it may play a key role for the development and design of nanoscaled pharmaceutical carriers. Unlike any other single method, it yields comprehensive data on the structure and the function of these systems under a large variety of conditions. The combination between high resolution and solid-state NMR together with the application of pulsed field gradient (PFG) turns out to be especially promising. The experimental techniques are quite straightforward and can be performed on standard commercial NMR spectrometers. Analysis of the resulting data is often complicated by the fact that slow rearrangements on the nanometer scale, e.g. rotational diffusion of the particles, affect line shapes and require numerical simulation of the spectra. However, these phenomena offer the chance to study motions on the microsecond scale such as particle tumbling. Thus, NMR becomes a valuable tool for the time-dependent observation of processes like particle degradation or agglomeration.

In the following, examples are presented that demonstrate the power and versatility of NMR spectroscopy in its application to nanoparticle dispersions. They include studies on basic particle characteristics such as the nanoparticle structure, phase transitions of the particle matrix, exchange processes on the particle surface, permeability of nanocapsule walls, release and particle degradation. Analysis of the NMR data is performed using adapted simulation procedures based on rotational and lateral diffusion of nanoparticles and their individual system components.

## 4.2 Structural Analysis of Nanoparticles

The unique power of NMR spectroscopy lies in its ability to simultaneously detect the chemical nature and molecular mobility of individual chemical components in a complex system. Identification of the chemical composition of a substance in the liquid or solid phase is a well-known feature of NMR and is practiced on a routine basis. With solid components, it requires solid-state techniques, with magic-angle spinning (MAS) as the most prominent representative. In addition, broad line NMR techniques and relaxation measurements have been applied for the analysis of rotational molecular mobility. Recently, commercial NMR instruments have also acquired the capability of detecting lateral motion, a method that generally combines classical echo sequences with pulsed magnetic field gradients. All three approaches may be successfully combined for studies on dispersed nanoparticles.

In a spectrum of a static sample, all solid constituents (like the particle matrix and capsule walls) are easily identified by their wide spectral lines, whereas all liquid and dissolved components yield relatively narrow signals due to their

**Fig. 4.1.** Comparison of a directly excited  $^{13}\text{C}$  spectrum of dispersed poly-n-butylcyanoacrylate nanocapsules (A) with the corresponding spectra of dissolved surfactant (B), of liquid triglyceride (C) and of a solution of the monomer used for capsule formation (D) [8].

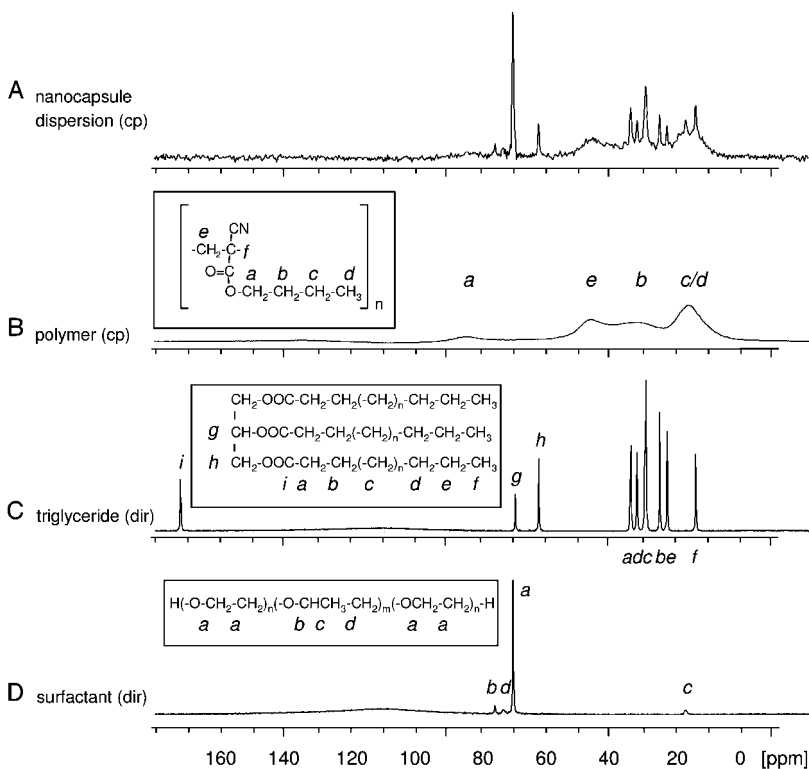

Capsule spectrum A shows no traces of the resonances of spectrum D (arrows), proving the absence of any residual monomer after capsule formation. For assignment of the signals see Fig. 4.2.

rapid isotropic rotational diffusion. Due to their spectral widths, the signals of the solid components usually appear at very small amplitude and often remain undetectable.

Figure 4.1(A) shows an example of a directly excited  $^{13}\text{C}$  spectrum of dispersed nanoparticles. It was obtained on an aqueous dispersion of poly-n-butylcyanoacrylate nanocapsules, a capsule system where the liquid core is formed by a commercial triglyceride (Miglyol®) and which is stabilized by a block-copolymer surfactant (Synperonic F68®) [9, 23–25]. The spectrum lacks all traces of the polymer forming the solid capsule walls, but clearly shows all liquid and dissolved components [8]. A comparison with reference spectra of the individual system components (Fig. 4.1B and C) allows for the identification of all capsule constituents in the liquid phase. The complete absence of the monomer signals (spectrum D in Fig. 4.1) proves the completion of the polymerization process dur-

ing capsule formation. The increased line widths in the presence of the capsules are assigned to partial immobilization of molecules on the capsule surface and the local inhomogeneity of the magnetic field.

To enhance the spectral contribution of the solid material, the  $(^1\text{H})$ - $^{13}\text{C}$  cross-polarization (cp) technique may be applied, which strongly amplifies signals from molecules with slow tumbling mobility [8, 17, 26] and therefore allows for the simultaneous observation of all constituents. The resulting  $(^1\text{H})$ - $^{13}\text{C}$  cp spectrum of the dispersion clearly shows relatively narrow signals superimposed on the characteristic wide line of the solid polymer (Fig. 4.2A). The broad contribution to the capsule spectrum is reproduced by a cp solid-state spectrum of a bulk sample of poly-n-butylcyanoacrylate (Fig. 4.2B). The positions of the narrow lines of the cap-

**Fig. 4.2.** Comparison of a  $(^1\text{H})$ - $^{13}\text{C}$  cross-polarization spectrum of dispersed poly-n-butylcyanoacrylate nanocapsules (A) with a corresponding spectrum of bulk solid poly-n-butylcyanoacrylate (B) and directly excited  $^{13}\text{C}$ -spectra of liquid triglyceride (C) and of an aqueous solution of the surfactant (D). All system components (B–D) are detectable in

the capsule spectrum A; their line widths depend strongly on their phase state (see text). The carbonyl signal of the triglyceride (signal *i* in spectrum C) and two carbon signals of the polymer remain invisible in cp spectra A and B due to lack of hydrogen at these positions. Signal assignments are given in the inserts.

sule spectrum are in good agreement with those of reference spectra of the liquid oil phase and the dissolved surfactant (Fig. 4.2C and D). Again, an increase in line width is detected in the presence of the capsules.

Clearly, identification of the solid components is difficult given the low resolution of the corresponding wide signals. Spectral amplitude and resolution can be improved significantly using sample spinning conditions such as magic-angle spinning (MAS), which has been widely used for bulk samples of solid polymers [27–29]. For particle dispersions, one generally faces the problem that a typical sample spinning process induces a gravitational field similar to the conditions of a centrifugation experiment [7]. However, if the dispersion is sufficiently stable, or the density of the particles is matched to the density of the liquid phase, the method can be applied to particle dispersions [7, 18].

Figure 4.3 shows an example for a sample-spinning experiment on a nanosized carrier system [18, 30]. The spectrum was obtained on an aqueous dispersion of

**Fig. 4.3.** Top: Result of a sample-spinning experiment of an aqueous dispersion of cetyl palmitate nanoparticles (SLN) obtained under direct excitation on  $^{13}\text{C}$  nuclei. The sample was spun at a rate of  $\omega_r/2\pi = 1660$  Hz and at an angle of  $52.5^\circ$ , which deviates from the magic angle. Signals A–C can be assigned to the central methylene, end methylene and end

methyl groups, respectively. Due to incomplete relaxation, the integrals of the signals do not reflect the corresponding number of nuclei. Bottom: comparison between signal line shapes A–C and their simulated fits based on the expected rotational diffusion of the particles.

solid lipid nanoparticles (SLNs) that consist of cetyl palmitate nanospheres with diameters between 100 and 200 nm [31]. Sample spinning was performed at a spinning rate of  $\omega_r/2\pi = 1660$  Hz and at an angle of  $52.5^\circ$ , which differs slightly from the magic angle ( $54.74^\circ$ ). Under these conditions, one obtains sufficient resolution for the assignment of the signals to the central methylene, end methylene and end methyl groups (signal A, B, and C, respectively, in Fig. 4.3). At the same time, the deviation from the magic angle leads to a characteristic variation of line shape that depends on the rate of rotational diffusion of the particles [18, 30]. Thus, the chemical composition of the particles can be studied together with their rotational diffusion. However, the influence of isotropic tumbling on signal line shapes is not at all straightforward. Analysis of the effect on the NMR spectrum requires a numeric simulation procedure that has been developed based on a finite element scheme: the time axis as well as the orientation in space is segmented into a set of discrete numbers and positions, such that the NMR time signal can be numerically calculated based on given sets of system parameters and experimental data [26, 32, 33]. The influence of rotational diffusion of the molecules is approximated by a corresponding spin exchange between adjacent “sites”, with rate constants depending on the equilibrium population, orientation and rotational diffusion constant. After Fourier transformation, the simulation procedure yields sets of NMR spectra that can be compared with experimental ones. A typical example for the end methyl group of cetyl palmitate under the experimental parameters given above is shown in Fig. 4.4. It refers to correlation times of isotropic rotational diffusion from 15 ms (front) to 15  $\mu$ s (back), showing the strong dependence of line shape on the rate of the motion [7, 18].

In some cases, the particle matrix undergoes local phase separations, leading to an inhomogeneous solid phase on the nanometer scale. On these occasions, analy-

**Fig. 4.4.** Set of simulated  $^{13}\text{C}$  spectra for the end methyl group of cetyl palmitate (signal C in Fig. 4.3) for different rates of isotropic rotational diffusion. The correlation time varies from 15 ms (front) to 15  $\mu$ s (back). Rotational sidebands are weak and not included in the

given frequency window [7, 18]. For all spectra, the simulated sample spinning has been adjusted to a frequency of  $\omega_r/2\pi = 1660$  Hz. The spinning axis is tilted at  $52.5^\circ$  with respect to the direction of the external magnetic field.

sis of spin diffusion between different components of the matrix material allows for the detection of inhomogeneous distribution and the determination of domain sizes [21]. Due to spin diffusion between all protons in the solid phase, only a single common relaxation curve is observed for all proton signals of a homogeneous matrix domain. As soon as different domains with sizes exceeding approximately 5 nm are formed, it is possible to identify different decay curves for the proton spin–lattice relaxation ( $T_{1\rho}$ ) in the rotating frame. Hereby, phase separations between a solid matrix and a solid active ingredient may be detected and quantified [21].

The methods introduced so far allow for the identification of chemical components together with their assignment to the liquid and to the solid phase. However, with nanocapsules, we often deal with two separate liquid compartments: the continuous (solvent) phase and the encapsulated liquid domain. The widths of the spectral signals or their development in a cross polarization spectrum does not differentiate between the two, as their rotational diffusion is within the same order of magnitude. The only physical property that differs between the two liquid compartments is represented by the characteristics of lateral self-diffusion. While molecules of the continuous phase undergo almost free self-diffusion, lateral motion of the encapsulated counterparts is strongly hindered by the capsule walls. Let us assume that we can observe the average lateral dislocation of the molecules in the liquid phase. If the observation period is very short, the difference between free and encapsulated becomes almost negligible as the number of molecules that collide with the capsule boundaries is very small. On extending the observation period, the number of wall collisions increases and the difference between the inner and the outer phase becomes increasingly evident. Finally, the residual mobility of the molecules in the capsule content appears to be identical to the mobility of the capsules as a whole.

In NMR, this theoretical consideration is experimentally reproduced by application of the pulsed field gradient (PFG) technique. In combination with echo sequences, like the Hahn or the stimulated echo, it allows the determination of mean-square displacements over given time intervals  $\Delta$ , which can be varied over a wide range [34–37]. This method has served for the characterization of heterogeneous systems such as emulsions [36, 38, 39]. Figure 4.5 shows an example for the application to poly-n-butylcyanoacrylate nanocapsules [9]. The basic pulse sequence (insert in Fig. 4.5) consists of a so-called stimulated echo sequence that produces a proton echo signal after three pulses of equal duration. In combination with two gradient pulses (FG) of a given duration ( $\delta$ ), the amplitude of the signal (and of the corresponding line spectrum) depends on the gradient strength and on the average lateral dislocation during the gradient pulse spacing  $\Delta$ . While the dependence on the gradient strength  $G_{\max}$  allows one to determine the average dislocation pattern, the variable  $\Delta$  determines the time window for the observation. The resonance signals shown in Fig. 4.5 correspond to different liquid or dissolved components in the capsule system: water, ethanol, triglyceride and the block-copolymer surfactant. With increasing gradient strength  $G_{\max}$ , the signals of water and ethanol show rapid decay, indicating free, efficient lateral self-diffusion. The

**Fig. 4.5.** Set of proton spectra obtained in a pulsed field gradient experiment on a dispersion of poly-n-butylcyanoacrylate nanocapsules. The pulse sequence (insert) consists of a stimulated echo sequence on protons combined with two gradient pulses FG. All signals in the displayed region can be assigned to liquid or dissolved system components: water, ethanol, triglyceride and

surfactant. The dependence of signal intensity on gradient strength ( $G_{\max}$ ) indicates lateral dislocation of the molecules within the given time window of  $\Delta = 30$  ms. Efficient self-diffusion leads to strong decays of the signals for water and ethanol, while those of the large surfactant molecules and the encapsulated oil show much smaller dependencies [9].

signal for the surfactant exhibits a much shallower decay, caused by slower self-diffusion connected to its much larger molecular mass. An even smaller dependence is observed for the triglyceride signal, which almost stays constant on the given scale. As the molecular mass of the triglyceride is much smaller than that of the surfactant, this observation strongly hints that the triglyceride oil is enclosed inside the capsule walls.

This becomes more evident if the echo decay of the triglyceride signal at 2.1 ppm is studied under variation of the diffusion time  $\Delta$ . Figure 4.6 shows a plot of the negative logarithmic echo intensity ( $-\ln I_{\text{rel}}$ ) vs. the parameter  $\gamma^2 G_{\max}^2 \delta^2 (\Delta - \delta/3)$ , with  $\gamma$  standing for the gyromagnetic ratio of the observed nucleus [9]. This type of plot yields linear dependencies with slopes identical to the apparent self-diffusion constant  $D_{\text{app}}$ . Evidently, the resulting apparent diffusion constant strongly depends on the diffusion time  $\Delta$  (Fig. 4.7). For very short observation periods ( $\Delta < 10$  ms), it comes close to the value of  $2.3 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$  found for a bulk triglyceride sample [9]. On this time scale, we observe local dislocations where the presence of the capsule walls affects only a small fraction of the oil molecules. Consequently, there is little difference between the behavior of free and encapsulated oil. On increasing

**Fig. 4.6.** Reciprocal echo decay plots for the triglyceride signal from an aqueous dispersion of poly-n-butyrylcyanoacrylate nanocapsules. Negative logarithmic echo intensities are plotted vs. the parameter  $\gamma^2 \delta^2 G^2 (\Delta - \delta/3)$  as derived from the triglyceride  $^1\text{H}$  signal at 2.1

ppm (Fig. 4.5). As typical for restricted diffusion, the observed slopes depend strongly on the diffusion time  $\Delta$ . Apparent diffusion constants  $D_{\text{app}}(\Delta)$  are determined from the slopes of the individual plots (Fig. 4.7).

**Fig. 4.7.** Dependence of the apparent self-diffusion constant ( $D_{\text{app}}$ ) of the triglyceride oil component on the observation time interval  $\Delta$  (diffusion time). For short  $\Delta$ ,  $D_{\text{app}}$  comes close to the self-diffusion coefficient of the bulk oil

( $D = 2.3 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$ , top line). For long diffusion times,  $D_{\text{app}}$  approaches the diffusion constant that describes the Brownian motion of the capsules in aqueous medium ( $D = 1.6 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$ , bottom line).

diffusion time, the apparent diffusion constant decreases significantly and finally approaches the value for the Brownian motion of the capsules in the aqueous dispersion (Fig. 4.7) [9]. In this case, the lateral shift of the encapsulated molecules becomes seriously restricted by the capsule walls. Finally, for  $\Delta > 50$  ms, the position of all oil molecules average out in the capsule center and we observe the mobility of the complete capsules.

The similarity between the apparent oil diffusion constant for short time intervals with that observed for the bulk oil can serve as proof that we actually deal with “hollow” capsules with obviously no diffusion barriers in the internal volume. This important structural information could hardly have been obtained with other techniques. In summary, the NMR approach allows chemical identification of the solid matrix and the external liquid as well as the liquid-encapsulated components. In addition, it yields data about the molecular dynamics of the system, from which further conclusions on the particle structure can be derived.

### 4.3

#### Phase Transitions of the Particle Matrix

Even if we restrict ourselves to solid particle matrices, we still have to consider certain varieties of the solid phase. A prominent example is the gel phase formed by extensively swollen polymers, which is often encountered when particles are formed by polymer precipitation [40]. This gel phase may be reversibly or irreversibly transformed into a “real” solid state by removal of the solvent. An example of an irreversible phase transition is represented by poly- $\epsilon$ -caprolactone nanoparticles formed by the emulsion-diffusion process [20, 41] (Fig. 4.8). Preparation starts with the polymer being dissolved in the organic phase of an o/w emulsion, the continuous water phase being saturated with the organic solvent ethyl acetate. In the next step, the aqueous phase is diluted, causing the ethyl acetate to diffuse from the droplets into the surrounding water. Hereby, the polymer, which is dissolved in ethyl acetate at the maximum concentration, precipitates and forms nanospheres (Fig. 4.8, left-hand column). In the presence of a hydrophobic oil component, the process leads to nanocapsules with the oil forming the liquid core (Fig. 4.8, right-hand column). In both cases, the organic solvent is subsequently removed by evaporation.

Initially, the solid matrix of the particles consists of a physically crosslinked network that is swollen by water and some residual ethyl acetate. A solid-state  $^{13}\text{C}$  NMR spectrum of the freshly prepared nanospheres (Fig. 4.9, top) reveals a very high degree of local mobility for the polymer chains. Compared with a solid-state spectrum of the bulk polymer (Fig. 4.9, bottom), the spectrum of the particles exhibits relatively narrow lines that are consistent with rotational diffusion on the microsecond time scale [7]. This means that, on a local scale, most of the polymer behaves as though in a dissolved state while it still forms the framework of a solid particle on the sub-micrometer size range. This apparent contradiction is explained

**Fig. 4.8.** Schematic representation of processes leading to the formation of gel phase nanospheres (left) and nanocapsules (right) by the emulsion-diffusion process. Top: a polymer dissolved in an organic solvent (optionally containing an oil component, right-hand column) is dispersed in an aqueous phase. Center: water is added to the dispersion, causing the organic solvent to

diffuse into the aqueous phase in connection with reestablishment of the distribution equilibrium. Bottom: polymer precipitation is induced by loss of solvent in the organic phase, forming gel nanospheres (a) or gel nanocapsules (b). In both cases, the polymer becomes physically crosslinked and is swollen beyond the point that accords with the thermodynamic swelling equilibrium [7, 20].

by assuming a gel state of the polymer induced by a high water content that is much beyond the value expected from the swelling equilibrium.

On removing the water, an irreversible phase transformation is observed (Fig. 4.10). Careful evaporation under lowered pressure induces the appearance of an increasing contribution of polymer in the classical solid state. At the same time, the process is accompanied by a slight decrease in particle diameter [20]. The transformation is irreversible, as addition of water does not lead back to the gel state. Alternatively, removal of water from the particle matrix can be induced by simple freezing of the sample [7, 20]. At all stages of water removal, the amount of polymer in both phase states can be quantitatively determined by solid-state NMR [7].

This phenomenon opens up the possibility for an interesting application of gel particles: the matrix of nanospheres or nanocapsules in the gel state may be re-

**Fig. 4.9.** Comparison of a  $(^1\text{H})\text{--}^{13}\text{C}$  cross-polarization spectrum of freshly prepared poly- $\epsilon$ -caprolactone nanospheres (top) with a corresponding spectrum of the bulk polymer (bottom). Obviously, the dispersed particles do not contain organic material in the classical solid state [7, 20]. A high degree of local chain mobility leads to narrow signals that can be assigned to the polymer (P). All other peaks derive from the surfactant [poly(vinyl alcohol)] and small amounts of poly(vinyl acetate). The insert indicates the pulse sequence used.

garded as an “open” carrier system, allowing ingredients to diffuse into or through the matrix. After the particles are loaded, they may be irreversibly “sealed” by a simple freezing step that turns the gel matrix into a relatively dense, impermeable solid polymer, a state that is preserved after melting the dispersion. The whole process of phase transition of the polymer and encapsulation of an active ingredient may be conveniently monitored by NMR spectroscopy.

#### 4.4

##### Adsorption to the Particle Surface

For medical applications of nanoparticles, it is of special interest to elucidate adsorption phenomena on the external particle surface. The most important adsorbent is the surfactant used to stabilize the particle dispersion. Additional components, such as encapsulated ingredients, may also adsorb to the particle surface. Surface adsorption usually means an equilibrium state, where adsorption and desorption processes take place simultaneously at equal rates. NMR offers an experimental approach for the study of adsorption phenomena and the molecular exchange connected to a continuous adsorption–desorption process [7, 17].

The use of cross-polarization in solid-state NMR generally favors the spectral

**Fig. 4.10.**  $(^1\text{H})\text{-}^{13}\text{C}$  cross-polarization spectra of dispersed poly- $\epsilon$ -caprolactone nanospheres in different stages of irreversible dehydration. With the original water content after the emulsion-diffusion process (a), all polymer signals (P) indicate a high degree of local mobility. After removal of ca. 50% of the swelling water (c), the complete polymer content has transformed into a rigid state. Spectrum (b) represents an intermediate situation [7, 20]. Pictograms on the left symbolize the corresponding stages of network formation.

contribution of solid constituents. It requires reduced mobility of the molecular environment and is therefore quite inefficient for dissolved molecules. However, there is a notable exception: if dissolved molecules become temporarily adsorbed to a solid surface, they remain relatively immobilized for a time interval in the millisecond range, which is sufficient to efficiently allow for the polarization transfer, e.g., between protons and carbon nuclei. The small adsorbed fraction is usually not directly detectable by NMR. However, after the molecules desorb, they again undergo rapid rotational diffusion and their cross-polarization induced carbon signal becomes a dominant contribution to the spectrum (Fig. 4.11).

In an aqueous dispersion of poly-*n*-butylcyanoacrylate nanocapsules, this phenomenon is observed for the block-copolymer surfactant as well as, to a somewhat smaller degree, for the encapsulated oil [7, 17]. Indications for an unusual mechanism of cross-polarization are obvious from the characteristics of cross-polarization development. While the solid-state signal of the nanocapsule wall material is already fully developed after a cross-polarization period of 0.1 ms, the narrow signals of the triglyceride and the surfactant still gain intensity after 1 ms and reach their maximum only after 5 ms [7]. After 10 ms of cross-polarization, the polymer signal is almost fully relaxed, while the signals for the triglyceride and the surfactant re-

**Fig. 4.11.** Schematic representation of the process of  $(^1\text{H})$ - $^{13}\text{C}$  cross-polarization induced by temporary adsorption of dissolved molecules to a nanocapsule wall. The degree of polarization is indicated by the intensity of the grey shading of the symbol. First, we focus on a molecule adsorbed shortly after an initial pulse is set to the proton nuclei (a). A spin-lock pulse may be included at this time to study spin-lattice relaxation [7, 17] (b). Later,

during the period of adsorption, simultaneous pulses on  $^1\text{H}$  and  $^{13}\text{C}$  nuclei are adjusted to fulfill the Hartmann-Hahn condition, which allows for an efficient  $(^1\text{H})$ - $^{13}\text{C}$  polarization transfer within the immobilized molecules (c). Finally, the molecule is desorbed, taking the strong polarization of the  $^{13}\text{C}$  nuclei into the fluid state, where it can be easily detected [7, 17] (d).

main constant for more than 30 ms. Such a cross-polarization and relaxation pattern is quite uncommon and indicates a special mechanism of polarization transfer.

Studies under variation of the spin-lock time have been performed to elucidate this polarization phenomenon, assuming an adsorption-desorption cycle on the capsule walls (Fig. 4.12). For comparison, corresponding relaxation curves obtained under direct excitation have been measured that focus on the triglyceride and surfactant molecules in the liquid phase. In this case, all data could be fitted assuming a mono-exponential decay and long relaxation times between 34 and 79 ms for the

**Fig. 4.12.** Relaxation curves showing the dependence of two aliphatic signals of triglyceride oil (top and center) and a single aliphatic signal of the surfactant (bottom) on the duration of a spin-lock period. With direct excitation experiments (left-hand column), the spin-lock period follows the initial pulse on the protons. All resulting relaxation curves can be fitted mono-exponentially. For cross-polarization experiments (right-hand column)

the spin-lock pulse is set before the cp period (see phase b in Fig. 4.11) and the signal intensity is observed via the corresponding carbon signals. The resulting relaxation curves are bi-exponential and consist of an initial steep decay, which corresponds to immobilized molecules (dotted line), and a subsequent shallow decay that can be assigned to molecules in the liquid phase (dashed line). Pulse sequences are indicated schematically at the top of each column [17].

direct measurement of  $T_{1\rho}^H$ :

indirect measurement of  $T_{1\rho}^H$  via cp:

triglyceride oil and 131 ms for the strongest signal of the surfactant [17]. With cross-polarization experiments (right-hand column in Fig. 4.12), the spin-lock pulse is set prior to the cp period (see Fig. 4.11b) and the signal intensity is observed via the corresponding carbon signals. No significant change in the resonance line shapes is observed during the full course of the experiment [17]. However, all resulting relaxation curves are distinctly bi-exponential and consist of an initial steep decay and a following shallow section of the relaxation curve. The latter is very similar to the results obtained by direct excitation with relaxation times that differ only slightly from those mentioned above [17]. This part clearly corresponds to the fraction of molecules in the desorbed state. The initial steep decay is connected to relaxation times of 1–2 ms, which resemble those of the solid polymer. This contribution obviously reflects the fraction of molecules that are in the adsorbed state. The complete signal decay curves from the cp experiment can be analyzed for adsorption–desorption characteristics using a relatively simple expression for relaxation under molecular exchange [42].

Figure 4.13 summarizes the results of the best fit to the complete set of relaxation data. They reveal that the average duration ( $\tau_{\text{ads}}$ ) of the adsorption step of an individual molecule is around 1 ms for the surfactant and 3 ms for the oil component. The overall signal intensities for both components consist of the signal

**Fig. 4.13.** System parameters obtained from a least-squares fit on the data shown in Fig. 4.12, based on an analytical expression for relaxation under molecular exchange [42].  $\tau_{\text{ads}}$  and  $\tau_{\text{des}}$  for the triglyceride oil and the surfactant refer to the average duration of adsorbed and desorbed states, respectively, of molecules taking part in the adsorption–desorption cycle.  $P_{\text{ads}}$ ,  $P_{\text{des}}$ , and  $P_{\text{free}}$  stand for signal contributions of the adsorbed, desorbed and “free” molecules, respectively. The latter fraction derives from those molecules in the liquid phase that do not take part in the adsorption–desorption cycle during the observation period.

fraction  $P_{\text{ads}}$  of the adsorbed molecules, the signal fraction  $P_{\text{des}}$  of the desorbed molecules, and finally the fraction  $P_{\text{free}}$  of the molecules that take no part in the adsorption–desorption cycle during the observation period. Notably, these fractions are relative signal contributions and do not reflect the actual number of molecules involved in these processes. The resulting average residence times of molecules on the particle surface compare well with results on similar systems obtained with pulsed field gradient NMR [43, 44]. Using comparable non-ionic surfactants, residence times between 7.0 and 13.4 ms were detected. These values were obtained with much lower surfactant concentrations than for the results illustrated in Fig. 4.13; it was also shown that the residence time decreases with increasing surfactant concentration. Therefore, the value of 1 ms found for the highly concentrated block-copolymer on the poly-*n*-butylcyanoacrylate nanocapsules is within the expected range.

Principally, cross-polarization NMR (as well as pulsed field gradient experiments) offers another promising experimental approach for the study of adsorption phenomena on surfaces. In contrast to field gradient techniques where lateral diffusion is the key parameter, it distinguishes adsorbed molecules from molecules in the fluid phase by their degree of rotational diffusion. As the immobilized fraction is only observed indirectly after desorption into the fluid phase, it is generally more sensitive in its detection. However, there is also a significant disadvantage. As cross polarization is involved, there is no possibility of quantitative analysis of the adsorbed and desorbed molecules. Conversely, the cp experiment gives access to the time scale of the adsorption–desorption cycle of all system components. Such adsorption–desorption phenomena on the nanoparticle surface are of key importance for the primary physiological response to nanoparticles when applied to living organisms.

#### 4.5 Molecular Exchange through Nanocapsule Membranes

According to the nomenclature of Kreuter [40], nanocapsules are nanoparticles that form a shell-like wall, encapsulating a generally liquid content. Nanocapsule walls can be very thin, with thicknesses down to few nanometers. For polymer capsule walls, this corresponds to only a few molecular layers. Obviously, this can not be considered as an impermeable barrier for compounds of small molecular weight. At the same time, the main purpose of nanocapsules is based on their ability to separate two fluid domains and to block the diffusion of encapsulated components into the continuous phase. Therefore, the capsule wall permeability represents a key parameter for the characterization of the capsule system.

A very straightforward approach for a physico-chemical determination of the capsule wall permeability involves fluorescent labels and the use of a dialysis cell. In many cases, however, transfer through the capsule membranes is too rapid to be followed in this manner. On these occasions, NMR offers an extremely versatile and reliable technique for the study of trans-membrane exchange in capsule dis-

persions. It relies on the fact that free and encapsulated molecules can be separated by the characteristics of their lateral diffusion (Section 4.2). This criterion can be used to follow release processes in a time-resolved manner, similar to experiments using fluorescent labels. In addition, for rapid exchange through capsule membranes, this method offers an especially promising alternative. It allows for the observation of trans-membrane exchange of a tracer molecule in the equilibrium state, a method that has been successfully applied to nanocapsules [9], micellar carriers [45, 46] and vesicles [47].

The basic idea of this experimental approach may be shown by the example of block-copolymer vesicles [48, 49]. The result of a pulsed field gradient (PFG) measurement on vesicles from poly(2-vinylpyridine-*block*-ethylene oxide) [47] is represented in Fig. 4.14. The external as well as the internal domain are completely identical in their chemical composition and mainly made up from water. Polyethylene oxide (PEO) molecules of variable molecular mass are used as water-soluble tracers to sample the permeability of the vesicle membrane. Figure 4.14 displays four of the resulting echo decay curves (cf. Figs. 4.5 and 4.6), showing dramatic changes of the exchange pattern depending on molecular mass of the PEO tracer. All echo intensities were obtained from the proton signal at 3.2 ppm and are plotted logarithmically in relation to the original echo intensity  $I_0$ . In the absence of trans-membrane exchange, interpretation of the plots is quite straightforward. In general, the steep initial decay corresponds to the free molecules, while the encapsulated fraction of the tracer is represented by the subsequent plateau. The level of the plateau indicates the fraction of encapsulated molecules, e.g., a  $\ln(I/I_0)$  of  $-4$  corresponds to a relative fraction of  $\exp(-4) = 0.0183$ , which means that 1.83% of the tracer is in the encapsulated state. The slope of the initial decay is identical to the negative self-diffusion coefficient of the tracer in the continuous phase, while the slope of the final plateau is dominated by the (relatively slow) Brownian motion of the vesicles themselves.

For tracers with high molecular mass (e.g., PEO-1500 with  $M_w = 1500 \text{ g mol}^{-1}$ ), the result of the PFG measurement basically follows this simple interpretation. As expected from impermeable vesicle membranes, the decay curves show no significant dependence on the diffusion time: for  $\Delta = 15$  to 300 ms, the plots are more or less identical. With both fluid domains strictly separated, the experimental result is not affected by a change in observation period. This result changes dramatically for a PEO tracer with  $M_w = 400 \text{ g mol}^{-1}$ . Here, the plateau value decreases with  $\Delta$ . This is due to the relatively high permeability of the vesicle membrane for PEO-400. With increasing time period ( $\Delta$ ), more and more of the initially encapsulated

**Fig. 4.14.** Experimental and simulated echo decay curves for a block-copolymer vesicle dispersion containing poly(ethylene oxide) tracer molecules of different molecular mass: PEO-1500 ( $M_w = 1500 \text{ g mol}^{-1}$ ), PEO-400 ( $M_w = 400 \text{ g mol}^{-1}$ ), PEO-300 ( $M_w = 300 \text{ g mol}^{-1}$ ), and PEO-200 ( $M_w = 200 \text{ g mol}^{-1}$ ). Echo intensities are plotted as  $\ln(I/I_0)$  vs.  $\gamma^2 \delta^2 C^2 (\Delta - \delta/3)$  such that the resulting slope is equivalent to the negative self-diffusion coefficient for free diffusion. Calculated curves (solid lines) are assigned by the symbols on the right-hand axis. Table 4.1 lists the parameters for the simulated curves [47].

PEO molecules will be exchanged with those from the external domain, which already have suffered a large lateral dislocation. Therefore, the resulting slope is determined by a certain mix of the external self-diffusion constant, the apparent constant for the restricted diffusion in the confined space and the Brownian motion of the vesicles. The influence of the exchange is increasingly relevant with increasing observation period  $\Delta$ . As expected, this dependence is even more dominant for PEO-300 and PEO-200, with  $M_w = 300$  and  $200 \text{ g mol}^{-1}$ , respectively. Finally, with PEO-200 and  $\Delta = 300 \text{ ms}$ , the rapid exchange does not allow for an experimental distinction between external and encapsulated tracer molecules and the encapsulated fraction is not detectable.

All in all, detailed analysis of the PFG data yields extensive information on the exchange characteristics of the different tracer molecules. However, such an analysis is not always straightforward. For very small nanocapsules where, to a first approximation, the internal diffusion may be neglected it is possible to use an analytical approach for molecular exchange between two domains with different signal decay properties [9, 45, 46], similar to that developed for magnetic relaxation [42]. If internal self-diffusion of the encapsulated tracer is significant, restricted diffusion within the nanocapsules has to be accounted for. Analysis of PFG NMR measurements for restricted diffusion in a spherical confinement has been treated analytically [50–52]. However, in combination with molecular exchange through the capsule walls, there is no simple solution to this problem [53]. This again asks for a numerical analysis approach that is once more based on a finite element approximation [7, 47]. In this case, the external as well as the internal volume is segmented into small finite elements in space along the axis of the field gradient. Lateral diffusion is then approximated by an exchange of spins between adjacent space elements with rates defined by the diffusion constant. An additional spin exchange between space elements for the internal and those for the external domain accounts for the simultaneous transfer of molecules through the capsule walls [47]. Except for the exchange of spin contributions, all processes are assumed to be in steady state equilibrium, therefore the net flow during the simulated tracer diffusion is zero.

The result of a simulated best fit to the experimental data is shown by solid lines in Fig. 4.14 [47]. Basically, all plots for a given PEO tracer are fitted by a single parameter that is the average exchange rate constant  $\bar{k}_{\text{ex}}$ . The encapsulated fraction  $x_{\text{in}}$  of the tracer, which is identical to the partial volume of the vesicles, can be determined from the echo decay plots as well as by independent measurements. The complete set of simulation data (including one for PEO-600, which is not shown in Fig. 4.14) is listed in Table 4.1. As expected, the trans-membrane exchange rate decreases with increasing molecular mass of the tracer. For the given mass range, the rates vary between  $0.05$  and  $1.6 \text{ s}^{-1}$ , which is equivalent to half-life times of the encapsulated state between  $13.8 \text{ s}$  and  $430 \text{ ms}$ . Of course, all molecules that leave the encapsulated domain are simultaneously replaced by molecules from the external domain in an equilibrium exchange. With exchange rates in the given range, the equilibrium state between the internal and the external domain is sufficiently established within minutes after addition of the tracer. So the actual experiment is

**Tab. 4.1.** Simulation parameters used for the numerical reproduction of the echo decay curves shown in Fig. 4.14 (including data for PEO-600) [47].

Tracer molecule	Approx. molar mass ( $\text{g mol}^{-1}$ )	Encapsulated fraction ( $x_{in}$ )	Exchange rate ( $\bar{k}_{ex}$ ) ( $\text{s}^{-1}$ )
PEO-200	200	$0.022 \pm 0.001$	$1.6 \pm 0.2$
PEO-300	300	$0.023 \pm 0.001$	$0.85 \pm 0.05$
PEO-400	400	$0.0205 \pm 0.001$	$0.38 \pm 0.02$
PEO-600	600	$0.015 \pm 0.001$	$0.075 \pm 0.01$
PEO-1500	1500	$0.028 \pm 0.001$	$0.05 \pm 0.01$

kept quite simple: the tracer is added to a given vesicle dispersion, the PFG-NMR experiment is started after a waiting period of approximately one hour. After completion of the measurement, the tracer A can be removed by successive washing/dialysis cycles and be replaced by a tracer B.

A systematic study of wall permeability using a series of tracers plays a significant role in a general characterization of capsule membranes. For block-copolymer vesicles, it is used to understand the mechanism of the molecular transfer through the vesicle walls. Figure 4.15 shows a logarithmic plot of the average exchange constant  $\bar{k}_{ex}$  vs. hydrodynamic radius of the PEO molecules in aqueous solution [47]. For molecular masses between 200 and 600  $\text{g mol}^{-1}$ , the plot shows a roughly linear dependence between  $\log \bar{k}_{ex}$  and the hydrodynamic radius. Based on the Arrhenius law, this indicates that the activation energy of the molecular transfer through the vesicle membrane is proportional to the radius of the molecule. Possibly, the energy barrier for the transfer is connected to a local disruption of the membrane

**Fig. 4.15.** Logarithmic plot of rate constants ( $\bar{k}_{ex}$ ) for the trans-membrane exchange (Table 4.1) vs. hydrodynamic radii of PEO tracers in aqueous solution. For molecular masses between 200 and 600  $\text{g mol}^{-1}$ , the dependence

of  $\log \bar{k}_{ex}$  on hydrodynamic radius is nearly linear, indicating that the activation energy for the membrane transfer is proportional to the size of the molecule [47].

– one that grows linearly with increasing size of the tracer molecule. Obviously, the tracer PEO-1500 does not obey this rule. This could be linked to a specific unfolding mechanism necessary for the transfer of larger molecules. In general, the use of tracers under systematic variation of size, polarity, conformational flexibility etc. leads to specific information on the membrane characteristics. Such information is crucial for the capsule design in order to optimize the stability, permeability and release properties.

## 4.6

### Particle Degradation and Release

The final steps during the life cycle of a particulate carrier system usually consist in the release of the active ingredients and, more or less simultaneously, degradation of the particles. Given the ability of NMR to distinguish between chemical components that are embedded in nanospheres, confined in nanocapsules or part of the continuous phase, it is not surprising that it gives easy access to release profiles. In general, all techniques described in Section 4.2 can be applied in a time-resolved manner; therefore, NMR represents an efficient method to follow structural changes such as the release of an active ingredient over time.

Figure 4.16 shows an example of a simple time-resolved measurement on polyelectrolyte nanospheres containing poly(ethylene oxide) as a model ingredient [54]. After dispersion in an aqueous environment, the directly-excited  $^1\text{H}$  signal of the PEO is followed over time in occasional measurements. While the solid PEO inside the nanospheres is practically invisible under these conditions, it is possible to determine the amount of dissolved PEO by detecting the integral of the single

**Fig. 4.16.** Time-resolved observation of the  $^1\text{H}$  signal of the model compound PEO incorporated in polyelectrolyte nanospheres. The signal is obtained under direct excitation, therefore only the released fraction of PEO is detected as a function of time after the addition of water at  $t = 0$ .

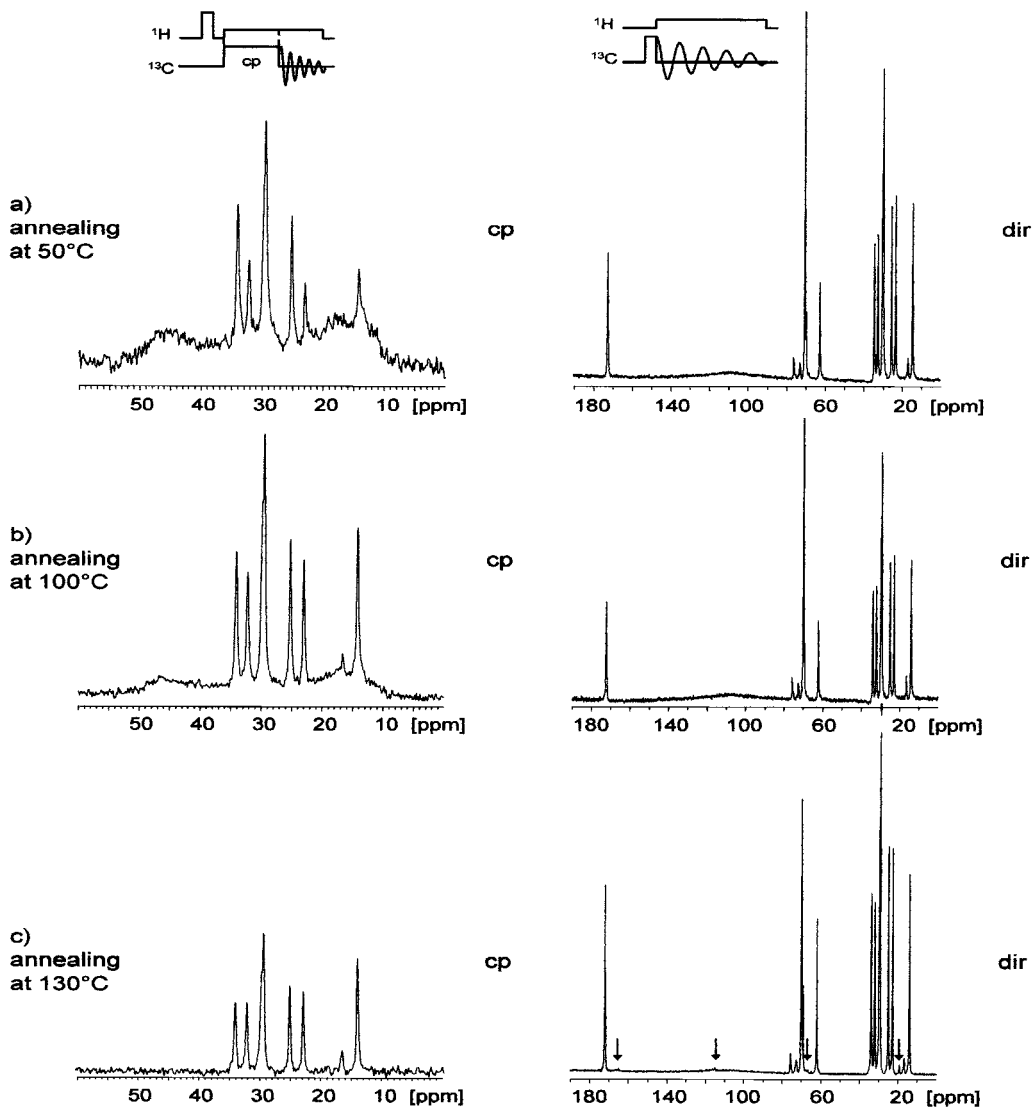

$^1\text{H}$  peak at 3.2 ppm. In direct excitation, the signal integral is strictly proportional to the quantity of the observed component. In the given case, the variation in peak intensity over time clearly shows a phenomenon that was quite undesired: on addition of water, the system undergoes a burst release of  $\sim 90\%$  of the model active ingredient within the first 3 min. The residual 10% of the PEO then slowly escapes into the fluid phase within the following 20 h. This observation yields the release profile, but also gives a certain clue about the particle structure. Most probably, the largest part (90%) of the PEO is loosely adsorbed onto the particle surface; only about 10% seems to be integrated into the particle matrix.

The solid matrix of nanospheres and nanocapsules is subject to various degradation processes. They take place during storage as well as during their *in vivo* application and may be connected to chemical as well as physical phenomena. They all affect the solid contribution to the magnetic resonance spectrum, so cross polarization is a promising technique to study particle degradation. However, some mechanisms of matrix decay also lead to the formation of low molecular weight components in the liquid phase. In this case, the direct excitation approach is especially suitable. Of course, both experimental methods can be combined to yield a complete analysis of the degradation process.

Figure 4.17 shows an example for such an analysis on an aqueous dispersion of poly-*n*-butylcyanoacrylate nanocapsules. It refers to thermal decomposition of the dispersion induced by storage for 3 h at different temperatures (50, 100, 130 °C) [55]. As mentioned before, the cp spectra (left-hand column of Fig. 4.17) focus on the solid matrix of the capsules. While the broad solid-state spectrum is virtually unchanged after treatment at 50 °C (a), it shows increasing loss in intensity after storage at 100 °C (b) and completely disappears after 3 h storage at 130 °C (c). The narrow peaks assigned to the triglyceride and the surfactant remain visible but suffer significant losses at higher temperatures. Their residual cp signal intensity corresponds to the fraction  $P_{\text{free}}$  (Fig. 4.13), which is independent of polarization transfer on the particle surface. Clearly, the solid-state components have vanished after 3 h treatment at 130 °C. Since obviously no new solid phase has been generated, the material that originally formed the solid matrix has to show up in the liquid phase. Traces of it can be seen in the directly excited spectrum (right-hand column in Fig. 4.17) after heat treatment at 130 °C (c, arrows). Figure 4.18 shows a scaled-up comparison between the “new” signals (top) and the counterparts from a spectrum of the monomer *n*-butylcyanoacrylate (bottom). Obviously, these “new” signals show up near corresponding peaks expected for the product of depolymerization. The slight deviations for the chemical shifts of 1 to 3 ppm may derive from differences in the chemical environment: the reference spectrum was taken in  $\text{CDCl}_3$  as a solvent, while the depolymerization product was dissolved in an aqueous environment containing some residual ethanol. Hence, the loss in solid polymer seems to be accompanied by the appearance of monomer in the fluid phase. This indicates that the matrix has been subject to a thermally induced depolymerization that finally leads to complete disintegration of the particles.

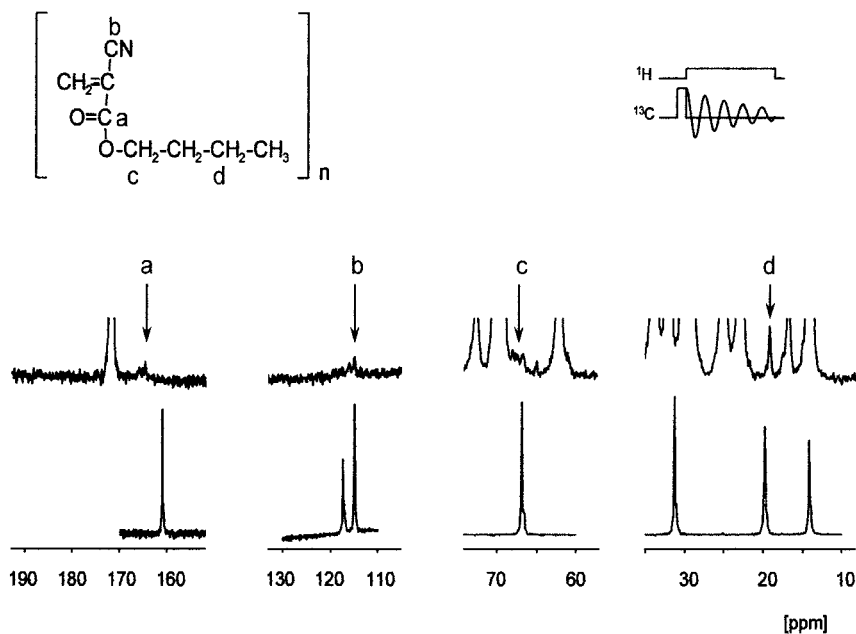

At this point, two varieties of particle defragmentation are possible: (a) depolymerization of the matrix could cause the capsule to separate into smaller solid

**Fig. 4.17.** Proton-decoupled  $^{13}\text{C}$  spectra of aqueous dispersions of poly-n-butylcyanoacrylate nanocapsules after heat treatment for 3 h at (a) 50 (b) 100 and (c) 130 °C. Wide lines in the ( $^1\text{H}$ )– $^{13}\text{C}$  cross-polarization spectra (left-hand column) indicate the loss of solid matrix material at higher temperatures. The superimposed narrow signals derive partially from adsorption

of liquid components to the capsule walls, and partially from the residual cp in the liquid phase. Direct excitation spectra (right-hand column) show the liquid and dissolved components and, for  $T = 130$  °C (c, arrows), indicate the formation of a depolymerization product (Fig. 4.18). Insets: pulse sequences used for cross-polarization and direct excitation experiments.

**Fig. 4.18.** Comparison between enlarged sections of direct excitation <sup>13</sup>C spectra obtained on poly-n-butylcyanoacrylate nanocapsules after heat treatment for 3 h at 130 °C (top line) and on a solution of n-butylcyanoacrylate in CHCl<sub>3</sub> (bottom line). The “new” signals a–d can be assigned to traces of

monomer resulting from depolarization of the capsule matrix. The obvious variation of the chemical shifts could result from the different solvent environments. Inserts: signal assignments and pulse sequence used for direct excitation.

fragments or (b) the capsule could essentially preserve its spherical geometry while the capsule wall corrodes and finally disappears. In the first case, the smaller solid fragments should lead to an increase in the tumbling rate, leading to a corresponding narrowing of the cp resonance lines of the solid-state spectrum. Figure 4.19 shows that this is clearly not the case: direct comparison of the spectra after annealing at 100 and 130 °C shows that the solid line shapes are virtually identical – no indications for a motional narrowing of the cp signal are found. This leaves the second alternative: while suffering increasing material loss, the capsule sphere preserves its overall geometrical shape and therefore keeps its original low tumbling rate.

One of the principal advantages of decomposition studies based on NMR detection is its variability for chemical and physical conditions. The NMR experiment can be performed under a wide variety of thermal, chemical or other influences on the sample during the time-resolved observation. At the same time, the impact caused by the static NMR measurement itself is insignificant, which allows for undisturbed and extended measurements over long periods.

**Fig. 4.19.** Comparison between enlarged sections of cross-polarization spectra of dispersed poly-n-butylcyanoacrylate nanocapsules after heat treatment for 3 h at 100 and 130 °C. The spectrum for 130 °C has been vertically expanded to match that for 100 °C in its solid-state contribution. Both solid-state line shapes (superimposed by narrow signals for the triglyceride and surfactant) are virtually identical. For the solid matrix, no motional narrowing is detected that would indicate the formation of smaller fragments with increased tumbling rate. Insert: pulse sequence used for the cp measurement.

#### 4.7

#### Summary and Outlook

This selection of NMR experiments on nanoparticles is meant to show the power of NMR in this field. Unlike any other analytical technique, it combines a distinctly non-invasive character with the ability to analyze for a chemical composition as well as for local mobility of individual system components. Its main disadvantages, most prominently represented by its relatively low sensitivity and the time consuming acquisition of experimental data, can be overcome by a suitable choice of pulse sequences and experimental conditions. Applied to nanoscaled pharmaceutical carrier systems, it gives access to several important structural details and system parameters. Table 4.2 gives an overview of various experimental NMR techniques that are suitable for studies focusing on different particle characteristics. Evidently, this scheme is by no means complete, but it may serve as a starting point to elucidate further approaches in NMR in this field.

One new technique that is presently under development may serve as an example: Studies are in progress that focus on the characterization of magnetic nanoparticles in liquid dispersion (magnetofluids) [56–61] used for medical applications, e.g., for the magnetically controlled local application of drug-loaded organic carriers. Here, the local perturbation of the magnetic field caused by the nano-sized magnets is detected by the observation of spins in the solid or fluid environment of the particles. It is used to characterize system parameters such as the magnetism of the particles and their distribution in space. The particle-induced magnetic perturbation may also be used in the opposite sense: by creating a very strong local field gradient it could allow for the observation of lateral molecular mobility on a very small scale. As for many other approaches of this kind, analysis of such experimental data requires a numerical simulation procedure that accounts for the local structures on the nanometer scale. Such algorithms are being developed based on the idea of small-scale susceptibility effects [61].

Tab. 4.2. Overview of the application of different NMR techniques for the analysis of different particle system characteristics.

	Direct excitation (incl. multi-dimensional NMR)	Cross polarization	Magic-angle spinning	Pulsed field gradient NMR	Relaxation curves ( $T_1, T_{1\rho}, T_2, \dots$ )
Identification of structural elements	Identification of fluid components	Observation of solid matrix	Identification of solid matrix	Identification of capsule contents	
Heterogeneity of the solid matrix					Detection of solid domain sizes
Phase transitions	Detection of new fluid components	Detection of new solid components	Identification of new solid matrix		
Adsorption to particle surface		Identification of adsorbed components		Time scale of adsorption–desorption cycle	Time scale of adsorption–desorption cycle
Permeability of capsule membranes				Detection of exchange rates	
Release	Release from nanospheres			Release from nano-capsules	
Degradation	Detection of fluid degradation products	Observation of disappearing solid components

## 5 Characterization of Nano Features in Biopolymers using Small-angle X-ray Scattering, Electron Microscopy and Modeling

*Angelika Krebs and Bettina Böttcher*

### 5.1

#### Introduction

Biological molecules and systems have several attributes that make them highly suitable for nanotechnology applications. For example, proteins fold into precisely defined three-dimensional (3D) shapes, and nucleic acids assemble according to structural rules. Antibodies are highly specific in recognizing and binding their ligands, and biological assemblies such as molecular motors can perform transport operations. Because of these, and other favorable properties, they are ideal for applications in nanotechnology. Gaining structural information of such complexes is crucial for understanding their functionality and for their successful incorporation in nano technologies.

Various techniques are available that provide information at various degrees of reliability and detail. Protein crystallography and multidimensional NMR are well-established methods that provide models of biological macromolecules on an atomic scale. With small-angle X-ray scattering the structure of macromolecules in solution can be investigated. Typical samples range from small proteins (from 5–10 kDa) to multi-domain proteins and protein complexes (up to MDa). The scattering data are sensitive to domain orientations and conformational changes and/or flexibility as well as to molecular associations; atomic resolution, however, will not be achieved. The technique is most powerful when used as a complementary tool with other structural techniques, such as three-dimensional electron microscopy (3D-EM). Three-dimensional image reconstructions from electron micrographs have become important in recent years, because near atomic resolution has been achieved with cryo-EM for several important systems. At the moment, low-resolution EM structures are obtained almost routinely for complex biopolymers and this information can be used advantageously in combination with other methods. One example is the merging of complex structures determined by EM at medium resolution with high-resolution crystal structures of their components. Another possibility, which is the scope of this chapter, is the merging of structural information obtained by EM with information obtained from SAXS.

After a general introduction to SAXS and EM, this chapter explains how both

methods together can be used successfully to gain structural information on the nanoscale.

## 5.2

### Small-angle X-ray Scattering

Small-angle X-ray scattering is a well-established technique for structural investigations of proteins on the nanometer length scale (1–300 nm), having its origins more than 50 years ago [1–4]. Recently, biological SAXS has gained additional importance, mainly due to outstanding hardware and software development. Very important in this context are new SAXS instruments and advanced methods to analyze SAXS data from macromolecular solutions (e.g., *ab initio* low-resolution structure analysis and rigid body refinement). Common applications in nanotechnology are the investigation of micro-emulsions or liquid crystals, the particle sizing of suspended nano-powders or investigations concerning structural information of polymer films and fibers. Applications in life science and biotechnology mainly deal with proteins, viruses and DNA complexes, whereby the border between nanotechnology and life science constantly diminishes.

#### 5.2.1

##### Scattering Technique

###### 5.2.1.1 Scattering Phenomenon

X-rays are photons with wavelengths in the range 0.1–100 Å and, depending on the frequency of electromagnetic waves, different interactions with matter are observable. They are usually generated by bombarding a target with electrons of energies of 10 000 eV or more. Upon collision, these high-energy electrons can knock electrons out of the target atoms, leaving vacancies in atomic shells. If, for example, a vacancy is produced in the innermost (K) shell of an atom, it rapidly will be filled by an electron descending from the next (L) shell, or one from the one after that (M). The photons emitted as a result of these transitions are the X-rays; they vary in wavelength according to the path of the electron. Copper is commonly used as a target, where  $\text{CuK}_\alpha$  radiation is emitted by electrons propagating from the L to the K shell and  $\text{CuK}_\beta$  is the radiation emitted by an electron changing from the M to the K shell.

X-rays interact with matter in different ways, i.e., absorption, elastic and inelastic scattering (Fig. 5.1). Elastic scattering is the basic event for X-ray scattering techniques. There, the incident X-ray photons undergo perfectly elastic collisions with the electron, leaving their energy unchanged and leading to radiation propagating away from the sample in all directions [1, 3–5].

The event behind that is the following: When a beam of electromagnetic radiation strikes an electron, some of the energy is momentarily absorbed and the electron becomes displaced from its unperturbed position due to the force exerted on it by the electric field. As a result, the electron is set into periodic motion with a fre-

**Fig. 5.1.** Scattering phenomenon. When a beam of electromagnetic radiation strikes an atom it is mainly the electrons that react. Some of the energy is momentarily absorbed and the electron becomes displaced from its unperturbed position due to the force exerted on it by the electric field. As a result, the electron is set into periodic motion with a frequency equal to that of the exciting

radiation. Since, according to the Maxwell equations, any accelerating or decelerating charge must radiate an electromagnetic wave in all directions, and since the radiation reemitted by the electron has the same frequency as the exciting radiation, experimental observation gives the impression that the incident radiation is scattered in all directions by the electron.

quency equal to that of the exciting radiation. Since, according to the Maxwell equations, any accelerating or decelerating charge must radiate an electromagnetic wave in all directions and since the radiations reemitted by the electron has the same frequency as the exciting radiation, the experimental observation gives the impression that the incident radiation is scattered in all directions by the electron. Thus the electrons can be considered as centers of secondary waves and the wavelength of the incident and the scattered radiation is the same (elastic scattering).

The amount of scattering is described by the Thomson equation [Eq. (1)], which states that scattered intensity from a single independent electron  $I(\theta)$  is given by:

$$I(\theta) = I_0 \frac{e^4}{m_0^2 c^4 a^2} \left\{ \frac{1 + \cos^2(2\theta)}{2} \right\} \quad (1)$$

where  $e$  is the electronic charge,  $m$  is the mass of the electron,  $c$  is velocity of light,  $a$  is the sample–detector distance and  $2\theta$  is the scattering angle. The product  $e^4/m_0^2 c^4$  is known as the electronic scattering factor (also termed electron-scattering cross section and Thomson’s constant), and the quantity in parentheses is known as polarization factor. The angle  $\theta$  is defined as one-half the angle of deflection of the incident beam relative to the scattered beam. In so-called reciprocal space the scattering vector  $h$  ( $\text{nm}^{-1}$ ) is usually used [Eq. (2)], where with  $\lambda$  is the wavelength.

$$h = (4\pi/\lambda) \sin \theta \quad (2)$$

While scattering from a single electron is extremely weak, in real systems, such as a protein in aqueous solution, we measure the total scattering from all electrons in the irradiated volume (which is of the order of 0.1 mL). Since the dimensions of macromolecules are always large relative to the wavelength of the incident X-ray radiation, interference occurs between the radiation scattered from individual electrons. Thus the spatial distribution of electrons in one molecule leads to several secondary waves that are able to interfere. The phase difference of the scattered waves depends on the path distance of the electrons in the molecule. This path difference increases with larger scattering angles and is the cause of diminishing scattering at larger angles. At very large scattering angles the scattered intensity is 0. This is why we observe small-angle X-ray scattering.

### 5.2.1.2 Scattering Curve and Pair Distance Distribution Function

In general, because electrons are not localized, it is better to describe an electron density  $\rho(\mathbf{r})$  in a volume element  $dV$ ; the scattering then is proportional to  $\rho(\mathbf{r}) dV$ . Therefore, for a continuous electron distribution, the sum of all secondary (scattered) waves  $e^{-ihr}$  is replaced by an integral [Eq. (3)].

$$F(h) = \int_V \rho(\mathbf{r}) e^{-ihr} dV \quad (3)$$

The integral is over the entire sample. This equation is the single fundamental equation that governs all X-ray scattering and diffraction. If the electron density distribution  $\rho(\mathbf{r})$  of a sample is known, one can compute the structure factor, and from this one can compute the expected X-ray scattering for all scattering geometries.

In solution small-angle X-ray scattering, however, the information contained in the 3D electron-density distribution  $\rho(\mathbf{r})$ , which describes the whole structure of the particle, is reduced to a one-dimensional distance distribution function  $p(r)$ , because the particles we measure are non-oriented in solution. [For solution scattering  $\rho(\mathbf{r})$  stands for the difference in electron density between sample and solvent.] The  $p(r)$  function is proportional to the number of lines with length  $r$  that connect any volume element  $i$  with any volume element  $k$  of the same particle. The spatial orientation of these connection lines is not important and the connection lines  $r$  are weighted by the product of the number of electrons situated in the volume elements  $i$  and  $k$  respectively. Each distance between two electrons of the sample as part of the function  $p(r)$  leads to an angular dependent scattering intensity. This physical process of scattering can be mathematically expressed by a Fourier transformation that defines how the information in real space (distance distribution function) is transferred into reciprocal space (scattering function) [Eq. (4)], with  $\gamma(r)$  as a measure of the probability of finding two points with the distance  $r$  within the particle of interest (correlation function).

$$I(h) = 4\pi \int_0^\infty \gamma(r) r^2 \frac{\sin hr}{hr} dr \quad (4)$$

The correlation function can be calculated from the scattering intensity using a Fourier transform [Eq. (5)].

$$\gamma(r) = \frac{1}{2\pi^2} \int_0^\infty I(h) h^2 \frac{\sin hr}{hr} dh \quad (5)$$

With  $p(r) = \gamma(r)r^2$  one can calculate the pair distance distribution function from the scattering intensity according to Eq. (6).

$$p(r) = \frac{r^2}{2\pi^2} \int_0^\infty I(h) h^2 \frac{\sin hr}{hr} dh \quad (6)$$

### 5.2.1.3 Determination of Scattering Parameters

SAXS parameters, such as the radius of gyration  $R_G$ , maximum particle size  $D_{\max}$ , volume  $V$  and molecular weight  $MW$  can be determined directly from the scattering behavior of the sample. In the following the procedures are outlined briefly:

(a) The radius of gyration,  $R_G$ , i.e., the root-mean-square of the distances of all the electrons of the particle from its center of electronic mass, is a characteristic geometric parameter of any particle. It can be determined according to a Guinier plot [ $\ln I(h)$  vs.  $h^2$ ] [Eq. (7), with  $I(0)$  as scattering intensity at zero angle].

$$I(h) = I(0)e^{-(h^2 R_G^2/3)} \quad (7)$$

Another way is to use the information given by the distance distribution function [Eq. (8)].

$$R_G = \sqrt{\frac{\int_V \rho(\mathbf{r}) r^2 dV}{\int_V \rho(\mathbf{r}) dV}} = \sqrt{\frac{1}{2} \frac{\int_V \rho(r) r^2 dr}{\int_V p(r) dr}} \quad (8)$$

(b) The maximum diameter  $D_{\max}$  of a particle can be determined by a linear diagram of  $p(r)$  vs. distance  $r$ .  $D_{\max}$  is then given by the crossover of the  $p(r)$  function with the  $x$ -axis.

(c) The hydrated volume can be assessed according to Eq. (9), with  $Q = \int I(h) h^2 dh$  being the invariant according to Porod.

$$V = 2\pi^2 \frac{I(0)}{Q} \quad (9)$$

(d) Finally, the relation of the scattered intensity to the primary intensity is a measure of the molecular weight of the biological sample [Eq. (10)].

$$MW = \frac{I(0)a^2}{N_A T_e P_0 (z_2 - v_2' \rho_1)^2 dc} \quad (10)$$

Fig. 5.2. Typical SAXS experiment.

where  $P_0$  is the primary intensity of the X-ray beam,  $N_A$  is the Loschmidt number,  $T_e$  is the Thomson factor, ( $7.9 \times 10^{-26} \text{ cm}^2$ ),  $z_2$  is the number of electrons per gram of the soluble sample in ( $\text{mol g}^{-1}$ ),  $\rho_1$  is the electron density of the solvent in ( $\text{mol mL}^{-1}$ ),  $v'_2$  is the isopotential specific volume in ( $\text{mL g}^{-1}$ ),  $d$  is the thickness of the sample in cm, and  $c$  is the concentration ( $\text{g mL}^{-1}$ ).

#### 5.2.1.4 Experimental Setup

With solution SAXS it is possible to study monodisperse as well as polydisperse systems. For monodisperse systems one can determine size, shape, interparticle interactions and internal structure of the particles. For polydisperse systems a size distribution can be calculated under the assumption that all particles have the same shape. In the SAXS experiments, the sample is irradiated by a well-defined, monochromatic X-ray beam (Fig. 5.2).

There exist laboratory instruments based on more conventional sources and synchrotron-based instrumentation. Synchrotron radiation sources with their intense brightness and natural collimation are ideal because biological materials are very poor scatterers. There is always some form of beam shaping required to maintain the small cross-section in going from the source to the sample and to reduce distortions from parasitic scattering from whatever obstacles, including air, are encountered. This is where much of the experimental effort is required and additional mathematical corrections take care of the non-ideal circumstances of a normal scattering experiment. A sample stage that may or may not involve heating/cooling elements then follows, ideally all within an in-vacuum path. No preparation such as staining of the material is required (in contrast to EM), and thicknesses of the biological sample between 1 and 3 mm are usually sufficient. Most commonly, small vials are used. As shown here the SAXS technique is performed in transmission mode. An extended sample–detector distance is usually required to give the barely scattered photons room to spread out from the main beam and also to reduce the detected X-ray background. Finally, a proportional counter, a scintillation counter, or a position sensitive detector, ideally two-dimensional, is required to measure the scattered intensity. As can be seen here, the black spot would be the beamstop that is absolutely essential to block the

main beam. To reduce errors, measurements are performed repeatedly, because the statistical error is inversely proportional to the square root of the counts.

## 5.2.2

### Interpretation of Data

#### 5.2.2.1 Direct Methods

Interpreting SAXS data can be very difficult, unless one is very lucky and the sample fits one of the many idealized models developed over the years. Regular wide-angle X-ray scattering tends to focus on the location, width, shifts, etc. of Bragg peaks that arise from crystalline lattice structures. One can still observe Bragg peaks in SAXS but these will result from regular spacings that are of the order of hundreds of angstroms. Most of the time, however, the observed curves tend to be apparently featureless.

Direct methods of analysis give us information based on interpretation of the clean (background corrected) data with no further manipulation [6]. All of these parameters are based on well-defined assumptions, such as the existence of uniform density within our particle, uniform density in the background, sharp interfaces between the two, etc.

At very small angles, the slope of the scattering in the so-called Guinier region (Fig. 5.3) can be used to get an idea of the radius of gyration of any distinct structure [see Eq. (7)]. For unisometric particles the radius of gyration of the cross-section and the radius of gyration of the thickness can be determined with equations similar to Eq. (7) (for further details see Ref. [4], p. 155). At higher angles, if we have a system of relatively identical particles, dilute enough for there to be no interactions, we may be able to see broad peaks that give us information on

**Fig. 5.3.** Scattering curve and SAXS model from a biopolymer on the nanometer scale (hemoglobin from the earthworm *Lumbricus terrestris*).

<sup>b</sup> Mean values and standard deviations result from averaging the 22 models included in the consensus model shown in Fig. 5.3.

<sup>c</sup> Threshold = 171, voxel-size =  $0.726 \times 0.726 \times 0.726$ .

<sup>d</sup> Threshold = 115, voxel-size =  $0.687 \times 0.687 \times 0.687$ .

the shape of the particles. At still higher angles, the so-called Porod region, the shape of the curve is useful in obtaining information on the surface-to-volume ratio of the scattering objects. This can also be used to gain information on the dimensions of our scattering particles. The area under the curve gives us the invariant, which is a measure of how much scattering material is seen by the beam and allows us to estimate the hydrated volume according to Eq. (9). The volume is a very important parameter, which we can determine with SAXS [the scattering amplitude is well defined according to Eq. (1)], whereas this is not easy in EM. Changes in the invariant can be used, for instance, to monitor the crystallization process in polymer materials. Finally, the shape of the  $p(r)$  function gives additional information on the size and overall structure of the particle as well as the maximum diameter. Thus we gain useful information rather quickly by careful analysis of the scattering behavior of the particle (Table 5.1).

### 5.2.2.2 Indirect Methods

For further interpretation purposes, it may be helpful if we propose specific structures and simulate their scattering behavior. The model-scattering data are then compared with the experimental data and the fit is a measure of the quality of the proposed structure. This approach, however, tends to imply that we already know the answer. Another possibility, therefore, if we don't really have any clear order to base our interpretation on, would be to assume a strongly disordered structure and to change this structure as long as it takes to gain a similar scattering behavior of the model and the experiment. This then is the basis of any indirect interpretation. In recent decades, various indirect modeling techniques have been described, including simple whole-body approaches, multi-body procedures and advanced *ab initio* modeling techniques (Fig. 5.4) (for summaries see Refs. [7, 8]).

Fig. 5.4. Modern SAXS modeling techniques.

**Conventional Whole-body and Multi-body Modeling Approaches** As a first approximation, biopolymers can be modeled as spheres, prolate or oblate ellipsoids or triaxial bodies with unequal axes. Approaches along this line are called whole-body modeling [9–11]. They consider hydration contributions by using experimental molecular properties such as the hydrated volume,  $V$ , which can be directly obtained by SAXS (see above). The surface of whole-body models is entirely smooth and therefore whole-body approaches are not used to determine structural details on the nanoscale.

For nano-applications the use of an assembly of spheres (beads) instead of a single geometrical body seems appropriate, e.g., Refs. [7, 12–18], because proteins and other types of biopolymers are often composed of various constituents. In multi-body modeling approaches the target experimental profile is simulated by a finite element method (“bead modeling”) and we can either use a small number of objects (each object would then simulate a subunit of the whole protein complex under investigation) or a large number of small spheres (in that case the spheres might be chosen to represent single amino acids or slightly larger details of the nano particle). Model scattering curves are usually calculated by means of Debye’s formula [4].

An example of a two-step multi-body approach is the consensus model of a giant multisubunit protein complex with a diameter of about 30 nm; this complex with a molecular weight of about 3600 kDa and an overall  $D_6$  symmetry [19, 20] is responsible for oxygen transport in the earthworm *Lumbricus terrestris* (Fig. 5.3). Due to considerable differences in mass estimations, the exact stoichiometry of the components was unclear for a long time [21, 22]. Two models have been proposed to explain the architecture of *Lumbricus* Hb: The first consists of 24 octameric subassemblies of globin chains and 24 linker chains [23]. In the second, the so-called “bracelet model” [21, 24–26] 12 dodecameric 200 kDa subunits, each composed of 3 monomeric and 3 trimeric heme-containing globin chains, and 36 heme-deficient linker chains form the HBL complex with a total mass of about 3.6 MDa. Several 3D reconstructions from cryo-EM have been presented [27–29] and the crystal structure at 5.5 Å resolution has been published [30], revealing an organization of 144 oxygen-binding hemoglobin subunits and 36 non-hemoglobin linker subunits, similar to the bracelet model.

Solution SAXS studies and subsequent multi-body modeling led to the consensus model, which consists of 6844 spheres of equal size (radius 0.66 nm) but unequal weight. In the first step, about 600 different models, all biased to represent the biopolymer structure in eclipsed arrangement (top and bottom half exactly on top of each other), were generated by trial and error and tested for equivalence in scattering with the protein complex. In the second step, the 22 best-fitting models were superimposed and averaged, a procedure that resulted in spheres of different weights according to the different occupation densities of positions [18]. No structural bias other than hexagonal symmetry (known from early EM studies) was imposed in the model calculations. The model shown here is an early example of generation of a SAXS model that allows us to determine better and worse defined areas of the model. This is an important step to produce more reliable SAXS models. The scattering behavior of this model is compared with the experimental data in Table 5.1.

**Structure Reconstruction by *Ab Initio* Modeling Approaches** A fascinating aspect of modern evaluation procedures for SAXS data is the possibility to establish *ab initio* reconstructions of low-resolution biopolymer shapes [7, 31–35], even without resorting to any kind of spatial information. Among these highly advanced methods, in particular the approaches based on simulated annealing [36–38], a genetic algorithm [39], Monte-Carlo approaches [40, 41] or a molecular-dynamics algorithm [42] need to be addressed.

In the simulated annealing approach [37] models from densely packed dummy atoms (beads) are established. Each dummy atom is ascribed either to the particle or the solvent. Starting from a random initial configuration in a chosen search space (in general a sphere of diameter exceeding slightly the particle diameter, or a chain-like ensemble of dummy residues to mimic the backbone of the protein structure and dummy water molecules to simulate hydration), simulated annealing is used as a global minimization algorithm to find a configuration matching the SAXS data. In the beginning symmetry information or other information on the

shape of the particle (from other methods, such as EM) may be introduced to increase the reliability of the generated models.

Using the genetic algorithm the scattering curves may also be iteratively fitted [39, 43]. There, a population of genes codifying a given mass distribution on a hexagonal lattice in a confined volume (e.g., an ellipsoidal search space of selected dimensions) is randomly generated. From each genotype the obtained model structure is compared to the observed SAXS data (by calculating the scattering profile of the model body by the Debye approach) and a fitness criterion is used to generate the next population by genetic operators (crossover and mutation), until, as a consequence of the selection pressure, the system converges, i.e., the best-fitting model is found. The fitting starts with a low number of large spheres and uses, incipiently, only the innermost portion of the scattering curve; during the run, the size of the spheres is gradually scaled down and the limit of resolution is increased by addition of further portions of the scattering curve. Monte Carlo approaches add and remove beads on a lattice until an optimum fit to the experimental SAXS profile is reached and the value of the score is at its minimum [40, 41].

In general, a thorough analysis to develop a structural model from SAXS data requires the execution of multiple runs for each condition chosen (e.g., bead radius, i.e., resolution) to avoid misinterpretations owing to unfavorable or ill-posed calculation conditions. A comparison of the results requires visualization, alignment and superimposing of the obtained models, followed by some kind of averaging and filtering. In any case, the resultant models cannot guarantee absolute uniqueness. In particular, for very complex structures or if considerable particle inhomogeneities exist, a note of caution is advised. In such cases, structural knowledge from other methods (such as EM) is extremely helpful for the creation of SAXS models and should therefore be introduced at the beginning of the model calculations.

**Generation of Averaged Models** Averaging of SAXS models is a legitimate procedure to point out structural tendencies by emphasizing the most persistent features [17, 44]. In this way, important, recurring features in the protein structure can be spotted and interpreted accordingly. Structural details at high resolution, however, may be lost during the averaging procedure and the averaged model may also provide a worse fit of the experimental data. Despite these reservations, averaging can be a valuable tool to reduce the problem of uniqueness of shape reconstructions and, nowadays, best-matching alignment and superposition of the bead models and subsequent averaging may be done automatically [44, 45].

### 5.3 Electron Microscopy

As we have seen in preceding paragraphs, interpretation of SAXS data greatly benefits from the incorporation of a priori knowledge of the structural organization of the nano-particles. Here EM can provide useful information on size and shape.

In addition, merging of different views allows reconstruction of the 3D image information. Such image reconstructions provide quite accurate phase information of the object but often show a modulation of the amplitude profile, which, in turn, can be corrected by combination with SAXS measurements.

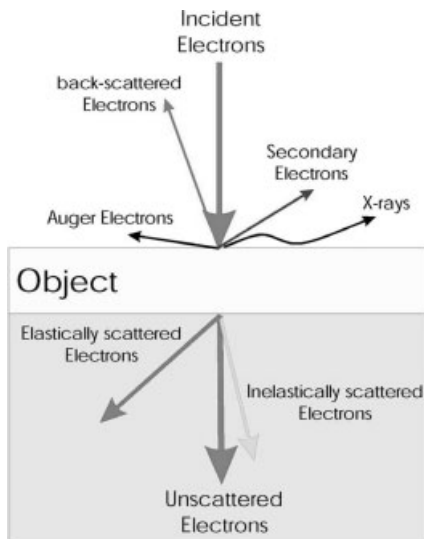

### 5.3.1

#### Image Formation

Microscopy, as other methods, relies on the interference of electromagnetic radiation with the object. In contrast to diffraction methods, images contain the complete image information, consisting of amplitude and phase information. In EM the source of electromagnetic radiation is electrons accelerated by high voltage in a vacuum. The velocity of these electrons is close to the speed of light. With a typical accelerating voltage of 200 kV the electrons already reach a speed of 210 000 km s<sup>-1</sup>, which is ~70% of the velocity of light. At these high relativistic speeds, electrons can be considered as waves with wavelengths of the order of a few picometer (2.5 pm at 200 kV).

##### 5.3.1.1 Interference of Electrons with Matter

Electron waves interfere with an object in several modes (Fig. 5.5). Most of the incoming electrons pass a thin object without interference. A certain fraction of electrons is elastically scattered by small angles and interferes with the unscattered

**Fig. 5.5.** Interaction of electrons with the object in EM. Phase contrast, which is the main source of contrast for thin unstained specimens composed of elements with low atomic numbers, is generated by interaction of the elastically scattered electrons with the unscattered electrons.

beam. These electrons contribute to the phase contrast, which is the main source of contrast in transmission EM of thin objects. Another fraction of electrons is scattered by higher angles and does not reach the back-focal plane. These electrons contribute to amplitude contrast. Some of the incoming electrons are scattered inelastically and deposit energy on the object, which leads to beam-damage and consequently to loss of high-resolution information. The event of inelastic scattering is not highly localized. Therefore, the inelastically scattered electrons do not contribute to the high-resolution information but contain image information at low spatial frequencies [46].

The cross-section of atoms in the sample for scattering electrons increases with the atomic number. Heavy metal atoms have much larger cross-sections than carbon, oxygen or nitrogen atoms, which are the main building blocks of biopolymers and organic polymeric materials. Therefore, heavy metal compounds play a crucial role as stains in EM. As a consequence of their larger cross-sections more electrons are scattered and contribute to the phase contrast. The stronger interaction also increases the number of electrons scattered by larger angles, leading to an increase in amplitude contrast. For a thin stained catalase crystal the amplitude contrast is of the order of 37% [47] whereas for unstained biological samples the amplitude contrast is only about 7% [48].

The cross-section for the inelastic scattering also depends on the atomic number. Up to an atomic number of about 10 the inelastic cross section is larger than the elastic cross section [49], meaning that for every elastic scattering event, which contributes to phase or amplitude contrast, at least one or more electrons are scattered inelastically and contribute to beam damage. Especially for biological objects and organic polymers, which consist mainly of elements with low atomic numbers, this leads to a serious limitation in resolution by beam damage. For example, in carbon, for each electron that is elastically scattered, three electrons are inelastically scattered (for an accelerating voltage of 100 kV), depositing an average energy between 10 and 25 eV on the sample. Therefore, to recover high-resolution information, electron doses are limited to about 5–10 e  $\text{\AA}^{-2}$ . However, at these small doses images are noisy. At large spatial frequencies the signal is much lower than the noise level. To recover the high-resolution information the image information of many low-dose images has to be merged. In theory the combination of only 3000–10000 individual images [50, 51] is sufficient to calculate a 3D image reconstruction to 3  $\text{\AA}$  resolution.

#### 5.3.1.2 Contrast Transfer Function

These considerations assume perfect transfer of contrast in the electron microscope. However, this is far from the real situation, where image contrast is modulated, depending on different parameters. In theory a thin object can be considered as a weak phase, weak amplitude object. Interference of the electron wave with the phase object introduces a phase shift  $\chi$ . This phase shift depends on the defocus  $\Delta$ , the spatial frequency  $R$  and the wavelength of the electrons  $\lambda$ . With a perfect lens a pure phase object in focus has no contrast. However, electron lenses are far from perfect. They deflect electrons much more strongly further from the optical axis

than in their centre. This causes an aberration, which introduces an additional phase shift that depends on the “hardware” of the electron microscope, such as the spherical aberration of the lens  $C_s$ , the wavelength of the electrons ( $\lambda$ ) and the spatial frequency  $R$ . The phase-shift  $\chi$  is given by Eq. (11).

$$\chi = \frac{\pi}{2}(c_s \lambda^3 R^4 - 2\Delta\lambda R^2) \quad (11)$$

In phase contrast the contrast is proportional to the sine of the phase shift, whereas amplitude contrast is proportional to the cosine. For an accurate description of the image information the exact ratio of amplitude and total contrast ( $a$ ) has to be known. For most conditions it is a sufficient approximation to assume that the ratio between amplitude and phase contrast is constant over the spatial frequencies. For the contrast transfer function (CTF) it follows that

$$\text{CTF} = a \cos(\chi) + \sqrt{1 - a^2} \sin(\chi) \quad (12)$$

According to Eq. (12), a pure phase object has almost no contrast at low spatial frequencies, whereas a pure amplitude object shows optimal contrast.

At high spatial frequencies, additionally to the modulation of the contrast-transfer due to the phase-shift, a decrease in contrast transfer occurs that is caused by imperfections of the electron optics such as spherical and chromatic aberrations. This dampening of contrast transfer can be described by exponential decay functions [52]. For spherical aberration, the function depends on the defocus and the illumination half-angle. This has serious implications for high-resolution imaging of low contrast phase objects. Usually, micrographs are taken with a defocus of 2–5  $\mu\text{m}$  to increase contrast at low spatial frequencies (visibility of the particles). At this defocus and with moderate exposure times of 1–2 s, the dampening of contrast transfer is already evident at spatial frequencies of about  $1/(2 \text{ nm})$  in electron microscopes with thermionic guns. For better contrast-transfer at higher spatial frequencies either electron microscopes with brighter electron sources such as field emission guns or longer exposure times, which require extremely stable sample holders, have to be used.

### 5.3.2

#### Sample Preparation

In contrast to SAXS, sample preparation in EM is an important issue. Sample preparation has three major aims: (1) The object has to be reduced to a suitable size (40–500 nm thick, less than 3  $\mu\text{m}$  in diameter). (2) The object has to be stabilized to resist the high vacuum inside the electron microscope. (3) The structure has to be preserved to withstand beam-damage over a high electron dose.

#### 5.3.2.1 Vitrification of Biological Specimens

Nano-particles such as biological complexes, viruses or artificial polymeric materials are in general small enough to be imaged as a whole. However, the high vac-

uum inside the electron microscope makes it impossible to image these particles in an aqueous environment, where the vacuum leads to instant evaporation of the solution. This evaporation can be avoided by lowering the vapor pressure of the water by cooling the sample [53]. However, slow cooling leads to the formation of ice crystals, which can destroy the fine-structure of the object. Therefore, the aim of preservation is to maintain a state of water that is as close to liquid as possible. Such a state is the vitrified form of water, where water solidifies in an amorphous modification [54–57]. Vitrification is achieved by high cooling rates, which are of the order of  $3 \times 10^6 \text{ K s}^{-1}$  [58]. These cooling rates are so rapid that water does not form sizeable ice crystals. Electron diffraction patterns of vitrified solutions show smooth rings, demonstrating the amorphous nature, with some variability in the average spacing between molecules [54]. The average nearest neighbor distance between two oxygen atoms in the vitrified state is 2.76 Å. The structural model, which had been proposed for the vitrified form of water, is based on cubic ice but with a greater variation of the second nearest neighbor distance [59].

In practice, vitrified samples are prepared by forming a thin film of particle suspension and plunge freezing it in liquid ethane. To form the thin film, 2–5  $\mu\text{L}$  of particle suspension are applied to a carbon-coated copper grid. The carbon film is used as support for the sample. Because strong interactions between the object and the carbon film can lead to distortions and the carbon adds an undesirable background, instead of a continuous film, often a film with holes (diameter 1–5  $\mu\text{m}$ ) is used, where the particle suspension spreads over the holes. For a good spread of particles and an even thickness of the vitrified water, a hydrophilic surface of the support film is required, which is achieved by mild plasma etching.

For formation of the thin film most of the sample is removed with filter paper. The thickness of the remaining film is ideally between 20 and 100 nm. Thicker films are possible but usually lead to micrographs of poor quality (low contrast, multiple scattering, charging). This is a major limitation for the investigation of large nano-particles, which are thicker than 100 nm. If the thickness of the film is below the diameter of the object, the particle experiences a considerable pressure, forcing it out of the aqueous environment into the air. This pressure can be so large that deformation (e.g., liposomes) or even bursting of the object (e.g., whole cells) occurs.

**Freezing Apparatus** Immediately after film formation the sample is rapidly frozen by plunging it into liquid ethane. The cooling rates in ethane are sufficient to prevent formation of ice crystals. The vitrified modification is stable and can be stored below the devitrification temperature of about 150–160 K for a prolonged time. To date, different types of apparatus have been used for vitrification. The simplest one is a guillotine in which the forceps holding the grid are mounted [57]. The sample is applied to the grid and then removed by pressing a filter paper against the liquid. Exact observance of the area where filter paper and sample touch allows determination of the best moment when the film has the right thickness. Then the guillotine is released and the forceps with the grid are plunged into a pot with liquid ethane, which is cooled by a surrounding bath of liquid nitrogen.

**Fig. 5.6.** Freezing apparatus for vitrifying samples. Forceps holding the grid are mounted in a humidified chamber (water soaked sponges). After release the grid is plunged by a spring driven mechanism into liquid ethane, which is cooled by a bath of liquid nitrogen.

The timing for blotting depends on ambient humidity, viscosity of the sample and concentration of solutes and requires some experience before reproducible results are achieved. Furthermore, evaporation of the sample leads to an increase of solute concentrations and a measurable drop in temperature. Evaporation can be reduced by surrounding the sample with a humidified chamber (Fig. 5.6), which can be temperature controlled if necessary [60]. Here blotting times are constant and no longer depend on ambient parameters. Alternatively, evaporation can be minimized by blotting the sample from both sides (e.g., Ref. [61]) where the surrounding filter paper wetted with the sample provides a defined microenvironment.

The ethane pot also requires special attention in the setup. At liquid nitrogen temperature ethane is solid. After condensation of ethane gas, ethane freezes within a relatively short time when cooled by a bath of liquid nitrogen. This provides only a short time window in which the thin film has to be formed before plunge freezing. This period can be increased if cooling is slowed by surrounding the ethane pot with an insulating layer. Alternatively, ethane can be heated with a thermo-foil to just above its freezing point. This provides constant conditions over long periods.

After freezing, the sample has to be transferred from the ethane tank to liquid nitrogen, where it is stored. During transfer, the grid is vulnerable to accumulating surface contaminations such as small hexagonal ice crystals formed by condensa-

tion of ambient humidity. Therefore, a dry environment for the transfer is desirable, which can easily be achieved by increasing the height of the walls of the surrounding nitrogen bath above the top of the ethane pot. Evaporation of liquid nitrogen forms a dry nitrogen atmosphere, which is usually sufficient to minimize surface contamination.

Vitrification preserves the sample in an environment that is similar to the aqueous phase. However, there are also important differences, such as the density of the vitrified phase, which is more similar to cubic ice than to liquid water [56, 59]. Consequently, the packing density of the water molecules must have decreased during the short period of freezing. Whether this sudden change in the structure of the water induces structural alterations in the nano-particles is still unclear. For the many biological objects investigated so far, there is no evidence that vitrification by itself induces damage. The change in density from the liquid to vitrified state increases the contrast between the nano-particle and the solvent. This has to be taken into account when combining data from EM and SAXS.

During imaging of vitrified samples constant cooling below the devitrification temperature is required. This cooling has the advantageous effect that beam damage is significantly reduced compared to that at room temperature [62–65]. One reason for this reduction is the decreased mobility of breakdown products at lower temperatures. Consequently, at even lower temperatures (4–10 K) this protective effect is further increased, permitting higher doses [66] without losing high-resolution information. In the past, this has been exploited in acquiring high-resolution information (2.8–4 Å) of two-dimensional crystals of membrane proteins (e.g., Refs. [67–71]). However, at low resolution (>20 Å) the protective effect is not evident; on the contrary, with increasing dose a massive loss in contrast occurs. This is most likely caused by an increase in density of the solute that surrounds the particles. The cause for such a change can be either a change in the modification of the water by a transition to a high density vitrified state [56] or/and the beam-induced enrichment of high density break down fragments, which usually evaporate at higher temperatures and therefore do not alter the contrast. These changes in density have to be taken into account when merging data from EM and SAXS.

### 5.3.3

#### **Two-dimensional Merging of Electron Microscopic Data**

To preserve a certain resolution of an organic or biological material the permissible dose is limited to about 5–20 e Å<sup>-2</sup>. At higher doses, in vitrified samples bubbles form at the surface of protein or carbon [54]. This event marks severe damage to the gross structure and defines the highest tolerable dose for structure determination. As a consequence, micrographs have to be taken with low electron doses, which results in poor counting statistics. To improve the signal-to-noise ratio, and thus recover the high-resolution information, many images of different particles have to be merged. As a prerequisite for a coherent merging of the data, particles must exist in multiple identical copies. For many biological complexes, which have

defined stoichiometries and assembly pathway, this is fulfilled. For artificially created nano-particles made of organic polymeric material the exact stoichiometry and shape is often not precisely determined. In this case, the assumption that the particles exist in multiple identical copies is no longer valid. For such particles, which are usually similarly sensitive to radiation as biological complexes, high-resolution structure determination becomes impossible.

### 5.3.3.1 Cross Correlation Function

Another prerequisite for coherent merging of image data is that the particle images show the same view of the object. If this is the case, the images are only variable by in-plane operations such as image-shift and image-rotation ( $x$  and  $y$  for the origin of the particle and  $\phi$  for the in-plane-rotation). These parameters can be calculated by cross-correlation functions between the noisy particle images and a common reference (Fig. 5.7). The relative image shift between the reference and the raw image is determined from the position of the maximum of the cross-

**Fig. 5.7.** Cross correlation function: Upper row: The cat on the left is correlated to the cat in the central panel. The cross-correlation function between the two cats shows a sharp peak (right-hand side). The position of this peak relative to the centre gives the translational shift between the two cats. Central row: The two cats vary by their in-plane

rotation. The correlation function between the two cats (right-hand panel) shows a broad peak. Lower row: Cats from the central row are transformed into cylindrical coordinates. The cross-correlation function (right-hand panel) shows a defined peak. The position of the peak relative to the centre gives the relative in-plane rotation.

correlation function relative to the image-centre. The height of the peak above background is a direct measure for the correlation and thus for the signal-to-noise ratio. If the reference and raw image do not match, the peak is broad without a well-defined shape. In this case, determination of the common origin from the cross correlation function becomes unreliable. A direct measure of how well the reference and raw image agree is the cross correlation coefficient, which ranges between  $-1$  and  $+1$ , where  $0$  means no correlation and  $1$  indicates that the compared images are identical. If the two images have opposite contrast, the cross-correlation coefficient becomes negative.

The rotational angle between reference and raw image is also determined by a cross correlation function but this time a polar-coordinate grid is used (Fig. 5.7). The position of the maximum in the cross-correlation function in this coordinate system gives the relative rotational angle. Exact determination of the rotational angle requires that reference image and raw image have the same origin. However, precise determination of the origin also requires the same rotational angle between the two compared images. To solve this dilemma, both origin and rotational angle are often searched alternately in an iterative process.

If all particle images in the data set are brought to a common origin and have the same in-plane rotation, the images can be averaged pixel-wise. Noise has random distribution whereas image information has the same position in all aligned images. By averaging many images the signal from the localized image information grows much faster than the one from the randomly distributed noise, increasing the signal-to-noise ratio.

For precise alignment of very noisy images the choice of reference plays a crucial role. Alignment of pure noise to a well-defined reference reproduces the basic features of the reference in the average [72, 73]. Averaging large numbers of pure noise images preserves the features of the reference over many iterative steps. This makes it difficult to spot whether a certain feature in an average is a genuine feature of the particle or arises from noise correlation. Recently, several strategies have been suggested to test data for such artifacts. One possibility is the exclusion of certain bands of spatial frequencies from the reference image. If the correlation in this resolution band is only due to noise correlation, after alignment to a reference with the missing spatial frequencies, the correlation will drop to levels below significance in this band. Another possibility is to mask off small areas in the reference image. If, after alignment, the feature in this “blind” spot of the reference is reproduced faithfully in the average, it represents a real feature of the particle and is not solely caused by noise correlation.

#### 5.3.3.2 Identification of the Different Views

Particles prepared for EM only rarely assume a single unique orientation – an exception is two-dimensional crystals. For single particle preparations a unique orientation of particles is uncommon. Instead particles usually have different orientations and often show a random distribution of views. This creates the problem of identifying the different views and merging only those particle images that represent the same view. Identification of the different views requires statistical

analysis of the image data, in which differences caused by noise are separated from those related to overall changes in shape related to a difference in particle orientation. The most common approach is a statistical method, which is similar to the principal component analysis used in the analysis of correlated data. The basic idea is that certain details of an image that are related to positional variations change in a concerted way, whereas noise varies independently across the image.

For the analysis of similarity between images, each particle image is represented as a single point in a multidimensional space. The space is defined by linear independent axes that point into the directions of the major differences between all images in the data set [74, 75]. The advantage of this representation is that comparable particle images will be in close proximity whereas images of different views will be further apart. Therefore, the distance between particle images can be directly used to group particle images according to similarity. The axes of the coordinate system can also be regarded as images (Eigenimage), representing the major changes between different views, and are therefore quite informative to identify common properties of the images. For example, in data of centered particles with random in plane rotation, rotational symmetry can be easily spotted in the Eigenimages [76]. In this case two of the major Eigenimages will show a ring of alternating bright and dark areas, which have the same rotational symmetry. Another property of the particles, which can be easily identified by analysis of the Eigenimages, is heterogeneity in size distribution [77]. Representation of particle images in Eigenimage space is the bases for the subsequent grouping of particles. Classification algorithms sort particle images in close proximity into the same class. These images represent approximately the same view and therefore fulfill the requirements for coherent merging, which leads to improvement of the signal-to-noise ratio.

For particle images representing different views (or different types of conformations or architectures), a single reference is no longer the best choice for alignment. Instead, multiple references, which represent all characteristic views, are more suitable and allow a more precise alignment. Appropriate sets of references can be generated from class averages to which each noisy particle image is aligned. As origin and rotational angle for the raw image the parameters from the alignment to the reference image with the highest cross correlation coefficient are chosen.

To reduce the bias introduced by the choice of an unrepresentative first reference a combination of classification and multi-reference alignment is favorable. This strategy was coined alignment by classification [76]. The basic idea is to classify a data-set of pre-centered particle images. A first set of references is generated from selected class-averages. By doing so only representative views are used as references and biasing by choosing an unsuitable single reference image is avoided. The limitations of this approach are connected to the accuracy of pre-centering. For approximately spherical particles quite accurate pre-centering is achieved by alignment to a rotationally averaged mean of all particle images. However, for elongated particles, where the different views vary significantly in their dimensions or

for spherical particles belonging to different size classes this gives unsatisfactory results.

Alternatively to the alignment by classification, neuronal networks are used to generate self-organizing maps to avoid biasing by the first reference [78]. Although this is a quite promising stable approach, it also relies on accurately pre-centered particles.

#### 5.3.4

#### Merging of EM-data in Three Dimensions

Due to the high depth of field caused by the small permissible apertures, an electron micrograph can be considered a good approximation of a projection of particle density. Consequently, no 3D information is obtained if the object is imaged from only one side. This is in contrast to light microscopy where the depth of field is much smaller than the thickness of the object. Here 3D image information is reconstructed by stacking consecutive focus layers.

##### 5.3.4.1 Sinogram Correlation

To reconstruct a three-dimensional volume from electron micrographs different projections have to be combined. With single particles, where the object has random orientations, the class averages can be considered as random projections of the object. A prerequisite for reconstructing the 3D volume is that the relative orientations of the projected particles are known. These orientations can be determined in real space by sinogram correlation [79] or in Fourier space by the equivalent method of cross common lines [80].

In 3D-Fourier space the 2D-Fourier-transform of a projection is a single plane. Fourier transforms of different projections have the same origin but different orientations, which depend on the direction of projection in real space. The planes in Fourier-space intersect along lines at which the phases and amplitudes in the two intersecting Fourier transforms are equal. These lines are called cross-common lines. The position of the cross-common lines in a pair of intersecting transforms reflects the angular relationship between the two projections in real space. Pair wise comparison of three transforms is sufficient to allow the determination of the complete angular relationship to which further projections can be fitted. The relative orientation of the first three projections can be determined by an exhaustive search. For finding the orientation of further projections, the cross-common lines between the transform of the projection with the unknown orientation and the set of transforms with known spatial relationship are searched for all possible orientations.

The real space approach uses sinograms [79], which are stacks of regularly angular-spaced 1D-line-projections of a 2D projection. Two different 2D-projections will share one 1D-line-projection with the same profile (Fig. 5.8). This line can be identified by sinogram correlation. The position of this 1D-line projection in the two sinograms depends on the angular relationship between the 2D projections.

**Fig. 5.8.** Sinogram-correlation: Two 2D-projections of the same object share a common 1D-line projection.

The common 1D-line-projection in sinograms is equivalent to the cross-common lines between the two Fourier transforms in the cross common line approach.

For asymmetric particles these two approaches are problematic because only a very small part of the image information is used for determining the relative angular relationship between the different projections (three pairs of line projections in real space or three pairs of cross-common lines in Fourier space). Therefore, this method is only reliable for very accurate projections, which have a very high signal-to-noise ratio and are centered precisely. To cover the space optimally three approximately orthogonal views should be chosen for the first three projections.

Other approaches for the determination of orientations work with multiple micrographs of the same object where the relative tilt angle between consecutive images and the position of the tilt axis are known. These methods are much more robust for determining the initial orientations from projections of asymmetric particles. One example of these strategies is the conical tilt reconstruction [81], where two micrographs of the same object are recorded. In the first micrograph the object is highly tilted (preferably  $60\text{--}70^\circ$ ) and in the second micrograph it is un-tilted. The same particles are selected pair wise from both micrographs. When the orientation of the tilt axis and the tilt angle are known the relative spatial orientation between the two projections of the particle can be calculated. For unambiguous determination of the spatial orientations only those particle images are considered that show the same projection in the un-tilted micrograph.

For a particular view the in-plane rotation of the particles is determined by standard alignment procedures of the images of the un-tilted object. Knowing the tilt axis and tilt angle gives the complete information on the relative spatial orientations for the complementing tilted images.

#### 5.3.4.2 Reconstruction of the Three-dimensional Model

The next step is to reconstruct the 3D model from the different projections with known orientations. This can be either done in real space or in Fourier space. In real space the back-projection is used [82], where each projection is projected back to a three-dimensional volume. The direction for the back-projections is the same as the original direction of projections. For a single projection, back-projection

**Fig. 5.9.** Back-projection: 2D-projections are projected back into 3D space using the same direction for back-projection as that initially used for generating the 2D-projections. Averaging of the back-projected volumes regenerates the original volume.

results in a prism, where the image information is smeared out in the direction of projection (Fig. 5.9). Many of these back-projected volumes are averaged to reconstruct the three-dimensional volume.

This approach leads to an overestimation of the low spatial frequencies, resulting in a blurred appearance. To reduce this problem filter algorithms are employed that take the angular spread of projections and the resulting degree of over-sampling into account. This leads to a faithful representation of the 3D volume.

Alternatively to reconstruction in real space, reconstruction can also be carried out in Fourier space. Here, for the different projections, Fourier-transforms are calculated, which are combined in 3D-Fourier space. The 2D-Fourier-transforms in 3D-Fourier space are given the same orientations as determined for the corresponding projections in real space. Fourier synthesis provides the final reconstructed three-dimensional volume [83]. As in real space, over-sampling of the low-resolution information occurs and has to be properly corrected. For an object that is tilted around a single axis the maximal obtainable resolution  $d$  is given by the diameter  $D$  of the particle and the number  $n$  of evenly spaced views between  $-90^\circ$  and  $+90^\circ$  [Eq. (13)].

$$d = \pi \frac{D}{n} \quad (13)$$

For a nano-particle of 50 nm diameter, for instance, about 80 regularly spaced projections are needed to reconstruct the volume at 2 nm resolution. At higher resolution the Fourier-space is under-sampled and can therefore not be reconstructed

properly. According to the formula thinner objects need less independent projections. Importantly, resolution depends not only on these spatial considerations but also on the signal-to-noise ratio, which is related to the cumulative number of scattered electrons [51] and the general quality of the micrograph.

Often the projections are not equally spaced over the asymmetric unit but cover only a certain area. In this case the resolution is no longer isotropic and is worse in the direction where views are missing. Such image reconstructions look blurred and elongated in one direction.

For further refinement of orientations, reference-based approaches are chosen where the 3D model is taken into account. For example, in sinogram correlation the orientation of a projection is determined by sinogram correlation against a set of sinograms of equally spaced “anchor”-projections of the three-dimensional volume. Alternatively a projection matching algorithm is employed, where the volume is projected in different directions and the particle images are aligned by multi-reference alignment to this set of references. After alignment the particle is assigned the same orientation as the direction of projection of the reference image to which the particle correlated best [84]. A similar approach is followed in Fourier-space. Here Fourier transforms of the particle images are compared to the 3D-Fourier-transform of the reference-volume, testing different orientations for the best match [85].

For high-resolution image reconstructions, the transfer of contrast by the electron microscope plays an important role. This modulation is described by the contrast transfer function. Depending on the defocus and other imaging conditions this function has zeros at certain spatial frequencies, where no information is transferred and pass-bands at other spatial frequencies, where the information is transferred alternately with positive or negative contrast. In the pass-bands the strength of contrast transfer varies between no transfer and complete transfer of information. The simplest approach to correction is the contrast-inversion in every other pass-band, which leads to transfer of image information with the same contrast. Doing that is sufficient for obtaining image reconstructions where the phases are accurately preserved but the amplitudes show a clear deviation from their true values. Especially at low spatial frequencies the amplitudes are severely underestimated (e.g., no phase contrast transfer at 0 spatial frequencies). More sophisticated approaches also attempt to correct for the amplitude information. However, at spatial frequencies, where the overall contrast transfer is close to zero or zero, the information is often too noisy and should not be amplified by huge factors. This problem is solved by a Wiener filtering algorithm in which a maximal permissible amplification factor is set (e.g., Ref. [86]). The choice of maximal amplification factor depends on the signal-to-noise ratio and is chosen close to 1 when correction for the contrast transfer function is done on raw images and can be considerably higher (e.g., 10; Ref. [86]) if the correction is done on averaged images. Even with these more sophisticated approaches to contrast transfer correction, low spatial frequencies are usually underestimated. Therefore, the amplitude profile is not correctly maintained. However, the relative amplitudes in a certain resolution band are preserved accurately.

## 5.4 Merging of Methods

### 5.4.1

#### Comparison of EM and SAXS Data

SAXS data provides information on the accurate amplitude profile. For a combination with electron microscopic data a relative scaling of the amplitude profiles is required. For such scaling it is necessary to understand the underlying mechanisms that influence the amplitude profile in the electron microscopic data. We have already discussed in detail the effect of the contrast transfer function. An exact knowledge of if and how it was corrected is a prerequisite for the interpretation of the amplitude profile. In addition, at low spatial frequencies the contrast between particles and solvent determines the amplitude profile. Here differences in density between water in the SAXS measurements and vitrified water in the electron microscopic measurements have to be taken into account. Furthermore, in many image reconstructions of electron microscopic images band-pass filtering of the data has been used to suppress information at low and high spatial frequencies. Again the exact filter parameters and the shape of the filter have to be known to reproduce the true amplitude profile. Another serious effect on the amplitude profile is decay in contrast-transfer at higher spatial frequencies, which is best described by a temperature factor, similar to the one known from X-ray crystallography. Many parameters contribute to this overall temperature factor, such as spherical and chromatic aberration of the microscope, stability of the holder, beam damage, charging, inaccuracy in the determination of particle orientations, effects of interpolation in image processing, and the modulation transfer function of the CCD or the photographic film and scanner. Typical cumulated temperature factors have been estimated to range between ca. 500 and 1000 Å<sup>2</sup> [51, 87], which is considerably larger than those observed in X-ray crystallography. Accurate estimates of the temperature factors in the raw data come from comparison of the amplitude profile from electron micrographs and SAXS measurements on Herpes Simplex Virus [88]. These temperature factors ranged between 50 and 200 Å<sup>2</sup>, depending on the defocus.

To illustrate that, we discuss here a direct comparison of SAXS and EM data from *Lumbricus terrestris* hemoglobin. SAXS data include the scattering curve,  $I(h)$ , pair distance distribution function,  $p(r)$ , radius of gyration,  $R_G$ , hydrated volume,  $V$  and the maximum diameter of the particle,  $D_{\max}$ . EM data provide information on the 3D electron density distribution (Table 5.1). For direct comparison the EM data need to be converted into data suitable for SAXS model calculations. As outlined in previous sections, in SAXS models, the protein mass is simulated with a large number of small spheres. Accordingly, to compare EM data with SAXS profiles, EM data are used to calculate models with a large number of small spheres, whereby the position of the spheres is given by the EM model coordinates. Then model scattering functions, pair distance distribution functions and molecular parameters (radius of gyration, maximum particle diameter, volume) of the EM

model can be calculated in a way similar to the calculation of the SAXS models (Table 5.1). To convert the EM electron density in a meaningful weighting scheme for the model calculations, the weight of spheres is chosen to represent density values between 0.3345 (electron density of water) and 0.4395 (averaged electron density of a protein). Here the value for the electron density of water was chosen, because vitrified water, as used in the EM experiment, forms no ice crystals (see above). Additionally, appropriate rescaling is necessary to fit the positions of the maxima of the experimental scattering curve and the model parameters (scaling due to magnification differences).

A common problem in EM is the exact determination of the volume of the biological sample and here knowledge from SAXS studies may help. Figure 5.10

Fig. 5.10. Comparison EM (dashed line) and SAXS data (experimental data dotted with error bars; model data solid line) for *Lumbricus terrestris* hemoglobin.

shows that the threshold of the EM model has to be chosen in a way that the model represents the hydrated particle volume rather than the “expected” volume of the protein to give good agreement of data. The “expected” particle volume is calculated by the molecular weight of the protein, and the partial specific volume. This is usually much smaller than the hydrated volume [18].

We see that SAXS and EM data agree very well up to a scattering angle of  $h = 1.2 \text{ nm}^{-1}$ . Careful analyses of the scattering curves reveal that the 1st minimum of the experimental scattering curve is not fitted within the limits of error by the scattering curve calculated from the EM data. The minimum of the model scattering curve seems to be more pronounced than the minimum of the experimental curve. This, however, must not be taken too seriously. In scattering experiments the randomly oriented particles in solution together account for the observed scattering and the structural information from all the particles in solution is summarized in one scattering curve. This summarizing of structural information may lead to an additional “smearing” of the minima of the scattering curve. If, on the other hand, the scattering curve of a model (e.g., an EM model) is calculated, the information of only one particle is present, giving rise to a very “clear” scattering curve. Therefore, model scattering curves sometimes show more pronounced minima than the experimental curves and consequently, as long as the positions of the minima and the heights and positions of the maxima are fitted correctly by the model data, this does not decrease the quality of a model.

The observed differences in the outer part of the scattering curve, however, may be due to slightly different structures of the protein observed in vitreous ice and in solution. Another explanation might be the contrast transfer of the magnetic lens of the electron microscope or the application of an additional filtering procedure during the EM reconstruction (as mentioned above).

In general, it is important to state that the value of the hydrated volume can only be determined with sufficient certainty from the SAXS data, whereas information on the 3D electron density distribution is contained in the EM data. Thus, both methods together give maximal information.

#### 5.4.2

#### **SAXS Modeling Approaches using EM Information**

We have seen that SAXS modeling is not unique and therefore SAXS data are usually interpreted by comparing the experimental data with model profiles. The creation of model profiles is not trivial and, as stated above, it is very useful to implement structural knowledge from other methods to increase the reliability of any SAXS modeling attempt. As an example we want to discuss here an indirect incorporation of information gained by EM into automated SAXS modeling: In this approach, first templates are created using the structural information gained by EM. Subsequently, those templates are used as starting models for the automated SAXS model creation.

In Fig. 5.11 different models of the hemoglobin from the leech *Macrobdella decora* are shown. Overall the protein complex is related to the hemoglobin from

**Fig. 5.11.** Models of *Macrobdella decora* hemoglobin: (A) two-step trial-and-error SAXS model, (B) automatic generation without information other than  $D_6$  symmetry, (C) automatic generation employing a template created with information from EM data.

*Lumbricus terrestris* and it has a similar appearance (hexagonal bilayer architecture). In Fig. 5.11 the trial-and-error approach from SAXS multi-body modeling is shown in part (A) (similar to the approach shown earlier for *L. terrestris* hemoglobin). Fig. 5.11(B) shows the automatically generated SAXS model calculated without structural information other than  $D_6$  symmetry (*ab initio* modeling). For Fig. 5.11(C) additional information concerning shape and internal structure was incorporated in the calculations by the use of a template derived from 3D EM reconstructions [89]. Clearly, this final example shows that SAXS modeling procedures can be increased in accuracy and reliability through the use of suitable EM templates. SAXS and EM model values are given in Table 5.2.

In conclusion, if characterization of a nano-particle is attempted by either SAXS or EM, a combination of knowledge gained by different methods is advisable. Although such approaches are not yet well established, the results shown here illustrate that this is the way forward for nano applications.

# ***In Situ* Characterization of Drug Nanoparticles by FTIR Spectroscopy**

*Michael Türk and Ruth Signorell*

### 6.1

#### **Introduction**

Infrared (IR) spectroscopy is an important tool to characterize nanomaterials in life sciences. Refs. [1–10] highlight only a few recent examples in this large field, including catalysis using nanoparticles, the targeted synthesis of nanoparticles, the use of nanoparticles as biosensors, and the characterization of drug nanoparticles. This chapter focuses on particulate matter built from molecules and in particular on drug nanoparticles. For the characterization of these molecular nanoparticles IR spectroscopy is particularly well suited. It is relatively sensitive and non-invasive, which is decisive for instance for the investigation of sensitive molecular particles. Furthermore, IR spectroscopy can be used for different kinds of particulate samples (aerosols, particles on a holder, or particles in a matrix) and under a broad range of different experimental conditions (temperature, pressure, etc.). For molecular particles, it opens a direct window to the characteristic intermolecular and intramolecular vibrational dynamics. The vibrational spectra of such large aggregates contain a wealth of information not only about the chemical composition or the phase behavior of the particles, but also about intrinsic particle properties such as the particle size, the particle shape, or structural changes in the particles' surface.

Approximately 80% of all pharmaceutical products are in solid dosage form. Thus, in biomedical applications both the size and shape of the solid particles are important quantities to know, for instance because they can affect the bioavailability of drug particles. The size of the particles manifests itself in the IR extinction spectra by scattering phenomena. They lead to slanted baselines and to a dispersion shape of the absorption bands. To determine the size distribution for a particle ensemble directly from the infrared spectrum it is crucial to know the frequency-dependent optical data (indices of refraction) of the particles. Nowadays, few databases provide refractive index data for particulate systems and most of these data bases focus more on molecular ice particles than on biomolecular substances. Since the optical properties of particles can differ markedly from those of the solid bulk, corresponding bulk data are often not suitable either. This clearly illustrates the need for optical data of particles, especially for substances of biomolecular in-

terest. The particles' shape can lead to characteristic band structures in IR extinction spectra. These phenomena, however, are pronounced only for very strong vibrational transitions. The structure and position of weak absorption bands are dominated by rather local effects, i.e., by interactions with neighboring molecules, such as the formation of specific hydrogen-bonded networks in the particles.

The main focus of this chapter lies in the *in situ* characterization of nanoparticles by Fourier-transform infrared (FTIR) spectroscopy. Most often, off-line techniques are used to investigate particles, which have, consequently, first to be collected on a holder. This approach is not only very slow, but the process of collecting can also affect the particles' properties. *In situ* characterization by contrast is quick, thus allowing us to investigate and control the particle properties during their formation. We compare and complement the results from direct absorption FTIR spectroscopy *in situ* with particle sizing using a scanning mobility particle sizer, with 3-wavelengths-extinction measurements, with scanning electron microscopy, with differential scanning calorimetry, and with X-ray diffraction.

The infrared investigations are combined here with two different particle generation methods, *viz.* Rapid Expansion of Supercritical Solutions (RESS) and electro-spraying. Rapid expansion of supercritical CO<sub>2</sub> solutions is a particularly useful method to micronize thermally labile drugs, which often consist of lipophilic compounds. The main advantage of the solvent CO<sub>2</sub> lies in its low critical data and in the fact that it can easily be separated from the product after particle formation. As an example, the mixing/coating of phytosterol with polymers (Eudragit®, L-PLA) is discussed. Encapsulation of drugs with polymers is especially attractive to avoid agglomeration and to control drug release in the body. Electro-spraying of aqueous or alcoholic solutions allows us to generate nanoscale particles of hydrophilic compounds. Here, the particle formation of sugar-like substances is discussed. This class of substances is attractive as carrier for administering drugs in solid dosage form.

## 6.2

### Particle Generation Methods

#### 6.2.1

#### Rapid Expansion of Supercritical Solutions (RESS)

The potential of RESS for the micronization of molecular substances has been demonstrated previously [11–15]. The key idea behind RESS is to dissolve the solute of interest in a supercritical fluid followed by a rapid expansion of the supercritical solution. This leads to an extremely fast phase change from the supercritical to the gas-like state, resulting in high supersaturation in the supersonic free jet and the formation of submicron particles. Since the solvent is a dilute gas after expansion, the RESS process offers a highly pure final product. Dissolution experiments demonstrate that the RESS processing of Griseofulvin leads to a signifi-

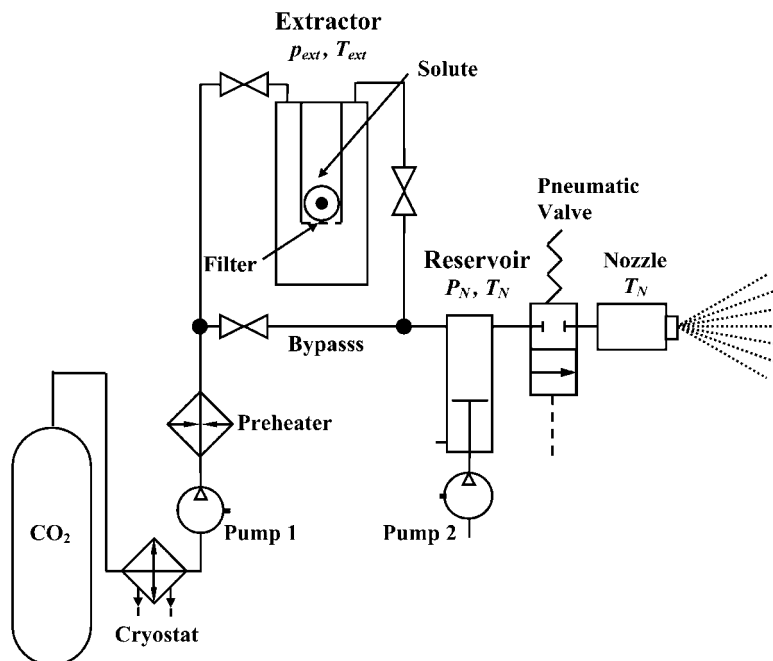

Fig. 6.1. Scheme of the RESS apparatus.

cantly better dissolution rate of the drug, resulting in an improved bioavailability [14].

We have built up several types of RESS apparatuses [14–18], which differ in size (continuous and batch RESS apparatuses) and in the mode of expansion, i.e. continuous expansion versus pulsed expansion. A general scheme of a RESS apparatus is depicted in Fig. 6.1. Our setup is designed for experiments in the temperature range 300–600 K and for pressures up to 60 MPa. The gaseous solvent ( $\text{CO}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{CHF}_3$ ) is taken from a reservoir, liquefied by a cryostat, and pressurized (pump 1: diaphragm pump or pneumatic pump) to the desired pressure in the extractor ( $p_{\text{ext}}$ ). For the formation of nanoscale particles of thermally labile drugs,  $\text{CO}_2$  is a particularly suitable solvent since it has low critical data ( $T_{\text{crit}} = 304$  K,  $p_{\text{crit}} = 7.38$  MPa), is non-toxic, and can be easily separated from the particulate phase after particle formation. The extractor is a heated ( $T_{\text{ext}}$ ) high-pressure autoclave that is packed with the solute. For continuous operation, the supercritical solution is expanded directly through the pinhole nozzle. For pulsed operation, a heatable high-pressure reservoir ( $T_N$ ,  $p_N$ ) is filled with the solution first. Expansion then takes place from this reservoir, the pressure of which is kept constant during the pulses (duration  $t_{\text{puls}} > 100$  ms) by a movable piston connected to pump 2. The length of the pulses is controlled by the pneumatic valve in front of the nozzle. The pinhole nozzles used have variable inner diameters of 20–200  $\mu\text{m}$  and lengths of

50–300  $\mu\text{m}$ . The nozzle is positioned in the expansion chamber, as further explained in Section 6.3.1.1 and depicted in Fig. 6.3 below.

Particle generation by RESS can be used, in principle, for a wide range of different solutes [11–14]. This statement, however, has to be qualified to some extent for thermally labile substances such as drugs for which the solvent has to meet special requirements. Here, carbon dioxide is often the only suitable solvent so that the application of RESS is restricted to compounds with reasonable solubility in supercritical  $\text{CO}_2$ . Micronization with RESS, in general, produces particles with rather broad size distributions [geometric standard deviation  $\sigma > 1.5$ , see Eq. (2)]. In this context, an important factor is the agglomeration of the primary particles, which leads to a broadening of the size distribution. Different methods (RESSAS, CORESS, CPD) for stabilizing the primary particles against agglomeration have recently been realized [19–26]. They are discussed briefly in Section 6.5.

## 6.2.2

### Electro-Spraying

Electro-spraying is a method of generating particles of molecular compounds that are preferentially soluble in polar solvents such as water or different alcohols. A scheme of the Electro Spray Aerosol Generator (EAG, TSI 3480) is depicted in Fig. 6.2 (see also Refs. [9, 27–30] for further information). The compound of interest is

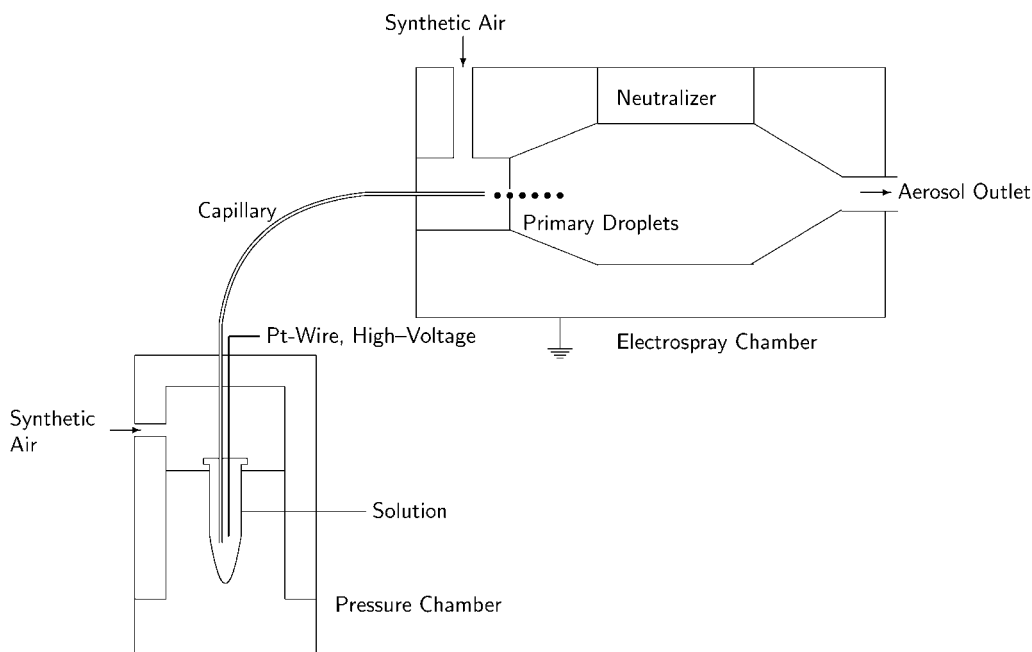

Fig. 6.2. Scheme of the electro spray.

dissolved in an aqueous buffer solution (ammonium acetate/ammonium hydroxide in  $\text{H}_2\text{O}$ ). The buffer solution serves to adjust the pH and to increase the electric conductivity of the solution (usually,  $500\text{--}2000\ \mu\text{S cm}^{-1}$ ). Typical concentrations of the solute lie between 2 and 10 vol%. The solute concentration determines the diameters of the final particles, which lie below  $\sim 100\ \text{nm}$ . The setup consists of a capillary that is immersed in the solution. The solution is driven through the capillary ( $\sim 70\ \text{nL min}^{-1}$ ) by a pressure gradient. Between the capillary tip and an electrode with a pinhole, a high voltage is applied so that highly charged primary droplets of the solution (diameters  $\sim 150\ \text{nm}$ ) are formed. The droplets are neutralized by a radioactive source and the solvent evaporates from these primary droplets in a sheath-flow of clean dry synthetic air ( $\text{N}_2/\text{O}_2$ ;  $\sim 2\ \text{L min}^{-1}$ ). The neutralized aerosol flow then enters the multireflection sheath-flow cell described in Section 6.3.1.1.

The electrospray generates small particles with relatively narrow size distributions. Typical geometric standard deviations amount to  $\sigma = 1.3$ . This is a great advantage over many other particle generation methods, which for molecular substances often lead to particles with fairly broad distributions ( $\sigma > 2$ ). As monodisperse products exhibit much more homogeneous properties they are usually highly preferred over polydisperse particle ensembles. However, particle generation by electro-spraying has two major disadvantages. One concerns the separation of the solvent. The commonly used solvents are liquid at atmospheric conditions and thus can easily condense on the particles collected from the gas phase. The second more severe problem is the clogging of the capillary, especially of the capillary tip. This reduces the general applicability of electro-spraying for particle generation to substances that are slow to crystallize at the capillary tip (i.e., with a tendency to form supersaturated solutions).

## 6.3 Particle Characterization Methods

### 6.3.1

#### *In Situ* Characterization with FTIR Spectroscopy

##### 6.3.1.1 Experimental Setup

Figure 6.3 shows the experimental setup for the *in situ* characterization with Fourier transform infrared spectroscopy (FTIR). The nozzle of the RESS apparatus (see Section 6.2.1 and Fig. 6.1) is positioned in the expansion chamber and is connected to the reservoir of the RESS apparatus with a high-pressure hose. The expansion chamber and the buffer volume are connected vacuum chambers with a total volume of  $0.8\ \text{m}^3$ . The buffer volume helps to limit the increase of pressure,  $p_c$ , in the expansion chamber. The whole vacuum part is evacuated to  $p_c = 0.03\ \text{mbar}$  by two rotary piston vacuum pumps (Leybold DK 100 and E 250) connected in parallel. With the  $50\ \mu\text{m}$  nozzle and a reservoir pressure of  $p_R = 400\ \text{bar}$ , the pressure in the chamber typically increases to  $0.16\ \text{mbar}$  after a pulse of  $0.5\ \text{s}$  duration. A pulse duration of  $2\ \text{s}$  leads to  $p_c = 0.55\ \text{mbar}$ . The IR spectra of nanoparticles were

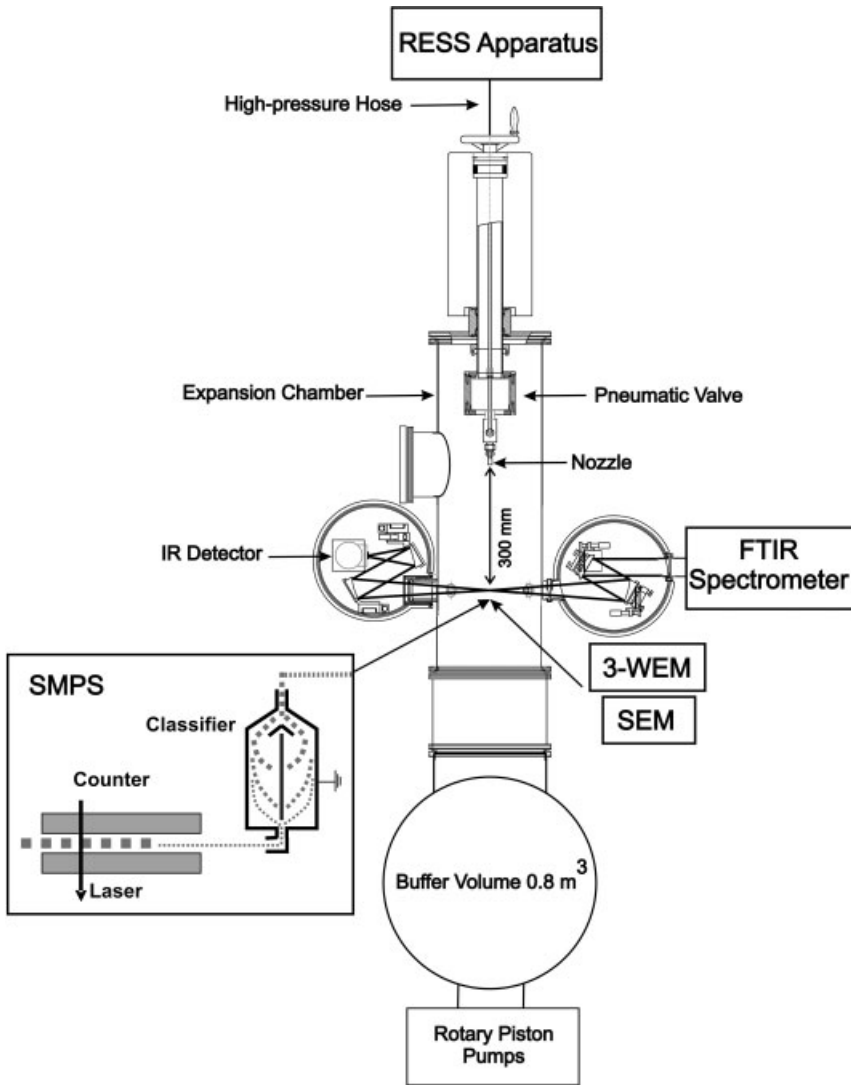

Fig. 6.3. Scheme of the vacuum apparatus for the *in situ* characterization with FTIR.

recorded *in situ* using a Bruker IFS 66v/S FTIR spectrometer. As depicted in Fig. 6.3, the supersonic flow is probed radially by the infrared beam. The infrared beam from the Globar light source is focused into the center of the expansion by a first off-axis parabolic mirror (327 mm focal length). After passing the expansion, the light is collected by a second off-axis parabolic mirror (327 mm focal length) and a third parabolic mirror (109 mm focal length) focusses the light onto a liquid nitrogen cooled MCT detector. The spectrometer and detector chamber are

separated from the expansion chamber by two KBr windows. The rapid-scan mode of the spectrometer allows us to synchronize the acquisition of IR spectra with the pulsed expansion. With a scanner velocity of 280 kHz, one scan is recorded in 30 ms at a resolution of  $2\text{ cm}^{-1}$ , which means that several scans can be made during one pulse (pulse duration  $> 100\text{ ms}$ ). To get a good signal-to-noise ratio, we typically accumulate more than 500 scans. A similar combination of direct absorption FTIR spectroscopy with intense fluid pulses through a slit-nozzle into the vacuum has been realized for the first time by Suhm and coworkers [31, 32] to study the vibrational dynamics of small clusters.

The investigation of particles during their generation in the aerosol phase by *in situ* FTIR spectroscopy has many advantages. First of all, IR spectra contain information about various particle properties such as the size distribution, chemical composition, and structural aspects. Therefore, the combination with rapid characterization *in situ* represents a very useful method for process control. With the setup described here, the particles do not have to be collected first but can be continuously analyzed during their generation. This allows us, for instance, to control their size by changing the process parameters such as the temperature, pressure, or concentration of the supercritical solution. It also enables us to control the portion of different components in the final product if supercritical solutions with several solutes are used. This is of interest for the coating of drug particles or for the generation of mixed drug/matrix particles (see also Section 6.5.3). In addition, with the vacuum option we can change the generation conditions of the particles by varying the pressure  $p_c$  in the expansion chamber. With phenanthrene particles, particles generated under vacuum conditions have smaller mean sizes but broader distributions than those generated at ambient pressure (see Ref. [10] and Section 6.5.1). Section 6.3.1.2 demonstrates that our setup can also be used to study the region of the expansion before the Mach disc, which is essential for a better understanding of the RESS and is crucial to verify corresponding theoretical predictions [12, 33–38].

Particles generated in the electrospray (Fig. 6.2) are investigated spectroscopically in a multireflection sheath-flow cell [30, 39]. The cell consists of two concentric cylinders. The carrier gas is introduced into the gap between the two, enters the inner cylinder through a large number of small holes, and is finally pumped off at the bottom. This creates a smooth sheath-flow for samples injected coaxially at the top of the inner cylinder. The cell is operated at room temperature with a sheath-flow of 1.5 L He per minute. The sheath-flow serves to guide the aerosol through the flow tube and to minimize contaminations of the mirrors. The cell is equipped with White optics with an optical path length of about  $h = 16\text{ m}$ .

#### 6.3.1.2 Characterization of the RESS Process

The mole fraction of the solute in supercritical  $\text{CO}_2$  typically lies below 0.1–0.01 [40]. In other words, the supercritical solution expanded in the RESS process mainly consists of  $\text{CO}_2$ . Evidently, the influence of  $\text{CO}_2$  on particle formation is not negligible. Due to the high supersaturation, one expects that not only the solute with its low volatility but also the  $\text{CO}_2$  itself condenses into small particles within

**Fig. 6.4.** Upper trace: Experimental IR spectrum of  $\text{CO}_2$  particles recorded in the collision-free region before the Mach disc. Experimental conditions: nozzle diameter  $d = 50 \mu\text{m}$ ,  $p_R = 400 \text{ bar}$ ,  $T_N = 298 \text{ K}$ . The sharp peaks arise from residual gas phase  $\text{CO}_2$

in the expansion. Lower trace: Calculated  $\text{CO}_2$  particles spectrum. For the fit we have used the refractive index data from Ref. [44], a Mie-model [42], and a log-normal distribution [Eq. (2)].  $\tilde{\nu}$  is the transition wavenumber.

the nozzle and some nozzle diameters downstream [12, 33–38]. Figure 6.4 shows that these solvent particles really can be observed in the collision-free region before the Mach disc. The experimental IR spectrum in the region of the antisymmetric stretching vibration  $\nu_3$  of  $\text{CO}_2$  is depicted in the upper trace. The sharp peaks superimposed on the broad band have nothing to do with the solvent particles, they arise from residual gas-phase  $\text{CO}_2$  in the expansion. The appearance of the broad band is characteristic of  $\text{CO}_2$  particles [41]. It allows us to estimate the size of the solvent particles [10] since both the width and the shoulder at about  $2340 \text{ cm}^{-1}$  strongly depend on the particle size. As a rough rule one can say that for larger particles the band broadens and the intensity of the shoulder increases. The size is an important quantity to know since the condensation/evaporation behavior of the solvent influences the particle formation processes. It is also of interest to verify corresponding theoretical predictions [12, 33–38]. The sizes are estimated by fitting calculated extinction spectra to the experimental IR spectrum. For that, we have assumed Mie theory [42] and a log-normal size distribution that is characterized by the mean particle radius ( $r_0$ ), the geometric standard deviation ( $\sigma$ ) and the particle number concentration ( $N$ ) [see Eq. (2)]. The refractive index data have been taken from Refs. [43, 44]. Typical parameters for expansions at temperatures between 298–398 K and pressures between 100–400 bar are listed in Table 6.1. As

**Tab. 6.1.** Geometric standard deviation  $\sigma$ , mean particle radius  $r_0$ , and particle number concentration  $N$  [see Eq. (2)]. Data from IR spectra have been obtained from a fit to the experimental data using Mie theory and two different sets of refractive index data [43, 44]. Since  $r_0$  and  $\sigma$  are strongly correlated, the value for  $\sigma$  has been fixed [10].

$p_N$ /(bar)	$T_N$ /(K)	$\sigma$	$r_0$ /(nm)	$N^{[a]}$ /( $10^8 \text{ cm}^{-3}$ )
400	298	1.4	300	0.2
100	298	1.4	180	0.1
400	360	1.4	210	0.2
400	298	2.1	70	3.9

<sup>a</sup> Values for  $N$  for a path length of  $h = 1 \text{ cm}$ .

expected, we find a systematic decrease of  $r_0$  with decreasing reservoir pressure ( $p_N$ ) and with increasing temperature. The values of the radii of the solvent particles in Table 6.1 lie well above 100 nm. However, because the parameters  $\sigma$  and  $r_0$  turned out to be highly correlated we have fixed the value of  $\sigma$  at 1.4 during the refinement procedure. For comparison, the last row of Table 6.1 gives one example with the geometric standard deviation fixed at  $\sigma = 2.1$ . Comparison with the first row shows that the mean size decreases if a broader distribution is assumed. Independent of the widths of the distribution, however, we can finally state that the mean particle radius of the solvent particles lies clearly above  $r_0 = 50 \text{ nm}$  for temperatures between 298 and 398 K and pressures between 100 and 400 bar [10].

In the collision-free region of the expansion,  $\text{CO}_2$  and the solute both exist as small particles due to the supersaturation and subsequent condensation upon expansion. This result is in good agreement with the modeling results published by Helfgen et al. [38]. From these calculations it follows that the decrease of pressure and temperature in the supersonic free-jet can lead to solvent condensation. Depending on the pre-expansion conditions, the condensate mass fraction goes up to around 30% for  $\text{CO}_2$  and 25% for  $\text{CHF}_3$ . As mentioned above, the mole fraction of the solute in supercritical  $\text{CO}_2$  lies below 0.1–0.01 so that the amount of condensed  $\text{CO}_2$  is much higher than that of condensed solute. But it is not clear whether the two components form (statistically) mixed particles or whether the solute condenses first to small particles that then act as condensation nuclei for the more volatile  $\text{CO}_2$  (coated particles). We have investigated this question for an expansion of a n-nonadecane/ $\text{CO}_2$  solution. Figure 6.5 shows the corresponding IR spectrum in the region of the CH-stretching vibrations of n-nonadecane ( $\text{C}_{19}\text{H}_{40}$ ) particles. The region of the antisymmetric stretching vibration of the  $\text{CO}_2$  particles is not shown again. It looks the same as already depicted in Fig. 6.4. The shape and the band positions in the spectrum of the nonadecane particles in Fig. 6.5 are the same as those for pure nonadecane particles [10]. We consider this fact a hint that coated particles rather than mixed particles exist in the collision-free region before the Mach disc. The preference of coated particles, however, is much more plausible since nonadecane is much less volatile than  $\text{CO}_2$  and thus condenses first, probably already within the nozzle [12, 33–38].

**Fig. 6.5.** Experimental IR spectrum of nonadecane in the region of the CH-stretching vibrations. The spectrum was recorded in the collision-free region before the Mach disc. In this region both nonadecane and the solvent  $\text{CO}_2$  condense to small particles.  $\tilde{\nu}$  is the transition wavenumber.

The conditions and processes before the Mach disc described in this section certainly influence the properties of the final particles. But the processes taking place at and after the Mach disc and the manner in which the particles are collected are much more important factors, for instance for the size of the final particles. All these factors can lead to coagulation and agglomeration of primary particles. The sudden temperature and pressure increase taking place at the Mach disc leads to evaporation of the solvent particles so that after the Mach disc only pure solute particles are present. However, we have shown previously [10] that complete evaporation of the solvent particles takes some seconds. Since agglomeration and coagulation seem to be important it is not astonishing that the electron microscopy images of the final products, which are further discussed in Section 6.5, often show agglomerates consisting of relatively small (50–100 nm) primary particles. One possibility to avoid this subsequent agglomeration is by coating the particles as discussed in Section 6.5.3.

### 6.3.2

#### ***In Situ* Characterization with 3-WEM**

In continuous particle formation processes, fast *in situ* measurement techniques for on-line particle size determination are desirable. In contrast to the usual off-line examination techniques, the particles are therefore measured in the expansion

chamber on-line and *in situ* with the Three-Wavelengths-Extinction (3-WEM) measurement technique (see Fig. 6.3). The 3-WEM measuring devices used are equipped with three lasers emitting at wavelengths of 405, 633, and 1064 nm (home-built device) and of 674, 814, and 1311 nm (WIZARD-DQ, Wizard Zahoransky KG, Todtnau, Germany), respectively. The fiber-coupled transmitter of the latter device is placed at the optical access of the test volume. The remaining light is detected with the opposite receiver. The relative transmissions of the three different wavelengths  $I/I_0$  are used for the evaluation on a PC. According to Mie theory [42], the system allows the measurement of particle diameters in a range from 0.2 to 4  $\mu\text{m}$  and particle concentrations ranging from  $10^5$  to  $10^8$  particles per  $\text{cm}^3$  [10, 45]. The advantages of the 3-WEM measurement technique are that it is a suitable method for measuring particle size and number concentration under sub-, near-, and supercritical conditions. In addition, the 3-WEM enables on-line process control because particle characteristics can be determined within  $10^{-6}$  s. However, for non-spherical and/or agglomerated particles the 3-WEM measurement technique can lead to incorrect results for the particle size distribution. To overcome this, a combination of different measurement methods has to be used to accumulate sufficient information on the size and structure of the particles investigated. Therefore, samples for additional SEM examination (see Section 6.3.3) were taken 300 mm from the nozzle exit directly behind the 3-WEM-probe. A more detailed description of the apparatus and the experimental procedure is given elsewhere [16].

### 6.3.3

#### Characterization with SMPS and SEM

The number size distribution of the aerosol is also measured on-line with a Scanning Mobility Particle Sizer (SMPS), which can be connected to the RESS expansion chamber (Fig. 6.3) or to the electro-spray (Fig. 6.2). The SMPS consists of a differential mobility analyzer (TSI 3080L/N), which classifies the particles according to their mobility in an electric field, and of a condensation nuclei counter (TSI 3022A), where the particles are counted optically. The SMPS only works at atmospheric pressure and at room temperature and, therefore, can only be used for a limited range of experiments. Compared with 3-WEM and IR spectroscopy it leads to more detailed size distributions since it measures the number of particles for each single size and does not rely on any assumption about the type of the size distribution (e.g., log-normal distribution). However, the SMPS is much slower than 3-WEM or IR spectroscopy. Typical acquisition times lie around 2 min. Examples for size distributions measured with the SMPS are given in Section 6.5.

To visualize the shape of nanoparticles and also to determine their approximate size, we use Scanning Electron Microscopy (SEM). This off-line characterization requires collection of the particles first, which often leads to agglomeration. We collect them either on a polycarbonate membrane or on a silicon holder previously covered with a thin gold layer (11 nm). After collecting, the sample is covered with a second gold layer (7 nm) to avoid evaporation of substances inside the SEM apparatus. Examples of SEM images are depicted in Section 6.5.

## 6.4

### Determination of Refractive Index Data in the Mid-infrared Region

Knowledge of the frequency-dependent complex refractive index  $n + ik$  of the solute particles is a prerequisite for *in situ* characterization with FTIR spectroscopy. Therefore, we have started to derive corresponding optical data from the measured infrared extinction spectra of organic aerosols and from size distributions determined experimentally with the SMPS and with 3-WEM (Section 6.3). The formalism is given below by Eqs. (1–5). The refractive index data thus derived are collected in Ref. [46] together with a short description and an estimate of their accuracy. There exist other databases for refractive indices in the mid-infrared region (see for instance Refs. [47–49]) which are, however, focussed more on molecular ices rather than on particles of biomolecular interest.

Our data are obtained from particle spectra and not from thin films. It is more difficult to derive accurate data from particle spectra than from thin films since it is often very difficult to get accurate information about the correct size distribution or the shape of the particles. On the other hand, the structure and even the chemical composition of the particles (crystalline/amorphous, modified structure of the particle surface [9, 30, 41, 50–52]) can strongly depend on the generation method and conditions. The latter aspect clearly illustrates the need for optical data obtained directly from particle spectra. Ref. [46] contains an accurate description of the methods used, but due to the limited information about size and shape of the particles the tabulated data only provide a first starting point towards the determination of more accurate data. Although we use three different methods (SEM, SMPS, and 3-WEM) for the characterization of the size and shape it is nearly impossible to get very accurate experimental data for these properties. The main disadvantage of SEM is that, upon collecting, the particles often agglomerate. Analysis with SMPS and 3-WEM relies on assumptions for the particle shape or the size distribution. Moreover, the derivation of the infrared optical data is based on models [see Eqs. (1–5)]. The Mie theory used for that purpose gives the solutions for the scattering and absorption of light by spherical particles. The assumption of a spherical shape is often regarded as an adequate approximation even for non-spherical particles. But this is more of an assertion than a fact and would have to be tested for each case [42, 53]. For instance, Mie theory fails for non-spherical particles in the case of strong vibrational transitions when transition dipole coupling is dominant [41, 54, 55]. We also neglect multiple scattering, which will not lead to major errors as long as the particle density is not too high.

The frequency-dependent complex refractive index  $n + ik$  of solute particles has been determined directly from the experimental extinction spectrum of the corresponding aerosols in the mid-infrared region by following two alternative approaches: (a) a Lorentz model fit and (b) a Kramers–Kronig inversion. Both proceed via the complex refractive index to characterize the optical properties of the particulate phase. We employed Mie theory for spherical particles [42] to calculate the observed extinction spectrum. The refractive index of the surrounding medium (different gases) was set to unity. The frequency dependent extinction cross section

( $C_j$ ) is calculated separately for each value of the particle radius ( $r_j$ ). The calculated total absorbance ( $A_{\text{calc}}$ ) is obtained by summing over all different radii using the experimentally determined particle size distribution:

$$A_{\text{calc}} = h \sum_j N_j C_j \quad (1)$$

where  $h$  is the optical pathlength and  $N_j$  is the number density of aerosol particles with size  $r_j$ . The experimental size distribution is determined either by the SMPS (Section 6.3.3), by 3-WEM (Section 6.3.2), or by a combination of both [9, 10, 15, 29, 30, 41]. The classifier of the SMPS determines the particle radii ( $r_j$ ) for different size intervals  $j$ . Each decade of particle size is divided into 64 equidistant logarithmic intervals. The particle counter of the SMPS then measures the particle number concentration ( $N_j$ ) in each interval  $j$ . The measurement range of the SMPS is limited to the region 7–1000 nm. Size distributions that exceed this range are extrapolated by using a log-normal distribution. A log-normal distribution for the particle radii ( $r$ ) is also assumed for the interpretation of the 3-WEM experiments. Its form is given by [56]:

$$df = \frac{1}{\sqrt{2\pi} \ln \sigma} \exp \left\{ -\frac{[\ln(r/u) - \ln(r_0/u)]^2}{2(\ln \sigma)^2} \right\} d[\ln(r/u)] \quad (2)$$

with the mean particle radius ( $r_0$ ) and the geometric standard deviation ( $\sigma$ ) as parameters;  $u$  is the unit radius. The product  $N \cdot h$  of the particle number concentration ( $N$ ) and the pathlength ( $h$ ) is determined by the absolute values measured for the extinction [Eq. (1)].

In the first approach to determine the complex refractive index of the nanoparticles we assume a model function for the (complex, frequency dependent) dielectric function ( $\varepsilon$ ) of the solute particles. The empirical parameters of this function are determined from a nonlinear least-squares fit of the calculated extinction,  $A_{\text{calc}}$  [Eq. (1)], to the experimental aerosol spectra. In this study we have used the so-called Lorentz model, which describes the optical properties of the solid by a collection of isotropic damped harmonic oscillators coupled to the electromagnetic field of the light by their effective charge. Solution of the classical equations of motion leads to the Kramers–Heisenberg dielectric function [42, 57]:

$$\varepsilon = \varepsilon_1 + i\varepsilon_2 = \varepsilon_e + \sum_s \frac{\tilde{\nu}_{sJ}^2 f_s}{\tilde{\nu}_s^2 - \tilde{\nu}^2 - i\gamma_s \tilde{\nu}} \quad (3)$$

The dielectric function is directly related to the complex index of refraction ( $n, k$ ):

$$n = \sqrt{\frac{\sqrt{\varepsilon_1^2 + \varepsilon_2^2} + \varepsilon_1}{2}} \quad k = \sqrt{\frac{\sqrt{\varepsilon_1^2 + \varepsilon_2^2} - \varepsilon_1}{2}} \quad (4)$$

The parameter  $\varepsilon_e$  is the dielectric function at frequencies that are high compared with the vibrational excitations considered (but low compared with electronic excitations, which are neglected here). Eq. (3) sums over all oscillators in the spectral region of interest. They are characterized by their resonance wavenumber ( $\tilde{\nu}_s$ ), their reduced oscillator strength ( $f_s$ ) and a width ( $\gamma_s$ ) resulting from the damping of the oscillator.

To the extent that a Lorentz oscillator can be compared to a molecular oscillator (e.g., a molecular normal mode),  $\tilde{\nu}_s^2 f_s$  is proportional to the absorbance  $\int A(\tilde{\nu}) d\tilde{\nu}$  integrated over the corresponding absorption band (also termed integrated intensity). Eq. (3), however, neglects any local field correction, i.e., it assumes that each oscillator experiences the external electric field, which is not necessarily a good approximation in the condensed phase. An approximate local field correction for isotropic media leads to a formally identical expression [58], but with shifted resonance wavenumbers and modified effective reduced oscillator strengths. For the relatively small values of the reduced oscillator strengths found in the vibrational spectrum of many of the solutes, the wavenumber shifts can be neglected. The modification of the reduced oscillator strengths significantly changes their absolute values, thus affecting their interpretation in terms of molecular transition moments [58]. The relative values, however, remain approximately unchanged by the local field correction.

In the second approach, we exploit the Kramers–Kronig relation between the real ( $n$ ) and the imaginary ( $k$ ) part of the complex refractive index [42, 57]. The optical constants can thus be derived from the experimental extinction spectrum without assuming any particular model. In its so-called subtractive form the Kramers–Kronig relation [59–61] is given by Eq. (5).

$$n(\tilde{\nu}') = n(\tilde{\nu}_r) + \frac{1}{\pi} \int_{\tilde{\nu}_{\min}}^{\tilde{\nu}_{\max}} \left( \frac{k(\tilde{\nu})}{\tilde{\nu} + \tilde{\nu}'} - \frac{k(\tilde{\nu})}{\tilde{\nu} + \tilde{\nu}_r} + \frac{k(\tilde{\nu})}{\tilde{\nu} - \tilde{\nu}'} - \frac{k(\tilde{\nu})}{\tilde{\nu} - \tilde{\nu}_r} \right) d\tilde{\nu} \quad (5)$$

Eq. (5) requires knowledge of the real index of refraction at some reference point,  $\tilde{\nu}_r$ . Although in principle arbitrary, it is best (for numerical reasons) chosen to lie within the spectral region of interest. Starting with some guess for the real part  $n$  of the refractive index its imaginary part  $k$  is adjusted (by bisection) so that the Mie scattering calculation reproduces the experimentally measured extinction separately for each value of the wavenumber  $\tilde{\nu}$ . Eq. (5) is then applied to  $k(\tilde{\nu})$  to produce an improved guess for  $n(\tilde{\nu})$ . The Cauchy principal value of the integral in Eq. (5) was calculated on a grid as described in Ref. [61] with the difference, however, that  $k(\tilde{\nu})$  was expanded to fourth order around the singularity at  $\tilde{\nu} = \tilde{\nu}'$ . The whole procedure is repeated until convergence is reached. Since the reference value  $n(\tilde{\nu}_r)$  of the real index of refraction cannot be determined through this procedure it enters as the only free parameter. Here it was set to the value obtained from the Lorentz model fit at  $2000 \text{ cm}^{-1}$ , where the experimentally measured extinction vanishes. Otherwise this second approach to the determination of optical constants constitutes an inversion of the experimental spectrum rather than a fit.

## 6.5.1

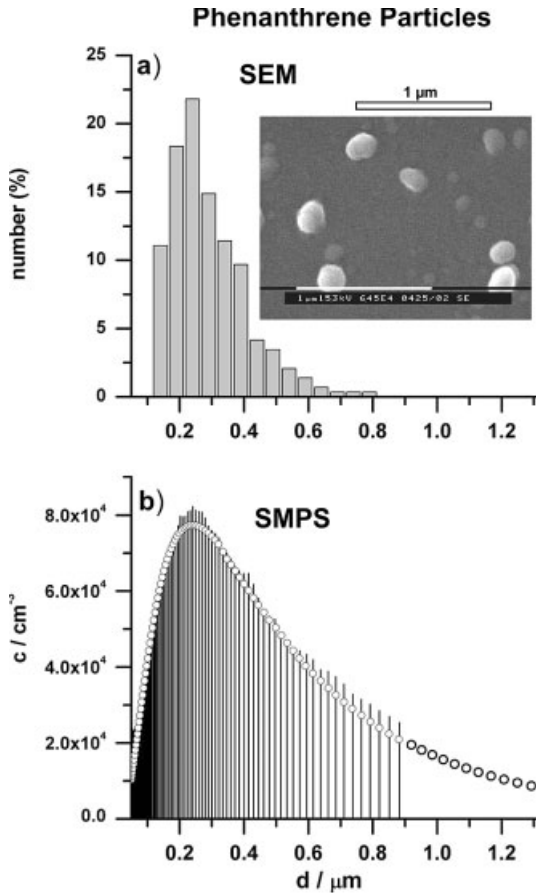

## Phenanthrene Particles: Size, Shape, Optical Data

Phenanthrene ( $C_{14}H_{10}$ ) serves here as a model system to demonstrate the different aspects of the particle generation and characterization methods described in Sections 6.2–6.4. Phenanthrene has been used as a representative compound in the modeling of particle formation processes with RESS [33, 36, 37]. Polycyclic aromatic hydrocarbons such as phenanthrene are of importance as pollutants in the atmosphere [62, 63] and have also been discussed in astrophysics as carriers of the “unidentified” infrared bands [64, 65].

We have generated phenanthrene particles with the RESS apparatus (Section 6.2.1) under various experimental conditions. In summary, we find that the phenanthrene particles are nearly spherical, as depicted in the SEM image in Fig. 6.6(a). Various SEM images also show that the tendency to form agglomerates is only minor for this substance, which is in contrast to the behavior of phytosterol particles discussed in Section 6.5.3. For phenanthrene, we found no major differences in the properties of the particles by changing the pre-expansion conditions (temperatures between 298 and 350 K, pressures between 20 and 40 MPa, and for different nozzle diameters). In this context we also mention the partly contradictory discussions in Refs. [15, 66–70]. One parameter that affects the size of the particles is the pressure  $p_c$  in the expansion chamber: Particles generated under vacuum conditions ( $p_c = 0.03$  mbar) have smaller mean diameters by about 30% but larger geometric standard deviation by about 30% than those formed at  $p_c = 960$  mbar. Whether this is a general trend for other substances as well remains to be seen.

Typical size distributions for the expansion against  $p_c = 1000$  mbar ( $T_{\text{ext}} = T_N = 298$  K,  $p_R = 400$  bar) are depicted in Fig. 6.6. From different SEM images recorded under equivalent conditions, we have determined a rough size distribution, which is shown by the bars in Fig. 6.6(a). Each bar represents the relative number of particles in the corresponding size interval. This size distribution is obviously very coarse and, in particular, it does not contain any information about the particle number concentration ( $N$ ) of the corresponding aerosol from which the SEM samples were collected. This information is important for the derivation of optical data from corresponding IR spectra as discussed below. Detailed information about the particle number concentration and the size can be obtained with the SMPS. The corresponding experimental number size distribution is shown by the bars in Fig. 6.6(b). The circles represent a fit to the measured distribution assuming a log-normal distribution [Eq. (2)]. This fit allows us to extrapolate the distribution beyond the measurement range (see Section 6.4) and leads to the following typical data for the phenanthrene particles:

$$r_0 \sim 120 \text{ nm}, \quad \sigma \sim 2.2, \quad \text{and} \quad N \sim 5 \times 10^6 \text{ cm}^{-3} \quad (6)$$

**Fig. 6.6.** (a) Bars: Size distribution of phenanthrene particles obtained from SEM measurements. Ordinate: Percentage of particles with sizes in size intervals of 50 nm. Inset: Typical SEM image. (b) Bars: Number size distribution of phenanthrene particles measured on-line with the SMPS.  $c$  is the

number concentration per logarithmic sampling interval. Bars indicate the center of the intervals. Circles: Fit to the measured distribution assuming a log-normal distribution [Eq. (2)]. Conditions for particle formation:  $T_{\text{ext}} = T_N = 298$  K,  $p_{\text{ext}} = p_N = 400$  bar.

Comparison of Fig. 6.6(a) and (b) shows that the size distribution from SEM and from SMPS are in good agreement. Since the phenanthrene particles are nearly spherical the 3-WEM should also lead to similar results as SEM and SMPS. In contrast to this expectation, the 3-WEM leads to larger mean radii (40%) and smaller geometric standard deviations (20%) than the two other methods. Similar behavior has already been observed in previous studies that compared 3-WEM with other sizing methods [16, 45, 71]. At the moment we cannot finally explain the origin of this deviation but it is, presumably, due to assumptions implicit in the analysis of the 3-WEM data (Section 6.3.2).

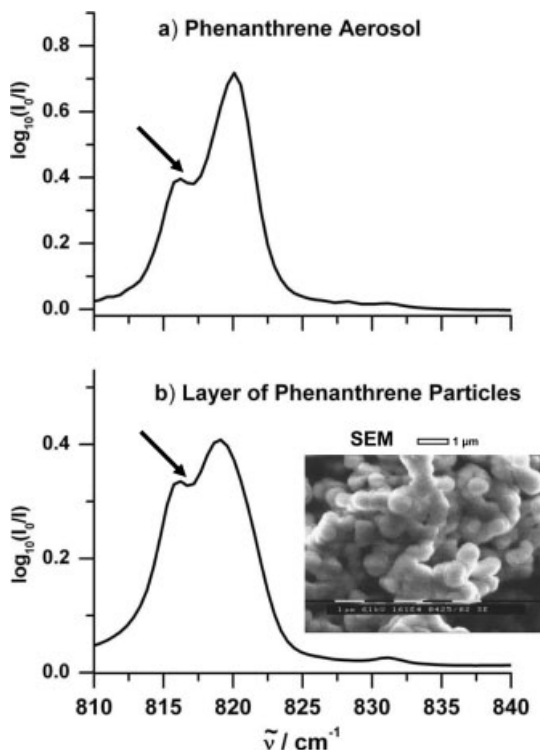

**Fig. 6.7.** (a) Experimental IR spectrum of phenanthrene aerosol particles. (b) Fitted infrared spectrum (see Section 6.4). (c) Imaginary part  $k$  of the complex index of refraction. (d) Real part  $n$  of the complex index of refraction.  $\tilde{\nu}$  is the transition wavenumber.

The size information is also contained in the IR spectrum of the aerosol depicted in Fig. 6.7(a). Thus, the scattering by the particles leads to the slanted baseline, which is characteristic for the size distribution of the particle ensemble. Note that the strong bands from gas-phase  $\text{CO}_2$  (residues of the solvent) below  $800 \text{ cm}^{-1}$  and between  $1900$  and  $2500 \text{ cm}^{-1}$  have been cut from this spectrum. The determina-

tion of the particle size distribution from the experimental mid-infrared spectrum requires knowledge of the corresponding refractive index data  $n + ik$  for the solute in this region (Section 6.4). Since these data were not known for phenanthrene particles, we have derived them from a fit to the experimental spectrum using the experimentally measured size distributions from the SMPS (Fig. 6.6b). We assumed Mie theory for spherical particles and a Lorentz model for the optical properties [Eqs. (3, 4), and [42]]. More details of this procedure can be found in Refs. [15, 30, 42]. According to Eq. (3) each Lorentz oscillator is characterized by three parameters: The resonance wavenumber, the oscillator strength, and the damping width. The number of oscillators is not determined *a priori*. It depends on the number of intra- and intermolecular vibrations and on interactions between them. The phenanthrene spectrum in Fig. 6.7(a) consists of sharp resolved absorptions. Therefore, we have assigned one Lorentz oscillator to each of these bands. The results from our Lorentz fit are depicted in Fig. 6.7(b–d). Trace (b) shows the fitted IR spectrum, which reproduces the experimental spectrum quite well. The region below  $2000\text{ cm}^{-1}$  is dominated by the strong absorption of the CH out-of-plane bending at  $819\text{ cm}^{-1}$ . All other vibrations in the mid-infrared region are rather weak. The region below  $2000\text{ cm}^{-1}$  consists of well-resolved individual transitions whereas the CH-stretching transitions around  $3100\text{ cm}^{-1}$  strongly overlap. Trace (c) shows the imaginary part  $k$  and trace (d) the real part  $n$  of the complex index of refraction. The corresponding fitted parameters and refractive index data together with a description of the estimated uncertainties ( $\sim 20\%$ ) are available in Ref. [46]. With these data the determination of the size distribution now becomes possible directly from IR spectra for phenanthrene aerosols.

Apart from the size, the IR spectrum also contains information about the chemical composition, about the structure (crystalline, amorphous), and sometimes about the particle shape. Comparison of the experimental spectrum in Fig. 6.7(a) with corresponding spectra for crystalline phenanthrene reveals the crystalline character of the phenanthrene particles [72]. Fig. 6.7(c) and (d) show that there exists a spectral range around  $819\text{ cm}^{-1}$  where  $n$  is small and  $k$  varies widely. In classical scattering theory, this is the condition for the occurrence of shape effects in particle spectra [42]. We have pointed out previously [44] that on a molecular level this can be explained by exciton coupling (transition dipole coupling), which elucidates that shape effects only occur for bands with relatively large molecular transition dipoles ( $\delta\mu > 0.1\text{--}0.2\text{ D}$ ). For phenanthrene this is fulfilled only for the band at  $819\text{ cm}^{-1}$ , which is shown in an expanded view in Fig. 6.8(a). By different examples [52, 54, 55, 73] we have illustrated that different particle shapes lead to different band structures for such strong absorption bands in the IR spectra. Figure 6.8(a) shows the band at  $819\text{ cm}^{-1}$  for spherical phenanthrene particles as depicted in the SEM image of Fig. 6.6(a). To modify the shape of the phenanthrene particles we have produced a layer of particles on a NaCl window and recorded its IR spectrum, which is depicted in Fig. 6.8(b). This layer no longer consists of single spherical particles but of strongly agglomerated/coagulated primary particles, as illustrated by the SEM image in trace (b). The deviation from the spherical shape obviously leads to a completely different band shape in the IR spectrum of the par-

**Fig. 6.8.** (a) Expanded view of the IR spectrum of phenanthrene aerosol shown in Fig. 6.7(a) in the region of the band at  $819 \text{ cm}^{-1}$ . (b) IR spectrum of a layer of particles on a NaCl window together with the

corresponding SEM image of this layer. The different band shapes in traces a and b most likely arise from the different particle shapes of the two samples.  $\tilde{\nu}$  is the transition wavenumber.

particle layer (trace in Fig. 6.8b) compared with the aerosol (trace a). In accordance with the explanations above, we do not observe such deviations between the two different spectra for the weak absorption bands.

### 6.5.2

#### Sugar Nanoparticles

Sugar-like substances such as cyclodextrins are attractive carriers for drugs to administer them in solid dosage form and improve their dissolution. Cyclodextrins are cyclic oligosaccharides of D-glycopyranose units able to form inclusion complexes with many drugs [74, 75]. Controlled particle deposition (CPD, [74, 76]) is one possibility to produce such complexes. In CPD the solute of interest is dissolved in supercritical  $\text{CO}_2$ . This solution then permeates the pores of the carrier where the drug precipitates after a fast drop of the pressure. Another possibility is to generate mixed particles with an electro-spray or with RESS by using a solution

of both the drug and the carrier (CORESS [19–22, 24, 74, 76]). This results in encapsulation of the drug by or mixing of the drug with the carrier. In this section we show some results concerning particle formation of different sugar-like substances with the electro-spray (Section 6.2.2) and with RESS (Section 6.2.1). The complicated network of hydrogen bonds in such sugar particles gives rise to various amorphous and crystalline forms that can affect their use in nanoparticle technology. Infrared spectroscopy again proves to be useful to elucidate the complex inter- and intramolecular hydrogen-bond dynamics in these particles.

We have investigated different sugar particles generated with the electro-spray, including glycolaldehyde, hydroxyacetone, glyceraldehyde dimer, dihydroxyacetone and its dimer, glucose, fructose, saccharose, ribose, 2-deoxyribose, and erythrose [9, 29, 30, 51]. Figure 6.9 shows, from top to bottom, the IR spectra of fructose particles ( $C_6H_{12}O_6$ ), glucose particles ( $C_6H_{12}O_6$ ), ribose particles ( $C_5H_{10}O_5$ ), and 2-deoxyribose particles ( $C_5H_{10}O_4$ ). Common to all of these spectra are the relatively broad absorption bands, which clearly indicate that the aerosol particles are amorphous and not crystalline. This statement has been further corroborated by comparing the particle spectra with spectra of the crystalline substances. In contrast to the particles the latter exhibit narrow bands in the IR spectra, as illustrated for 2-deoxyribose by Fig. 6.10(b), with the corresponding particle spectrum shown in Fig. 6.10(a). Comparison of the four spectra in Fig. 6.9 also shows that the finger-

**Fig. 6.9.** Infrared spectra of aerosol particles of (a) fructose, (b) glucose, (c) ribose, and (d) deoxyribose. Fructose, glucose, and ribose molecules form pyranose rings in the particles, as indicated by the molecular structures. For

deoxyribose a furanose ring is shown, but it is not clear in this case whether the particles consist of furanose or pyranose rings.  $\tilde{\nu}$  is the transition wavenumber.

**Fig. 6.10.** (a) Experimental IR spectrum of deoxyribose aerosol particles. (b) Experimental IR spectrum of crystalline deoxyribose in KBr. (c) Optimized damping constants  $\gamma_s$  and (d) optimized relative transition intensities  $\tilde{\nu}_s^2 f_s$  from the Lorentz model [Eq. (3)]. (e) Real part  $n$  and (f) imaginary part  $k$  of the complex refractive index obtained by a Kramers–Kronig inversion of the experimental particle spectrum [Eq. (5)].  $\tilde{\nu}$  is the transition wavenumber.

print region below  $1800\text{ cm}^{-1}$  is characteristic for each compound, even for compounds as similar as the two isomers fructose and glucose. The fingerprint region does not only allow us to distinguish between different sugars, it even provides information about the structure of the molecules in the particles. For instance the missing carbonyl band (expected at  $1750\text{ cm}^{-1}$ ) in all four spectra proves that the sugar molecules are not present in their open form but that they form ring structures in the particles. In addition, from comparison of the IR spectra with quantum chemical calculations it is possible, for some sugars, to make statements about the kind of ring structure (e.g., furanose or pyranose). For fructose, glucose, and ribose the pyranose rings seem to be predominant, as indicated by the molecular structures (insets) in Fig. 6.9. For deoxyribose, however, it is not clear from the analysis of the IR spectra whether the particles consist of pyranose or furanose rings.

In contrast to the fingerprint region, the OH-stretching region around  $3300\text{ cm}^{-1}$  looks almost identical for all four sugars. It is characterized by a single, unstructured, very broad band, which is shaded towards lower frequencies. This spectral region is strongly influenced by the formation of inter- and intramolecular hydrogen bonds. The characteristic band shape seems to reflect a more general behavior that is common to all four carbohydrate particles. To elucidate this phenomenon we have performed a band shape analysis assuming a Lorentz model that leads to the dielectric function given by Eq. (3). The relation to the refractive index data is given by Eq. (4). The same procedure as described in the previous section for phenanthrene particles was used to determine the optical data. As a result, we obtained the oscillator strengths ( $\tilde{\nu}_s^2 f_s$ ) and the damping widths ( $\gamma_s$ ) of the different Lorentz oscillators with resonance wavenumbers ( $\tilde{\nu}_s$ ). For deoxyribose, the values for  $\gamma_s$  are depicted in Fig. 6.10(c) and the values for  $\tilde{\nu}_s^2 f_s$  in 6.10(d). Here, we are mainly interested in the OH-stretching region. The sequence of oscillator strengths and widths found in this region for the particle spectra reveals a hierarchy of different hydrogen bonds: large redshifts ( $\tilde{\nu}_s$ ) of OH-stretch transitions are accompanied by an increase in transition intensity ( $\tilde{\nu}_s^2 f_s$ ) and a stronger coupling to the environment ( $\gamma_s$ ). We interpret this observation as a result of a certain degree of short-range order in the amorphous solid particles caused by intermolecular hydrogen bonds. Since the other three sugars give the same qualitative results as discussed here for deoxyribose this hints at similarities in the kind of short range order for the different sugar-like substances. The band shape analysis with the Lorentz model also yields refractive index data. We have further improved these data by a Kramers–Kronig inversion [Eq. (5)]. The final refractive index data  $n$  and  $k$  are listed in Ref. [46] and are shown in Fig. 6.10(e) and (f) respectively. With these data, the determination of the size distribution now becomes possible for deoxyribose aerosols.

In addition to the electro-spray generation, a batch RESS apparatus has been used to investigate the formation of submicron sugar particles. This apparatus is designed for experiments in the temperature range from 270 to 370 K and pressures up to 25 MPa. The RESS experiments were performed at a pre-expansion temperature of 338 K and a pre-expansion pressure of 20 MPa. In all experiments the extraction conditions were  $T_{\text{ext}} = 323\text{ K}$  and  $p_{\text{ext}} = 20\text{ MPa}$ . Figure 6.11 shows, on the left-hand side, maltodextrin particles and, on the right-hand side, lactose particles produced by RESS. These SEM pictures are typical examples of the products obtained and show that the spherical particles are less than 300 nm in diameter. However, notably, due to the very low solubility of both maltodextrin and lactose in supercritical  $\text{CO}_2$  a co-solvent should be used in further investigations to enhance the solubility of the sugars in  $\text{CO}_2$ .

### 6.5.3

#### Drug Nanoparticles

One main problem arising from the micronization of drugs with RESS is that in the final products the small primary particles often coagulate or agglomerate to

**Fig. 6.11.** Maltodextrin particles (left) and lactose particles (right) produced by RESS. The particles are 300 nm in diameter.

form much larger aggregates. These processes can take place either upon particle formation, or upon collecting the particles, or during storage of the powders. Coagulation and agglomeration leads to a decrease of the active surface and thus reduces the dissolution rate and the bioavailability of drugs. This can be overcome by mixing with or encapsulating by a second substance that avoids or at least reduces agglomeration. For instance, this can be achieved by rapid expansion of a ternary supercritical mixture which leads to co-precipitation of the two solutes (CORESS). Until now, much work has been done on producing particles of pure solutes by RESS, but only a few studies have been devoted to the simultaneous co-precipitation of two solutes [19–22, 24, 26, 74, 76]. Another way to prevent particle growth through coagulation and agglomeration and to stabilize the particles is to spray the supercritical solution directly into an aqueous surfactant solution (RESSAS [14, 18, 23, 25]). Encapsulation of particles is not only of interest for stabilizing primary particles, it is also a promising way for controlled drug delivery in the body. For instance, the coating can allow for targeted drug release in different intestinal regions (pH-dependent release). We have investigated such aspects for different pharmaceutical agents such as griseofulvin (oral antifungal drug), ibuprofen (anti-inflammatory drug), and phytosterol [10, 14, 18, 24, 74, 76]. In this section, we discuss the agglomeration behavior of phytosterol particles generated with RESS and the influence of co-expanding a polymer in the supercritical solution (CORESS). Phytosterol is a mixture of 85%  $\beta$ -sitosterol, 10% stigmasterol, and 5% campesterol. The main component  $\beta$ -sitosterol can be used as an additive for cosmetic substances or as an agent to reduce the amount of cholesterol in the human blood.

Pure phytosterol particles generated by RESS have a strong tendency to coagulate/agglomerate. This is documented by the two SEM images in Fig. 6.12. The survey in trace (a) shows that micronized phytosterol has a spongy structure that consists of coagulated/agglomerated primary particles. This can be seen best in trace (b), which represents an expanded view of trace (a). The agglomerated

**Fig. 6.12.** SEM images of pure phytosterol particles produced by RESS. (a) Survey and (b) detailed view.

spongy structure consists of primary particles with diameters between 50 and 150 nm. With our *in situ* characterization methods we have tried to find out where the agglomeration of the phytosterol particles takes place. In principle, the particles can agglomerate before and at the Mach disc, after the Mach disc in the gas phase, or during the particle collection on the sample holder for the SEM examination. From our measurements, we cannot make firm statements about agglomeration processes taking place before and at the Mach disc, but the 3-WEM at least indicates that the phytosterol particles are quite small ( $r_0 \sim 50$  nm,  $\sigma \sim 1.8$ ) immediately after the pulse and after all  $\text{CO}_2$  has evaporated. After the pulse has finished, however, we can observe the behavior of the aerosol in the expansion chamber as a function of time. For the very large agglomerated particles depicted in Fig. 6.12(a), we would expect a decrease of the extinction in the IR spectra and a decrease of the extinction signals recorded for the 3-WEM with increasing time. The reason for that is the settling of the agglomerates. For comparison, settling of the phenanthrene particles with mean diameters around 400 nm leads to a decrease of the extinction by 70% already after 10 min. In contrast to these expectations, both the infrared signal and the 3-WEM signal are almost completely constant for more than 15 min after the end of the pulse. This is shown in Fig. 6.13(a) and (b). Both figures show only a minor change of the signal with time. This means that most of the particles in the gas phase are very small and stay small (no agglomeration). Bigger particles or agglomerates would settle down in our chamber and thus lead to a decrease in the extinctions for FTIR and 3-WEM. This is a clear experimental hint that the agglomeration takes place predominantly during the sample collection for the SEM measurements.

Based on a modified RESS-process (CORESS [19–22, 24, 74, 76]), additional experiments were performed with biodegradable polymers [Eudragit® and poly-L-lactic-acid (L-PLA)] and phytosterol as solutes. In these experiments both phytosterol and the polymer are thoroughly mixed and weighed out and then packed into the extraction vessel. Experiments with Eudragit® were performed with the batch apparatus (see Section 6.2.1) at pre-expansion temperatures between 310

Fig. 6.13. (a) Infrared spectra of pure phytosterol aerosol particles recorded at  $t_1 = 230$ ,  $t_2 = 440$ , and  $t_3 = 650$  s after the end of the expansion pulse ( $t = 0$  s).  $\tilde{\nu}$  is the transition wavenumber. (b) Extinction signals

from 3-WEM for the three lasers with wavelengths  $\lambda_1 = 405$ ,  $\lambda_2 = 633$ , and  $\lambda_3 = 1064$  nm. The signals remain nearly constant as a function of time ( $t$ ) after the end of the expansion pulse.

and 340 K and a pre-expansion pressure of 20 MPa. With L-PLA the continuous RESS apparatus was used. These experiments were performed at an extraction temperature of 313 K, pre-expansion temperatures between 348 and 388 K and a pre-expansion pressure of 20 MPa. To avoid clogging, the nozzle temperature was 10 K higher than the respective pre-expansion temperature. These pre-expansion conditions were chosen to prevent particle precipitation inside the capillary nozzle. SEM was used to observe the morphology of the particle surface. The size of the particles produced by CORESS was measured online with 3-WEM. Differential Scanning Calorimetry (DSC) was used for physical characterization (melting point, heat of fusion, and crystallinity) of the original and the processed materials. The decrease of the heat of fusion obtained in the first heating-run allowed us to estimate the amount of polymer in the mixture. In addition, the unprocessed and the processed substances were characterized by X-ray diffraction (XRD).

Figure 6.14 shows, on the left, typical results for the co-precipitated phytosterol/Eudragit® particles. As mentioned above, the pure phytosterol particles are usually agglomerated and show a spongy structure. Contrary to these results the CORESS experiments performed with mixtures of phytosterol/Eudragit® (mass ratios of 1:1 and 1:10) lead to finely dispersed particles with diameters in the range of 250 nm.

**Fig. 6.14.** Phytosterol/Eudragit<sup>®</sup> particles (left) and phytosterol/L-PLA particles (right) produced by CORESS. The amount of Eudragit<sup>®</sup> is ~10 wt% and the amount of L-PLA is ~12 wt%.

The particles thus obtained were analyzed by DSC and compared with the unprocessed materials to determine the amount of polymer in the particles. The melting temperature and the heat of fusion of the original phytosterol were found to be 413 K and 56.9 J g<sup>-1</sup>, respectively. These values differ markedly from those of the submicron phytosterol/Eudragit<sup>®</sup> particles (407 K and 37.1 J g<sup>-1</sup>, respectively, for a mass ratio of 1:10). Depending on the initial mass ratio of the mixture in the extraction vessel, the amount of Eudragit<sup>®</sup> in the particles varies from ~10 to ~35 wt%. Additional FTIR analysis of the phytosterol/Eudragit<sup>®</sup> particles obtained confirm these results.

Additional CORESS experiments were performed with mixtures of phytosterol/L-PLA (mass ratios of 1:5 and 1:8). As shown in the right-hand part of Fig. 6.14, the experiments again lead to dispersed particles 250 nm in diameter. The product was characterized by DSC and XRD. Both the melting temperature and the heat of fusion were reduced in comparison to pure phytosterol. Typical DSC curves of pure phytosterol particles, of phytosterol/L-PLA particles, and of pure L-PLA particles are depicted in Fig. 6.15. The curve of pure phytosterol shows a melting peak in the range between 403 and 415 K while the curve of the phytosterol/L-PLA particles shows a broad peak between 388 and 411 K, corresponding to the microencapsulation of phytosterol. Depending on the initial mass ratio of the mixture in the extraction vessel, the amount of L-PLA varied from 12 to 40 wt%. Figure 6.16 displays typical XRD patterns of pure phytosterol particles, of phytosterol/L-PLA particles, and of pure L-PLA particles. For both the pure phytosterol and the phytosterol/L-PLA mixture diffraction peaks characteristic for crystalline phytosterol are obtained. These diffraction peaks disappear for the submicron L-PLA particles. Thus, the L-PLA particles are in the amorphous state. This result is in good agreement with the DSC analyses where no melting peak of crystalline L-PLA was observed (Fig. 6.15).

IR spectroscopy allows us to determine and thus to control the amount of L-PLA

Fig. 6.15. DSC curves of (a) pure phytosterol particles, (b) phytosterol/L-PLA particles, and (c) pure L-PLA particles.

*in situ* during particle formation. This is much faster and simpler than the analysis with DSC and allows us to optimize the amount of polymer by adjusting the process parameters during particle formation. Figure 6.17 compares the IR spectrum of pure phytosterol particles (trace a) with two spectra of mixed phytosterol/L-PLA particles (traces b and c). The spectrum of pure phytosterol particles has strong absorption bands in the OH/CH-stretching region around  $2900\text{ cm}^{-1}$  but only weak absorption bands in the fingerprint region below  $1800\text{ cm}^{-1}$ . Although there are many bands in this region, they are barely visible due to their weakness. Traces

Fig. 6.16. XRD patterns of (a) pure phytosterol particles, (b) phytosterol/L-PLA particles, and (c) pure L-PLA particles.

**Fig. 6.17.** (a) Infrared spectrum of pure phytosterol aerosol particles. (b) and (c) IR spectra of mixed phytosterol/L-PLA aerosol particles. There is  $\sim 70\%$  more polymer in the particles of trace (c) than in trace (b).  $\bar{\nu}$  is the transition wavenumber.

(b) and (c) show that the strongest band of L-PLA in the fingerprint region is the carbonyl stretching-band around  $1765\text{ cm}^{-1}$ . In contrast to the other absorption bands of L-PLA in the fingerprint region it is well separated and does not overlap with phytosterol bands or  $\text{CO}_2$  bands. Moreover, L-PLA shows no significant absorbance above  $2800\text{ cm}^{-1}$ . Therefore, the ratio of its carbonyl band intensity to that of the phytosterol OH/CH absorption is well suited to determine the relative content of L-PLA in the particles. From trace (b) to trace (c) the amount of L-PLA in the particles increases by  $\sim 70\%$ .

In summary, these results illustrate that the simultaneous co-precipitation of two solutes is a promising method to produce composite particles. The particles obtained from the CORESS process appear as a drug core encapsulated in a polymer coating. This encapsulation helps to prevent agglomeration and to control drug release, which both depend on the amount of polymer in the particles. The easiest way to control the amount of polymer is by *in situ* FTIR spectroscopy during particle formation.

## 6.6

### Summary and Conclusion

FTIR spectroscopy provides a wealth of information about molecular nanoparticles, which makes it an particularly powerful method for the characterization of such systems. Vibrational spectra of particulate systems allow us to draw conclusions about the chemical composition, the size, the shape, and about structural properties of the particles. Especially attractive is the use of *in situ* direct absorption FTIR spectroscopy, which allows us to characterize and control the particle properties during or shortly after their generation. For these investigations it is crucial that *in situ* FTIR spectroscopy is fast, that it can be combined with various particle generation methods, and that it can be used under very different experimental conditions.

The different examples in this chapter document the general applicability of this characterization method and the wide range of information it provides for biomolecular particles. This comprises different aspects of particle characterization. One example is the investigation of the particle formation process itself. In agreement with previous modeling results the RESS experiments show that, depending on the pre-expansion conditions, condensation of the solvent CO<sub>2</sub> can occur in the initial stage of particle formation. Such information is very useful for the evaluation of the obtained particles since the condensation/evaporation behavior of the solvent has a strong influence on particle formation and therewith on the properties of the final solid particles. Another example is the on-line control of particle composition. This is crucial, for instance, for polymer encapsulated drugs when a well defined amount of polymer in the particles has to be maintained.

A prerequisite for a successful analysis of the information contained in the IR spectra is the knowledge of the corresponding refractive index data. These data provide information, for instance, about the size effects and the shape effects to be expected in extinction spectra. We have demonstrated that the determination of accurate optical data from experimental IR spectra is not easy. The main reason lies in the lack of accurate information about the size, shape, and number concentration of the particles and in the model assumptions used in the derivation of the optical data. Therefore, it is not astonishing that, nowadays, only a few databases provide optical data for particulate systems and nearly none for nanoparticles of interest in life sciences. The lack of these data certainly represents one of the major restrictions for the routine application of FTIR spectroscopy for particle characterization. To alleviate that restriction is one of the most important challenges in the field.

# Characterization of Nanoscaled Drug Delivery Systems by Electron Spin Resonance (ESR)

*Karsten Mäder*

### 7.1

#### Introduction

Nanoscaled drug delivery systems (nano-DDS) have been heavily investigated due to their large potential to make drug therapy more efficient. After years of intense research, they have entered the pharmaceutical market and many systems have reached the late clinical state. Nano-DDS are only defined by their submicron size. They are made from different materials (e.g., lipid or polymer based) and include very different kinds of associates and particles. Examples include (mixed) micelles, polymer micelles, liposomes, microemulsions, polymer nanoparticles, solid lipid nanoparticles, nanocapsules. The main applications are in peroral and parenteral drug delivery, although nano-DDS are also considered for other administration routes (dermal, pulmonal). In peroral drug delivery, higher absorption rates and decreased variabilities of poorly soluble drugs are achieved. Nano-DDS make the i.v. injection of poorly soluble drugs feasible and help to push drug targeting strategies from the conception to reality.

The performance of nano-DDS strongly depends on many parameters, including composition, particle size, surface charge and the physical state of the matrix. Appropriate characterization of nanoparticle systems is a serious challenge due to following reasons:

- the submicron size of the objects;
- the sensitivity of many Nano-drug delivery systems to environmental changes, including drying, freezing or dilution;
- the coexistence of several colloidal species;
- the importance of dynamic phenomena;
- material properties might differ significantly from bulk material.

Some commonly used methods require tedious sample preparation (electron microscopy) or fixing of the particles (AFM). Fixation by drying of the samples composed of soft matter such as lipid nanoparticles, however, will change considerably the sample characteristics. Therefore, there is a need for methods that are can char-

acterize Nano-drug delivery systems with no or minimized sample preparation. NMR spectroscopy, fluorescence and other optical techniques, Raman-spectroscopy and ESR are methods that offer possibilities to conduct such studies. The challenge of appropriate characterization is considerable higher for characterization in biological surroundings *in vitro* or *in vivo*. Most techniques are not capable of *in vivo* measurements. Radiolabeling techniques are used to monitor the distribution of Nano-drug delivery systems in the body of animals and man; however, they provide no information about the physicochemical changes of the drug delivery system caused by interaction with the environment or metabolic processes. Consequently, our knowledge of the detailed fate of the drug and drug carrier *in vivo* is still rather limited. This chapter will discuss how ESR can contribute to shedding more light on nanoscaled drug delivery systems. The basic requirements of ESR will be discussed. Examples will show which information can be extracted from the spectra and how this information can be used to characterize drug delivery systems. Finally, the opportunities and limits of ESR for the *in vivo* characterization will be shown.

## 7.2

### ESR Basics and Requirements

Electron Spin Resonance (ESR) or synonymously Electron Paramagnetic Resonance (EPR) can be regarded as a sister method for Nuclear Magnetic Resonance (NMR). Both methods were first described about 60 years ago and both require the presence of a magnetic moment. In NMR, the magnetic moment comes from the nuclear spin (e.g.,  $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{19}\text{F}$ ), in ESR it derives from unpaired electrons. Sources of unpaired electrons are free radicals and certain oxidations states of transition metals.

The basic magnetic resonance experiment (NMR and EPR) requires the positioning of the sample in a homogenous magnetic field. The applied magnetic field leads to parallel or anti-parallel alignment of the spins. Irradiation of the sample with an appropriate frequency (= resonance frequency) leads the spins to switch between both states. Under such conditions, part of the energy is absorbed and a signal observed. Higher magnetic fields lead to higher sensitivity and need higher frequencies. Typical NMR frequencies are radiofrequencies (e.g., 20–600 MHz), whereas typical ESR frequencies are in the microwave range (10 GHz). However, the recent development of high-field NMR (800 MHz and higher) and low-frequency ESR (1 GHz and 300 MHz) have led to partial overlapping of the NMR and ESR frequency ranges. Due to the high dielectric loss, the standard ESR frequency of 10 GHz penetrates only 1–2 mm in water-containing samples (e.g., biological tissue). The development of low frequency ESR was necessary to make possible the investigation of larger samples with high water content. It permits ESR experiments on whole living mammals (mice and rats). Refs. [1, 2] give a broad coverage of basic ESR and biological related applications.

NMR is per se less sensitive than ESR due to the smaller magnetic moment of

Tab. 7.1. Comparison of NMR and ESR.

	ESR	NMR
Prerequisite	Electron spin	Nuclear spin
Examples	Free radicals, $\text{Cu}^{2+}$ , $\text{Mn}^{2+}$ , $\text{Fe}^{3+}$	$^1\text{H}$ , $^{13}\text{C}$ , $^{19}\text{F}$ , $^{35}\text{P}$
Magnetic moment ( $\text{J T}^{-1}$ )	Larger: $\mu_{e^-} = 9.274 \times 10^{-24}$	Smaller: $\mu_{\text{H}} = 5.051 \times 10^{-27}$
Typical frequency	9–10 GHz	100–800 MHz
Mode of operation	Continuous wave	FT-NMR
Typical line widths	MHz	<Hz
“Time window” (s)	$10^{-9}$ – $10^{-11}$	$10^{-5}$ – $10^{-9}$

the nuclear spin. However, this disadvantage is compensated by the much higher concentrations of nuclear spins and the development of pulsed NMR. Most ESR spectrometers work in the continuous mode because most radicals relax very rapidly and, therefore, pulsed methods are difficult or impossible to apply. Table 7.1 summarizes the main features of NMR and ESR.

The basic instrumentation of ESR requires a magnet, a microwave bridge, and a resonator with phase sensitive detection. Of course, modern spectrometers are operated via a computer interface. Most spectrometers operate at 9 to 10 GHz (X-band). Due to the high dielectric loss, the measurement of samples with high water content is limited to a size  $< 1$ – $2$  mm. Recent progress in the design of instruments has resulted in small, sensitive benchtop spectrometers at reasonable prices (Fig. 7.1). Larger objects with high water content (tablets or small animals) can be assessed by spectrometers that work at lower frequencies, e.g., 0.3 or 1 GHz (Fig. 7.2).

We will focus only on drug delivery and will not consider other important applications such as ESR oximetry [3], the measurement of nitric oxide [4] or the direct detection [5] of radical metabolites. Spin trapping is a method that transfers very reactive radical intermediates into more stable spin adducts [6]. However, very careful preparation of the experiments and interpretation of the results is necessary to avoid artifacts [7, 8]. Artifacts might be caused by impurities of the com-

Fig. 7.1. Benchtop 9 GHz ESR-spectrometer (X-band) with temperature unit (below the spectrometer).

**Fig. 7.2.** L-band (1 GHz) ESR spectrometer with imaging possibility. The lower frequency of the L-band permits noninvasive measurement of larger samples with high water content, including mice and rats. The

spectrometer consists of a computer (a), a magnet power supply (b), a microwave bridge (c), the magnet with resonator (d) and power supply for the imaging gradients (e).

mercial spin traps, non-radical reactions or instability of the spin adduct. Inexperienced researchers often misinterpret the experimental results due to their poor knowledge of the reactivity of the radical, the trapping efficiency, the instability of the trap under the experimental conditions and the adduct stability. ESR spin trapping has been used recently to detect the radical formation from  $\text{TiO}_2$  nanoparticles [9] and the antioxidant potential of selenium nanoparticles [10].

Paramagnetic species that can be detected by ESR are free radicals and certain oxidation states of metal ions. ESR spectra of metal ions (e.g.,  $\text{Fe}^{3+}$ ,  $\text{Cu}^{2+}$ ,  $\text{Mn}^{2+}$ ) are in most cases very broad due to short relaxation times and magnetic interactions. Sometimes, their detection requires study at very low temperatures (77 K and below). ESR spectroscopy of metal ions permits the characterization of enzymes and organs, but it is of low importance in drug delivery. Some materials like bentonite and kaolin contain  $\text{Fe}^{3+}$  as impurity. Nearly all ESR studies in the field of drug delivery are based on the detection of free radicals, because most samples are ESR silent. Endogenous radicals could be present in the case of gamma sterilized or mechanical treated samples, if the delivery matrix or the drug is in the crystalline state and has a high melting point [11, 12]. Gamma irradiation induced radicals will rapidly decay in liquid and semisolid matrices and in polymers with a low glass transition temperature, but they can be detected and quantified by

spin-trapping techniques or at low temperatures [13]. Gamma irradiation induced radicals can be used to follow water penetration in biodegradable polymers *in vitro* and *in vivo*, if they have sufficient thermostability (e.g., slow decay rates at 37 °C) [14].

Magnetite is a very important material for both diagnostic and therapy, and exhibits endogenous ESR signals. Magnetite is used as an MRI contrast agent as well as for local hyperthermia. Magnetite has very broad ESR lines. These can be used to quantify and characterize the material, including the uptake in cells and tissue [15, 16, 17].

However, most samples are ESR silent and require the addition of radicals. For this reason, the addition of radical probes is a necessity. In most cases, nitroxide radicals are used. A large variety of nitroxides with different hydrophobicity, charge and functional groups is commercially available. Most nitroxides derive from piperidine, pyrrolidine or imidazolidine structures. Examples of nitroxide radicals are illustrated in Fig. 7.3.

The numerous different structures (hydrophilic, hydrophobic, charged, uncharged, aliphatic or aromatic) permit one to choose a molecule with the desired

Fig. 7.3. Examples of nitroxide radicals with different hydrophilicities.

physicochemical properties. Nitroxides can be used as spin probes (= model drugs) to monitor processes of drug delivery *in vitro* and *in vivo*. Larger molecules (e.g., proteins, PVA, chitosan) can be spin labeled by the covalent linking of a chemically activated nitroxide to a suitable group of the macromolecule (e.g., amino, hydroxyl, carboxyl groups). For most macromolecules, the spin labeling procedure will lead to small and insignificant changes in the properties the molecules; however, this has to be verified. Spin labeling of low molecular weight compounds will lead to significant changes in molecular properties because the nitroxide moiety contributes significantly to the whole molecule.

### 7.3

#### Information from ESR Spectroscopy and Imaging

The following information can be obtained by EPR spectroscopy and imaging:

1. nitroxide concentration
2. micropolarity and microviscosity
3. microacidity
4. distribution of radicals and spatial resolution of parameters 1–3 (by imaging techniques or using different nitroxide isotopes).

Let us consider the information content step by step.

#### 7.3.1

##### Nitroxide Concentration

Nitroxide concentrations can be used to follow the release and distribution kinetics of drug carriers. ESR spectra are recorded in most cases in the form of the first derivative. Therefore, the nitroxide concentration can be obtained by double integration of the spectra. The signal intensity depends on the radical concentration, the parameters of measurement (microwave power, modulation amplitude, resonator type, filling factor, sample positioning, temperature etc.) and the dielectric loss of the sample. Samples with higher dielectric loss will give lower signal intensities for equal radical concentrations. It is highly recommended to use internal standards for quantitative measurements and to take great care about the positioning of the sample, reproducible filling factors, and sufficient scan width.

The hydrophilic ascorbic acid reduces piperidine nitroxides rapidly to the EPR silent hydroxylamines, and the loss of the EPR signal intensity indicates the accessibility of the nitroxide to the aqueous outer phase (Fig. 7.4). Solid lipid nanoparticles (SLN) and nanostructured lipid carriers (NLC) are less protective, respectively, than a nanoemulsion. This finding can be explained by the platelet structure of the SLN and the expulsion of foreign molecules during lipid crystallization.

**Fig. 7.4.** Kinetics of nitroxide reduction of different colloidal lipid carriers. The lipophilic nitroxide TEMPOLBENZOATE is reduced more rapidly from solid lipid nanoparticles (SLN) and nanostructured lipid carriers (NLC) than with a standard nanoemulsion.

### 7.3.2

#### Micropolarity and Microviscosity

The unpaired electron of the nitroxide group is distributed between the nitrogen and oxygen of the nitroxyl group. Mesomeric forms of the distribution are illustrated in Fig. 7.5.

The nitrogen nucleus has a nuclear spin of 1. Magnetic interaction between the electron and nuclear spins of the nitrogen leads to a splitting of the ESR signal into three lines, which is also called hyperfine splitting (Hfs). Hfs is given by the Hfs constant  $a_N$  (Fig. 7.6).

The oxygen atom has no nuclear spin and therefore does not contribute to the splitting. Polar solvents (e.g., water) will favor the left-hand form in Fig. 7.5 and increase the spin density (= density of the unpaired electron) at the nitrogen. Non-polar solvents (e.g., oil) will increase localization of the spin at the oxygen and, therefore, decrease the spin density at the nitrogen. As a result, a smaller hyperfine coupling constant  $a_N$  will be observed (Fig. 7.6). Figure 7.7 shows quantitative values of hyperfine splitting in different solvents of pharmaceutical relevance.

For nitroxides, hyperfine coupling between the electron and nuclear spins is anisotropic. The  $a_N$ s are smaller for the  $x$  and  $y$  direction (around 0.6 mT) than

**Fig. 7.5.** Mesomeric forms of the nitroxyl group. The free electron is distributed between the nitrogen and oxygen atom.

**Fig. 7.6.** ESR spectra of the spin probe TEMPOL in middle chain triglycerides (MCT) (oil) and water. Note the larger hyperfine splitting ( $a_N$ ) in the solvent with higher polarity.

for the  $z$  direction (around 3.3 mT). The anisotropy is averaged by rapid movement of the nitroxide in low viscous environments and an isotropic Hfs of around 1.5 mT results:  $a_{N\text{-iso}} = (0.6 + 0.6 + 3.3 \text{ mT})/3 = 1.5 \text{ mT}$ .

Viscous or even solid environments permit only partial or no averaging of the anisotropy. Incomplete averaging of the Hfs results in changes of the spectral shape and increased linewidths (Fig. 7.8). Initially, increased line widths, but no changes in line positions, are observed. The third line is most sensitive for mobility changes and shows the largest broadening, which leads to the smallest amplitude (see spectrum at 15 °C). If mobility of the nitroxides is further restricted, the line shape changes and anisotropic spectra are observed (Fig. 7.8). If the nitroxide tumbling is very slow (e.g., microseconds and below), no averaging occurs and the ESR spectrum depends on the orientation of the nitroxide axis to the magnetic field. Typical “powder” ESR spectra are recorded if the nitroxide is randomly orientated (Fig. 7.8,  $-30 \text{ }^\circ\text{C}$ ).

The following examples demonstrate how the sensitivity of ESR spectra to micro-polarity and microviscosity might be used to characterize nanosized drug delivery systems.

**Fig. 7.7.** Hyperfine coupling constants of TEMPOL in different solvents of pharmaceutical relevance.

**Fig. 7.8.** Influence of temperature on ESR spectra of TEMPOL in poly(oxyethylene-pentaerythrol): Lower temperatures increase the viscosity and lead to a decreased averaging of the anisotropy of the hyperfine coupling. The high mobility of TEMPOL at 60 °C leads to a nearly isotropic shape; higher viscosities at lower temperatures lead to imperfect averaging (15 to -15 °C) of the anisotropy. At -30 °C, no averaging occurs on the ESR timescale and fully anisotropic spectra are recorded.

Nitroxide mobility might differ in different environments of heterogeneous systems. It will also change with time due to water penetration or degradation of the delivery matrix. Figure 7.9 shows simulated spectra and their integrative forms of different ratios of samples where immobilized and mobile nitroxide molecules

**Fig. 7.9.** Simulated ESR spectra of nitroxides with high and low mobility. The ratio indicates the ratio of mobile to immobile nitroxide molecules. Simulated ESR spectra (left) and their integrals (right) of different ratios of both components are represented.

coexist. The ESR spectra (= 1<sup>st</sup> derivative) are very sensitive to narrow lines and, therefore, mobile (= solubilized) nitroxides are detected below 1%. Immobilized nitroxides are more difficult to detect due to their broad lines and low signal amplitudes. They are easily overlooked in the ESR spectra if their concentration is below 50% of the total content. It is recommended that ESR spectra are integrated to make them more visible (Fig. 7.9).

The surface properties of nanoparticles play a significant role *in vivo*. Chauvierre et al. have used covalent ESR spin labeling of the dextran coat to investigate the surface properties of poly(isobutylcyanoacrylate) nanoparticles. They found a superposition of different nitroxide mobilities (similar to Fig. 7.9) and a dependency on the method used for particle synthesis [18]. The authors measured the mobile and immobile compartments in a quantitative manner. Italian scientists have used ESR to characterize the influence of lipid composition and the chain length of PEG on the characteristics of pegylated liposomes [19].

ESR can not only be used to characterize drug delivery systems before their use, it is also a method to shed more light on the release mechanisms themselves. The method can give unique and important information because different release mechanisms lead to different changes in spectral intensity and shape. Pure surface erosion will lead to a decrease in signal intensity, but no changes in spectral shape. In contrast, diffusion-controlled drug release can be recognized by changes in spectral shape due to increased mobility of the incorporated nitroxide.

The next example investigates the influence of temperature on the polarity of Poloxamer 188 solutions. Figure 7.10 shows ESR spectra of the lipophilic spin probe TEMPOLBENZOATE in 2% Poloxamer solutions. The ESR spectrum recorded at 25 °C indicates that the nitroxide is localized in a polar environment. The spectrum can be simulated with one species with a Hfs constant of  $a_N = 1.66$  mT. Heating the sample to 60 °C leads to significant changes in spectral shape, which are most visible in the region of the third line. Obviously, the experimental spectrum is now a superposition of at least two ESR spectra from TEMPOLBENZOATE localized in different microenvironments. Simulation results for the ESR spectrum show that about 25% of the probe is localized in a polar environment ( $a_N = 1.66$  mT, third spectrum from top from Fig. 7.10). This environment is highly polar and very similar to the one and only environment observed at 25 °C. About 75% of the spin probe, however, is localized in a less polar, more viscous environment ( $a_N = 1.568$  mT, bottom spectrum in Fig. 7.10). This environment was not observed at 25 °C. Therefore, heating Poloxamer 188 solutions results in a new hydrophobic environment, in which lipophilic molecules accumulate. Experimental results demonstrate the thermal reversibility of this process. The temperature-induced formation of this hydrophobic environment has to be kept in mind if heating of Poloxamer solutions takes place (e.g., DSC).

The usefulness of ESR to get more insights has also been demonstrated for colloidal lipid carriers. The results indicate that the loading capacity of colloidal solid lipid dispersions is very low due to the crystalline nature of the lipid. They also showed that solid lipid nanoparticles (SLN) and nanostructured lipid carriers (NLC, composed of solid and liquid lipids) do not offer the proposed advantages in

**Fig. 7.10.** ESR spectra of TEMPOLBENZOATE in 2% (w/w) Poloxamer 188 solutions at 25 and 60 °C. Note the different line shape at 60 °C, as indicated by the arrow. The bottom spectra are the result of simulating the experimental 60 °C spectrum, indicating the distribution of the nitroxide in two environments with different polarity.

comparison with a submicron emulsion, because lipid crystallization leads to expulsion of the lipophilic nitroxide into the aqueous phase. Detailed analysis of the ESR spectra shows that about  $\frac{2}{3}$  of TEMPOLBENZOATE were exposed to a polar environment in a 10% colloidal dispersion of Compritol (a mixture of different glycerolbehanates) – which demonstrates the poor performance of SLN (Fig. 7.11) [20]. Incorporation into the lipid is even worse if the lipid crystal is more perfect. The incorporation rate of lipophilic nitroxides in cetylpalmitate is close to zero (own unpublished results).

Lipid crystallization might be retarded in nanosized systems due to the small size. Therefore, sample storage might greatly influence the lipid crystallization and localization of the incorporated drug. Figure 7.12 shows that the nitroxide TEMPO distributes in a ratio of 1:3 between the polar (aqueous) and nonpolar (lipid) environment, if the sample is stored at room temperature. Data from NMR, DSC and X-ray measurements show that the lipid matrix does not crystallize under such conditions. Storage at low temperatures induces crystallization of the lipid, at least partially. The lipid crystallization is connected with a redistribution of the nitroxide into a more polar environment and a 1:1 distribution is observed. Clearly, solid lipids can accommodate only traces of foreign molecules, because the concentration of the spin probe is rather low ( $3 \text{ mmol kg}^{-1}$ ).

An important aspect of colloidal drug delivery systems is dynamic phenomena, e.g., the kinetics of distribution processes. The dilution assay monitors the change in spectral shape after further addition of the outer phase (Fig. 7.13). Current re-

**Fig. 7.11.** Localization of the lipophilic spin probe TEMPOLBENZOATE (TB) in different colloidal lipid carriers. Note that the nitroxide is almost exclusively localized in liquid lipids and only partially in solid lipid nanoparticles (SLN) and nanostructured lipid carriers (NLC).

sults obtained from different colloidal carriers (SLN, NLC, nanoemulsions, nanocapsules and polymeric nanoparticles) suggest that distribution processes take place in the range from seconds to minutes for nitroxides with moderate lipophilicity ( $\log P < 4$ ). This is not surprising with respect to the very short diffusion length within the particles and the very small thickness (e.g., 10 nm) of the shell of nanocapsules [21]. Nitroxides with very high hydrophobicity such as HDPMI (Fig. 7.3) can be simulated with one component before and after dilution. They do

**Fig. 7.12.** 2.1 GHz ESR spectra of TEMPO loaded (20% w/w) WITEPSOL (mixtures of triglycerides and partial glycerides) dispersions, (a) experiment: sample stored at room temperature, (b) experiment: stored at refrigerator, (c) simulation: lipophilic component, (d) simulation: hydrophilic component.

**Fig. 7.13.** ESR spectra of TEMPOLBENZOATE loaded nanocapsules before (top) and after (bottom) 1:4 dilution with the outer phase. The change in spectral shape is caused by increased localization of the probe in the aqueous environment.

not change their spectral shape due to their high preferential localization in the lipophilic environment.

ESR has been used to follow the pH-induced micelle-to-vesicle transformation of oleic acid in more detail [22]. Changes in the ESR spectra can also be used to follow the interaction between colloidal drug carriers and colloidal lipid dispersions with cells. Slovenian scientists found that the transfer depends on the spin probe, colloid matrix, and surfactant [23].

### 7.3.3

#### Monitoring of Microacidity

The development of pH-sensitive nitroxides offers the opportunity to monitor microacidity in drug delivery systems *in vitro* and *in vivo*. Figure 7.14 illustrates the principle.

Kroll et al. reported the first pharmaceutical application, monitoring drug degradation induced pH changes inside nontransparent w/o-ointments [24]. The pH is of crucial importance in the field of biodegradable polymers, because commonly used materials such as polyhydroxyesters, polyanhydrides and polyorthoesters are hydrolyzed to acids. The pH might affect the stability and solubility of incorporated drugs and, furthermore, also the degradation rate of many polymers to a large extent. The first *in vivo* measurement of the pH inside degrading PLGA implants was published in 1996 [ ]. The pH drops to as low as 2 inside subcutaneous PLGA implants in mice.

EPR has also been used to determine the acidity in PLGA-PEG microparticles designed for protein release [26]. For this purpose, albumin was covalently linked to a pH-sensitive label. Another study describes the influence of drugs and buffer substances on the acidity within the microparticles. Gentamicine base and sodium acetate are able to increase the pH inside the particles [27]. ESR is, therefore, a useful tool to monitor the success of a formulation measure in influencing the pH inside drug delivery systems. The principles of pH-measurement by ESR can also be applied to colloidal drug carriers and I am sure that we will soon witness further applications in this field.

**Fig. 7.14.** Principle of pH measurement by imidazolidine nitroxides. Protonation of the nitrogen at position 3 leads to significant changes in the spin density and hyperfine coupling constant. At  $pK_a$  4.7, the ESR

spectrum results from equal contributions of protonated (small Hfs) and unprotonated (larger Hfs) forms of the nitroxide. The influence of pH on Hfs is shown in the lower part of the figure.

#### 7.3.4

#### ESR Imaging

From the ESR spectrum, conclusions can be drawn on the nitroxide concentration, micropolarity, microviscosity and (using appropriate nitroxides) pH. Deeper insight into drug delivery processes is possible if the information can be attributed to a certain layer of the delivery system. Spectral-spatial information can be obtained by ESR imaging techniques. For example, pH gradients of almost two units within a distance of a few micrometers have been found in degrading polyanhydrides [28]. A more recent study showed the formation of pH gradients in polymers composed of polyorthoester and polylactide units [29]. Another study demon-

strated that commercial ointments can modify the microacidity in human skin *in vitro*, leading to pH gradients in the skin [30]. The resolution of ESR imaging, in the range of a few microns, is insufficient to monitor distributions inside nano-scaled systems. However, it can be used to follow the fate of nanostructures with a macroscopic controlled release system (e.g., tablets that release nanoparticles) or, even more interestingly, to follow the fate of nanocarriers in mice and rats.

#### 7.4

##### ***In Vivo* ESR**

The development of low-frequency spectrometers and imagers has made noninvasive ESR studies on mice and rats possible. *In vivo* applications include the characterization of antacid induced pH changes of the stomach in mice [31].

Correlation of *in vitro* and *in vivo* data is very important for the development and quality control of delivery systems. Major differences may arise from decreased water accessibility *in vivo*, different pH or buffer capacities or the involvement of enzymes. EPR is a useful tool to figure out whether the general release mechanism *in vitro* corresponds to the *in vivo* situation in a small mammal. For example, incomplete release of a water-soluble nitroxide has been found *in vivo* due to encapsulation of the polymer implant [32].

EPR observations show that release processes from biodegradable polyesters and polyanhydrides are rather complex [25, 33]. A surface erosion front mechanism with zero-order kinetics has been observed for P(CPP-SA) 20:80 polyanhydrides. The *in vivo* release was 1.5× slower than for *in vitro* experiments [33]. Substitution of the aromatic dicarboxylic acid CPP by long-chain aliphatic dicarboxylic acids (FAD) leads to increased mobility inside the manufactured polyanhydride and a more complex release pattern with partially diffusion-controlled processes [32]. For P(FAD-SA) implants, an intermediate increase in viscosity inside the degrading polymer has been observed, which was caused by precipitation of the dicarboxylic acids. EPR spectra of nitroxide-loaded poly(lactide-co-glycolide) implants did not change in shape or intensity during the first week, indicating an initial lag time. During the second week, a small portion of the nitroxides became solubilized within the polymer. The ratio of solubilized/immobilized nitroxides increased with time and a rapid, almost pulse-like release was observed after four weeks. The authors were able to distinguish release processes of the core from the outer layers by manufacturing sandwich implants that contained <sup>14</sup>N-nitroxides in the outer layers and <sup>15</sup>N-nitroxides in the core [33]. These studies show the possibility of obtaining unique information about drug delivery processes *in vivo*.

#### 7.5

##### **Summary and Outlook**

ESR can be applied to samples that are otherwise difficult to assess, e.g., nontransparent, solid or multiphase samples, or samples with heterogeneities in the nano-

meter range. This allows monitoring of the distribution kinetics and protection capacity of nanoscaled drug delivery systems.

Technical developments now permit sensitive ESR spectroscopy and imaging of mice and rats. An increasing number of *in vivo* spectrometers are being built, and I am sure that we shall soon see many papers that focus on the *in vivo* characterization of nanoscaled drug delivery systems by ESR spectroscopy and imaging.

### Acknowledgment

I thank the former and present members of my group, S. Liedtke, K. Jores, A. Rube, C. Augsten, and R. K. Narayanan for the measurement of samples and discussions.

### Introduction

The properties of matter at nanoscale dimensions can be dramatically different from the bulk or the constituent molecules. The differences arise through quantum confinement, altered thermodynamics or changed chemical reactivity. In general, electronic structure ultimately determines the properties of matter, and it is therefore natural to anticipate that a complete understanding of the electronic structure of nanoscale systems will lead to progress in nanoscience and bioscience, not inferior to that seen in recent years.

The ability to control the particle size and morphology of nanoparticles is of crucial importance, both from a fundamental and industrial point of view, considering the tremendous amount of high-tech applications of nanostructured metal oxide materials devices such as dye-sensitized solar cells, displays and smart windows, chemical, gas and biosensors, lithium batteries, supercapacitors. Controlling the crystallographic structure and the arrangement of atoms along the surface of nanostructured material will determine most of its physical properties.

So far the electronic structure and dynamics in biological systems have been little investigated. Synchrotron-based X-ray diffraction has been used to determine the molecular geometry that in many cases can determine the biological function of the molecule. Unfortunately, as crystallography was unable to address the local structural geometry of a chemisorbed molecule on surface, disordered biological systems may be a challenge too. When studying biological systems it is necessary to perform the experiments in a natural environment, i.e., in water/liquid solutions. We show later in this chapter that X-ray photon-in and photon-out spectroscopy can be used for *in situ* spectroscopic studies of wet systems.

X-rays originate from an electronic transition between a localized core state and a valence state. By the second half of the twentieth century, technological advances in detector and X-ray spectrometry produced a renaissance of interest in X-ray spectroscopy as an analytical tool in chemical analysis and as a tool for studying the solid state in general [1]. The parallel development of computational methods in solid-state physics and quantum chemistry, abetted by modern high-speed com-

puters, enabled theoreticians to return to the many unrevolved problems in X-ray spectroscopy. Thus, the last decade has seen a rebirth of effort in expanding the methods of X-ray spectroscopy as well as applications to a growing lists of studies in various fields of science.

Soft X-ray spectroscopy has some basic features that are important to consider [2]. As a core state is involved, elemental selectivity is obtained because the core levels of different elements are well separated in energy, meaning that the involvement of the inner level makes this probe localized to one specific atomic site, around which the electronic structure is reflected as a partial density-of-states contribution. The participation of valence electrons gives the method chemical state sensitivity and, further, the dipole nature of the transitions gives particular symmetry information.

An introduction to soft X-ray absorption spectroscopy (XAS) along with soft X-ray emission spectroscopy (XES) is given in Section 8.2, and their chemical sensitivity in nanostructured and molecular materials is discussed in Section 8.3. A number of examples, including some recent findings, then illustrate the potential of XAS and XES applications in the nanoscience (Section 8.4) and bioscience (Section 8.5).

## 8.2

### Soft X-ray Spectroscopy

Synchrotron radiation has become an indispensable tool in many areas of science. Synchrotron radiation is the light emitted by electrons as they circulate around a high-energy accelerator. This light covers the spectrum from hard (short wavelength) X-rays through soft (long wavelength) X-rays, ultraviolet (UV), visible, and infrared. The use of synchrotron radiation has grown to a powerful research tool in science in the last decade. Vacuum ultraviolet and X-ray photons emerging from storage rings are now among the most frequently used probes for advanced investigation of the electronic and geometric structure of matter.

The newly developed theoretical methods in band theory and quantum chemistry, as well as the use of different instrumentation, set the soft X-ray community apart from hard X-ray spectroscopists [3]. This separation has long been symbolized by the existence of separate triannual international conference series on Vacuum Ultraviolet Radiation Physics [4] and X-ray Physics and Inner Shell Ionization [5].

The utility of hard X-ray absorption spectroscopy as a probe of chemical identity in the biological, environmental and biomedical sciences is well documented [6–12]. Metals in enzymes can be probed in all oxidation states and spin states, and environmental samples can be examined in a chemically undisturbed form. In appropriate cases, intact tissues or even an entire organism can be examined. For example, a 23 amino-acid synthetic lytic peptide (Hecate) has been covalently linked to magnetite nanoparticles, and the lytic peptide-bound nanoparticles characterized by X-ray absorption near-edge structure spectroscopy [13]. In recent years, the ad-

vent of synchrotron sources as the best source for both X-ray regions has greatly reduced the barriers between the two communities [14]. Soft X-ray absorption fine structure, or NEXAFS technique, has become a powerful tool to study molecules bonded on surfaces [15].

Current developments in synchrotron radiation techniques have led to extremely bright undulator sources. The use of synchrotron radiation for the excitation of soft X-ray emission spectra adds several important qualities to this spectroscopic method. Firstly, it provides a very intense photon-excitation source. Secondly, monochromatized soft X-ray photons offer a higher degree of energy selectivity than do electrons. Thirdly, synchrotron radiation offers the possibility of exciting soft X-ray spectroscopy by polarized light.

### 8.2.1

#### Soft X-ray Absorption Edges

The X-ray absorption spectrum of a given element consists of series of edges, each corresponding to excitation of a different core electron. Electron levels with the quantum number  $n$  equal to 1–4 are named as K, L, M, N levels, respectively. K-edges arise from the innermost 1s orbital, L-edges from the second shell, M-edges from the third and N-edges from the fourth. While there is only one K-edge, the higher order edges are further divided by the angular momentum of the resulting core electron vacancy. Hence, there are three L-edges, denoted  $L_1$ ,  $L_2$  and  $L_3$ , arising from 2s,  $2p_{1/2}$  and  $2p_{3/2}$  final states, respectively. Similarly, there are five M-edges and seven N-edges. These edges are well separated in energy. With  $\text{Fe}_2\text{O}_3$ , for example, the O K-edge is at 530 eV, and the Fe  $L_2$  and  $L_3$ -edges are close together at 720 and 707 eV, while the observable M-edge has a very low energy of 52 eV.

The soft X-ray region ranges from about 50 to 1200 eV. Much of biological and environmental science can be based on soft X-ray spectroscopy measurements. This is because the X-ray edges in this region offer routes to chemical information not readily obtained by other techniques. Edges in the soft X-ray region include: the light element K-edges, including C, N, O, F, Si; the first transition metal L-edges, including Ti, Cr, Mn, Fe, Co, Ni, Cu, Zn; the M-edges of Fe through to the lanthanides, and N-edges of the lanthanides etc. All the absorption edges can be found on a website of the Center for X-ray Optics, Lawrence Berkeley National Laboratory [16], and some of the edges are illustrated in Fig. 8.1.

### 8.2.2

#### Soft X-ray Emission Spectroscopy

In soft X-ray emission, the core vacancy left by the excited 1s electron is filled by a valence-orbital electron, thereby also giving direct information about the chemical bonding. Characteristic X-ray emission spectra consist of spectral series with lines having a common initial state with the vacancy in the inner level. The emission intensity from a disordered sample is given by the formula

**Fig. 8.1.** Schematic illustration of X-ray absorption edges from the K-edges of some light elements and L-edges from some transition metals.

$$I \propto \sum_f \omega_{if}^3 |\mathbf{r}_{if}|^2 \Delta(\omega' - \omega_{if}, \Gamma) \quad (1)$$

Eq. (1) can be further simplified in the one-electron approximation. To be specific let us consider the K-emission of atom  $n$  in a molecule. The transition matrix element  $\mathbf{r}_{if}$  describes now the one-electron transition between the  $1s_n$  core orbital and occupied molecular orbital (MO)  $i$ , the effective wavefunction of which can be written as

$$\phi_i = \sum_n \chi_n c_{in} \quad (2)$$

where  $\chi_n$  is the p-orbital of the atom  $n$ . Thus, the intensity Eq. (1) becomes

$$I \propto \sum_i c_{ni}^2 \Delta(\omega' - \omega_{i,1s}, \Gamma). \quad (3)$$

where  $\omega_{i,1s} \approx \varepsilon_i - \varepsilon_{1s}$ ,  $\varepsilon_i$  and  $\varepsilon_{1s}$  are the energies of the  $1s$  electron and MO  $i$ .

Further simplification could be made by retaining only the first term in the expansion of the exponential function, i.e., the so-called *dipole approximation*. This important approximation assumes  $kr \ll 1$ . Such an approximation works well for soft X-ray radiation. As result of the dipole approximation, K-emission probes the p-character of a molecular orbital  $\phi_i$ , while L-emission probes the contributions of s and d atomic orbitals in  $\phi$ . One can map the MO  $\phi$  by measuring spectra of all series (K, L, M, ...) of all atoms.

Fig. 8.2. Left: schematic illustration of X-ray absorption and emission spectroscopy. Right: X-ray absorption and emission of a water molecule.

### 8.2.3

#### Soft X-ray Absorption Spectroscopy

A soft X-ray absorption spectrum provides information about the unoccupied states. For example, in the oxygen K-edge absorption, the oxygen 1s electron is excited to empty electronic states in the water unoccupied molecular orbitals, and the dipole selection rule provides a tool to study locally the O 2p character of these unoccupied valence band (Fig. 8.2). The atomic nature of the core hole implies elemental and site selectivity. The probability of such a transition is related to the X-ray absorption cross section. The intensity of these secondary electrons or the photons can be measured as a function of incoming photon energy. This will reflect the absorption cross section as the intensity of the secondary electrons/emitted photons are proportional to the absorbed intensity. Because of the short mean free path of electrons, the electron-yield-detection method is very surface sensitive. If the out-coming photons are detected (fluorescence yield), the X-ray absorption becomes bulk probing (about 100–200 nm) due to the comparatively larger attenuation lengths.

The photoabsorption transition probability for a transition from an initial state  $|i\rangle$  to a final state  $|f\rangle$  is governed by Fermi's "Golden Rule":

$$P_{if} = \frac{2\pi}{\hbar} |\langle f|V|i\rangle|^2 \Delta(\omega - \omega_{fi}, \Gamma_{if}), \quad \omega_{fi} = \varepsilon_f - \varepsilon_i \quad (4)$$

where  $\varepsilon_f$  and  $\varepsilon_i$  are energies of final and initial states of the system, and  $\Gamma_{if}$  is the width of the spectral transition,  $V$  describes the interaction between molecule and light, and  $\Delta(\varepsilon, \Gamma)$  is the Lorentzian function

$$\Delta(\varepsilon, \Gamma) = \frac{\Gamma}{\pi(\varepsilon^2 + \Gamma^2)} \quad (5)$$

The final electron state  $|f\rangle$  could be a bound or a continuum state, depending on the photon frequency  $\omega$ .

Thus, the expression for the X-ray absorption (XAS) cross section is obtained as Eq. (6).

$$\sigma = \frac{4\pi^2}{m^2} \frac{e^2}{c} \frac{1}{\omega} |\langle f | \mathbf{e} \cdot \mathbf{p} | i \rangle|^2 \Delta(\omega - \omega_{fi}, \Gamma_{if}) \quad (6)$$

#### 8.2.4

#### Resonant Soft X-ray Emission Spectroscopy

The big improvement in the performance of synchrotron radiation based soft X-ray spectroscopy during the last decade is the high brightness of the third generation source combined with high quality optical systems for refocusing the monochromatized soft X-ray beam. The new generation synchrotron radiation sources producing intense tunable monochromatized X-ray beams has opened up new possibilities for soft X-ray spectroscopy. X-ray absorption and emission have been traditionally treated as two independent processes, with the absorption and emission spectra providing information on the unoccupied and occupied electronic states, respectively.

The possibility to select the energy of the excitation has created an extra degree of freedom compared with traditional spectroscopy pursued with high-energy electron or characteristic X-ray excitation. The energy selectivity makes it possible to perform resonant excitation, i.e., exciting to particular empty states [28–30]. The introduction of selectively excited soft X-ray emission has opened a new field of study by disclosing many new possibilities of soft X-ray resonant inelastic scattering (RIXS). Among the new tools available with this technique are site selectivity in high- $T_c$  superconducting materials [31], femtosecond dynamics [32] and chemical bonding mechanism [33] by detuning from resonance, etc.

Resonant inelastic X-ray scattering at core resonances has become a new tool for probing the optical transitions in transition metal oxides. The scheme of RIXS process is presented in Fig. 8.3. For the hard X-ray K-edge RIXS process, the intermediate state in a transition metal is the same as the final state in a K absorption measurement, while the RIXS final state (when scanning the  $K\alpha$  region) is the same as in L absorption spectroscopy [21, 22]. For L-edge and M-edge RIXS, the final states are typical d–d or f–f excitations [23, 24].

Final states probed via such a channel, RIXS or XRS, are related to eigenvalues of the ground state Hamiltonian. The core–hole lifetime is not a limit on the resolution in this spectroscopy. According to the many-body picture, an energy of a photon, scattered on a certain low-energy excitation, should change by the same amount as a change in an excitation energy of the incident beam, so that inelastic

Fig. 8.3. Schematic representation of RIXS process (a), soft X-ray RIXS in study of dd (ff) excitations (b).

scattering structures have constant energy losses and follow the elastic peak on the emitted-photon energy scale.

The formulations of RIXS lead to a Kramers–Heisenberg type dispersion formula for the cross section, with generally only the resonant part of the scattering process taken into account [17–20]. Second-order perturbation theory for the RIXS process leads to the Kramers–Heisenberg formula for the resonant X-ray scattering amplitude. Using this starting point RIXS has been analyzed in periodic solids as a momentum conserving process, suggesting that it can be used as a novel “band-mapping” technique in diamond and graphite [25–27].

The spectral and polarization properties of the RIXS process can be described by a double differential cross section

$$\frac{d^2\sigma}{d\omega' d\Omega} = \sum_v \sum_n \frac{\omega'}{\omega} |F_{vn}(\omega)|^2 \Delta(\omega - \omega' - \omega_{vn}, \Gamma_{vn}) \Phi(\omega - \omega_0) \quad (7)$$

where  $\omega$  and  $\omega'$  are the frequencies of incident and scattered X-ray photons, respectively.  $\Gamma_{vn}$  is the final-state lifetime broadening.  $\Phi(\omega - \omega_0)$  is the spectral profile of the incoming beam. The broadening of the core excitations  $\Gamma_{vk}$  is much larger than the lifetime broadening  $\Gamma_{vn}$  of optical transitions  $n \rightarrow v$ . It is thus reasonable to assume that  $\Gamma_{vn} = 0$ , replacing the  $\Delta$  function by a Dirac  $\delta$ -function. This is the basis for super-highly resolved X-ray spectroscopy, which allows us to record X-ray fluorescence resonances without the lifetime broadening [18]. Further discussion on resonant soft X-ray emission spectroscopy is beyond the scope of this chapter, but it can be found in earlier reviews [34–37].

### 8.2.5

#### Experimental Details

An outline of an undulator beamline, such as beamline 7.0.1 of the Advanced Light Source [38], is presented in Fig. 8.4, showing its principle elements. It consists of a

**Fig. 8.4.** Outline of an undulator beamline, including an undulator, monochromator and a Rowland circle geometry grating spectrometer and channeltron for soft X-ray fluorescence detection.

5 m, 5-cm period undulator and a spherical grating monochromator (SGM) covering the spectral range from 60 to 1200 eV. It is designed for high resolution operation with maximum photon flux and a small spot size (typically, 50–100 mm) at the sample, matched to the acceptance of the experiment spectrometers.

The experimental set-up at a synchrotron radiation beamline is called the end-station, since it constitutes an interchangeable experiment at the end of the beamline. The end-station consists of three main parts: analysis chamber, preparation chamber and loadlock chamber, separated by valves [39].

X-ray absorption spectra are recorded in total-electron-yield (TEY) mode or fluorescence-yield (FY) mode. TEY is measured from sample drain current, and the FY is obtained from a channeltron. X-ray emission spectra are recorded by using a grazing incidence grating spectrometer. Figure 8.5 shows a common experimental set-up for soft X-ray spectroscopy.

**Fig. 8.5.** A Rowland circle geometry grating spectrometer (a) and a static liquid cell (b) for soft X-ray spectroscopic study of liquid samples.

The high-resolution grating spectrometer was mounted parallel to the polarization vector of the incident photon beam to detect the emitted X-ray (Fig. 8.5a). The grazing-incidence grating spectrometer is based on Rowland geometry. It consists of slit, gratings and detector. Three spherical gratings are optimized to cover an operation range of 50–1000 eV. The gratings are mounted at angles of incidence to have a joint fixed slit, and the emitted X-rays are detected using a two-dimensional detector that can be positioned and oriented tangentially to the pertained Rowland circle. The detector consists of multi-channel plates and a resistive anode with a four-electrode readout.

Solid-state samples can be studied by placing the solid sample in front of the spectrometer slit, as shown in Fig. 8.5(a). While for the liquid (or wet) samples, a liquid cell has to be used. The liquid cell has a window to attain compatibility with UHV conditions of the spectrometer and beamline. The synchrotron radiation enters the liquid cell through a 100 nm thick silicon nitride window and the emitted X-rays exit through the same window. The thin silicon nitride window is commercially available [42]. The test showed that a 100 nm thin  $\text{Si}_3\text{N}_4$  membrane of  $2.25 \times 2.25 \text{ mm}^2$  could hold one atmosphere pressure. The liquid cell (Fig. 8.5b) consists of a metal container and a  $1 \times 1 \text{ mm}^2$  and 100 nm thin  $\text{Si}_3\text{N}_4$  membrane, which can withstand the differential pressure between the liquid on one side and UHV on another side. The transmission of X-rays at the C, O K-edge, and Fe L-edge for a 100 nm thick window is about 46%, 66%, and 82%, respectively. Silicon nitride membranes are not the best choice when compared to other materials with respect to their transmission of X-rays in the energy region 80–1000 eV, but their mechanical properties and fabrication process make them the only candidate at present. They also allow experiments to be performed at a vacuum pressure of less than  $1 \times 10^{-9}$  Torr.

### 8.3 Chemical Sensitivity of Soft X-ray Spectroscopy

The region from 200 to 700 eV covers the K-edges of the biologically relevant light elements carbon, nitrogen, oxygen and fluorine. The useful properties of soft X-ray spectroscopy stem from the electric dipole nature of the transitions involved. The emission originates from an electronic transition between a localized core state and a valence state. The energy of the emitted X-ray is equal to the difference in energy of the two states. Involvement of the inner level makes this probe localized to one specific atomic site, around which the electronic structure is reflected as a partial density-of-states (DOS) contribution. Chemical sensitivity is obtained when the resolution of the detected emission lines is high enough to resolve fine structure. The line shapes are determined by the valence electron distribution and the transitions are governed by dipole selection rules. For solids, essentially a partial DOS mapping is obtained. This is exemplified by the carbon  $K\alpha$  emission spectra of the carbon solids shown in Fig. 8.6 (see also Fig. 8.8a).

**Fig. 8.6.** Schematic representation of carbon in different allotropic forms: diamond, graphite, C<sub>60</sub>, and nanotubes. (From Ref. [41].)

### 8.3.1

#### Electronic Structure and Geometrical Structure

The difference in structural arrangement of these allotropic forms (Fig. 8.6) of carbon gives rise to the wide differences in their physical properties. Carbon has an atomic number of 6 and has a  $1s^2 2s^2 2p^2$  configuration in the electronic ground state. The atoms in diamond are tetrahedrally bonded to their four nearest-neighbors using linear combinations of  $2s$ ,  $2p_x$ ,  $2p_y$ , and  $2p_z$  orbitals in an  $sp^3$  configuration. In contrast, in graphite, strong in-plane bonds are formed between a carbon atom and its three nearest-neighbors from  $2s$ ,  $2p_x$ , and  $2p_y$  orbitals; this bonding arrangement is denoted by  $sp^2$ . The remaining electron with a  $p_z$  orbital provides only weak interplanar bonding, but it is responsible for the semi-metallic electronic behavior of graphite.

The  $sp$ -orbital, and the  $sp^3$ -hybrid orbital indicate rotational symmetry. Bonds of this kind are called  $\sigma$ -bonds. The electrons involved in such bonds are called  $\sigma$ -electrons. With double bonds, so-called  $\pi$ -orbitals occur with corresponding  $\pi$ -electrons. Such orbitals are not symmetrical with regard to their bonding orientation. Figure 8.7 displays X-ray absorption spectra of highly oriented pyrolytic graphite (HOPG) recorded at different incidence angles [40]. When the polarization vector of the incident beam is parallel to the basal plane only excitations to  $\sigma$  states are possible. Excitations to  $\pi$  states become more likely the more perpendicular to the basal plane the polarization vector is. Thus, one can see that the main feature below 292 eV has mainly  $\pi$  character, while the  $\sigma$  states are observed at energies above 292 eV. Notably, the sharp absorption feature appearing at 292.0 eV is not due to the band structure but to an excitonic state, which has been discussed in detail elsewhere [26].

The normal carbon  $K_\alpha$  XES spectra of diamond, graphitic carbon, C<sub>70</sub>, C<sub>60</sub>, and benzene are presented in Fig. 8.8(a), where large differences in spectral profile are observed. The spectra of diamond and graphitic carbon show a wide band with

Fig. 8.7. Polarization dependent X-ray absorption spectra of HOPG.

some shoulder structures, where the energy positions of the peak maximum and band shapes are largely different. In some studies related to vapor deposition the XES spectral profile has been used as a means to identify certain chemical states [34]. In contrast, the spectra of benzene,  $C_{60}$ , and  $C_{70}$  exhibit clearly resolved emission peaks, indicating strong molecular character in their solid phases. The marked resolved emission features in benzene can find their counterpart in the emission spectra of  $C_{60}$  and  $C_{70}$ , and all the fine structures are washed out in diamond and graphite.

Fig. 8.8. (a) Non-resonant carbon  $K\alpha$  SXES spectra of diamond, amorphous carbon (graphitic),  $C_{70}$ ,  $C_{60}$ , and benzene; (b) X-ray absorption spectra of  $C_{60}$ , carbon nanotubes, HOPG, and diamond.

Figure 8.8(b) shows the X-ray absorption spectra of  $C_{60}$ , carbon nanotubes (C-NT), HOPG, and diamond. The X-ray absorption spectral shape of carbon nanotubes is similar to that of HOPG, which is different to that of  $C_{60}$ . The  $\pi^*$  shows a shift towards low photon energy in the X-ray absorption of C-NT.  $C_{60}$  gives more resolved absorption features, which indicate a strong molecular character of  $C_{60}$ . Non-resonant carbon  $K\alpha$  XES spectra of carbon nanotubes and  $C_{60}$  show a similar shape, but resonantly excited XES spectra reveal large differences in the electronic structure of these two systems. The XAS spectrum of diamond shows no  $\pi^*$  contribution, and the absorption feature at 288.85 eV is the diamond exciton. The 2nd bandgap at 302 eV is also clearly observed.

### 8.3.2

#### Hydrogen Bonding Effect

A very important but hitherto less addressed question is that of the hydrogen bond effect on the electronic structure. This effect is essential for understanding the physical and chemical properties of many chemical and biological systems. The reason for this neglect, however, is the limited experimental access to the electronic structure of liquids. The application of spectroscopic methods to study the electronic structure of liquids has been hampered by the incompatibility of wet samples and high-vacuum conditions. Hence, even understanding the properties of pure liquid water remains a challenge.

Water is the most abundant substance on our planet, and it is the principal constituent of all living organisms. Chemical reactions taking place in liquid water are essential for many important processes in electrochemistry, environmental science, pharmaceutical science, and biology in general. Many models have been proposed to view the details of how liquid water is geometrically organized by a hydrogen bond network. Hydrogen bonding is an attractive interaction from a link of a hydrogen atom and one of the highly electronegative and non-metallic elements that contain a lone pair of electrons. Although H-bonds are much weaker than conventional chemical bonds, they have important consequences on the properties of water. Diffraction of X-rays [43] and neutrons [44] provides strong evidence that tetrahedral hydrogen-bond order persists beyond the melting transition, but with substantial disorder present [45]. Important questions remain about the precise nature of the disorder and how it is spatially manifested.

A network with four hydrogen bonds connects most of the water molecules in the liquid phase. Such a network can often be terminated by local structures with three or even two hydrogen bonds.

Soft-X-ray emission spectroscopy is essentially bulk sensitive, since the attenuation length of photons in this energy range is typically hundreds of nanometers in solid matter. The penetration depth offers a few experimental opportunities not present in electron-based spectroscopy. Figure 8.9 shows XAS and XES spectra of water in the gas phase and liquid phase at room temperature.

Another X-ray absorption study of liquid water [46] suggests that the four hydrogen-bonding networks mainly contribute to a single broad feature, while a shoulder located at 534.7 eV suggests the presence of the broken hydrogen bonds.

**Fig. 8.9.** X-ray emission spectra of the water molecules and liquid water, formed as electrons from the three outermost occupied molecular orbitals, schematically depicted in the right panel, fill a vacancy in the  $1a_1$  core-

level. The excitation-energy is 543 eV, well above the ionization limit but sufficiently low so that the emission from multiply excited states can be neglected.

Indeed, recent theoretical simulations assign this pre-edge structure to a particular three-hydrogen bond structure with one missing hydrogen bond at the hydrogen site.

### 8.3.3

#### Charge and Spin States of Transition Metals

Many metals that play important roles in biological and environmental sciences lack the partially filled d-shells used for UV-visible spectroscopy. Still, there are always soft X-ray resonances that can be exploited.

First transition metal L-edge spectroscopy is a relatively new technique for biological samples. L-edge spectra can be analyzed through theoretical simulation using ligand field multiplet theory (LFMT). LFMT is a multi-electron approach that describes the initial and final states as multiplets that are mixed and split by the symmetry of the ligand field [47–51].

The experimental Fe- $L_{2,3}$  absorption spectra for  $K_4[Fe(CN)_6]$  ( $Fe^{2+}$ ) and  $K_3[Fe(CN)_6]$  ( $Fe^{3+}$ ) are displayed in Fig. 8.10. The first peak at 704.5 eV is observed in the ( $Fe^{3+}$ ) derivative but not in the ( $Fe^{2+}$ ) one. It corresponds to the excitation  $2p^6t_{2g}^5 \leftrightarrow 2p^5t_{2g}^6$  which is absent in the  $Fe^{2+}$  configuration ( $t_{2g}^6$  ground state). This peak is a signature of the  $Fe^{3+}$  configuration [52]. The other peaks between 707 and 715 eV correspond to multiplet structures arising from transitions from  $2p$  to  $e_g$  orbitals.

The second peak, which corresponds to the transition from  $2p_{3/2}$  to empty  $e_g$  orbitals, exhibits at least five structures, which have to be analyzed with a multiplet model, taking into account the exchange interaction between the  $2p$  hole and  $3d$  electrons [51]. Note that the splitting of the  $L_3$  line is related, but not directly scaled, to the  $10Dq$  crystal field strength parameter (energy separation between

**Fig. 8.10.** Fe  $L_{2,3}$ -edges absorption from  $K_3[Fe(CN)_6]$  and  $K_4[Fe(CN)_6]$  in both solid state and water solutions. The peak labeled “ $A_1$ ” corresponds to a singlet excitation.

the levels  $t_{2g}$  and the center of mass of the  $e_g$  levels). The Fe L-edge of both complexes,  $K_3[Fe(CN)_6]$  and  $K_4[Fe(CN)_6]$  presented the significant changes in the spectral profile when they were dissolved in water solutions.

The Ni L-edge XAS and RIXS spectra of NiO and  $(Ph_4As)_2Ni[S_2C_2(CF_3)_2]$  are shown in Fig. 8.11 [53]. NiO is a typical high-spin  $Ni^{2+}$ , and the complex of  $(Ph_4As)_2Ni[S_2C_2(CF_3)_2]$  is a Ni dithiolene, which has a low-spin  $Ni^{2+}$ . The dd and charge-transfer excitations can be observed along with some contributions of normal emission. The transition of dd excitations in the high-spin compound NiO was within 3.0 eV, while the low-spin system shows dd excitations with larger energies. Examination of these Ni models will serve as a first step in measuring real biological nickels, and one can create a spectral data base for use in future biological spectra analysis. Preliminary experiments on a small number of Ni compounds also confirm the feasibility.

#### 8.4 Electronic Structure and Nanostructure

In the nano-regime, two effects dominate the chemical and physical properties: (a) increasing contribution of surface atoms (surface effect). The surface atom to bulk

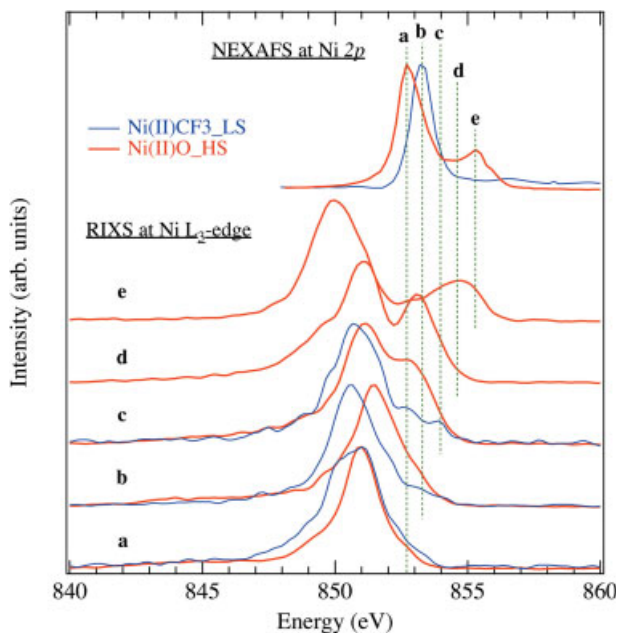

Fig. 8.11. X-ray absorption and RIXS spectra of NiO ( $\text{Ni}^{2+}$  in high spin) and  $(\text{Ph}_4\text{As})_2\text{Ni}[\text{S}_2\text{C}_2(\text{CF}_3)_2]$  ( $\text{Ni}^{2+}$  in low spin).

atom ratio increases dramatically as the particles size decreases. For a 30-nm particle, about 5% of all the atoms are on the surface, while for 3 nm particle, up to 50% of the atoms are on the surface, (b) quantum confinement as nanoclusters decrease down to a few nanometers (size effect), where electrons begin to feel the effects of quantum confinement when the size of the structure becomes comparable to the electron wavelengths.

Synchrotron radiation with photon energy at or below 1 keV is giving new insight into such areas as wet cell biology, condensed matter physics and extreme ultraviolet optics technology. In the soft X-ray region, the question tends to be, what are the electrons doing as they migrate between the atoms? [54].

#### 8.4.1

#### Wide Bandgap Nanostructured Semiconductors

Soft X-ray spectroscopy has proved useful in probing the electronic structure of nanostructured solids [55, 56]. The development of the electronic band structure of solids from discrete localized atomic states is one of the key points of interest in cluster physics. As the size of nanocrystal extends into a truly molecular regime, such as cadmium thiolate  $[\text{Cd}_8(\text{SR})_{16}]$  units, the optical excitation energies for the dissolved particles increase from 2.5 eV for CdS bulk to around 4.7 eV for Cd thiolate [57–59].

**Fig. 8.12.** Right: S L-edge XAS spectra of CdS bulk and Cd nanocrystallites. The dotted lines show the separation into excitonic and LPDOS excitation. Left: S L3 SXE spectra mapping the local DOS of the upper VB. Gray bars indicate the linear extrapolation of the emission cutoffs and the LPDOS absorption onsets, respectively. Courtesy of [60].

Figure 8.12 shows the S L-edge XAS and XES spectra for different samples (labeled by the number of Cd atoms per cluster) [60]. For decreasing particle size, an increase of the bandgap was observed. This opening of the bandgap can be separated into valence band and conduction band contributions.

X-ray absorption spectra have also been used to measure the band edges of silicon nanocrystals, with average diameters ranging from 1 to 5 nm [61]. The conduction band (CB) edge shift (from XAS measurements) and the valence band (VB) edge shift (from photon emission measurements) vary as a function of nanocrystal diameter. If the observed VB or CB shifts are due to quantum confinement, one would expect the size of the band shifts to increase as the particle size of the nanocrystalline Si is decreased. Other X-ray absorption studies of quantum confinement have examined CdSe and InAs nanocrystals [62], nanodiamonds [63], and porous silicon [64], etc.

## 8.4.2

**Cu Nanoclusters**

Copper nanoclusters have been studied due to potential applications in optics, magneto-electronics and catalyst systems [65–67]. Silicon carbide provides a structurally and chemically stable support for such nanoclusters due to its stability against copper [68]. Although there are some studies on copper island formation on silicon carbide, the reports relied on the indirect spectroscopic results, mainly focusing on the stability of Cu/SiC interfaces [69–71]. Recently, we have observed the morphology of copper nanoclusters by high-resolution transmission electron microscopy (TEM) where copper nanoclusters had an ellipsoid shape inside a SiC matrix [72]. XAS studies can give a detailed description of the size dependence of the electronic structure of the copper nanoclusters in order to understand the nature of chemical bonds due to size effects.

Figure 8.13 shows the Cu L-edge XAS spectra of a series of Si/Ta(100 nm)/[Cu(0.5–3 nm)/SiC(2 nm)]<sub>10</sub>/Ta(5 nm) and the reference Cu. The bulk Cu sample shows three distinct features in the L<sub>3</sub>-edge region, which are associated with the unoccupied 3d states in Cu. In a free Cu atom, the 3d orbital is fully occupied. In contrast, a solid Cu is characterized by a re-mixing of the valence wave functions in the ground state, gaining a small amount of non-vanishing 3d hole. According to dipole-selection rules, the dominant transition in XAS of Cu is from the Cu 2p<sub>3/2</sub> and 2p<sub>1/2</sub> states to the unoccupied Cu 3d states [73]. Thus, the peak at the onset of the L<sub>3</sub>-edge is associated with the Cu 3d-derived character due to 3d–4s hybridization, giving a sharp 2p → 3d transition superimposed on the smooth 2p → 4s transitions. The peak at 939 eV and the peak at 943 eV are attributed to transitions

Fig. 8.13. XAS spectra of Cu L-edge with different nanocluster sizes.

towards empty states, mainly mixed with s, p characters. As the nanocluster size decreases, two distinct changes occur. First, the peaks move slightly to higher energy. Second, the peaks at 939 and 943 eV drastically decrease in intensity. The decrease of these peaks indicates that the s–p–d hybridization becomes weaker. This behavior can be attributed to the surface effect. The Cu atoms at surface have lower coordination number and see fewer Cu neighboring atoms, giving rise to a reduction in Cu–Cu interaction. The Cu–Cu interaction is mainly determined by d–d interaction and stronger Cu d–d interaction favors s–p–d re-hybridization [12, 13]; reduction of the d electron will weaken the hybridization.

#### 8.4.3

#### ZnO Nanocrystals

ZnO, a wide band-gap semiconductor, has attracted considerable attention recently due to its potential technological applications such as, for instance, highly efficient vacuum fluorescent displays (VFD) and field-emission displays [76]. ZnO has also been used for short wavelength laser devices [77], high power and high frequency electronic devices [78], and light-emitting diodes (LED) [79, 80]. ZnO shows many advantages: (a) it has a larger exciton energy (60 meV) than GaN (23 meV); (b) the band-gap is tunable from 2.8 to 4 eV [81, 82]; (c) wet chemical synthesis is possible; (d) low power threshold at room temperature; (e) dilute Mn-doped ZnO shows room temperature ferromagnetism [83]. Recently, quantum size effects on the exciton and band-gap energies were observed in semiconductor nanocrystals [61, 84].

The controlled synthesis of ZnO nanostructures and in-depth understanding of their chemical/physical properties and electronic structure are the key issues for the future development of ZnO based nanodevices.

The XES spectra of bulk and nanostructured ZnO are displayed together with the corresponding XAS spectrum in Fig. 8.14 [85]. The O K-edge emission spectrum reflects the O 2p occupied states (valence band), and the O K-edge absorption spec-

**Fig. 8.14.** Oxygen X-ray absorption–emission spectrum reflected conduction band and valence band near the Fermi-level of ZnO nanoparticles in comparison with bulk ZnO.

trum reflects the O 2p unoccupied states (conduction band). In the photon energy region of 530–539 eV, the X-ray absorption can be mainly assigned to the O 2p hybridized with Zn 4s states. In the region 539–550 eV the spectrum is mainly attributed to O 2p hybridized with Zn 4p states. Above 550 eV, the contribution comes mainly from O 2p–Zn 4d mixed states [86]. Stronger s–p–d hybridization was revealed in nanostructured ZnO since the contributions of features at 520 and 523 eV are enhanced. A well-defined band-gap can be observed between the valence-band maximum and conduction-band minimum. Our absorption–emission spectrum yields a fundamental band-gap energy of 3.3 eV.

## 8.5

### Electronic Structure and Molecular Structure

Our microscopic understanding of a liquid is based very much on the study of spatial and of spatio-temporal correlation functions. This is the main bequest by the liquid state to the whole of physics: think in terms of correlations, be these between molecules in water or between galaxies in the cosmos. The study of correlations allows us to appreciate the local organization of one molecule around others, and to unravel the microscopic dynamics. Neutron diffraction and scattering have and continue to play a major role in these studies. X-ray diffraction is important as well, and very recently X-ray inelastic scattering has become available. We should add to these the soft X-ray spectroscopy experiments.

Using X-ray absorption and selectively excited X-ray emission spectroscopy to probe unoccupied and occupied electronic states, one can establish a firm interpretation for the unusual thermodynamic properties of molecular liquids. Furthermore, one can elucidate finer details of their structural properties. XAS and XES spectra reflect the local electronic structure of the various conformations; in this case, the oxygen lineshape is sensitive to the hydrogen bonding configurations.

#### 8.5.1

##### Hydrogen Bonding in Liquid Water

The local structure of liquid water is still under debate. Soft X-ray emission spectra, emanating from the radiative decay, subsequent to core excitation, can be useful in assigning structures in XAS spectra [87–90], and especially we have, earlier, shown that resonantly excited XES spectra of liquid water are compatible with the traditional view that three and four hydrogen bonds dominate in the structure [89]. Here we show that a theory that assumes that most water molecules in liquid water only make two hydrogen bonds fails to reproduce the experimental XES spectra.

Both the experiment and calculation have been described earlier [89], and the salient results are shown in Fig. 8.15. At excitation high above threshold (545.5 eV), the XES spectrum is well described by a calculation both with symmetric four-fold coordination, and conformations with one broken hydrogen bond. Thus, at high

**Fig. 8.15.** Resonantly (excitation energy at 534.7 eV) and non-resonantly (at 545.5 eV) excited XES spectra of liquid water, compared to calculations for the SYM and DASYM species. Excitation energies are marked in the XAS spectrum.

excitation energy the spectra are not predicted to be sensitive to the breaking of a single hydrogen bond. When tuning the excitation energy to the pre-peak at 534.7 eV, the spectral changes comply with what is expected when structures with one broken hydrogen bond at the hydrogen donor site (DASYM) [46, 89] are resonantly excited. We have shown elsewhere that a thorough analysis of XES spectra excited in the threshold region can give further details on the contributions by various structures to the XAS spectrum [91].

### 8.5.2

#### Molecular Structure in Liquid Alcohol and Water Mixture

Near-edge X-ray absorption spectra of water, methanol and a mixture of the two are displayed in Fig. 8.16. The X-ray absorption spectra of all samples present a similar shape: a strong pre-edge at 534.5 eV (B) and a broad main absorption threshold arising from 537.0 eV (C). The pre-edge (B) in liquid water has been the fingerprint of the particular water cluster with a broken hydrogen bond at the hydrogen side [89]. In methanol, the ring-structure configuration contributes mostly to the pre-edge (B) and the chain-structure configuration contributes mostly to the main threshold (C) of the absorption spectra [92]. Upon mixing water and methanol, a small X-ray absorption peak (A) appears at 531.5 eV, below the known X-ray ab-

Fig. 8.16. X-ray absorption spectra of liquid water, methanol and a mixture of molar concentration 7:3.

sorption pre-edge (B). The new absorption peak (A) suggests direct interaction between water molecules and methanol molecules.

To understand the origin of the pre-peaks in X-ray absorption spectra, resonant X-ray emission measurements were performed (Fig. 8.17). Structures of rings and chains for methanol and mixtures of water clusters and methanol are fully optimized at the hybrid density functional theory B3LYP level with 6-31G basis set using GAUSSIAN 98 [92]. The theoretical X-ray emission spectra of methanol were generated by the group theory formulation [20], using the adiabatic approximation (ground state electronic structure) for intensities as established for molecules and clusters [93]. All transition moments and orbital energies were calculated at the canonical Hartree–Fock level with the Sadlej basis set by using the DALTON program [94].

Fig. 8.17. Experimental and calculated X-ray emission spectra of liquid methanol.

The double structure emission band centered at 527 eV indicates two major different chemical species (molecular structure) in the alcohol and water mixtures. Comparison between experiment and theory shows that the two species originate from the combination of methanol rings and chains. These two peaks clearly have different origins: the one at higher energy side is from the chains, and the other from the rings. From the intensity distribution, it was found that the chains and rings have a similar size with same portion.

As to the mixtures of liquid water and methanol, when selecting the excitation energies around the pre-peak (A) in the X-ray absorption, the main emission band becomes very narrow and shifts towards higher photon energy, opposite to the shifting of the elastic peak. Is the interaction between water molecules and these chains or rings be responsible for the sharp spectral features in the resonantly excited X-ray emission spectra? We learnt previously [90] that the dominant chain and ring structures in methanol are those with 6 and 8 molecules. Of course, we do not know if this is the answer or just one of the possibilities. Notably, when methanol mixes with water, the ring and chain become the same. The results from alcohol–water mixtures of different concentrations are prerequisites to support the experimental findings from the equimolar study [11]. Thus, we know that the exact mixing level is not critical to our conclusions.

This study shows that, when a few water molecules interact with chains, the chains start to bend over to form open-ring structures. By adding water, the alcohol structures become more compact. The formation of such ordered molecular structure upon mixing provides evidence that the entropy of the alcohol and water mixture is not less than expected for ideal solutions.

We find a strong involvement of hydrogen bonding in the mixing of water and methanol molecules. The local electronic structure of water and methanol clusters, where water cluster is bridging within a six-membered open-ring structured methanol cluster, is separately determined. The experimental findings suggest an incomplete mixing of water–alcohol systems and a strong self-association between methanol chain and water cluster through hydrogen bonding. The enhancement of joint water–methanol-ring structure explains the loss of entropy of the aqueous solutions.

The answer to this specific question is likely to be of interest to a much broader scientific community of readers. The novelty of this work is that it relies on a spectroscopic probe to investigate problems that have, largely, been the territory of scattering methods. This technique could have great impact to the extent that this approach can be generalized to investigate other solvent mixtures.

### 8.5.3

#### **Electronic Structure and Ion Solvations**

Ion solvation is a phenomenon that is of fundamental interest in many chemical contexts because solvated ions are almost omnipresent on Earth. Hydrated ions occur in aqueous solution in many chemical and biological systems [95, 96]. Metal-ion transport in both aqueous- and polymer-solvent media involves continual

**Fig. 8.18.** Sample snapshots showing configurations with water molecules in the first and second solvation shells for (a)  $\text{Li}^+$ , (b)  $\text{Na}^+$ , (c)  $\text{Mg}^{2+}$ , and (d) ion pair water solutions.

solvent–ligand exchange. Metal-ion coordination chemistry is therefore fundamental to these phenomena where a dramatic exchange of ligand occurs. Alternatively, the effects of solvated cations could be monitored via examining the spectra of solvent. The great advantage of this approach is that the restriction to cations no longer applies. For example, it can be used in studying what happens when salts of the alkali and alkaline earth metals are added to aqueous solvent.

An ion in solution disturbs the local solvent structure. The local structure around a  $\text{Li}^+$  ion central water molecule, a  $\text{Na}^+$  ion, and a  $\text{Mg}^{2+}$  ion in water solutions as obtained using the polarizable MD model is shown in Fig. 8.18. The influences of cations on the water molecular structure can be seen as the threshold shifts towards higher energy in the X-ray absorption spectra; the mixing of molecular orbital in  $3a_1$  symmetry is reinforced as the intensity of  $3a_1$  is further reduced. We find that the charge difference of the cations may not be the only factor that accounts for the interactions between the cations and water molecules.

Figure 8.19 reports the O K-edge absorption spectra of liquid water and  $\text{NaCl}$ ,  $\text{MgCl}_2$ ,  $\text{AlCl}_3$  water solutions. The pre-peak (marked as  $\alpha$ ) in XAS spectrum of

**Fig. 8.19.** X-ray absorption spectra of liquid water and  $\text{NaCl}$ ,  $\text{MgCl}_2$ ,  $\text{AlCl}_3$  water solutions.

water has partly  $4a_1$  symmetry. The major difference on going from pure water to ion–water solutions can be seen as a shift of 0.4 eV for the absorption pre-peak (A), which is probably a result of a higher degree ionic character of the chemical bonding between cations and oxygen. The front slope of the absorption threshold has shifted most away from that of pure water for  $\text{Al}^{3+}$ -water, followed by  $\text{Na}^+$ -water, while  $\text{Mg}^{2+}$ -water shows a tendency to resemble that of pure water in the region marked by A. For the monovalent  $\text{Na}^+$ , the distance between the water molecules in the first and second solvation shells is long, 2.40–2.50 Å [97], and rather unaffected by the ion. For  $\text{Mg}^{2+}$  and  $\text{Al}^{3+}$ , the distances are substantially shorter, 2.00–2.14 Å and 1.87–1.90 Å, respectively. Thus, the changes observed XAS spectra are not in line with the charge order of the cations:  $\text{Na}^+$ ,  $\text{Mg}^{2+}$ , and  $\text{Al}^{3+}$ .

#### 8.5.4

##### Drugs in Water Solution

All orally administered drugs must be dissolved, absorbed, and transported by the blood stream to the site of action. It is a pharmaceutical challenge to establish predictive models for this complex process. One essential aspect of the problem is the lack of understanding of solubility on the microscopic level. Especially when hydrogen bonding is involved, the situation is often too complex for reliable predictions.

It is possible to understand drug solubility by applying X-ray spectroscopy to substances in solid phases, in aqueous solution, and in the gas-phase (Fig. 8.20). The influence of the molecular surrounding on the local electronic structure is reflected in soft X-ray absorption fine structure, and in site-selectively excited X-ray emission spectra.

The overall shapes of the XAS spectra recorded at the nitrogen and oxygen K edges of atenolol and nadolol are similar (Fig. 8.21), apart from some remarkable exceptions. In atenolol there is an additional sharp resonance that is virtually absent in nadolol, both at the oxygen and nitrogen edge. These resonances can be assigned to excitations at specific sites by considering the structure of the molecules (Fig. 8.21). Nadolol has a single nitrogen site, ( $-\text{NH}-$ ), whereas atenolol contains an additional amino-group nitrogen ( $-\text{NH}_2$ ). It is, therefore, straightforward to assign the additional peak at 400.5 eV to excitations at this site. The smaller resonance at 398.5 eV can be assigned to the ( $-\text{NH}-$ ) site, as it is present in both molecules. Similarly, the atenolol resonance at around 532 eV in the oxygen spectrum can be assigned to the ( $=\text{O}$ ) site, which is unique to this molecule. Regions in the spectra with less pronounced features cannot be assigned without theory, and, especially at higher energies, overlapping intensity from several non-equivalent sites is difficult to disentangle.

#### 8.5.5

##### Electronic Structure of Bases in DNA Duplexes

Characterization of electronic states near the Fermi level of DNA duplexes has been desired to clarify the mechanisms of long-range charge migration in DNA [98–103].

Fig. 8.20. X-ray emission spectra of atenolol in solid powder and water solution.

It was recently reported that the N K-edge XAS and Resonant Photoemission (RPE) spectroscopy characterized the electronic structure near the Fermi level of DNA duplexes to specify the charge migration mechanism [104]. The samples were thick GC- and AT-DNA films on  $\text{SiO}_2/\text{p-Si}(111)$  substrates. Since N atoms are included in only bases in DNA duplexes, the RPE spectra excited from N 1s to unoccupied states purely extract the electronic orbital features of the bases in DNA. It was concluded that the charge-hopping model is suitable for electric conduction in DNA duplexes rather than the charge-transfer model via delocalized states when electrons pass through the  $\pi^*$  states of DNA bases.

Soft X-ray absorption and emission spectroscopies have been applied to study the nitrogen bonding structure in poly(dC) ··· poly(dG) [105]. The three sharp peaks at 398.5, 399.5, and 400.9 eV (Fig. 8.22a) indicate that absorption features originate from the well-defined structures. From previous studies of carbon nitride films [88, 106], the nitrile structure ( $\text{N}_1$ -site) aligns very well with the peak of 399.5 eV.

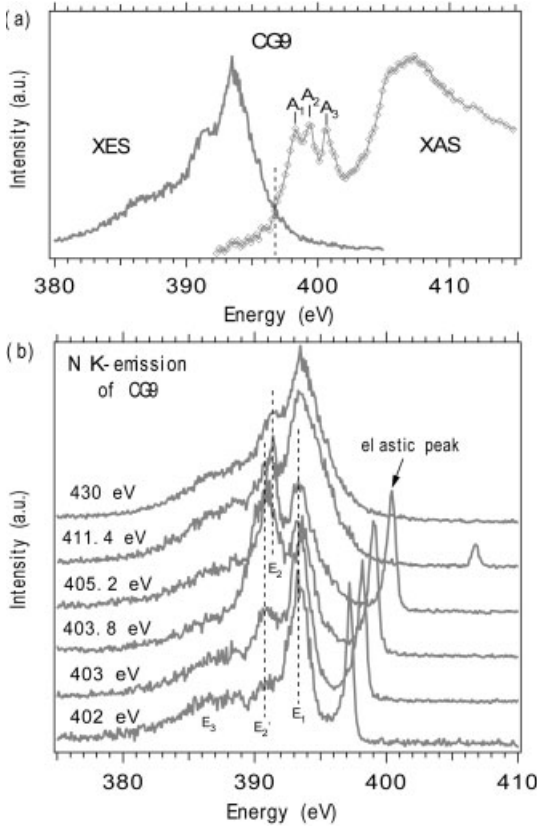

Fig. 8.21. XAS spectra of atenolol and nadolol, measured at the nitrogen and oxygen K edges.

Since the nitrile bond predominantly has p-character, this peak appears strong in the  $\pi^*$  region. The 398.5 eV peak corresponds to pyridine-like N ( $N_2$ -site). The spectra for graphite-like  $N_3$ -site shows a peak at 401.7 eV, with a shoulder to the low energy side. This could be a low-energy  $\sigma^*$  resonance; however, with the complex structure in DNA it is difficult to separate the  $\pi$  and  $\sigma$  bonds. This structure together with pyridine-like N are, possibly, the origin of the absorption peak at 400.9 eV in XAS spectrum.

Nitrogen K-emission spectra are shown in Fig. 8.22(b). The excitation energies were selected to correspond to the absorption features in the XAS spectrum. The fact that N atoms in different bonding environments are excited depending on the photon energy is clearly reflected by the differences in XES spectra. For the lowest excitation energy (398.5 eV), presumably corresponding to the  $1s \leftrightarrow \pi^*$  transition of pyridine-like N, the main emission line is centered at 393.5 eV. The overall spectral shape is similar to that of pyridine. When the excitation energy is increased to 399.5 eV, mainly nitrogen in the  $N_1$  structure should be excited. However, the emission spectra indicate that a large fraction of the pyridine-like N atoms are also excited at this energy. This can be explained by a relatively broad signal corresponding to pyridine-like N due to shifts that depend on the second nearest neighbors. Thus the emission spectrum can be modeled by a superposition of the  $N_1$  and  $N_2$  spectra. The excitation energy of 400.9 eV, however, mainly excites the  $N_1$  structure.

X-ray transitions, where a core-level vacancy is filled by a valence-orbital electron, give direct information about the chemical bonding. While such transitions have been analyzed using X-ray spectrometers since the late 1920s, interest in the technique is presently booming due to the advent of third generation synchrotron radiation sources. Today the method is frequently applied in research fields ranging

**Fig. 8.22.** (a) N K-edge absorption and emission spectra of poly(dC) ··· poly(dG). (b) N K-edge emission spectra recorded at selected excitation energies.

from atomic and molecular physics to materials research. Understanding protein functionality is of fundamental importance in biochemistry. Soft-X-ray absorption and emission study of poly(dC) ··· poly(dG) can elucidate the relation between the structure and functionality of proteins.

### Acknowledgments

This chapter would not exist without the contributions from my collaborators. I acknowledge some of them for their support over the years, to name a few: Y. Luo, J. Nordgren, J.-E. Rubensson, A. Augustsson, C. L. Dong, S. Kashtanov, C. L. Chang, L. Vayssieres, S. Butorin, L. Duda, C.-J. Englund, S. H. Yang, D. W. Shin, J. Söderström, P.-A. Glans, T. Learmonth, K. Smith, etc. Preparation of the manuscript for

this chapter was also supported by the office of Science, Basic Energy Sciences, and the Department of Energy under contract DE-AC03-76SF000098 at Lawrence Berkeley National Laboratory.

# Some New Advances and Challenges in Biological and Biomedical Materials Characterization

*Filip Braet, Lilian Soon, Thomas F. Kelly, David J. Larson, and  
Simon P. Ringer*

### 9.1 Introduction

The three sections of this chapter identify new and recent advances as well as challenges in the microscopy of selected biological and biomedical materials using (1) atom probe tomography, (2) atomic force microscopy and (3) cryo-transmission electron microscopy.

Section 9.2 describes the fundamental principles of atom probe tomography, a time-of-flight mass spectroscopy method that exploits the quantum-mechanical tunneling phenomenon that occurs when many conducting solids are raised to very high electric fields. The resultant ionization associated with the tunneling liberates an ion with a specific mass-to-charge ratio that is subsequently accelerated towards a position-sensing detector. Time-of-flight data is transformed into mass-to-charge ratios in a way that provides identification of the individual isotopes of the elements, as well as molecular species. This section also provides the results of recent applications of atom probe to biomedical materials that are used as human-prosthetic devices and components. These applications demonstrate the core competency of the atom probe technique in analyzing three-dimensional (3D) atomic-level compositional information of materials. Probing interfaces using compositional profiles, identifying the presence, or otherwise, of chemical heterogeneities within phases and measuring the local composition near and within nanoscale precipitate phases are key areas where this technique can contribute to the science and technology of biomedical materials. Applications data are also presented for biological materials after a brief review of work to date. This section concludes with some of the challenges facing the field in terms of sample preparation issues, specimen stability issues under high fields and the challenge of interpreting mass spectra from complex molecules.

Sections 9.3 and 9.4 provide a correlative microscopy context for fenestral studies in the hepatic endothelial cell model. Section 9.3 focuses on atomic force methods and Section 9.4 focuses on electron microscopy approaches and data. The result is a new insight into the morpho-function and structure of the liver sieve.

## 9.2

### Modern Atom Probe Tomography: Principles, Applications in Biomaterials and Potential Applications for Biology

#### 9.2.1

##### The Need for an Ideal Microscope

The length scale at which human knowledge and endeavor operates is directly linked to the scale of our microscopies. Though people have long been able to conjecture about the nature and significance of length scales beyond our ability to observe, be they microscopical or astronomical, practical technologies always require observations and measurements that can transform such conjecture into fact. Examples include the postulation of the very concept of the atom [1], the potential for a double helix DNA structure [2] and the notion that crystal defects (dislocations) were the origin of the discrepancy between the observed and theoretical strength of metals and alloys [3]. As we enter the century of nanotechnology, the need for the “ideal” microscope will grow because the critical dimensions of materials and devices trend towards the truly atomic. Modern atom probe microscopy is coming closer to this ideal than any other microscopy. In this section, the modern instrument is reviewed and some of the significant challenges and potential opportunities of the technique and its application in both biomaterials and in biological science are discussed.

##### 9.2.1.1 Field Ion Microscopy and the Modern Atom Probe Instrument

As introduced above, Greek philosophers were, interestingly, able to hypothesize the existence of atoms, but it took 25 centuries before they were first observed by humans with, in fact, a field ion microscope (FIM) pioneered by Erwin Müller [4]. The technique is mentioned here because of its potential significance in imaging molecules and the close relation to the atom probe technique. Miller et al. [5] provide a detailed explanation of the FIM, and Panitz [6] has provided a detailed review of the technique as applied to molecules. Essentially, a high positive potential is applied as a standing voltage to a cryogenically cooled specimen-tip in a controlled ultra-high vacuum (UHV) chamber. An inert gas such as He, Ne or Ar is leaked into the chamber to fill a back pressure of  $\sim 10^{-3}$  Pa and, in the presence of the applied field, the gas atoms are field polarized and so are gradually drawn towards the tip. The gas atoms eventually make contact with the specimen tip and migrate, though a series of collisions towards positions of low potential energy. Once these gas atoms have lost most of their kinetic energy and are trapped by the very high field of the specimen, they may be field ionized by electron tunneling processes. Such ions are repelled from the tip and projected in an almost radial direction towards a fluorescent screen. Field ionization occurs preferentially at the atomic steps and terrace positions and so forms a stereographic-like projection image of the material surface with atomic resolution. A tungsten (W) FIM image is

**Fig. 9.1.** Field ion micrograph of W atoms imaged using Ne. Each bright dot is an individual atom.

provided in Fig. 9.1, where each bright dot corresponds to an individual atom. The concentric circles around low-index crystallographic poles correspond to the outer atoms of atomic planes, one atop another.

Figure 9.2(a) is a simplified schematic of the atom probe principle, showing how the application of a positive high voltage pulse,  $V_{\text{pulse}}$ , to a sharp needle-shaped specimen under a standing positive voltage,  $V_{\text{dc}}$ , can raise the local field on the sample so as to render some of the surface atoms as ions, through the quantum mechanical process of electron tunneling. This field-induced ionization of the surface atoms results in their “evaporation” from the specimen along trajectories close to normal to the tangent to the sample surface. These ions eventually strike a single-ion detector and this *stop* signal is compared to the *start* of the initial pulse to generate an ion flight-time. The mass-to-charge ( $m/n$ ) ratio of the ion is determined by equating the potential energy of the ion just prior to field evaporation to the kinetic energy just after, such that

$$neV = \frac{1}{2}mv^2$$

**Fig. 9.2.** (a) Atom probe principle: individual atoms are field ionized from the sample surface and accelerated towards a detector. Time-of-flight mass spectroscopy is used to identify the atom species and this is correlated to spatial orientation ( $x, y$ ) by the position-sensitive detector. Tomographic data is generated when the 2D image slices are

correctly reconstructed along  $z$ . (b) Atom probe tomography from a spinodal alloy, revealing a spinodal interface with separate Fe- and Ni-rich regions [7, 8]. Isoconcentrational surfaces for 10 at% Ni are charted in the upper 3D atom map ( $30 \times 30 \times 25$  nm). Blue = Mn, red = Fe, yellow = Ni and teal = Al.

a

b

and so

$$\frac{m}{n} = KV \frac{t^2}{d^2} \quad (1)$$

where  $n$  is the number of electrons removed in the field ionization,  $e$  is the elementary charge,  $V$  is the total electric field on the specimen,  $m$  and  $v$  are the mass and velocity of the ion, respectively,  $d$  is the flight distance from the specimen to the detector and  $K$  is a constant. The identity of the ion is then correlated spatially to the hit-position ( $x, y$ ) on the detector and the depth  $z$  within the sample. Figure 9.2(b) is an example of 3D atom probe tomographic data. Within this analysis volume is a spinodal interface decorated with solute atoms of Fe, Ni, Mn and Al, revealing nanoscale phase separation into the Fe-rich and Ni-rich phases. In this way, researchers can view a tomographic reconstruction of materials, since 3D images of the internal structure are generated by the reconstruction along  $z$  of thousands of 2D  $x$ - $y$  slices. This approach to nanostructural analysis has taken microscopy and materials characterization into a new era and is opening up new directions for materials research and development [5–9]. Excellent texts on the workings, instrumentation, historical development and applications of conventional 1D and 3D atom probe techniques are available [5, 6, 9].

The current state-of-the art of atom probe employs a local electrode ahead of the specimen to mediate extraction of ions (Fig. 9.3). Figure 9.3(a) is drawn so as to emphasize that the sample may be an individual needle or tip or may be composed of an array of many tips (Fig. 9.3b). Such arrays have the advantage that they can present geometrically similar tips to the local electrode and so effectively normalize many of the stochastic field evaporation issues. Arrays will also allow statistical evaluations of structures in the same way that cryo-electron microscopy enables single-particle image analysis, via thousands of images of randomly-oriented individual protein molecules. Figure 9.3(b) is a schematic that emphasizes this approach and conveys the importance of the proximity or “local” effects of the counter electrode with the specimen [10–12]: hence the name, local electrode atom probe or LEAP®. Here, the cryogenically cooled needle-shaped specimen, Fig. 9.3(c) – or planar array specimen (Fig. 9.3d) – is mounted on a nanopositioning stage and pointed towards a funnel-shaped local electrode. The specimen is aligned to the aperture of the local electrode with the aid of a pair of orthogonal long-range optical microscopes. The initially detected field evaporated ions are used to finalize the alignment.

For a specimen positioned close to a local electrode aperture of  $\sim 20$ – $30 \mu\text{m}$  in diameter, the field at the specimen apex is very high even at relatively low voltages. It is viable to build suitable pulsers (2 ns fwhm pulse with amplitudes of up to 2000 V) that can operate at pulse repetition rates of up to 200 kHz. This rate is two orders of magnitude faster than previous instruments. In addition, the ions that are field evaporated from the specimen reach the local electrode in a significantly shorter time (tens of picoseconds) and thereafter are shielded from time-varying fields as the  $V_{\text{pulse}}$  decays. This eliminates the major source of energy defi-

**Fig. 9.3.** (a) LEAP<sup>TM</sup> principle: individual atoms are field ionized from the sample surface and accelerated towards a detector. (b) The local electrode enhances the field on the specimen, permitting lower applied voltages  $V_{ex}$  and  $V_{pulse}$ , which allow a much higher pulsing frequency. In addition, having a small  $V_{ex}$  and a large  $V_{accel}$  effects an acceleration of the ions through the local electrode that provides for highly sensitive mass separation (high mass resolution time-of-flight mass

spectroscopy). The time-of-flight mass spectroscopy is used to identify the atom species and this is correlated to spatial orientation ( $x$ ,  $y$ ) by the position-sensitive detector. Tomographic data is generated when the 2D image slices are correctly reconstructed along  $z$ . (c) Close-up optical image of a sharpened tip in the vicinity of the local electrode. (d) Demonstration application of an array of tips.

cits. Therefore, the local electrode atom probe can achieve high mass resolution (better than  $\Delta m/m$  of 1/500) over a 1.5 steradian field of view. This mass resolution is sufficient to separate the individual isotopes of all the elements. The wide field of view permits up to  $\sim 10^8$  atoms to be collected routinely from a specimen.

To position correctly ions at these higher pulse rates, a novel crossed delay line (CDL) detector is used. The CDL detector features a pair of delay lines, placed perpendicularly, in place of the phosphor screen or anodes used in the other variants of 3DAP. When electrons from the microchannel plate strike the delay line at some location, they travel to each end of the line. The position of the ion's impact is therefore determined from the arrival times measured at each end of the delay line. These times are converted into true  $x$  and  $y$  distances on the detector. A crossed delay line detector and high speed digital timing system that provides

Fig. 9.4. Potential for a modern atom probe (LEAP) to be combined with other analytical techniques so as to probe the structure and, in particular, chemical composition of materials.

600 × 600 pixels at rates up to 25 000 ions per second has been developed by Imago.

The new features – local electrode, high speed pulser and high speed single atom sensitive CDL detector – are incorporated in a commercial instrument [12] that achieves the high-performance gains originally envisioned for this geometry. The Imago LEAP® microscope can collect data at sustained rates of up to 20 000 correctly positioned ions per second (one million ions per minute). These developments have dramatically improved the overall performance of atom probe tomography for a wide range of materials. In particular, the characterization of planar specimens in addition to traditional needle-shaped specimens is now practical [13].

Figure 9.4 is a survey of a range of analytical microscopy techniques and shows the analytical capacity of the modern atom probe in the context of related techniques. The strengths of the LEAP are clear and the potential for solving problems over various length-scales by a correlative microscopy approach, such as is advocated in this chapter, is very high. There are interesting opportunities and significant challenges for those working in biological science and technology and some of these will now be introduced.

#### 9.2.1.2 Applications in Biomaterials

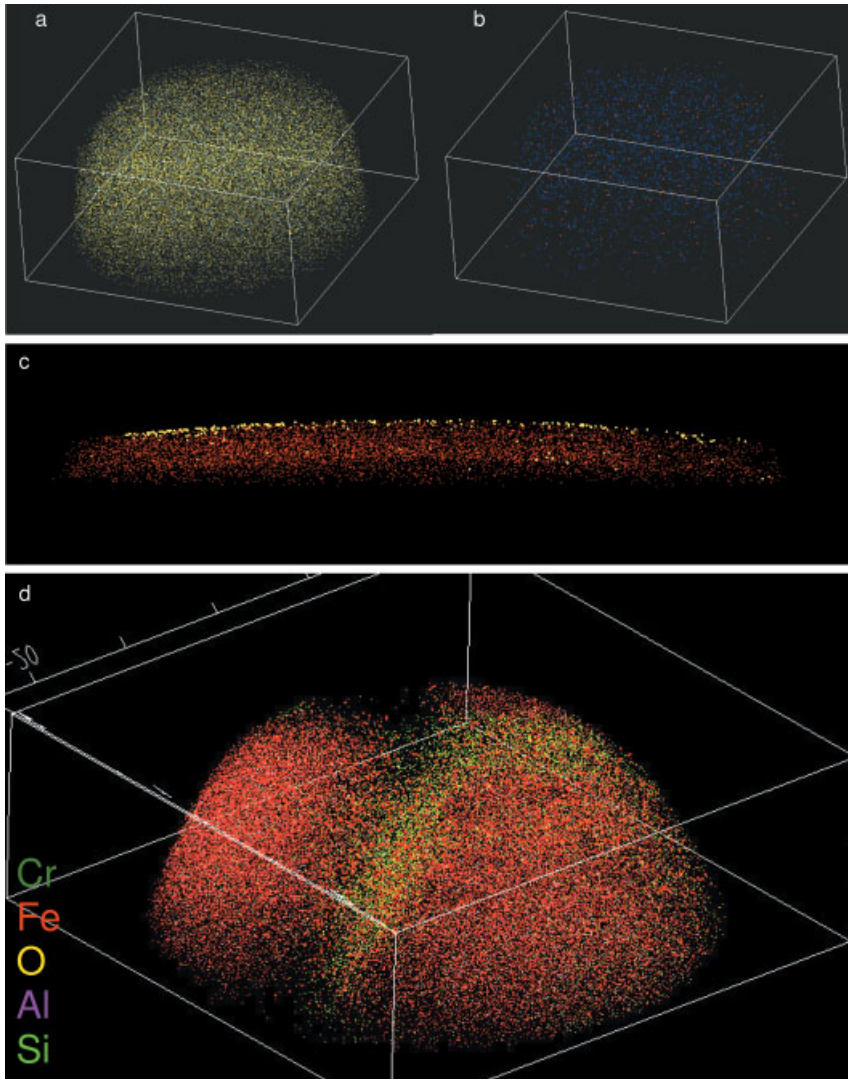

As other chapters in this volume affirm, the term “biomaterials” is very broad. One important class of biomaterials is those used as implants that replace or augment components of the human body such as tissue, organs, skeletal or the like. The most common examples include the use of medical grade austenitic 316 stainless

steels, which are used as implanted spinal fixation devices, bone screws, cardiovascular and neurological stents, and as critical components of minimally invasive surgical devices. These applications are made possible due to suitable physical and mechanical properties, good corrosion resistance in biological environments, reasonable biocompatibility, and ease of manufacture [14].

These steels are thermomechanically processed so as to ensure the thermodynamic stability of the austenite ( $\gamma$ ) phase at high temperatures and to suppress the formation of martensite at lower (near ambient) temperatures. The typical composition of these alloys is (wt%): Fe, <0.03 C, 16–18.5 Cr, 10–14 Ni, 2–3 Mo, <2 Mn, <1 Si, <0.045 P, <0.03 S and they possess yield strengths of at least 170 MPa. Elements that stabilize the  $\gamma$ -phase include Ni, Mn and N, usually in some combination [15, 16]. The relatively common allergy affects attributed to Ni and the potential for carcinogenic effects associated with this element have driven the development of Ni-free 316 grade stainless steel. In more general terms, the conventional theory of Cr-oxide passivation applies to these steels and is the main protection mechanism that results in their high corrosion resistance. However, other corrosion processes, such as crevice corrosion and pitting, can be very damaging in biomaterials applications. Therefore, much of the design of composition and thermomechanical processing for these alloys aims to mitigate or overcome these damage mechanisms by minimizing precipitation of a second phase that is electrochemically active with respect to the  $\gamma$ -phase. This requires suppression of precipitation of carbides, nitrides, or even body-centered-cubic  $\alpha$  or  $\delta$  ferrite. This is effected by lowering the amount of C and N that remains in the  $\gamma$ -phase. This, in turn, can be achieved by alloying with strong carbo-nitride forming elements such as Ti and Nb, so that these elements preferentially scavenge the interstitials and form highly stable, electrochemically inactive carbo-nitride M (CN) precipitates. This approach is particularly effective in avoiding the deleterious process of sensitization where Cr-based carbo-nitrides nucleate heterogeneously on  $\gamma/\gamma$  grain boundaries and so deplete the capacity of Cr to protect the surface of the component (resulting in severe local attack). Therefore, the electrochemical activity of the grain boundaries must be kept low and it is essential to minimize any localized changes in alloy chemistry that can produce electrochemical interaction with body fluids.

This is a formidable materials requirement and effectively requires the control of nanostructure and composition of the material. For example, the surface of such alloys will be especially critical since biological responses and corrosion occur at the material–environment interface. In addition, precise control of the chemistry and structure of buried interfaces such as grain boundaries and other chemical heterogeneities is critically important. Such characterization requires microscopy in three-dimensions (3D) at high resolution: reference to the foregoing discussion and to Fig. 9.2(b) reveals that the modern atom probe can provide key insights into these issues.

Figure 9.5(a–d) presents recent research on both the nanostructure of surfaces and buried interfaces in medical device 316L stainless steel. Figure 9.5(a) and (b) show a 3D atom map reconstruction of a 316L grade, chemically modified at Med-

**Fig. 9.5.** (a, b) Bulk structure of a Medtronic 316L specimen. Each color-coded dot shows the location of an individual atom. Cr is in yellow, Ni in light blue, Si in blue and Cu in red. Image is 20 nm wide and 10 nm high. (c) Near-surface structure of a 316L wire specimen; Cr in red, oxygen in gold. The image is about 25 nm wide. (d) Region that is thought to be a grain boundary triple point in a 316L wire specimen, showing clear enrichment of O.

tronic [14]. To determine the bulk structure of the Medtronic sheet specimens, segments were cut from the interior volume and polished. These were then mounted in holders, electropolished with 10% perchloric acid in acetic acid at 8–20 V DC to a nominal end radius of 20–50 nm, to provide the necessary needle-shape for atom

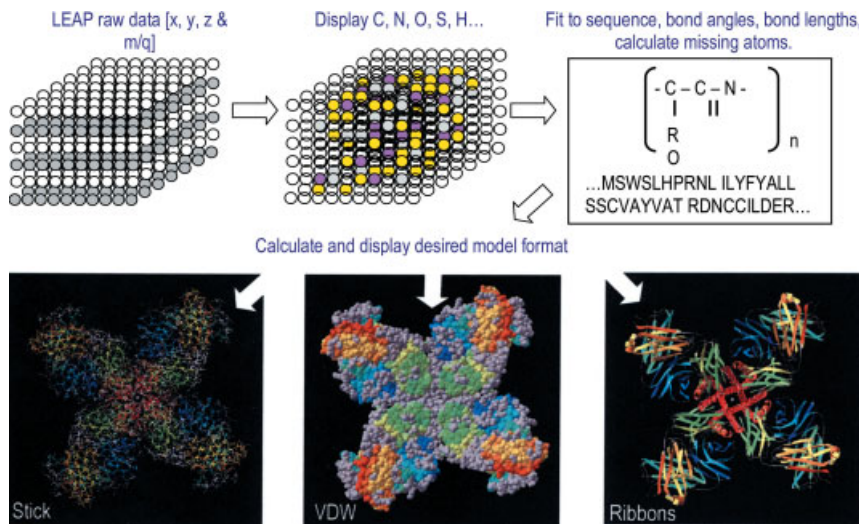

probe analysis. The bulk atomic composition and structure of this material was then studied with a LEAP microscope. All anticipated elements were located in the specimen, including Fe, Cr, Ni, C, P, Si, Mo, and Cu, with a uniform elemental distribution and without precipitates or grain boundaries in the analyzed regions. This is highly significant because of the relation between biocompatibility, related performance as a biomaterial and the uniformity of the solid solution  $\gamma$ -phase. Figure 9.5(c) provides 3D atom map reconstructions from a commercial 316L grade procured as wire 0.38 mm in diameter, 1/8 hard, from a commodity supplier. The commodity 316L wires were electropolished as described above. During electropolishing and subsequent air exposure, a thin oxide naturally forms on the surface of the sharpened wire. This oxide was used to develop specimen preparation methods for analysis of oxides on medical-grade 316L samples. Notably, there is relatively little atom probe work examining metal oxide surfaces with atom probe microscopes. To prepare the surface oxide for LEAP analysis, a  $\sim 15$  nm thick capping layer of Ni was applied to the sharpened wire specimens by argon (Ar) ion sputtering to protect the surface during the first stages of atom probe analysis. Analyses demonstrated that such coatings provided some preservation of the oxide layer, enabling the imaging of the oxide–stainless steel interface, Fig. 9.5(c). Note the presence of oxygen (O) at the stainless steel surface (for clarity, Ni atoms species are not shown in this projection). Although the volume and total number of atoms in this image are limited, there is a clear oxygen-rich layer on the specimen surface.

Significantly, this data gives access to the body fluid/oxide/ $\gamma$ -phase interface chemistry, since it is the first 20–50 nm of the biomaterial (in this case 316L stainless steel) over which ionic mass transport occurs and is almost always mediated via an oxide layer. An understanding of surface roughness, oxide thickness and elemental compositional profiles near these oxides is essential for thorough characterization of biomaterials interfaces. In Fig. 9.5(c), the oxide is seen to be  $\sim 1$  nm thick, and [O] atoms are also observed deeper into the  $\gamma$ -phase. Roughness indices on both sides of the oxide interface can be developed, as can concentration profiles.

Figure 9.5(d) provides a 3D atom map reconstruction from the commodity 316L wire-stock, revealing a significant oxide-based chemical heterogeneity within the analyzed volume, which is thought to be a grain boundary. Such chemical heterogeneities at the grain boundaries of biomaterials are very serious for reasons explained above, since they have the potential to increase the potency of these sites for heterogeneous nucleation, leading ultimately to sensitization of the steel. Moreover, depending on the proximity of these O/Cr/Si enriched boundaries to the body fluids, there is the risk of developing a localized electro-active region that leaches toxic elements into the body and stimulates a corrosion reaction. The regions of 316L such as presented in Fig. 9.5(d) are inferior to those such as in Fig. 9.5(a) and (b), where the degree of chemical homogeneity is much higher.

### 9.2.1.3 Applications and Challenges for Biological Science

It is almost 50 years since Erwin Müller first observed the flicker of individual atoms on a phosphor (P) screen from field ion microscopy, along with his work shortly after in pioneering the atom probe to select individual atoms from the

**Fig. 9.6.** Idealized atom probe experiment of biological material. The LEAP acquires positional ( $x$ ,  $y$  &  $z$ ) and atom identity data, via  $m/q$ . Specific individual atoms are identified and displayed, and an informatics-like algorithm would fit and identify the molecular structure, which could be displayed in the appropriate format.

FIM image and analyze them [17]. Today, we see the core-competence of the atom probe in analyzing multi-million atom data-sets and representing a premium high-resolution analytical technique for materials metrology and characterization. The examples provided in Figs. 9.2 and 9.5 demonstrate this.

Having discussed the capacity of the atom probe to analyze individual atoms in 3D in the inorganic context of biomaterials, it is appropriate to also examine the capacity of this instrument to solve complex problems in organic biological materials. From the preceding discussion on the analysis of alloy biomaterials, where individual atoms can be mapped in 3D, lattice-plane by lattice-plane, the biologist might be tempted to view the instrument as something akin to an atom-level confocal microscope. The possibility of reconstructing molecular conformation in 3D, such as is performed, albeit with some experimental difficulty using cryo-electron microscopy (see, e.g., Ref. [18]), is highly attractive. Questions related to the structure of proteins and macromolecular complexes, proteins at interfaces, virus structures, ligand binding, protein membrane structure and so on represent seminal questions in modern structural biology. The concept here is outlined in Fig. 9.6. In this experiment, individual light elements are displayed and mathematical filters applied to the data that display selected atoms (C, N, O, S, H etc.) with specific coordination in terms of angles, density or simple proximity [19]. These could then be fitted to the molecular sequence and ultimately display complete biological structures [20]. This approach is not unlike the computational methods applied to X-ray synchrotron and cryo-electron microscopy data and, in particular, to the computational data-fitting that has recently become so successful in nuclear magnetic

**Tab. 9.1.** Biological specimen preparation methods and relevance to atom probe.

<i>Method</i>	<i>Comment for atom probe</i>
Chemical fixation	Not suitable for all biological samples
Dry specimens	Use of low-tension solvents, freeze drying
Embedded and crosslinked samples	Offer possibilities for stabilizing molecules under the electric field
Provide electrical conductivity	Metal coatings, OsO <sub>4</sub> , RuO <sub>4</sub> or conductive embedding agents can assist the molecules to field ionize via electrically pulsed atom probe

resonance (NMR). However, there are access, sample preparation and cost issues with these types of characterization, which require significant equipment installations, and the experiments are non-trivial. The idealized atom probe experiment described above requires the following research and development in at least three specific areas.

**Sample Fabrication Issues** Biomolecules need to be stabilized for imaging under high vacuum conditions, since these conditions are far from their natural state. Fortunately, electron microscopists have developed numerous technologies to address this issue, many of which seem relevant here. Indeed, such has been the recent progress in biological specimen preparation that this is no longer the limiting factor for achieving high resolution. In fact, destructive electron-beam specimen interactions are more limiting.

Table 9.1 lists various biological specimen preparation methods and mentions some of the issues that require attention in assessing these methods for atom probe. Certainly, with respect to stabilizing the specimens for UHV, there seem to be excellent prospects of adapting a method for atom probe tips or tip arrays.

**Stability of the Specimen under High Electric Fields** The response of biomolecules to the very high applied electric fields that occur with an atom probe is one of the most complex and problematic aspects of these experiments. However, Panitz has examined Poly(GC) DNA using FIM [21] and Machlin has published FIM images that are reported to come from tRNA [22]. Other work has appeared on synthetic polymers, including polypyrrole [23] and octacyanophthalocyanine metal complexes [24]. These pioneering experiments have shown that the stability of the molecules under the field can be resolution-limiting. Figure 9.7(a) provides schematic images that describe the preparation of a specimen of human immunoglobulin G via FIM: a W tip is Au-coated before application of the IgG. This was chemically fixed and examined in the FIM (Fig. 9.7b shows the results). Individual bright dots are seen in the images that may correlate to individual molecules or groups thereof. Progressive evaporation of the sample revealed systematic changes in the FIM image until, eventually, the IgG material was all evaporated and the substrate Au became visible (Fig. 9.7b, final two images). These FIM images are

**Fig. 9.7.** (a) Schematic showing the three stages of specimen preparation for a human IgG specimen: a polished W tip is sputter-coated with a few nm of Au, offering excellent bonding for the IgG-fixed molecule. (b) Series of FIM images recorded with Ne imaging gas.

The series show self-consistent and uniform contrast: progressive evaporation of what are thought to be the biomolecules continues until the substrate Au is revealed. (c) Ne FIM image of amorphized alloy. The uniform contrast of amorphous alloys provides similar contrast.

very similar to the image (Fig. 9.7c) to a Cu-Co multi-layer film device amorphized by a Ga focused ion beam [25]. In this respect, amorphous inorganic materials represent closer analogies to organic molecular samples than their crystalline counter-parts and the so comparison is of interest. Whereas the bright contrast in the image in Fig. 9.7(c) arises, almost certainly, from individual atoms on the alloy surface, a contrast theory for the series of images in Fig. 9.7(b) is not available: bright spots may be individual atoms or could be particular functional groups or the domains thereof. There are numerous other artifacts that could, in principle, also explain the contrast observed in these early experiments. Nevertheless, the systematic character of the images suggests that there is some local equilibrium at the surface of these tips and that we are observing molecular species. It is unlikely that the images are from Au metal or any oxide thereof. The challenge is to reproduce such images and to understand them in terms of the primitive molecular structure of the specimen. The recent discussion by Panitz [26] also supports the notion that stable images may be formed from biomolecules in FIM. As powerful as the atom probe technique is, it is suggested that a significantly better understanding of FIM images such as those provided in Fig. 9.7 is required and that stable FIM imaging may be a necessary precursor to sound atom probe analysis.

**Mode of Field Evaporation: Notion of the Molecular Probe** As described earlier, atom probe experiments usually involve the application of energy pulses to a sam-

ple under an applied standing voltage so that the surface atoms are field evaporated as ions that can be identified by time-of-flight mass spectroscopy. The energy is usually transmitted via a high voltage pulse although it can be transmitted via a laser to effect, e.g., a thermally-induced evaporation process. In any case, there are at least three modalities by which one can imagine the field evaporation of a biomolecule may occur.

*Type I* field evaporation involves, predominantly, the liberation of individual atoms from the molecule surface. In this case, the mass spectra are closely similar to those obtained for inorganic materials.

*Type II* field evaporation involves, predominantly, the liberation of molecular fragments. An enormous range of molecular bonds may be sheared from the sample, providing C, C–C, C–C–C, C–H, C–H–H etc. In this case, the mass spectra will be very complex. Clearly, a major challenge in developing atom probe science to solve problems in biology is to provide a system for understanding the mass spectra.

*Type III* field evaporation involves predominantly the liberation of rational molecular fragments, as recognizable functional groups. In this scenario, an enormous range of molecular bonds may also be sheared from the sample. However, conceivably, the proposed *molecular probe* could apply look-up tables of known molecular species that correspond to specific mass-charge ratios, in the same way that *atom probe* uses the charge state of the isotope abundances to develop range files that window signals from the individual elements in the specimen.

Clearly, the exact effect of the energy pulse on biomolecules is a fertile area for new research. Such efforts will need to use both modeling and experiments and also utilize the rapidly developing knowledge-base arising from the success of other spectroscopic techniques, particularly SIMS and nanoSIMS, XPS and MALDI (matrix-assisted laser desorption/ionization). Figure 9.8 provides one representation of these techniques, where the different modalities of signal generation are emphasized. Whereas the high-energy ion beam in SIMS generates variable fragments of the initial molecular specimen (closer to type II field evaporation), XPS causes an emission of characteristics electrons, and MALDI causes ionization of whole molecules (closer to type III). We expect an atom probe to cause field evaporation across all three types listed above.

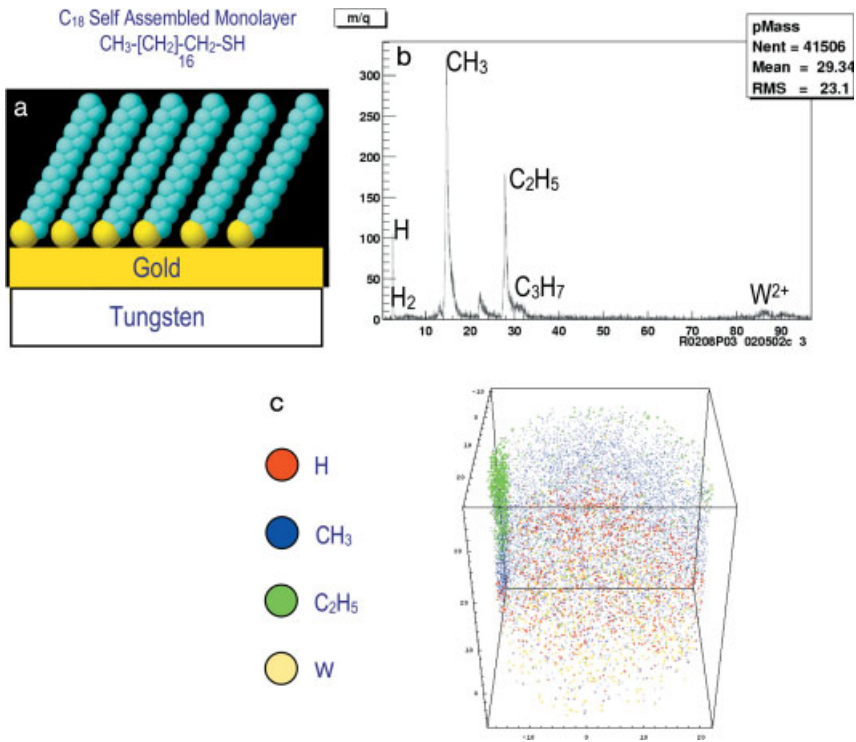

Figure 9.9 is the mass spectrum for a C<sub>18</sub> self-assembled-monolayer (SAM). Here, the raw number of counts of detector-events is plotted as a function of  $m/q$ . The mass spectrum is “indexed” by attributing the known or expected molecular fragments to the significant peaks. In the same way that we have presented indicative early-stage FIM data in Fig. 9.7 from quite new experiments that demonstrate the challenges in comprehensive interpretation of FIM images, Fig. 9.9 reveals the opportunities and challenges for molecular probing of these sorts of samples. An encouraging aspect of Fig. 9.9 is the clear success of the instrument in probing the molecular species of the specimen, since discrete peaks of organic matter are identified in the mass spectra, as opposed to Au peaks etc. Prima facie, most of the peaks can be plausibly identified and labels are provided. Moreover, the data can be reconstructed in 3D (Fig. 9.9c). Here, the outer surface is displayed in the 3D

**Fig. 9.8.** Schematic representation of signal modalities from a selection of molecular analysis techniques. The SIMS technique is a mixture of type II and type III evaporation, liberating variable fragments of the original molecule. XPS uses characteristic electrons. MALDI (matrix-assisted laser desorption/ionization) TOF is capable of ionizing whole molecules.

reconstruction-cube, and the species are clearly located at the surface. As a method of probing biointerfaces, this approach seems promising. However, a key uncertainty in such data, which will require unequivocal resolution, is the specific identity of mass spectra peaks. In Fig. 9.9, for example, we have left a significant peak at  $m/q = 22$  unidentified. Also, the significance of the particular type of molecular species that occur in the mass spectra is uncertain, since certain species clearly evaporate more readily than others. Another important question relates to the effect of molecular size and asymmetric charge distribution on trajectory aberrations. Since the ultimate molecular properties depend on coordination, orientation and bond angles, it is strongly desired that these characteristics are preserved when the molecules hit the position-sensing detector. Nevertheless, the results of initial experimentation with these ideas using the LEAP, taken together with other pioneering work attempting FIM and atom probe of organics referred to here, suggests that, under certain circumstances, biomolecules may be imaged and analyzed using these techniques. Clearly, much experimentation and development remains.

**Future Developments** Figure 9.10 reveals the common range of bond energies, comparing ionic, covalent and the dispersion bond forces. One of the intriguing characteristics of biomolecular atom probe specimens is the way that they can, potentially, present an enormously diverse range of bond energies to the instrument. The fact that the field evaporation process must occur across such a range of inter-atomic or inter-molecular forces would seem to imply that a substantial range of fragmentation will occur in response to the pulse. Figure 9.10 also lists some of

**Fig. 9.9.** (a) Schematic of a  $C_{18}$  self-assembled monolayer chemisorbed on an Au-coated W-tip via the thiol headgroup. (b) A LEAP mass spectrum. (c) 3D atom map reconstructed from the mass spectrum in (b).

the key interatomic bond energies that are so prevalent in biomolecular materials. As shown, the probe pulse must rupture significant interatomic bond energies before individual atoms are ionized and detected as single events on the detector. A theme of developments in this area will be to mitigate the effects of the variety of bond-energies through specimen preparation strategies.

## 9.3

### Atomic Force Microscopy

#### 9.3.1

##### Introduction

In 1986, Binnig et al. [28] revolutionized microscopy through the invention of the atomic force microscope (AFM). Marketable instruments of this new imaging technique began to appear in the five years following its discovery. In the early 1990s,

**Fig. 9.10.** Range of bond energies in organic and inorganic materials, together with a table summarizing the more significant interatomic bond energies in organic materials such as biomolecules [27].

Henderson et al. [29] and Radmacher et al. [30] both illustrated the potential of the instrument to image biological preparations in real time under near physiological conditions with nanometer resolution. From then onwards the AFM has fascinated biologists and the number of publications describing biological applications of AFM has grown swiftly [31].

Atomic force microscopy is becoming a valuable tool for determining biological structure and function [32]. It can be operated *in vitro* on live cells without the necessity for further specimen preparation such as fixation or staining [33]. Atomic force microscopy potentially provides for nanometer-scale resolution [34, 35]. Recently, it has been combined with simultaneous confocal laser scanning microscopic imaging [35]. It also can be used to image individual isolated cellular complexes (i.e., proteins, DNA, organelles, etc.) [36]. In addition, biomolecular probing with functionalized tips can be used to generate force versus displacement curves, providing the capability to obtain single-molecule bond-strength information [37]. Furthermore, the elasticity or softness or compliance of biological samples can be assessed [38].

### 9.3.2

#### Instrumentation

A range of materials, methods and notes have appeared with regard to imaging cultured cells with the AFM [39]. In general, maintenance of steady-state culture conditions involves a high degree of thermal stability ( $37 \pm 0.5$  °C), continual renewal of the culture medium (osmolarity of  $\pm 320$  mOsmol per kg-H<sub>2</sub>O) and a neutral pH ( $7.4 \pm 0.3$ ), stabilized by the use of 20 mM HEPES buffer and/or a flow of CO<sub>2</sub> through the AFM cell chamber to maintain a steady-state concentration of 5%. Fluctuations in temperature, osmotic pressure and pH have severe af-

fects on cell viability and structure, making consistent AFM imaging difficult [40]. Commercial liquid cells for studying biological samples under controlled conditions are available, but are only useful for a limited number of special application problems. Therefore, biologists have designed their own set-ups and, consequently, various home-made systems, which differ from laboratory to laboratory, are found when reviewing the literature.

Our AFM studies used (a) the Topometrix Explorer™ TMX equipped with a 100 μm XY/12 μm Z TrueMetrix Linearized Liquid Scanner installed on a Zeiss IM 35 inverted microscope with a home-made XY specimen stage adaptation; and (b) a home-made fluid cell in combination with a heating stage. This design allows positioning of the cantilever in the optical axis of the inverted microscope, movement of the sample via the inverted microscope independently of the AFM, and minimizes cantilever drift by controlling temperature-induced variations. Time-lapse images of living cells in contact [33, 41–43] or non-contact mode [43, 44] have been obtained over 2–3 h, before peripheral parts of the cytoplasm started to detach from the substrate or before cell viability started to decrease as determined by the trypan blue exclusion test [38].

#### 9.3.2.1 Live Cell Imaging

The major advantages of AFM over scanning electron microscopy (SEM) for imaging cells are that no coating and no vacuum are required, electrons are avoided and imaging can be carried out in an aqueous environment. As a result, living cell studies under near physiological conditions can be performed. Evidence for the successful application of AFM for biological imaging comes from abundant studies in the past decade, where the dynamic behavior of living cells at a resolution comparable with SEM has been imaged and analyzed (for reviews see Refs. [31] and [32]). In our set-up, images of living cells in contact mode could be obtained repeatedly over a period of 1 h (Fig. 9.11) and more [33, 43] depending on the cell type used, and at the same time we observed no scanning-induced artifacts such as lateral deformation. Instead, attention-grabbing cell biological processes such as moving membrane sheets at the rim of the cytoplasm of rat hepatocytes could be observed, illustrating lamellipodial activity (Fig. 9.11, 0–60 min). In some instances, prolonged AFM-imaging of cells may result in removal of parts of cells or even cells *in toto* from the substrate due to repeated tip contact (Fig. 9.11, 75 min). Therefore, to assure optimal viability of the cells, scanning of the sample should be carried out for a maximum of 2(–3) hours, after which the sample should be replaced. At the end of the experiment, the viability should be checked routinely with the aid of the trypan blue and/or the propidium iodide test. In our combined AFM-light microscope set-up the overall viability usually drops by ~6% with every hour. In addition, the combined AFM/inverted microscope allows the cell and AFM tip to be seen by the optical microscope at all times during the scanning process. By doing so, the morphology of the cells during AFM imaging can be easily judged and tip-induced alterations such as detachment or removal of the peripheral parts of the cytoplasm can be easily observed. These tip-induced changes are typical morphological signs for the onset of decreased cell viability.

**Fig. 9.11.** Rat liver parenchymal cells. Time-lapse AFM series of moving membrane sheets at the rim of the cytoplasm in living rat liver parenchymal cells (hepatocytes). Arrows denote the lamellipodial activity observed at

the rim of the cytoplasm of the hepatocytes over time. Note that prolonged scanning resulted in artifactual smearing and even removal of cell parts (arrowhead).

The AFM can gather, simultaneously, correlative topology and submembranous structures on the same cell at high resolution [33]. Sample deformation is an important component of the contrast mechanism in the visualization of living cells by AFM, and originates from local variations in stiffness when the tip palpates the cell membrane [29]. The cell stiffness or elasticity is determined mainly by the various organelles lying in the cytoplasm of the cell, and high-resolution imaging of submembranous cell compartments in the past was only possible when cells underwent detergent-extraction, fixation and/or immunocytochemical staining, thereby precluding dynamic studies [38, 40]. Therefore, indirect AFM imaging of organelles underneath the plasma membrane is a powerful tool to probe subcellular dynamics at nanometer resolution in intact living cells without the necessity of further preparative steps. The most prominent submembranous structure that can be probed with the AFM is the cytoskeleton of cells. An example is given in Fig. 9.12(A), illustrating the presence of long actin fibers with a straight outline in rat liver fibroblasts. We previously reported cytoskeletal changes in living rat skin fibroblasts for up to one hour after applying the microfilament-disrupting drug latrunculin A [33]. Interestingly, when cells underwent short fixation with 0.1% glutaraldehyde the morphology of the cell surface changed drastically (Fig. 9.12B); i.e., (i) there was an increase in cell height (Fig. 9.12C versus 12D); (ii) underlying

cytoskeleton structures and clearly depicted cell contours could no longer be observed, even when the imaging force was increased 10-fold; and (iii) images were dominated by topographic information (Fig. 9.12A versus 9.12B). The latter two points can be explained by the fact that the stiffness of the cell membrane is much higher after fixation than the spring constant of the AFM-cantilever used, resulting in less deformation of the membrane around rigid submembranous structures. This is confirmed by the softness (i.e., elasticity) measurements performed on living versus fixed fibroblasts (Fig. 9.12E). The elasticity of those cells, as calculated by the Hertz model, increased  $\sim 12$ -fold, i.e., from 10 kPa for the living cell to more than 120 kPa for the fixed status.

### 9.3.3

#### Summary

Finally, much can be expected from the recent integration of atomic force and confocal fluorescence microscopies in one instrument, combining the high-resolution topographical imaging of probe microscopy with the reliable biomolecular identification capabilities of optical microscopy [35].

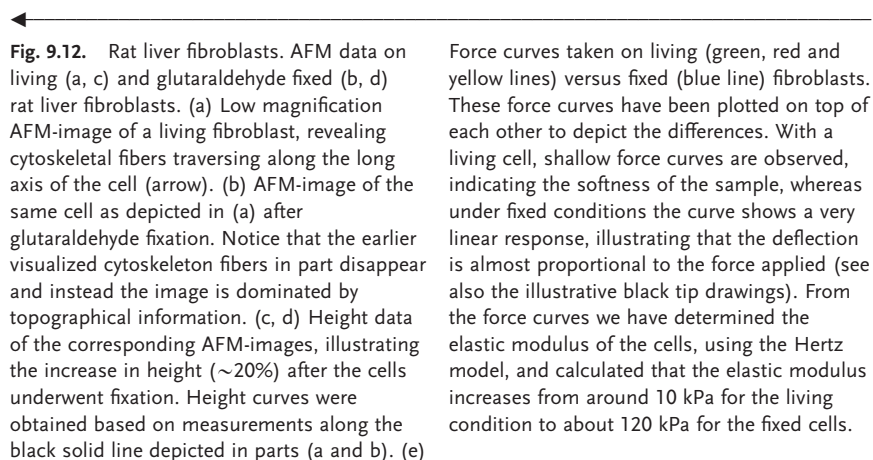

## 9.4

### Cryo-electron Microscopy

#### 9.4.1

##### Introduction

Cryo-electron microscopy has seen an increase in biological applications in the past fifteen years with the advent of significant technical innovation [45]. This microscopy method incorporates both vitrification, a freezing process that subverts

crystalline ice formation, and image acquisition under cryo-conditions. The cryo-fixation process is rapid, of the order of 0.1 ms, which is  $10^4$  times faster than conventional infiltration methods [46, 47], and preserves spatial as well as temporal biological states. In addition, sample preparation methods such as high-pressure freezing allow vitrification of specimens up to 200  $\mu\text{m}$  thick. Significant achievements have also been made in the understanding and technology of freezing thin samples such as hepatic endothelial monolayers that are vulnerable to osmotic and temperature effects, as described in following section.

#### 9.4.2

##### Instrumentation

Chemical fixation, dehydration and drying or embedding/sectioning of cells can induce image artifacts, resulting in different observations when different preparation techniques are applied [48]. In cryo-electron microscopy, living cells are physically fixed by rapid cooling, enabling their study as whole mounts without the necessity of further preparation steps. However, transmission electron microscopy of thin cells *in toto* (whole mount) has long been tried and considered impossible or extremely difficult due to the mass-thickness of the specimen. This view is usually substantiated by failures reported in the literature. Culturing cells as a single layer thick on grids, beam-specimen interaction resulting in specimen damage, and problems associated with cryo-specimen preparation have all been held responsible for this failure, depending on the spirit of the time. Over ten years ago the possibilities of cryo-electron microscopy on whole-mounted cells was discussed. By that time, the isolation and culture of hepatic endothelial cells on electron microscopy grids had become established [49], and cryo-electron microscopy had become an accepted approach for cellular imaging, as supported by the cryo-observations on intact blood platelets [50] and bacteria [51], revealing subcellular details such as organelles, membranous structures and cytoskeleton elements. It was argued, based on preliminary atomic force microscopy data [52], that the thickness of hepatic endothelial cells was of the same dimensional order as blood platelets and bacteria, and thus cryo-electron microscopy imaging could be expected using intermediate voltages. This holds especially for the thin fenestrated areas of cultured hepatic endothelial cells, which are less than 100 nm thick. As a result, electron beam-related problems (damage) or electron optical limitations were not expected. By that time, the development of an automated, computer-controlled vitrification system had begun that ultimately culminated in the Vitrobot<sup>TM</sup> [53–55] and a temperature and humidity controlled glove box in conjunction with a Vitrobot<sup>TM</sup> [55–57].

##### 9.4.2.1 Cryo-electron Microscopy Imaging

The use of a temperature and humidity controlled glove box in conjunction with a Vitrobot<sup>TM</sup> is essential for the manipulation of whole-mount hepatic endothelial cells from culture conditions in preparation for cryo-electron microscopy investigation [56, 57]. The fenestrae and surrounding cytoskeleton elements and different

**Fig. 9.13.** High magnification image of the fenestrated cytoplasm of a vitrified hydrated whole-mounted hepatic endothelial cell obtained under controlled sample handling conditions by using a temperature and humidity controlled glove box in combination with the Vitrobot™, as described previously

[35, 36], showing fenestrae and the associated cytoskeleton rings (arrow). Note the cytoskeleton elements (arrowhead) running next to the fenestrae and membrane-bound vesicles (asterisk). Scale bar: 500 nm. (Courtesy of Dr Peter Frederik & Paul Bomans, University of Maastricht, The Netherlands).

membrane-bound organelles are easily observed in these types of cryo-images without the presence of preparation-induced artifactual gaps (Fig. 9.13), indicating that our earlier observations on the fenestrae-associated cytoskeleton are not an artifact introduced by chemical fixation, partial extraction or other preparation procedure [57]. Further improvements in cryo-imaging may be expected when higher accelerating voltages are used (300 instead of 120 kV) in conjunction with electron tomography [45].

#### 9.4.3

#### Summary

Once a biological sample is vitrified correctly the challenge becomes to extract all the available 3D information and in the time-domain. Tomography at the cryo-electron microscopy level can resolve details at a 3D resolution better than 3 nm in a specimen of 100 nm thick, providing a solid basis for tomography as an emerging 3D technology that may greatly contribute to the 3D study of intact cells at the (supra-)molecular level [58].

### 9.5

#### Conclusions

Imaging in biology has seen increasingly improved resolutions over the decades with the advent of new microscopical techniques. Applications of high-resolution microscopy span different sectors, from medical to biotechnology to fundamental-type research; analytical surveys serve as measures of quality control and materials improvement in medical technology; and the nano-world of basic biology bridges

the structure–function relationship at several levels, from macromolecular to cellular and physiological, as seen with the wide use of AFM and cryo-EM. Soon, atomic resolutions from the atom probe will allow better device diagnostics and the generation of new questions and fields in biology appropriate for this new level of analysis. There will also be a continued need for correlative microscopy to develop control measures and for cross-referencing of methodologies from sample preparation to software development for data interpretation and rendering.

## Acknowledgments

The facilities, scientific and technical assistance from staff in the NANO Major National Research Facility at the Electron Microscope Unit, the University of Sydney are gratefully appreciated. We gratefully acknowledge the staff of Imago Scientific Instruments, in particular Mr Tom Kunicki for helpful discussions and insights, and Dr Steve Goodman now at 10H, Inc. Consulting ([www.10htech.com](http://www.10htech.com)) for contributions to experimental data and illustrations. With respect to the cryo-electron microscopy data, the authors gratefully acknowledge the work of Drs Peter Fredrik and Paul Bomans (University of Maastricht, The Netherlands).

# Dynamic Light Scattering Microscopy

*Rhonda Dzakpasu and Daniel Axelrod*

### 10.1

#### Introduction

We describe here a novel imaging technique for optical microscopy based on dynamic light scattering. Conventional dynamic light scattering (DLS, also known as quasielastic light scattering, QELS) is a well-established laser-based nonmicroscopic, nonimaging technique commonly used to measure diffusion coefficients of proteins in solution [1, 2]. DLS is based on the time-dependent interference among electric fields emanating from scattering centers in relative motion and is sensitive to relative motions that are six times smaller than the optical resolution of the microscope. We have adapted DLS to microscopy (DLSM) and, with the use of a CCD camera in a line-streaking mode, we use the rate of data readout transfer as the rate of data collection. This allows us to image rapid motions over submicroscopic distances. Rather than creating images based on static index of refraction variations, spatial maps based on the rates of motions are produced. This can provide valuable insight into the processes imaged in biological systems.

The theory of DLSM is presented here, followed by a description of a detection system that uses a slow scan (a few Hz exposure rate) CCD to record the rapid (kHz range) fluctuations of DLS, and finally followed by tests on a model system (small polystyrene beads in suspension) and a living cell system (macrophages). The goal of the tests on macrophages is not to answer any particular biological question at this point, but rather to verify the applicability of DLSM to cell biological systems.

Previously reported applications of DLS in a microscope have been limited to a single point (rather than spatial mapping) measurement of diffusion coefficients and flow rates (velocimetry) [3–15]. These works did not address the theoretical question as to how intensity fluctuations can occur from scattering centers mutually close enough to fall within the optical resolution distance of the microscope; this question is addressed here.

DLSM in its present form is chemically nonspecific, as are dark field, phase contrast, and differential interference contrast. Unlike those techniques that detect spatial but temporally static variations in local refractive index, DLSM detects tem-

porally dynamic variations in a spatially resolved format. We discuss possible extensions of the technique that might increase its chemical specificity while preserving its ability to detect rapid motions in submicroscopic regions.

This chapter is divided into five further sections: Section 10.2 presents the theoretical solution for the functional form of the scattered electric field from a single and then a collection of scattering centers. The temporal and spatial autocorrelation function is derived for the intensity at the image plane of the microscope. We show there can be significant intensity fluctuations due to the relative motion of scattering centers within the optical resolution of the microscope. In addition, we show that fast time scale fluctuations can be measured with this technique.

Section 10.3 describes the experimental realization of the technique for our control system of polystyrene beads and the first application to cell biology, macrophage cells.

Section 10.4 describes the data analysis performed on the intensity fluctuations obtained from the experimental system.

Section 10.5 presents results for the two experimental systems. We show that the rates of motion obtained for different bead sizes agree with those expected from hydrodynamic theory for such beads and are in relative agreement based on their size ratio. In addition, we also show that we can observe spatially resolved differences in the decay rates in macrophages, both untreated and treated by a pharmacological agent.

Section 10.6 discusses the experimental and theoretical results stemming from this work. It also presents possible applications of the technique and suggests potential improvements.

## 10.2

### Theory

This section presents a theoretical derivation of the functional form of the scattered electric field at the image plane of a microscope (which is modeled as a simple lens), first from a single scattering center and then from a collection of centers. From the resulting intensity, the temporal and spatial autocorrelation functions are derived. The theory is essentially a combination of scalar diffraction theory for a simple lens and a generalization of the conventional DLS theory as presented in Ref. [16].

The optical resolution of a microscope specifies the minimum separation of two objects in object space required to form distinctly separated images. If the separation is greater than the resolution distance, then clearly little interference can occur in the image plane. We show here that for scattering centers spaced closer than the optical resolution distance, sufficient phase variations still exist to create intensity fluctuations in the image plane.

As individual scattering centers can enter and/or leave an imaged region monitored by a single pixel in the detector, additional intensity fluctuations are created due to the change in particle number. These intensity fluctuations would occur even for incoherent light scattering (e.g., fluorescence). We derive an expression

that includes the effect of intensity fluctuations due to both phase and number variations.

The characteristic decay time of the temporal intensity autocorrelation function guides what is the minimum sample time that should be employed in the detection system. The characteristic decay distance of the spatial autocorrelation function guides what is the maximum pixel size that should be employed in the detection system.

### 10.2.1

#### Single Scattering Center

We first consider the electric field as it scatters from a single particle toward the objective lens, refracts through the lens, and propagates to the image plane. The scattering center is assumed to be much smaller than the wavelength of the incident light  $\lambda$  (the Rayleigh scattering limit); the polarization of the incident light is assumed to be linear and the polarization of the scattered light is assumed to be the same as the incident light. The electric fields are thereby represented as (complex) scalars rather than vectors. All of the light (incident and scattered) is monochromatic so the common factor  $\exp(i\omega t)$  is everywhere suppressed.

The coordinate systems are depicted in Fig. 10.1. Scattering center (object) space, objective lens space, and image space coordinates are unprimed, primed, and double primed, respectively. The optical axis of the microscope is defined as the  $z$ -axis. The incident light is formed from a collimated laser beam propagating in the  $y$ - $z$  plane and passing through a cylindrical lens. This lens focuses in the  $x$ -dimension only and leaves the incident light as a thin stripe along the  $y$ -direction, although still much larger in every dimension than the optical resolution. Therefore, the illumination electric field amplitude  $E_0$  can be considered constant over a region competent for mutual interference at one detector pixel. The direction of propagation and focusing is such that no direct incident light reaches the objective (i.e., essentially dark field). If  $\mathbf{k}_0$  is the incident wave vector and  $\mathbf{r}$  is the location of a

**Fig. 10.1.** Coordinate systems used in Section 10.2. The object is shown as a discrete black dot, and the point spread intensity in the image region as a blur. The origin in image

space is located in the plane of the detector. The origin in object space is chosen at a point on the optical axis such that its focused image is centered at the origin in image space.

particular scattering center in object space, then the incident electric field  $E(\mathbf{r})$  at a single scattering center is:

$$E(\mathbf{r}) = E_0 \exp(i\mathbf{k}_0 \mathbf{r}) \quad (1)$$

At the position of the objective lens (before propagating through it), the scattered light will produce an electric field  $E'(\mathbf{r}')$  with amplitude proportional to both  $E(\mathbf{r})$  and some scattering efficiency factor dependent upon the polarizability of the scattering center. However, this scattering efficiency factor is assumed constant among all scattering centers and also isotropic over the range of angles gathered by the lens, so its appearance will be suppressed in the expression for  $E'(\mathbf{r}')$ :

$$E'(\mathbf{r}') = E(\mathbf{r}) \exp(ik_s |\mathbf{R} - \mathbf{r}|) \quad (2)$$

where  $\mathbf{R}$  is the vector from the origin in  $\mathbf{r}$ -space to a point on the objective lens represented by two-dimensional vector  $\mathbf{r}'$  in the plane of the lens;  $|\mathbf{R} - \mathbf{r}|$  is the distance from the scattering center to that point on the objective; and  $k_s = |\mathbf{k}_s|$  is the amplitude of the scattered wave vector.

The electric field  $E''(\mathbf{r}'', z'')$  in the image region (with positions denoted in cylindrical coordinates) is given in Ref. [17]:

$$E''(\mathbf{r}'', z'') = \frac{\exp(ik_0 L)}{i\lambda L} \iint E'(\mathbf{r}') \exp\left(\frac{-ik_0 r'^2}{2f}\right) \times \exp\left\{\frac{ik_0 r'^2}{2} \left[\frac{1}{L} \left(1 - \frac{z''}{L}\right)\right] - \frac{ik_0 \mathbf{r}' \cdot \mathbf{r}''}{L}\right\} d^2 \mathbf{r}' \quad (3)$$

where  $f$  is the focal length of the objective lens,  $k_0 \equiv |\mathbf{k}_0|$  and  $L$  is the distance from the objective to the image plane. Assuming a small angle (i.e., small numerical aperture) approximation, the term  $\exp(-ik_0 r'^2/2f)$  corresponds to the phase shift imposed by the objective lens. The factor

$$\exp\left\{\frac{ik_0 r'^2}{2} \left[\frac{1}{L} \left(1 - \frac{z''}{L}\right)\right] - \frac{ik_0 \mathbf{r}' \cdot \mathbf{r}''}{L}\right\}$$

describes the phase alteration as the field propagates in the empty space from the objective lens to the image region.

Combining Eqs. (1-3), noting that  $\mathbf{k}_s$  is oriented in the same direction as  $\mathbf{R} - \mathbf{r}$  with  $k_s \approx k_0$ , and regrouping, we obtain:

$$E''(\mathbf{r}'', z'') = E_0 \frac{\exp(ik_0 L)}{i\lambda L} \exp(i\mathbf{k}_0 \cdot \mathbf{r}) \iint \exp\left\{ik_0 |\mathbf{R} - \mathbf{r}| - \frac{ik_0 \mathbf{r}' \cdot \mathbf{r}''}{L} - \frac{ik_0 r'^2}{2} \left[\frac{1}{f} - \frac{1}{L} \left(1 - \frac{z''}{L}\right)\right]\right\} d^2 \mathbf{r}' \quad (4)$$

For  $r \ll R$ , we can substitute an approximation for  $|\mathbf{R} - \mathbf{r}|$ :

$$|\mathbf{R} - \mathbf{r}| = \left\{ R^2 \left[ 1 + \left( \frac{r}{R} \right)^2 - \frac{2\mathbf{r} \cdot \mathbf{R}}{R^2} \right] \right\}^{1/2} \cong R + \frac{1}{2} \left( \frac{r^2}{R} \right) - \frac{\mathbf{r} \cdot \mathbf{R}}{R} \quad (5)$$

Since  $\mathbf{R} = \mathbf{r}' + J\hat{\mathbf{z}}$ , where  $J$  is the object distance,  $1/R$  can be written in the small aperture approximation ( $r' \ll J$ ) as:

$$\frac{1}{R} = (r'^2 + J^2)^{-1/2} \cong \frac{1}{J} \left[ 1 - \frac{1}{2} \left( \frac{r'}{J} \right)^2 + \dots \right] \quad (6)$$

Substituting Eqs. (5) and (6) into Eq. (4), and noting that  $\frac{1}{f} = \frac{1}{J} + \frac{1}{L}$ , the electric field in the image region becomes:

$$E''(\mathbf{r}'', z'') = E_0 \frac{\exp ik_0(L+J)}{i\lambda L} \int \exp ik_0 \left( -\mathbf{r} \cdot \mathbf{Q}(\mathbf{r}') + \frac{r'^2 \gamma(r'')}{2J} - \frac{\mathbf{r}' \cdot \mathbf{r}''}{L} - \frac{z'' r'^2}{2L^2} \right) d^2 \mathbf{r}' \quad (7)$$

where

$$\gamma(r') \equiv 1 - \frac{r'^2}{2J^2} \quad (8)$$

and

$$\mathbf{Q}(\mathbf{r}') \equiv \gamma \left( \frac{\mathbf{r}'}{J} + \hat{\mathbf{z}} \right) - \hat{\mathbf{k}}_0 \quad (9)$$

Vector  $k_0 \mathbf{Q}$  is a generalized conventional scattering vector, analogous to  $\mathbf{q}$  ( $\equiv \mathbf{k}_s - \mathbf{k}_0$ ) in conventional nonimaging DLS. Here,  $\mathbf{Q}$  additionally takes into account the range of scattering angles gathered by the microscope objective lens.

To simplify Eq. (7) further, we assume that the detector is located in the image plane ( $z'' = 0$ ). The scattering centers imaged within the same optical resolution area are then very close to the origin in object space so that  $r \ll r'$  for almost the entire range of the integral. Therefore, the exponent term  $\mathbf{r} \cdot \mathbf{Q} \gg r^2 \gamma / 2J$ , implying that the factor  $\exp(-ik_0 \mathbf{r} \cdot \mathbf{Q})$  in Eq. (7) varies much more rapidly than  $\exp(-ik_0 r^2 \gamma / 2J)$  over the range of the  $r'$ , so that the latter factor can be assumed constant and close to unity. Eq. (7) then becomes:

$$E''_{z''=0}(\mathbf{r}, \mathbf{r}'') = E_0 \frac{\exp ik_0(L+J)}{i\lambda L} \int \exp ik_0 \left( -\mathbf{r} \cdot \mathbf{Q} - \frac{\mathbf{r}' \cdot \mathbf{r}''}{L} \right) d^2 \mathbf{r}' \quad (10)$$

## 10.2.2

**Multiple Scattering Centers**

Each scattering center  $i$  located at position  $\mathbf{r}_i$  produces an electric field at  $z'' = 0$  according to Eq. (10). The total electric field  $E$  and the consequent intensity  $I$  at the image plane depend on the set of all the  $\mathbf{r}_i$  positions ( $I = 1, \dots, N$ ) as follows:

$$E(\{\mathbf{r}_i\}, \mathbf{r}'', t) = \sum_i^N b_i(t) E_{z''=0}''(\mathbf{r}_i, \mathbf{r}'') \quad (11)$$

$$I(\{\mathbf{r}_i\}, \mathbf{r}'', t) = E * E \quad (12)$$

To understand the meaning of the  $b_i(t)$  parameters, we define an “equivalent volume”  $v_{\text{pix}}$  in object space that contains all of the  $\mathbf{r}$  positions that contribute to the intensity observed by a single CCD camera pixel at one position in the image plane. (Of course, the actual region from which scattered light is gathered has graded rather than sharp edges.) We also define an arbitrarily larger volume  $V$  that subsumes  $v_{\text{pix}}$  and contains the  $N$  scattering centers included in the sum in Eq. (11). The occupation number  $b_i(t)$  equals unity if scattering center  $i$  is in  $v_{\text{pix}}$  at time  $t$  and zero otherwise. We assume that the positions  $\mathbf{r}_i$  are statistically independent and randomly time-dependent (e.g., due to Brownian motion). These random motions cause  $E$  to fluctuate in both phase and amplitude, and the resulting intensity to fluctuate in amplitude. The temporal and spatial behavior of the intensity fluctuations can be investigated through autocorrelation functions.

## 10.2.3

**Temporal Autocorrelation of Intensity**

The temporal autocorrelation is defined as

$$\Gamma(\tau) = \langle I(t_1)I(t_2) \rangle \quad (13)$$

where  $\tau \equiv t_2 - t_1$ , the intensities at the two times are measured at the same  $\mathbf{r}''$  position in the image plane, and the ensemble average indicated by the brackets is taken over all possible  $\{\mathbf{r}_i\}$  configurations. Because the system is assumed to be in equilibrium,  $\Gamma$  depends only on the time difference  $\tau$  and not the absolute times. After substituting Eqs. (10–12) into Eq. (13), we get Eq. (14).

$$\begin{aligned} \Gamma(\tau) = & \left( \frac{|E_0|}{i\lambda L} \right)^4 \sum_{i,j,k,l}^N \langle b_i(t_1)b_j(t_1)b_k(t_2)b_l(t_2) \rangle \\ & \times \iiint \left\langle \exp(-ik_0\mathbf{r}_i(t_1) \cdot \mathbf{Q}_a) \exp(ik_0\mathbf{r}_j(t_1) \cdot \mathbf{Q}_b) \right. \\ & \left. \exp(ik_0\mathbf{r}_k(t_2) \cdot \mathbf{Q}_c) \exp(-ik_0\mathbf{r}_l(t_2) \cdot \mathbf{Q}_d) \right\rangle \end{aligned}$$

$$\begin{aligned}
& \times \exp\left(-\frac{ik_0\mathbf{r}'_a \cdot \mathbf{r}''}{L}\right) \exp\left(\frac{ik_0\mathbf{r}'_b \cdot \mathbf{r}''}{L}\right) \exp\left(\frac{ik_0\mathbf{r}'_c \cdot \mathbf{r}''}{L}\right) \\
& \times \exp\left(-\frac{ik_0\mathbf{r}'_d \cdot \mathbf{r}''}{L}\right) d^2\mathbf{r}'_a d^2\mathbf{r}'_b d^2\mathbf{r}'_c d^2\mathbf{r}'_d
\end{aligned} \tag{14}$$

The phase fluctuations (arising from the complex exponential factors) are uncorrelated with number fluctuations (arising from the  $b$  factors); this is why the single ensemble average in Eq. (13) can be separated into a product of two ensemble averages (number and phase) in Eq. (14).

The summation in Eq. (14) can be separated according to the relationships among the summation indices  $i, j, k, l$  such that

$$\Gamma = \left(\frac{|E_0|}{i\lambda L}\right)^4 \sum_{m=1}^6 (\sum_m \Gamma_m^{\text{num}} \Gamma_m^{\text{ph}}) \tag{15}$$

where  $\Gamma_m^{\text{num}}$  and  $\Gamma_m^{\text{ph}}$  are the number and phase fluctuation factors, respectively, and  $\sum_m$  represents sums over  $i, j, k, l$  restricted as shown in Table 10.1.

#### 10.2.4

##### Phase Fluctuation Factors

In the first three cases ( $m = 1, 2, 3$ ) at least one index is unique from all of the others. In such cases, a factor  $\langle \exp(-ik_0\mathbf{r} \cdot \mathbf{Q}) \rangle$  with the unique index on the  $\mathbf{r}$  vector can be factored out from the overall ensemble average since the motions of the scattering centers are mutually independent. That factor can be handled as follows (written here for a particular scattering index  $i$ ):

$$\langle \exp(-ik_0\mathbf{r}_i(t_1) \cdot \mathbf{Q}_a) \rangle = \int \chi_i(\mathbf{r}_i) \exp(-ik_0\mathbf{r}_i \cdot \mathbf{Q}_a) d^3\mathbf{r}_i \tag{16}$$

where  $\chi_i$  is the probability density that the particle is located in the vicinity of position  $\mathbf{r}_i$ . The scattering centers  $i$  are assumed to be uniformly distributed over the volume  $v_{\text{pix}}$  imaged by an individual pixel in  $r$ -space so that  $\chi_i(\mathbf{r}_i) = \chi = 1/v_{\text{pix}}$ . Eq. (16) becomes:

**Tab. 10.1.** Number of unique indices.

$m$ Index	Scattering center indices	Number of unique indices
1	$i \neq j \neq k \neq l$	4
2	$i \neq j \neq k = l$	2
3	$i \neq j = k = l$	1
4	$i = j \neq k = l$	0
5	$i = k \neq j = l$	0
6	$i = j = k = l$	0

$$\langle \exp(-ik_0 \mathbf{r}_i(t_1) \cdot \mathbf{Q}_a) \rangle = \frac{1}{v_{\text{pix}}} \int \exp(-ik_0 \mathbf{r}_i \cdot \mathbf{Q}_a) d^3 \mathbf{r}_i = \frac{(2\pi)^{3/2}}{v_{\text{pix}}} \delta(k_0 \mathbf{Q}_a) \quad (17)$$

The integral over  $\mathbf{r}'_a$  in Eq. (14) then becomes:

$$\begin{aligned} & \int \langle \exp(-ik_0 \mathbf{r}_i(t_1) \cdot \mathbf{Q}_a) \rangle \exp\left(-\frac{ik_0 \mathbf{r}'_a \cdot \mathbf{r}''}{L}\right) d^2 \mathbf{r}'_a \\ &= \frac{(2\pi)^{3/2}}{v_{\text{pix}}} \int \delta(k_0 \mathbf{Q}_a) \exp\left(-\frac{ik_0 \mathbf{r}'_a \cdot \mathbf{r}''}{L}\right) d^2 \mathbf{r}'_a \\ &= \frac{(2\pi)^{3/2}}{v_{\text{pix}}} \left(\frac{J}{k_0 \gamma}\right)^2 \int \delta(k_0 \mathbf{Q}_a) \exp\left(-\frac{ik_0 \mathbf{r}'_a \cdot \mathbf{r}''}{L}\right) d^2(k_0 \mathbf{Q}_a) \end{aligned} \quad (18)$$

The integral has a nonzero value only when  $k\mathbf{Q}_a = 0$ . From the definition of  $\mathbf{Q}_a$  in Eq. (9), we can obtain the  $\mathbf{r}'_a$  for which this condition is satisfied:

$$\mathbf{r}'_a|_{\mathbf{Q}_a=0} = \frac{J}{\gamma} \hat{\mathbf{k}}_0 - J\dot{\mathbf{z}} \quad (19)$$

This particular  $\mathbf{r}'_a$  is located where the extension of the incident beam crosses the plane of the objective lens. Since our experimental setup was designed so that the incident light misses the objective, the integral over  $\mathbf{r}'_a$  in Eq. (18) (which is limited to the area of the objective) does not include  $\mathbf{r}'_a|_{\mathbf{Q}_a=0}$ . Thus, those terms in the sum of Eq. (15) with at least one unique summation index (i.e.,  $m = 1, 2, 3$ ) are zero.

The phase term for the  $m = 4$  case from Eq. (15) is given by Eq. (20).

$$\begin{aligned} \Gamma_4^{\text{ph}} &= \iint \langle \exp ik_0 [\mathbf{r}_i(t_1) \cdot \Delta \mathbf{Q}_{ab}] \rangle \exp\left(\frac{ik_0 \Delta \mathbf{r}'_{ab} \cdot \mathbf{r}''}{L}\right) d^2 \mathbf{r}'_a d^2 \mathbf{r}'_b \\ &\quad \times \iint \langle \exp -ik_0 [\mathbf{r}_k(t_2) \cdot \Delta \mathbf{Q}_{cd}] \rangle \exp\left(\frac{-ik_0 \Delta \mathbf{r}'_{cd} \cdot \mathbf{r}''}{L}\right) d^2 \mathbf{r}'_c d^2 \mathbf{r}'_d \\ &= \left| \iint \langle \exp ik_0 [\mathbf{r}_i(t_1) \cdot \Delta \mathbf{Q}_{ab}] \rangle \exp\left(\frac{ik_0 \Delta \mathbf{r}'_{ab} \cdot \mathbf{r}''}{L}\right) d^2 \mathbf{r}'_a d^2 \mathbf{r}'_b \right|^2 \end{aligned} \quad (20)$$

where  $\Delta \mathbf{Q}_{\alpha\beta} \equiv \mathbf{Q}_\beta - \mathbf{Q}_\alpha$  and  $\Delta \mathbf{r}'_{\alpha\beta} \equiv \mathbf{r}'_\beta - \mathbf{r}'_\alpha$ . The terms of the form  $\langle \exp ik_0 [\mathbf{r}(t_1) \cdot \Delta \mathbf{Q}] \rangle$  are similar to that in Eq. (17), except for the factor  $\Delta \mathbf{Q}$  instead of  $\mathbf{Q}$ . Therefore, the integral in Eq. (20) can be reduced to:

$$\begin{aligned} & \frac{1}{v_{\text{pix}}} \iint \left( \int \exp ik_0 [\mathbf{r}_i(t_1) \cdot \Delta \mathbf{Q}_{ab}] dx_i dy_i dz_i \right) \exp\left(\frac{ik_0 \Delta \mathbf{r}'_{ab} \cdot \mathbf{r}''}{L}\right) d^2 \mathbf{r}'_a d^2 \mathbf{r}'_b \\ &= \frac{I_{\text{pix}}(2\pi)}{v_{\text{pix}}} \iint \delta(k_0 \Delta \mathbf{Q}_{ab}) \exp\left(\frac{ik_0 \Delta \mathbf{r}'_{ab} \cdot \mathbf{r}''}{L}\right) d^2 \mathbf{r}'_a d^2 \mathbf{r}'_b \end{aligned}$$

$$\begin{aligned}
&= \frac{(2\pi)}{s_{\text{pix}}} \left( \frac{J}{k_0\gamma} \right)^4 \iint \delta(k_0\Delta\mathbf{Q}_{ab}) \exp\left(\frac{ik_0\Delta\mathbf{r}'_{ab} \cdot \mathbf{r}''}{L}\right) d^2(k_0\mathbf{Q}_a) d^2(k_0\mathbf{Q}_b) \\
&= \frac{(2\pi)}{s_{\text{pix}}} \left( \frac{J}{k_0\gamma} \right)^4 \iint \left[ \exp\left(\frac{ik_0\Delta\mathbf{r}'_{ab} \cdot \mathbf{r}''}{L}\right) \right] \Big|_{a=b} d^2(k_0\mathbf{Q}_b) \\
&= \frac{(2\pi)}{s_{\text{pix}}} \left( \frac{J}{k_0\gamma} \right)^4 \int d^2(k_0\mathbf{Q}) = \frac{(2\pi)}{s_{\text{pix}}} \left( \frac{J}{k_0\gamma} \right)^2 \int d^2\mathbf{r}' = \frac{(2\pi)}{s_{\text{pix}}} \left( \frac{J}{k_0\gamma} \right)^2 A \quad (21)
\end{aligned}$$

where  $l_{\text{pix}}$  is the  $z$ -dimension of the observed volume  $v_{\text{pix}}$ ;  $s_{\text{pix}}$  is the area of the observed volume; and  $A$  is the area of the objective. Therefore,

$$\Gamma_4^{\text{ph}} = \frac{(2\pi)^2}{s_{\text{pix}}^2} \left( \frac{J}{k_0\gamma} \right)^4 A^2 \quad (22)$$

For the  $m = 5$  term in Eq. (15),

$$\begin{aligned}
\Gamma_5^{\text{ph}} &= \left| \iint \langle \exp ik_0[\mathbf{r}_i(t_2) \cdot \mathbf{Q}_c - \mathbf{r}_i(t_1) \cdot \mathbf{Q}_a] \rangle \right. \\
&\quad \times \left. \exp\left(-\frac{ik_0\mathbf{r}'_a \cdot \mathbf{r}''}{L}\right) \exp\left(\frac{ik_0\mathbf{r}'_c \cdot \mathbf{r}''}{L}\right) d^2\mathbf{r}'_a d^2\mathbf{r}'_c \right|^2 \\
&= \left| \iint \langle \exp(-ik_0\Delta\mathbf{r}_i \cdot \mathbf{Q}_c) \exp(-ik_0\mathbf{r}_i(t_2) \cdot \Delta\mathbf{Q}_{ac}) \rangle \right. \\
&\quad \times \left. \exp\left(-\frac{ik_0\Delta\mathbf{r}'_{ac} \cdot \mathbf{r}''}{L}\right) d^2\mathbf{r}'_a d^2\mathbf{r}'_c \right|^2 \\
&= \left| \iint \langle \exp(-ik_0\Delta\mathbf{r}_i \cdot \mathbf{Q}_c) \rangle \langle \exp(-ik_0\mathbf{r}_i(t_2) \cdot \Delta\mathbf{Q}_{ac}) \rangle \right. \\
&\quad \times \left. \exp\left(-\frac{ik_0\Delta\mathbf{r}'_{ac} \cdot \mathbf{r}''}{L}\right) d^2\mathbf{r}'_a d^2\mathbf{r}'_c \right|^2 \quad (23)
\end{aligned}$$

where  $\Delta\mathbf{r}_i \equiv \mathbf{r}_i(t_2) - \mathbf{r}_i(t_1)$ . The term  $\langle \exp(-ik_0\mathbf{r}_i(t_2) \cdot \Delta\mathbf{Q}_{ac}) \rangle$  reduces to a  $\delta$ -function, so we obtain:

$$\begin{aligned}
\Gamma_5^{\text{ph}} &= \left| \frac{(2\pi)}{s_{\text{pix}}} \left( \frac{J}{k_0\gamma} \right)^4 \iint \left[ \delta(k_0\Delta\mathbf{Q}_{ac}) \exp\left(-\frac{ik_0\Delta\mathbf{r}'_{ac} \cdot \mathbf{r}''}{L}\right) d^2(k_0\mathbf{Q}_a) \right] \right. \\
&\quad \times \left. \langle \exp(-ik_0\Delta\mathbf{r}_i \cdot \mathbf{Q}_a) \rangle d^2(k_0\mathbf{Q}_c) \right|^2 \\
&= \left| \frac{(2\pi)}{s_{\text{pix}}} \left( \frac{J}{k_0\gamma} \right)^2 \int \langle \exp(-ik_0\Delta\mathbf{r}_i \cdot \mathbf{Q}) \rangle d^2\mathbf{r}' \right|^2 \quad (24)
\end{aligned}$$

where the subscript “ $c$ ” on the  $\mathbf{r}'_c$  factors has been suppressed. The ensemble average in Eq. (24) can be rewritten as:

$$\langle \exp(-ik_0 \Delta \mathbf{r}_i \cdot \mathbf{Q}) \rangle = \int p[\Delta \mathbf{r}_i(\tau)|0] \exp(-ik_0 \Delta \mathbf{r}_i \cdot \mathbf{Q}) d^3 \Delta \mathbf{r}_i \quad (25)$$

where  $p[\Delta \mathbf{r}_i(\tau)|0]$  is the conditional probability of finding a particle at position  $\Delta \mathbf{r}_i$  at time  $\tau$  given that it was at the origin ( $\Delta \mathbf{r}_i = 0$ ) at  $\tau = 0$ . The right-hand side of Eq. (25) is the Fourier transform of  $p[\Delta \mathbf{r}_i(\tau)|0]$ :

$$\langle \exp(-ik_0 \Delta \mathbf{r}_i \cdot \mathbf{Q}) \rangle = (2\pi)^{3/2} \tilde{p}(\mathbf{Q}) \quad (26)$$

where  $\tilde{p}(\mathbf{Q})$  is the Fourier transform of  $p[\Delta \mathbf{r}_i(\tau)|0]$  into  $\mathbf{Q}$ -space.

We assume that the scattering centers are undergoing random diffusive motion. Taking the Fourier transform of the diffusion equation  $\partial p / \partial \tau = D \nabla^2 p$  from  $\Delta \mathbf{r}_i$ -space to  $\mathbf{Q}$ -space gives:

$$\frac{\partial \tilde{p}}{\partial \tau} = -D k_0^2 \mathbf{Q}^2 \tilde{p} \quad (27)$$

so that

$$\tilde{p}(\mathbf{Q}) = (2\pi)^{-3/2} \exp(-D \mathbf{Q}^2 k_0^2 \tau) \quad (28)$$

and therefore, in combination with Eq. (26):

$$\langle \exp(-ik_0 \Delta \mathbf{r}_i \cdot \mathbf{Q}) \rangle = \exp(-D \mathbf{Q}^2 k_0^2 \tau) \quad (29)$$

Eq. (24) then becomes:

$$\Gamma_5^{\text{ph}} = \frac{(2\pi)^2}{s_{\text{pix}}^2} \left( \frac{J}{k_0 \gamma} \right)^4 A^2 \left| \frac{1}{A} \int \exp(-D \mathbf{Q}^2 k_0^2 \tau) d^2 \mathbf{r}' \right|^2 \quad (30)$$

For the  $m = 6$  term in Eq. (15),

$$\begin{aligned} \Gamma_6^{\text{ph}} &= \iiint \langle \exp ik_0 [\mathbf{r}_i(t_1) \cdot \Delta \mathbf{Q}_{ab}] \exp ik_0 [\mathbf{r}_i(t_2) \cdot \Delta \mathbf{Q}_{cd}] \rangle \\ &\quad \times \exp\left(\frac{ik_0 \Delta \mathbf{r}'_{ab} \cdot \mathbf{r}''}{L}\right) \exp\left(\frac{ik_0 \Delta \mathbf{r}'_{cd} \cdot \mathbf{r}''}{L}\right) d^2 \mathbf{r}'_a d^2 \mathbf{r}'_b d^2 \mathbf{r}'_c d^2 \mathbf{r}'_d \\ &= \iiint \langle \exp ik_0 [\mathbf{r}_i(t_1) \cdot (\Delta \mathbf{Q}_{ab} + \Delta \mathbf{Q}_{cd})] \exp ik_0 [\Delta \mathbf{r}_i(\tau) \cdot \Delta \mathbf{Q}_{cd}] \rangle \\ &\quad \times \exp\left(\frac{ik_0 \Delta \mathbf{r}'_{ab} \cdot \mathbf{r}''}{L}\right) \exp\left(\frac{ik_0 \Delta \mathbf{r}'_{cd} \cdot \mathbf{r}''}{L}\right) d^2 \mathbf{r}'_a d^2 \mathbf{r}'_b d^2 \mathbf{r}'_c d^2 \mathbf{r}'_d \\ &= \frac{1}{v_{\text{pix}}} \iiint \left( \int \exp ik_0 [\mathbf{r}_i(t_1) \cdot (\Delta \mathbf{Q}_{ab} + \Delta \mathbf{Q}_{cd})] dx_i dy_i dz_i \right) \end{aligned}$$

$$\begin{aligned}
& \times \langle \exp ik_0[\Delta\mathbf{r}_i(\tau) \cdot \Delta\mathbf{Q}_{cd}] \rangle \exp\left(\frac{ik_0\Delta\mathbf{r}'_{ab} \cdot \mathbf{r}''}{L}\right) \\
& \times \exp\left(\frac{ik_0\Delta\mathbf{r}'_{cd} \cdot \mathbf{r}''}{L}\right) d^2\mathbf{r}'_a d^2\mathbf{r}'_b d^2\mathbf{r}'_c d^2\mathbf{r}'_d \\
& = \frac{(2\pi)l_{\text{pix}}}{v_{\text{pix}}} \left(\frac{J}{k_0\gamma}\right)^2 \iiint \left[ \int \delta(\mathbf{Q}_b - \mathbf{Q}_a + \mathbf{Q}_d - \mathbf{Q}_c) \right. \\
& \quad \left. \times \exp\left(\frac{ik_0\mathbf{r}'' \cdot (\Delta\mathbf{r}'_{ab} + \Delta\mathbf{r}'_{cd})}{L}\right) d^2(k_0\mathbf{Q}_a) \right] \\
& \quad \times \langle \exp ik_0[\Delta\mathbf{r}_i(\tau) \cdot \Delta\mathbf{Q}_{cd}] \rangle d^2\mathbf{r}'_b d^2\mathbf{r}'_c d^2\mathbf{r}'_d \\
& = \frac{(2\pi)}{s_{\text{pix}}} \left(\frac{J}{k_0\gamma}\right)^2 \iint \langle \exp ik_0[\Delta\mathbf{r}_i(\tau) \cdot \Delta\mathbf{Q}_{cd}] \rangle d^2\mathbf{r}'_c d^2\mathbf{r}'_d \int d^2\mathbf{r}'_b \\
& = \frac{(2\pi)}{s_{\text{pix}}} \left(\frac{J}{k_0\gamma}\right)^2 A \iint \exp(-Dk_0^2\Delta Q^2\tau) d^2\mathbf{r}'_c d^2\mathbf{r}'_d \quad (31)
\end{aligned}$$

### 10.2.5

#### Number Fluctuation Factors

The total volume of the imaged sample is  $V$  and the total number of scattering centers in that volume is  $N$ . The volume “imaged” by a single pixel is  $v_{\text{pix}}$ . The number of particles  $M(t)$  (assumed  $\ll N$ ) and its expectation value in the volume  $v_{\text{pix}}$  can be written:

$$M(t) = \sum_i^N b_i(t) \quad (32)$$

$$\langle M \rangle = \left\langle \sum_i b_i(t) \right\rangle = \sum_i \langle b_i(t) \rangle = N \langle b_i \rangle \quad (33)$$

The variance of  $M$  can be derived from Eqs. (32) and (33):

$$\text{var } M = N \text{ var } b_i \quad (34)$$

The assumption that  $\langle b_i \rangle \ll 1$  implies that  $M$  follows a Poisson distribution and, therefore,  $\text{var } M$  equals  $\langle M \rangle$ . Therefore,

$$\text{var } b_i = \langle M \rangle / N = \langle b_i \rangle \quad (35)$$

and the temporal autocorrelation function for  $b_i$  can be written as:

$$\langle b_i(t_1)b_i(t_1 + \tau) \rangle = (\text{var } b_i)g_{\text{num}}(\tau) + \langle b_i \rangle^2 \approx \frac{\langle M \rangle}{N} g_{\text{num}}(\tau) \quad (36)$$

where  $g_{\text{num}}(\tau)$  is a normalized number fluctuation autocorrelation function such that

$$g(0) = 1 \quad \text{and} \quad g(\infty) = 0$$

We are now set to consider the terms  $\Gamma_m^{\text{num}}$  that appear in Eq. (15). Since the  $m = 1, 2, 3$  terms in Eq. (15) are forced to zero by their phase fluctuation factors, we need consider only  $\Gamma_{4,5,6}^{\text{num}}$ . We make the approximations that  $N \gg \langle M \rangle \gg 1$ .

For the  $m = 4$  term of Eq. (15),

$$\begin{aligned} \Gamma_4^{\text{num}} &= \sum_{i \neq k}^N \langle b_i^2(t_1) b_k^2(t_1 + \tau) \rangle = \sum_{i \neq k}^N \langle b_i(t_1) b_k(t_1 + \tau) \rangle = \sum_{i \neq k}^N \langle b_i(t_1) \rangle \langle b_k(t_1 + \tau) \rangle \\ &= (N^2 - N) \langle b_i \rangle^2 \approx \langle M \rangle^2 \end{aligned} \quad (37)$$

For the  $m = 5$  term,

$$\begin{aligned} \Gamma_5^{\text{num}} &= \sum_{i \neq j}^N \langle b_i(t_1) b_i(t_1 + \tau) b_j(t_1) b_j(t_1 + \tau) \rangle \\ &= \sum_{i \neq j}^N \langle b_i(t_1) b_i(t_1 + \tau) \rangle \langle b_j(t_1) b_j(t_1 + \tau) \rangle \\ &= (N^2 - N) \langle b_i(t_1) b_i(t_1 + \tau) \rangle^2 \approx \langle M \rangle^2 g_{\text{num}}^2(\tau) \end{aligned} \quad (38)$$

For the  $m = 6$  term,

$$\begin{aligned} \Gamma_6^{\text{num}} &= \sum_i^N \langle b_i^2(t_1) b_i^2(t_1 + \tau) \rangle = \sum_i^N \langle b_i(t_1) b_i(t_1 + \tau) \rangle \\ &= N \langle b_i(t_1) b_i(t_1 + \tau) \rangle \approx \langle M \rangle g_{\text{num}}(\tau) \end{aligned} \quad (39)$$

The  $m = 6$  term is smaller than the  $m = 4$  and  $m = 5$  terms by a factor of  $\langle M \rangle$ ; therefore, it will be neglected. The complete temporal autocorrelation function thereby becomes:

$$\Gamma(\tau) = \langle I \rangle^2 \left\{ 1 + g_{\text{num}}^2(\tau) \left[ \frac{1}{A} \int \exp(-DQ^2 k_0^2 \tau) d^2 \mathbf{r}' \right]^2 \right\} \quad (40)$$

where  $\langle I \rangle$  is the mean intensity observed at a pixel from the  $\langle M \rangle$  scattering centers in its view:

$$\langle I \rangle = \left( \frac{|E_0|}{i\lambda L} \right)^2 \frac{(2\pi)}{s_{\text{pix}}} \left( \frac{J}{k_0 \gamma} \right)^2 A \langle M \rangle \quad (41)$$

To compare the result given in Eq. (40) with experimentally obtained autocorrelation functions, we construct the normalized temporal autocorrelation function:

$$g_T(\tau) \equiv \frac{\Gamma(\tau) - \langle I \rangle^2}{\langle I \rangle^2} \quad (42)$$

Combining Eqs. (40) and (42) shows that  $g_T(\tau)$  monotonically decays to zero:

$$g_T(\tau) = g_{\text{num}}^2(\tau) \left[ \frac{1}{A} \int \exp(-DQ^2 k_0 \tau) d^2 \mathbf{r}' \right]^2 \quad (43)$$

### 10.2.6

#### Characteristic Times and Distances

Figure 10.2(a) shows  $g_T(\tau)$  [Eq. (43)] plotted as a function of the unitless time variable  $Dk_0^2 \tau$  with the indicated integration performed numerically for the particular case where the objective numerical aperture NA equals 0.4 (as used in the experimental setup).

The characteristic decay time  $Dk_0^2 \tau_c$ , defined as the time required for  $g_T(\tau)$  to reach its  $e^{-1}$  value, is  $Dk_0^2 \tau_c \approx 0.52$  for this particular numerical aperture. In that time, the mean distance  $r_c$  the particle travels laterally by three-dimensional diffusion is:

$$r_c \equiv (4D\tau_c)^{1/2} = (4 \cdot 0.52/k_0^2)^{1/2} = 0.23\lambda \quad (44)$$

This characteristic distance is about a factor of six smaller than the resolution of the microscope, which according to the Raleigh criterion is  $r_{\text{res}} = 0.61\lambda/\text{NA} = 1.5\lambda$  for  $\text{NA} = 0.4$ . This proves that dynamic light scattering intensity fluctuations of significant amplitude do occur amongst scattering centers within a resolution distance of each other.

The actual characteristic time  $\tau_c$  can be estimated for an aqueous suspension of 200 nm diameter polystyrene nanospheres as used in some of our experiments. Hydrodynamics predict  $D = 2.2 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$  for such spheres. For  $\lambda = 632.8 \text{ nm}$ , the characteristic time of the temporal intensity autocorrelation function would be  $\tau_c = 2.4 \text{ ms}$ . The experimental detection system must be able to observe these fast time-scale fluctuations.

### 10.2.7

#### Spatial Autocorrelation of Intensity

We define the spatial correlation region to be the spatial extent of the intensity fluctuations at the image plane. It is measured as the characteristic distance of the spatial autocorrelation function and determines the maximum pixel size allowable for measuring the temporal behavior of the intensity fluctuations. For example, if a pixel is larger than several characteristic spatial correlation regions, then the rela-

**Fig. 10.2.** Theoretical temporal autocorrelation function of the scattered light intensity [as calculated from Eq. (43)] vs. the unitless time parameter  $Dk_0^2\tau$ . Three curves are plotted. (a) The black dashed line curve is obtained from a numerical integration of Eq. (43) for a 0.4 numerical aperture objective. (b) The black solid curve is a single exponential decay, fitted to the points obtained from the numerical integration. (c) The grey dashed line is the pure exponential decay obtained from the zero aperture limit.

tive size of the observed fluctuations will be greatly reduced, compromising the signal-to-noise ratio. Ideally, a pixel should cover less than one spatial correlation region.

We start the calculation of the spatial autocorrelation function in a manner similar to the temporal autocorrelation function [Eq. (14)] except here using the intensities at two different *positions*  $\mathbf{r}_{1,2}''$ , recorded at the same time. (Because of the similarity of the mathematical procedures, we will skip most of the details here.) We count only those scattering centers that are actually present in the illuminated region at one snapshot of time, so all the  $b_i(t)$  factors can be set equal to unity.

$$\begin{aligned}
 \Gamma_S(\Delta\mathbf{r}'') = & \left(\frac{|E_0|}{i\lambda L}\right)^4 \left\langle \sum_{i,j,k,l}^N \int \exp(-ik_0\mathbf{r}_i(t_1) \cdot \mathbf{Q}_a) \exp(ik_0\mathbf{r}_j(t_1) \cdot \mathbf{Q}_b) \right. \\
 & \left. \times \exp(ik_0\mathbf{r}_k(t_1) \cdot \mathbf{Q}_c) \exp(-ik_0\mathbf{r}_l(t_1) \cdot \mathbf{Q}_d) \right\rangle
 \end{aligned}$$

$$\begin{aligned}
& \times \exp\left(-\frac{ik_0\mathbf{r}'_a \cdot \mathbf{r}''_1}{L}\right) \exp\left(\frac{ik_0\mathbf{r}'_b \cdot \mathbf{r}''_1}{L}\right) \exp\left(\frac{ik_0\mathbf{r}'_c \cdot \mathbf{r}''_2}{L}\right) \\
& \times \exp\left(-\frac{ik_0\mathbf{r}'_d \cdot \mathbf{r}''_2}{L}\right) d^2\mathbf{r}'_a d^2\mathbf{r}'_b d^2\mathbf{r}'_c d^2\mathbf{r}'_d
\end{aligned} \tag{45}$$

As in the calculation for the temporal autocorrelation function, the spatial autocorrelation function terms corresponding to  $m = 1, 2, 3$  (see Table 10.1) produce zero values and the  $m = 4, 5, 6$  terms produce non-zero values. In the latter terms, an integral appears that can be related to a first-order Bessel function:

$$\int \exp\left(\frac{-ik_0\mathbf{r}' \cdot \Delta\mathbf{r}''}{L}\right) d^2\mathbf{r}' = \frac{2J_1(\mu)}{\mu} \tag{46}$$

where  $\Delta\mathbf{r}'' \equiv \mathbf{r}''_2 - \mathbf{r}''_1$  and  $\mu = k_0 r_o' \Delta\mathbf{r}''/L$  and  $r_o'$  is the radius of the objective.

The final form of the spatial autocorrelation function becomes:

$$\Gamma_S(\Delta\mathbf{r}'') = \langle I \rangle^2 \left\{ \left[ 1 + \left( \frac{2J_1(\mu)}{\mu} \right)^2 \right] + \langle M \rangle^{-1} \left[ \left( \frac{2J_1(\mu)}{\mu} \right)^4 - \left( \frac{2J_1(\mu)}{\mu} \right)^2 - 1 \right] \right\} \tag{47}$$

For large  $\langle M \rangle$ , the  $\langle M \rangle^{-1}$  term is small and is not included in further calculations. The leading term of the spatial autocorrelation function has the same distance dependence as the point spread function of the microscope objective at the image plane (an Airy disk). In analogy with Eq. (42), a normalized form of  $\Gamma_S(\Delta\mathbf{r}'')$  can be written as

$$g_S(\Delta\mathbf{r}'') = \frac{\Gamma_S(\Delta\mathbf{r}'') - \langle I(\mathbf{r}'') \rangle^2}{\langle I(\mathbf{r}'') \rangle^2} \tag{48}$$

The characteristic spatial correlation distance is qualitatively the average distance in the image plane from constructive to destructive interference [18, 19]. It can be defined quantitatively as the distance  $l_c$  in  $\mathbf{r}''$ -space corresponding to  $\mu = 1$ . Parameter  $\mu$  [see after Eq. (46)] can be rewritten in terms of the numerical aperture (NA) and magnification (mag) of the objective (in the low aperture, air immersion case) as:

$$\mu = \left( \frac{2\pi}{\lambda} \right) \left( \frac{\text{NA}}{\text{mag}} \right) \Delta\mathbf{r}'' \tag{49}$$

Thus the spatial correlation distance  $l_c$  is:

$$l_c = \Delta\mathbf{r}''_c = \left( \frac{\lambda}{2\pi} \right) \left( \frac{\text{mag}}{\text{NA}} \right) \cong 8 \mu\text{m} \tag{50}$$

The size of the CCD camera pixel in the experiments reported here is  $6.3 \mu\text{m}$ , so that approximately one spatial correlation distance is observed in each pixel.

### 10.2.8

#### Variance of Intensity Fluctuations: Mobile Fraction

We define the mobile fraction  $\beta$  to be the ratio of the scattered intensity from the mobile scattering centers  $\langle I \rangle_{\text{mob}}$  to the total scattering intensity  $\langle I \rangle$  in the collection volume of each pixel:

$$\beta = \frac{\langle I \rangle_{\text{mob}}}{\langle I \rangle} \quad (51)$$

where

$$\langle I \rangle = \langle I \rangle_{\text{mob}} + \langle I \rangle_{\text{fix}} \quad (52)$$

and  $\langle I \rangle_{\text{fix}}$  arises from fixed scattering centers (such as the sample substrate). The mobile fraction  $\beta$  can be estimated from the variance of the intensity fluctuations, which is the difference between the extrapolated values of the temporal autocorrelation function values at  $\tau = 0$  and at  $\tau = \infty$ . Combining the definition of  $\Gamma$  in Eq. (13) with Eq. (52), we get

$$\begin{aligned} \Gamma(\tau) = & \langle I_{\text{mob}}(t)I_{\text{mob}}(t+\tau) \rangle + \langle I_{\text{mob}}(t)I_{\text{fix}}(t+\tau) \rangle \\ & + \langle I_{\text{fix}}(t)I_{\text{mob}}(t+\tau) \rangle + \langle I_{\text{fix}}(t)I_{\text{fix}}(t+\tau) \rangle \end{aligned} \quad (53)$$

The first term in the above equation can be reduced to  $\langle I \rangle_{\text{mob}}^2 + g(\tau)\langle I \rangle_{\text{mob}}^2$  where  $g(0) = 1$  and  $g(\infty) = 0$ . The next two terms are each  $\langle I \rangle_{\text{mob}}\langle I \rangle_{\text{fix}}$  and the last term is  $\langle I^2 \rangle_{\text{fix}} = \langle I \rangle_{\text{fix}}^2$  since the scattering due to the immobile intensity does not fluctuate. Therefore,

$$\Gamma(0) = 2\langle I \rangle_{\text{mob}}^2 + 2\langle I \rangle_{\text{mob}}\langle I \rangle_{\text{fix}} + \langle I \rangle_{\text{fix}}^2 \quad (54)$$

and

$$\Gamma(\infty) = \langle I \rangle_{\text{mob}}^2 + 2\langle I \rangle_{\text{mob}}\langle I \rangle_{\text{fix}} + \langle I \rangle_{\text{fix}}^2 = \langle I \rangle^2 \quad (55)$$

and therefore

$$\beta^2 = \frac{\langle I \rangle_{\text{mob}}^2}{\langle I \rangle^2} = \frac{\Gamma(0) - \Gamma(\infty)}{\Gamma(\infty)} \quad (56)$$

## 10.3 Experimental Design

### 10.3.1 Optical Setup

Light from a CW helium neon laser (15 mW, 632.8 nm) was focused through an 8-mm focal length cylindrical lens and propagated down towards the sample (at  $\sim 60^\circ$  from the vertical) such that the direct incident light missed the objective (Fig. 10.3a). The resulting illumination region was a thin line, 2  $\mu\text{m}$  full-width at half-maximum and oriented so that the stripe was in the plane of incidence.

A Leitz Diavert inverted microscope with a 0.4 NA, 32X long working distance objective collected the scattered light from the sample. The objective focused the scattered light at an image plane above the microscope at which a 5  $\mu\text{m}$  wide slit was located. Lens L in the path between the image plane and the face of the CCD camera refocused the scattered light and image plane slit onto the CCD array of a digital camera with no additional magnification. The image plane slit served to select a clean-edged line of scattered light that illuminated only a single column of pixels in the CCD camera (Fig. 10.3b). The image plane slit also created a confocal-like effect, reducing the out-of-focus light at the camera.

The sample chamber containing either cells or beads (see below) was placed on a motorized stage (Maerzhaeuser Wetzlar, Germany) that could be translated step-wise in the direction transverse to the illumination stripe.

Emission path filters (Chroma Technology, Corp., Brattleboro, VT) were chosen depending upon whether light scattering (for DLSM experiments) or fluorescence (for number fluctuation experiments) was performed. For DLSM, a  $632 \pm 10$  nm laser narrow bandwidth filter was used. For the number fluctuation experiments, a long pass 650 nm filter was used to block scattered excitation light and transmit fluorescence from dye-labeled beads.

### 10.3.2 Data Acquisition

During an image acquisition period, the camera shutter remained open. The progressive scan cooled CCD camera (Pentamax-KAF-1400, Roper Scientific, Trenton, NJ, pixel size  $6.8 \times 6.8 \mu\text{m}$ ) reads out data column-by-column such that the intensities recorded in each pixel column shifts one column (Fig. 10.4) every 300  $\mu\text{s}$ . The shifting continues until the full frame of the CCD array is read. Therefore, each pixel along the column of illumination formed by the image plane slit in our optical setup gave rise to a temporal streak of intensity fluctuations with a “bin time” of 300  $\mu\text{s}$ .

Custom PC software written in LabView and interfaced to a data acquisition board (National Instruments, Austin, TX) coordinated the image acquisition with the microscope stage controller (Lang MCL-2, Huttenberg, Germany). Images

**Fig. 10.3.** Schematic drawing of experimental setup. (a) A cylindrical lens focuses the beam from a He-Ne laser to create a thin stripe of illumination (oriented in the page plane here) on the sample. A motorized stage controls the motion of the sample and the sample is moved in the  $x$ -direction only (normal to the page plane). A 32X, 0.4 NA, objective gathers the scattered light from the sample and focuses it onto a  $5\ \mu\text{m}$  wide slit placed in the image plane and oriented in the direction of

the illumination stripe. A lens (L) re-images the slit onto the face of a CCD camera without additional magnification. (b) Detail of the imaging on the CCD array, with lenses omitted from the drawing. The slit excludes out-of-focus light and creates a well-defined focused line of scattered illumination that gets mapped onto a single column of the CCD camera array. Other columns of the CCD camera array are not illuminated.

were taken every 500 ms, followed by the advancement of the microscope stage to a new position on the sample. The sequence was repeated until the entire sample had been stepped through, resulting in a stack of images containing the intensity fluctuations from every point in the sample. Images were stored using a Windows 98, 600 MHz Intel P-III computer running WinView (Roper Scientific, Trenton, NJ).

**Fig. 10.4.** Schematic of CCD readout mechanism. The dashed rectangle represents the column of the CCD array that is constantly exposed to the scattered light. The CCD array readout shift register is represented by the column of pixels at the extreme right. (Between the illuminated columns and the shift register there may be intermediate columns but these are not shown.) The (progressive scan) camera is operated in its normal readout mode, except with the camera shutter always open. At the end of every  $300 \mu\text{s}$  interval, accumulated intensity data in the illuminated column of pixels is advanced rightward column-by-column toward the shift register. At the same time, blank counts from the pixel columns to

the left are shifted into the illuminated column, effectively clearing it, and data in the shift register is read into an array in the computer memory. This process continues until the shift register has read every column of the CCD array, thereby completing image acquisition for a single stage position of the sample. The final “image” as recorded in the computer consists of a time sequence ( $\Delta t = 300 \mu\text{s}$ ) of 800 intensity readings at each pixel along the illuminated pixel column. The next streak-like image is acquired after the motorized microscope stage has advanced to the next position on the sample. The whole image acquisition process is complete when the stage has stepped through the entire sample.

### 10.3.3

#### Sample Preparation: Polystyrene Beads

For dynamic light scattering experiments, 200 and 500 nm diameter polystyrene nanospheres (Duke Scientific, Palo Alto, CA) were tip-sonicated (to break up large clusters) and loaded at their undiluted aqueous suspension concentrations of  $2.1 \times 10^{12}$  particles  $\text{mL}^{-1}$  (200 nm) and  $1.4 \times 10^{11}$  particles  $\text{mL}^{-1}$  (500 nm) into separate rectangular cross-section glass microcapillary tubes (inner thickness  $0.05 \times 0.5$  mm wide, Wilmad Specialty Glass, Buena, NJ) by capillary action. The two microcapillary tubes containing the two bead sizes were placed side-by-side on a plastic holder and oriented at a diagonal across the microscope field of view so that laser light line illuminated both microcapillary tubes simultaneously. Vacuum grease was used to seal the ends of the microcapillary tubes and to adhere them to the holder. For number fluctuations measurements, 200 nm carboxylate-modified fluorescent dark red FluoSpheres were obtained from Molecular Probes (Eugene, OR). FluoSpheres were drawn into microcapillary tubes at their undiluted concentration of  $5.3 \times 10^{12}$  particles  $\text{mL}^{-1}$  and mounted similarly.

The CCD camera acquired 40 images of the polystyrene beads assembly, each of which represented a line position 10  $\mu\text{m}$  apart on the sample.

#### 10.3.4

##### **Sample Preparation: Living Macrophages**

Coverslips (25 mm diameter, #2 thickness, and 32.5 mm diameter, #1.5 thickness) were treated for several hours in concentrated  $\text{H}_2\text{SO}_4$  in a porcelain holder and then rinsed for 2 h in distilled water and oven dried overnight at 130 °F. This treatment greatly reduced the light scattering from the coverslips.

Two aqueous buffers, Ringer (RB) (155 mM NaCl, 5 mM KCl, 2 mM  $\text{CaCl}_2$ , 1 mM  $\text{MgCl}_2$ , 2 mM  $\text{NaH}_2\text{PO}_4$ , 10 mM HEPES, pH 7.2, 10 mM glucose) and Ringers with acetate (ARB) (80 mM NaCl, 70 mM sodium acetate, 5 mM KCl, 2 mM  $\text{CaCl}_2$ , 1 mM  $\text{MgCl}_2$ , 2 mM  $\text{NaH}_2\text{PO}_4$ , 10 mM HEPES pH 6.8, 10 mM glucose) were prepared for use during the experiment.

Monoclonal mouse macrophage cultures (RAW 264.7, American Type Tissue Culture, Manassas, VA) were obtained from the laboratory of Dr Joel Swanson (Department of Immunology, University of Michigan Medical School). The cultures were maintained in 60 mm diameter polystyrene tissue culture dishes in 10 mL of a 0.2  $\mu\text{m}$  filtered (Millipore, Bedford MA) solution of Dulbecco's modified Eagle's medium containing 10% heat-inactivated fetal bovine serum, high glucose, L-glutamate and sodium pyruvate (DMEM, Grand Island Biological Company, Grand Island, NY) and penicillin–streptomycin. For replating onto the glass coverslips, cells were dislodged by vigorous trituration. A 1:30 dilution of the resulting suspension in DMEM was prepared, plated onto 32.5 mm coverslips (pre-cleaned as described above) in polystyrene dishes, and incubated for two days at 37 °C. Macrophage cells on a glass coverslip can spread to  $\sim 80$   $\mu\text{m}$  diameter circular shapes, with thicknesses of a couple of microns at the periphery and about 5  $\mu\text{m}$  in the center.

The cell sample chamber consisted of a 25 mm diameter, 50  $\mu\text{m}$  thick Teflon spacer ring, cut into two slightly separated halves to provide a channel for easy fluid exchange by capillary action. These spacers were placed on top of the 32.5 mm coverslip with adherent cells. A 25 mm diameter coverslip was then placed over the spacers to create a cell sandwich chamber, which was clamped with plastic clips over a drilled hole in a plastic plate. The cells in the chamber were gently rinsed with 1 mL of RB.

#### 10.3.5

##### **Buffer Changes during Data Acquisition**

The CCD camera first took 120 successive streak images of the cell in RB with a 5  $\mu\text{m}$  step stage motion between each image. Subsequently, 1 mL of ARB was exchanged into the cell coverslip sandwich and incubated for 20 min before a second similar round of streak image recording was initiated over the same cell area. A final 1 mL of RB buffer was exchanged into the sample chamber, another 20 min of

incubation time elapsed, and the camera acquired a final similar sequence of 120 streak images over the same area.

## 10.4 Data Analysis

The two types of intensity autocorrelation functions – temporal and spatial – for each pixel along an illuminated line can be calculated from the width and height, respectively, of the same streak image (Fig. 10.5a).

### 10.4.1 Temporal Intensity Autocorrelation Function

Normalized temporal autocorrelation functions  $g_T(\tau)$  of the experimental intensity fluctuations [see Eq. (42)] were calculated along the rows for each point on the line of illumination.

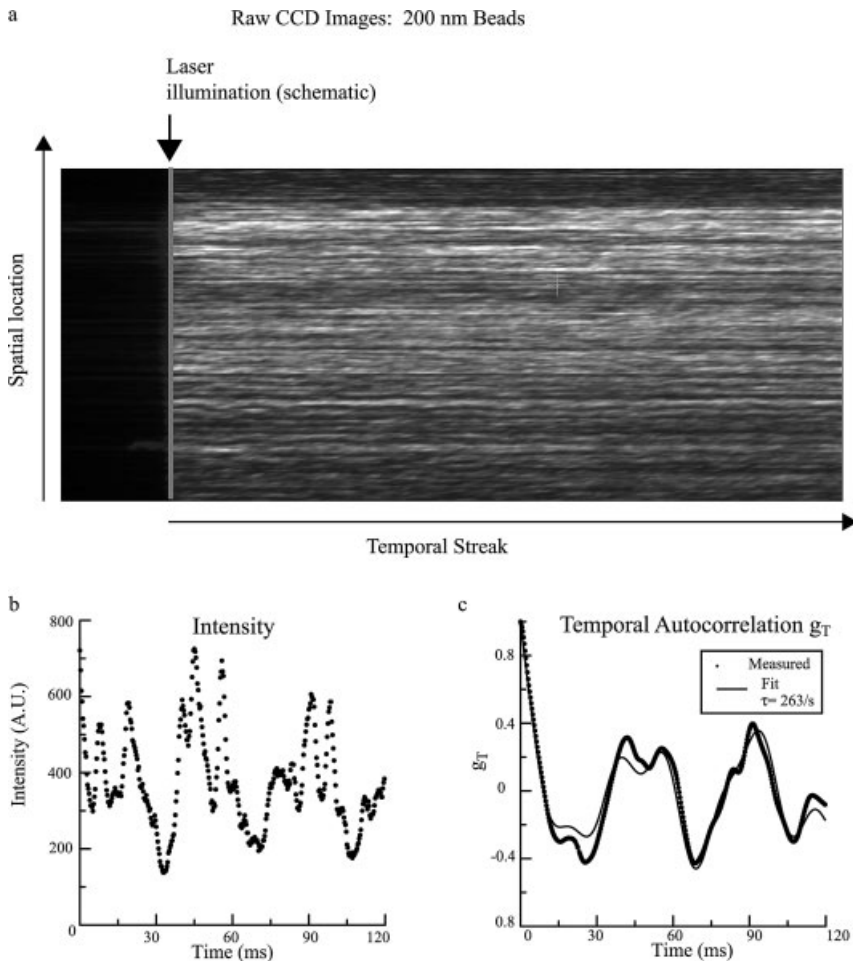

The theoretically expected temporal autocorrelation function [Eq. (43)] can be integrated numerically and fit to a single exponential (Fig. 10.2b). The close agreement between the fitted function and the numerical integration justifies approximating the experimental data with a single exponential. However, DLSM is very sensitive to extraneous sources of noise, such as table and acoustic vibrations and laser source fluctuations. To remove these largely periodic noise effects, the obtained temporal autocorrelation functions were fit to a sum of a single exponential, three sine waves, and a constant:

$$g_{\text{fit}}(\tau) = A_0 e^{-A_1 \tau} + A_2 \cos(2A_3 \pi \nu \tau) + A_4 \cos(2A_5 \pi \nu \tau) + A_6 \cos(2A_7 \pi \nu \tau) + A_8 \quad (57)$$

where  $A_{0-8}$  are the fitting parameters. The  $A_1$  decay rate parameter was assigned a pseudocolor for each pixel to create a spatial map of the fluctuation decay rates. The mean value of the decay rates for each bead size was used to calculate the apparent diffusion coefficients using  $Dk_0^2 \tau_c \approx 0.52$  where  $\tau_c = 1/A_1$ .

### 10.4.2 Spatial Intensity Autocorrelation Function

We calculated the normalized spatial autocorrelation function  $g_s(\Delta \mathbf{r}'')$  [see Eq. (48)] along each of the columns of a streak image of the intensity fluctuations from polystyrene bead suspensions. To obtain a single spatial autocorrelation function for comparison with theory, all of the  $g_s(\Delta \mathbf{r}'')$  were averaged over all of the columns. The result was not fit to the theoretical function, but the characteristic decay distance was compared with theory [see Eqs. (49) and (50)].

**Fig. 10.5.** (a) Example of an image recorded by the CCD camera of a 200 nm polystyrene bead suspension. The image is recorded from a single stage position on the sample. The vertical column corresponds to spatial positions on the sample illuminated by the thin line. Each horizontal row is the temporal streak recorded during the readout process of

the CCD camera at this location. (b) An example of a recorded intensity fluctuation along one of the rows. (c) The autocorrelation function of the intensity time course shown in (b), based directly on the experimental intensities (dotted line) and then subsequently fitted with the form of Eq. (43) (solid line).

#### 10.4.3

##### Mobile Fraction

Mobile fraction  $\beta$  was calculated pixel-by-pixel from  $\Gamma(0)$  and  $\Gamma(\infty)$  [Eq. (56)], and the calculated values were assigned different pseudocolors for display. Eq. (56) assumes that phase fluctuations are the only contributors to  $\Gamma(\tau)$ . However, in an actual experiment,  $\Gamma(\tau)$  can also be affected by other factors, as follows.

- (a) *Photon shot noise* contributes to the amplitude of  $\Gamma(\tau)$ , but only at  $\tau = 0$  since the photon arrival times are uncorrelated. Thus, to obtain an accurate estimate of  $\Gamma(0)$  apart from shot noise, a linear extrapolation was performed from the values of  $\Gamma(1)$  and  $\Gamma(2)$ .
- (b) *Number fluctuations* were recorded on a sample that produces no coherent phase fluctuations: fluorescent beads. Here, the variance was very small, only marginally above the noise level in  $\Gamma(\tau)$ , and  $\Gamma(0)$  was estimated as  $\Gamma(1)$ .
- (c) *Overly large pixels size* can decrease the recorded variance; pixels should be smaller than the spatial correlation distance, as indeed occurs here (see Section 10.2).

## 10.5

### Experimental Results

Polystyrene beads were used to quantitatively test the DLSM technique and compare the experimental values of the mean decay rates and mobile fractions with values predicted from theory. DLSM was then applied to macrophage cells as a test on a living biological system. Macrophages are very motile and their motility can be altered pharmacologically.

#### 10.5.1

##### Polystyrene Beads: Temporal Phase Autocorrelation

An example of scattered light intensity fluctuations along with the corresponding autocorrelation function is displayed in Figs. 10.5(b) and (c). The temporal autocorrelation functions were fit to a linear combination of a single exponential and three sine waves [Eq. (57)]. The sine waves were added to the fitting function because the obtained autocorrelation functions exhibited some pseudo-oscillatory behavior with varying frequencies in addition to the expected exponential decay. An average of the ( $\sim 1000$ ) temporal autocorrelation functions obtained from the rows of a single streaked image of 200 nm polystyrene beads is displayed in Fig. 10.6. This average exhibits only an exponential decay, indicating that the pseudo-oscillations in some individual rows are random noise arising from the low number of correlation times in the time represented by a streak (240 ms).

Figure 10.7(b) shows a DLSM decay rate pseudocolor spatial map of a section of two adjacent microcapillary tubes containing 200 and 500 nm diameter beads, respectively. Although the range of colors suggests a wide distribution of decay rates in each tube, there are more pixels with shorter decay rates for the system of 200 nm beads than for 500 nm beads, as can be seen in normalized histograms of the decay rates for both sonicated and unsonicated beads of both sizes (Fig. 10.8). Fluctuation decay rates are generally much faster for the 200 nm beads. In addition, sonication resulted in an increase of the average decay rates towards the theoretical values. Average values of decay rates measured with our technique were 209 and 256  $s^{-1}$  (non-sonicated and sonicated, respectively) for the 200 nm beads and

**Fig. 10.6.** Temporal autocorrelation function of 200 nm polystyrene beads, averaged over all the rows of the streaked image shown in Fig. 10.5(a).

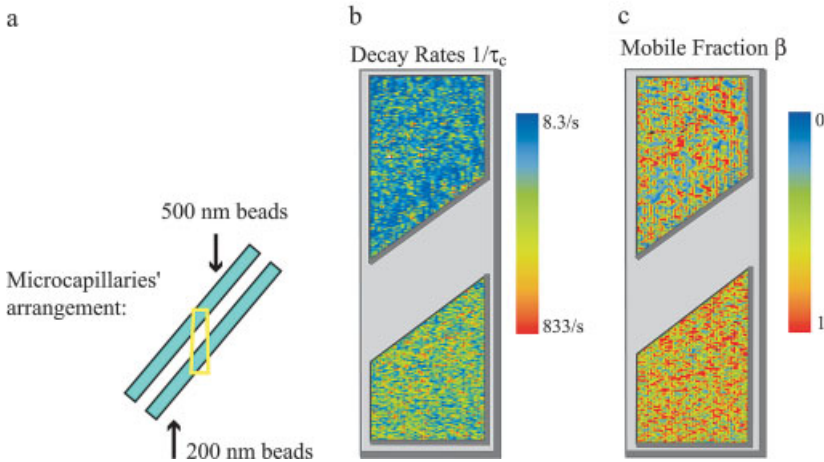

107 and  $144 \text{ s}^{-1}$  (non-sonicated and sonicated, respectively) for the 500 nm beads. These decay rates correspond to diffusion coefficients of  $1.35 \times 10^{-8}$  and  $8.75 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$  for the sonicated 200 and 500 nm beads, respectively. Table 10.2 compares the experimentally obtained results with the theoretically predicted values. The experimental results are in good agreement with the hydrodynamic theory values for the 500 nm sonicated beads and about 40% lower than the theoretical expectation for the 200 nm sonicated beads. There is no obvious correlation between variations in the local decay rates and the local mean scattered light intensity (data not shown).

### 10.5.2

#### Variance of Intensity Fluctuations on Beads: Phase Fluctuations

A qualitative representation for the size of the intensity fluctuations can be obtained by visual inspection of an image from the CCD camera. Figure 10.9 shows a raw streaked image recorded by the CCD camera for scattered light (DLSM fluctuations, Fig. 10.9a) and for fluorescence (number fluctuations, Fig. 10.9c), both recorded from 200 nm carboxylate-modified dark red FluoSpheres. Figure 10.9(b) shows the normalized temporal autocorrelation function,  $g_T(\tau)$ , for a typical row in the DLSM streaked image depicted in Fig. 10.9(a). Figure 10.9(d) shows a corre-

## Polystyrene Beads: Spatial Maps

**Fig. 10.7.** Experimental spatial maps for the polystyrene beads. (a) Two different sizes of polystyrene beads were used in a single experiment: 200 and 500 nm. The beads were in separate microcapillary tubes oriented at an angle with respect to the optical axis and mounted on a homemade microscope sample chamber. The yellow box represents the field of view of the microscope. (b) Spatial map of the decay rates in the field of view. Note the faster diffusion of the 200 nm beads, as expected. (c)

Spatial map of the mobile fractions, obtained using Eq. (56), in the same field of view. A zero on the scale implies that most of the scattering centers are immobile whereas unity implies all of the scattering centers are mobile. Both bead sizes show a large mobile fraction: for the 200 nm beads  $\beta_{avg} = 0.63$ , and for the 500 nm beads  $\beta_{avg} = 0.42$ . The 200 nm beads show a smaller spread of the degree of mobility than the 500 nm beads.

sponding normalized temporal autocorrelation function for the number fluctuation experiment of Fig. 10.9(c). The relative variance of phase fluctuations is much larger than the relative variance of number fluctuations.

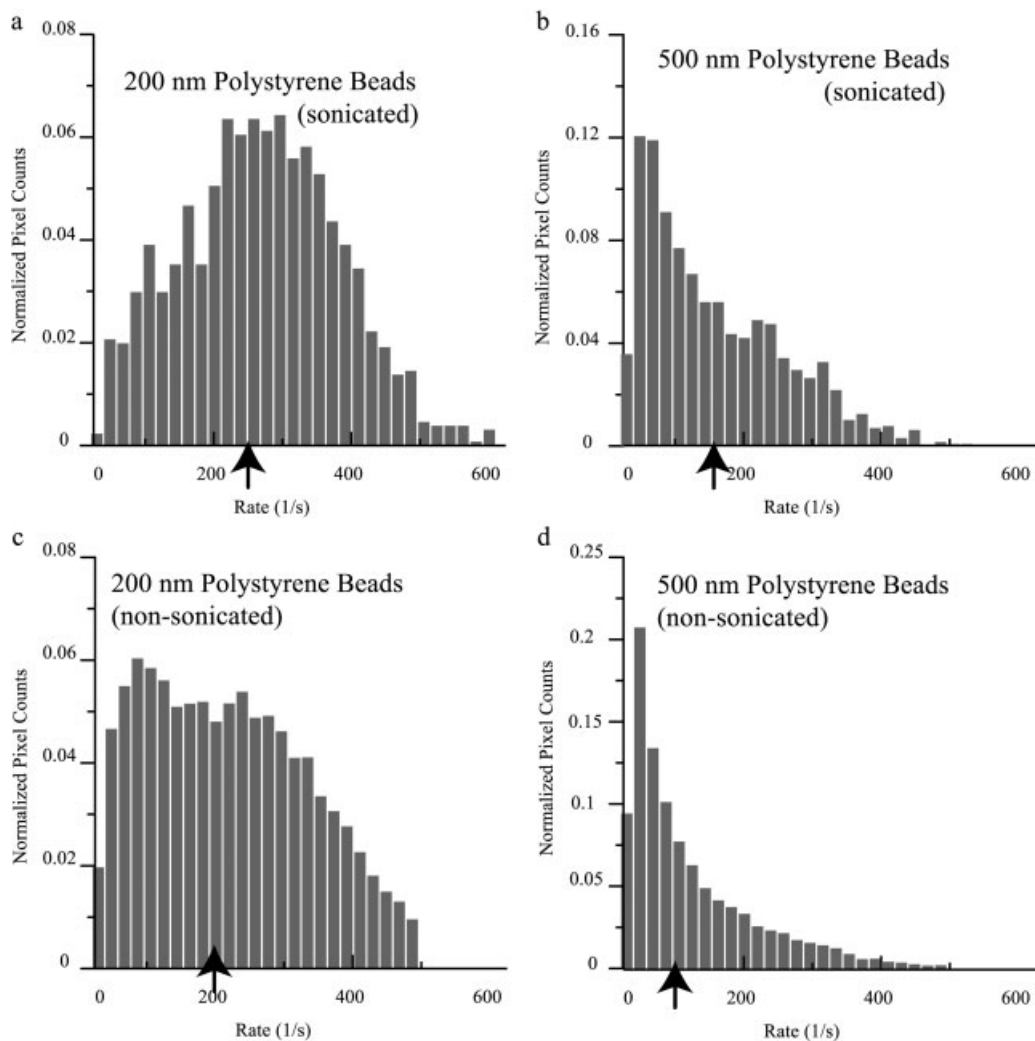

In principle, the amplitude of the normalized autocorrelation function for an entirely mobile DLSM sample should be unity. But, as can be seen from Fig. 10.9(b), the experimental value is  $\sim 0.6$ . This decreased amplitude is probably due to a fixed scattering background and a consequent “mobile fraction” that is less than unity.

## 10.5.3

**Polystyrene Beads: Number Fluctuations**

Number fluctuations without contamination by phase interference effects could be autocorrelated from streaked images of the fluorescence from labeled polystyrene beads. The average value of the normalized variance for all of the temporal autocorrelation functions from number fluctuations was only  $10^{-3}$ . Thus, we conclude that the fluctuations observed at 632 nm were due almost exclusively to dynamic light scattering phase fluctuations rather than number fluctuations of particles dif-

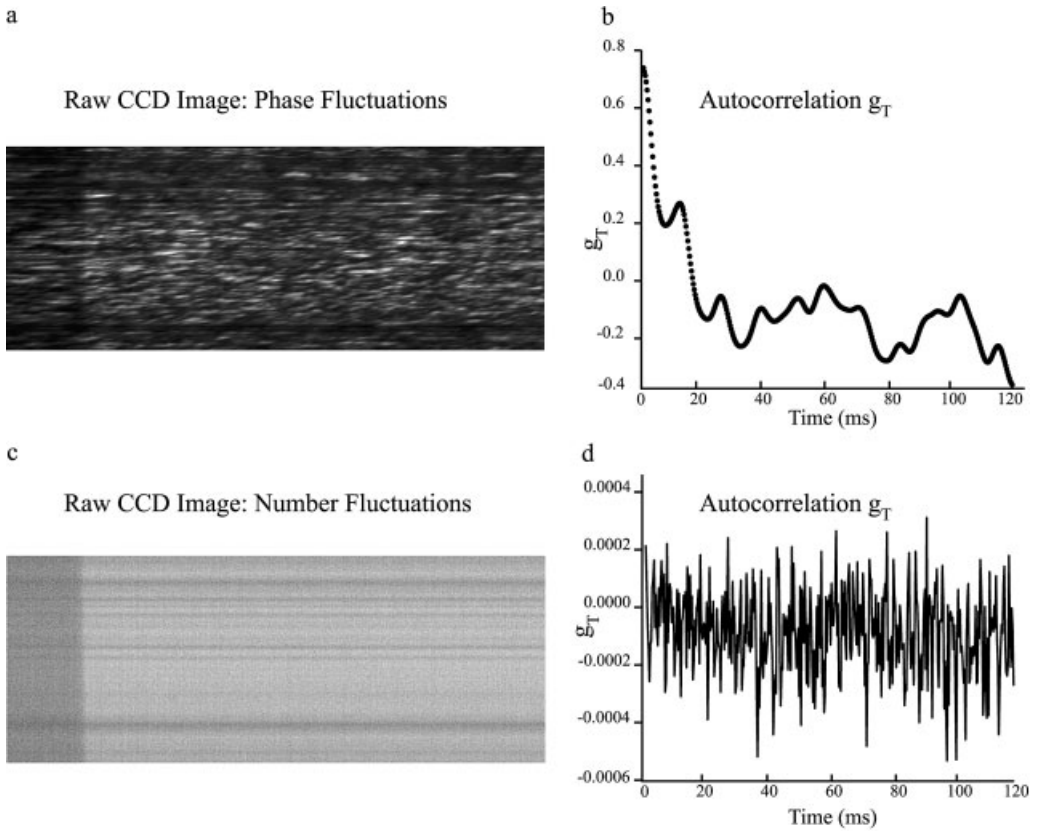

**Fig. 10.8.** Histograms of the decay rates for the polystyrene beads. (a, c) 200 nm beads (sonicated and unsonicated). (b, d) 500 nm beads (sonicated and unsonicated). Arrows indicate mean values.

**Tab. 10.2.** Mean diffusion coefficients of polystyrene beads (average experimentally measured diffusion coefficients for 200 and 500 nm beads along with expected values from hydrodynamic theory).

<i>Diffusion coefficient</i> ( $10^{-8} \text{ cm}^2 \text{ s}^{-1}$ ) $\pm$ S.E.	<i>200 nm sonicated beads</i> ( $2.1 \times 10^{12} \text{ particles mL}^{-1}$ )	<i>500 nm sonicated beads</i> ( $1.4 \times 10^{11} \text{ particles mL}^{-1}$ )
Experimental	$1.35 \pm 0.03$	$0.875 \pm 0.03$
Theoretical	2.23	8.76

**Fig. 10.9.** CCD camera images and their corresponding autocorrelation functions of intensity fluctuations from 200 nm carboxylate-modified dark red FluoSpheres. (a) Raw streak image from dynamic light scattering measurement. (b) Normalized temporal autocorrelation function for panel a, calculated using Eq. (43). The large variations in intensity across the raw image imply a large amplitude in the temporal autocorrelation function. (c) Image from the number fluctuation experiment

is taken from the same sample as in panel a, but with a long pass 650 nm filter placed in the emission path. The image is very smooth, indicating small intensity variations. (d) Normalized temporal autocorrelation function for panel c. The function has a very small amplitude, implying that the contribution from particle number variations to the DLSM intensity fluctuations seen in panels a and b is very small.

fusing in and out of the volume observed by a pixel. The intensity fluctuations resulting from the fluorescence emission were so small that decay rates could not be reliably extracted from the temporal autocorrelations.

#### 10.5.4

##### Polystyrene Beads: Spatial Autocorrelation

Figure 10.10 shows the spatial autocorrelation function obtained for the 200 nm sonicated polystyrene beads along with the theoretically predicted one [Eq. (48)].

**Fig. 10.10.** Normalized spatial autocorrelation function for the 200 nm polystyrene beads. The experimentally obtained spatial autocorrelation function is depicted by black dots connected by dashed lines. The theoretical spatial autocorrelation function [based on Eq. (48)] is depicted by the solid line. The characteristic decay distance of the spatial autocorrelation function (where  $\mu = 1$ ) is marked for both the experimentally and theoretically obtained curves.

The amplitude at which the characteristic distance is defined ( $\mu = 1$ ) is indicated, from which the spatial correlation distance  $l_c$  can be derived [Eq. (50)]. The spatial correlation distance obtained from the theoretical curve is approximately  $l_c = 1.27$  pixels, which corresponds to  $8 \mu\text{m}$ , whereas the value calculated from the experimentally obtained spatial autocorrelation function is  $l_c = 1.1$  pixels, which corresponds to  $6.93 \mu\text{m}$ . Thus, the experimentally obtained value of the spatial correlation distance agrees well with the theoretically derived one. In addition, since the size of the CCD camera pixel is  $6.3 \mu\text{m}$ , each pixel will observe intensity fluctuations from approximately one spatial correlation area.

### 10.5.5

#### Polystyrene Beads: Mobile Fractions

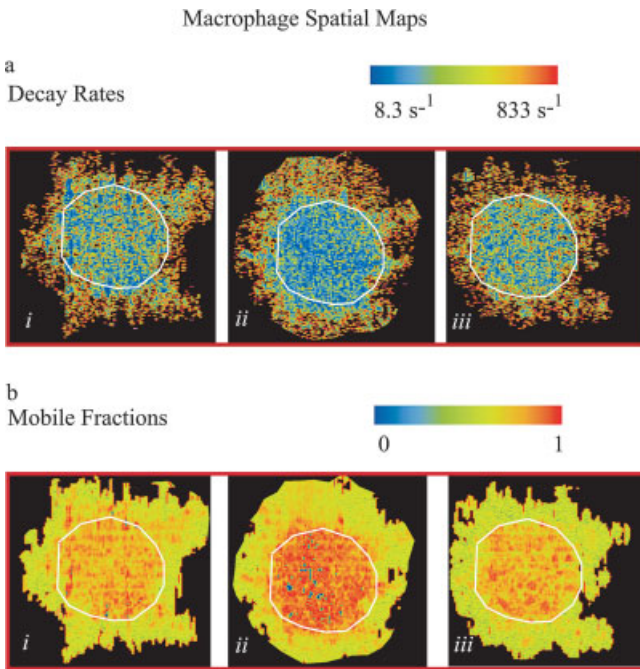

Mobile fractions were calculated using Eq. (56). Figure 10.7(c) shows the spatial map of the mobile fractions obtained from the dynamic light scattering intensity

fluctuation measurements for the 200 and 500 nm beads. The 200 nm beads show a higher overall relative mobility than the 500 nm beads. This is because the concentration of the 200 nm beads is an order of magnitude larger than that of the 500 nm beads, which caused the mean light scattering intensity to be larger from the smaller beads. Thus, scattering from the smaller beads constituted a larger fraction of the total scattering in the experimental system, which includes background scattering from the microcapillary tubes and optics.

### 10.5.6

#### Living Macrophage Cells: Temporal Autocorrelation

DLSM experiments were performed on a total of 21 macrophage cells as follows: (a) 10 min after the cell was removed from the incubator and washed with Ringers

**Fig. 10.11.** Experimental spatial maps of a macrophage cell. For both panels a and b, each map depicts one of the three treatments on the cell: (i) Cell was flushed with 1 mL of Ringer's buffer (RB); (ii) cell was flushed with 1 mL of an acetate-containing RB (ARB) and incubated for 20 min; (iii) the ARB was washed out with RB and the cell was incubated for 20 min. (a) Spatial map of the temporal autocorrelation intensity fluctuation decay

rates. There is a noticeable decrease in motility of the acetate-treated cell. Washing out the acetate reverses this attenuated motility, restoring the cell to its initial state. Black pixels occur where the scattering intensity was too low to obtain useful data. (b) Spatial map of the mobile fractions  $\beta$  of macrophages. The mobile fraction data are plotted on a logarithmic scale. Most of the motion occurs in the central interior portion of the cells.

buffer; (b) 20 min after the acetate-containing Ringers buffer was introduced; and (c) 20 min after Ringers buffer with acetate was replaced with plain Ringers buffer to remove the acetate. Figure 10.11(a) shows pseudocolor spatial maps of the fluctuation decay rates created for the three conditions for a typical cell.

A white overlay line divides the cell image into outer and inner regions. In all three maps, the outer region of the cell shows faster motility than the inner region. Additionally, the center of the cell shows a noticeable decrease in the macrophage motility when acetate is added. The original motility seems to be restored when acetate is washed out. The black areas within the periphery of the cell region represent the locations at which the decay rates could not be reliably calculated because the scattered intensity was too low.

#### 10.5.7

##### **Living Macrophage Cells: Mobile Fraction**

Figure 10.11(b) shows the spatial maps of the mobile fractions on a log scale for the three treatments described above. Overall, the mobile fraction is quite low, especially in the outer region where the mean scattering intensity from the cell is a smaller fraction of the background scattering.

## 10.6

### **Discussion**

We have demonstrated that the dynamic light scattering imaging technique presented here is a viable method to observe and image small relative motions among nearby scattering centers in a microscope [20, 21]. These relative motions, visualized as intensity fluctuations, are detected in both non-biological and biological systems using a slow scan CCD camera. Fluctuations as fast as  $250 \text{ s}^{-1}$  were measured and relative motions between scattering centers on the order of a fraction of a wavelength were spatially mapped. The technique provides information about the relative motion of the scattering centers (rather than their relative location as with conventional microscopy) without sacrificing optical resolution.

#### 10.6.1

##### **Polystyrene Beads**

The experimental diffusion coefficients were relatively correct for the ratio of 200 vs. 500 nm polystyrene beads with the values for the 200 nm beads slower than expected. However, both were somewhat lower than theoretically predicted from hydrodynamics. This discrepancy can be explained by the fact that aggregates were most likely present in both samples, forming particles with larger effective sizes and therefore lowering their diffusion rate. Sonication of the bead suspensions increased the diffusion rates towards the theoretical value.

Because of the high concentration of beads in these samples, we would expect that number fluctuations should be small, as was experimentally confirmed. Also, because the relevant characteristic volume for number fluctuations (i.e., the effective volume observed by a pixel) is typically larger than the characteristic volume leading to phase fluctuations, number fluctuations are likely to be slower than phase fluctuations, as was also experimentally confirmed. Number fluctuations do not contribute much to the DLSM streaked images observed here.

Although not relevant to our experimental conditions, extreme cases could show interesting number fluctuation effects, according to the theory. In the limit of one scattering center, the only contribution to the intensity autocorrelation function will arise entirely from number fluctuations and so there will not be a contribution due to phase fluctuations. If the number fluctuations occur on a faster time scale than the phase fluctuations, there would be an appreciable decay of the autocorrelation function before a phase fluctuation took place. Thus, only if the phase fluctuations occur on a faster time scale than the number fluctuations will any phase fluctuations be detected.

The spread in diffusion rates is in part due to the noisiness of the temporal autocorrelation function. This effect arises from the fact that the temporal autocorrelation function is computed over a relatively small number of coherence times. The coherence time of the intensity fluctuations for the 200 nm polystyrene beads ( $\tau_c$ ) was approximately 3 ms and the intensity fluctuations were collected over a 240 ms period ( $T$ , the time duration of a streak in the CCD record). The signal-to-noise in the autocorrelation function is thereby expected to be

$$(T/\tau_c)^{1/2} \approx 9$$

As an alternative approach to estimating the spread of autocorrelation decay rates arising solely from a finite experimental time  $T$ , we calculated the temporal autocorrelation function from an ensemble of numerically generated “telegraph” signals, over the same number of coherence times as in the experiment. A telegraph signal has transitions between +1 and -1 at completely uncorrelated times (but at a certain average rate) and has an exponentially decaying autocorrelation function [22].

Figure 10.12(a) shows the experimentally obtained distribution of decay rates for 200 nm polystyrene beads. Figure 10.12(b) is the distribution of decay rates from the autocorrelation function of the telegraph signal. The mean decay rate of the telegraph signal was scaled to match that of the experimental data. Comparison of the two confirms that much of the spread of experimental characteristic rates on the beads is due to an insufficient number of correlation times in  $T$ . However, the width of the distribution of the decay rates for the beads is still somewhat wider than that for the noise signal and it is skewed towards the slower decay rates. This indicates that the width of the distribution for the beads is in due in part to spatial heterogeneity of different sized aggregates in the 240 ms time scale of the experiments.

The theoretical calculation indicates that the amplitude of the normalized tem-

**Fig. 10.12.** Comparison of distribution of decay rates for the 200 nm polystyrene beads and for a numerically generated telegraph signal with the same average rate and number of coherence times for calculation. (a) Normalized intensity fluctuation decay rates for 200 nm polystyrene beads. (b) Normalized intensity fluctuation decay rates for the telegraph signal. The finite number of coherence times results in a spread in the intensity fluctuation decay rates for both the experimental data as well as the numerically generated noise signal.

poral autocorrelation function should be unity. However, the amplitude of the experimentally obtained autocorrelation function for polystyrene beads is significantly less. This amplitude reduction could arise for two reasons. First, there is a large background of immobile scattering emanating from the collection optics. This background does not contribute to the intensity fluctuation decay of the autocorrelation function, but does increase in the overall light intensity. Secondly, since the spatial correlation distance covered a region less than two pixels in size, not all the parts of a single pixel will see the same intensity, thereby decreasing the pixel-to-pixel variance of the recorded intensities.

The “proof-of-concept” experiments were performed on 200 and 500 nm polystyrene beads. However, notably, this technique is limited not by the size of the scattering center, but by the “scattering power”. If the scattering center is large but has the same index of refraction as the surrounding environment it will not be detected, but if the scattering center is extremely small but index mismatched to the surrounding environment it will be detected. If, in a microscope resolution region, the scattering center emits less light than the Rayleigh scattering of the water, it will not produce much of a DLSM effect.

### 10.6.2

#### Macrophages

Macrophages are immune system cells well known for their high motility. They are found in all tissues and in the blood. They are scavenger cells, acting as the first line of defense in recognizing and killing foreign microorganisms through phago-

cytosis [23]. During phagocytosis, the macrophage invaginates foreign material and breaks it down enzymatically.

Previous work on macrophages showed there are two distinct regions of the cell, a thin outer section and a thicker central section [24]. The DLSM spatial maps of the fluctuation decay rates of the imaged cells confirm this finding. Those maps indicate that the outer zone has faster fluctuations than the center of the cell. This result is particularly interesting because previous experiments from this lab, using polarized total internal reflection fluorescence microscopy, [25] showed the plasma membrane in the outer zone to be rather flat and inert whereas the plasma membrane of the central zone was quite bumpy and dynamic. Evidently, other intracellular scattering centers in that outer zone are moving rapidly.

Treatment with acetate-containing buffer reduced the rate of motion of scattering centers in the interior zone (Fig. 10.11). Previous studies have shown that exposure of the macrophage to acetate-containing Ringer's buffer acidifies the cell and causes the lysosomes concentrated in the center of the cell to migrate radially outward to the cell edge [26]. This causes certain regions within the cell to switch from high activity to quiescence.

The studies on macrophages here show that DLSM is feasible on living cells. It essentially provides contrast in unlabeled cells based on rapid rates of submicroscopic motion rather than static refractive index gradients. However, background scattering can be significant and can make some of the least-scattering regions of a cell unusable for DLSM.

### 10.6.3

#### **Improvements for DLSM**

Further improvements in DLSM should aim to increase its spatial and chemical specificity. Our current optical setup works in an epi-illumination mode. Since the depth of the focal region is approximately  $2\ \mu\text{m}$ , the entire thickness of the cell is illuminated. Therefore, the scattered light intensity comes from multiple layers of scattering centers in the region of illumination. To begin to understand the various physical processes contributing to the intracellular motion causing the phase fluctuations, the illuminated region should be better defined to a thin optical slice, such as obtainable with total internal reflection (TIR) illumination [27]. With TIR illumination, the cell membrane and submembrane structure would be the major component in the region of illumination.

Another improvement to DLSM would be to increase its chemical specificity while maintaining the coherent scattering necessary for intensity phase fluctuations. One possibility is to combine DLSM with second harmonic generation imaging microscopy (SHIM) [28]. Second harmonic generation (SHG) is a second-order optical process such that the monochromatically scattered light is coherent but is double the frequency of the incident light. SHG signals can only arise from scattering centers lacking a center of symmetry. Cell membranes and many highly ordered structural proteins intrinsically lack this symmetry center and can be imaged via SHIM. In addition, chemical dyes are available having the required second-

order optical nonlinearities. The dyes can be specifically bound to target organelles and have been used to increase the SHG resolution and contrast within the membrane of the cell [29].

Another technique that could be combined with DLSM is a modification of resonance light scattering microscopy (RLS) [30, 31]. RLS in its current form produces highly monochromatic scattered light from gold particles in suspension illuminated by a xenon lamp, with the scattered color dependent upon the size of the particles. In an application to cell biology, these gold particles could be biochemically modified to specifically label organelles within a cell. The gold particles have a high light-scattering power and are unbleachable. Illumination with a wavelength-tunable laser tuned to the resonance of the gold particles would produce coherent scattered light emanating mainly from the gold particles. Phase intensity fluctuations would occur between neighboring gold particles; these fluctuations could then be autocorrelated to measure relative motions among specifically constituents in the cell.

### Acknowledgments

We thank Drs Kenneth Christensen, Adam Hoppe, and Joel Swanson for macrophage cell culturing assistance.

# X-ray Scattering Techniques for Characterization of Nanosystems in Lifesciences

*Cheng K. Saw*

### 11.1 Introduction

This chapter aims to provide the basics of using X-ray diffraction techniques to obtain information on the structure and morphology of nanosystems, and also to point out some of its strengths and weaknesses when compared to other characterization techniques. X-ray scattering techniques cover a wide range of density domains, from a tenth to a thousandth of an angstrom. Essentially, this covers a whole range of condensed matter, including the structure and morphology of nanosystems, which is particularly useful for examining nanostructures in the life-sciences. This range of domain size requires both wide-angle X-ray scattering (WAXS) and small-angle X-ray scattering (SAXS) techniques. Roughly, WAXS covers from 2 nm down, and SAXS covers from 0.5 to 100 nm and possibly 1000 nm for a finely tuned instrument. A brief theoretical description of both WAXS and SAXS is given in this chapter. WAXS is a powerful technique in providing information on the crystallographic structure, or lack of structure, atomic positions and sizes in a unit cell and, to some extent, chemical compositions and chemical stoichiometry. Examples of such experiments will also be given. To describe the technique of X-ray scattering, some historical and theoretical background will be given in the hope of making this subject both interesting and simple.

Over the past 10 to 20 years, the major development in this scattering technique is in the instrumentation. Better and faster detectors have been developed. Solid-state detectors and position sensitive detectors clearly play an important role in energy discrimination and high-speed data acquisition. The X-ray beams are conditioned with the latest technology in monochromators, mirrors and multi-layers and they can also be made to focus or collimate to the desired probe sizes without significant reduction in X-ray flux. X-ray optics have been improved drastically. Improvements in data quality have also been demonstrated. The basic theory regarding X-ray diffraction and interactions of X-ray with matter developed in the early nineteenth hundreds remains. The arrival of synchrotron radiation for materials probe afforded a quantum leap in all aspects of diffraction capabilities (Section 11.13). Some examples are given in the later part of this chapter.

By and large, X-ray diffraction capability is a major, and necessary, component in any modern characterization laboratory. In most cases, several diffraction instruments are needed for numerous reasons, e.g., high through-put, different X-ray optics for high resolution requirements, different incident energies may be needed, different scan types and so on. Some of these will be more apparent in the later part of this chapter. In general, X-ray scattering is the quickest and cheapest method to obtain a great deal of structural information. For example, identification of crystalline phases, phase impurities, additional disordered phases and the quality of the phases as well as lack of phases. It is also non-destructive and requires very little, or no, major sample preparation. In today's technological world, structural information is required on very different sample types, e.g., thin films, multilayers, very small amounts of samples, specific crystalline orientations, residual stresses and so on. X-ray diffraction has also played an important part in protein crystallography where high quality data with an enormous number reflections are needed for analysis to determine the structure of the protein. Clearly, with such sophisticated demands the experimental setups have to be somewhat unique for each investigation. This chapter also points out the experimental difficulties and ways to compensate and optimize the scattering properties when carrying out these types of experiments on different nanosystems. These small and unique changes in the set-up determine the quality of data and, thus, the success of the experiment.

X-ray scattering techniques also play a major role in obtaining information on both the structure and morphology of materials in nanosystems in the lifesciences. Clearly, the understanding of structure and morphology of materials is a basic requirement for one to design and generate materials with particular desired functions. Other characterization techniques, well established over the years for materials science, also play major roles in characterizing nanosystems for lifescience applications.

Experiments requiring higher resolution or sensitivity can be carried out using more sophisticated national facilities, like the synchrotron and neutron sources at several major research facilities. In fact, the development of synchrotron sources for characterization purposes represents a major advancement for X-ray scattering techniques. Experiments that are either not possible or very difficult to perform using in-house sources can now be easily carried out on one of the beamlines at a synchrotron source. It has greatly enhanced X-ray scattering capabilities. Most national facilities are open to general users around the world. Synchrotron radiations are also X-rays. In this case, the X-rays are highly collimated, polarized, tunable and also have enormous brightness. Many new techniques, e.g., absorption spectroscopy, anomalous scattering, elastic scattering and diffraction at different energies and high spatial resolution techniques (microprobes), to name a few, are being developed. To enhance atomic speciation, anomalous WAXS and SAXS have also been developed and are often used in advanced laboratories. This arises from the tunability of the X-ray to the desired energies close to the absorption edges to enhance the scattering power by taking advantage of anomalous scattering factors. These techniques are covered elsewhere in this volume (e.g. Chapter 8).

In general, nanostructures are crystalline structures with very small crystallite

sizes in the nanometer range. However, they can also be disordered in the angstrom domains but highly ordered in the nanometer range. If the crystallites are small enough, the diffraction peaks are essentially very broad. As the size decreases, the material goes from paracrystalline to, eventually, the amorphous state. This chapter will describe the concept of small crystallite size, paracrystallinity and, briefly, “structures” in an amorphous state.

Nanostructures in the application of nanostructure technology, very often, are formed with some kind of coating around each particle to prevent agglomeration or the fusing of the particles to form a bigger crystallite size. Characterization of this size domain is generally well suited and carried out using the SAXS technique. SAXS is also used to examine morphology and molecular ordering in lifesciences, particularly with proteins, micelles and lipids. Essentially, SAXS is used in two major cases: dilute and highly correlating systems. A dilute system refers to non-interacting nanostructure entities, e.g., proteins and micelles in solutions. Highly correlating systems, for example, can be lipids and collagen where the overall molecules are highly ordered. In other situations, particularly polymer chains, mass fractal analysis is required. This will not be discussed here. Readers are encouraged to examine foundation books listed in the reference section. Several fundamental X-ray diffraction books used in formulating this chapter are listed in the reference section [1–13].

## 11.2

### **Brief Historical Background and Unique Properties**

In 1895, Wilhelm Konrad Röntgen, while experimenting with electric discharges in a tube noted that a barium platinocyanide treated paper lit up as a result of fluorescence induced by unknown so-called X-rays. The X-rays originated from the tube and showed great penetration power, which is inversely proportional to the atomic number. The earliest application of X-ray was in radiography in surgical operations, which clearly revolutionized the medical field. For this discovery, Röntgen won the Nobel Prize in 1901. Another prominent discovery was by C. G. Barkla, who noted that there is a homogeneous energy component in the emitted X-ray operating under certain conditions and is characteristic of the target elements. He also noted that there are two main groups of emission lines, known as K and L lines, which clearly play a major role in Niels Bohr atomic model. For this he won the Nobel Prize of 1917. As the theory developed, X-rays were found to be electromagnetic radiation with a wavelength in the range of atomic spacing. Friedrich and Knipping first recorded the diffraction diagram of a copper sulfate crystal. With this information Laue formulated the theory of diffraction, which won him the Nobel Prize in 1914.

W. L. Bragg explained and correlated the X-ray spots with the atomic spacing and suggested that the diffraction of X-rays is caused by planes of atoms arranged in a lattice. Together with his son, W. H. Bragg, he built the first X-ray spectrometer and carefully recorded the quantitative diffracted intensity and angular positions.

Fig. 11.1. Diagram showing the constructive interference of monochromatic X-rays.

As a result, the concept of diffraction was described and Bragg's law was introduced. These findings won them the Nobel Prize of 1915.

This phenomenon is explained by supposing that the wave property of X-rays is scattered by individual atoms, spherically, in the lattice (Fig. 11.1). The scattered waves then interfere either constructively or destructively at some distance away in space. Therefore, it is a phase issue. For the waves to add up constructively, the Bragg condition has to be satisfied, i.e.,

$$n\lambda = 2d \sin \theta \quad (1)$$

where  $n$  is the order of reflection,  $\lambda$  is the incident wavelength,  $\theta$  is the observed angle and  $d$  is the interatomic spacings. The right-hand side of Eq. (1) is essentially the difference in path lengths when the waves are scattered at positions  $O$  and  $O'$  (see Fig. 11.1). These  $d$ -spacings are generated by the atomic locations of positions in lattices. As a result, many crystal structures were found, lattice spacings were accurately measured and, also, characteristic X-rays from different elements were found and better defined. This is indeed a big advance in materials science and fundamental atomic physics.

Energy is often used to describe the X-ray, instead of wavelength, and is related by

$$E(\text{keV}) = h\nu = \frac{hc}{\lambda(\text{Å})} \quad (2)$$

where  $hc = 12.4$ ;  $h$  is Planck's constant and  $c$  is the speed of light.

### 11.3 Scattering of X-rays

To see how scattering theory developed, it is important to start by describing the scattering of X-rays by a charged particle, say an electron. This result can then be carried over to represent the scattering intensity of an assembly of electrons, say in an atom, and then to a larger volume of mass. Because matter is essentially surrounded by electrons, X-ray scattering is accomplished by X-ray–electron interac-

tions. Basically, there are two major components of scattered X-rays, coherent and incoherent, assuming monochromatic incident X-ray beam. Coherent refers to scattered X-rays that have the same wavelength (energy) as the incident X-rays. Incoherent refers to those X-rays that change wavelength (energy), implying that the incident X-rays imparted part of their energy to the charged particle. The incoherent component (also referred to as inelastic) is a slowly varying function over the scattering angles. The coherent component, which eventually interacts via diffraction, is the elastic component, and will be considered in this chapter.

Classically, an X-ray is described as a wave and is represented by the electric and magnetic field components. The wave is then incident on a charged electron, is then modified, either coherently or incoherently, and is then spherically scattered. The X-ray intensity is proportional to the square of the amplitude. The intensity of X-ray scattering by a charged particle is given by the classic Thomson formula [14],

$$I_e = I_o \frac{e^4}{m^2 c^4 R^2} \left( \frac{1 + \cos^2 2\theta}{2} \right) \quad (3)$$

where  $e$  is the electron charge,  $m$  is the mass of the electron,  $c$  is the velocity of light, and  $R$  is the distance between the observer or detector and the electron. The component in parenthesis is referred to as polarization factor. As Warren [10] has pointed out, the component to the left is the scaling number of the order of  $10^{-26}$  for 1 electron; however, even in milligram amounts of sample there are  $10^{20}$  electrons. The scattering by an individual atom with atomic number  $Z$  can be written as the summation of individual electron scattering.

This is not totally correct, since the electrons are not located at a point. There is an electronic distribution function around an atom. Hence, the structure factor  $f$  is introduced into the scattering equation. This factor is an integral of the electronic density distribution function, generally derived by empirical means. Without going into details of the derivation, the structure factor is given by Eq. (4), where  $k = (4\pi \sin \theta)/\lambda$ ,  $\lambda$  is the X-ray wavelength, and  $\rho(r)$  is the electronic density distribution.

$$f = \frac{4\pi}{e} \int_0^\infty r^2 \rho(r) \frac{\sin kr}{kr} dr \quad (4)$$

Thus,  $f$  is proportional to the atomic number  $Z$  at an angle of  $0^\circ$  and diminishes at higher angles. Notably, Eq. (4) is valid only if the distribution is truly spherical and the energy of the incident X-ray is not close to the absorption edge. Due to the anharmonicity of the electron distribution function and the wavelengths near the absorption edges, the structure factor is more complicated and has two additional modifying terms,

$$f = f_o + \Delta f' + i\Delta f'' \quad (5)$$

where  $f'$  and  $f''$  are, respectively, the real and imaginary components, often re-

ferred to as the anomalous dispersion. Derivation of these factors will not be discussed here. These values are also tabulated in the *International Table of Crystallography* [15].

#### 11.4 Crystallography

As the result of the development of X-ray diffraction and the complexity of Bragg's planes, a method of defining the X-ray peak positions and intensities is need. This is essentially accomplished by mathematical development through space groups. Again, the results of this work have been accurately tabulated, in the four-volume series *International Table for X-ray Crystallography*, a widely used reference. More detailed descriptions of crystallography appear in many fundamental X-ray diffraction books.

The crystallographic planes generated by lattices defined by the space groups are correlated to the X-ray scattering peaks. Hence, it is important to know where the atoms are located and what kind of planes they generate, in order to calculate the peak positions. Crystallography describes the atomic arrangements in a lattice, which are defined by atomic translations and rotations forming some kind of periodic arrangements. The smallest unique atomic arrangement used to generate the crystal by rotations and translations is called the unit cell. Unit cell parameters are defined by three axes and three angles defined by the axes. There are seven forms of large subgroups of crystallographic systems and 14 unique Bravais lattices for the atoms to arrange themselves in. The seven systems are triclinic, monoclinic, orthorhombic, tetragonal, hexagonal, rhombohedral and cubic. Essentially, they are defined by the relationship of the lattice parameters of three axes  $a$ ,  $b$  and  $c$ , and three axial angles  $\alpha$ ,  $\beta$  and  $\gamma$  defined by the axes. Table 11.1 lists the crystal structures and characteristic parameters of the axes and angles.

With the atoms placed in the unit cell positions, 14 unique systems can then be described. In the cubic system, there are three lattices, namely simple, body-centered, and face-centered cubic. There are two tetragonal structures (simple and body-centered), four orthorhombic structures (simple, body-centered, end-centered

Tab. 11.1. Crystal systems and their axes [16].

System	Axes	Axial angle
Triclinic	$a \neq b \neq c$	$\alpha \neq \beta \neq \gamma \neq 90^\circ$
Monoclinic	$a \neq b \neq c$	$\alpha = \gamma = 90^\circ, \beta \neq 90^\circ$
Orthorhombic	$a \neq b \neq c$	$\alpha = \beta = \gamma = 90^\circ$
Tetragonal	$a = b \neq c$	$\alpha = \beta = \gamma = 90^\circ$
Hexagonal	$a = b \neq c$	$\alpha = \beta = 90^\circ, \gamma = 120^\circ$
Rhombohedral	$a = b = c$	$\alpha = \beta = \gamma \neq 90^\circ$
Cubic	$a = b = c$	$\alpha = \beta = \gamma = 90^\circ$

and face-centered), and two monoclinic (simple and end-centered). Additional atoms can be placed in each of the unit cells; however, these positions are simple equivalent positions.

These lattices generally have a unique set of  $d$ -spacings; hence, in X-ray diffraction experiments, these spacings are reflected in the intensity of the scattered X-ray at specific Bragg angles by these unique planes. Eventually, X-ray diffraction from crystals progressed to such a level that a simpler way of identifying these planes had to be developed. This is accomplished by so-called Miller indices ( $hkl$ ). X-ray peak positions can be correlated to the type of lattices or space group.

## 11.5

### Scattering from a Powder Sample

The most common X-ray diffraction experiments are carried out on powder or bulk material with random crystalline orientation. Single-crystal diffraction experiments are also performed quite often; however, they have to be carried out using a four-circle goniometer. When the unit cell is complex with a large number of atoms, a single crystal experiment may be the only way to extract the desired structural information. Single-crystal experiments are generally far more complicated and difficult to perform without significant experience. Also, when the samples are prepared they are polycrystalline. Therefore, the selection of a single homogeneous crystal is often very tedious and difficult.

The total intensity from a powder pattern for a particular ( $hkl$ ) at the angle  $2\theta$  is generally given by the scattering power [10],

$$P = I_o \left( \frac{e^4}{m^2 c^4} \right) \frac{V \lambda^3 m |F_{hkl}|^2}{4v_a^2} \left( \frac{1 + \cos^2 2\theta}{2 \sin \theta} \right) \quad (6)$$

where  $I_o$  is the intensity of the primary beam,  $e$ ,  $m$ ,  $c$ ,  $\lambda$  and  $\theta$  take their usual meaning,  $V$  is the effective volume of the crystalline material in the powder sample,  $m$  is the multiplicity for that reflection and  $|F_{hkl}|^2$  is the structure factor squared. The term in brackets on the right is known as the Lorentz polarization factor. For an actual experiment using a diffractometer, the scattering power is divided per unit length of the diffraction circle.

In an actual experiment, Compton scattering needs to be subtracted, a temperature factor needs to be added and the scattering power per unit detection length calculated. In most cases, with slits, the sample-detector distance is kept the same. Then, the scattering power is given by Eq. (7),

$$P = Km_{hkl}|F_{hkl}|^2(\text{LP})_{hkl} \quad (7)$$

where  $K$  is a constant with intensity proportional to the multiplicity  $m_{hkl}$ , structure factor square  $|F_{hkl}|^2$  and Lorentz polarization factor  $(\text{LP})_{hkl}$ . The structure factor is essentially,

Fig. 11.2. Simulated XRD pattern for two phases of titanium oxide.

$$F_{hkl} = \sum_n f_n e^{2\pi i(hx_n + hy_n + lz_n)} \quad (8)$$

where  $f_n$  is the scattering factor, which is directly dependent on the atomic number, and  $e^{2\pi i(hx_n + hy_n + lz_n)}$  is the form factor, which has the sinusoidal property and turns the intensity on or off. There are some exceptions to this rule, which will be described below.

Figure 11.2 shows a typical diffraction pattern for a simulated pattern of two phases of titanium oxide; the major phase is anatase and the minor is rutile. Along with the plots are the reported peak intensities and positions from the ICDD database. Both phases are tetragonal, with different cell parameters. Thus, phases can be identified even for the same compound. Such results are common.

The structure factor as described in Eq. (8) is summed over all the atoms in the unit cell. For example, in the face-centered cubic (FCC) cell, for simplicity, there are four atoms, located at  $(0, 0, 0)$ ,  $(0, \frac{1}{2}, \frac{1}{2})$ ,  $(\frac{1}{2}, 0, \frac{1}{2})$  and  $(\frac{1}{2}, \frac{1}{2}, 0)$ . Eq. (8) will become,

$$F_{hkl} = [1 + e^{\pi i(h+k)} + e^{\pi i(h+l)} + e^{\pi i(k+l)}] \quad (9)$$

noting that  $e^{\pi im} = (-1)^m$  when  $m$  is an integer. Hence, it can be concluded that  $F_{hkl} = 4$  if the indices  $hkl$  are all odds or evens, and  $F_{hkl} = 0$  when the indices are mixed. Turning our attention to a body-centered cubic (BCC) structure, with two atoms  $(0, 0, 0)$  and  $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$  per unit cell. Eq. (8) becomes

$$F_{hkl} = [1 + e^{\pi i(h+k+l)}] \quad (10)$$

For  $F_{hkl}$  to be non-zero,  $(h + k + l)$  must be even. Hence, in FCC, reflections occur when  $hkl$  are all even or all odd, but with a BCC structure,  $(h + k + l)$  has to be even. For another FCC system, for example, the rock salt structure of sodium chloride, having four Na atoms and four Cl atoms per unit cell, the summation in Eq. (8) will result in slightly different  $F_{hkl}$ . Again, the simple rule applied here is that  $hkl$  have to be all evens or all odds. However, for the even case,  $F_{hkl}$  will be four times the sum of the scattering factors, whereas for the odd case  $F_{hkl}$  will be four times the difference of the scattering factors.

In the order-disordered structure of non-monatomic systems, it is possible to violate the above  $hkl$  requirements. This is because, even though the atomic positions are periodic, the atomic species may not be. The scattering factors do not completely cancel out, resulting in the observation of non-allowed peaks. A good example is the well-known  $\text{Cu}_3\text{Au}$  alloy [10]. Another system that needs to be considered is materials with antiphase domains where the atoms of different species have been interchanged, resulting in super structures and X-ray diffraction peaks not normally allowed.

## 11.6

### Scattering by Atomic Aggregates

In practice, not all matter in life has atoms arranged in nice lattices. The most interesting of these materials are those with complex atomic connectivity and having long atomic chains and no kind of ordering in the unit cell range. Examples of such systems are given Section 11.11, which describes the component of amorphous and highly disordered scatterings. It is often very difficult to distinguish between an amorphous structure, similar to liquid or gas, and an extremely small crystallite state, also sometimes referred as a “paracrystalline” state. For nanostructures, it may be important to determine whether the structure is amorphous or simply paracrystalline.

For time average scattering of non-interacting scatterers like mono-atomic gases, the scattering is given by the Debye equation,

$$I_{cu} = \sum_m \sum_n f_m f_n \frac{\sin kr_{mn}}{kr_{mn}} \quad (11)$$

where  $f_m, f_n$  are the scattering factors and  $r_{mn}$  are the interatomic distances. This equation is represented in Fig. 11.3 for  $r_{mn} = 1$ . This result clearly shows that even for a non-interacting system there is a ripple effect, which declines very rapidly on going from low to high scattering angles. For polyatomic systems, the result is the same except that the ripples are much broader.

For a condensed system like a liquid, the summation from Eq. (11) can be simplified to

Fig. 11.3. Intensity function of a monatomic gas.

$$I_{eu} = Nf^2 \left( 1 + \sum_m \frac{\sin kr_{mn}}{kr_{mn}} \right) \quad (12)$$

where the 1<sup>st</sup> term is the summation onto itself and the 2<sup>nd</sup> is the interacting term. This equation can then be converted into an integral [Eq. (13)].

$$I_{eu} = Nf^2 \left[ 1 + \int 4\pi\rho(r) \frac{\sin kr}{kr} dr \right] \quad (13)$$

Using algebraic manipulation and defining  $\rho(r) = [\rho(r) - \rho_0] + \rho_0$ , Eq. (13) becomes

$$k[i(k)] = 4\pi \int_0^\infty r[\rho(r) - \rho_0] \sin kr dr \quad (14)$$

Where  $i(k) = [I_{eu}/(N - f^2)]/f^2$ , for simplicity, and by using the theorem of Fourier's conversion we can write the radial distribution function as Eq. (15).

$$4\pi r^2 \rho(r) = 4\pi r^2 \rho_0 + \frac{2r}{\pi} \int_0^\infty k[i(k)] \sin kr dk \quad (15)$$

Eq. (15) provides a mean of converting the intensity function, which is in  $k$  space, into the radial distribution function in real space. In this formulation, the atoms are arranged in completely random fashion, giving an amorphous state. There are

broad diffraction peaks, which belong to the amorphous structure. Unlike crystals, there is no crystallographic ordering. Several papers have demonstrated on model calculations from ideal random atomic arrangements and then determined the radial distribution functions. The density distribution function can be converted into the intensity or interference distribution function and be compared to the experiments [17]. For binary systems, with atoms of A and B species, for example, the intensity function  $i(k)$  is a composite of the three partial functions  $i_{A-A}(k)$ ,  $i_{A-B}$  and  $i_{B-B}(k)$ . It is, therefore, impossible to extract each partial density distribution function without further experiments. Because of differences in scattering factors for X-ray, neutrons and electrons, partial distribution functions can be extracted using a combination of the three experiments. Anomalous scattering experiments can and have also been performed to extract the partial distribution functions. By using the dense random packed models and comparing the calculated  $i_{\text{total}}(k)$  with the experimental observations, the partial functions can be determined [18]. This is particularly useful in the understanding of atomic and chemical short-range order. Clearly, for ternary systems the functions get very complex.

## 11.7

### Crystallite Size and Paracrystallinity

Paracrystalline is a term used to describe small size ordering. Essentially, when the crystalline size is small enough, the resulting diffraction peaks will be broadened; however, the peak positions, if they can be deconvoluted, will fall precisely at the crystalline positions. Extraction of the crystallite size from the peak widths can never be accurate. Hence, in most cases crystallite size is generally an estimate. There are many factors that impact on the peak width, e.g., lattice distortions possibly due to the thermal vibrations, micro-strains, nature of the paracrystallinity. In general, to improve the precision of extracting the crystallite size, the instrumentation broadening component can be subtracted out by performing an exact experiment on a highly ordered structure like silicon powder. Instrument factors are due to misalignment, horizontal divergence (on a vertical goniometer), energy spread of the incident beam, interference of the  $\alpha_1$  and  $\alpha_2$  doublets, and also absorption of the X-rays by the sample. Notably, instrument broadening does not remain constant with all  $2\theta$  but, rather, increases with increasing angle. For this discussion, we are only concerned with determining the estimated crystallite size  $D_{hkl}$  of nanoparticles; it is generally given by the Scherrer equation,

$$D_{hkl} = \frac{K\lambda}{\beta \cos \theta_{hkl}} \quad (16)$$

where  $\beta$  is the peak broadening with the inherent instrument broadening subtracted out,  $\theta_{hkl}$  is the Bragg angle measured at  $hkl$  reflection.  $K$  is normally taken to be 0.9 or unity, depending on the crystal shapes. For details on different values of  $K$ , refer to Refs. [3, 4]. Figure 11.4 shows a plot of crystal size against X-ray peak

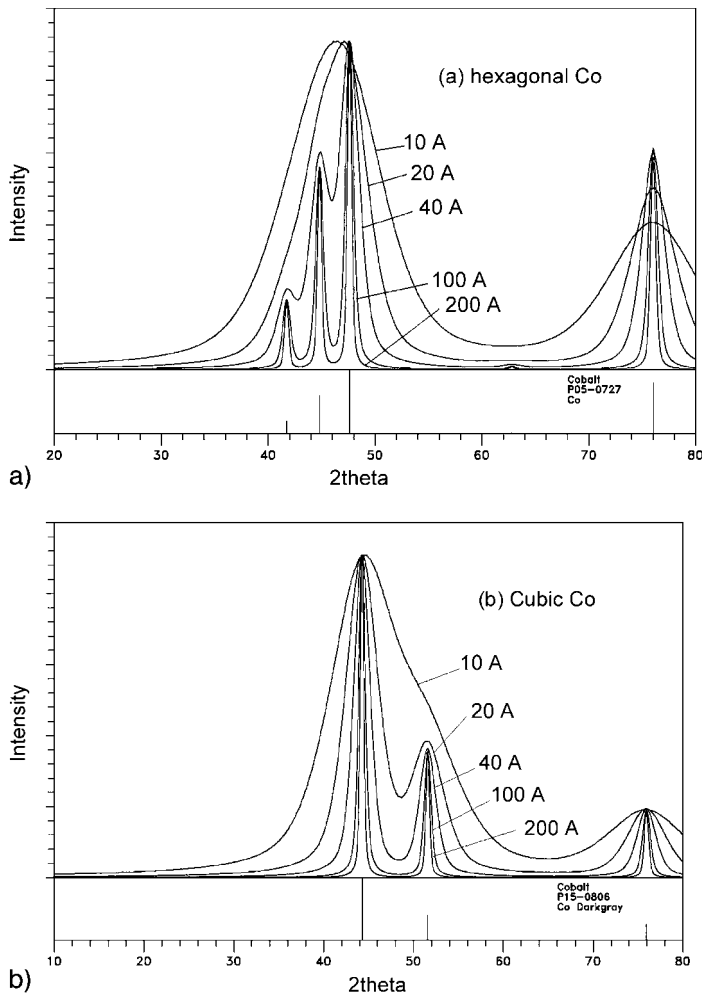

Fig. 11.4. Crystallite size versus FWHM.

broadening (fwhm – full-width at half-maximum) using Eq. (16) and assuming  $2\theta_{hkl} = 20^\circ$ , indicating the sensitivity in the measurement of small crystallites but not large ones. That is, a small change in fwhm translates into a large change in crystallite size in the small width region and a small change in crystallite size in the large width region. Very often, due to uncertainty in the measurements, “apparent crystallite size” is used.

As the crystallite size decreases, the peak broadens. Figure 11.5(a) and (b) compare the simulated diffraction spectra of crystalline hexagonal and cubic Co as a function of crystallite size, calculated using Jade software (MDI) for copper  $K_\alpha$  radiation. Multiple peaks are observed in the hexagonal structure for crystallite sizes of 40 Å and above. Below 40 Å, the three distinct peaks between 40 and 50° ( $2\theta$ ) diminish; hence it is not so clear whether the Co is either cubic or hexagonal phase. Moreover, without significant features, it can be concluded that the Co may be essentially amorphous. In this case, above 40 Å should not be a problem in making the distinction.

## 11.8 Production of X-rays

It is important to understand the production and properties of the X-ray used in the probe. X-rays are generated when electrons emitted from a tungsten filament are accelerated with sufficiently high energy onto a specific target. Typically, X-ray tube voltages are set at 20 to 50 keV. Interaction between the electrons and the electrons of the target materials results in a broad continuous X-ray spectrum. This radiation is often referred to as white radiation or the Bremsstrahlung (German for braking) radiation. This radiation is useful in the energy dispersive type of diffrac-

**Fig. 11.5.** Simulated spectra of crystalline hexagonal (a) and cubic (b) cobalt of different crystallite sizes.

tion experiment or a Laue experiment for single crystals but is a nuisance when monochromatic radiation is needed. The energies and intensity of the Bremsstrahlung radiation are affected by changing the tube voltage.

With sufficiently high kinetic energy, the electrons can kick out bound (orbital) electrons from the target. Subsequently, the decay of higher bound state electrons to the lower bound state results in the release of energy by emitting X-rays of characteristic energies and wavelengths, referred to as the K series, with  $K_{\alpha 1}$ ,  $K_{\alpha 2}$ ,  $K_{\beta 1}$  and  $K_{\beta 2}$  radiations. The population of the  $\alpha$  series is much greater than that of the  $\beta$  series. In general, most diffraction experiments are carried out using  $K_{\alpha}$  radiation, and  $K_{\beta}$  radiation is masked off by several techniques.

Less than 1% of the energy incident on the target is converted into X-rays. Hence, this is a very inefficient method. Most of the energy is dissipated as heat at the target. This heat needs to be removed immediately otherwise the targets can melt away. Generally, targets are designed to be on top of a highly thermal conducting heat sink, which is also under constant cooling. Because of this heating issue, there is a limiting power at which the X-ray generator can operate. This clearly depends on the tube design to achieve optimum cooling of the targets. Another target design, which allows for higher power setting, is the rotating anode X-ray generator. The target element is deposited on a highly thermal conducting rotating drum (usually made of copper), which is constantly cooled. The drum rotates at a very high speed, thus constantly changing the target position where the electrons hit. This design alleviates the heat dissipation problem and, therefore, a higher power setting can be achieved, resulting in higher X-ray flux. Unfortunately, maintaining vacuum conditions with a rotating shaft is a challenge.

## 11.9

### Absorption of X-rays

It is also important to understand the absorption behavior of X-rays through opaque materials. In general, X-rays are absorbed whenever they pass through matter. The equation governing this rule is simply

$$I = I_0 e^{-\mu\tau} \quad (17)$$

where  $I_0$  is the incident intensity,  $I$  is the transmitted intensity,  $\mu$  is the linear absorption coefficient ( $\text{cm}^{-1}$ ) and  $\tau$  is the thickness (cm) of the absorber. This is assuming that the X-ray energy is far from the absorption edge. For convenience, the mass absorption coefficients  $\mu/\rho$  ( $\text{cm}^2 \text{g}^{-1}$ ) are used and have been tabulated [15].

$$I = I_0 e^{-(\mu/\rho)\rho\tau} \quad (18)$$

Hence, the mass absorption coefficient is independent of density, and the overall absorption coefficient will just be the summation of the coefficients weighted according to the composition. For X-ray energies close to the absorption edges, the coefficient of absorption changes abruptly. This is directly related to the work function required to knock electrons from their original shells. The absorption coefficient can also be calculated empirically [15].

## 11.10

### Instrumentation: WAXS

Crystallographic structural information on nanoparticles has to be obtained using conventional X-ray diffraction techniques. In general, the most common diffraction

Fig. 11.6. Para-focusing Bragg-Brentano geometry.

experiments are carried out on bulk and powder samples. Again, most materials are polycrystalline. Occasionally, single-crystal experiments are very useful for obtaining detailed structural information, small lattice anisotropy and complex unit cell or cells with a large number of atoms. Single crystal experiments have to be carried out on a four-circle goniometer and will not be described here. Also, there are times when special scans are needed, e.g., to measure residual stress, pole figures, rocking curves etc. a four-circle X-ray goniometer is needed.

The most common and widely used X-ray powder diffraction technique is the Bragg-Brentano method. It is self-focusing and optimizes for intensity and resolution using the conventional in-house X-ray sources. Figure 11.6 shows the X-ray optics. Such diffractometers are essentially very versatile. The distance from the source F to the sample and from the sample to the receiving slit is always kept equal and constant at all scattering angles. Parallel vertical slits P and RP are added to improve the scattering signal. D is the defining slit and R is the receiving slit. Because of the focusing requirement, alignment of the sample is critical for accurate peak position measurements. To help in alignment and calibration, a known standard is used, e.g., a well-characterized silicon powder standard from NIST.

Traditionally, the X-rays are detected using high sensitivity film. In some cases, they are still used. The films are then processed and read by a digitizer, which is essentially a measurement of transmitted light over the spatial positions on the films. X-ray films are also used when examining two-dimensional scattering. Because of the difficulty in processing the film, the modern image plate was invented. Here, an image reader is needed.

For pulse counting techniques, a gas ionization counter, also known as a Geiger-Müller counter, is used. Essentially, it consists of exposing a gas-filled region, normally a noble gas like argon, krypton or xenon mixed with a small amount of quenching gas, held at high potential to the X-rays. Normally, this region is protected by an X-ray-transparent window. When an X-ray enters the compartment it ionizes the gas, producing electrons. These electrons are accelerated to the anode, thus creating a current pulse. The quantum efficiency of this detector greatly depends on the design and type of gas it uses. The energy resolution is poor and the detector can be saturated without going to very high count rates.

A more convenient scintillation has also been developed. This type of detector depends greatly on the fluorescence of certain crystals, e.g., sodium iodide or cesium iodide crystal doped with thallium. Other crystals are also used. These crys-

tals emit light when exposed to X-rays. The light is then converted into an electron pulse via a set of multiplier plates that can then be counted by the electronics. In this case, the dead time is much shorter and counting for higher count rates can be achieved.

The energy resolution of the above two counts is not optimal for normal diffraction techniques. The  $K_\beta$  radiation and other background radiations, e.g., contamination from the X-ray tube, need to be discriminated. Traditionally, foil filters are used. Selection of the foils is based on the absorption edges, e.g., when using copper  $K_\alpha$  radiation a nickel filter foil of 0.0158 mm is needed, which will absorb 98.4% of the  $K_\beta$  radiation [4].

Another way of removing background radiation is the commonly used analyzing crystal (also called diffracted beam monochromator), which is placed in front of the detector (which can either be the gas proportional counter or the scintillation counter) and after the receiving slit. The choice of crystal is based on the crystal mosaic, for energy selectivity and efficiency. The most widely used energy discriminator is usually graphite for efficiency without significantly sacrificing X-ray intensity. For experiments with more stringent energy discrimination, a LiH monochromator is used. In most cases, the analyzing crystal does not have sufficient resolution to remove the  $K_{\alpha 2}$  radiation.

Another way of improving the scattering signal is to use a solid-state detector (SSD). Normally, the detector consists of Si(Li) (silicon-lithium drifted) or Ge(Li) (germanium-lithium drifted) held at liquid nitrogen temperature. When an X-ray impinges on the detector, an electron-hole pair is created and the number of electron-hole pairs is proportional to the energy. Hence, in this case, the energy resolution is roughly about 130 eV.  $K_\beta$  radiation can be eliminated as well as other background radiations and fluorescence from the sample.

The high energy-resolution of the solid-state detector permits energy dispersive diffraction. Essentially, this takes advantage of the full broad energy spectrum of X-rays coming from the tube because of the Bremsstrahlung radiation and, by having the detector at specific angle, a full range of Bragg scattering can be obtained from the energy dispersion. The advantage here is that there is no moving part when conducting the experiment. It makes use of the full range of X-rays and counting statistics can be greatly improved. The drawbacks are that Bragg peak is significantly broader than that of the conventional scanning technique. The detector is big and clumsy, and has to be constantly cooled with liquid nitrogen. However, a newer version of SSD known as a Peltier detector is electrically cooled. This is also rather heavy and clumsy.

A normal mono-energetic experiment makes use of the strong  $K_\alpha$  radiations, which consist of  $K_{\alpha 1}$  (8.04778 keV) and  $K_{\alpha 2}$  (8.02783 keV) energies [19]. For copper  $K_\alpha$  radiation,  $K_{\alpha 2}$  intensity is about half that of  $K_{\alpha 1}$ .  $K_{\alpha 2}$  radiation is an unwanted component of the incident beam. The difference in energies is about 20 eV. However, if a more stringent monochromator is used, the intensity will be drastically reduced. Most powder diffraction experiments simply ignore it. However, when one examines nanostructures where the crystallite size is very small, the presence of  $K_{\alpha 2}$  will not be a factor. On the other hand, if one chose to use higher energetic

radiation, like molybdenum, the difference is about 105 eV. Normally, the best solid-state detectors have a resolution of 130–150 eV.

Unfortunately, this setup is not favorable for samples with elements excitable by the incident X-ray with energy 8.04 keV for copper  $K_\alpha$  radiation, e.g., magnetic nanoparticles Fe and Co-containing samples. In these situations, some form of tighter discrimination is needed to extract the coherently scattered X-rays and not the fluorescence from the sample, which is essentially noise for the diffraction experiment. A way around this problem is to change the probe radiation to that of  $CoK_\alpha$  for cobalt-containing samples and  $FeK_\alpha$  for iron-containing samples. In this way the X-ray probe energies will not be sufficient to cause fluorescence. By changing incident X-ray energies, one has to be aware that the penetration depth is decreased and the energy discrimination needs to be readjusted. Another way to carry out diffraction experiments on highly fluorescent samples is to ensure that the incident energies are sufficiently far from the fluorescence of the samples, e.g., using  $MoK_\alpha$  radiation on iron- and cobalt-containing samples. In this way, the diffracted beam crystal can easily filter out the fluorescent signals.

### 11.11

#### Small Angle X-ray Scattering

The regime covered by small angle X-ray scattering techniques typically covers 0.5 to 100 nm and, according to Bragg's equation, this turns out to be only a few degrees in  $2\theta$ . This regime also turns out to be very useful for examining many types of nanostructures. In general, for the application of nanostructures, it is customary to have a layer of polymer coated on each particle. Information on size, shapes, interparticle correlations and density fluctuations of nanostructure are of importance and can be obtained using this technique. In lifesciences, for example, biological cells and cell tissues, proteins and protein folding, colloids, micelles, bacteria and viruses can also be investigated using SAXS. This technique has also been widely used in examining tumors and cancerous cells, and distinctions in the diffraction patterns between healthy and cancerous cells have been shown. It is the information on the macro-scale, the connectivity and arrangement of the local domains, that is critical in understanding the behavior of these systems. For example, a SAXS study examining healthy and cancerous human breast tissues found that the collagens have very different structures [20]. It has also been widely used to examine tumors and cancerous cells [21], and, again, distinctions have been drawn between healthy and cancerous cells. Further research by many groups is continuing to try to understand the causes of cancer. Even so, by combining SAXS and WAXS characterization techniques, experiments can be carried out on well chosen cell tissue samples that will provide information for the understanding of disease processes evolution. This represents a new form of diagnostic capability for health sciences.

Information on the nanostructure, size, shapes, interparticle correlations, density fluctuations are of importance and can be obtained. In the lifesciences, most systems, such as those listed above, are highly disordered at the local level (ang-

stroms) and at times they are even semi-crystalline. Clearly, they are very complex and in most cases consist of interpenetrating components of the different make-up of molecules. These molecules, which can have odd shapes, essentially hinder the formation of unit cell arrangements. Again, the macro-crystalline arrangements are critical in the generation of properties.

Another example of X-ray scattering experiments in lifesciences is in understanding the structure and morphology of bone. Bones are made up of fibrillar collagens with nano-particles of crystalline hydroxyapatite distributed in the macro-structure. It is this macro-arrangement of the collagen and the crystalline component that provides the optimal compression strength for the load bearing of the anatomy [22]. A network of collagen fibers is deposited and grown within and between the collagen fibrils [23]. SAXS experiments can provide information on the macro-domains. One area in lifesciences that SAXS will play an important role is in understanding the cell membrane. Information on the structure of the lipid moieties in the cell membrane essentially defines the functionality of the membrane [24]. Even though lipids are considered to have bilayer structures, monolayer structures do exist. Of particular interest is understanding lipid behavior in solvent, which again can be carried out using SAXS. Depending on the acquisition time, *in situ* experiments as a function of temperature or time decay can also be carried out.

For nanostructures in biological materials SAXS analysis is used to extract information relating to the macro-lattice on highly correlating domains, which often can be periodic. A typical example for this is the tendons. Many biological systems also possess periodic structures, e.g., animal tail tendons and myelin membranes in the nerve. In polymers, the scattering signal arises from the stacking of lamellar crystals and block copolymers having segregating density domains.

Laboratory prepared nanoparticles (or crystals), e.g., cobalt [25] when coated with organic layers, can self-assemble into superstructures. The structure and dimension of these superstructures have also been examined using both WAXS and SAXS, thus providing a full description of the overall structure. The superstructure of biomaterials like colloidal particles of glycolipids has also been examined using SAXS. The technique was able to provide information on the structure of the dispersed particles [26].

The analysis of SAXS data can be divided into three groups: dilute systems, highly correlating systems and fractals. In dilute systems, when the structures are non-interacting, information on the shape, size and mass of the molecules can be obtained. For highly correlating systems, the basic formulation follows Bragg's law. The fractal component is generally useful for polymers and polymer chains and will not be discussed here. The reader is encouraged to refer to other sources [7, 12].

### 11.11.1

#### **Dilute Systems**

The scattering for dilute systems assumes that the scattering from each particulate is independent. Hence, it is critical for the sample to have an appropriate thickness

so that no multiple scattering can occur. The X-ray interacts with the electron fluctuations surrounding the particulates and the total intensity is merely the sum of all the individual scattering components. Therefore, information on sizes, shapes and mass can be obtained. The generalized scattering function is essentially given as

$$I(k) = (\rho_0 v)^2 F^2(k) \quad (19)$$

where  $\rho_0$  is the density difference over total volume  $v$ , and  $F(k)$  is the structure factor. The form factor is simply represented by

$$F(k) = \int \rho(r) e^{ikr} dr \quad (20)$$

where the integral is over the electron density over each particulate and the exponential component is the form factor. By expanding the form factor and dropping out the higher order terms, Guinier has shown that the intensity function is

$$I(k) = \rho_0^2 v^2 \exp\left(-\frac{1}{3} k^2 R_g^2\right) \quad (21)$$

or

$$I(k) = I(0) \exp\left(-\frac{1}{3} k^2 R_g^2\right) \quad (22)$$

where  $I(0)$  is the scattering at zero angle. Essentially, this function is Gaussian. Very often,  $\ln I(k)$  is plotted against  $k^2$  and the radius of gyration  $R_g$  can be extracted from the resultant slope. Shape information is obtained from  $R_g$ ; the value of  $R_g$  for many forms of particulate has been calculated and will not be discussed here. Actually,  $R_g$  is defined as in Eq. (23) and described as the root-mean-square distance of all points in the particle from the center of mass weighted accordingly.

$$R_g^2 = \frac{\int_0^\infty \rho(r) r^2 dr}{\int_0^\infty \rho(r) r dr} \quad (23)$$

The size of the particle is conveniently expressed by  $R_g$  and, assuming the shape is known, the radius of gyration can be extracted accurately. The radius of gyration for some common shapes has been tabulated in many review articles. By knowing or assuming the shape of the particle examined, the dimension of the particle can be gotten by solving for the radius of gyration. Extrapolation of the Guinier plot to scattering at zero angle results in  $\rho_0^2 v^2$ , which provides information on the particle molecular weight and volume. However, in this case, accurate intensity of the main beam is needed.

For homogenous particles with distinct boundaries between the particles and the matrix, which can be a solution or another media with different density, e.g., in

polymers with crystalline and amorphous components, Porod has indicated that the scattering  $I(k)$  should decrease as  $k^{-4}$  for large  $k$  and the proportionality constant is related to the total area  $S$  occupied by the boundaries and is expressed as

$$I(k) \rightarrow \frac{2\pi\rho_0^2 S}{k^4} = \frac{P}{k^4} \quad (24)$$

By plotting  $\log(I(k))$  versus  $\log(k)$  and extrapolating to  $k = 0$ , the  $P$  (Porod constant) can be extracted. When this parameter is divided by the “invariant”, which is the scattering intensity for the total volume, the surface area to volume ratio can be gotten. When this parameter is divided by the density, the total surface area (m/g) resulted. The information is particularly useful, especially in the area of catalysis when the amount of surface area controls the property of the material.

### 11.11.2

#### Highly Correlating Systems

Most systems in lifesciences are highly correlated or rather densely packed with significant density fluctuation and are also highly oriented. For example, collagens are very well packed in a fibrillar fashion and the diffraction pattern shows many orders of reflections. The peaks are also very sharp, with a dimension of 67 nm for native rat tendon [26]. Obviously, for densely packed systems, the scattering theory is governed by Bragg's law.

Collagens are common in lifescience. It is a major constituent in tendon, bone, skin, cornea, cartilage and other parts that require strength and flexibility. Clearly, the packing and deformation of collagens will reveal the state of the matter when compared with healthy tissue. The arrangement of collagen is believed to be liquid-crystalline-like as well as having large scale triple helices arrangements for roughly 300 nm [27, 28]. The change in packing indicates some kind of mineralization that prevents proper function of the component. It is indeed a mystery that collagen, which is abundant in our anatomy, has so many functions. It is the arrangement on the macro-scale that changes its properties [29].

As described earlier [24], examination of protein bilayers is of great importance in biological science. Essentially, these are highly correlated systems. Clearly, the structure and makeup of these bilayers constitute the working of the membranes, peptides etc. There are enormous numbers of biological systems for which both SAXS and WAXS can be utilized for understanding their behavior. Biological systems are normally very complex.

## 11.12

### SAXS Instrumentation

A SAXS experiment, in principle, has a very simple geometry (Fig. 11.7); however, improperly arranged and aligned components will result in all kinds of problems, e.g., parasitic scattering, calibrations, peak profiles and background noise. The

Fig. 11.7. Optics for carrying out SAXS experiment using the three-slit system.

quality of the instrument greatly depends on the level of noise because the diffuse scattering intensity for most samples can be very weak for different reasons. A very well-defined X-ray beam is needed for this application.

Numerous SAXS instrumentations are available commercially. Essentially, there are two types of configuration, pin-hole and the line source technique, each with its own strengths and weaknesses. The pin-hole technique is useful for examining anisotropic materials, e.g., fibers, films and any sample with orientations. However, there is an inherent loss in intensity, resulting in long data acquisition time. A two-dimensional detector system is required, e.g., conventional highly sensitive X-ray film, image plate, 2D proportional gas detector and even the CCD (charge coupled device) detector systems. Both the film and image plate require X-ray exposure and then have to be processed and read by some kind of digitizer or image reader. In this way, some level of spatial resolution and dynamic range will be lost. When small peaks are of interest or accurate intensity function is required, these are not the desired techniques. Moreover, real-time experiments or experiments performed as a function of temperature will be extremely tedious and inefficient.

A basic requirement for a good experimental setup for SAXS is in the collimation. This is because SAXS is a measurement of extremely small intensity at very small angle, next to a very strong incident main beam. Hence, the scattering around the incident beam has to be as clean as possible and protected against parasitic scattering caused by the defining slits and beam blocker. Commonly used in the pin-hole technique for the in-house systems is the three pin-hole slits system with different sizes (Fig. 11.7). They have to be properly arranged and matched with the size of the beam blocker to obtain the clean primary beam and reach to the lowest angle. The third slit is the guard slit that filters out the parasitic scattering from the defining slits. Not that the beam diverges from the source. To avoid air scattering, the beam path has to be under vacuum, which inherently introduces two X-ray windows. The weakly scattered X-ray from the sample has to penetrate these windows without changing in energy and direction. The advantage of the pin-hole technique is that anisotropic samples can be examined, e.g., fibers and films. By translating the sample, localized spot examination can also be carried out.

The more advanced 2D gas proportional detector system has also been used. The heart of the detector is the multi-wire grid; the spatial resolution is limited to the

Fig. 11.8. Kratky block collimation system.

wire spacings. Normally, this is limited to about 1 mm, even though some advances have been made (0.2–0.3 mm) through electronic and software developments. As a consequence, pin-hole SAXS instruments require long path lengths to expand the image for the detector to receive.

To increase the intensity, the second method, using a line source, is often used. The optics are essentially similar to the pin-hole system shown in Fig. 11.7. This method increases the flux of the incident beam; however, only isotropic sampling can be carried out. Unfortunately, because of the fixed slit, desmearing of the data is needed. Again, three line slits properly arranged are used to minimize parasitic scattering. Adjustments to these slits are often very sensitive and difficult. Consequently, the Kratky block collimation (Fig. 11.8) was introduced and is still used today. It is easier to align and there are not too many adjustments. It can also achieve much smaller  $k$  ( $\text{\AA}^{-1}$ ) than the normal three-slit system.

Another method of increasing the incident beam flux and improving the spatial resolution is by using focusing mirrors and monochromators. To achieve even smaller in  $k$ , the Bonse-Hart technique is used. By taking advantage of a tighter energy filter, an even smaller angle can be achieved. This is accomplished by having the X-ray bounce several times through a channel cut crystal on the incident end as well as the diffracted end. This technique also requires significant alignments, which are normally set up at dedicated beam lines at synchrotron sources. Again, this is also a line source and the issue of desmearing will have to be considered.

### 11.13 Synchrotron Radiation

Undoubtedly, synchrotron radiation has played a major role in extending X-ray scattering capabilities. As pointed out in the introduction, unlike in-house X-ray sources, synchrotron radiation has unique properties. The generation of synchrotron radiation will not be covered here. The X-rays generated by a synchrotron source are highly collimated, highly polarized, tunable, and have high brightness. The probe size can be made small, down to 2  $\mu\text{m}$ , which essentially provides an insight into the composition of biological cell and local structure that is not possible using in-house sources.

The high collimation enables diffraction experiments to be carried out with improved precision. The peak width spread will be extremely small. The fwhm will be essentially due to the character of the sample and not the instrument. Divergence will be extremely small. By using an incident monochromator, unlike the in-house source, only a mono-energetic beam is allowed to pass the incident monochromator. Because of the small divergence of the beam, SAXS experiments can be better set up.

To enhance atomic speciation, anomalous WAXS and SAXS have also been developed and often used in advanced laboratories. This arises from the tunability of the X-ray to the desired energies close to the absorption edges to enhance the scattering power by taking advantage of anomalous scattering factors. These techniques are covered elsewhere in this volume (see Chapter 8). Clearly, there are more examples of utilizing the advantages of performing X-ray diffraction experiments using a synchrotron source.

#### 11.14

##### **Concluding Remarks**

In the field of materials characterization, X-ray scattering stands out as the preferred method for obtaining information on the structure and morphology of all sorts of materials. Essentially, X-rays are scattered by electrons, and all matter has electrons. The domain size that fits both wide angle and small angle X-ray scattering ranges from a fraction of a nm to 100 nm. At the low end, X-ray diffraction has provided information on atomic positions, lattices, bond lengths, atomic speciation and structure. By carefully examining the character of the scattering, secondary information, like the crystallite size, lattice distortion and occupancy, can also be extracted. The penetration depth of an X-ray is also sufficiently high compared with X-ray photoemission or electron scattering, hence X-ray scattering can be considered as bulk probing.

With the theory and technique firmly understood, the method has been used on more complex organic and polymeric systems. Unfortunately, in general, these systems are not fully crystalline. They are semi-crystalline and, more often, it is this semi-crystallinity that provides the unique properties of polymers, essentially controlling their morphology. This is one of the reasons for the development of small angle X-ray scattering.

Both the wide angle and small angle techniques are quite well developed. Basically, these characterization techniques have been extended to different aspects of biological and lifescience. The structure of cells and cell tissues, lipid membranes, proteins and protein behavior, the building blocks of many organs in our anatomy, are now being examined using both the wide angle and small angle X-ray techniques.

Structures or nanostructures in biological and lifescience are generally very complex. However, with the advancement of computing power, high energy and the spatial resolution of synchrotron sources, experiments on tissues, like cancer, tu-

mors or sclerosis, are now possible. Clearly, X-ray scattering, together with synchrotron and neutron scattering, covers a whole range of characterization for organic and inorganic condensed matter, crystalline and semi-crystalline, and amorphous structures. These experiences have also developed into the biological field and lifesciences.

### Acknowledgment

This work was performed under the auspices of the U.S. Department of Energy by the University of California, Lawrence Livermore National Laboratory under Contract W-7405-Eng-48. Thanks are given to Dr Art Nelson for reviewing the manuscript.

## Preface

Welcome to the world of nanoscale devices! The fourth volume of the series on Nanotechnologies for the Life Sciences is in front of you, providing glimpses of the exciting possibilities that exist in the world of tiny devices. Nanotechnology and nature are intimately intertwined. Such an intimate partnership is critical for reaping the benefits of nanotechnology by unraveling the mysteries of nature. Therefore, this volume, *Nanodevices for the Life Sciences*, is timely and provides a broader perspective to this partnership and enlightens us on the theory, physics, chemistry, biology and engineering of nanodevices that are being constructed in the laboratory as well those that are already being utilized by nature. See for example a recent article in *Science* (Vol 312, pp 860–861, 2006) that describes the possibilities to utilize biomolecular motors in nanometer-scale devices to perform mechanical work. Three chapters (chapters 7, 8 & 13) in the book are specifically dedicated to provide glimpses of the power of such natural nanoscale devices and I am certain that these chapters will catalyze development of new ideas and tools for non-biologists interested in utilizing the underlying principles.

Theory and experiments will have to go hand in hand as deeper understanding of the complexities associated with nanoscale devices bring us a step closer to designing devices that are as efficient as in nature. Therefore, the first two chapters have been dedicated to provide theoretical and computational understanding of nanoscale devices with potential applications in life sciences. The first chapter illuminates on *The Physics and Modeling of Biofunctionalized Nanoelectromechanical Systems*. Two leading theoreticians, M. R. Paul from Virginia Polytechnic Institute and State University in Virginia, USA, and J. E. Solomon from the California Institute of Technology in Pasadena take readers to the realm of theoretical challenges associated with modeling of BioNEMS. I have no doubt that the information provided in this chapter will form a strong basis for deeper understanding of many other nanoscale systems that one encounters in our laboratories as well as in biological systems. The second chapter is a contribution from the laboratories of Vittorio Cristini from the University of California at Irvine delving on intricacies of modeling various components associated with nanoscale drug delivery for the treatment of cancer. The chapter, *Mathematical and Computational Modeling: Towards the Development and Application of Nanodevices for Drug Delivery*, is a great source of information on mathematical models and computer simulations of important steps in the journey of intravenously injected nanovectors into tumoral

tissue in order to deliver drug in the most effective manner. This chapter is a must for all those interested in utilizing nanotechnologies for drug delivery.

Moving from utilizing theory, modeling and computational tools for fabrication of nanodevices, the rest of the book is a testimony to the rapid advances being made in the application of a variety of experimental techniques and tools for building nanoscale devices and for application of such devices in a number of fields ranging from biosensors to bioelectronics. In the third chapter, which is contributed by J. C. Garno and co-workers from Louisiana State University in Baton Rouge, USA, a detailed description is given of how scanning probe techniques are proving to be versatile tools for fabricating arrays of self-assembled monolayers (SAMs) and proteins. In this chapter, *Nanolithography: Towards Fabrication of Nanodevices for the Life Sciences*, the authors describe how nanolithography is revolutionizing the fabrication of nanoscale biomolecular devices in general and proteins in particular through precise control over chemical functionality, shape, dimensions and spacing on the nanometer scale. Continuing on a similar theme, H. D. Espinosa, K.-H. Kim and N. Moldovan from Northwestern University in Illinois, USA, have carried out a remarkable job in delineating the importance of microcantilevers for biopatterning and biosensing in scanning probe microscopy (SPM)-based techniques. Their contribution in the fourth chapter, entitled *Microcantilever-based Nanodevices in the Life Sciences*, is very unique in the sense that it covers not only various approaches for fabrication of microcantilevers but also their applications in the emerging field of bionanotechnology. The chapter clearly demonstrates the fact that microcantilevers are fundamental tools for biopatterning and biosensing in SPM-based techniques, and with the possibility of integrating micro/nanofluidics into microcantilevers, they are in the process of revolutionizing the field of bioanalytical nanodevices.

The fifth chapter in this volume, *Nanobioelectronics*, is a testimony to the fact that there have been several advances made in the field of molecular electronics over the last decade particularly in utilizing biomolecules for fabrication of molecular-scale devices and integrated computers. The authors from the University of Lecce in Italy, R. Rinaldi and G. Maruccio reviewed these advances in the field of nanobiomolecular electronics describing the fabrication of devices such as rectifiers, amplifiers, information storage devices based on biomolecules in general and DNA and proteins in particular. Highlight of the chapter is the information on interconnecting biomolecules and exploitation of their self-assembly properties leading to nanobiodevices. It is particularly heartening to see that the progress made so far in the field of nanobioelectronics is very promising and is likely to fill the void in the face of current limitations with CMOS devices and post-optical lithographies. While the fifth chapter focuses on electronic devices using DNA, the sixth chapter provides complete information on the most important properties of DNA and how these properties are being exploited in building functional devices such as DNA-based molecular motors and automata with possible applications in the life sciences. Friedrich Simmel from Ludwig-Maximilians-Universität München, Germany, has provided an up to date review on this subject and is very optimistic that the recent advances are likely to lead to the development of autonomous molecular-scale devices which can sense environmental information, perform compu-

tations and act independently as molecular motors, drug reservoirs, or as signal transducers. The chapter is aptly titled as *DNA Nanodevices: Prototypes and Applications*. While the fifth and sixth chapters provide a broader perspective to build nanoscale devices from DNA and proteins, the next two chapters contain very specific information on nanodevices made from G-protein coupled receptors and Kinesin-microtubule systems respectively. The seventh chapter, *Towards the Realization of Nanobiosensors Based on G-protein-coupled Receptors*, a contribution from the laboratories of Cecilia Pennetta, also from Lecce University, provides a thorough review on G-protein-coupled receptors (GPCRs) including different techniques to prepare and immobilize them on a substrate, followed by utilization of the electrochemical impedance spectroscopy (EIS) technique for the detection of biosensing events at the electrodes. A very unique aspect of the chapter is that it covers several theoretical aspects investigating the current response to an applied AC voltage of a nanodevice realized by a single GPCR embedded in its membrane and in contact with two functionalized metallic nanoelectrodes. The chapter is extremely valuable for nanotechnologists exploring applications in life sciences as GPCRs are one of the widest groups of receptor proteins known and they can be activated by a large variety of extracellular signals, such as light, odorant molecules, hormones, peptides, lipids, neurotransmitters and nucleotides. GPCRs mediate the sense of vision, smell, taste and pain, and are involved in an extraordinary number of physiological processes. Competing for prominence with GPCRs are the Kinesin-microtubule-driven systems as they hold significant potential as molecular motors due to their compactness, high efficiency in vitro in extracting energy from the aqueous environment. The eighth chapter, *Protein-based Nanotechnology: Kinesin-Microtubule-driven Systems for Bioanalytical Applications*, assumes enormous importance in this volume as it has valuable information on how kinesin molecular motors can be integrated with microtubule tracks into microdevices for bioanalytical applications. The chapter is an important contribution for the book as the author, William Hancock from Pennsylvania State University, USA, covers wide-ranging topics from cell biology and biophysics, in vitro assays, theoretical aspects, biofunctionalization of the kinesin-microtubule system in addition to experimental approaches to integrating into functional microscale devices for potential analytical applications.

Carbon Nanotubes (CNTs) are finding extraordinary applications in the field of life sciences especially in biosensing, drug delivery, diagnosis, imaging and so on. These applications are further complimented by recent efforts in fabricating CNT-based nanodevices especially field-effect transistors (FETs) having very interesting performance characteristics. The ninth chapter, *Self-assembly and Bio-directed Approaches of Carbon Nanotubes: Towards Device Fabrication*, begins with a review on important characteristic of CNTs followed by the synthesis methods reported in the literature. The central theme of the chapter, written by Arianna Filoramo from the Laboratory of Electronic Materials in Gif sur Yvette, France, is however the utilization of self-assembly approaches (bio as well as non-bio directed) for fabrication of CNT devices for application in the electronics industry. Alternative strategies to CMOS technologies such as bio-inspired technologies for nanoscale devices as described in this chapter as well as in chapter five are likely to revolutionize the electronics industry in the near future. Focusing primarily on biosensing, chapter

ten explores the possibility of fabricating nanodevices based on nanophotonic/optoelectronic platforms and on nanomechanical platforms. The chapter, *Nanodevices for Biosensing: Design, Fabrication and Applications*, contributed by L. M. Lechuga and co-workers from the Microelectronics National Center (CNM) in Spain, is a valuable source of information for design, fabrication and testing of nanosensors and their integration with microfluidics, optical and electronic functions on a single chip. Chapter eleven, *Fullerene-based Devices for Biological Applications*, written by Dirk M. Guldi from Friedrich Alexander University in Erlangen-Nürnberg, Germany, and his collaborators is complimentary to the ninth chapter, describing in detail the solubility, toxicity and major biological applications of fullerenes and their potential application in nanoscale devices. It provides a basic framework for fabricating fullerene-based nanoscale devices in near future. A more general approach for utilization of nanotechnological principles for the fabrication of biomedical devices is presented in the twelfth chapter, wherein Lars Montelius from Lund University in Sweden describes various types of nanotechnologies that are employed in the biomedical field in general and biomedical engineering in particular, together with suitable examples. The chapter, *Nanotechnology for Biomedical Devices*, provides a fundamentally strong backbone for the realization of nanoscale devices for biomedical applications.

Finally, the book ends with a chapter dedicated to providing an overview of nanoscale devices that nature utilizes. Chapter thirteen, *Nanodevices in Nature*, written by Alexander Volkov and Courtney Brown from Oakwood College in Huntsville, USA, complements more specialized information in chapters seven and eight. The chapter elegantly delineates the role of various nanodevices in a wide variety of biological processes focusing more specifically on cytochrome oxidase, photosynthesis and phototropism, membrane transport, molecular motors, and electroreceptors. In my view the last chapter is a grand finale to the excellent source of information that the authors of this book gathered and reminds me of a great statement from *Vedas*, one of the oldest Indian scriptures, which describes universal power as the smallest of the smallest and biggest of the biggest. Truly, the power that encompasses the universe comes from nanodevices!

As I conclude this preface, there is no doubt in my mind that a book of this magnitude and high quality would not have been possible without the timely contributions of all authors, and I am always grateful to them for sharing my vision for this book as well as for the rest of the series. I am glad to let you know that Volumes 1–3 and 5–6 of this exciting series have already been published and you might have seen them in your library or obtained a personal copy. The remainder of the series, volumes 7–10, is currently in press and will be available to you before the year ends. In addition to the authors, a project of this magnitude is not possible but for unwavering support from my employer, family, friends and Wiley-VCH publishers. This is yet another opportunity for me to convey my thanks to them. Before I take leave, I would like to request you, the reader, who is sharing the knowledge with me and rest of the authors, to let me know your comments, suggestions and constructive criticism to make further improvements to this exciting series.

## 1

## The Physics and Modeling of Biofunctionalized Nanoelectromechanical Systems

Mark R. Paul and Jerry E. Solomon

## 1.1

### Introduction

Experimental fabrication and measurement are rapidly approaching the nanoscale (see, e.g. Refs. [1–4]). With this comes the potential for many important discoveries in both the physical and life sciences, with particularly intense attention in the fields of medicine and biology [5]. As Richard Feynman famously predicted in the early 1960s, there is indeed plenty of room at the bottom [6, 7]. A particularly promising avenue of research with the potential to make significant contributions is that involving what we will call biofunctionalized nanoelectromechanical systems [(BIO)NEMS]. This is a large and burgeoning field, and we do not attempt to present a survey, but rather we have picked an interesting example of a (BIO)NEMS device in order to highlight the dominant physics and types of modeling issues that arise.

This is not to imply that molecular-scale science is something new – scientists and engineers have been manipulating atoms and molecules for decades. (For an interesting discussion about where nanotechnology fits in with molecular science, see Ref. [8].) However, one new and exciting feature is the ability to fabricate micro- and nanoscale structures that can be used to manipulate, interact and sense biological systems at the single-molecule level.

For a better perspective of the length scales in question it is useful to place micro- and nanometers on biological scales; a human hair has a diameter of about 1 mm, a red blood cell has a diameter of about 10  $\mu\text{m}$  ( $1 \mu\text{m} = 1 \times 10^{-6} \text{ m}$ ), the diameter of the bacteria *Escherichia coli* is about 1  $\mu\text{m}$ , the diameter of the protein lysozyme is about 5 nm ( $1 \text{ nm} = 1 \times 10^{-9} \text{ m}$ ) and the diameter of a single hydrogen atom is about 0.1 nm. When viewed in this context, a device with a characteristic length scale of 100 nm falls in the middle of these biological length scales, i.e. the device is quite large compared to single atoms, yet quite small when compared to single cells or large molecules. It is important to consider this when modeling these systems, as we illustrate below.

The force landscape descriptive of biological and chemical interactions occurs at the piconewton scale ( $1 \text{ pN} = 10^{-12} \text{ N}$ ). Biologically relevant force magnitudes are

related to the breaking and manipulation of chemical bonds. For example it takes hundreds of piconewtons to break covalent bonds, and on the order of 10 pN to break a hydrogen bond or to describe the entropic elasticity of a polymer (see, e.g. Refs. [9, 10]).

The dominant biological time scales of small numbers of molecules are also dictated by their chemical interactions. The time scales of chemical reactions vary over many orders of magnitude, e.g. protein conformational changes can take of the order of milliseconds, binding reactions such as those that occur between transcription factors and genes or between enzymes and substrates are of the order of seconds, covalent bond modifications such that occur with phosphorylation is of the order of minutes, and new protein synthesis in a cell can take tens of minutes.

With these biological length, force and time scales in mind it becomes clear that a major challenge facing the successful development of a single-molecule biosensor is to measure on the order of tens of piconewtons on microsecond time scales. Despite the rapid advancement of new technologies such as surface plasmon resonance [11], optical tweezers [12, 13], microneedles [14, 15] and scanning force microscopy [16–19], detailed knowledge of the real-time dynamics of biomolecular interactions remains a current challenge.

An attractive device with the potential to measure the biophysical properties of a single molecule is based upon the dynamics of nanoscale cantilevers in fluid. In discussing the physics and modeling of (BIO)NEMS we will focus on this type of device. In some aspects this device can be thought of as the miniaturization of atomic force microscopy (AFM) which depends upon the response of micron-scale cantilevers. The invention of AFM [20] has revolutionized surface science, paving the way for direct measurements of intermolecular forces and topographical mapping with atomic precision for a wide array of materials, including semiconductors, polymers, carbon nanotubes and (CNTs) biological cells (see Refs. [21, 22] for current reviews). AFM is most commonly performed in one of three different driven modalities; contact mode, noncontact mode and tapping mode. In contact mode, the cantilever remains in contact with the surface and direct measurements are made based upon the cantilever response as it interacts with the sample. Despite its great success, contact-mode microscopy raises concerns about strong adhesive forces, friction and the damage of soft materials. In response to these issues emerged the noncontact- and tapping-mode modalities which are often referred to as dynamic AFM [23–28].

In noncontact mode, an oscillating cantilever never actually makes impact with the surface, yet its response alters due to an interaction between the cantilever tip and surface forces. The noncontact mode allows the measurement of electric, magnetic and atomic forces. In tapping mode, the cantilever oscillates near the sample surface making very short intermittent contact. Commonly the oscillation amplitude is held fixed through a feedback loop and as the cantilever moves over topographical features of the sample, the change in deflection is measured and related to the surface features. As a result of this minimal impact, and by greatly reducing the effects of adhesion and friction, the tapping mode has become the method of

**Figure 1.1.** Schematic illustrating possible single-molecule detection modalities using small-scale cantilevers immersed in fluid.

choice for high-resolution topographical measurements of soft and fragile materials that are difficult to examine otherwise.

We would like to focus here upon something quite different – the stochastic dynamics of a passive cantilever in fluid. By passive we mean that the cantilever is not being dragged along a surface or forced to tap a surface, but that the cantilever is simply immersed in the fluid. However, recall that at microscopic length scales there is a sea of random thermal molecular noise. Experimental measurement is often limited by this inherent thermal noise; however, with current technology this noise can be exploited to make extremely sensitive experimental measurements [29] including the highly sensitive measurements to be made by gravitational wave detectors [30].

The basic idea is illustrated in Fig. 1.1. A small cantilever placed in fluid will exhibit stochastic dynamics due to the continual buffeting by water molecules that are in constant thermal motion (Brownian motion). In Fig. 1.1, all of the cantilevers will exhibit such oscillations; the four dark lines around each cantilever tip are meant to indicate these oscillations and their degree of shading represents the relative magnitude of these oscillations. One way to measure such oscillations in the laboratory would be through the use of optical methods. The cantilever on the far left is bare and is simply a reference cantilever placed in fluid. The adjacent cantilevers suggest various detection modalities that could also be considered. The fundamental idea is that in the presence of a biomolecule, either attached directly to a single cantilever or between the a cantilever and something else, the cantilever response will change. Measuring this change can then be used to detect the presence of a single biomolecule or, in more prescribed situations, details of the response will yield information about the dynamics of the molecule being probed.

An important advantage of this approach is that small cantilevers have large resonant frequencies, allowing the measurement of these dynamics on natural chemical time scales. In fact, nanoscale cantilevers immersed in water can have resonant frequencies in the megahertz range. The last cantilever on the right shows the case where the target biomolecule is bound between the cantilever and a very large molecule. The purpose of this would be to take advantage of its large surface area and, as a result, its increased fluid drag to enhance the change in response.

An additional complication is that the stochastic dynamics of cantilevers placed in an array, such as those shown in Fig. 1.1, will become coupled to one another through the resulting fluid motion. In other words, if one cantilever moves this

will cause the fluid to move, which will cause the adjacent cantilevers to move and *vice versa*. At first this may appear as just another component of background noise to contend with. However, it is interesting to point out that this correlated noise can be exploited to significantly increase the sensitivity of these measurements. Consider measuring the cross-correlation of the fluctuations between two cantilevers in fluid supporting a tethered biomolecule. By examining only the correlated motion of the two cantilevers we have effectively eliminated the random uncorrelated component of the noise acting on each cantilever. In fact, this approach has been used to measure femtonewton forces ( $1 \text{ fN} = 10^{-15} \text{ N}$ ) on millisecond time scales between two micron-scale beads placed in water [12]. Additionally, this approach was used to quantify the Brownian fluctuations of an extended piece of DNA tethered between the beads leading to the resolution of some long-standing issues concerning the dynamics of single biomolecules in solution [13].

Whatever the manner in which the measurements will actually be made in the laboratory, it will be essential to have a firm understanding of the complex and sometimes counterintuitive physics at work on these scales in order to interpret them (for an excellent introduction to the modeling of micro- and nanoscale systems, see Ref. [31]).

The purpose of this chapter is to shed some light upon this for the particularly illustrative case where the Brownian noise of small cantilevers in fluid is exploited for potential use as a single-molecule biosensor. Before these measurements can be made and understood, the following questions must be answered:

- (a) What are the stochastic dynamics of an array of nanoscale cantilevers immersed in fluid in the absence of the target biomolecules?
- (b) How much analyte will arrive at the sensor and what are the time scales for its capture?
- (c) Successful measurements will require the discernment between the noise when the biomolecule is attached and the background noise. What signal processing schemes can be used to make these measurements?

We address these questions in the following sections.

## 1.2

### The Stochastic Dynamics of Micro- and Nanoscale Oscillators in Fluid

#### 1.2.1

##### Fluid Dynamics at Small Scales

The dynamics of fluid motion at small scales contains many surprises when compared with what we are accustomed to in the macroscopic world. In fact most of life involves the interactions of small objects in fluidic environments (see Ref. [32] for an introduction or Refs. [33, 34] for a detailed discussion).

At the molecular scale a fluid is clearly composed of individual molecules. How-

ever, most fluid analysis is done assuming that the fluid is a *continuum*. What this implies is that at any particular point in space (no matter how small) the properties of the fluid (velocity, pressure, etc.) are well defined and well behaved. Another way to think of this is that for any experimental measurement in question we assume that our probe is effectively sampling the average behavior of many molecules.

As our domain of interest becomes smaller it is clear that this assumption will eventually break down. This raises the difficult question – at which point does the continuum approximation become invalid? An approximate answer can be provided by physical reasoning. In the continuum limit one would like the mean free path of collisions of the fluid molecules to be much smaller than a characteristic fluid length scale. This idea is captured by the Knudsen number  $\text{Kn} = \lambda/L$ , where  $\lambda$  is the mean free path and  $L$  is a characteristic length scale. For the case of water, and of liquids in general, the molecules are always in very close contact with one another and the characteristic mean free path can be approximated by the diameter of a single molecule. For water this yields  $\lambda \approx 0.3$  nm.

For the stochastic oscillations of small cantilevers we will use the cantilever half-width  $w/2$  as the characteristic length. This is because while a cantilever oscillates most of the fluid flows around spanwise over the cantilever. Assuming the cantilever has a width of  $w = 1$   $\mu\text{m}$  and is immersed in water yields  $\text{Kn} \approx 6 \times 10^{-4}$ . Since  $\text{Kn} \ll 1$  this indicates that the continuum approximation is good for the fluid dynamics even at these small scales. A quantitative understanding of when the continuum approximation breaks down and what the effects will be is currently an active and exciting area of research with many open questions (see, e.g. Ref. [35]).

The classical equations of fluid dynamics in the continuum limit are the well-known Navier–Stokes equations (see Ref. [36] for a thorough treatment):

$$R_\omega \frac{\partial \vec{u}}{\partial t} + R_u \vec{u} \cdot \vec{\nabla} \vec{u} = -\vec{\nabla} p + \nabla^2 \vec{u}, \quad (1)$$

$$\vec{\nabla} \cdot \vec{u} = 0 \quad (2)$$

Equation (1) is an expression of the conservation of momentum (we have neglected the body force due to gravity). Equation (2) expresses the conservation of mass for an incompressible fluid. We have written the equations in nondimensional form using  $L$ ,  $U$  and  $T$  as characteristic length, velocity and time scales, respectively. Two nondimensional parameters  $R_\omega$  and  $R_u$  emerge in Eq. (1) that multiply the two inertial terms on the left-hand side.

It is worthwhile discussing these two parameters in more detail, which will lend some insight into the dominant physics at small scales in fluids. The parameter:

$$R_u = \frac{UL}{\nu_f} \quad (3)$$

expresses the ratio between convective inertial forces and viscous forces (where  $\nu_f$  is the kinematic viscosity of the fluid, for water  $\nu_f \approx 1 \times 10^{-6}$   $\text{m}^2 \text{s}^{-1}$ ). This is the

**Figure 1.2.** Examples of different phenomena occurring over a range of 10 orders of magnitude in the velocity-based Reynolds number,  $R_u$ .

velocity-based Reynolds number. It is clear that for micron or nanoscale devices both the characteristic velocity and length scales become quite small, resulting in what is commonly referred to as the low Reynolds number regime. A precise definition of what is meant by “low” is not clear. For perspective, Fig. 1.2 illustrates the Reynolds numbers for some particular cases of interest. Note the vast range of phenomena that occurs over 10 orders in magnitude of the Reynolds number. As the Reynolds number decreases, the effects of viscosity dominate inertial effects. For example, if a 1- $\mu\text{m}$  microorganism swimming in water at  $10 \mu\text{m s}^{-1}$  suddenly turns off its source of thrust, say by flagellar or cilia motion, it will come to rest in the fraction of an angstrom. This is nothing like what we are used to on the macro-scale. An important consequence when  $R_u \ll 1$  is that the nonlinear convective inertial term  $\vec{u} \cdot \nabla \vec{u}$  becomes negligible. As a result, the equations become linear, greatly simplifying the analysis. The parameter:

$$R_\omega = \frac{L^2}{\nu_f T} \quad (4)$$

expresses the ratio between inertial acceleration forces and viscous forces. Notice that if we take the characteristic velocity to be simply  $L/T$ , the frequency and the velocity-based Reynolds numbers become equivalent. However, it is useful not to make this assumption here because we want to consider further the case where the oscillations are imposed externally and the inverse frequency of these oscillations is taken as the time scale. The result is the frequency-based Reynolds number,

$$R_\omega = \frac{\omega w^2}{4\nu_f} \quad (5)$$

where again we have used the cantilever half-width,  $w/2$ , as the characteristic length scale.

The frequency-based Reynolds is the appropriate Reynolds number to describe micro- or nanoscale cantilevers immersed in fluid. Let us consider further the type of cantilever currently under consideration for the next generation of biosen-

**Figure 1.3.** Schematic of a proposed cantilever geometry for use as a single-molecule biosensor (not drawn to scale):  $l = 3 \mu\text{m}$ ,  $w = 100 \text{ nm}$ ,  $l_1 = 0.6 \mu\text{m}$ ,  $b = 33 \text{ nm}$ . The cantilever is silicon with a density  $\rho_s = 2330 \text{ kg m}^{-3}$ , Young's modulus  $E_s = 125 \text{ GPa}$  and spring constant,  $k = 8.7 \text{ mN m}^{-1}$  [2, 41].

sors. Approximate values for the cantilever geometry are a width  $w \approx 1 \mu\text{m}$ , height  $h \approx 100 \text{ nm}$ , resonant frequency  $\omega \approx 2\pi \times 1 \text{ MHz}$  and we will assume water is the working fluid. As we show later, the maximum cantilever deflection due to Brownian motion will be of the order of  $0.01h$  (and often much less depending upon the particular geometry in question). Using these numbers the characteristic velocity is  $U = 0.01h\omega$ , which yields a velocity-based Reynolds number of  $R_u = 3 \times 10^{-3}$ . Since  $R_u \ll 1$ , the nonlinear inertial term can be neglected. However, the frequency-based Reynolds number is  $R_\omega = 1.6$ . As a result, the first inertial term must be kept in Eq. (1), making the resulting linear analysis more difficult. The governing equations are now:

$$R_\omega \frac{\partial \vec{u}}{\partial t} = -\vec{\nabla} p + \nabla^2 \vec{u} \quad (6)$$

$$\vec{\nabla} \cdot \vec{u} = 0 \quad (7)$$

These equations are known as the time-dependent Stokes equations. In what follows we will drop the subscript  $\omega$  on  $R_\omega$  and assume that  $R$  represents the frequency-based Reynolds number. Although these equations are linear it is still a formidable challenge to derive an analytical solution for all but the simplest scenarios. One such example is when the cantilever is modeled as an oscillating two-dimensional (2-D) cylinder (discussed in more detail in Section 1.2.3). However, even in simple cases the fluid-coupled motion of arrays of oscillating objects still presents a challenge. This is in addition to the fact that most experimental geometries are not simple, which further complicates the analysis (e.g., see Fig. 1.3). This has led to the development of an experimentally accurate numerical approach to calculate the stochastic dynamics of small-scale cantilevers [37] (discussed below).

## 1.2.2

**An Exact Approach to Determine the Stochastic Dynamics of Arrays of Cantilevers of Arbitrary Geometry in Fluid**

At first sight the determination of the stochastic dynamics of an array of fluid-coupled nanoscale oscillators appears quite challenging. Considering the nature of the equations (a system of coupled partial differential equations) and the complex geometries under consideration for experiments, the appeal of a numerical solution is apparent. However, the important question then arises of how to carry out such a numerical investigation? One approach that may come to mind is to perform stochastic simulations of the precise geometries in question that resolves the Brownian motion of the fluid particles as well as the motion of the cantilevers. In principle, this could be done in the context of a molecular dynamics simulation. However, this would be extremely difficult, if possible at all. Two major problems with this approach are:

- (a) There are simply too many molecules. A small box with side length of  $L = 10 \mu\text{m}$  will contain of the order of  $10^{13}$  water molecules. For low Reynolds number flows fluid disturbances are long range and will be of the order of microns even if the oscillators are nanoscale. The length scale of the fluid disturbance scales as approximately  $\sqrt{\nu_F/\omega}$ . This length scale describes the distance from the oscillating cylinder over which the bulk of the fluid momentum is able to diffuse.
- (b) There are vastly disparate time scales. For every oscillation of the cantilever, many water collisions will have had to occur. On average, a water molecule undergoes a collision every picosecond ( $1 \text{ ps} = 1 \times 10^{-12} \text{ s}$ ). However, the cantilever oscillates about once per microsecond. In other words, a million water molecules collide with the cantilever for every single cantilever oscillation – imposing considerable overhead upon our numerical scheme. To make matters worse, in order to get good statistics the numerical solution will have to run for many cantilever oscillations or, equivalently, many numerical simulations will have to be run for different initial conditions and averaged.

However, there is a much better approach if one exploits the fact that the system is in *thermodynamic equilibrium*. This allows the use of powerful ideas from statistical mechanics and, in particular, the fluctuation–dissipation theorem, which relates equilibrium fluctuations with the way a system, that has been slightly perturbed out of equilibrium, returns to equilibrium. In other words, if one understands how a systems dissipates near equilibrium, one understands how that same system fluctuates at equilibrium. The fluctuation–dissipation theorem was originally discussed by Callen and Greene [38, 39]; also see Chandler [40] for an accessible introduction.

It has recently been shown that the fluctuation–dissipation theorem allows for the calculation of the stochastic equilibrium fluctuations of small-scale oscillators using only standard *deterministic* numerical methods [37]. For the case of small

cantilevers in fluid, the dissipation is mostly due to the viscous fluid although internal elastic dissipation of the cantilever could be included if desired.

We will introduce the use of this approach for the case of two opposing cantilevers as shown in Fig. 1.7(a). Consider one dynamic variable to be the displacement of the cantilever on the left  $x_1(t)$ . This is a classical system, so  $x_1(t)$  will be a function of the microscopic phase space variables consisting of  $3N$  coordinates and conjugate momenta of the cantilever, where  $N$  is the number of particles in the cantilever. We now take the system to a prescribed excursion from equilibrium and observe how the system returns to equilibrium, which, in effect, quantifies the dissipation in the system. A particularly convenient way to accomplish this is to consider the situation where a force  $f(t)$  has been applied to the cantilever on the left at some time in the distant past and is removed at time zero. The step force is represented by:

$$f(t) = \begin{cases} F_1 & \text{for } t < 0 \\ 0 & \text{for } t \geq 0 \end{cases} \quad (8)$$

This force couples to  $x_1(t)$  causing a deflection in the cantilever. For this case the Hamiltonian of the system  $H$  is given by:

$$H = H_0 - fx_1 \quad (9)$$

We only consider the case of small  $f$  so the response of  $x_1(t)$  remains in the linear regime. In the linear response regime, the change in the average value of a second dynamical quantity  $X_2(t)$  (here we will use the displacement of the cantilever on the right, which is again a function of the  $3N$  coordinates and conjugate momenta) from its equilibrium value in the absence of  $f$  is given by:

$$\Delta X_2(t) = \frac{F_1}{k_B T} \langle \delta x_1(0) \delta x_2(t) \rangle_0 \quad (10)$$

where  $k_B$  is Boltzmann's constant ( $k_B = 1.38 \times 10^{-23} \text{ J K}^{-1}$ ) and  $T$  is the absolute temperature. The equilibrium fluctuations are given by:

$$\delta x_1 = x_1 - \langle x_1 \rangle_0 \quad (11)$$

$$\delta x_2 = x_2 - \langle x_2 \rangle_0 \quad (12)$$

where the average  $\langle \rangle_0$  denotes the equilibrium average in the absence of the force  $f$ . However, for our case the cantilevers fluctuate about an equilibrium of zero deflection,  $\langle x_1 \rangle_0 = \langle x_2 \rangle_0 = 0$ , which then implies that  $\delta x_1 = x_1$  and  $\delta x_2 = x_2$ . The average behavior of the cantilever deflection in the linear response regime is:

$$\Delta X_2(t) = X_2(t) - \langle x_2(t) \rangle_0 \quad (13)$$

However, as just mentioned,  $\langle x_2(t) \rangle_0 = 0$ , which also implies  $\Delta X_2(t) = X_2(t)$  and yields:

$$X_2(t) = \frac{F_1}{k_B T} \langle x_1(0)x_2(t) \rangle_0 \quad (14)$$

Using this result we can calculate a general equilibrium cross-correlation function in terms of the linear response as:

$$\langle x_1(0)x_2(t) \rangle_0 = \frac{k_B T}{F_1} X_2(t) \quad (15)$$

Similarly, the autocorrelation of the fluctuations is given by:

$$\langle x_1(0)x_1(t) \rangle_0 = \frac{k_B T}{F_1} X_1(t) \quad (16)$$

where  $X_1(t)$  is the average behavior of the deflection of the cantilever in which the force was applied. The spectral properties of the correlations can be found by taking the cosine Fourier transform of the auto- and cross-correlation functions. This yields the noise spectra,  $G_{11}(\nu)$  and  $G_{12}(\nu)$ , given by:

$$G_{11}(\nu) = \int_0^\infty \langle x_1(0)x_1(t) \rangle \cos(\omega t) dt, \quad (17)$$

$$G_{12}(\nu) = \int_0^\infty \langle x_1(0)x_2(t) \rangle \cos(\omega t) dt \quad (18)$$

where  $\nu$  is the frequency defined by  $\omega = 2\pi\nu$ . The noise spectra are important because they are precisely what would be measured in an experiment.

This result is exact with the only assumptions being classical mechanics and linear behavior. Equations (15) and (16) are extremely useful in that they relate the *stochastic* cantilever dynamics on the left-hand side to its *deterministic* response to the removal of a step force on the right-hand side. In other words, Eq. (16) relates the equilibrium fluctuations of the cantilever to its average deflection as it returns to equilibrium from a prescribed excursion to a nonequilibrium state.

With this in mind, the remaining challenge is to calculate the deterministic quantities  $X_1(t)$  and  $X_2(t)$  for use in Eqs. (15) and (16). Since the dynamic variables of interest are macroscopic (after all they are the cantilever deflections  $X_1$  and  $X_2$ ), they can be calculated using the deterministic macroscopic equations which govern the fluid and solid dynamics. This can be from analytics, simplified models or large-scale numerical simulation.

To summarize, the scheme consists of the following steps in a deterministic calculation:

**Figure 1.4.** Schematic of a simple cantilevered beam of length  $L$ , width  $w$  and height  $h$ .

- (a) Apply an appropriate force  $f$  that is constant in time and small enough so that the response remains linear. An appropriate force is one that couples to the variable of interest  $X_1$ . After applying the force, allow the system to come to steady state.
- (b) Turn off the force at a time labeled  $t = 0$ .
- (c) Measure some dynamical variable  $X_2(t)$  (which might be the same as  $X_1$  to yield an autocorrelation function) to yield the correlation function of the equilibrium fluctuations via Eqs. (15) and (16).

For the case of small cantilevers in fluid, the fluid motion can be calculated using the incompressible Navier–Stokes equations and the dynamics of the solid structures can be computed from the standard equations of elasticity. Using the sophisticated numerical tools developed for such calculations it is possible to find accurate results for realistic experimental geometries that may be quite complex, e.g. the triangular cantilever design often used in commercial AFM or the paddle geometries currently under investigation for use as detectors of single biomolecules as shown in Fig. 1.3.

### 1.2.3

#### An Approximate Model for Long and Slender Cantilevers in Fluid

Let us first consider a long and slender cantilever ( $L \gg w, h$ ) that is fixed at its base and free at its tip with the simple beam geometry as shown in Fig. 1.4. This configuration is particularly useful because this geometry is commonly used for AFM. A simplified and effective model analysis is available for this case [42, 43]. In this model, the dynamics of the beam motion is described using classical elasticity theory:

$$\mu \frac{\partial^2 w(y, t)}{\partial t^2} + EI \frac{\partial^4 w(y, t)}{\partial y^4} = F_f(y, t) \quad (19)$$

where  $w(y, t)$  is the displacement of the beam as a function of distance  $y$  along the length of the beam and time  $t$ ,  $\mu$  is the mass per unit length of the cantilever,  $E$  is Young's modulus,  $I$  is the moment of inertia of the cantilever, and  $F_f$  is the force acting on the cantilever due to the fluid. In this expression we have neglected internal dissipation in the elastic body, tensile forces leading to a stressed or strained

state when the cantilever is at equilibrium and gravity forces (it is straightforward to show that small cantilevers do not bend significantly in a gravitational field). It is important to note that Eq. (19) is coupled with the fluid equations Eqs. (6) and (7) through the force  $F_f$ , and that the coupled system of equations are linear. The equations governing beam dynamics are well studied and well understood (see Ref. [44] for an excellent reference on the theory of elasticity). The viscous dissipation in a low Reynolds number fluid is quite large and will dominate any other modes of dissipation such as internal elastic dissipation in the beam itself.

This leaves the important question of how to determine the flow field. Since the beam is long and slender, most of the fluid will interact with the beam by flowing around the sides as opposed to flowing over the beam tip. In this case one can assume that the cantilever is infinite in length and consider only the flow over a 2-D cross-section of the beam [42]. It can then be shown that it is a small correction to then assume that the usually rectangular cross-section of the beam is cylindrical. This is particularly convenient because an analytical solution for the flow field over an oscillating cylinder is available. In fact, the fluid problem was first solved in 1851 by Stokes; however, for a modern treatment, see Ref. [45].

Since the fluidic damping dominates the cantilever motion we can further simplify the analysis by considering only the fundamental mode of the beam dynamics (the higher harmonics will be damped out by the fluid). This additional simplification aids in clarifying the approach without significantly affecting the results (for the analysis using the full beam equation, see Ref. [42]). The equation of motion describing the fundamental mode of a beam immersed in fluid then becomes:

$$m_e \ddot{x} + kx = F_f + F_B \quad (20)$$

where  $x$  represents the deflection of the cantilever tip,  $m_e$  is the effective mass of the beam in vacuum,  $k$  is the effective spring constant of the beam and  $F_B$  is the random force due to Brownian motion. Notice that  $F_f$  contains both the fluid damping as well as the fluid loading due to the additional fluid mass that the beam “carries” as it moves.

It is convenient to transform into frequency space by taking the Fourier transform of this equation to give:

$$(-m_e \omega^2 + k) \hat{x} = \hat{F}_f + \hat{F}_B \quad (21)$$

where:

$$\hat{F}_f = m_{\text{cyl},e} \omega^2 \Gamma(\omega) \hat{x} \quad (22)$$

and:

$$m_{\text{cyl},e} = 0.243 m_{\text{cyl}} = 0.243 \rho_1 \left( \frac{\pi}{4} w^2 L \right) \quad (23)$$

which is the effective mass of a fluid cylinder of radius  $w/2$ , where  $\rho_1$  is the fluid density. The prefactor of 0.243 ensures that mode-shape mass is equivalent for the mass of the cantilever, the fluid loaded mass and the fluid damping. The Fourier transform convention we are using is:

$$\hat{x}(\omega) = \int_{-\infty}^{\infty} x(t)e^{-i\omega t} dt \quad (24)$$

$$x(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \hat{x}(\omega)e^{i\omega t} \quad (25)$$

Here,  $\Gamma(\omega)$  is the hydrodynamic function and is defined to be:

$$\Gamma(\omega) = 1 + \frac{4iK_1(-i\sqrt{iR})}{\sqrt{iR}K_0(-i\sqrt{iR})} \quad (26)$$

where  $K_1$  and  $K_0$  are Bessel functions. Note that by this definition the arguments on the right-hand side are  $R$  and not the frequency  $\omega$ . The cantilever is effectively loaded by the fluid which can be characterized by an effective mass,  $m_f$ , larger than  $m_e$  that takes into account the fluid mass that is also being moved. The fluid also damps the motion of the cantilever, which can be expressed as an effective damping  $\gamma_f$ . Relations for  $m_f$  and  $\gamma_f$  can be found by expanding  $\Gamma(\omega)$  into its real and imaginary parts  $\Gamma_r$  and  $\Gamma_i$  in Eq. (21), and rearranging such that:

$$-m_f(\omega)\omega^2\hat{x} - i\omega\gamma_f(\omega)\hat{x} + k\hat{x} = \hat{F}_B \quad (27)$$

to give:

$$m_f = 0.243m_c(1 + T_0\Gamma_r) \sim \Gamma_r(\omega) \quad (28)$$

$$\gamma_f = 0.243m_{\text{cyl}}\omega\Gamma_i \sim \omega\Gamma_i(\omega) \quad (29)$$

Notice that both the fluid loaded mass of the cantilever and the fluidic damping are functions of frequency. The ratio of the mass of the fluid-loaded cantilever to the effective mass of the cantilever in vacuum,  $m_e$ , as a function of frequency is shown in Fig. 1.5. The cantilever has a mass of nearly 20 times the effective value at  $R \approx 1$ . Over 4 orders of magnitude in frequency the mass changes by a factor of about 200. The fluidic damping is shown in Fig. 1.5. There is a slight frequency dependence, over 4 orders of magnitude in frequency the damping changes by a factor of 7, which is much less than the frequency dependence of the mass loading.

From the fluctuation–dissipation theorem the spectral density of the fluctuating force,  $G_{F_B}(v)$ , can be related to the dissipation due to the fluid and is given by:

$$G_{F_B}(v) = 4k_B T m_e T_0 \omega \Gamma_i(\omega) \quad (30)$$

**Figure 1.5.** (a) The ratio of the mass of a fluid-loaded cantilever to the effective mass of the cantilever in vacuum as a function of the frequency-based Reynolds number. (b) The fluidic damping of a cantilever immersed in fluid as a function of the frequency-based Reynolds number. Shown is the nondimensional damping  $\gamma^* = R\Gamma_1(R)$ .

where  $T_0$  is the ratio of the mass of fluid contained in a cylindrical volume of radius  $w/2$  to the mass of the cantilever. The analysis of Ref. [42] does not take into account the frequency dependence of the damping and assumes that the numerator is constant. Although the frequency dependence of the damping is not large as shown in Fig. 1.5, it should be accounted for. Solving for the spectral density of the displacement fluctuations,  $G_x(v)$ , from Eqs. (21) and (30) yields:

$$G_x(v) = \frac{4k_B T}{k} \frac{1}{\omega_0} \frac{\tilde{\omega} T_0 \Gamma_i(R_0 \tilde{\omega})}{[(1 - \tilde{\omega}^2(1 + T_0 \Gamma_r(R_0 \tilde{\omega})))^2 + (\tilde{\omega}^2 T_0 \Gamma_i(R_0 \tilde{\omega}))^2]}$$

where  $\tilde{\omega} = \omega/\omega_0$  is the frequency relative to the vacuum resonance frequency  $\omega_0 = \sqrt{k/m}$  and  $R_0$  is the frequency-based Reynolds number using  $\omega_0$ . Using the equipartition of energy theorem and applying it to the cantilever's potential energy, we arrive at:

$$\frac{1}{2} k \langle x^2 \rangle = \frac{1}{2} k_B T \quad (31)$$

Using this we scale  $G_x(v)$  in Eq. (31) such that:

$$\int_0^\infty |\hat{x}(\omega)|^2 d\omega = \frac{k_B T}{k} \quad (32)$$

The value of  $\omega$  at the maximum value of  $|\hat{x}(\omega)|^2$  yields a theoretical prediction of the fundamental frequency in fluid  $\omega_f$ . Once  $\omega_f$  is known, an approximation for the quality factor of the oscillator,  $Q$ , is:

$$Q \approx \frac{\frac{1}{T_0} + \Gamma_r(\omega)}{\Gamma_i(\omega)} \quad (33)$$

Equation (33) is valid only for  $Q \gtrsim 1/2$  because it neglects to account for the frequency dependence of the mass and fluid loading in Eq. (27) (by considering only the explicit frequency dependence) which become very important for highly overdamped cantilevers (i.e.  $R \lesssim 1$ ).

Using what we have discussed so far let us quantify the stochastic dynamics of an AFM placed in water. We consider a cantilever with the simple beam geometry as shown in Fig. 1.4. The cantilever dimensions are length  $L = 197 \mu\text{m}$ , width  $w = 29 \mu\text{m}$  and height  $h = 2 \mu\text{m}$ . These are chosen so that we can compare with the analytical and experimental results of Ref. [43]. From beam theory, the effective spring constant of a cantilever is:

$$k = \frac{3EI}{L^3} \quad (34)$$

which, for the cantilever in question, yields  $k = 1.3 \mu\text{N m}^{-1}$ . Using the approach described in Section 1.2 we use a step force  $F_1 = 26 \text{ nN}$  and calculate the deterministic response of the cantilever,  $X_1(t)$ , as it returns to equilibrium. For detailed information on the particular computation algorithm we used to solve the deterministic fluid–solid equations, see Refs. [46, 47]. The value of  $\langle x_1(0)x_1(0) \rangle^{1/2}$  is interesting in that it yields the magnitude of the deflections that would be expected

**Figure 1.6.** The noise spectrum as calculated from full finite element deterministic numerical simulation (solid line) and the noise spectrum from the approximate analytical theory (dashed line) for an AFM immersed in water (for experimental results see cantilever c2 in Ref. [43]). The full numerical simulations include all of the cantilever modes including two that are shown in the frequency range of the figure identified by the two peaks in the simulation results. The analytical model only considers the

fundamental mode of the cantilever oscillation resulting in only one peak. Note that more modes could be included if desired; however, as shown in the figures, the higher-frequency modes are strongly damped and will not be significant in experiment. The micron-scale cantilever used for this calculation is of the geometry shown in Fig. 1.4, and has a length  $l = 197 \mu\text{m}$ , width  $w = 29 \mu\text{m}$  and height  $h = 2 \mu\text{m}$ . The applied step force is  $F_1 = 26 \text{ nN}$ .

in an experiment. For this case we find that  $\langle x_1(0)x_1(0) \rangle^{1/2} = 3.16 \times 10^{-21} \text{ m}^2$ . This indicates that the deflection of the cantilever due to Brownian motion in an experiment is about 0.056 nm or about 0.003% of the thickness of the cantilever – an extremely small value even on an atomistic scale. Multiplying this quantity by the spring constant gives an estimate of the force sensitivity of 73.1 pN, which is clearly too large to be used as a biological force detector (recall biological force scales are around 10 pN). The noise spectrum is shown in Fig. 1.6, where there is good agreement with the approximate analytical theory available for this case.

#### 1.2.4

#### The Stochastic Dynamics of a Fluid-coupled Array of (BIO)NEMS Cantilevers

We now use this approach to find the auto- and cross-correlation functions for the equilibrium fluctuations in the displacements of the tips of two nanoscale cantilevers with the experimentally realistic geometries depicted in Fig. 1.3. For this case we would like to emphasize that no analytical expressions or simplified models are currently available. However, we can again use full numerical simulations and exploit the fluctuation theorem, which remains exact.

**Figure 1.7.** Schematic showing various cantilever configurations. In all configurations the step force  $F_1$  is released at  $t = 0$ , resulting in the cantilever motion referred to by  $X_1(t)$ . The motion of the neighboring cantilever is

$X_2(t)$  and is driven through the response of the fluid. (a) Two cantilevers with ends facing, (b) side-by-side cantilevers and (c) cantilevers separated along the direction of the oscillations.

To do this we again calculate the deterministic response of the displacement of each cantilever tip, which we call  $X_1(t)$  and  $X_2(t)$  after switching off at  $t = 0$  a small force applied to the tip of the first cantilever,  $F_1$ , given by Eq. (8). Various possible cantilever configurations are shown in Fig. 1.7(a–c); however, we will only consider the case where two cantilevers face one another end-to-end as shown in Fig. 1.7(c).

Again, the equilibrium auto- and cross-correlation functions for the fluctuations  $x_1$  and  $x_2$  are given by Eqs. (15) and (16), and the noise spectra  $G_{11}(\nu)$  and  $G_{12}(\nu)$  are given by Eqs. (17) and (18). The cantilever autocorrelation function and the two cantilever cross-correlation function are shown in Fig. 1.8(b and c, respectively). The value of  $\langle x_1(0)x_1(0) \rangle$  is  $0.471 \text{ nm}^2$ , indicating that the deflection of the cantilever due to Brownian motion in an experiment would be  $0.686 \text{ nm}$  or about 2.3% of the thickness of the cantilever. Multiplying this quantity by the spring constant gives an estimate of the force sensitivity of  $6 \text{ pN}$ ; therefore, a (BIO)NEMS cantilever with this geometry is capable of detecting the breakage of a single hydrogen bond, indicating its potential as a single-molecule biosensor. The cross-correlation of the Brownian fluctuations of two facing cantilevers is small compared with the individual fluctuations. The largest magnitude of the of the cross-correlation is  $-0.012 \text{ nm}^2$  for  $s = h$  and  $-0.0029 \text{ nm}^2$  for  $s = 5h$ . The noise spectra for both the one- and two-cantilever fluctuations are shown in Fig. 1.9(a and b).

The variation in the cross-correlation behavior with cantilever separation as shown in Fig. 1.8(c) can be understood as an inertial effect resulting from the non-zero Reynolds number of the fluid flow. The flow around the cantilever can be separated into a long-range potential component that propagates instantaneously in

**Figure 1.8.** Predictions of the auto- and cross-correlation functions of the equilibrium fluctuations in displacement of the cantilevers shown in Figs. 1.3 and 1.7(a). The step force applied to the tip of the first cantilever is  $F_1 = 75$  pN. (a) Autocorrelation and (b) cross-correlation of the fluctuations (5 separations are shown for  $s = h, 2h, 3h, 4h$  and  $5h$ , where only  $s = h$  and  $5h$  are labeled, and the remaining curves lie between these values in sequential order).

the incompressible fluid approximation and a vorticity containing component that propagates diffusively with diffusion constant given by the kinematic viscosity  $\nu_f$ . For step forcing, it takes a time  $\tau_v = s^2/\nu_f$  for the vorticity to reach distance  $s$ . For small cantilever separations the viscous component dominates, for nearly all times,

**Figure 1.9.** (a) The noise spectrum  $G_{11}(\nu)$  and (b) the noise spectrum  $G_{12}(\nu)$  as a function of cantilever separation  $s$  for two adjacent experimentally realistic cantilevers. Five separations are shown for  $s = h, 2h, 3h, 4h$  and  $5h$ , where only  $s = h$  and  $5h$  are labeled, and the remaining curves lie between these values in sequential order.

and results in the anticorrelated response of the adjacent cantilever in agreement with [12]. However, as  $s$  increases, the amount of time where the adjacent cantilever is only subject to the potential flow field increases, resulting in the initial correlated behavior.

The complex fluid interactions between individual cantilevers in an array are still an area of active research. Nevertheless, using the thermodynamic approach described here it is now possible to describe quantitatively, with experimental accuracy, the stochastic dynamics of micro- and nanoscale oscillators in fluid. A compelling feature about these results is that the proposed experiments are just beyond the reach of current technologies, making the theoretical results that much more important, as the insight gained will be critical in guiding future efforts.

### 1.3

#### The Physics Describing the Kinetics of Target Analyte Capture on the Oscillator

Now that we have developed the methods necessary to understand the stochastic dynamics of small cantilevers in fluid we turn to the physics describing the capture of target analyte. In order to provide analyte specificity, cantilever surfaces are generally *functionalized* to contain an array of receptor molecules complementary to the target analyte (ligand). This functionalization is carried out by constructing a self-assembling monolayer (SAM), consisting of alkanethiol chains, to which specific receptor molecules are linked. Among other things, the overall performance of (BIO)NEMS cantilever-type sensors will depend on the analyte–receptor capture kinetics and we now discuss a number of issues related to this problem. The basic situation for analyte binding to the functionalized surface of a cantilever is shown in Fig. 1.10.

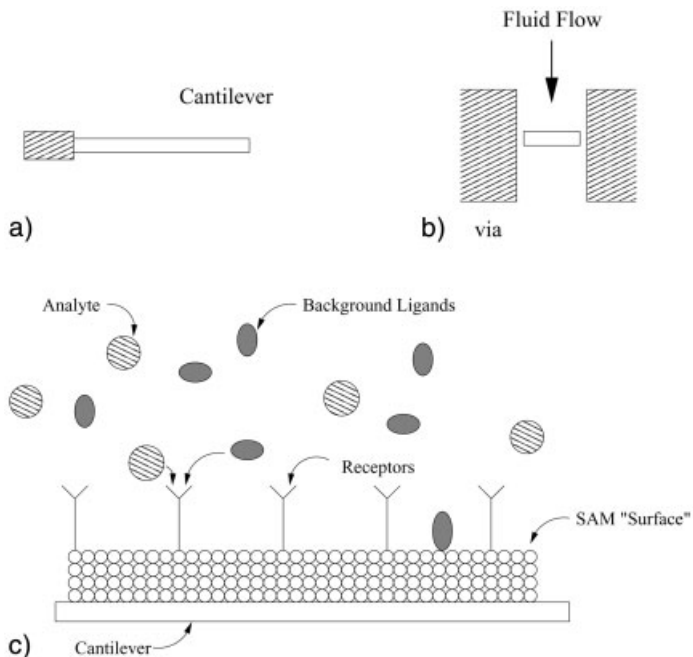

The binding of analyte from bulk solution to a fixed array of receptors located on a cantilever tip can be described by the kinetic equations relevant to the case of ligand binding to cell surface-bound receptors [48–50], i.e.:

$$\frac{dB}{dt} = [k_{\text{on}}L_oR_o - (k_{\text{on}}L_o + k_{\text{off}})B] \left[ 1 + \frac{k_{\text{on}}(R_o - B)}{k_+} \right]^{-1} \quad (35)$$

where  $B$  is the number of analyte–receptor bound complexes,  $L_o$  is the analyte concentration and  $R_o$  is the total number of receptors in the functionalized array. This model equation describes the reversible biochemical reaction:

The parameters  $k_{\text{on}}$  and  $k_{\text{off}}$  are the usual forward and reverse rate constants for analyte–receptor binding, and  $k_+$  is the so-called diffusion rate constant, which for the case at hand is just  $k_+ = 4\pi\mathcal{D}a_c$ . The quantity  $\mathcal{D}$  is the analyte diffusion coefficient and  $a_c$  is a length which characterizes the size of the functionalized area,

**Figure 1.10.** (a) The side view of a single cantilever. (b) A schematic placing the cantilever in a via. Fluid flows through the via and around the cantilever shown as a rectangular box in the center. (c) A closeup view of a cantilever tip that has been biofunctionalized.

e.g. its width. Defining new variables,  $u = B/R_o$  and  $\tau = k_{\text{off}}t$ , this equation may be put into the more useful nondimensional form:

$$\frac{du}{d\tau} = \frac{K' - (1 + K')u}{[1 + \beta(1 - u)]} \quad (37)$$

with dimensionless parameters  $K' = L_o k_{\text{on}}/k_{\text{off}}$  and  $\beta = R_o k_{\text{on}}/k_{\text{+}}$ . This rather simple kinetic equation describes the analyte–receptor binding under reaction–diffusion conditions, where the parameter  $\beta$  indicates the extent to which the binding is reaction limited ( $\beta \ll 1$ ) or diffusion limited ( $\beta \gg 1$ ).

To give the reader some quantitative insight into this problem, consider the case of biotin–streptavidin ligand–receptor binding. The functionalized region of the cantilever tip is taken to have an area of  $1 \mu\text{m}^2$ , with a total of  $10^4$  receptors linked to the SAM surface. Note that receptor densities achievable using SAM construction are several orders of magnitude larger than those observed for specific receptors found on biological cell surfaces. The forward binding rate constant is approximately  $k_{\text{on}} = 5 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ , with a reverse rate constant of  $k_{\text{off}} \sim 10^{-3} \text{ s}^{-1}$ . In

addition, we find that  $k_+ \approx 10^{12} \text{ M}^{-1} \text{ s}^{-1}$ ; thus,  $\beta = 0.05$  and the ligand–receptor binding process is essentially reaction limited. In fact, for cantilever-type devices designed for detection of biomolecules, we find that the capture process is almost invariably reaction limited. This means that the capture kinetics is dominated by the  $k_{\text{on}}$  and  $k_{\text{off}}$  rates of the analyte–receptor pair.

There are two issues of importance when it comes to evaluating the performance of these devices:

- (a) The ultimate sensitivity, which will depend on the total number of analytes captured on the cantilever surface;
- (b) The time required to achieve a specified sensitivity, which is determined by the capture kinetics.

If no other processes of significance are involved in analyte capture, then ultimate sensitivity can be estimated from a steady-state solution of the model equation given above. Thus, at steady-state, the fraction of total surface receptors that are bound by analyte is given by:

$$u_s = \frac{L_o K_a}{(1 + L_o K_a)} \quad (38)$$

where  $K_a$  is the analyte–receptor binding *affinity*. However, depending on the actual analyte–receptor rate constants and the analyte concentration, this may take a considerable time to achieve.

In addition to the basic model equation describing the capture of analyte from bulk solution to surface-bound receptors, there are at least two additional processes that should be considered in connection with sensor performance evaluation:

- (a) The effects of background *contaminant* biomolecules;
- (b) possible surface-enhanced analyte–receptor binding.

Interference by contaminant biomolecules may arise from two distinct mechanisms. The first of these is by *competitive* binding with the surface receptors, thus lowering the number of receptors available for analyte capture. Competitive binding effects may be analyzed by using a straightforward extension of the basic model equation discussed above. Results of such analyses show that these effects may generally be neglected even for background biomolecule concentrations approaching 10 times the analyte concentration. This is of course largely due to the fact that binding affinities for such biomolecules are 1–3 orders of magnitude smaller than the analyte–receptor binding affinities. The second mechanism involves non-specific binding of contaminant biomolecules to the SAM surface itself and would be important if analyte detection were accomplished by mass-loading effects. Even though achievable receptor surface densities for these devices approach  $10^{12} \text{ cm}^{-2}$ , a molecule in solution still “sees” mostly bare SAM surface. Thus, contaminant biomolecules may become attached to the cantilever through nonspecific surface

binding. If one treats the alkanethiol end groups as discrete binding sites on the SAM surface, then this problem may be handled by a model equation analogous to the analyte–receptor capture kinetics equation.

Since the concept was first introduced by Adam and Delbruck [51], the possibility of so-called surface-enhanced ligand–receptor binding has been studied by a number of investigators [48, 52, 53]. This mechanism involves a two-step process:

- (a) Nonspecific binding of ligand from bulk solution to a surface;
- (b) Ligand–receptor binding following 2-D diffusion along the surface.

Although this process may easily be modeled by a pair of coupled kinetic equations, actual quantitative assessment is made difficult by the lack of reliable values for the relevant parameters, i.e. surface nonspecific binding rate and the so-called *collision-coupling* rate constant,  $k_c$  [48]. The parameter  $k_c$  is the rate constant for a surface-diffusing ligand to bind with a surface-bound receptor and is a difficult quantity to measure experimentally. Nevertheless, it may be useful to attempt to estimate the magnitude of this effect for a particular device implementation since it can result in significant enhancement of the analyte capture efficiency for certain combinations of parameters.

Without considering the parameters of a fully specified sensor it is difficult to give general estimates for cantilever capture performance. However, if we consider the  $k_{\text{on}}$ ,  $k_{\text{off}}$  rates of the biotin–actin system described above, then the binding affinity will be  $K_a = 5 \times 10^9 \text{ M}^{-1}$ . Thus, the steady-state receptor coverage is expected to be 33% for an analyte concentration of 0.1 nM. While this represents a very substantial capture efficiency, it should be noted that for these parameter values it will take many 10s of seconds to approach this coverage. This simple example points up an important issue that often arises when attempting to implement specific sensors of this type: One must usually make a trade-off between achievable sensitivity and the time required to make a measurement. A number of applications of these sensors require that detection of the presence of analyte be accomplished in times that are less than 1 s; not infrequently one wishes to achieve millisecond (or less) detection times.

So far the discussion has assumed that analyte transport to the cantilever is accomplished by diffusion only; however, most proposed cantilever sensor implementations involve the use of a microfluidic system to provide constant flow of analyte in a carrier fluid. Thus, in principle, one must consider analyte capture in the context of a reaction–diffusion–convection problem and examine the impact of convection on analyte capture efficiency. Given the previous discussion regarding the reaction rate-limited nature of the analyte capture process, one expects that convection will not have a significant impact on capture efficiency. We can also arrive at this conclusion based on two different fluid dynamics arguments. If one can show that diffusion effects dominate over convection effects in the system, then our previous argument regarding the reaction-limited character of the process still holds and convection cannot contribute significantly to analyte capture. A dimensionless parameter, the Peclet number:

$$\text{Pe} = \frac{LU}{\mathcal{D}} \quad (39)$$

measures the relative importance of convective flow versus diffusive transport; here,  $L$  is a characteristic length of the system,  $U$  is the flow velocity and  $\mathcal{D}$  is the diffusion coefficient. For example, if we take  $L = 1 \mu\text{m}$ ,  $U = 10 \mu\text{s}^{-1}$ , and  $\mathcal{D} = 100 \mu\text{m}^2 \text{s}^{-1}$ , then we have  $\text{Pe} = 0.1$ , and diffusion is the dominant transport process. We may also observe that for laminar flow perpendicular to the cantilever surface a diffusion boundary layer of thickness  $\delta$  is formed. This boundary layer thickness is given approximately by:

$$\delta \approx L(1/\text{Pe})^{1/3} \quad (40)$$

For the parameter values just used this yields a diffusion boundary layer thickness of about  $2.2 \mu\text{m}$ ; thus, at this flow rate essentially all analyte transport to the cantilever surface must be by diffusion. Of course one may also consider significantly increasing the fluid flow velocity; however, nanoscale cantilevers can easily be damaged by high flow rates. Even if the flow velocity is not high enough to actually damage a cantilever, it can result in a “bending bias” of the cantilever which can interfere with detection of binding events. We should point out, however, that these arguments should be re-examined when considering specific sensor implementations.

The use of mass-action-derived kinetic equations for the purpose of analyzing analyte capture performance is completely adequate for analyte concentrations down to about  $0.1\text{--}1.0 \text{ nM}$ . However, when we consider analyte concentrations in the picomolar (or smaller) range, concentration fluctuations may become important in describing the overall performance of the sensor system. Recall that an analyte concentration of  $1 \text{ nM}$  corresponds to a molecular density of slightly less than  $1 \text{ molecule } \mu\text{m}^{-3}$ . In this event one must resort to stochastic methods for describing the reaction–diffusion process of analyte capture. For this case we mention an approach originally developed by Gillespie [54, 55] for “exact” stochastic simulation of coupled chemical reactions. Since the approach has been extended by Stundzia and Lumsden [56] to incorporate diffusion effects, the combined algorithm is suitable for providing a stochastic analysis of the analyte capture problem.

The Gillespie approach is based on the fact that at the microscopic level chemical reactions consist of discrete events that may be described by a joint probability density function (PDF). Thus, given a total of  $\mu = 1, 2, \dots, M$  coupled reactions, consisting of a total of  $\nu = 1, 2, \dots, N$  species, the appropriate joint PDF is  $P(\mu, \tau)$ , where  $\tau$  is the time interval between reactions. This is simply the joint probability that the  $\mu$ th reaction occurs after a time interval of  $\tau$ , which may be written as  $P(\mu, \tau) = P(\mu)P(\tau)$ . Expressions for the individual probabilities are readily derived; these expressions may then be used to implement a rather simple computer algorithm that simulates the evolution of the discrete species concentrations as a function of time, thus yielding the stochastic kinetics for the system. As Gillespie has shown [57], the resulting algorithm is an “exact” simulation of the stochastic master equation describing the coupled chemical system.

As mentioned above, as long as analyte concentrations are expected to be in a range where concentration fluctuations are not important, i.e. greater than about 0.1–1.0 nM, then use of the usual mass-action-derived kinetic equations is perfectly satisfactory in estimating the capture kinetics of the sensors considered here. However, since by its nature the mass-action-derived kinetics computes average values, this method cannot give one any insight into the stochastic behavior of the system. While there are no well-defined rules as to when one must consider fluctuations, it is generally true that when the total number of reactant molecules (ligands) in the reaction volume is only of the order of several hundred, then one should begin to suspect that fluctuations may play an important role in the system behavior. In such cases it is advisable to investigate this possibility through the use of a stochastic simulation algorithm such as the one described above.

#### 1.4

#### Detecting Noise in Noise: Signal-processing Challenges

Although space does not permit a detailed analysis of the various signal-processing methods that may be used in conjunction with (BIO)NEMS cantilever-type sensors, we present a simple analysis of the most basic signal detection method that one might employ. For this analysis we assume a single passive cantilever that utilizes a piezoresistive transducer to sense the fluctuations in the cantilever tip. As discussed before, the term passive simply means that we do not actively drive the cantilever motion in order to provide for a lock-in detector-type processing system. Under these assumptions, and with no analyte bound to the cantilever, the mean-square displacement of the cantilever tip due to fluid fluctuations is given by:

$$\langle x^2(t) \rangle = \frac{4k_B T \gamma_e}{k^2} \quad (41)$$

where  $k_B$  is Boltzmann's constant,  $T$  is the temperature,  $\gamma_e$  is the effective damping constant for the cantilever and  $k$  is the effective spring constant for the cantilever. The mean-square voltage signal into the front end of a signal-processing system is then just:

$$\langle v^2(t) \rangle = |\mathcal{G} \cdot I|^2 \langle x^2(t) \rangle \quad (42)$$

with  $\mathcal{G}$  being the transducer conversion coefficient and  $I$  being the piezoresistive bias current.

We next assume that the presence of bound analyte on the cantilever tip appears as a change in the effective cantilever damping constant, i.e.  $\gamma_e \rightarrow \gamma_e^b$ . Note that in this situation our “signal” appears as a change in the mean-square fluctuations of the cantilever tip. From a signal detection theory standpoint we are attempting to discriminate against the presence of two random voltages, both being Gaussian

distributed but having different variances. Our expressions for the mean-square voltage fluctuations yield a (power) signal-to-noise ratio,  $(\text{SNR})_p$ , of:

$$(\text{SNR})_p = \frac{\gamma_e^b}{\gamma_e} \quad (43)$$

Note that since our expression for the mean-square displacement fluctuations was essentially derived from a fluctuation–dissipation theorem, these expressions are for a system with infinite bandwidth. Our expression for  $\text{SNR}_p$  may thus be called an *inherent* signal-to-noise ratio for this detection modality. The simplest possible processing of this signal then amounts to sending it through a low-noise root mean square (r.m.s.) detector with threshold. The threshold is set to achieve the desired balance between probability of detection and false-alarm probability (*cf.* Ref. [58]).

Of course, since it is usually required that one achieve the highest possible system sensitivity, more sophisticated signal-processing techniques than the simple r.m.s. detector are usually required. We will mention only two such possibilities:

- (a) Passive detection using a *reference* cantilever;
- (b) Active detection using a reference cantilever and lock-in (phase) detection.

In the first case we incorporate an additional cantilever, which is *not* functionalized, into the system. One may then use a technique which is analogous to one developed in the early days of radio astronomy. In this implementation one periodically switches between the reference and sensing cantilevers to make what amounts to a phase-detection measurement of the “signal” power. The method allows one to eliminate the front-end electronics noise and to make a much better estimate of the no-signal power, thus allowing an improved signal-to-noise ratio. In the second approach we move to an active system where the reference and sensing cantilevers are subjected to periodic deflection forces that are  $90^\circ$  out of phase. This allows one to directly utilize lock-in amplifier (phase detector) technology to achieve significant enhancements to the achievable signal-to-noise ratio. For details on these and other more sophisticated signal-processing approaches to the detection of cantilever sensor signals, the reader is referred to Refs. [58–60].

## 1.5

### Concluding Remarks

The physics and modeling of (BIO)NEMS devices poses many theoretical challenges that must be faced as experiment continues to push measurement to the nanoscale. In this chapter we have just scratched the surface of this exciting new field. In picking one particular example to focus upon it was our intent to leave the reader with an idea of some of the physics and modeling issues that one may encounter.

## Acknowledgments

Our research in the modeling of MEMS and NEMS has benefited from many fruitful discussions with the Caltech BioNEMS effort (M. L. Roukes, PI) and we gratefully acknowledge extensive interactions with this team.

### 2.1

#### Introduction

Within recent decades, quickening research and development of liposomal and nanoparticle delivery systems has made Paul Ehrlich's dream of *zauberkugeln* – therapeutic magic bullets – a reality. Although these bilipid and polymeric fabrications of the modern laboratory never received the scrutiny of his microscope, their potential to seek out and destroy specific pathogens while leaving the body's healthy tissues relatively unharmed promises to fulfill the paradigm of targeted drug delivery that he envisaged. A critical advantage afforded by the use of molecularly targeted nanovectors over conventional free-drug and antibody-based therapy is highly tunable selectivity, which greatly increases the therapeutic index of any given drug.

A plethora of excellent experimental work has been undertaken ranging from surface modification to prolong circulation, to ligand–particle conjugation to augment selectivity [1–17]. Mathematical and computational modeling can complement this experimental work by providing insight and guidance in both the fabrication and the performance of nanotechnology. A popular concern of such modeling is exemplified in work [18, 19] in which drug-release behavior of nanodevices is modeled according to the laws of mass balance and Fickian diffusion. However, the performance of micro- and nanodevices must be considered in the context of a dynamic biological environment, spanning several scales and modes, including the intravascular, the intratumoral and even the intracellular. Therefore, it is not merely what such devices do in isolation that requires investigation, but also what they do in the body, and what the body does, or attempts to do, to them. From this perspective, a principal consideration in the optimization of nanodevice performance is a thorough understanding of those bodily environments and systems with which the devices will interact. Thus, we do not merely use mathematics and computation to model the nanodevice, but rather to model the performance of the nanodevice/body system. The implications for improvement in not only the devices themselves, but also modes of delivery and possible adjuvant treatments to maximize performance (see, e.g. Ref. [20]), can be readily appreciated.

The treatment of cancer employing liposomes and nanoparticles provides fertile

ground for demonstrating this approach. For example, the modeling and simulation of vasculogenesis and hemodynamics [21–23] point out difficulties in homogeneously delivering nanovectors to tumoral lesions. This has consequences for their design specifications, such as circulation time, loading and release kinetics. Furthermore, fundamental performance limitations imposed by the biological environment must be defined in order for the direction of future development to be determined. Work on opsonization prevention by authors such as Torchilin and coworkers [24], and work on receptor–ligand binding by Bell [25] and Cozens-Roberts and coworkers [26, 27], has a direct influence on the design of liposomes and nanoparticles. Overprotection from protein adsorption may interfere with desirable receptor–ligand binding and therefore both potentials must be mutually optimized. Alternately, methods could be developed that circumvent interference. As yet another example, *in silico* modeling of nanoparticle chemotherapy, such as that performed by Sinek and coworkers [28], can demonstrate potential strengths as well as weaknesses in the particle-vectored delivery paradigm. Knowing the obstacles and options along one’s path is at least half of what is required in planning one’s journey.

The treatment of cancer motivates the lion’s share of nanodevice drug delivery research and provides excellent modeling opportunities in the spirit of what has been discussed above. In this chapter we identify four critical scales or environments which intravenously injected nanovectors must navigate in order to extravasate in sufficient quantity into tumoral tissue and deliver drug in the most efficacious manner. The corresponding functions at each of the scales they must successfully perform are

- To avoid uptake by the reticuloendothelial system (RES) while in circulation.
- To navigate irregularities of tumoral vasculature and homogeneously extravasate.
- To selectively bind to cancer cells and undergo endocytosis.
- To release drug at a level and on a timescale that optimizes cell kill without precipitating tumoral fragmentation.

Mathematical models and computer simulations regarding each of the four phases are discussed in the following sections. The mathematics used ranges from simple force-balance systems to stochastic processes and sophisticated reaction–diffusion solvers. To our knowledge, while facets of nanodevice drug delivery modeling have been expertly treated, no attempt has been made at integrated modeling encompassing the many scales of the problem. Defining those scales while providing examples of models that address each of them is a beginning to unification.

## 2.2 RES Avoidance

The RES is a system of macrophages and specialized cells lining the liver, spleen, bone marrow and lymphatic tissue. Unprotected colloidal moieties, including lipo-

somes and nanoparticles, are sequestered and removed from circulation by the RES too rapidly for them to be effective [29]. A representative accumulation due to sequestration by the reticuloendothelial system is in the liver (60–90% of injected dose), spleen (2–10%), lungs (3–20%) and bone marrow (above 1%) [30, 31]. Not only does removal from circulation prevent particles from reaching their intended target, but also the accumulation in unintended sites could present a toxic threat.

A critical factor in avoiding this uptake is the prevention of opsonization, i.e. the accrual of proteins on the particle surface. The principal way in which this is achieved is by making suitable surface modifications to the particles [12]. Developments chiefly revolve around coating particles with hydrophilic polymers and surfactants. In an early study, Wilkins and Myers [1–3] treated polystyrene particles with polylysyl gelatin and gum Arabic, resulting in an altered distribution throughout the RES, but ultimately the same total sequestered fraction as with untreated particles. Later, Tröster and coworkers [4] and Tröster and Kreuter [5] performed an extensive study of 13 surfactants and polymers as coatings for nanoparticles, and were able to significantly reduce total RES uptake at 30 min post-injection, with uptake increasing to the same level as with uncoated nanoparticles after 7 days. Bazile and coworkers [6] developed nanoparticles based on methoxy poly(ethylene glycol) (PEG)–poly(lactic acid) (PLA) blends, and, by employing  $^{14}\text{C}$  labeling, demonstrated a reduction in their capture by cultured THP-1 monocytes. Poloxamine- and poloxamer-coated nanoparticles have also been studied with respect to liver and spleen uptake and circulation longevity in rabbits and rodents with favorable results [7–11]. Today, popular coating materials are PEG, poly(ethylene oxide) (PEO), poloxamer, poloxamine, polysorbate (Tween-80) and lauryl ethers (Brij-35) [12].

Insight can be gained in modeling the mechanisms by which polymers like PEG and PEO reject protein adhesion to nanovectors. Lasic and coworkers [32] offer a qualitative model of particle rejection in which steric repulsion is generated by a surface of hydrated PEG chains that “brush” away incoming macromolecules. Indeed, the term “steric stabilization” has become standard in describing polymer-mediated protection. In what follows, we present models by Torchilin and coworkers [24] and Jeon and coworkers [33]. In the former, statistical simulations demonstrate the area of coverage of polymer chains as functions of their flexibility and length. The optimization of these parameters as well as the surface coating density is one goal. The latter model focuses on the balance of forces keeping proteins removed from the particle or liposome surface.

### 2.2.1

#### **A Statistical Model of Nanovector Surface Coverage**

Torchilin and coworkers [24] model nanoparticle protection as statistical “clouds” produced by surface-grafted PEG chains that rapidly transit within a “space” of conformations. The surface covered by these clouds is unavailable for blood protein binding, and therefore the density and area of coverage produced by each polymer chain is of interest.

**Figure 2.1.** Model of a polymer chain attached to the particle or liposome surface. (a) Single conformation of one chain. (b) Superposition of 11 random conformations. (Reprinted from Ref. [24], p. 14, © 1994, with permission from Elsevier.)

A single polymer chain is modeled as being composed of a number of segments (e.g. 20), each a fixed unit in length (e.g. 1 nm). Each joint can be selectively articulated and, reckoning from joint 0 anchored into the particle, the mass of each segment is assumed to be concentrated at the distal end (Fig. 2.1). By simulating numerous conformations, an empirical probability distribution in the space directly above the liposome surface can be constructed. By coupling this distribution with the rate of conformation change, the apparent density of the cloud and, therefore, its ability to sterically hinder proteins can be known. Three parameters are critical – the degrees of freedom (or flexibility, as Torchilin calls it) of the polymer chain, its length and its rate of conformation change. To simulate a flexible polymer chain (one having many degrees of freedom), one would allow complete articulation at each joint. To simulate a less-flexible chain, some of the joints would be locked. The probability distributions in Fig. 2.2 show the effects of chain length and flexibility.

Torchilin's model can be used to optimize steric protection, which must be balanced against targeting affinity, if this is desired (see Section 2.4). In general, density and area of coverage increase as the length (weight) and flexibility of polymer chains increase. From the model simulations, the number of polymer chains to be attached to a given nanovector required for a specified degree of coverage, while still providing for accessibility to targeting ligands, can be calculated. Results are given in Fig. 2.3 and are in agreement with experimental data [24–35].

**Figure 2.2.** Simulated distributions of polymer conformations in space directly above the particle surface. (a–c) Effect of polymer length. (a) Short-chain polymer provides little protection. (b) Optimal chain length provides adequate protection while leaving enough surface exposed for receptor–ligand interaction. (c) Excessive length hinders the function of potential targeting ligands on the polymer surface. (d) Rigid polymer is

simulated in the upper panel by assuming four segments of 5 nm each. Although the area of protection appears large, the density of coverage is compromised. Flexible polymer is simulated in the lower panel by assuming 20 segments of 1 nm each. All simulations assume the density of the segments is concentrated in their distal ends. (Reprinted from Ref. [24], pp. 16 and 15, © 1994, with permission from Elsevier.)

**Figure 2.3.** Model predictions for the minimum number of PEG molecules of a given weight needed for 100% coverage of a liposome of radius 100 nm. (Reprinted from Ref. [24], p. 17, © 1994, with permission from Elsevier.)

**Figure 2.4.** Pictorial description of the model used by Jeon and coworkers. The two principal forces that mediate binding are steric repulsion due to compression of the PEO chains, and

hydrophobic attraction between the protein and solid substrate. Van der Waals attraction plays a minor role. (Reprinted from Ref. [33], p. 150, © 1991, with permission from Elsevier.)

## 2.2.2

**Modeling the Forces Mediating Protein Approach and Binding**

While surface availability is one determinant of opsonization, ultimately it is the forces between a particle and approaching protein that determine whether it binds. Jeon and coworkers [33] model the approach of a protein with a hydrophobic patch to a hydrophobic particle substrate surfaced with PEO chains as in Fig. 2.4.

The principal forces considered are steric repulsion due to compression of the PEO chains and hydrophobic attraction between the protein and the substrate, although van der Waals attraction plays a minor role. These forces are functions of PEO chain separation distance  $D$  (a measure of density) and polymerization  $N$  (a measure of length). Their corresponding free energies are given as:

$$F_{\text{St}} = K_1 N D^{-11/3} \left[ \left( \left( \frac{K_2 N D^{-2/3}}{d} \right)^{5/4} - 1 \right) + \frac{5}{7} \left( \left( \frac{d}{K_2 N D^{-2/3}} \right)^{7/4} - 1 \right) \right]$$

$$F_{\text{Hyd}} = -K_3 e^{-d/14}$$

where the  $K$ 's are positive constants, and  $d$  is the separation of protein and polymeric substrate.

Consulting Fig. 2.5, as the protein approaches the PEO-coated substrate, it experiences hydrophobic and, to a lesser extent, van der Waals attraction. The hydrophobic attraction free energy is negative and decreasing with approach, as shown in Fig. 2.5(a). However, strong repulsive steric forces generated by compression of the PEO chains are soon encountered and dominate (Fig. 2.5(b)). Depending on  $D$  and  $N$ , the sum of their free energies can produce an energy well as illustrated in Fig. 2.5(c). It is the depth of this well that determines how tightly bound the protein becomes. As might be expected, high surface density (low values of  $D$ ) and long chain length of PEO (high values of  $N$ ) are desirable for optimal protein resistance, with surface density having a greater effect. Furthermore, PEO retains an advantage among water-soluble synthetic polymers due to its low refractive index, resulting in low van der Waals interaction with the protein.

## 2.3

**Tumoral Vasculature and Hemodynamics**

All systemically administered drug therapy, whether free or nanovectored, relies upon the tumoral vasculature to gain access to malignant cells. As the quantity and uniformity of extravasated nanovectors is of pivotal importance to the success of therapy, models of tumoral vasculogenesis and hemodynamics are indispensable. However, the tumor vasculature is notorious for its irregularity [20, 36, 37]. The tumor vasculature does not follow the normal organizational pattern in which an artery connects to an arteriole to a capillary to a postcapillary venule to a venule to a vein. Instead, a tumor venule may connect to another venule via capillaries or

postcapillary venules. The organization may also be spatially and temporally heterogeneous. The blood flow in tumors grown in transparent windows has been investigated and found to be intermittent, periodically abating and reversing [37, 38]. Tumor vessels are also dilated, saccular and hyper-fenestrated, often containing cancer cells within the vessel endothelial lining. Hobbs and coworkers [39] found that the pore sizes in one human and five murine tumors ranged from 380 to 780 nm, significantly higher than in normal tissue. While this pore size is used to advantage in the preferential extravasation of particles at lesion sites, it also leads to increased fluid extravasation and interstitial pressure. As extravasation from the vasculature depends in part on convection, this increased pressure may unfavorably influence transport. In addition to interstitial fluid pressure, a tumor has a separate mechanical pressure associated with cellular proliferation. Padera and coworkers [40] found that this mechanical stress plays a key role in the collapse of tumor vessels and further restriction of the blood supply in the tumor.

Mathematical models have revealed that the topology of the tumoral vasculature may have a significant impact on blood flow through the network. Secomb and Hsu [41] suggested that irregularities in the vascular geometry could lead to a 2-fold increase in the vascular resistance, relative to the resistance measured in a uniform tube with the same mean diameter. Baish and coworkers [22] have found similar characteristics. In a later work, Baish and coworkers [42] showed that the excessive compliance and leakiness of tumoral vasculature causes blood flow to be diverted from the center of the tumor to its periphery. Recently, Sinek and coworkers [28] have demonstrated that vasculature irregularities are as detrimental to particulate drug delivery systems as to free-drug administration. Results such as these suggest the need for therapies designed to “normalize” the vasculature [22, 20]. Pruning immature and inefficient blood vessels may lead to a more normal vasculature of vessels reduced in diameter, density and permeability, with the potential of restoring more normal hemodynamics.

We next consider models and simulations of both vasculogenesis as well as hemodynamics [21–23]. We furthermore review work performed [43] regarding erythrocyte and leukocyte dynamics within capillaries, which is highly nonlinear and cannot be inferred solely from the dynamics of a strictly Newtonian fluid.

### 2.3.1

#### An Invasion Percolation Model of Vasculogenesis and Hemodynamics

Baish and coworkers [22] used an invasion percolation model of vasculogenesis to investigate the heterogeneity of vessel perfusion and resistance to flow. The principle of invasion percolation is that vascular growth follows the gradient of a sub-

---

←

**Figure 2.5.** (a) Free energy due to hydrophobic attraction and (b) free energy of steric repulsion. Depending on the values of  $D$  and  $N$ , an energy well can be created as in panel (c). The depth of the well determines the force of binding. For low values of  $D$  (high density), steric repulsion dominates; for higher values, energy wells are produced. Strongest binding occurs for  $D = 9$  or above. (Panel c reprinted from Ref. [33], p. 157, © 1991, with permission from Elsevier.)

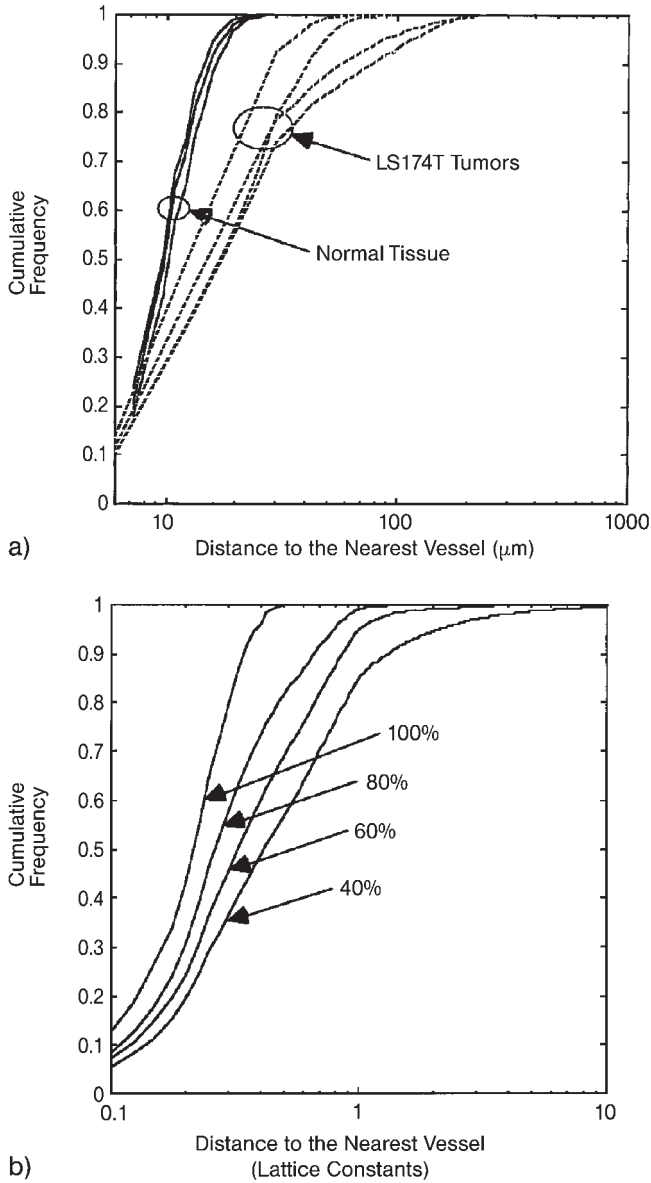

**Figure 2.6.** Examples of two networks produced by the invasion percolation model of Baish and coworkers, showing the network produced when 80 (a) or 60% (b) vessel occupancy is specified. (Reprinted from Ref. [22], p. 332, © 1996, with permission from Elsevier.)

strate’s material weakness rather than responds to a physiological stimulus, such as the gradient of oxygen. To simulate the network, the model begins with a square array of lattice points to which material “strengths” are assigned. The network is then “seeded” at the lower left point. In subsequent iterations it extends to, or invades, the point adjacent to the network that has the lowest strength. This is repeated until a desired vessel “occupancy” (density) is attained (Fig. 2.6).

The structure of their simulated networks was characterized by two measurements propounded earlier by Gazit and coworkers [44] in their studies on mice – the fractal dimension  $d_{\text{vasculature}}$  and the minimum path length  $d_{\text{min}}$ . The table reprinted here as Fig. 2.7 compares several known network growth processes to

Dimension	Known Growth Processes			Observed <i>in vivo</i>		
	Space-filling growth	Diffusion limited aggregation	Invasion percolation	Normal capillaries	Normal arteries and veins	Tumor vessels
$d_{\text{vasculature}}$	2.00	1.71	1.90	$1.99 \pm 0.01$	$1.70 \pm 0.03$	$1.88 \pm 0.04$
$d_{\text{min}}$	1.00	1.00	1.13	$1.00 \pm 0.02$	$0.99 \pm 0.02$	$1.10 \pm 0.04$

**Figure 2.7.** A comparison of the values of  $d_{\text{vasculature}}$  and  $d_{\text{min}}$  for several known growth processes and processes observed *in vivo*. Note the agreement between the invasion percolation model and tumor vessels. (Reprinted from Ref. [22], p. 331, © 1996, with permission from Elsevier.)

**Figure 2.8.** (a) Probability distributions of distance from the nearest vessel for both normal and tumoral tissue. (b) Probability distributions produced by the invasion percolation model set to various vessel

occupancies. The long “tail” of the distributions is a hallmark of tumoral tissue and is well reproduced in the model simulations. (Reprinted from Ref. [22], pp. 334 and 335, © 1996, with permission from Elsevier.)

those observed *in vivo* by Gazit and coworkers [44], and demonstrates the close correspondence between the results of invasion percolation and tumoral vessels.

With respect to the heterogeneity of perfusion, Fig. 2.8 shows typical probability distributions of distance from the nearest vessel. The important characteristic here is the long tail seen in tumoral vasculature distributions, which is qualitatively reproduced by the percolation model. This means that a significant portion of tumoral tissue is distant from vessels, not only reducing oxygenation, but also the transport of chemotherapeutic agents, especially particles that are expected to deliver their death signal via endocytosis.

The percolation model also predicts inefficient and heterogeneous flow as well as the increased resistance found in tumoral vasculature. In contrast to the fairly uniform fluid flux found in a regular mesh, a few of the vessels of a percolation network carry a disproportionately large flux, while some of the vessels are almost stagnant. In line with this, tumors are typically associated with a higher flow resistance than normal tissue even though they contain a higher proportion of large-diameter vessels [38, 45–48]. For example, tumoral vessels are typically 50% greater in diameter than those of normal tissue. Since flow resistance varies inversely with the fourth power of diameter, one would expect the resistance to be 20% of that in normal tissue. Even decreasing the vascular density by half would only increase resistance 2-fold, still yielding a net 40% of resistance found in normal tissue. According to the percolation model, however, halving the vascular density increases the resistance *7-fold* – more than enough to offset the vessel diameter advantage.

### 2.3.2

#### Flow Simulations Using Anderson and Chaplain's Model

Unlike the previous angiogenesis model [22], Anderson and Chaplain's model [21] relies heavily upon physiological stimuli. In order to produce veridical networks, they note that tumor angiogenic factors (TAFs), such as vascular endothelial growth factor, and fibronectin, a large, non-diffusing molecular constituent of the extracellular matrix, play key roles. TAFs, produced by perinecrotic cells starved of nutrients, induce a chemotactic response in endothelial cells (the essential component of blood vessels), causing them to degrade their parent vessel's basement membranes and migrate towards the tumor. Fibronectin, existing naturally in most tissues and also produced and degraded by endothelial cells, forms an adhesive matrix upon which they can migrate. As the endothelial cells move chemotactically up the gradient of TAFs towards the tumor, consumption of fibronectin produces lateral gradients enabling them to spread via haptotaxis. The interaction of endothelial cells with the extracellular matrix is crucial to the model. In particular, without the interaction of endothelial cells and fibronectin, the lateral motion of the cells, necessary to form vessel loops, requires a much higher random diffusivity than is experimentally measured.

Anderson and Chaplain's is a hybrid continuum–discrete model. Endothelial cell density  $e$ , along with TAF  $c$  and fibronectin  $f$ , are modeled with a system of continuum reaction–diffusion equations incorporating chemotaxis and haptotaxis:

$$\frac{\partial e}{\partial t} = D_e \nabla^2 e - \nabla \cdot (\alpha e \nabla e) - \nabla \cdot (\beta e \nabla f)$$

$$\frac{\partial f}{\partial t} = v_f e - \eta_f e f$$

$$\frac{\partial c}{\partial t} = -\eta_c e c$$

The first term on the right-hand side in the first equation represents cell diffusion (relatively weak) with diffusivity  $D_e$ , while the second and third represent chemotaxis up the TAF gradient and haptotaxis up the fibronectin gradient.  $\alpha$  and  $\beta$  can be constant; however, it is more realistic to have  $\alpha$  be a decreasing function of TAF [21]. The terms in the second equation represent production and uptake of fibronectin by endothelial cells, with  $v_f$  and  $\eta_f$  being constant. The term in the last equation represents uptake of TAF, with constant rate  $\eta_c$ . Initial conditions for endothelial cell density are set by seeding several small regions of high-density “sprouts” along a parental vessel (see below in Fig. 2.10). Initial fibronectin and TAF are assumed to be produced from the parental vessel and the perinecrotic rim just within the tumor, respectively. This results in concentrations decaying with distance from their sources. (Evolution of endothelial cell density is shown in Fig. 2.10.)

The discrete portion of the model is a reinforced random walk of blood vessel tips that begin at the endothelial sprouts. These tips probabilistically follow endothelial cell density as shown in Fig. 2.9. Higher densities of cells bias the random walk of the tip in their direction. Further rules determine capillary branching and

**Figure 2.9.** The vessel tip is initially in the middle. At the next time step it transits to one of the four neighboring grid points with probabilities  $P_1$ – $P_4$  or it stays at its present location

with probability  $P_0$ . The probabilities are determined by the underlying endothelial cell density as shown in Fig. 2.10. (Reprinted from Ref. [23], p. 679, © 2002, with permission from Elsevier.)

a)

b)

**Figure 2.10.** (a) The evolution of endothelial cell density of Anderson and Chaplain's model, beginning with three dense regions (sprouts) in the top left. Density proceeds across the region up the gradient of TAF towards the tumor, whose boundary is assumed on the right edge. Consumption of fibronectin

produces gradients that allow for the lateral spreading of the cell density. (b) The evolution of the actual vessels, whose tips probabilistically follow endothelial cell density. (Reprinted from Ref. [21], pp. 870 and 883, © 1998, with permission from Elsevier.)

the formation of loops (anastomoses) enabling circulation. The result is a realistic capillary network with its essential dendritic structure as well as the reproduction of the experimentally observed “brush border”, whereby extensive branching is observed just before the network penetrates the tumor [49, 50].

McDougall and coworkers [23] used Anderson and Chaplain’s model to simulate blood and drug flow to tumors. They analyzed effects of blood viscosity, pressure drop across parental vessel, mean radius of capillaries and radius of parental vessel by tracking the total quantity of drug within the vasculature in time.

The specifics of the model are as follows. A network is generated using Anderson and Chaplain’s algorithm as in Fig. 2.10, which is then mapped to a Cartesian grid. Then a radius  $R_{ij}$  is randomly assigned from a probability distribution to each element (vessel segment) joining nodes  $i$  and  $j$  on the grid. At each node  $i$  there exists a pressure  $P_i$ , and through each element joining nodes  $i$  and  $j$  there exists a flux  $Q_{ij}$ . This flux is assumed to obey Poiseuille’s law:

$$Q_{ij} = \frac{\pi R_{ij}^4 \Delta P_{ij}}{8\mu L_{ij}}$$

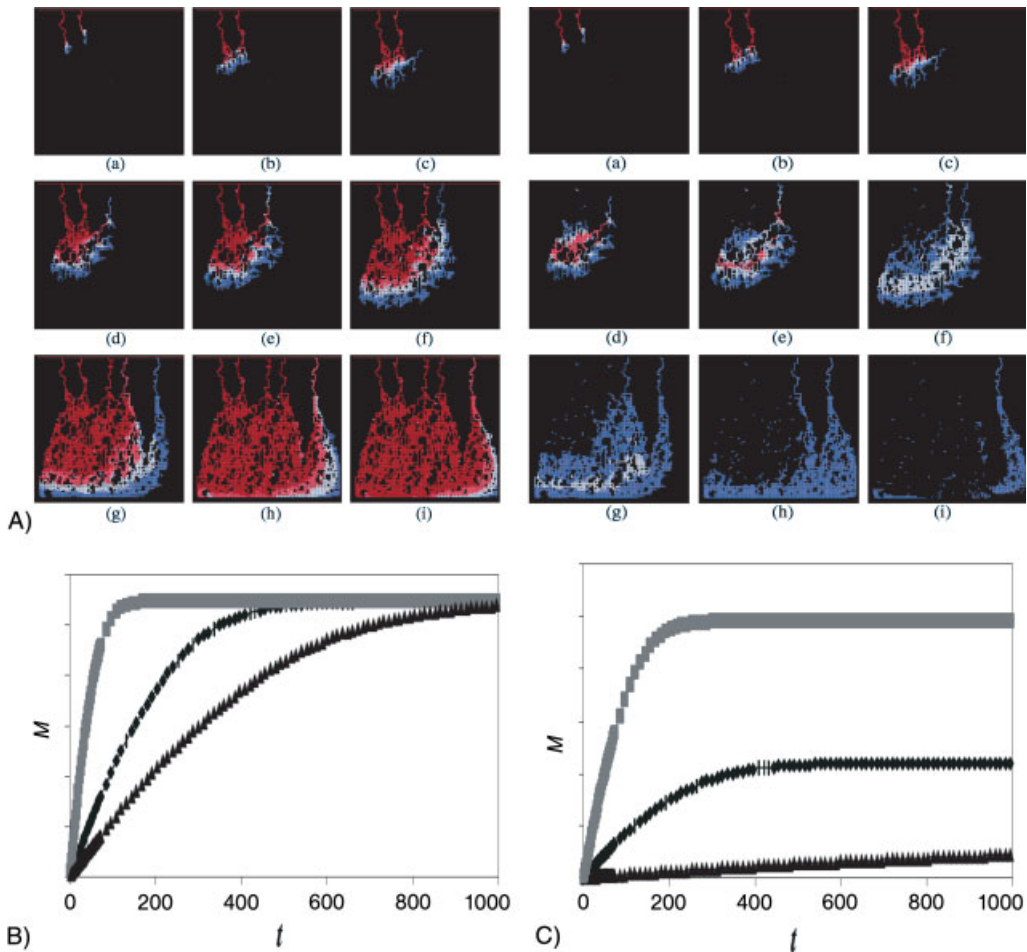

where  $L_{ij}$  is the length of element  $ij$  and  $\mu$  is fluid viscosity. Imposing mass conservation at each node  $i$  via:

$$\sum_{1 \leq j \leq 4} Q_{ij} = 0$$

where  $j$  varies over the four adjacent lattice nodes results in an exactly determined system of linear equations given the pressure drop across the parental vessel. The parental vessel feeds all capillaries going into the tumor.

To analyze drug flow, total drug mass  $M$  within the vasculature is tracked in time for values of four important parameters: blood viscosity, pressure drop across parental vessel, mean radius of capillaries and radius of parental vessel. A steady-state infusion as well as a bolus injection is shown in Fig. 2.11 for a base set of parameter values. The graph of  $M$  in time is shown for the continuous infusion and is compared to other graphs that result when, for example, mean capillary radius or viscosity are changed. When viscosity is raised, although the same limiting amount of drug mass is eventually reached within the vasculature  $M_\infty$ , the time required to reach that level is greater. Lowering the mean radius of the capillary bed, however, decreases the carrying capacity of the network so that  $M_\infty$  is, itself, reduced.

It is apparent that understanding results such as these is crucial to optimizing nanovector delivery. With increasing precision of measurement of the tumoral environment so as to provide more accurate input parameters, such simulations may improve to the point that they can quantitatively model a given patient’s lesion and contemplated therapy, bringing to bear the full weight of intervention on the disease.

**Figure 2.11.** Simulations of drug delivery. The parental vessel runs across the top, with blood flowing from left to right. The tumor boundary runs along the bottom. (A) The left upper set of panels show a continuous infusion for a base set of parameters (blood viscosity, pressure drop across parental vessel, mean radius of capillaries and radius of parental vessel). Blood begins to flow into the vascular bed through the first two vessels in (b) and (c). It begins to flow out of the bed back towards the parental vessel in frames (d)–(f). Steady-state is reached by frame (i). The right upper set of panels show a bolus injection for

the same base set of parameters. The lower set of graphs shows the effects of changing parameter values on the amount of drug in the vasculature  $M$  in scaled time  $t$  (continuous infusion). (B) From top to bottom shows the effect of increasing viscosity of blood: time to vascular saturation is lengthened although the saturation level remains constant. (C) From top to bottom shows the effect of decreasing the mean capillary radius: saturation capacity is severely reduced. (Reprinted from Ref. [23], pp. 689, 696, 690 and 691, © 2002, with permission from Elsevier.)

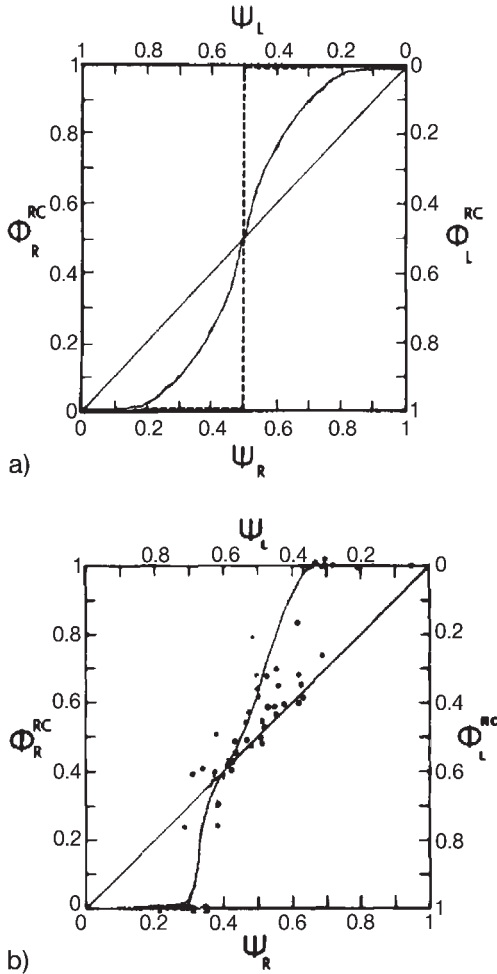

**Figure 2.12.** Diagram of a vessel bifurcation. Some important parameters are the branching angles  $\theta_L$  and  $\theta_R$ , the radii of the daughter vessels, and the eccentricity of the approaching liposome or particle. The latter is defined as axial displacement divided by vessel radius.

### 2.3.3

#### Particle Dynamics within the Tumoral Vasculature

The fluid flow dynamics discussed above become even more complex when particulate carriers are involved. Schmid-Schönbein and coworkers [43] model the flow of blood cells at vascular branches and find that the distribution of cells at a vessel bifurcation is nonlinearly related to bulk fluid flow through the branches. The analysis easily extends to liposomes and, to a lesser extent, nanoparticles. Figure 2.12 depicts the situation where a parental vessel splits into two daughter vessels. Here, important parameters are the left and right angles of separation  $\theta_L$  and  $\theta_R$  and the radii of the daughter vessels  $r_L$  and  $r_R$ . A particle that approaches the bifurcation may not be centered in the vessel, thus we measure its eccentricity  $e$ , defined as its distance from the centerline divided by the radius of the parental vessel. Letting the proportions of particles that enter either the left or right daughter vessel of a symmetric bifurcation ( $\theta_L = \theta_R$  and  $r_L = r_R$ ) be denoted by  $\varphi_L$  and  $\varphi_R$  ( $\varphi_L + \varphi_R = 1$ ), and also letting the proportions of total flow (all particulate matter and plasma) that enter each daughter be  $\psi_L$  and  $\psi_R$ , we can write particulate distribution as a function of total flow distribution and eccentricity  $\varphi = \varphi(\psi, e)$ , “R” and “L” subscripts having been dropped. Note that in the symmetric case it is not necessary that  $\psi_L = \psi_R = 0.5$  since blockages may exist downstream of one of the daughters. In the general case, this function will also depend upon the branching angles, daughter vessel radii and possibly other geometric information.

Several important results are obtained, perhaps the most notable being the nonlinear relationship shown in Fig. 2.13 in the case of symmetric branching. For particles whose diameter is small compared with the diameter of the vessel,  $\varphi_R = \psi_R$ .

**Figure 2.13.** Relationship between bulk flow distribution into left and right daughter vessels ( $\psi_L$  and  $\psi_R$ ) and particle flow distribution ( $\phi_L$  and  $\phi_R$ ). (a) For particles that are small in comparison to vessel radius, bulk flow distribution and particle flow distribution are the same (diagonal line). As the relative particle size grows, a sigmoidal relationship

becomes evident. At the limit, the step function results where  $\phi_R = 1$  for  $\psi_R > 0.5$ .

(b) Data from an experiment performed by Schmid-Schönbein and coworkers on red blood cells (dots) together with a least-squares fit (solid curve). (Adapted from Ref. [43], pp. 24 and 27, © 1980, with permission from Elsevier.)

Otherwise,  $\phi_R$  is very sensitive to deviations in  $\psi_R$  from 0.5, resulting in the steep curve. In the limit where the diameter of the particle is almost equal to the diameter of the vessel, this curve becomes vertical, so that for  $\psi_R > 0.5$ , all particles flow to the right, i.e.  $\phi_R = 1$ . However, there are notable exceptions for particles that cling to the endothelium, such as leukocytes. In some experiments performed by

Schmid-Schönbein and coworkers [40], in spite of a high percentage of the bulk flow to the right ( $\psi_R \geq 73\%$ ), white blood cells that were biased to the left, with some rolling along the endothelium, still entered the left branch. Although the eccentricity of the cells had an effect, this behavior was far less pronounced for red blood cells under similar conditions.

## 2.4

### Receptor–Ligand-mediated Binding

Much effort has been devoted to conjugating cell-targeting ligands on nanoparticles and liposomes in an attempt to improve specificity. The objective is that particles whose surface is covered by a layer of “adhesive molecules” (ligands) will tether to target cells expressing receptors for the ligands. These targets may be cells of tumor endothelium or the tumor cells themselves, which typically overexpress certain receptors, e.g. folate receptors, in comparison to normal cells. Lee and Low [51] were among the first to suggest that liposomes could be targeted to cancerous KB cells by conjugating them with folic acid (Fig. 2.14). Folate conjugates have a high affinity for cell-surface folate receptors ( $K_D \sim 10^{-10}$  M) [52]. Additionally, folate is inexpensive, stable during storage and *in vivo* circulation, and nontoxic. The steps in the folate-targeting of liposomes to cancer cells are shown in Fig. 2.15 and are as follows [17]:

- Liposomes pass through the tumor microvasculature.
- The increased vascular permeability of the tumor tissue enables the liposomes to extravasate into the tumor interstitial fluid.

**Figure 2.14.** Scheme for creating folate-targeted doxorubicin(DOX-PEG-FOL) Nan conjugates. The folate-targeting moieties at the end of the PEG chains improve the targeting efficiency of the nano-aggregates. (Reprinted from Ref. [15], p. 248, © 2004, with permission from Elsevier.)

a)

b)

**Figure 2.15.** (a) Schematic diagram illustrating the concept of folate-targeting of liposomes to cancer cells. After preferential extravasation from hyper fenestrated tumoral vasculature, conjugates bind to tumor cells and are endocytosed. (Reprinted from Ref. [17], p. 1179, © 2004, with permission from Elsevier.)

(b) Folate receptor-mediated endocytosis of nanovectors containing anticancer drugs. The formation of endosomes that encapsulate the conjugates protects them from P-glycoprotein, MRP, GS-X and other efflux proteins. (Adapted from Ref. [53], p. 40, © 1998, with permission from Elsevier.)

- Drug is released gradually from the liposomes that remain in the interstitial fluid, enters the tumor cells as free drug, and exerts a cytotoxic effect.
- The other liposomes bind to the folate receptors on the surface of tumor cells via the folate ligand. It is important to note that due to the limited diffusion capacity of the liposomes, generally only the tumor cells closest to the blood vessels are associated with this binding.
- These liposomes are then internalized by the tumor cells via folate receptor-mediated endocytosis.

- The internalized liposomes then release the drug, which is free to exert its cytotoxic effect on the cells.

Research has shown that conjugates can overcome the multidrug resistance effect of the P-glycoprotein efflux pump due to their cellular uptake via folate receptor-mediated endocytosis [54]. According to Turek and coworkers [52], the process of endocytosis consists of receptor–ligand binding followed by internalization in clathrin-coated pits (clathrin is a protein that is the major constituent of the “coat” of the coated pits that are formed during the endocytosis of materials at the surface of cells) or “uncoated” caveolae (small invaginations in the plasma membrane that play a role in endocytosis as well as signal transduction and are observed especially in endothelial cells). As seen in Fig. 2.15, when the receptors bind to their target molecules, the pit deepens until a clathrin-coated vesicle is released into the cytosol. Due to the fact that the liposomes are encapsulated in these endosomal vesicles, they escape being effluxed by the P-glycoprotein efflux pumps.

Understanding the kinetics of receptor-mediated cell attachment would be of service in the design and optimization of ligand-conjugated nanovectors. An important question is, what are the strength and density of bonds needed to achieve adequate adhesion under various stresses? Bell [25] developed a deterministic model for cell attachment in the absence of fluid stress and cell detachment in the presence of fluid stress. We give an account of his work first, followed by a stochastic reanalysis. Another stochastic treatment of receptor–ligand binding can be found in Cozens-Roberts and coworkers [26].

#### 2.4.1

##### Bell's Deterministic Model

Once a cell and nanoparticle or liposome have been brought into proximity via non-specific interactions such as Brownian motion and van der Waals forces, receptor–ligand bond formation may occur. The proximate cell and particle surface, each with its associated protein receptor or ligand available for contact, are shown in Fig. 2.16. The cell's receptor and liposome's ligand are free to diffuse in the plane of the phospholipid bilayer, while for a polymeric nanoparticle ligand is presumably limited to local gyrations. The most elementary formulations assume single receptor–ligand binding.

**Figure 2.16.** Proximate cell and particle or liposome surfaces with some free and bound receptors and ligands.

Letting  $N_1$  and  $N_2$  be the densities of total available receptor and ligand, respectively, and letting  $X_t$  be the density of bound receptor–ligand complex at time  $t$  with  $N_1 \gg X_t$  for all  $t$  to simplify the exposition, bond formation is governed by:

$$\frac{dX_t}{dt} = k^+ N_1 (N_2 - X_t) - k^- X_t \quad (1)$$

where  $k^+$  and  $k^-$  are the forwards and backwards kinetic rate constants. At equilibrium, we have:

$$X_\infty = \alpha N_2 (1 + \alpha)^{-1} \quad (2)$$

where  $\alpha = KN_1$  and  $K = k^+/k^-$  and is the association constant.

The forwards and backwards rate constants can in theory be derived from the planar diffusion constants  $D_1$  and  $D_2$  of membrane-bound receptor and ligand, although rotation and gyration of species also play a part. In order to do this, the binding is assumed to take place according to the two-step reaction:

where  $R \circ L$  represents an “encounter complex” in which receptor and ligand are within some critical radius  $C$ , and  $RL$  represents bound receptor–ligand. The  $d$ 's and  $r$ 's represent directional reaction rates for the steps. The former are related to the receptor and ligand planar diffusion constants according to:

$$\begin{aligned} d^+ &= 2\pi(D_1 + D_2) \\ d^- &= 2(D_1 + D_2)C^{-2} \end{aligned} \quad (4)$$

In many cases the rate of change of the encounter complex is negligible. Setting  $d[R \circ L]/dt = 0$  then allows for the net reaction rates in (1) to be approximated as  $k^+ = d^+ r^+ / (d^- + r^+)$  and  $k^- = d^- r^- / (d^- + r^-)$ . If, furthermore,  $r^+ \gg d^-$ , as is the case for receptors and ligands in a viscous membrane, then these rates reduce to  $k^+ = d^+$  and  $k^- = d^- r^- / r^+$ .

This, then, provides the basis for determining the strength of bonding between, for example, a ligand-conjugated liposome and a receptor-rich cell. The question can be asked, what force is required to break a bound particle–cell complex? To answer this question, we assume that a force  $F$  is applied to separate the surfaces in Fig. 2.16. Under this condition kinetic theory provides that the reverse reaction rate  $k^-$  in Eq. (1) is modified to  $k^- \exp(AF/X_t)$ , where  $A$  is a constant, so that the equation becomes:

$$\frac{dX_t}{dt} = k^+ N_1 (N_2 - X_t) - k^- \exp(AF/X_t) X_t \quad (5)$$

From this expression it can be seen that as the force is increased, so does the reverse reaction rate and therefore the equilibrium number of bonds will be decreased. However, this rate also increases as the number of bonds  $X_t$  decreases because the force is being applied over fewer bonds. This is reflected by the presence of  $X_t$  in the denominator of the exponential. Therefore, the dynamics will be different than for the case of no applied force; for forces in excess of a critical minimum  $F_c$ , the net rate of bond formation  $dX_t/dt$  will always be negative.

This can be seen from Fig. 2.17, which shows  $dX_t/dt$  as a function of  $X_t$  for four different forces, all other parameters being held constant. In all cases (possibly unstable) equilibrium occurs where the curve crosses the horizontal axis. The upper curve represents the case where no force is applied. The three other curves in descending order represent the effects of a subcritical force  $F_{\text{sub}}$ , the critical force  $F_c$  and a supercritical force  $F_{\text{sup}}$ . For all curves, net bond formation is positive above the horizontal axis and we move to the right along the curve. Net bond formation is negative below the horizontal axis and we move to the left. It can be appreciated that for  $F_{\text{sup}}$  the curve is completely negative so that no new equilibrium can be reached, i.e. the particle–cell complex separates. The critical force  $F_c$  results in a curve that just touches the axis, but otherwise is completely negative, and any force greater than this results in separation. Assuming the association constant  $K = 1$  and fixing the density of receptors at  $N_1 = 10^3 \mu\text{m}^{-2}$ , Bell calculates a representa-

**Figure 2.17.** The  $y$ -axis is the right-hand side of Eq. (5) and represents the rate of bond formation under various separation forces. In all cases, when above the axis, the dynamics

moves to the right along the curve; otherwise, it moves to the left. Forces represented from top to bottom are: none, a subcritical force  $F_{\text{sub}}$ , the critical force  $F_c$  and a supercritical force  $F_{\text{sup}}$ .

tive value of  $F_c/N_2 \sim 4 \times 10^{-6}$  dynes per total available ligand. In the foregoing we have abused notation in that  $N_2$  is here being used as the absolute number of available ligands in a specific  $1\text{-}\mu\text{m}^2$  patch.

This critical force can be compared to other biologically relevant forces, such as the stress created by a fluid flowing past a bound liposome or nanoparticle. Stokes' law says that for a spherical body of radius  $r$  the force generated by a fluid flowing past at velocity  $v$  is given by  $F = 6\pi\eta rv$ , where  $\eta$  is fluid viscosity. For a liposome of radius  $4\text{ }\mu\text{m}$  this is calculated to be  $5.3 \times 10^{-5}v$  dynes. Using the values of  $K$  and  $N_1$  above, and again abusing notation, we set  $4 \times 10^{-6} = F_c/N_2 = 5.3 \times 10^{-5}v/N_2$  to yield  $N_2 \sim 13v$  potential bonding sites. Thus, the liposome would need only 13 available ligands to resist a fluid velocity of  $1\text{ cm s}^{-1}$ .

#### 2.4.2

##### A Stochastic Model

Stochastic formulations may be more appropriate for receptor–ligand binding, especially when the bonds are few. Again we base our model upon the deterministic equation (5) with the understanding that  $N_1 \gg X_t$  at all times. This time, though, we must recognize that  $X_t$  is a stochastic process. Most importantly, this means that rather than assuming any particular value at a given time, it is a probability *distribution* of bonds. Even after having attained equilibrium as  $t \rightarrow \infty$ , it becomes a limiting distribution  $X_\infty$ . In what follows we limit our attention to one square unit of area, since otherwise the values of  $X_t$  are not discrete. Nonetheless, the results are completely general. Following Bailey [55] and letting  $X_{\Delta t} \equiv X_{t+\Delta t} - X_t$  we have, for  $1 \leq X_t \leq N_2 - 1$ :

$$P[X_{\Delta t} = j|X_t] = \begin{cases} k^+ N_1(N_2 - X_t)\Delta t + o(\Delta t) & \text{if } j = 1 \\ k^- \exp(AF/X_t)X_t\Delta t + o(\Delta t) & \text{if } j = -1 \end{cases} \quad (6)$$

Making appropriate adjustments for  $X_t = 0$  and  $X_t = N_2$ , this results in the system of partial differential equations for the discrete probabilities  $p_i(t) \equiv P[X_t = i]$ :

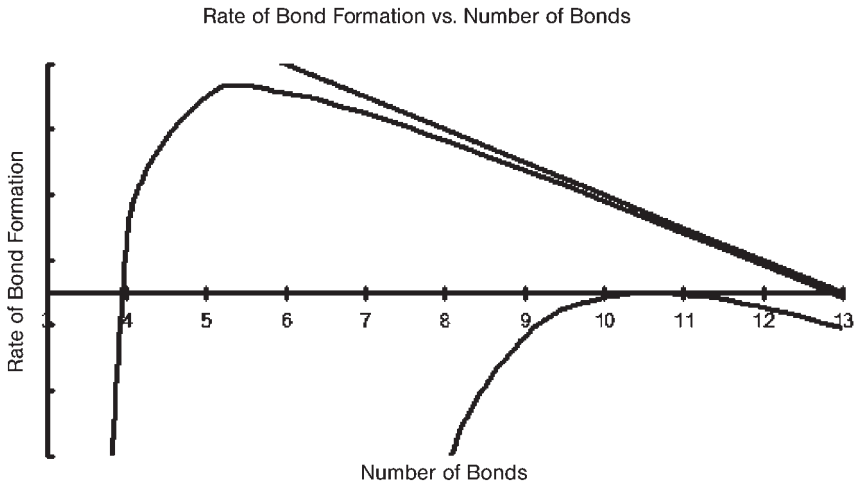

$$\begin{aligned} \frac{\partial p_0(t)}{\partial t} &= k^- \exp(AF) p_1(t) - k^+ N_1 N_2 p_0(t) \\ \frac{\partial p_i(t)}{\partial t} &= k^+ N_1(N_2 - (i - 1)) p_{i-1}(t) + (i + 1)k^- \exp\left(\frac{AF}{i+1}\right) p_{i+1}(t) \\ &\quad - \left(k^+ N_1(N_2 - i) + ik^- \exp\left(\frac{AF}{i}\right)\right) p_i(t) \quad \text{for } 0 < i < N_2 \\ \frac{\partial p_{N_2}(t)}{\partial t} &= k^+ N_1 p_{N_2-1}(t) - N_2 k^- \exp\left(\frac{AF}{N_2}\right) p_{N_2}(t) \end{aligned} \quad (7)$$

With the further restriction that  $\sum p_i = 1$  we can find the distribution of  $X_\infty$  by solving for the steady-state solution of the above, yielding:

$$\begin{aligned}
 p_i(\infty) &= \frac{N_2!}{(N_2 - i)!} \frac{\alpha^i p_0(\infty)}{\prod_{1 \leq j \leq i} i \exp(\frac{\Delta E}{i})} \\
 p_0(\infty) &= \left( \sum_{0 \leq i \leq N_2} \frac{N_2!}{(N_2 - i)!} \frac{\alpha^i}{\prod_{1 \leq j \leq i} i \exp(\frac{\Delta E}{i})} \right)^{-1}
 \end{aligned} \tag{8}$$

where  $\alpha = KN_1$  and  $K = k^+/k^-$  is the association constant. In the case of no separating force, the probability generating function  $P(\theta) = \sum_{i \geq 0} p_i \theta^i$  is discovered from this to be the Taylor expansion of  $(1 + \alpha)^{-N_2} (1 + \alpha \theta)^{N_2}$ . A quick check on the mean yields  $\bar{X}_\infty = P'(1) = \alpha N_2 (1 + \alpha)^{-1}$ , in agreement with (2).

Although the variance as well as any chosen moment could also be calculated, it is perhaps of more interest to calculate the probability of complete disengagement of all bonds under various values of  $F$ . This means we are interested in  $p_0$  (henceforth understanding this to mean  $p_0(\infty)$ ), which, in the case of no applied force, is simply  $(1 + \alpha)^{-N_2}$ . For the values of  $\alpha = 10^3$  and  $N_2 = 13$  used for the example in Section 2.4.1 this yields  $9.9 \times 10^{-40}$ , hardly consequential. However, in contrast to the deterministic analysis, the stochastic analysis demonstrates that even a sub-critical force that is little more than *half* of the critical force is sufficient to dislodge the liposome. Consulting Fig. 2.18, we see three curves that result from using the aforementioned values of  $\alpha$  and  $N_2$ , and three different forces: none,  $F_{\text{sub}}$  ( $\sim 0.5F_c$ ) and  $F_c$ . (Strictly speaking, these are *scaled* curves of the rate of bond formation (Eq. (5)) because we do not know  $k^+$  or  $k^-$  independently. Moreover, we

**Figure 2.18.** The example from Section 2.4.1 reanalyzed ( $\alpha = 10^3$  and  $N_2 = 13$ ). The top curve has no separation force applied. The bottom curve results from applying  $F_c$ . The middle curve results from applying

$F_{\text{sub}} \sim 0.5F_c$ . The deterministic model predicts no separation until  $F_c$  is reached; however, the stochastic model predicts the probability of separation for  $F_{\text{sub}}$  to be greater than 0.9958.

do not quote units of force. Nonetheless, for the relevant computations to find probabilities at equilibrium,  $k^+$  and  $k^-$  only enter as a ratio, and  $AF$ , as a product. Only one value of this product will result in a critical force curve. The two product values used in the calculations were  $AF_c = 57.5$  and  $AF_{\text{sub}} = 30$ .) While it is no surprise to learn that  $F_c$  results in  $p_0 = 1$  to more than 20 decimals, it may yet be surprising that  $F_{\text{sub}}$  results in  $p_0 > 0.9958$ .

The application of both the deterministic and stochastic models to the optimization of receptor–ligand binding is apparent. Subtle differences in the models may become significant in light of the necessity of balancing binding affinity with protein rejection needed to avoid RES uptake (Section 2.2).

## 2.5

### Intratumoral and Cellular Drug Kinetics and Pharmacodynamics

Once nanovectors have successfully evaded the RES, navigated the tortuous topology of tumoral vasculature and extravasated at their intended site, cellular-level drug kinetics and pharmacodynamics determine modeling concerns. Liposomes are too large to penetrate much more than two or three cell layers into tumoral interstitium, while most nanoparticles fair no better. In many cases, lesion tissue is within 100  $\mu\text{m}$  of the nearest vessel and a typical cell diameter is about 10  $\mu\text{m}$ . Thus, for ligand-conjugated vectors, expected to enter into individual cells, penetration into and destruction of three cell layers means that 30% of the tumor can hypothetically be eradicated with one treatment. If, furthermore, as tissue is destroyed, inner layers are next exposed to unspent particles, more cell kill is potentially possible. For “plain” nanovectors, it is not penetration that is the issue, but rather the sustained release of sufficient concentration of drug. This may also be an issue for ligand-conjugated vectors, since some of their charge will be released into tumoral interstitium.

The physics of liposomal and nanoparticle drug release is well researched, with the Higuchi, power law and Weibull models sometimes used as phenomenological approximations. Although these models are not considered to be mechanistic, Kosmidis and coworkers [19] make the case for such an interpretation of the Weibull model, which is a single exponential asymptotically approaching 100% release in time. In fact, nanoparticle release profiles frequently evince a simple bi-exponential release pattern described by  $C_t = C_\infty - (Ae^{-\alpha t} + Be^{-\beta t})$ , where  $C_\infty$  is the total drug,  $C_t$  is the amount of drug released by time  $t$ ,  $A$  is the rapidly released portion of drug with rate constant  $\alpha$ , and  $B = C_\infty - A$  is the slowly released portion of drug with rate constant  $\beta$  [28, 29, 56]. If the release can be sustained long enough, then the bi-exponential becomes approximately linear with release rate  $B\beta$ .

Even with the above simplification, cellular-level drug kinetics and transport is highly nonuniform not only because of the inhomogeneous transport of vectors through and extravasation from tumoral vasculature discussed in Section 2.3, but also because of drug gradients due to cellular uptake and metabolism. Below, we present models and simulations of chemotherapy [28, 57] that highlight intratumoral and cellular-level drug release and kinetics.

## 2.5.1

**A Two-Dimensional Model of Chemotherapy**

In 2004, Sinek and coworkers simulated nanoparticle-mediated chemotherapy and tumor response using a two-dimensional multiscale tumor simulator due to Zheng and coworkers [58]. The simulator is built upon continuum-scale reaction–diffusion equations for its growth component following the previous work of Byrne and Chaplain [59, 60] and Cristini and coworkers [61], together with a combined continuum–discrete model of angiogenesis based upon the work of Anderson and Chaplain [21]. It is capable of tracking cancer progression from its avascular stage, through the transition from avascular to vascular growth and into the later stages of invasion of normal tissue. Sinek’s group focused on the case of glioblastoma multiforme by using microphysical parameters characterizing malignant glioma cells obtained from *in vitro* experiments by Frieboes and Cristini [62] and clinical data. Glioblastoma is an aggressive brain tumor that may present as the last stage of astrocytoma progression or *de novo*. It is extremely recalcitrant to all forms of therapy, whether surgical, genetic, chemical or radiological. This is in part due to the high motility of glial cells, rendering the tumor highly diffuse on the periphery [63].

They first simulated the growth of a highly perfused lesion of glioma. This was then exposed to simulated chemotherapy in which nanoparticles were assumed to remain at their point of extravasation from the vasculature and function as a constant source of drug along the vessels. Extravasation, diffusion and cellular uptake of both drug and nutrient was simulated according to the quasi-steady-state reaction–diffusion equations:

$$\begin{aligned} 0 &= v_s \delta_V + D_s \nabla^2 s - \eta_s s \\ 0 &= v_n \delta_V + D_n \nabla^2 n - \eta_n s \end{aligned} \quad (9)$$

where  $s$  and  $n$  are the local concentrations of drug and nutrient, respectively, the  $v$ ’s are (spatially and temporally variable) production rates related to release of drug and supply of nutrient, the  $\eta$ ’s are uptake rates by cancer cells, and the  $D$ ’s are diffusion coefficients.  $\delta_V$  is the Dirac delta function indicating the location of the vasculature. Drug action was then modeled as cell kill being proportional to normalized drug concentration  $\bar{s}$  acting on the fraction of cycling cells, given by the normalized nutrient  $\bar{n}$ . When combined with the growth of cells, modeled as the product of a mitosis constant and normalized nutrient  $\lambda_M \bar{n}$ , the net local growth or regression of tumor cells (the velocity field divergence) becomes:

$$\nabla \cdot \mathbf{u} = \lambda_M \bar{n} - \lambda_D \bar{s} \bar{n} \quad (10)$$

where  $\lambda_D$  is the killing power of the drug.

Sinek’s group performed two classes of simulations. The first recognized extravasational difficulties due not only to irregular vascular topology generated using Anderson and Chaplain’s model (Section 2.3.2), but also pressure variations within tumor interstitium. The latter was accomplished by using  $v_n =$

**Figure 2.19.** Simulations of nanoparticle chemotherapy. Clockwise, from upper left corner: tumor at equilibrium after many months of simulated continuous therapy, pressure contours, drug concentration contours and nutrient contours. Inhomogeneities in nutrient delivery and initial

nanoparticle extravasation and subsequent diffusion and uptake of drug result in stable equilibrium at significant tumor mass. (Adapted from Ref. [28], Fig. 4(b), © 2004 Kluwer Academic Publishers. With kind permission from Springer Science and Business Media.)

$v'_n(p_V - p)(n_V - n)$  in Eq. (9), where  $v'_n$  is constant,  $p_V$  and  $p$  are the pressures in the vasculature and tumor, respectively, and  $n_V$  and  $n$  are the nutrient concentration in the vasculature and tumor, respectively. A similar function for  $v_s$  was used for the initial extravasation of particles. This model qualitatively demonstrated that inhomogeneities in drug delivery and action, even using nanoparticles releasing

drug at a constant rate, had the potential to diminish chemotherapeutic efficacy, still leaving substantial regions of tumor unharmed after months of simulated therapy (Fig. 2.19).

The second class of simulations addressed the possible benefits of improving drug delivery via the use of adjuvant antiangiogenic drugs to “normalize” tumor vasculature [20, 40, 64]. To do this, Sinek’s group let  $v_s$  in Eq. (9) be constant so that the source of drug was uniform along the vasculature. Again, although cell kill was significantly greater, inhomogeneities due to drug diffusion and cellular uptake resulted in nonuniform tumor regression, and eventually fragmentation at significant equilibrium masses (Fig. 2.20). These results compare favorably with experimental data. Antiangiogenic and chemotherapeutic treatments have been observed to induce tumor mass fragmentation, cancer cell migration and tissue invasion [65–67]. Cristini and coworkers [68] have termed this behavior “diffusional instability”. It is a phenomenon known to materials scientists and is analogous to the processes whereby dendritic ice crystals form or water droplets in ice migrate via a melt-and-freeze process over an imposed temperature gradient. The existence of this phenomenon with regard to tumor response would have significant influence on the design of all modes of chemotherapy.

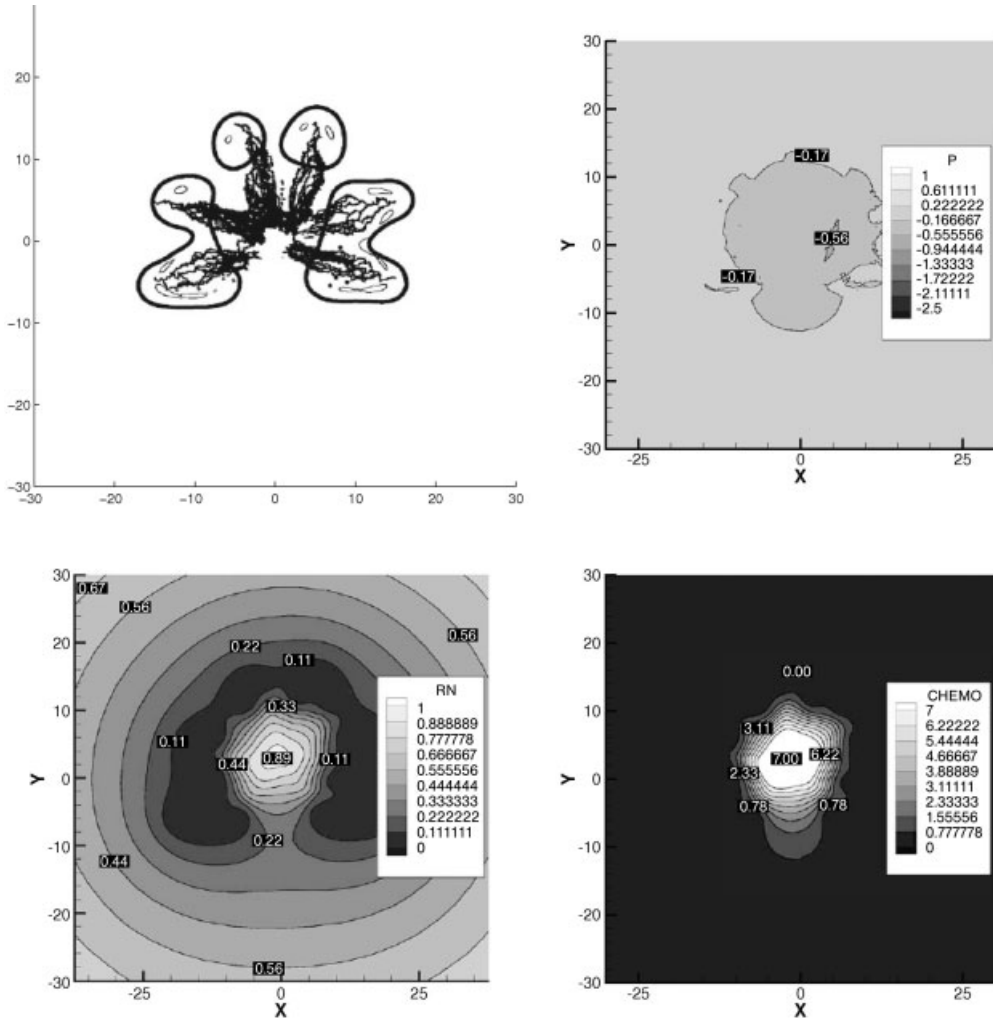

### 2.5.2

#### Refinements of the Model

In Eq. (9), the two parameters  $D_s$  and  $\eta_s$  are critical to the penetration of drug into the tumor. One criticism of the previously described simulations is that, although drug gradients formed for the values chosen, these values were not experimentally measured. If the ratio  $D_s/\eta_s$  should actually be relatively high, then drug would be uniformly presented to tumor cells and it is possible that the simulations would have revealed complete tumor regression with no fragmentation. A subsequent work of Sinek and coworkers [57] obtains values of the drug diffusion coefficient  $D_s$ , the uptake rate  $\eta_s$  and the killing power  $\lambda_D$  for the drugs, cisplatin and doxorubicin.

In order to more accurately model the cellular drug kinetics of cisplatin and doxorubicin, compartmental models were constructed by Sinek and coworkers [57] following earlier work of Dordal and coworkers [69, 70], Jackson [71] and El-Kareh and Secomb [72]. Three compartments are assumed (Fig. 2.21): Compartment 1 is extracellular interstitium, Compartment 2 is intracellular free drug and Compartment 3 is intracellular DNA-bound drug. For cisplatin, the system of equations determining drug kinetics is:

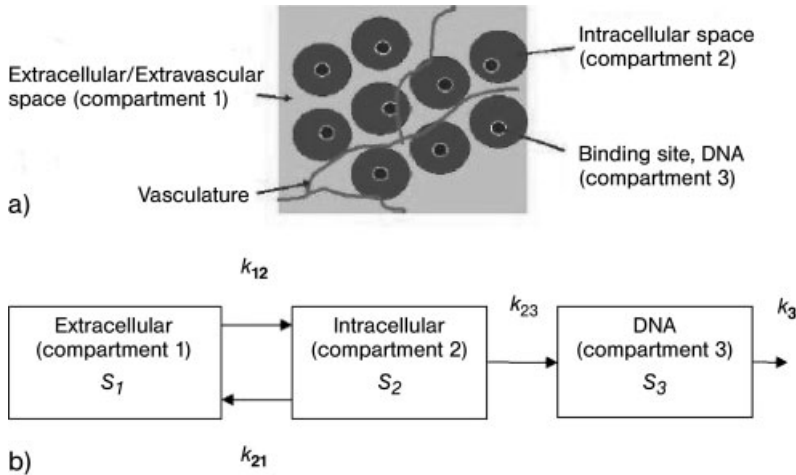

$$\begin{aligned}\frac{\partial s_1}{\partial t} &= v_s \delta_V + D_s \nabla^2 s_1 - k_{12} s_1 + k_{21} s_2 \\ \frac{\partial s_2}{\partial t} &= k_{12} s_1 - k_{21} s_2 - k_{23} s_2 \\ \frac{\partial s_3}{\partial t} &= k_{23} s_2 - k_3 s_3\end{aligned}\tag{11}$$

**Figure 2.20.** Nanoparticle chemotherapy after antiangiogenic “normalization”, simulated by making drug release constant along the vasculature. Clockwise, from upper left: tumor at equilibrium after many months of simulated continuous therapy, pressure contours, drug concentration contours and nutrient contours.

Although tumor kill is greater than that in Fig. 2.19, diffusional instability (see text) results in fragmentation and aggressive phenotype. (Adapted from Ref. [28], Fig. 5, © 2004 Kluwer Academic Publishers. With kind permission from Springer Science and Business Media.)

where  $s_i$  is drug concentration in Compartment  $i$ , and the  $k_{ij}$ 's are transfer rates from Compartment  $i$  to  $j$ . In particular,  $k_{12}$  is determined by the “inward” cell membrane permeability,  $k_{21}$  by the “outward” permeability and  $k_{23}$  by the drug–DNA binding affinity.  $k_3$  is a repair rate of DNA platinum adducts. The system for

**Figure 2.21.** The compartment model used by Sinek and coworkers [28].  $k$ 's represent transfer rates, while  $s$ 's represent concentrations. Cell death is ultimately due to  $s_3$ .

doxorubicin is similar; for purposes of illustration we shall refer to the cisplatin model.

It is well established that cisplatin induces apoptosis by forming DNA–platinum adducts and that doxorubicin kills cells via DNA intercalation [73, 74]. Thus, of critical importance is the value of  $s_3$ . If we reduce the situation to one dimension with a boundary condition at  $x = 0$  representing the vessel source, then the steady-state form of Eq. (11) can be written in terms of  $s_3$  alone:

$$0 = D_s(k_{21} + k_{23}) \frac{d^2 s_3}{dx^2} - k_{12} k_{23} s_3 \quad (12)$$

The solution of this equation is  $s_3 = C_1 e^{-ax} + C_2 e^{ax}$ , where:

$$a = \sqrt{\frac{k_{12}}{D_s(k_{21}/k_{23} + 1)}}$$

The constants are determined according to the boundary value of drug at the vessel source along with a no-flux condition at approximately 100  $\mu\text{m}$  from the vessel (since another vessel is assumed to exist approximately 200  $\mu\text{m}$  from the one being modeled). It is the negative exponential in which we are most interested, with high values of  $a$  resulting in gradients. Thus, high cell permeabilities ( $k_{12}$ ) as well as poor interstitial diffusion ( $D_s$ ) result in gradients and, thus, presumably poor lateral penetration into tumor (Fig. 2.22). This is in line with studies that demonstrate doxorubicin penetration is particularly poor (severe gradients) in comparison with cisplatin penetration. Doxorubicin enters cells much more rapidly than cispla-

**Figure 2.22.** The normalized steady-state DNA-bound drug ( $s_3$ ) as a function of distance from nearest vessel (located at distance = 0). Gradients are sensitive to drug-cell permeability. A drug like doxorubicin, which penetrates cells quickly and possesses high affinity for cell endosomes and DNA, would give rise to the lower graph.

tin, and it has particularly high affinities for cell endosomes and DNA [69, 70, 75–79].

The apparent paradox that high cell permeability should result in poor tissue penetration underscores the power of mathematical modeling in overcoming the prejudice of intuition. Upon reflection it can be appreciated that if drug is removed from interstitium quickly due to high cell permeability as it diffuses from its originating vessel, there will be correspondingly less to continue further along, hence low penetration. It should be noted, however, that significant *lateral* penetration at the expense of insignificant *cellular* penetration is also undesirable, but rather an optimal balance of the two must be sought.

Values of the transfer and repair rates in Eq. (11) can be obtained via several techniques including measuring the time uptake of intracellular and bound cisplatin concentrations for cells in monolayer exposed to constant serum drug concentrations. The repair rate  $k_3$  is estimated from two different experiments performed by Sadowitz and coworkers [80], wherein the adducts per million nucleotides fell in 2 h from 75 to 5 in one case and from 185 to 40 in the other. Using the exponential repair model  $s'_3 = -k_3 s_3$ ,  $k_3$  is estimated to be between 0.013 and 0.023  $\text{min}^{-1}$ . An initial estimate of  $k_{23}$  is made as follows. Sadowitz shows that cells incubated in 7  $\mu\text{M}$ , in 2 h cells accumulate about 25 DNA adducts per million nucleotides. This converts to  $1.03 \times 10^{-19}$  moles of platinum docked on the DNA. Neglecting the cell membrane and supposing the DNA to be exposed directly to the *cis* solution, we solve the ODE  $s'_3 = 7k_{23} - k_3 s_3$ , substituting 0.015  $\text{min}^{-1}$  for  $k_3$ .  $k_{23}$  is thereby estimated to be  $2.6 \times 10^{-16}$   $\text{min}^{-1}$ . Finally,  $k_{12}$  and  $k_{21}$  are estimated by

**Figure 2.23.** Troger and coworkers [81] plotted total intracellular ( $s_2 + s_3$ ) platinum versus time for cells exposed as monolayers to four different concentrations of cisplatin. Curves represent best fits obtained by adjusting  $k_{12}$  and  $k_{21}$  in the second two equations of (11). In the equations,  $s_1$  is set to the concentrations that Troger used. (Adapted from Sinek and coworkers [57].)

fitting the second two equations in (11) with intracellular cisplatin time-uptake data of Troger and coworkers [81]. They exposed cells in monolayer to four different concentrations of cisplatin and then measured the total intracellular platinum content at selected times. The graph in Fig. 2.23 shows Troger and coworker's data (symbols) along with the fits (lines) for four different extracellular concentrations. For this purpose, in the equations  $s_1$  was set to be constant and equal to the concentrations that Troger and coworkers used. Then the sum  $s_2 + s_3$  was plotted, with values for  $k_{12}$  and  $k_{21}$  chosen to provide the best fits. Although these parameters are obtained from different experiments using different cell lines, they provide a starting point for producing quantitatively accurate simulations.

## 2.6 Conclusion

We have identified four critical phases of nanovector performance, each requiring a thorough understanding in order to optimize delivery and anticancer action. In the service of this understanding, mathematics and computation provides its own laboratory of pencil, paper and silicon chip, lending insight, providing guidance and offering testable prediction. The models of protein rejection in Section 2.2, in conjunction with the models of ligand binding in Section 2.4, can facilitate optimized surface preparation, yielding particles and liposomes that reject opsonization and therefore circulate long, yet bind effectively when finally presented to target cells.

The models of tumoral vasculature and hemodynamics presented in Section 2.3 reveal the “nature of the beast”, at once starkly exposing the tremendous difficulties in homogenous nanovector delivery and extravasation, while offering hope in quantifying the improvement that proposed therapies, such as vascular normalization, might bring. Finally, multiscale models of nanoparticle chemotherapy in Section 2.5, incorporating vasculogenesis, particle extravasation, nutrient and drug diffusion and uptake, and cellular-level phenomena such as DNA repair, suggest the existence of powerful mechanisms, such as diffusional instability, that can possibly be tempered, or even used to advantage, with the right approach.

Biological systems are “murky”, rarely providing simple, solid boundaries. Rather, their behavior is the sum of myriad processes spanning the scales of the whole body, tissues, cells and molecules. The nascent field of mathematical biology in conjunction with nanoscale therapeutics development is therefore presented with great opportunities. New technological designs and paradigms provide exciting grist for the mathematical mill. In turn, advanced mathematical methods along with computational techniques shine a bright and promising light on the future potential of technology. We hope that the foregoing has offered illuminating ideas that will guide this potential to fruition.

## Nanolithography: Towards Fabrication of Nanodevices for Life Sciences

*Johnpeter Ndiangui Ngunjiri, Jie-Ren Li, and Jayne Carol Garno*

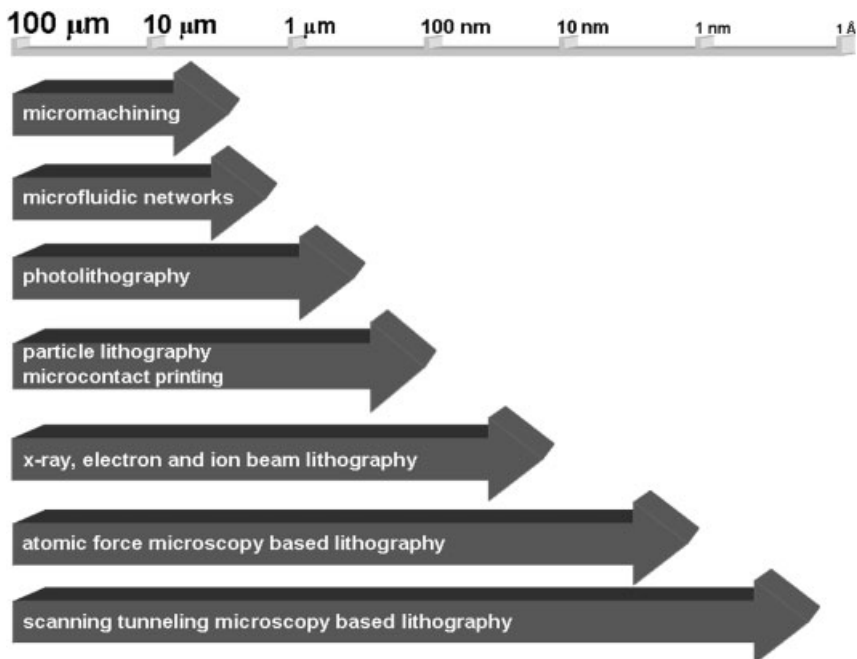

### 3.1

#### Introduction: Engineering Surfaces at the Nanoscale

Tools for nanofabrication have begun to provide important contributions for life sciences investigations, for developing biochip and biosensing technologies, as well as supplying basic research in protein–protein interactions and protein function. Scanning probe microscopy (SPM) supplies tools for visualization, physical measurements and precise manipulation of atoms and molecules at the nanometer scale. Nanoscale studies can facilitate the development of new and better approaches for immobilization and bioconjugation chemistries, which are key technologies in manufacturing biochip and biosensing surfaces.

Protein patterning is essential for the integration of biological molecules into miniature bioelectronic and sensing devices. To fabricate nanodevices for the life sciences it is often necessary to attach biomolecules to surfaces with retention of structure and function. For example, controlling the interaction of proteins, biomolecules and cells with surfaces is important for the development of new biocompatible materials. Precisely engineered surfaces can be used for the exploration of biochemical reactions in controlled environments. Spatially well-defined regions of surfaces can be constructed with reactive or adhesive terminal groups for the attachment of biomolecules. Micropatterning of proteins has been applied for biosensors and biochips [1–4]. Direct applications of protein patterning include biosensing, medical implants, control of cell adhesion and growth, and fundamental studies of cell biology [5–7]. Protein patterning has been accomplished at the micrometer level using microcontact printing [8–13], photolithography [14–16] and microfluidic channels [17, 18]. Thus, the capabilities for micrometer-scale methods for controlling the spatial arrangements of biomolecules have been well established and offer valuable new research methodologies for life sciences investigations. Collectively, these techniques provide a means for assembling proteins at a size scale of hundreds of nanometers or larger.

To progress to even smaller sizes, atomic force microscopy (AFM)-based lithography can be applied to pattern surfaces at nanometer dimensions. Scanning probe lithography (SPL) provides versatile approaches for designing the chemistry of sur-

**Figure 3.1.** Overview of the hierarchy of dimensions which can be achieved using various micro- and nanopatterning methods.

faces at the nanoscale. Figure 3.1 shows the dimensions which can be achieved using various micro- and nanopatterning methods. Arrays of self-assembled monolayers (SAMs) and proteins can be fabricated via SPL, with precise control over chemical functionality, shape, dimensions and spacing on the nanometer scale. Combined with the capabilities for high-resolution imaging and characterization, SPM enables a molecular-level approach for directly investigating changes that occur on surfaces during biochemical reactions. The tools of SPL are accessible to investigators across a broad range of disciplines and do not require costly instrument modifications.

Cutting-edge research has begun to apply nanolithography for studying proteins on surfaces, possibly at the level of single-molecule detection. At present, nanodevices constructed by SPM-based lithography are being conceptualized and, to the best of our knowledge, SPL has not yet been applied for making nanodevices. Readers are referred to recent reviews which discuss potential nanoscale devices [19, 20]. Although there are also many studies which investigate peptides, DNA and cells, we limit the focus of this chapter to studies which apply nanoscale lithography to proteins and to applications using SPL for nanoscale protein assays. This chapter provides an overview of advances in the application of nanolithography using SPM and latex particle lithography for protein patterning. Beginning with a general introduction of the chemistry for immobilization of proteins on sur-

faces, the application of SAMs for coupling proteins to surfaces is presented. Nanolithography methods including bias-induced lithography, AFM-based force-induced nanolithography, “dip-pen” nanolithography (DPN) and latex particle lithography are described, including examples of protein nanopatterning. The chapter concludes with a discussion of nanoscale detection of protein binding and future directions in cantilever array technology.

## 3.2

### Immobilization of Biomolecules for Surface Assays

A number of factors need to be considered for choosing a successful protein-immobilization strategy, such as the efficiency and rate of binding, potential side-reactions, and the strength and resilience of the attachment. For protein assays, the binding site recognized by immunoglobulin G (IgG) on an antigen is relatively small; consisting of only 5–6 amino acids or several sugar residues. The recognition element is referred to as an antigenic determinant or epitope. Proteins must be attached in such an orientation that their active sites or binding domains are accessible for binding and not buried or blocked by the surface. The binding site is only a small part of the total surface area of the protein. Adsorption on a surface may impair or prevent the protein’s activity. The eventual orientation of proteins on surfaces is determined by multiple factors such as the type of binding, the positions and composition of external residues on the protein surface, the isoelectric point of the protein, and the pH of buffers used during application.

Proteins have a three-dimensional (3-D) structure which is critical to their function and activity. Most proteins have both positively and negatively charged regions that interact with surfaces. Upon encountering a surface, intramolecular forces within proteins can be disrupted, causing the proteins to unfold and become denatured. Some proteins are known to lose activity when bound to a solid surface, due to a loss of tertiary structure. For example, the strong polarization forces at metal surfaces along with ionic or covalent interactions on many inorganic metal oxides and semiconductor surfaces may cause denaturation of biomolecules [21]. For retention of activity, chemistries for protein arrays should permit the immobilization of proteins on surfaces such that perturbation to the native 3-D structure is minimized. Using a spacer or linker molecule on the sensor surface often enables biomolecules to retain their functionality and 3-D structure. The tools of organic chemistry provide a wealth of chemical strategies and binding motifs for conjugating biomolecules such as proteins to solid surfaces [22, 23].

#### 3.2.1

##### Strategies for Linking Proteins to Surfaces

Increasingly, researchers have begun to use the self-assembly of functionalized alkanethiol and alkylsilane molecules as model surfaces for protein binding. The terminal moieties of SAM surfaces mediate the type of binding, such as through

**Figure 3.2.** Strategies for linking proteins to surfaces include electrostatic interactions, covalent bonding, antigen–antibody recognition and biotin–streptavidin specific interactions.

electrostatic interactions, covalent binding, molecular recognition or via specific interactions (Fig. 3.2). The following sections introduce representative examples of chemical immobilization strategies which have been applied for protein patterning.

#### 3.2.1.1 Electrostatic Immobilization

The strategy of functionalizing a surface through electrostatic assembly is often used to immobilize biomolecules on surfaces. Electrically charged amino acids are found mostly on the exterior of proteins and can mediate assembly on charged surfaces. Proteins contain both positively and negatively charged domains that interact with surfaces via long-range electrostatic forces. The electrostatic attraction between oppositely charged molecules is nonspecific and surfaces are negatively or positively charged, depending on the solution pH.

Electrostatic binding is physically mediated and proteins often retain their activity after immobilization. It is a direct, simple method for attaching proteins to surfaces without requiring multiple steps for chemical activation. Binding is reversible, since certain buffers and detergents can remove proteins from surfaces. However, a potential disadvantage of electrostatic immobilization is that the resulting orientation of proteins on surfaces is random; electrostatic-mediated binding does not provide a means for directing the protein assembly in a designed conformation. Representative examples of chemistries for the electrostatic immobilization of proteins which have been applied for nanopatterning proteins are summarized in Tab. 3.1. For example, alkanethiols or alkylsilanes terminated with functional groups, such as  $\text{NH}_2$  or  $\text{COOH}$ , have been used to immobilize biomolecules through electrostatic interactions.

#### 3.2.1.2 Covalent Immobilization

Covalent immobilization is important for applications in which displacement or desorption of proteins can be a problem. Covalent bonds occur when two molecules share atoms and form the strongest chemical bonds for surface immobiliza-

tion. The methods of covalent attachment are boundless – thousands of proteins have been immobilized on hundreds of different solid supports for affinity-capture assays [22]. The best choice for covalent immobilization will depend on the functionalities of both the protein and the surface. Several amino acids provide suitable functional groups for covalent modification. Common functional groups of amino acids used for covalent immobilization include: amino groups from the side-chains of lysine and the N-terminus; carboxyl groups from the C-terminus, aspartic and glutamic acids; sulfhydryl groups of cysteine; hydroxyl groups of serine and threonine; and the phenyl groups of phenylalanine and tyrosine. Since proteins typically present a number of these groups, the chemical nature of the solid surface becomes a primary consideration. A specific chemical reaction is chosen to activate the surface and then proteins are immobilized upon exposure to the active surface groups. Examples of chemistries for covalent immobilization of proteins include activation of surface hydroxyl groups, carboxyl groups and amines. Also, bifunctional crosslinking reagents such as glutaraldehyde have been used to covalently couple proteins to various surfaces. Further examples of covalent immobilization chemistries are listed in Tab. 3.1.

An important factor to be considered in covalent attachment of proteins is the possibility of chemically altering the protein in such a way that its reactivity is reduced. For example, covalent approaches may be hindered by competing side-reactions. It is possible that groups associated with the active site or binding site of a protein could be involved in the reaction. In addition, chemical crosslinking within protein domains could occur, causing damage to the protein's tertiary structure.

#### 3.2.1.3 Molecular Recognition and Specific Interactions

Highly specific interactions between binding pairs can be used effectively for protein immobilization. Examples include affinity capture ligands such as biotin–streptavidin binding and molecular recognition through antigen–antibody recognition. Such affinity ligands require either physical or covalent immobilization of one moiety of the affinity pair onto the surface. Small-molecule receptors such as biotin offer viable strategies for the immobilization of proteins. Further examples are listed in Tab. 3.1. A strong advantage of specific immobilization is to provide a means for directing the protein assembly in a designed conformation. The orientation of proteins on surfaces can be designated by selectively targeting certain amino acid residues of the protein for specific coupling.

#### 3.2.1.4 Nonspecific Physical Adsorption to Surfaces

By far the most widely used method of protein immobilization for protein arrays uses nonspecific adsorption of proteins dried on solid supports. Forces which nonspecifically influence the binding of proteins to almost any substrate include ion bridging, hydration forces, hydrophobic forces and short-range attractive or repulsive forces. This approach produces randomly oriented proteins, some of which may be denatured. Surface assays typically include a blocking step, such as with the adsorption of bovine serum albumin (BSA) to prevent nonspecific binding of

Tab. 3.1 Strategies used for biomolecule immobilization applied for nanopatterning proteins.

Type of interaction	Surface derivatization	Proteins studied	Surface	SPL method	Dimensions	Reference
Chemisorption	S-Au attachment of C-terminal thiol groups	bundle metalloproteins	Au(111)	nanografting	100 nm	80
Chemisorption	gold surface	thiolated collagen	Au(111)	DPN	30–50 nm	92
Covalent	3-mercaptopropional patterns in a decanethiol resist	lysozyme, IgG	Au(111)	nanografting	40–350 nm	74
Covalent	MHA passivated with EG <sub>3</sub> -SH, then activated to form aldehyde groups	elastin-like polypeptide	Au(111)	DPN	200 nm dots	91
Covalent	1,2-diols cleaved to produce aldehydes	acetylcholine esterase–insulin	Au(111)	nanografting	50–200 nm	79
Covalent and specific	EDC activation of mixed hydroxyl and carboxyl SAMs, then biotin–streptavidin binding	anti-IgG, protein G	Au(111)	uCP	10 $\mu$ m	10
Electrostatic	MHA SAM decanethiol resist	lysozyme	Au(111)	nanografting	100–400 nm	74
Electrostatic	MHA and dodecanethiol SAMs	lysozyme	Au(111)	natural assembly	<1 $\mu$ m	137
Electrostatic	MHA passivated with ethylene glycol SAM	rabbit IgG, lysozyme	Au(111)	DPN	100–350 nm	86
Electrostatic	MHA	mouse anti-p24 HIV-1 p24 antigen	Au(111)	DPN	60 nm	108
Electrostatic	gold surface	cytochrome <i>c</i>	Au(111)	DPN	200 nm dots	87

Electrostatic	mercaptoundecanoic acid passivated with octanethiol and glycol SAMs	rabbit IgG anti-rabbit IgG	Au(111)	nanografting	500 nm–1 $\mu\text{m}$	78
Electrostatic	mercaptohexanol, mercaptopropionic acid, N-(mercapto)hexylpyridinium bromide thiols in matrix terminated with hexa(ethylene glycol) resist	lysozyme, bovine carbonic anhydrase, rabbit IgG	Au(111)	nanografting	200–400 nm	77
Electrostatic and specific	biotin–streptavidin on MHA, with oligoethylene glycol SAM passivation	biotinylated BSA	Au(111)	DPN	100–230 nm	89
Physical adsorption	PDMS stamping onto glass surfaces	rabbit IgGs, BSA, avidin	glass	uCP	40–100 nm	138
Physical adsorption	nickel oxide surface	ubiquitin and thioredoxin	nickel oxide	DPN	80 nm	95
Physical adsorption	direct writing on bare gold; passivation with PEG	lysozyme, rabbit IgG	Au(111)	DPN	45–200 nm	94
Physical adsorption	direct writing on modified $\text{SiO}_2$	IgG, anti-rabbit IgG	$\text{SiO}_2$	DPN	55–550 nm	93
Specific avidin–biotin	oligo-(ethylene glycol) SAM	avidin–biotin–BSA	Si(111)	bias-induced SPL	90 nm	66
Specific avidin–biotin	oxidized regions of PMMA layer spin-coated onto p-doped silicon wafer	biotin IgG–avidin	Si wafer	bias-induced SPL	0.5–1.5 $\mu\text{m}$	61
Specific maleimide–cysteine	maleimide substituted SAM as ink for specific immobilization of cysteine-labeled biomolecules	virus capsid particles	Au(111)	DPN	150 nm	90

proteins. BSA is a globular serum protein which is often used in bioassays to back-fill uncovered areas of surfaces where proteins did not attach.

### 3.2.2

#### SAM Chemistry

SAMs provide a chemical method for creating well-defined surfaces with controllable surface functionality [24]. Due to their stability, ease of preparation and well-ordered surface structures, SAMs of alkanethiols and alkylsilanes provide excellent models for studying protein binding, since layers of defined thickness and designed properties can be generated [25, 26]. Thiol endgroups of *n*-alkanethiols bond via chemisorption to metal surfaces. SAM surface properties can be flexibly controlled by changing the functional (head) groups of the alkyl chain (Fig. 3.3) and these end groups can also be used for further chemical reactions. The acidity, adhesion, wetting and structural properties of surfaces can be modified by choosing specific chemical headgroups (such as  $\text{NH}_2$ ,  $\text{OH}$ ,  $\text{COOH}$ ,  $\text{CH}_3$ , glycol, etc.) [27, 28]. For example, surfaces can be made hydrophilic by introducing SAMs with polar moieties such as hydroxyl or carboxyl groups. Nonpolar functionalities such as methyl-terminated groups yield hydrophobic surfaces. The preparation, characterization and properties of SAMs have been described and reviewed previously [28–32]. SAMs have promising applications in biosensing, corrosion inhibition, lubrication, surface modification and molecular device fabrication. This section introduces the chemistry and structure of SAMs of alkanethiols and alkylsilanes (Fig. 3.3), which are often applied for nanolithography with proteins.

Close-packed *n*-alkanethiol SAMs can be readily prepared with high reproducibility to present functional groups such as alkyls, amides, esters, alcohols, etc., on

**Figure 3.3.** General structural features of self-assembled monolayers of (A) *n*-alkanethiols/Au(111) and (B) *n*-alkylsilanes/Si(111).

surfaces of gold or coinage metals. Typically, alkanethiol SAMs are formed by soaking gold thin films in dilute (0.1–1.0 mM) solutions of thiols dissolved in solvents such as 2-butanol, hexane or ethanol. Typically, substrates can be stored in a thiol solution for 1–7 days at room temperature to ensure the formation of mature monolayers. Alkanethiols on Au(111) form a close packed, commensurate ( $\sqrt{3} \times \sqrt{3}$ )R30° lattice on Au(111) surfaces [33–36]. In surface assemblies of alkanethiol SAMs, according to studies by IR, near-edge X-ray absorption fine structure (NEXAFS) spectroscopy and grazing incidence X-ray diffraction (GIXD), the alkyl chains of thiol molecules are tilted approximately 30° from surface normal (Fig. 3.3A) [36–38]. The sulfur atoms of alkanethiol molecules are considered to bind at the triple hollow sites of Au(111) lattices [29].

STM and AFM studies have confirmed the long-range order and periodicity of alkanethiol monolayers, and have provided a direct view of defects such as domain boundaries, etch pits, steps and dislocations within SAM films [29, 39]. SPM images visualize the intricate details of the surface topography of SAMs. Figure 3.4 displays a typical topographic view of an octadecanethiol SAM/Au(111) acquired in ethanol by AFM. These molecular landscapes may appear somewhat rough, because at the atomic scale most surfaces are not truly smooth and flat, and contain defects. Considering that the height of gold steps is 0.25 nm, the overall surface roughness of the underlying gold substrates for these images is less than 1 nm. The monolayer surfaces consist of domains of closely packed thiol molecules decorated with etch pits. Readers are referred to several works using STM for a more detailed discussion of the morphology and packing of *n*-alkanethiol SAMs [29, 39–41].

**Figure 3.4.** Contact-mode AFM topographs of an octadecanethiol self-assembled monolayer on Au(111). (A) Terrace arrangement of flat gold steps coated with octadecanethiol SAM ( $400 \times 400 \text{ nm}^2$ ). (B) Zoom-in view displays etch pits ( $80 \times 80 \text{ nm}^2$ ).

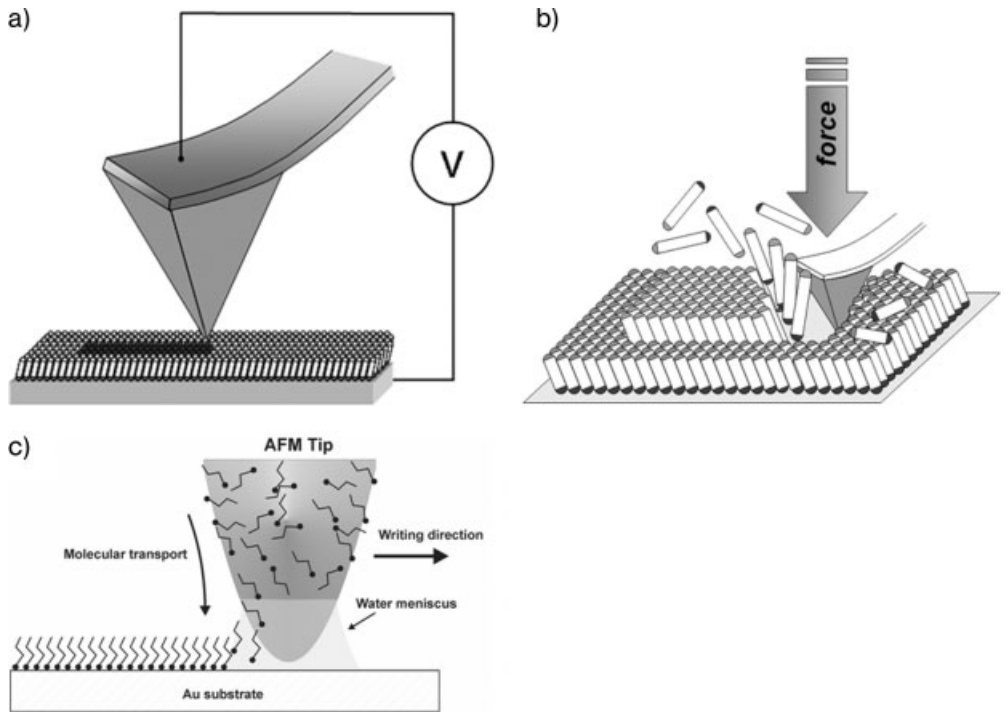

Similar to alkanethiols, the chain length and terminal moieties of alkylsilane SAMs can be tailored to meet experimental requirements; however, the properties of alkylsilane assemblies are quite different from SAMs of alkanethiols. SAMs of alkylchlorosilanes, alkylalkoxysilanes and alkylaminosilanes require hydroxylated surfaces to form polysiloxane, which is connected to surface silanol groups ( $-\text{SiOH}$ ) through a network of  $\text{Si}-\text{O}-\text{Si}$  bonds. Substrates on which silane SAMs have been prepared include silicon oxide, aluminum oxide, quartz, glass, mica, zinc selenide and germanium oxide [32]. High-quality alkylsilane SAMs are not as simple to produce as thiol SAMs, because of the need to carefully control the presence of water in solutions. Reproducibility can be a problem, since the quality of the monolayers formed is very sensitive to reaction conditions. Silane monolayers on mica typically consist of domains separated by boundaries. Within domains, silane molecules form structures without long-range order or periodicity [42–44]. The headgroups of silane SAMs crosslink into a  $\text{Si}-\text{O}$  network and the chains are estimated to tilt  $15^\circ$  from surface normal (Fig. 3.3B) [42, 43].

Mixed SAM surfaces can be engineered to avoid nonspecific protein adsorption, yet make specific interactions with targeted proteins to be assayed, by choosing the appropriate buffered conditions as well as an effective matrix layer, resistive to protein adsorption (such as glycol-terminated SAMs). Very few surfaces resist protein adsorption and it remains a challenge to understand the mechanisms that contribute to protein resistance or adhesion to surfaces. To prepare monolayers that resist protein adsorption, the groups of Whitesides [45–48], Mrksich [49] and Grunze [50] have conducted systematic studies of functionalized SAMs to determine the molecular characteristics that impart resistance to protein adsorption. The factors that determine the resistance to protein adsorption were found to include characteristics such as the hydrophilicity of the terminal group, lateral packing density, the presence of hydrogen bond accepting groups and the absence of hydrogen bond donor groups, and terminal groups with overall electrical neutrality.

Approaches which use chemical methods for the activation of SAM surfaces are beginning to gain importance for the surface coupling of biomolecules. Thus far, most reactions for the surface activation of SAMs for protein adsorption have been accomplished after the SAM has been formed with monolayers terminated with carboxyl, amino or hydroxyl groups. Hundreds of synthetic pathways can be applied for *in situ* activation chemistry, including reagents such as *N*-hydroxysuccinimide (NHS), 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC) and dithiobis(succinimidyl undecanoate) (DSU) [10, 51].

### 3.3 Methods for Nanolithography with Proteins

With the invention and continuing development of scanning probe techniques, such as scanning tunneling microscopy (STM) [52] and AFM [53], surface changes became evident when too much force was applied by an AFM tip, or if the applied bias voltages exceeded certain thresholds using STM or conductive AFM imaging.

**Figure 3.5.** Schematic representations of three AFM-based nanofabrication techniques: (A) bias-induced lithography, (B) force-induced nanolithography (nanografting) and (C) DPN. (Panel C reproduced with permission from Ref. [56].)

Researchers began experimenting to deliberately and selectively control these alterations. Molecules of SAMs can be written precisely on surfaces using a variety of different SPL methods. Figure 3.5 illustrates the fabrication principles of the three most predominant SPL methods applied for patterning proteins. SPL provides flexible and convenient approaches to construct SAM nanopatterns with designated functionalities in selected nanosized areas. These nanoengineered surfaces can then be used to selectively immobilize desired proteins through covalent, electrostatic or specific recognition approaches.

A common feature of all SPL methods is that an SPM tip is used as a tool for both nanofabrication and characterization of surfaces. A helpful analogy for describing SPL methods with SAMs is an SPM tip (pen) which writes with molecules (ink) on various surfaces (paper). SPL provides exquisite control of surface chemistry including parameters such as the spatial arrangement, chemical composition and the written density of molecular ligands. The shape and dimensions of the tip dictate the detailed resolution of written nanostructures – SAM patterns as small as 5 nm have been reported and it has become routine to achieve patterns

of 20–50 nm (or larger). Since the dimensions of proteins range from tens to hundreds of nanometers, SPL methods are ideally suited for surface studies of protein binding. Particle lithography is another promising method for protein nanopatterning, which can produce arrays of protein nanostructures. Table 3.2 provides a comparison of approaches which have been successfully applied for protein patterning. The next sections of this chapter present further details of these nanolithography methods, including nanografting [54], bias-induced lithographies [55], DPN [56] and latex particle lithography [57].

As a tool for high-resolution characterization, the same SPM tips used to write nanopatterns on surfaces are also used to explore the morphology of nanopatterns after protein adsorption. Both AFM and STM are highly suitable, well-established methods for visualizing surfaces with high resolution. The new tools of AFM and STM have emerged as significant and powerful techniques for imaging surfaces at the molecular scale. Unlike electron microscopy methods which require high vacuum environments and conductive coating of specimens, *in situ* AFM/STM experiments can be accomplished under physiological conditions in aqueous buffered environments. Experiments using SPM provides exquisite resolution for the detailed characterization of molecular structures, has versatility in imaging modes and can be used for local modification of surfaces by lithography. Topographic images provide direct visualization of changes on surfaces after proteins bind to nanopatterns. Commercial advances continue to improve SPM resolution by providing consistently higher-quality probes at lower cost and by the ongoing development of imaging modes for viewing chemical contrast differences for surfaces. Various AFM imaging modes can be applied for probing friction, softness, surface charge, polarizability, magnetic domains and viscoelasticity at the atomic scale.

### 3.3.1

#### **Bias-induced Nanolithography of SAMs**

When an electric field is applied at elevated bias voltages between a conductive SPM tip and sample, local chemical or physical changes occur in the area under the tip. Depending on the nature of the surface and environmental conditions (ambient versus UHV), the “bias-induced” changes may result from electrochemistry (oxidation) at either the tip or sample which occurs from electric field effects [58], or the changes may result from ohmic heating, which induces evaporation or desorption of organic layers [59, 60]. This section describes the method of bias-induced lithography and then presents an example of bias-induced nanofabrication applied for protein nanopatterning.

Figure 3.5(A) displays the general principle of bias-induced lithography. For bias-induced SPL, short (microsecond to millisecond) pulses of bias voltage are applied between a conductive SPM tip placed very near, but not in contact with, the surface. The size of the surface features are determined by the duration and magnitude of the electric field, and also by the dimensions of the area probed by the SPM tip. Often, with bias-induced oxidation, the chemical changes produced by an electric field do not manifest height changes and thus are not detectable by top-

Tab. 3.2 Comparison of methods applied for nanopatterning proteins.

Nanopatterning method	Pen	Paper	Mechanism	Surface chemistry	Reference
Bias-induced oxidation	biased tip STM/AFM	conductive or semiconductive substrate	surface oxidation	oxidization of surfaces or SAM terminal groups	66
Bias-induced replacement lithography	biased tip STM/AFM in solution	conductive or semiconductive substrate with SAM	displacement of SAMs under elevated bias	replace matrix SAM with new molecules	55, 62

ographic imaging. However, SPM imaging modes which display contrast between different terminal groups, such as force modulation, lateral force imaging and current/electrical force images, can clearly differentiate areas that are modified based on chemical changes.

Bias-induced lithography is emerging as a flexible and convenient means for nanofabrication of designed surface components, using either silane or thiol SAMs. Requirements for bias-induced nanofabrication include a conductive or semiconductive substrate and a conductive SPM probe. To prepare conductive AFM tips, a thin film of metal (usually gold) is sputter-coated onto the surface of probes precoated with a precursor binding layer of chromium or titanium. Conductive tips and cantilevers comprised of doped silicon exhibit sufficient electrical conductivity for bias-induced modification of surfaces without requiring metal coatings. Bias-induced SPL methods are now accessible techniques for most SPM users, as a result of improvements in instruments, and in the quality, cost and availability of commercial AFM probes, which now include coatings of cobalt, diamond-like carbon, doped diamond, platinum, platinum/iridium, tungsten carbide, titanium nitride and nickel.

Researchers have begun to apply biased-induced SPL to pattern proteins. Bias-induced lithography was used directly for protein patterning by attachment of IgG–biotin to an array of 30-dot patterns generated using 1-ms voltage pulses (40–80 V) [61]. The substrate was a poly(methyl methacrylate) (PMMA) layer spin-coated on polished p-doped silicon wafer. Differences in hydrophobicity between the patterned areas and the substrate provided a driving force for the selective electrostatic deposition of proteins on nanopatterns. After reaction with avidin–fluorescein isothiocyanate (FITC), micron-sized patterned regions could then be imaged by fluorescence microscopy.

To further extend the capabilities of bias-induced lithography for patterning SAMs with designated surface chemistries, methods which include replacement or addition of new molecules from solution have recently been developed [55]. After voltage pulsing, small areas of the surface were exposed for adsorption of new molecules using bias-induced replacement lithography [62–64]. In another approach, bias conditions which selectively oxidize SAM terminal groups (tip-induced electro-oxidation) were used to generate surface oxides of SAMs. Oxidized areas then were used to chemically attach new molecules with desired functional groups [58, 65]. Nanopatterned protein arrays were fabricated by Cai and co-workers using bias-induced oxidation followed by protein adsorption (Fig. 3.6) [66]. Bias-induced SPL was applied to oxidize the headgroups of monolayers of

**Figure 3.6.** More than 100 protein dots produced by bias-induced nanofabrication. (A) AFM height and (B) friction image of nanoholes produced by bias-induced nanofabrication after treatment with EDAC/avidin ( $4 \times 4 \mu\text{m}^2$ ). The lines provide a reference for corresponding features. The dots are approximately 90 nm in diameter. (C) Topography and (D) friction images of the same area after incubation with biotinylated BSA. (E) After the nanopatterns of biotinylated BSA were reacted with avidin a positive height was observed for the nanodot arrays. (Reproduced with permission from Ref. [66].)

$\alpha$ -hepta(ethylene glycol) methyl  $\omega$ -undecenyl ether on Si(111) substrates. Bursts of 1-ms pulses of +17 V were applied to the sample, to generate rows of spots (90 nm diameter) separated by about 270 nm. The nanopatterned templates were then used to attach avidin followed by biotinylated BSA.

Although bias-induced lithography has not yet been widely applied for nanopatterning proteins, the newly introduced capabilities of customizing surface chemistry by tethering coupling agents to oxidized surfaces holds promise for new applications of bias-induced lithography in future investigations.

### 3.3.2

#### Force-induced Nanolithography of SAMs

Nanofabrication of SAMs can be accomplished by applying mechanical force to an AFM tip during scans. An intrinsic advantage of AFM instruments is the superb control of forces applied between the tip and sample, ranging from pico- to nanonewtons. For high-resolution and faithful imaging of surface topography it is critical to apply minimal, nondestructive forces. When too much force is applied by an AFM tip, areas of the surface can be swept clean or “nanoshaved” [59]. Nanografting was first invented in 1997 and combines nanoshaving with the simultaneous replacement of matrix SAM molecules by the self-assembly of new molecules [54, 67]. A broad range of thiolated molecules have been nanografted to provide tremendous flexibility in choosing the desired molecular lengths and terminal groups for experimental designs [68–72]. This section describes the procedure for nanografting SAMs, presents an example using automated nanografting with SAMs and then reviews examples which apply force-induced lithography (nanografting) for protein patterning.

Nanografting (Fig. 3.5B) is accomplished in dilute SAM solutions containing the selected molecule to be patterned by exerting a high local force on an AFM tip, pushing through the matrix SAM to contact the underlying gold surface. During scanning, pressure between the tip and surface displaces the SAM matrix molecules underneath the tip. As matrix molecules are removed, new thiol molecules from solution immediately adsorb onto the uncovered areas of the substrate to form nanopatterns, following the scanning track of the tip. SPM controllers can be programmed for automated lithography, to rapidly and consistently generate desired surface arrangements of arrays of SAM nanopatterns [73]. Commercial instruments typically include software with capabilities to control the length, direction, speed, bias pulse duration, residence time and the applied force of the scanning motion of the SPM tip, analogous to a pen-plotter. Automated SPL offers tremendous advantages for the speed and reproducibility of nanopatterning, and can produce highly sophisticated pattern arrangements and geometries, with superb precision and reproducibility for the alignment, spacing and shapes of nanopatterns. Examples of SAM nanopatterns generated by force-induced AFM-based lithography (nanografting) are shown in Fig. 3.7.

The AFM contact-mode topograph (Fig. 3.7A) displays 16 nanopatterns of 11-mercaptopundecanoic acid (11-MUA) written within a resist of octadecanethiol.

**Figure 3.7.** Nanopatterned array generated by automated nanografting. (A) Topography and (B) corresponding friction images ( $1.0 \times 1.0 \mu\text{m}^2$ ) of nanopatterns of 11-mercaptoundecanoic acid grafted in octadecanethiol/

Au(111). (C) Design of nanopatterned (100 nm) ring elements. (D) Close-up view of four patterns. (E) Zoom-in view of a single pattern ( $250 \times 250 \text{ nm}^2$ ). (F) Cross-section taken along the line in (E).

The corresponding frictional force image (Fig. 3.7B) more clearly displays the arrangement and shapes for the nanopatterned array of circular designs. Nanografting was executed using a programmable computer module interfaced to the AFM controller for translating the tip rapidly and uniformly across the surface to create designed arrangements of nanopatterns (controllers from RHK Technology, Troy, MI). A computer script (written in-house) was used to apply a higher load on the tip to inscribe the pretzel-shaped designs. Each design was generated by writing four 100-nm diameter rings as in Fig. 3.7(C). The rings were inscribed by outlining each circle 3 times with the AFM tip, beginning with the bottom ring and moving in a clockwise direction around the center intersection. It required approximately three minutes to complete the entire  $4 \times 4$  array, (around 12 s to write each pattern). After nanografting, AFM images were acquired under normal imaging conditions using minimal force. Figure 3.7(D) displays a close-up view of four nanopatterns, exhibiting nearly perfect alignment and symmetry. The high-resolution topograph of a single nanopattern in Fig. 3.7(E) reveals the exquisite capabilities of AFM-based nanolithography to write and visualize surface details. The height difference between the (ODT) nanopattern and the 11-MUA matrix SAM is indicated by the cursor profile (Fig. 3.7F) to be approximately  $0.7 \pm 0.1 \text{ nm}$ , in close

agreement with the theoretical height difference (0.7 nm). The line width of the rings is approximately 10 nm. Commercial silicon nitride cantilevers with an average spring constant of  $0.58 \text{ N m}^{-1}$  were used for both imaging and lithography (Veeco Probes, Santa Barbara, CA). The patterning and imaging experiments for Fig. 3.7 were conducted *in situ*, in a liquid environment.

Typically, it requires less than 1 min to fabricate individual nanopatterns using force-induced SPL such as nanoshaving and nanografting. Hundreds of nanopatterns can be written during an experiment without evidence of tip damage, provided that a minimal threshold force is applied. The fabrication forces used for force-induced SPL typically range from 2 to 30 nN, depending on the system under investigation and the geometries and spring constants of the cantilevers. Of course, if far too much force is applied the tip or substrate can be damaged, so it is critical to determine the minimum force for nanofabrication with each experiment. Commercially available soft  $\text{Si}_3\text{N}_4$  cantilevers have mostly been used for nanofabrication by mechanical force, with force constants ranging from 0.03 to  $2.0 \text{ N m}^{-1}$ . When imaging in liquid, the total force applied typically is less than 1 nN, to prevent damage to substrate layers.

The first studies using nanografting to immobilize proteins were conducted in 1999 by Gang-Yu Liu and coworkers using either electrostatic or covalent interactions to immobilize lysozyme, rabbit IgG and BSA on SAM nanopatterns [74]. Since then, a growing number of investigators have taken advantage of the flexibility of nanografting in liquids for surface studies with biomolecules. The typical general steps of an *in situ* protein binding experiment are (a) to fabricate nanopatterns of adhesive tethering molecules, (b) bind proteins to these nanopatterns and (c) test the activity of the immobilized proteins by introducing a second antibody or protein that will bind specifically to the surface-bound protein.

An important advantage of nanografting is the capability to conduct experiments *in situ*, viewing the successive changes in surface topography after the steps of nanopatterning SAMs, rinsing, and introducing buffers and proteins. With *in situ* nanografting, the protein patterns are not subjected to air exposure, and remain in a carefully controlled environment by rinsing and exchanging solutions within the liquid cell. As molecules bind to nanopatterns, *sequential real-time AFM images expose reaction details at a molecular level*, uncovering critical details of the adsorption of proteins to nanostructured surfaces. Figure 3.8 illustrates the basic steps of an *in situ* protein adsorption experiment using nanografting.

In the initial investigations of protein immobilization on nanografted SAMs, Liu et al., used functionalized alkanethiol SAMs to mediate electrostatic and covalent binding of IgG and lysozyme [74]. The reactivity and stability of protein nanopatterns was studied in further reports, and included investigation of the retention of specific activity of the immobilized proteins for binding antibodies [75, 76]. Protein patterns sustained washing with buffer and surfactant solutions and were stable for at least 40 h of AFM imaging. The smallest protein feature yet produced by nanografting is a  $10 \times 150 \text{ nm}^2$  line containing three proteins [74, 76].

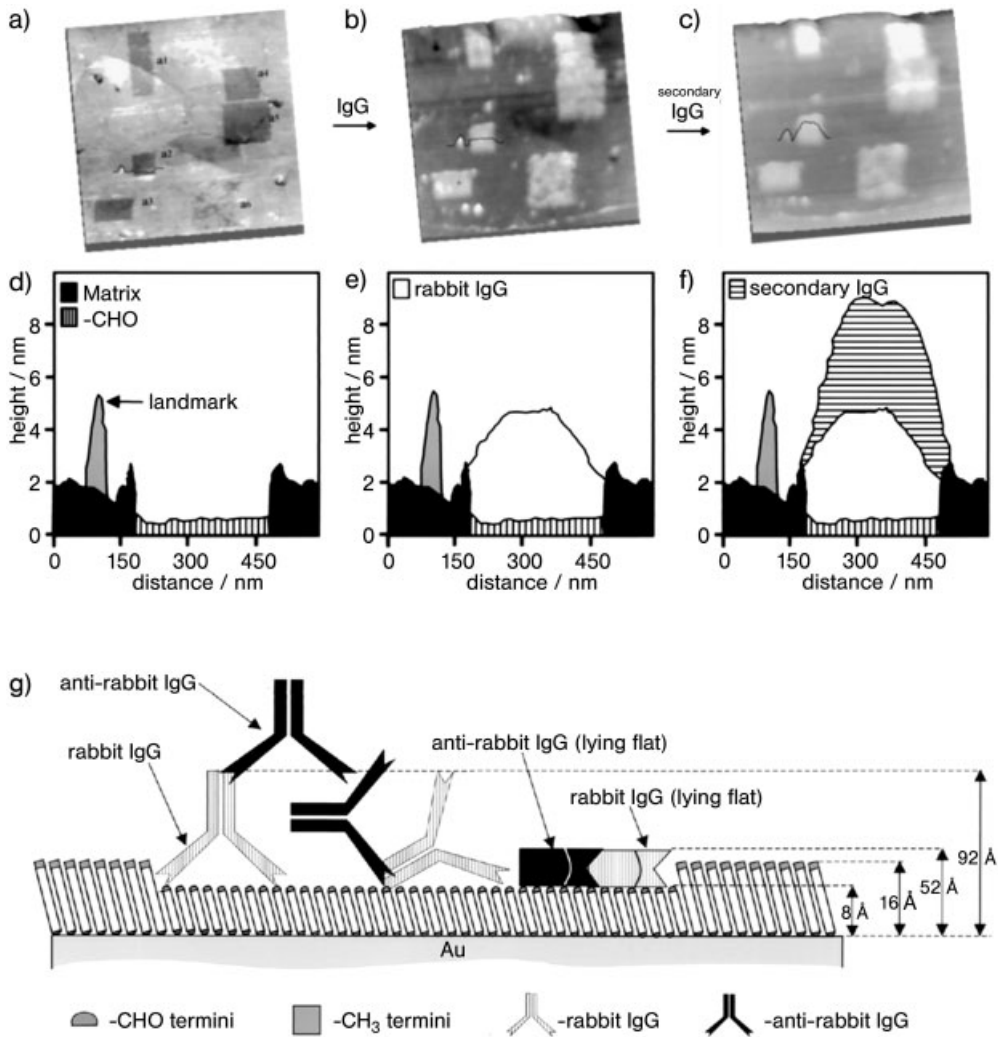

The first *in situ* antigen–antibody binding AFM experiment with nanofabricated SAMs was conducted using nanografting to direct protein immobilization [75].

**Figure 3.8.** Steps for nanopatterning proteins using force-induced lithography. (A) A flat area is chosen for writing nanopatterns by imaging at low, nondestructive forces. (B) Nanofabrication is accomplished by applying higher force to write new SAM molecules. (C) Proteins are introduced by exchanging liquids. (D) Protein nanostructures can be characterized under low force.

The activity of covalently immobilized rabbit IgG was tested by reactivity toward mouse anti-rabbit IgG. AFM topographs of protein binding on nanografted patterns of an aldehyde-terminated SAM are shown in Fig. 3.9. Several aldehyde-terminated nanopatterns, a1–a5, were first grafted into a dodecanethiol SAM matrix. The depth of these patterns measured  $0.8 \pm 0.2$  nm and images display dark contrast where the rectangular patterns were inscribed (Fig. 3.9A). After injecting rabbit IgG and rinsing with a surfactant solution, selective adsorption was observed on all six nanopatterns (Fig. 3.9B) in which the bright contrast indicates heights taller than the matrix SAM. In the next step, mouse anti-rabbit IgG was introduced (Fig. 3.9C), showing further height increases. By comparing the height of nanopatterns before and after secondary IgG binding, it was observed that immobilized IgG may adopt various configurations (Fig. 3.9G).

Several investigators have applied nanografting to write nanopatterns for protein immobilization. Abell and coworkers conducted a side-by-side comparison of protein adsorption on multifunctionalized surfaces at the nanoscale using nanografting. Protein adsorption on three differently charged linkers nanografted within a hexa(ethylene glycol) terminated alkanethiol resist SAM was monitored *in situ* by AFM at various pH values [77]. The adsorption of proteins onto nanografted patterns ( $400 \times 400$  nm<sup>2</sup>) of 6-mercaptohexan-1-ol (MCH), *n*-(6-mercapto hexyl) pyridinium bromide (MHP) and 3-mercaptopropionic acid (MPA) was studied with lysozyme, IgG and carbonic anhydrase II. They conclude that in addition to the overall charge of protein molecules, the charge of local domains of the proteins plays a role in immobilization. In the same paper, Abell and coworkers used nanografting to assemble multilayered protein G/IgG/anti-IgG nanostructures through

**Figure 3.9.** The steps of protein binding and molecular recognition with nanografted patterns captured by AFM topographic images. (A) Five nanopatterns of 3-mercaptopropional were written in a dodecanethiol SAM. (B) The image contrast changed after rabbit IgG bound covalently to the aldehyde-terminated nanopatterns. (C) After introducing mouse anti-rabbit IgG, the patterns display

further height changes, indicating the antibody binds specifically to the protein nanopatterns. Cursor traces across pattern a2 indicate the height changes (D) after nanografting, (E) after injecting IgG and (F) after introducing anti-rabbit IgG. electrostatic interactions as a potential means to orient IgG molecules for antibody-based biosensor surfaces.

Using force-induced SPL methods of nanografting and nanoshaving, Porter and coworkers compared three approaches for protein patterning [78]. They successfully combined force-induced SPL with immobilization of IgG via EDC activation of 11-mercaptopundecanoic acid; through direct adsorption of Fab'-SH fragments to nanoshaved regions of an EG<sub>3</sub>-OMe matrix, and through chemisorption of a disulfide coupling agent, DSU. Ducker and coworkers applied nanografting to immobilize insulin and acetylcholinase esterase on nanografted 1,2-diols which were activated by sodium periodate to produce aldehyde groups [79]. Retention of catalytic activity was demonstrated for nanopatterned enzymes. Nanografting was applied to directly pattern designed metalloproteins by Au-S chemisorption by Scoles and coworkers [80]. The bundle protein structure was designed to present the C-termini of three helices, terminated with D-cysteine residues for assembly in a vertical orientation, normal to the Au(111) substrate.

A potential disadvantage for nanografting is that exchange takes place between solution molecules and the surface matrix SAM for some systems of alkanethiols. Natural self-exchange is an issue particularly when nanografting longer chain thiols into a shorter chain matrix layer, thus it is important to use very dilute (below 0.1 mM) solutions for nanografting. Exchange can be detected within 2–4 h (depending on the age of the matrix SAM) when molecules from solution adsorb onto defect sites and at step edges.

Although not yet practical for high-throughput applications and manufacturing, combining SPL with protein immobilization enables new approaches for directly investigating changes that occur on surfaces during biochemical reactions. Nano-engineered surfaces are useful for viewing antigen-antibody binding at the nanometer scale, to assess the specificity of selective binding, and to evaluate protein orientation and the accessibility of ligands for binding. Advantages of force-induced SPL include the ability to precisely produce nanometer-sized patterns of bioreceptors, and to successively image and conduct fabrication *in situ*, within well-controlled environments. For protein nanopatterning, force-induced SPL can be applied to either directly write proteins on surfaces via nanoshaving, or can be applied to write molecules for attaching proteins to surfaces through electrostatic, covalent or specific binding chemistries.

### 3.3.3

#### **DPN of SAMs and Proteins**

DPN, developed by Chad Mirkin and coworkers in 1999, has emerged as an important and versatile method for producing multicomponent arrays of SAM nanopatterns, as well as other molecules and nanomaterials [81]. This section describes the DPN nanofabrication method and then presents examples of DPN applied for protein nanopatterning. Protein nanopatterning has been accomplished by several different approaches via DPN. For SAM molecules written directly by DPN, proteins may be attached to nanopatterns through electrostatic, covalent or specific interac-

tions on nanopatterns after surface passivation. Another strategy is to use surface activation of nanopatterned amine, carboxylate or hydroxyl groups for protein immobilization. Direct writing of proteins has also been accomplished by DPN using modified AFM tips.

In DPN, an AFM tip (pen) is coated with a molecular “ink” to write on clean gold substrates or “paper” under ambient conditions in air [56, 82]. Ink molecules migrate from the coated AFM tip through a capillary meniscus to the substrate by diffusion (Fig. 3.5C). Capillary transport of molecules from the AFM tip to the substrate can be used to directly write arrays of SAM nanopatterns. Additional mechanical force is not applied to the AFM tip or “pen.” When an AFM tip is used in air to image a surface, the narrow gap between the tip and surface forms a tiny capillary meniscus from the condensation of water. Nanopatterns such as individual lines, dots, grids and arrays of alkanethiols have been written on bare gold surfaces [56, 83, 84]. The size of the water meniscus that bridges the tip and substrate depends on the tip shape and the relative humidity [85]. In DPN, the meniscus is used to transport molecules from the tip to the surface. The resolution of DPN depends on several parameters, such as the geometry of the AFM tip, the humidity of the ambient environment, as well as the duration over which the inked tip is placed in contact with the surface – typically of the order of approximately 1–10 s. With commercial cantilevers, DPN routinely generates feature sizes down to 15 nm.

Protein arrays were produced with DPN by patterning 16-mercaptohexadecanoic acid (MHA) for immobilizing lysozyme and IgG through electrostatic interactions by Mrksich and coworkers (Fig. 3.10) [86]. After writing MHA dots (diameter 100–350 nm) the gold surface was passivated with 11-mercaptoundecyl-tri(ethylene glycol). The MHA patterns were exposed to proteins by immersing substrates in a solution containing the desired protein. The arrays were then rinsed with buffer and imaged in air by tapping-mode AFM. The reaction of IgG patterns with rabbit antibody and with mixtures of proteins was also studied using AFM to investigate and detect nonspecific binding to nanopatterns and to passivated areas of the substrate. In another study, Choi and coworkers immobilized cytochrome *c* through electrostatic adsorption on nanopatterns of MHA written by DPN [87]. The areas surrounding the MHA nanopatterns were passivated with octadecanethiol.

Covalent attachment of synthetic peptides was accomplished by Ivanisevic and Cho using DPN [88]. First, nanopatterns of amine-terminated silane molecules (3-aminopropyl-triethoxysilane) (APTES) were written on  $\text{SiO}_x$  surfaces by DPN. Next, the heterobifunctional cross-linker *N*-hydroxysuccinimide ester (SMPB) was conjugated to the APTES nanopatterns. In the final step, a TAT peptide was covalently linked to SMPB via a cysteine residue in the peptide sequence.

The molecular recognition-mediated, stepwise fabrication of patterned protein nanostructures was accomplished by Zauscher and colleagues using DPN [89]. First, a SAM of MHA was patterned on gold by DPN, shown in Fig. 3.11. Next, the surrounding regions were passivated with a protein-resistant oligoethylene glycol-terminated alkanethiol SAM [11-mercaptoundecyl-tri(ethylene glycol) ( $\text{EG}_3\text{-SH}$ )]. Nonspecific adsorption of proteins on the background was prevented by pas-

No height change or nonspecific

adsorption is detected. (C) A rabbit IgG array before and (D) after treatment with a mixture containing lysozyme, goat/sheep anti-IgG, human anti-IgG and rabbit anti-IgG. The height of the nanopatterns increased from  $6.5 \pm 0.9$  to  $12.1 \pm 1.3$  nm, indicating the binding of anti-IgG onto IgG nanopatterns. (Reproduced with permission from Ref. [86].)

sivation with EG<sub>3</sub>-SH. In the third step, an amine-terminated biotin derivative was covalently conjugated with the MHA nanopatterns through a reaction with NHS and 1-ethyl-3-(dimethylamino)propyl carbodiimide (EDAC). The surface was then incubated with streptavidin in a fourth step, mediated by molecular recognition between biotin and streptavidin. In the final step, protein nanopatterns were fabricated by molecular recognition-mediated immobilization of biotinylated protein (BSA) in solution. This method provides a generic platform for immobilization of biotin-tagged molecules mediated by biospecific interactions of biotin–streptavidin ligands.

For the specific immobilization of cysteine-labeled cowpea mosaic virus (CPMV) capsid particles, Mirkin and coworkers applied DPN to write a mixture of two dia-

**Figure 3.11.** Nanopatterns of biotin–BSA imaged by tapping mode AFM. [A(i)] An array of 144 dots written by DPN; [A(ii)] zoom-in view of the area within the frame, showing the size of the dots. (B) The 3-D dot array with 1- $\mu\text{m}$  features. (Reproduced with permission from Ref. [89].)

lky disulfides as ink [90]. The areas surrounding the nanopatterns were passivated with penta(ethylene glycol) groups. The density of maleimide groups provided efficient thiol capture through Michael addition of the thiol from cysteine residues of engineered CPMV particles to the nanopatterned maleimide groups.

Surface activation of nanopatterns of MHA written by DPN was used by Zauscher and coworkers to fabricate nanostructures of stimulus-responsive elastin-like polypeptide (ELP) [91]. First, patterns of MHA were written directly using DPN. The surface was then passivated with 11-mercaptoundecyl-tri(ethylene glycol). Next, the COOH groups of the nanopatterned MHA were reacted with

NHS and EDAC to covalently conjugate ELP to the surface. ELP was end-grafted to the surface through an amine group to dictate the surface orientation.

Mirkin and colleagues have presented several studies with direct writing of proteins using DPN. Thiolated collagen was used as ink for direct writing of collagen nanopatterns on gold substrates [92]. Using a modified AFM tip, IgG was written directly on either negatively charged SiO<sub>2</sub> or on aldehyde-modified SiO<sub>2</sub> surfaces by DPN [93]. Tips were coated with 2-[methoxypoly(ethyleneoxy)propyl]trimethoxysilane (Si-PEG), which forms a biocompatible and hydrophilic surface layer on AFM tips for protein inking. Protein arrays of IgG and lysozyme were nanopatterned by direct writing using metallized AFM tips (gold) with a thioctic acid coating, for protein adsorption [94]. Humidity is a critical variable in transporting proteins from tips to a surface, for direct writing of proteins; optimum results were obtained in a glove box at 80–90% humidity to achieve consistent transport properties. Direct writing of proteins on nickel oxide surfaces also was accomplished using tips modified with nickel. For direct write DPN, AFM tips were coated with 5 nm of nickel to facilitate transfer of histidine-tagged proteins (ubiquitin and thioredoxin) as inks [95]. High humidity enabled diffusion from the tip to the surface and also served to minimize the denaturation of protein structures on nickel substrates. Oxidized nickel has a high affinity for polyhistidine residues and patterns could not be generated for protein inks without histidine tags. The binding activity of the nanopatterns was investigated by reaction with fluorescently labeled antibodies, indicating that surface structures remained active for fluorescent labeling.

Another strategy for DPN nanopatterning is accomplished by combining bias-induced electrochemistry and DPN [96]. Electrochemical DPN (E-DPN) was used to immobilize histidine-tagged proteins on nickel substrates [97]. Silicon AFM probes were coated with polyhistidine-tagged peptides, proteins and free-base porphyrins for nanopatterning. By applying a negative bias (–2 to –3 V) to the coated AFM tips, nanopatterns could be written on nickel surfaces using tapping-mode AFM. Without an applied potential, protein deposition was not observed.

DPN provides methods for directly writing chemical inks on surfaces for complex, multistep fabrication of nanostructures of proteins. Chemical reagents can be delivered directly to nanosized areas of a surface and then the surrounding uncovered areas can be passivated with resistive SAMs. The DPN method is amenable to conducting experiments at ambient temperatures in air and ink transfer is facilitated by controlling humidity. After each reaction step, samples can be characterized *ex situ* by AFM imaging. Different molecules can be deposited by exchanging tips to produce multicomponent arrays of nanopatterns. For protein nanopatterning, DPN can be applied to either directly write proteins on surfaces using modified tips or to nanopattern SAM molecules for attaching proteins to surfaces through electrostatic, covalent or specific binding.

#### 3.3.4

#### Latex Particle Lithography with Proteins

Particle or nanosphere lithography is an approach for nanopatterning which uses physical adsorption of materials to surfaces. Monodisperse latex particles self-

assemble into periodic structures on flat surfaces, which have then been used as structural templates or photomasks for defining the deposition of proteins or other materials. The latex particles are removed by various approaches, such as calcination, solvent dissolution or simple rinsing with water. Particle lithography has been successfully applied for patterning metals, sols, polymers and inorganic materials [98–102]. Researchers have also applied colloidal lithography with latex beads as photomasks to construct functional surfaces for selective protein adsorption on lithographically defined regions [102, 103]. This section describes a method of particle lithography which can be applied directly for controlling the organization of proteins on surfaces through physical adsorption [57].

Particle lithography can be used to construct arrays of protein nanostructures on surfaces, with superb control of the distribution of proteins within a single layer over micron-sized areas [57]. An outline of the steps for patterning proteins using latex particle lithography is shown in Fig. 3.12. First, the protein and latex are mixed together in an aqueous solution. For best results, the solution containing protein and latex should be allowed to remain at room temperature for time intervals not longer than 4 h. (To maintain protein activity the solutions should be freshly prepared and to minimize contaminants the latex particles should be pre-washed to ensure that the particles are free of surfactants.) In the second step, a small volume ( $10 \mu\text{L cm}^{-2}$ ) of the colloidal suspension is deposited at the center of the substrate surface, using a pipette. The liquid spreads out into a thin layer across the surface as it dries. The protein and latex mixture forms ordered assem-

**Figure 3.12.** Fabrication steps for creating arrays of protein nanostructures via particle lithography. (A) Monodisperse latex particles are mixed with protein. (B) The mixture is deposited on a flat surface such as

mica(0001). (C) After the droplet dries, an ordered crystalline layer is formed. (D) Latex are removed by rinsing with deionized water, leaving a layer of protein nanostructures on the surface.

blies supported by mica or gold. During drying, the convective motion of water as it evaporates pulls the latex together into close-packed assemblies. After the deposits have dried, the latex is rinsed away with deionized water to leave a single layer of protein nanostructures on the surface. The assembly of latex particles and the protein nanostructures can be characterized using AFM throughout the fabrication process.

Example images of BSA arrays formed from 500- and 200-nm diameter spheres are shown in Fig. 13(A and B, respectively). The 2-D AFM topographs reveal an organized arrangement of circular dark holes (uncovered areas of mica) surrounded by clusters of BSA. The periodicity of the resulting nanopatterns depends on the separation of latex spheres, which is observed to be 10–15% smaller than the original latex diameters. This is likely attributable to the shrinking and deformation of latex particles during drying. Using 500 nm particles, the ratio of BSA:latex was 55 000:1 which roughly corresponds to a single layer of proteins encapsulating a sphere. For the 200 nm particles, the ratio of BSA:latex was 9000:1, also corresponding to a monolayer shell. The ratios for successful lithography have

**Figure 3.13.** Periodic arrays of BSA nanostructures generated with latex nanoparticle lithography. (A) BSA nanopatterns from 500-nm particles, using a BSA:latex ratio of 55 000:1. The corresponding cursor indicates the period-

icity of the BSA nanostructures is  $422 \pm 33$  nm. (B) BSA nanostructures generated using 200-nm particles and a BSA:latex ratio of 9000:1. The periodicity of the BSA nanostructures measured  $179 \pm 21$  nm.

ranged from approximately half of monolayer coverage of spheres to that of two layers, yielding different distributions and surface morphologies. Particle lithography uses mild conditions (ambient temperatures, buffers), yet provides nanometer-level control of the spatial distribution of proteins organized within a single surface layer. Particle lithography was also successfully applied for nanopatterning rabbit IgG [57]. Both IgG and BSA nanopatterns retained the ability to bind corresponding specific antibodies.

Particle lithography is a highly reproducible and robust method for patterning proteins, and serves as an excellent starting point for continuing to develop more complex bioassays with different surfaces and proteins. Using latex particles to control the arrangement of proteins on surfaces is a practical technology which is amenable to microspotting or immersion methods used for protein microarrays and biochips. Latex bead immobilization has been applied in spotting solutions to create microarrays for detection of antibodies [104]. Particle lithography offers the advantages of nanometer precision and high throughput, since a small vial of solution can produce hundreds of replicate samples. Future investigations will address the suitability of particle lithography to other surfaces and to other proteins, for application in surface-bound immunoassays.

### 3.4

#### Detection of Protein Binding at the Nanoscale

Nanoengineering approaches for the development of nanoscale bioassays capitalize on the unique *in situ* and high-resolution capabilities of SPM. Designed surfaces can be created with precisely placed proteins, which are subsequently monitored during the binding of secondary antibodies. SPM can be applied directly for detection, measuring changes in the heights of nanopatterns with protein binding. The height changes indicate the side-on or end-on orientation of immobilized proteins (Fig. 3.14) [74]. In some investigations, fluorescent labels were conjugated to antibodies for microscopic examination of samples. Optical microscopy can detect changes in fluorescence after antigen–antibody binding. An important question to address is whether or not the tagging entity hinders the affinity and efficiency of antigen–antibody binding. Many fluorescent dyes currently used are hydrophobic, which substantially decreases the solubility of protein–dye conjugates. This could adversely influence signal intensity for fluorescent detection [105]. Nanoscale studies can be applied to refine critical parameters used to link and organize proteins on surfaces of biochips and biosensors. SPM images of protein binding can be beneficial for evaluating the effectiveness of different bioconjugation chemistries for biomarkers.

At the core of biosensing is detection of biomolecular binding events with high selectivity and sensitivity. Typically, bioassays for surface-bound proteins are not as sensitive as approaches which use solution chemistry, due in part to the accessibility of molecules for binding. Pressing the limits of protein patterning to the nanometer scale will furnish direct views of the differences in immobilization chemis-

**Figure 3.14.** Nanografted patterns of aldehyde-terminated SAMs were used to covalently immobilize proteins via imine bonds. (A) Nanopattern of 3-mercaptopropanal ( $150 \times 150 \text{ nm}^2$ ) written in decanethiol; (B) after *in situ* immersion in buffer containing rabbit IgG; (C) combined cursor profiles for lines in (A) and (B). tries. Conventionally, biosensors and biochips rely on microspotting or solution deposition to place proteins on various surfaces, without control of the placement and arrangement of target proteins. There is a requirement for efficient yet mild immobilization chemistries which preserve tertiary structure and maximize the activity of fragile biomolecules.

Biomolecules immobilized on a surface serve as the receptor and in some cases as the signal transducer in biosensors. Therefore, the placement of biological ligands in precisely defined locations can increase the density of sensor elements and lead to improved detection limits with molecular-level control of the surface reactivity [106, 107]. As a proof-of-concept, Wolinsky and Mirkin have reported a nanometer-scale antibody array prepared by DPN to test for the presence of the human immunodeficiency virus type 1 (HIV-1) in blood samples [108]. The HIV-1 antibodies were immobilized on the MHA nanopatterns for hybridizing (HIV-1 p24) antigen and bound proteins. With a nanoarray of 100-nm features written by DPN, the three-component sandwich assay exceeded the limit of detection of con-

ventional enzyme-linked immunosorbent assay (ELISA) based immunoassays by 1000-fold.

### 3.5

#### Future Directions

It can be anticipated that array-based technologies in proteomics including protein-based biochip and biosensing devices will significantly advance biotechnology, clinical diagnostics, tissue engineering and targeted drug delivery [109–111]. Ultra-small protein patterns can be used in biosensing, control of cell adhesion and growth and in biochip fabrication [5, 6, 112]. Methods of high-throughput protein analysis offer immense potential for fast, direct and quantitative detection, including the possibility of screening thousands of proteins within a single sample to test for protein, ligand and drug interactions. Improved binding to surfaces onto which capture proteins are arrayed and improved sensitivity of detection are technical challenges advancing protein microarray technology. The next section first discusses the motivation for advancing beyond microtechnology to the nanoscale frontier and then describes new technologies which are being developed for multiplexing AFM systems for parallel processes.

#### 3.5.1

##### Advantages of Nanoscale Detection

Tools for nano- and microfabrication will provide important contributions in developing biochip and biosensing technologies, as well as supply basic research in protein–protein interactions. With the rapid progress in development of large sets of characterized antibodies, protein and antibody arrays will provide tremendous advantages for diagnostics and medical science. Miniaturization provides rewards of reduced quantities of analytes and reagents, increased density of sensor and chip elements, and more rapid reaction response [107, 113–115]. Multiplex screening of many interactions in a parallel fashion reduces analysis time and gives insight into the multiplicity of factors involved in diseases. Protein microarrays used in experiments based on AFM detection may soon reach capabilities for routinely achieving single-molecule detection.

Nanotechnology offers advantages not only for array production, but also for sample detection for bioarrays. In the nanoscale size regime, material properties are different than at macroscopic scales, exhibiting phenomena such as electromagnetic field enhancement, narrow emission band fluorescence, surface plasmon resonance, and conductivity and signal amplification. These properties enable new signaling and recognition capabilities for use in sensor systems. For example, bioconjugates of nanoparticles and quantum dots may provide improved stability and sensitivity for quantitative fluorescence detection with advantages over the conventional approach of fluorescent staining which suffers from the disadvantage of photobleaching [116]. With regard to biomolecule detection, new strategies based on

functionalized metal nanoparticles, in combination with magnetic detection have been reported, using superparamagnetic beads coated with antibodies for detection [117].

### 3.5.2

#### Development of Cantilever Arrays

Using SPM-based nanofabrication, the single pen-and-ink approach is far too slow for cost-effective manufacturing of protein arrays. AFM-based lithography offers the ultimate capabilities for nanometer-scale control of surfaces with extremely high spatial precision; however, it has the limitation of relatively low throughput by fabricating each pattern individually. If higher throughput can be accomplished for nanoscale biochips, such arrays would offer immense capabilities. Miniaturization of protein sensing to nanodimensions will require techniques for rapid, efficient and high-throughput writing of biomolecules and SAMs. New designs for AFM probe arrays are being developed which will provide parallel and multiplexing capabilities for surface characterization and fabrication. Readers are referred to two recent reviews which detail the developments in multiple probe systems [81, 118].

Successful lithography with probe arrays has been demonstrated by several researchers, and representative examples are summarized in Tab. 3.3. Initial designs of tip arrays used feedback from a single cantilever for operation. This can sometimes be problematic for lithography because of variations in tip geometries and difficulties for precise alignment [119]. Micromachined arrays of cantilevers operated in parallel ( $2 \times 1$ ,  $5 \times 1$ ,  $10 \times 1$ ,  $32 \times 1$  and  $50 \times 1$ ) were used for bias-induced oxidation of silicon as reported by Quate and coworkers [119–121]. Proof-of-concept experiments were presented for operation of parallel AFM probes for bias-induced lithography using as many as 50 probes. Arrays with integrated  $z$ -axis control were found to improve the quality and reproducibility of writing. There are several approaches for control and actuation of individual probes within cantilever arrays, including piezoelectric sensing [121–123], optical interferometric detection [124], thermal actuation of bimetallic tips [125–129] and conductivity sensing of tip–surface contact [130].

DPN has been advanced to parallel processes through the use of 1-D cantilever arrays [131, 132]. Control of the horizontal and vertical movements of AFM probes can be achieved using the laser signal feedback of a closed-loop AFM scanner. Using an eight-cantilever array, a miniaturized combinatorial chemical sensor was produced with DPN by writing multiple inks as sensor elements [133]. Also, examples have been reported using tip arrays for simultaneously writing multiple patterns of octadecanethiol using DPN [128–130].

Two-dimensional cantilever arrays have been developed and tested, including designs which combine passive (feedback from deflection of a single tip) and active control through actuation of multiple tips [134]. A group at IBM has implemented an addressable  $32 \times 32$  probe array designed for high-density data storage [135, 136]. The “Millipede” array format with 1024 cantilevers measures  $3 \times 3 \text{ mm}^2$

**Tab. 3.3** Examples of AFM probe arrays which have been successfully demonstrated for AFM imaging/lithography applications.

Year	Array size	Tip actuation method	Application	Reference
1995	2 × 1	integrated piezoelectric sensor and piezoresistive sensor for both tips	parallel constant-force AFM imaging	139
1995	2 × 1, 5 × 1	single tip feedback (piezoresistive levers)	bias-induced oxidation of silicon (100–200 nm line patterns)	119
1996	2 × 1	integrated piezoelectric actuators for each tip	bias-induced oxidation of silicon (micron patterns)	121
1998	10 × 1, 32 × 1, 50 × 1	thermal actuation of individual probes, piezoresistive sensors and integrated ZnO actuators	bias-induced oxidation of silicon (1.1- $\mu$ m line patterns) and parallel AFM imaging	120
1999	5 × 5	integrated piezoresistive sensing using five actuators	multiplexed AFM imaging	134
2000	2 × 1	thermal bimorph actuator, metal-oxide-semiconductor (MOS) electronics	AFM imaging with constant height mode, tapping mode, constant force mode	126
2000	2 × 4	piezoresistive deflection sensors	parallel AFM imaging	123
2000	32 × 32	thermal actuation, corner sensors for z-feedback control of entire chip	data storage read/write operations	135, 136
2001	5 × 1	optical interferometric detection	parallel AFM imaging, constant height mode	124
2002	2 × 2, 2 × 7	piezoresistive sensing with integrated electrical interconnects	parallel contact-mode imaging of large sample areas	122

2002	8 × 1, 32 × 1	single tip actuation and optical deflection feedback	DPN with octadecanethiol/gold	131
2003	8 × 1	single tip actuation and optical deflection feedback	DPN with sol inks for chemical sensing	133
2003	10 × 1	conductivity-based sensing of tip–surface contact	simultaneous DPN writing with eight probes	130
2004	10 × 1	integrated thermal actuation of probes with piezoresistive stress sensors	parallel constant-force AFM imaging	127
2004	12 × 1	thermal actuation of bimetallic probes, piezoresistive Wheatstone bridge detection	AFM imaging and force–distance measurements	125
2004	10 × 1	individual tip control by thermal actuation of bimorph probes	simultaneous DPN writing with 10 probes	128, 129

---

**Figure 3.15.** The “Millipede” array of 1024 cantilevers. (A) Photograph of the entire chip. (B) SEM images of cantilevers of the  $32 \times 32$  array. (C) A single cantilever with integrated silicon tip. (Reproduced with permission from Ref. [135].)

and each cantilever is assigned to read and write areas of  $100 \times 100 \mu\text{m}^2$ . The Millipede approach is not based on individual  $z$ -feedback for each cantilever; feedback control is applied for the whole chip. This design requires stringent control of tip fabrication parameters via micromachining to generate uniform probe dimensions (Fig. 3.15). Although the Millipede design is intended for read/write data storage, other applications can be envisaged using SPL.

### 3.5.3

#### Concluding Remarks

Fundamental understanding of the interactions of protein binding to substrates or antibodies is essential for developing workable technologies for life sciences. The new capabilities to study and control processes on the nanometer scale are emerging as valuable assets in both fundamental and applied research. At present, SPM and SPL are primarily used as research tools in laboratories rather than as tools for manufacturing. However, in the future, nanoscale technology in manufacturing is predicted to bring an even greater impact and benefit to society than present-day microfabrication technologies. Potential applications include the development of a new generation of chemical and biosensors, biochips, and molecular electronic devices. We anticipate that nanoscale research will define new directions in areas such as biosensing, biomimetic surfaces for drug delivery and biomolecule-based electronics. This chapter provides insight on the tremendous versatility of several new SPL methods applied for protein nanopatterning. In addition, there are many new nanofabrication methods being developed which may be suitable in the future for engineering surfaces for nanoscale protein assays.

Applying the *in situ* tools of lithography with proteins will enable systematic evaluation of the differences in bioaffinity for various chemical immobilization strategies, with direct views of how the morphology and geometry of nanoengineered surfaces direct and influence the binding of antibodies and proteins. Conceptually, by arranging and orienting proteins on well-defined surfaces, the selectivity and sensitivity of surface-based protein assays can be substantially improved. These studies will facilitate the development of new and better approaches for immobilization and bioconjugation chemistries – key technologies used in manufacturing biochip and biosensing surfaces.

# Microcantilever-based Nanodevices in the Life Sciences

*Horacio D. Espinosa, Keun-Ho Kim, and Nicolaie Moldovan*

### 4.1

#### Introduction

Microcantilevers were initially developed for atomic force microscopy (AFM), where precise force sensing is critical for atomic-resolution imaging [1, 2]. Microcantilevers were required to have a low force constant and a high mechanical resonance frequency for a superior signal-to-noise ratio. Such requirements were met by cantilevers made by microfabrication techniques, which had been originally developed for integrated circuit (IC) process technology, but were later on applied to micrometer-scale silicon sensors and actuators [3, 4]. Microfabrication also permitted the integration of sharp tips at the free ends of microcantilevers for high lateral resolution in AFM scanning and manipulation. Microfabrication techniques further tailored microcantilevers to broaden the AFM techniques for probing, material delivery, manipulation, biomaterial sensing and lithography. Most of such applications take advantage of the high-precision positioning and subnanometer deflection-detection capabilities of scanning probe microscopy (SPM), which includes scanning tunneling microscopy (STM), AFM, near-field scanning optical microscopy (NSOM) and a plethora of conductive, capacitive, magnetic or thermal probing techniques. Among the extended use of microcantilever applications, patterning of biological materials at the submicron scale is of great importance to fabricating ultra-miniaturized bioanalytical tests and devices. Patterning using biological materials at the miniaturized scale has been pursued by many methods such as ink-jet printing [5, 6], photolithography [7], microcontact printing [8–10], microfluidic devices [11, 12] and “dip-pen” nanolithography (DPN) [13–15]. To date, the DPN technique, an AFM-based direct-write lithographic method, provides the best resolution. Features smaller than 100 nm in size containing patterned biomolecules have been obtained. In such direct-write patterning techniques, the tip sharpness is critical. Through micromachining, tip radii as small as a few nanometers have been obtained [16].

In the initial application of the DPN technique, microcantilevers were used to pattern self-assembled monolayers (SAMs) formed by the adsorption of alkanethiols onto gold surfaces [13]. The SAMs have extraordinary utility to control inter-

facial characteristics, such as the adsorption of proteins and the attachment of cells, and for use in biological analysis including array-based high-throughput screening and diagnostic applications [14, 15]. Also, SAM-coated microcantilevers can detect specific chemical interactions via an optical beam-deflection technique [17]. Direct delivery of biomaterials without the use of a SAM as a binding agent has also been pursued. In biopatterning applications, it is usually required to maintain and transport biomaterials in a liquid environment. Hence, the incorporation of microfluidic systems has been attempted. For example, a commercial AFM tip with a small opening at its apex was reported [18]. These tips allow the on-demand deposition of small single droplets at a predetermined location on a sample. The demand to use liquid as a transport medium has created versatile micro- and nanofluidic tools, specifically engineered for biopatterning, based on the popular microcantilever architecture. Micromachining techniques made the development of such useful structures possible.

Practical implementation of biopatterning and sensing by SPM techniques requires high throughput. This is being pursued by means of microcantilever parallelization [19, 20]. A two-dimensional (2-D) array of independently addressable microcantilevers was developed for high-density data storage [21]. Although this design was conceived for thermal patterning, it is possible to imagine similar tools for biopatterning. With such a massively parallel biopatterning tool, the feature sizes of DNA [22] or protein [23] chips can be further miniaturized, leading to nanoscale assays. For instance, specialized microfluidic probes arranged in a 2-D array would be able to produce ultra-miniaturized, high-density assays, requiring only extremely small analyte volumes, and allowing the simultaneous processing and massively parallel integration of proteins. The massive parallelization at the nanoscale benefits the technique by decreasing the reaction time and by drastically increasing the statistical significance of the experiments. This has the potential to have a huge impact on applications in the life sciences, such as drug discovery and diagnosis devices.

In this chapter we describe how microfabrication techniques were utilized to build micro- and nanoscale devices which facilitated research and development in the life sciences. Microfabrication techniques in general are now available from many sources; books dedicated to topics of microfabrication for versatile SPM cantilever probes have also been published [16, 24, 25]. Furthermore, versatile principles and applications of the SPM techniques have been reviewed [26–30]. Without claiming to exhaust the field, we include a list of currently available books and review articles related to the construction and working principles of general microcantilever probes in Tab. 4.1 for easy reference. However, none of the existing books and reviews bring together the microfabrication aspects and life sciences applications, to discuss them in their close, technologically-targeted relationship. For example, the microfabrication of apertured tips was introduced [16], but their applications in life sciences were not considered for delivering biosamples. Similarly, articles on principles/applications lack information on how the microcantilevers were constructed. In addition, since the development of microfluidic probes for bio-nano applications is an emerging field, to the best of our knowledge, there are

no current review articles or books that provide a systematic treatment. We hope that this book chapter helps researchers to broaden their viewpoints in this hot topic, organize their thoughts to rise from microfabrication to principles and stimulate new ideas.

Our focus is on devices and methods for surface patterning that typically involve SPMs, although some other interesting devices and concepts will be briefly introduced, such as integration of microchannels. Section 4.2 gives a description of how conventional types of microcantilevers have been microfabricated and used in biotechnology. Beyond the use of conventional microcantilevers, many efforts have been made to integrate microfluidic systems in micro- and nanocantilever devices. Microfluidic systems are of interest because most applications in life sciences require liquid samples to be delivered or probed. Such advanced microcantilevers involving microfluidics are in Section 4.3 and their applications in biopatterning are presented in Section 4.4. Conclusions and outlook are given in Section 4.5.

## 4.2 Microcantilevers

The most commonly used cantilevers in SPM-based biopatterning and sensing are rectangular or V-shaped. The preferred materials in microcantilever fabrication are thin films, such as silicon oxide, silicon nitride, single crystal silicon, diamond or metals. Sharp protruding tips are necessary at the free end of the cantilever for

high-resolution imaging or manipulation, allowing the interaction area between the tip and the sample surface to be minimized. The force constant of microcantilevers used in AFM has been accustomed by practical experience to be in the range from  $10^{-2}$  to  $10^2$  N m<sup>-1</sup> in order to achieve atomic resolution in the contact mode. The force constant  $k$  of a rectangular cantilever with fixed-free boundary condition is defined as follows:

$$k = \frac{Ewt^3}{4L^3} \quad (1)$$

where  $E$  is the modulus of elasticity,  $w$  is the width,  $t$  is the thickness and  $L$  is the length of the cantilever. Surface micromachining techniques are typically used to fabricate micro- and nanoscale cantilevers with or without integrated tips. The fundamental fabrication methods for AFM microcantilevers were established in the late 1980s and their basic concepts are still being used, but with improved features. However, since AFM started to be used for purposes other than for surface profiling, many modified and specific designs have been proposed, leading to a large diversity of micro- and nanocantilever probes. For example, microcantilevers with an apertured pyramidal tip were used to pattern surfaces with liquid contained in a small reservoir just above the tip.

In this section we describe microfabrication techniques of versatile micro/nanocantilevers and their applications in life sciences.

#### 4.2.1

##### **Microfabrication of Miniaturized Probes**

The fabrication methods of cantilevers can be basically divided into two classes [31]. The first uses thin films deposited or diffused into a silicon substrate; in the second fabrication method, all parts of the cantilevered are micromachined out of bulk materials. In the first method, cantilevers beams were commonly formed from thin films such as silicon nitride and silicon oxide. Thin films were deposited on a (100) silicon substrate and then patterned through lithographic processes to define the cantilever shape. The cantilevers were released by etching the substrate, e.g. in aqueous potassium hydroxide (KOH) solutions or ethylenediamine/pyrocatechol/water mixtures (EDP) [4]. Depending on the requirements, sharp tips can be integrated on the cantilever, as discussed later.

Rectangular microcantilevers were employed as biological or biochemical detectors utilizing the bending by adsorption-induced surface stress. The advantage of cantilever-based biosensors is label-free detection and subnanometer deflection sensitivity. In biological sensing applications, the cantilever generates either a static deflection or a change in the resonance frequency when target molecules are adsorbed on the surface of the cantilever [32]. Measurements of such changes can be achieved by either electrical or optical means. Electrical methods include capacitance and piezoresistive sensing, whereas optical techniques include optical lever and interferometric methods.

Figure 4.1. SEM image of a microcantilever sensor array [33].

Arrays of silicon cantilevers were produced by a combination of dry and wet etching techniques [33], to form an “artificial nose”, working on the principle of bending stress induced by surface adsorbed molecular species. Individual cantilevers were made (Fig. 4.1) with rectangular dimensions of 500  $\mu\text{m}$  in length, 100  $\mu\text{m}$  in width and 0.8  $\mu\text{m}$  in thickness, resulting in a typical spring constant of 0.02  $\text{N m}^{-1}$ .

A thiol-gold immobilization system [34] was used to form stressed monolayers to induce bending of the cantilevers in detection schemes for vapor thiols. For this application, silicon nitride cantilevers with a 20-nm gold layer evaporated on one side were used as sensors for gas-phase adsorption of alkanethiols [35]. The optical detection scheme of an AFM was used to measure deflections down to the picometer scale. Alkanethiol vapors were generated by placing a few microliters of alkanethiol in a closed glass beaker. After thermal equilibrium was reached, the cantilever was exposed to the alkanethiol vapor. The deflection was measured as a function of time to show how the chemisorbed alkanethiols caused compressive surface stress during the progressive self-assembly. With the same methodology, single-strand (ss) DNA [36, 37] and proteins [38, 39] were detected utilizing DNA hybridization and antigen–antibody interaction as a mechanism to cause surface stress change. The biomaterials were delivered onto the cantilever in liquid environment.

In addition to deflection detection, the change in resonance frequency was used for the detection of target materials adsorbed on a cantilever [40–42]. The cantilever was driven close to the resonance frequency by a piezoelectric actuator. The oscillation was detected by the AFM optical detection. The deposited material increased the mass of the cantilever system, thus decreased the resonance frequency. Assuming there is negligible stiffness change of the cantilever due to the layer of adsorbed materials, the mass change  $\Delta m$  can be calculated from the following equation [40]:

$$\Delta m = \frac{k}{0.72\pi^2} \left( \frac{1}{f_1^2} - \frac{1}{f_2^2} \right) \quad (2)$$

where  $k$  is the spring constant of the cantilever, and  $f_0$  and  $f_1$  are the resonance frequencies before and after adsorption, respectively. Simultaneous use of deflection and resonance frequency detection was also reported [43].

Furthermore, the force exerted by conformational changes of a surface-tethered DNA system was investigated on microfabricated cantilevers [44]. The ability to manipulate the direction and amplitude of bending of cantilevers envisioned potential for micromechanical machinery, including valves, switches and actuators triggered by molecular shape.

In order to integrate tips onto thin film cantilevers, molds for tips needed to be fabricated on the silicon substrate prior to the deposition of the thin film [45]. Either pits or convexities produced on a substrate were exploited as molds. Since molds were employed for tip integration, those types of techniques for thin-film cantilevers were frequently referred to as micromolding or microcasting techniques.

The fabrication of molding-pit cantilevers started with the formation of pits on a (100) silicon surface by an anisotropic etchant such as KOH solutions with a circular or square opening on a mask layer. Such an anisotropic etching produced a pyramidal pit delineated by (111) planes. Subsequently, a thin film was deposited to conformally coat the pit and patterned to delineate the cantilever shape. By removing the whole silicon substrate underneath the cantilever, a protruding tip integrated on the cantilever was obtained [45, 46]. Hybrid tip/cantilever structures were reported by replacing the tip materials with metals, such as tungsten [45] and gold [47], while keeping the cantilever body made of silicon nitride, with better mechanical properties. In a different design, Rasmussen and coworkers [48] reported having all parts of the probe, including the tip, cantilever and support, made out of electroformed metal. The general disadvantage of this type of molding technique is that the fabricated tips point into the substrate, which makes the substrate impractical to use as a chip handling body. Thus, the addition of an extra handling body is needed on the opposite side of the tip, prior to the releasing step. Wafer bonding [45] or electroplating techniques [48] were used to form a handling body. The sharpness of the released tip is determined by that of the molding pit on the silicon substrate, whose final tip angle is around  $70^\circ$  due to the characteristic of anisotropic etching of silicon [3]. However, the sharpness, as well as the aspect ratio, of the tips can be improved by sharpening the molding pit using thermal oxidation at around  $950^\circ\text{C}$  [49]. Oxidation at such a low temperature caused the growth of a nonuniform silicon dioxide film in the pit, resulting in a narrower angle between the walls of the pit, giving a sharper molded tip. With modified pits, tips with curvature radii as low as  $110\text{ \AA}$  were obtained [49].

Convex tip molds were also used to integrate tips onto microcantilevers [45]. In this fabrication scheme, a precursor cap and isotropic etching were used to create a molding tip out of the silicon substrate. For this purpose, a masking layer ( $\text{SiO}_2$  or  $\text{Si}_3\text{N}_4$ ) was deposited on a (100) silicon wafer, followed by lithographically patterning the layer to produce a tip mask of square or circular shape. During a subsequent etching process, the tip mask was undercut to form a silicon post underneath. The silicon etching was a combination of isotropic and anisotropic plasma etching. Extended etching formed a sharp tip with the cap detached. Subsequent thermal oxidation at  $1100^\circ\text{C}$  forms a silicon oxide layer incorporating the tip. A cantilever was lithographically formed on the silicon oxide layer and finally re-

leased by removing the silicon substrate in a KOH solution. When a protruding tip is used as a mold, the molded tip faces in the opposite direction of the silicon substrate, which allows the substrate to be used to form a handling chip. An oxidation sharpening technique can also improve the geometry of convex-molded tips [50, 51]. This technique is based on an experimental study showing that the oxide growth is about 30% slower at silicon step edges than on flat surfaces at temperatures ranging between 900 and 950 °C [50, 51]. The effect is related to the stress-induced diffusion anisotropy of oxygen in silicon oxide, which allows oxidation sharpening to be used both for sharpening concave and convex silicon molds. The low temperature during the oxidation process is important, since at above 950 °C silicon oxide suffers a softening and flow, thus eliminating the stress and the diffusion anisotropy.

As for the materials for a cantilever/tip structure other than silicon oxide, single-crystal silicon doped with boron was used [52]. Also, a silicon nitride layer deposited onto a convex mold was reported [53].

Instead of thin film cantilevers, whole parts of the structure (i.e. tips, cantilevers and handling chips) can be micromachined entirely out of bulk silicon. In the scheme reported by Wolter and coworkers [31], the fabrication was done by etching a (100) silicon wafer through a rectangular etch widow in a mask layer on the reverse side until a thickness of twice the desired thickness of the cantilever remained. The cantilever was subsequently defined on a mask layer on the front side of the wafer, followed by resumed KOH etching until both sides met. The tip integration was achieved with a precursor and undercut. The thickness of the cantilever was controlled by the etching time in KOH. Accurate geometry control by timing the etching is generally impeded by the following factors: (a) the etching is not uniform on a wafer due to stirring-induced flow, liquid flow induced by bubble generation and strong proximity effects, and (b) the etch rate cannot be precisely controlled on every batch. Hence, etch stop techniques, such as boron doping [54, 55] and buried oxide [56, 57], were pursued to precisely define the cantilever thickness.

The molding techniques are particularly important for fabricating tips and cantilevers out of materials hard to pattern directly, such as diamond, silicon carbide, platinum, silicon elastomers, resins, etc. Some of these cases will be treated in more depth in the following sections.

Sharp integrated tips are essential in many SPM-based applications including lithography and manipulation of nano-objects in order to produce smaller nanopatterned or assembled structures. For example, such tips integrated on cantilevers allowed the manipulation of single molecules, and measurements of intermolecular [58–60] and intramolecular [61–63] forces. Force spectroscopy with SPM was typically achieved by functionalizing a tip with a partner suitable for specific interaction with a target molecule bound onto a substrate. When the tip and substrate were brought into contact, the molecular partners interacted. Subsequently, the cantilever was retracted to stretch the target molecule. Mechanical properties of the intermolecular bond established between partners were identified for biomolecular combinations including biotin–streptavidin, antibody–antigen, complemen-

tary strands of DNA and interactions between proteins. By stretching molecules bound between a tip and a substrate, unfolding events were measured to determine rupture forces associated with various numbers of base pairings [61, 62]. Many applications in SPM force microscopy may be found in the literature [26].

The fabrication methods of the aforementioned types of cantilevers with integrated tips are summarized in Tab. 4.2. In the following sections we discuss how microcantilevers with integrated tips have been used for nanofabrication and manipulation.

#### 4.2.2

#### **Cantilever Probes for Nanopatterning**

Tips integrated on microcantilevers may function as pens or quills, to locally deliver molecules previously present on the tip surface. The tip sharpness allows sub-100 nm patterning with various molecular species. The domain becomes relevant for life sciences if these molecules achieve a local functionalization of the surfaces, such that specific biochemical experiments can be conducted at these length scales. DPN is a direct-write lithographic technique which uses AFM tips to locally deposit materials on a variety of surfaces [13, 30]. The deposited material and the substrate usually have to be paired, such that a chemical reaction occurs upon delivery, or a SAM is formed, so that a reading is possible using the same AFM technique. In some cases, this reaction or SAM formation is not needed, such as the case of simple patterning with fluorescent dyes, when the reading can be achieved optically. In the DPN technique, the species form a thin molecular layer on the tip surface, such that the tip geometry is not significantly altered. When the tip is placed in contact with a target surface, the molecules migrate from the tip onto the surface and the time of surface contact directly correlates with the amount of materials transferred. DPN was originally reported to pattern gold surfaces with a solution of alkanethiols [13], and its applications have been subsequently extended

to patterning surfaces with versatile types of materials such as biomolecules [14, 15, 64], polymers [65], small organic materials [66], sol precursors [67] and metal salts [68]. One of the advantages of the DPN technique is that biomolecules, such as DNAs or proteins, can be patterned both by direct-write and indirect assembly [14, 15, 69–72], which can be utilized to build nanoscale biomolecular sensor arrays with higher sensitivity and selectivity due to much smaller sample volumes. For example, modified ssDNAs with a thiol group on one end were patterned on a gold surface and used to capture complementary DNA sequences tagged with nanoparticles [14]. In this way a pattern of gold particles could be assembled (bottom up) on the surface, in a completely different way than by thin film deposition and etching or lift-off (traditional top-down techniques). Feature sizes ranging from a few micrometers to less than 100 nm were achieved.

The water meniscus formed by capillary condensation was suggested as the mechanism of molecular transfer from a tip to a substrate in DPN and the formation of such a meniscus was recently confirmed using an environmental scanning electron microscopy (SEM) technique [73]. Once transferred to the substrate, the molecules spread across the surface depending on the humidity, temperature, reactivity of the ink with the substrate and contact radius of the tip. Assuming the environmental conditions and types of ink and substrate are optimized, the patterning of small feature sizes is critically dependent on the radius of curvature of the tips integrated on AFM cantilevers. The most commonly used probes in the DPN technique are made of silicon nitride with integrated pyramidal tips, which are typically fabricated using the pyramidal-pit-molding technique [45]. For higher resolution of DPN writing, sharper tips improved by the oxidation-sharpening technique [49] are usually employed. The dimensions of the cantilevers meet the reported range of desired force constants of the cantilever  $0.03\text{--}0.3\text{ N m}^{-1}$  [74].

Once a tip is coated with molecules of interest, patterning is typically controlled by commercially available AFM instruments to precisely deposit desired amounts of molecules at controlled locations. DPN writing has been typically performed with a single probe; however, patterning large areas with a single tip, due to its serial nature and limited AFM scan size, is very inefficient. In an effort to improve the throughput of the DPN technique, the feasibility of parallel DPN patterning with a commercially available tip array was demonstrated in a commercially available AFM [74].

Furthermore, linear arrays of high-density probes with integrated tips for DPN were microfabricated [19, 20]. Two types of DPN probe arrays were developed using surface micromachining techniques. The first type, or type-1 probe array, was made out of thin-film silicon nitride using the molding technique with a protruding tip, whereas the second type, or type-2 probe array, was fabricated from heavily boron-doped silicon (Fig. 4.2). The type-1 probe array consists of 32 straight probes in a 1-D arrangement with the space between consecutive probes being  $100\text{ }\mu\text{m}$ . The dimensions of an individual cantilever were  $400\text{ }\mu\text{m}$  long,  $50\text{ }\mu\text{m}$  wide and  $0.6\text{ }\mu\text{m}$  thick. The type-2 array had eight probes separated from each other by a

**Figure 4.2.** SEM micrographs of DPN probe arrays with the type-1 (left) and type-2 (right) arrays [20].

spacing of 310  $\mu\text{m}$ , whereas each cantilever was in a multifold configuration. The dimensions are 1400  $\mu\text{m}$  long, 15  $\mu\text{m}$  wide and 10  $\mu\text{m}$  thick.

The fabrication of the type-1 probe started with growing a thin oxide film on a (100) silicon wafer. The oxide film on the front side was patterned to serve as precursor caps for the subsequent etching (Fig. 4.3a). Anisotropic etching in KOH solution undercut the precursors to create tips protruding out of the silicon substrate until the tips had small flat top surfaces (Fig. 4.3b). Subsequently, a thermal oxidation process sharpened the tip and removed the precursor cap (Fig. 4.3c). As a result, uniform sharpness was obtained for the produced tip array. A layer of silicon nitride film was deposited through a low-pressure chemical vapor deposition (LPCVD) process and then patterned to form the shanks of the individual probes (Fig. 4.3d). The cantilevers were released in the ensuing anisotropic wet etching in ethylene-diamine pyrocatechol (EDP) solution at 95  $^{\circ}\text{C}$  (Fig. 4.3e).

The fabrication of the type-2 probes started from a silicon wafer having two extra layers on the top, consisting of a 10- $\mu\text{m}$  layer heavily doped with boron and a 10- $\mu\text{m}$  silicon layer grown epitaxially on top of the doped layer. The wafer was thermally oxidized to form a 500-nm oxide layer, from which tip precursors were lithographically patterned (Fig. 4.4a). Tips were created from the epitaxial silicon layer by underetching the silicon oxide precursor caps (Fig. 4.4b). Thermal oxidation followed to sharpen the tips (Fig. 4.4c). Another layer of oxide film was formed to protect the front side during the subsequent etching (Fig. 4.4d). The bulk silicon substrate was etched away using EDP until the boron-doped etch-stop layer was reached (Fig. 4.4e). A final reactive ion etching (RIE) process was performed to define the cantilever shape (Fig. 4.4f).

This fabricated array of probes was used to pattern gold surfaces with 16-mercaptohexadecanoic acid (MHA) and octadecanethiol (ODT), and to demonstrate parallel DPN capabilities in a conventional AFM. Only one cantilever was monitored by the optical beam-deflection scheme of the AFM, while the others in the array followed in a passive manner. Eight duplicate copies of patterns with a 60-nm feature size were generated by parallel-writing, while only one cantilever was used for the deflection sensing.

In addition, a linear array of 26 tips was operated in a parallel fashion to deposit patterns of MHA on a gold surface to form a mask for a subsequent gold-etching

**Figure 4.3.** Fabrication process of a type-1 probe array [20]. The sequence is described in detail in the text.

step [75] (Fig. 4.5). Results obtained demonstrated that the line widths were nearly identical without any writing failure at individual tips (Fig. 4.6). Patterning with an array of three 26-tip arrays produced more than 34 000 dot features in 7.3 min. Furthermore, arrays containing up to 250 probes performed parallel DPN writing in a high-throughput fashion over the centimeter length scale. Patterning of multilayer organic thin films was also demonstrated in parallel fashion [76].

By addressing the throughput issue of DPN with microcantilever arrays, it was envisaged that parallel-probe lithography would lead to many applications in high-resolution patterning over large areas with the aforementioned versatile inks such as biomolecules, organic materials, polymers, sol precursors, metal salts, etc. [30].

#### 4.2.3

##### **Elastomeric AFM Probes**

Hard materials, especially silicon nitride, have been the preferred tip materials for DPN patterning probes. However, tips made of soft materials such as silicon elastomers were also reported [77]. Poly(dimethylsiloxane) (PDMS) has been widely used in microcontact printing, and is known to be compatible with a wide range of chemicals and biological media [78]. A molded AFM tip was made of PDMS and integrated at the end of a polyimide cantilever (Fig. 4.7). The microfabricated tip demonstrated DPN patterning capabilities with ODT as ink and achieved dot sizes as small as 330 nm in diameter.

The fabrication sequence of the PDMS probe is presented in Fig. 4.8. A tip mold was made on a (100) silicon wafer using an oxide mask layer via wet etching in EDP (Fig. 4.8a). After the oxide layer was etched, an aluminum film was deposited as a sacrificial layer (Fig. 4.8b). A 10:1 mixture of Sylgard 184 silicone elastomer base and curing agent was coated on the wafer (Fig. 4.8c). Excessive liquid-state PDMS was plowed out using a rubber blade leaving the PDMS only in the pit and curing was performed at 90 °C for 30 min (Fig. 4.8d). A thin polyimide layer was spin-coated over the processed surface and patterned to define a cantilever shape

**Figure 4.7.** Optical micrograph of a probe chip with two cantilevers with elastomeric tips. Inset shows a SEM image of the integrated PDMS tip [77].

(Fig. 4.8e). A thick PDMS piece was bonded on the patterned polyimide layer as a handling body (Fig. 4.8f). An aluminum etchant removed the sacrificial aluminum layer to release the cantilever/tip structure without damaging either the PMDS tip (Fig. 4.8g) or the silicon mold, which could be reused after cleaning.

The polyimide cantilever in this example was 400  $\mu\text{m}$  long, 100  $\mu\text{m}$  wide and 4  $\mu\text{m}$  thick. The minimal printed ODT dot diameter was consistent with the PDMS probe radius of curvature of 300 nm.

Another use of PDMS for DPN printing was reported by Zhang and coworkers, who coated commercially available silicon nitride tips with PDMS and used them to pattern surfaces with sub-100-nm resolution [79]. The advantage of using PDMS as the tip material is that it provides higher coating efficiency, especially when the inks are macromolecules such as biomolecules and polymers, for which rich experience is available from the domain of microcontact printing with PDMS stamps [78, 80]. The advantage comes at the expense of a serious decrease in writing resolution, due to the soft nature of the contact between the tip and substrate. In contrast, DPN with silicon nitride tips needed functionalization of the tip surface to improve ink-coating efficiency when used for DNA patterning [14, 81], but achieved 100-nm resolution.

#### 4.2.4

#### **Monolithically Fabricated Conductive Diamond Probes**

Since DPN is performed in contact-mode operation, wear of tips is expected during extended use. Tips made of the aforementioned materials such as silicon nitride, silicon oxide, silicon and PDMS would be good enough for laboratory-level experiments; however, the use of wear-resistant tips is of great importance to probe arrays for high-throughput manufacture of bioassays. Hard materials are typically employed to enhance the wear characteristics and diamond is the hardest known material. Furthermore, tailoring its surface properties would allow diamond to become a platform material to construct bioinorganic interfaces [82].

**Figure 4.8.** Fabrication process of the cantilever with an integrated elastomeric tip [77]. The sequence is described in detail in the text.

A wear-resistant probe for contact-mode AFM techniques was fabricated using ultra-nanocrystalline diamond (UNCD) [83]. The all-diamond probe demonstrated molecular writing capability in DPN mode and potential use in scratch-based lithography. The probe was monolithically microfabricated with a pyramidal tip utilizing the molding technique on pits. Electroplating was utilized to form a handling body. The diamond was microfabricated to be either electrically conductive by nitrogen doping or nonconductive. The growth of diamond film was achieved by microwave plasma CVD (MPCVD) using a methane/argon mixture, which also contained nitrogen in the case of nitrogen-doped films [84]. This doped film permits AFM potentiometry and a large variety of conductive AFM techniques [85, 86] with an extended tip life cycle. Furthermore, diamond is chemically and biolog-

**Figure 4.9.** (a) SEM image of a UNCD cantilever with a tip. (b) SEM image of a UNCD tip after 1 h of scanning on a diamond substrate. Inset shows the tip before scanning. ically inert, and forms an excellent electrode for electrochemical applications. It also has a tunable hydrophobicity that can be achieved by surface functionalization [82].

Two types of cantilevers were fabricated: V-shaped and arrow-shaped. The lengths and thicknesses of both cantilevers were 170 and 0.8–1.4  $\mu\text{m}$ , respectively. The arm width of the V-shaped cantilever was 18.8  $\mu\text{m}$ , whereas the rectangular one was 12  $\mu\text{m}$  wide. The V-shape cantilevers had a stiffness of around 2  $\text{N m}^{-1}$ , and were better suited for contact and tapping mode AFM techniques, while the rectangular cantilevers had a stiffness of around 1  $\text{N m}^{-1}$  and performed well in lateral force imaging, well-suited for imaging DPN patterns. The fabrication started by forming of a thermal oxide on a (100) silicon wafer to be used as a mask in subsequent microfabrication steps and patterning square holes into it lithographically. Pyramidal pits were formed by KOH etching to be used as a molds for the future tips (Fig. 4.10a) and then sharpened by thermal oxidation utilizing the nonuniform growth of the oxide in the pit (Fig. 4.10b). The wafer was immersed in a diamond powder solution in methanol, followed by ultrasonication for uniform seeding. The growth of a diamond layer was achieved by MPCVD using a combination of argon and methane gases, with or without nitrogen gas (Fig. 4.10c). An aluminum layer was deposited by electron beam evaporation and then patterned to define cantilevers (Fig. 4.10d). The UNCD film was etched using the aluminum as a mask by oxygen RIE (Fig. 4.10e), followed by the removal of the aluminum mask (Fig. 4.10f). An etch window was patterned on the reverse side

**Figure 4.10.** Microfabrication steps for UNCD probe [83]. Detailed steps are described in the text.

oxide layer for subsequent release of the cantilevers and chips (Fig. 4.10g). A seeding layer for electroplating was deposited and patterned on the front side (Fig. 4.10h). A thick photoresist (SU-8) was spin-coated and patterned to form a mold for the handling body of the chip (Fig. 4.10i). A layer of gold was then electroplated up to 300  $\mu\text{m}$  thickness onto the seed layer to form the chip body (Fig. 4.10j). The top side of the gold was then flattened by polishing (Fig. 4.10k). After removing the photoresist (Fig. 4.10l), the chip was released in KOH solution (Fig. 4.10m).

The DPN compatibility of the diamond probe was tested. A commercial AFM (Digital Instruments; Dimension 3100) was used for the writing test using MHA as ink and gold substrates to write on. Lines produced were around 200 nm wide, whereas the smallest dots generated had a diameter of around 80 nm. In addition to the compatibility with the DPN technique, the UNCD probe demonstrated AFM imaging capabilities of topography and lateral force when used for scanning right after the patterning (Fig. 4.9c). Surface scratch testing was also performed, promising a favorable tool for scratch nanolithography. Furthermore, the scalability of the probes batch-fabricated with the integration of diamond films could lead to 1- and 2-D arrays of probes that could be used for massively parallel DPN-based fabrication of nanostructures. Such probes have the potential to perform DPN for long working times, virtually wear free.

We have described microfabrication aspects of simple microcantilevers in several applications related to the fabrication and manipulation of nanostructures and the detection of minute volumes of substances. Although microcantilevers are relatively simple structures, they have served as powerful tools for such purposes.

However, advanced applications demand more functionality from the devices. In the next section we discuss advanced microcantilevers that allow delivery of fluid materials and suspensions.

### 4.3

#### **Cantilevers with Integrated Micro- and Nanofluidics**

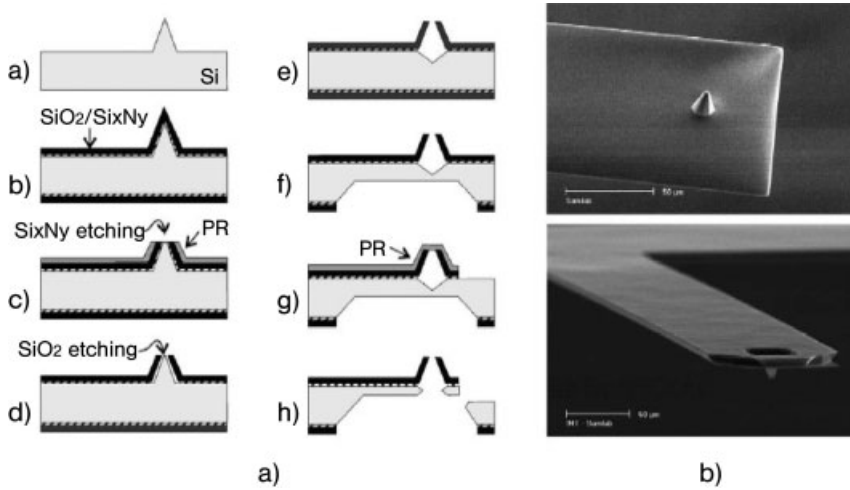

Material delivery in suspension has many potential applications, especially when the materials are macromolecules, such as biomolecules and polymers, nanoparticles, catalysts, and nanotubes. Controlled delivery of such materials would permit the fabrication of complicated nanostructures and nanoelectromechanical systems (NEMS). Also, in life sciences, it is oftentimes required to deliver large-size molecules and it is challenging to carry out scanning probe-based lithography with such molecules if the microcantilevers are not equipped with microfluidic systems. The implementation of micro- and nanofluidics into microcantilevers has been pursued to achieve material delivery in suspension as well as surface patterning with high resolution. Dispensing femtoliter or smaller volumes was achieved with a modified version of a conventional silicon nitride microcantilever [53]. Split-pin-type spotters for the fabrication of gene chips have been further miniaturized by microfabrication [87, 88]. Micro- and nanopipette-based AFM probes were used to deliver minute amounts of liquids [89]. Micropipette arrays with buried microchannels were micromachined for drug injection [90]. A nanofountain probe (NFP) was fabricated and tested, having an on-chip reservoir, cantilevers with embedded microchannels and high-resolution dispensing tips [91, 92].

In this section we describe microfabrication techniques for micro- and nanofluidic cantilevers and their applications along with their potential impact in life sciences.

#### 4.3.1

##### **Apertured Pyramidal Tips**

The on-demand dispensing of single liquid attoliter droplets using AFM probes was demonstrated with modified tips containing a simple orifice. Meister and co-workers [18] created an aperture at the apex of a commercially available probe using focused ion beam (FIB) milling. The hollow reverse side of the pyramidal tip was used as a reservoir to store the liquid. Flow of the liquid was initiated simply by contacting the pipette with a surface and stopped by lifting it from the surface. Created features had dimensions of 100 nm and below. As the FIB process is serial in nature and precludes high-volume production, microfabrication techniques were employed to build directly apertured pyramidal tips integrated on cantilevers [53]. The device has potential applications in nanofabrication for the direct deposition of versatile materials, including biomolecules, catalysts, etch resists and nanoparticle suspensions. With the reservoir on the reverse side, extended writing was possible without reloading.

**Figure 4.11.** Microfabrication process for cantilevered probes with apertured tips [53]. Detailed steps are described in the text.

The fabrication process for the cantilevers with the apertured tips is illustrated in Fig. 4.11. The probes consisted of a hollow silicon nitride tip on a compound cantilever of silicon and silicon nitride. The molding technique on a pyramid was employed to integrate the tip on the cantilever. A molding tip was first fabricated on a silicon (110) wafer by underetching a precursor cap (Fig. 4.11A-a). The wafer was thermally oxidized, followed by LPCVD deposition of a silicon nitride layer to form a mold (Fig. 4.11A-b). Photoresist was spin-coated in such a manner that the tip apex was uncovered. With this opening at the tip apex, only that portion of the silicon nitride layer was etched by RIE (Fig. 4.11A-c). Through the opening of the silicon nitride layer, hydrofluoric acid etched the underlying silicon oxide layer (Fig. 4.11A-d) and, subsequently, KOH etching removed the underlying mold pyramid to produce an empty space surrounded by a pyramidal silicon nitride shell (Fig. 4.11A-e). A combination of photolithography and RIE patterned the silicon nitride and silicon oxide layers on the reverse side to open an etching window on the reverse side (Fig. 4.11A-f), while a cantilever was defined on the compound layer from the front side (Fig. 4.11A-g). Etching in KOH solution not only released the cantilever, but also opened a hole on the silicon portion of the hollow space of the tip to be used as a reservoir (Fig. 4.11A-h). The final thickness of the cantilever was 7–8  $\mu\text{m}$ .

The patterning of the microfabricated probe was tested using alkanethiols to be deposited on gold substrates as well as Cy3 fluorescent dye in glycerol to be deposited on glass. The loading of the hollow probe was done by hand pipetting under an optical microscope. The probe had a pre-patterned loading area to avoid wetting the entire cantilever while loading the solution. A lower limit on the size of the deposition was given by the diameter of the aperture (around 100 nm to 1.5  $\mu\text{m}$ ). In

addition, it was a challenge to routinely load ink into the reservoir island located at the end of the cantilever. Furthermore, evaporation constituted a major problem in this approach, preventing long-term writing.

#### 4.3.2

#### Open-channel Cantilevered Microspotters

In microspotting technologies, a biochemical sample is loaded into a spotting pin by capillary action, and a small volume is transferred to a solid surface by physical contact between the pin and the solid substrate [93]. Other than microspotting pins, capillaries or tweezers can act as a printhead of biochemical samples. Printheads are moved by an  $xyz$  motion control system and brought into a contact with a surface to transfer pre-made substances. In an effort to fabricate massively parallel, high-density DNA, protein and cell chips, microfabricated cantilevers have been used as printheads (Fig. 4.12). Microcantilever spotters were used for depositing biological samples [87, 94] and nanoparticles [95].

Arrays of microcantilevers were also produced by microfabrication techniques. Deposition was achieved by direct contact between the cantilevers and the surface by capillary transport. An electrowetting technique for controlling surface tension was applied for the loading of the liquid. A passivated aluminum layer integrated on the cantilevers was employed as an electrode for the electrowetting. The sample loading required a droplet of a solution containing biological samples to be placed on a conductive solid substrate. After the end of cantilevers was dipped into a droplet of liquid to be deposited, an electric field was applied between the electrode and the substrate to increase the affinity of the liquid. The electric-field introduced a modified charge distribution that changed the free energy, causing the liquid to spread and wet the surface of the cantilevers [96]. As a result, the height of liquid rise on the cantilever surface was increased.

**Figure 4.12.** Optical photographs of microfabricated cantilever spotters [87, 95].

**Figure 4.13.** Microfabrication process of cantilevers [87]. Detailed steps are described in the text.

Figure 4.13 illustrates the fabrication steps of the cantilever microspotter as described by Belaubre and coworkers [87]. The microfabrication used a silicon-on-insulator (SOI) substrate with a 5- $\mu\text{m}$  thick top silicon layer. First, a layer of low-temperature silicon oxide (LTO) was deposited by LPCVD (Fig. 4.13A). Aluminum electrodes were defined by a lift-off process (Fig. 4.13B). A second layer of LTO was deposited for passivation purposes (Fig. 4.13C). Cantilever shanks were defined by photolithography to be used as a mask for the following etching of the LTO layers by RIE. Subsequently, the top silicon layer of the SOI wafer was etched by another RIE step (Fig. 4.13D), in which microchannels and microreservoirs were formed on the cantilevers. Finally, the reverse side of the wafer was removed through etch windows in a deep RIE step. Etching was stopped by the buried oxide layer of the wafer. The silicon oxide layer was then etched from the reverse side by RIE to release the cantilevers (Fig. 4.13E). Arrays of cantilevers, with a spacing of 450  $\mu\text{m}$ , were microfabricated, where each cantilever was 2 mm long, 210  $\mu\text{m}$  wide and 5  $\mu\text{m}$  thick.

The microfabricated cantilevers were used to pattern a glass slide with 1-pL volumes of a solution containing Cy3-labeled oligonucleotides (15mers) [94]. In addition, protein, anti-goat IgG (rabbit), microarrays were generated on a glass slide coated with dendrimer molecules as crosslinkers. With both molecules, 30- $\mu\text{m}$  diameter spots were obtained. It was also demonstrated that two different biological samples were deposited with the same cantilevers using a cleaning procedure, in which no cross-contamination was observed.

Furthermore, microspotter cantilevers were used to deposit functionalized amorphous silica nanospheres on coated silicon surfaces by Leichle and coworkers [95]. Colloidal solutions, containing poly(ethylene glycol) (PEG)-600 and aminopropyltriethoxysilane (APTS) nanoparticles with diameters of around 300 and 150 nm,

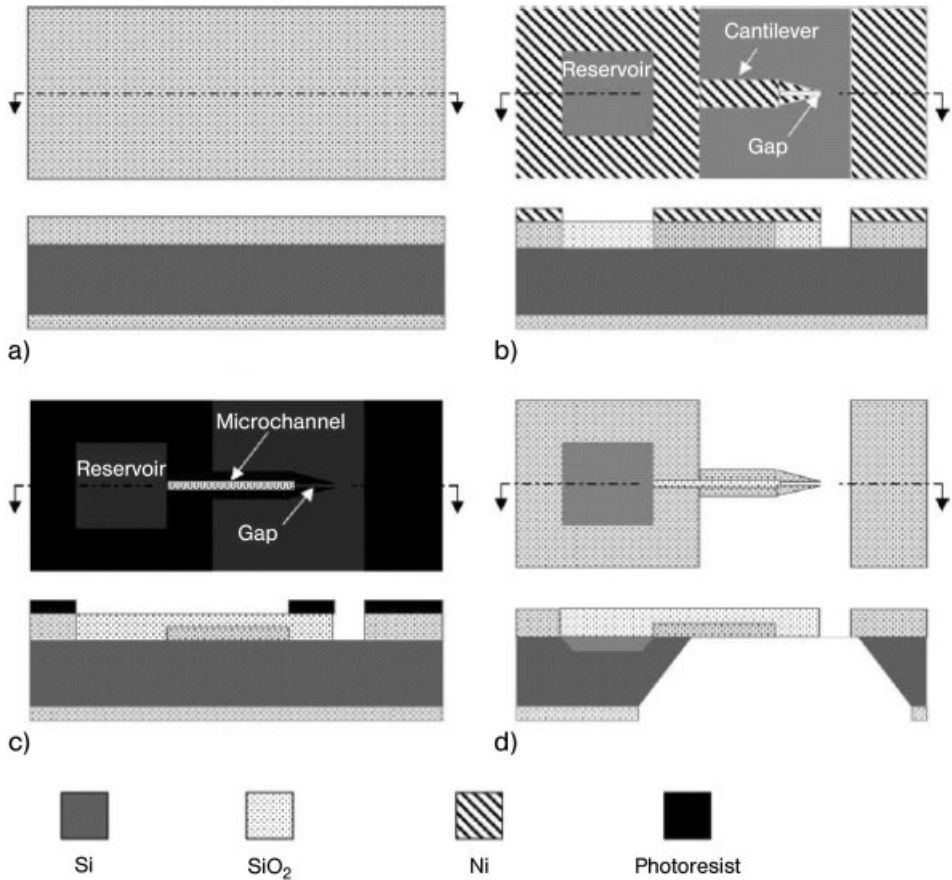

**Figure 4.14.** Schematic of the quill-type cantilever and SEM images of fabricated cantilever [88].

respectively, were deposited on surfaces to form spots of various diameters ranging from around 10 to more than 100  $\mu\text{m}$ .

The minimum spot size writable with a common cantilever spotter is around 10  $\mu\text{m}$  in diameter. To achieve higher resolution, cantilever microspotters were further miniaturized. A microcantilever-based tool with a 1- $\mu\text{m}$  wide split gap at the end (Fig. 4.14) has been reported by Xu and coworkers [88]. Named the surface patterning tool (SPT), this device had integrated on-chip sample reservoirs and fluid transportation microchannels, which addressed limitations inherent in the use of the conventional AFM probes. An SPT consisted of a cantilever with a split gap at the end, a reservoir on the handling chip, and a 1- $\mu\text{m}$  deep transportation microchannel connecting the gap and the reservoir. Sample loading was carried out by filling the reservoir with sample solutions as well as by dipping the cantilever end into sample fluid. These new designs, dedicated to biomolecular patterning, allowed reliable patterning of large molecular species and reduced reloading requirements.

The length of the SPT cantilevers ranged between 200 and 300  $\mu\text{m}$ , and the width between 20 and 40  $\mu\text{m}$ . The split gap was around 1  $\mu\text{m}$  wide and around 40  $\mu\text{m}$  long. At the fixed end of the cantilever, a 10- $\mu\text{m}$  deep rectangular reservoir was located on the handling substrate. The depth and width of the microchannel

**Figure 4.15.** Schematic diagram of the microfabrication processes for the quill-type SPT [88].

were 1 and 1–10  $\mu\text{m}$ , respectively. Silicon oxide was selected as the material for the cantilever due to its advantages in terms of mechanical properties, fabrication requirements and biocompatibility.

The fabrication steps of the SPT are shown in Fig. 4.15. A (100) double-side polished silicon wafer was thermally oxidized to have a thickness of 2–3  $\mu\text{m}$ . The front side oxide layer was lithographically processed to define a cantilever shank, a split gap and a reservoir. In order to fabricate the cantilever with the 1- $\mu\text{m}$  gap using conventional photolithography, a nickel layer was electroplated on top of the oxide to be used as mask, using a negative photoresist pattern. The oxide layer was then anisotropically etched by RIE with a gas mixture of  $\text{CHF}_3$  and  $\text{SF}_6$  (50:1  $\text{cm}^2$ ) and power of 50 W at 50 mTorr pressure. After patterning the cantilever and the gap, a 1- $\mu\text{m}$  deep microchannel was etched by RIE. Finally, a window was patterned on the backside layer of  $\text{SiO}_2$ , followed by releasing the cantilever in KOH solution of concentration 35 wt%, at 80 °C.

Testing of the fabricated SPTs was performed using a dedicated commercial instrument called a NanoArrayer (BioForce Nanosciences, Ames, IA). This instrument was equipped with a precision motion control system and an environmental chamber. Although this instrument used an optical lever deflection scheme employed in an AFM, it did not scan or acquire images. SPTs were mounted to form a  $12^\circ$  angle with the deposition substrates such that only the tip end was in contact with the substrate. Patterning was demonstrated using Cy3–streptavidin in a standard protein patterning application [88]. The Cy3–streptavidin sample solution was loaded into the reservoir using a micropipette, prior to mounting the SPT into the NanoArrayer. Spots were patterned on a dithiobis(succinimidyl undecanoate) (DSU) monolayer coated on a gold surface. Fluorescence microscopy was utilized to analyze the patterned features. A  $10 \times 10$  array of spots with a diameter of 2–3  $\mu\text{m}$  was routinely obtained. With a single loading, more than 3000 spots could be printed in about 1 h. It was also demonstrated that quantum dots conjugated to streptavidin could be deposited in patterns of lines and spots using the SPT [97]. Those features had line widths of around 150 nm to 7  $\mu\text{m}$  and spot diameters of 3–5  $\mu\text{m}$ .

Multiple cantilever-based SPTs for multiplexed biomolecular arrays were also reported by Xu and coworkers [98]. Their SPT featured a 1-D array of microcantilevers and a corresponding microfluidic network that was capable of transporting multiple fluid samples from macro-scale reservoirs located on the SPT substrate through micro-scale channels to the distal end of the cantilevers. Five cantilevers and five reservoirs were arranged in a chip so that multiple biological samples could be transferred from the reservoirs to the SPT cantilever array. The overall size of an SPT chip was  $3 \times 6 \text{ mm}^2$ . Each cantilever was 250  $\mu\text{m}$  long, 30  $\mu\text{m}$  wide and 2  $\mu\text{m}$  thick, and consecutive cantilevers were separated by a spacing of 50  $\mu\text{m}$ . The microchannel on each cantilever was 15  $\mu\text{m}$  wide and 1  $\mu\text{m}$  deep.

The fabrication steps for the multiple-cantilever SPT are illustrated in Fig. 4.16. A double-side polished (100) silicon wafer was first thermally oxidized to form a 2.2- $\mu\text{m}$  thick oxide film. The oxide layer on the front side was photolithographically patterned to define the cantilevers, reservoirs and channels, and etched by RIE (Fig. 4.16a). Subsequently, a 1- $\mu\text{m}$  deep microchannel was etched on the cantilevers by overlay photolithography and follow-up RIE (Fig. 4.16b). In the next step, the oxide layer on the reverse side was patterned to form an etching window and the cantilevers were released by KOH etching (30 wt%). A wafer holder was used to protect the front side oxide pattern during the KOH step. Finally, once leakage began to occur through the wafer holder in the KOH etching bath, the wafer was released from the hold and dipped in a 40 wt% KOH solution to form the reservoirs and microchannels (Fig. 4.16c).

The multiple ink loading and patterning were tested using two types of fluorescent proteins: Cy2–donkey anti-goat IgG and Texas Red–donkey anti-rabbit IgG. These two proteins were diluted in phosphate-buffered saline (PBS) and alternatively loaded into the five reservoirs by hand pipetting. The solutions transferred from the reservoirs to the distal end of each channel by capillary action and the fluids were confined inside the microchannels without observed cross-contamination. A DSU/gold surface was patterned to generate  $10 \times 10$  multiple

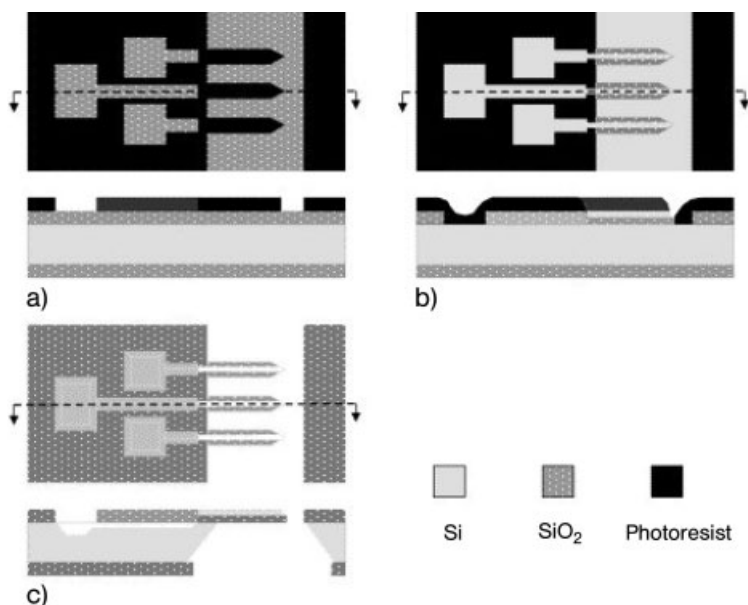

Figure 4.16. Fabrication steps for an array of SPT cantilevers [98].

ink dot arrays, with the mean spot diameter being about 12  $\mu\text{m}$ . The SPTs generated biological arrays with a routine spot size of 2–3  $\mu\text{m}$ . Several thousand spots could be printed without reloading. It was reported that the minimum spot size of the SPT was mainly limited by its gap width. The gap size can be further reduced with a higher-resolution lithography technique.

The SPTs have open microchannels integrated on cantilevers. This type of open channel has advantages of being clog-free, and allowing easy cleaning and simple microfabrication. However, such open microfluidic elements including microchannels and reservoirs are prone to cross-contamination via vapor by different types of samples, especially when loaded in arrays of cantilevers [99]. Also, evaporation may be critical in some applications, although its rate can be reduced with environmental conditioning. Enclosed microchannels are beneficial in such cases, although they are relatively difficult to microfabricate and the clogging issue needs to be addressed. Pipettes are conventionally used microfluidic devices with enclosed channels. Microneedles with embedded microchannels were also demonstrated to deliver liquid materials. In the following subsections, microcantilever devices with enclosed microchannels are described.

#### 4.3.3

##### Closed-channel Cantilevered Nanopipettes

Pipettes are essential tools in biomedical applications in order to precisely manipulate and deliver fluidic samples, and they have been miniaturized for applications

of local delivery of liquid/gaseous materials at the nanometer scale. It was reported that apertures as small as 3 nm at the tip with outer diameters at the tip of 10 nm were produced [89]. Such nanopipettes permit delivering or probing liquid samples in small volumes. In addition to delivering precise volumes of samples, accurate positioning is pivotal in biomedical applications. Nanopipettes were used in AFM for precise positioning to deliver liquid or gaseous materials on surfaces for localized chemistry [89, 100–104]. Nanopipette-based probes were used to deliver minute amounts of materials such as Cr etchant [89], photoresist [103], DNA [104], proteins [100] and enzymes [101, 102]. They are capable of continuous sample feeding through the capillary. In certain applications, nanopipettes were bent to have a cantilevered portion so that they could be used in AFM. The deflection, or contact force, of such cantilevered micropipettes was regulated by the AFM optical beam-deflection scheme, whereas straight nanopipettes, not compatible with the optical deflection scheme of AFM, employed other techniques such as shear-force feedback control [103] or an electrical current between the pipette and solution [104].

Protein solutions readily flowed through cantilevered nanopipettes to be directly deposited on a surface with dot diameters of around 200 nm [100]. A proteolytic enzyme was used to locally break a layer of bovine serum albumin (BSA) [101, 102]. Photoresist was delivered through the aperture formed at the end of a pulled nanopipette [103]. In this case, direct-write with photoresist replaced conventional photolithographic steps including spin-coating, mask alignment, exposure to UV light and developing. A nanopipette was used in a solution environment, whereas the tip-sample separation was controlled by the feedback signal of the ionic current established between two electrodes – one in the pipette and the other in the solution [104].

Production of cantilevered pipettes is based on pulling quartz capillary tubes by computerized systems called micropipette pullers. These pullers apply a controlled axial load on the capillaries, while heating them locally with a flame, electrical solenoid or, for better control, a laser beam. Two pipettes can be obtained after the pulled capillary breaks. A desired bending can be produced to make the probes usable in scanning probe systems [105, 106] (see Fig. 4.17).

The bending can be obtained close to the tip by heating the micropipette over a microflame. The operation can be performed in specialized tools called bevelers. Such cantilevered glass micropipettes can be coated with metals in order to allow the optical deflection detection scheme of AFM to function (Fig. 4.17). The diameter of the cantilevered portion of the micropipette can be around 12  $\mu\text{m}$  and the cantilever length around 300  $\mu\text{m}$ . Such dimensions of the glass cantilevers resulted in resonance frequencies up to 400 kHz and force constants ranging from tenths to tens of Newtons per meter. It was also reported that a filament made of metal thread was installed inside a pipette to mechanically strengthen the pulled tapered region [103]. The filament improves the wetting characteristics of the inner wall of the pipette such that the liquid can spontaneously fill the pipette lumen.

Taha and coworkers [100] reported micropipette printing of a yeast protein onto aldehyde-coated glass slides, in which an aldehyde group on the surface reacted

**Figure 4.17.** (a) Experimental setup of the cantilevered nanopipette in an AFM. (b) SEM image of a cantilevered nanopipette. Scale bar: 100  $\mu\text{m}$ . (c) Close-up of the tapered end of a 50-nm aperture nanopipette. Scale bar: 500 nm [101].

preferentially with the primary amino group of the N-terminus of the protein for immobilization as described in Ref. [23]. A solution of the protein in PBS 100  $\mu\text{M}$  with 10% glycerol to keep the proteins hydrated was prepared and manually loaded from the large end of the pipette with a syringe. The capillary action delivered the solution to the end of the pipette. Subsequently, the nanopipette deposited a line of the protein which was around 500 nm wide and around 40 nm thick. The experiment was performed at room temperature without humidity control. The same type of pipette was also used to pattern dots and lines of green fluorescent protein (GFP) on BSA-coated glass slides, resulting in dot diameters of around 250 nm and line widths of around 450 nm. This method demonstrated that the feature size can be made 1000 times smaller than with conventional spot arrays.

A nanopipette filled with a solution of DNA or protein was utilized by Bruckbauer and coworkers [104] to pattern surfaces in an aqueous environment with a voltage applied between the pipette and surface. This method was based on scanning ion conductance microscopy (SICM) [107]. In this report, a pipette was filled with a solution of 100 nM DNA or protein and the pipette tip was inserted into a bath of ionic solution. The ion current was used to control the dispensing rate of molecules as well as the tip-to-surface distance. Spots of ssDNA labeled with Rhodamine Green were deposited on a streptavidin-coated glass surface and the mea-

sured full width at half-maximum (FWHM) was  $830 \pm 80$  nm. Spots of Protein G were also patterned onto a positively charged glass surface utilizing electrostatic interaction as an immobilization mechanism. Measured feature sizes were 1.3  $\mu\text{m}$ .

Although pulled micropipettes are capable of delivering small volumes of samples with precise positioning, it is a challenge to accomplish reproducibility and scalability when expansion to arrays is required, which is essential for tools in bio-nano applications, e.g. to fabricate microarrays or nanoarrays. Micromachined pipettes in the following section will give an idea how microcantilevers with channels can be microfabricated to address the reproducibility and scalability of conventionally produced micropipettes.

#### 4.3.4

#### **Micromachined Hypodermic Needle Arrays**

Microcantilevers with closed microchannels were microfabricated to be used as micropipettes and microneedles for drug injection applications. The applications of micromachined cantilevered needles are different from the microcantilevers discussed in the preceding sections in terms of size (larger) and functionality (not for surface patterning). However, they are integrated with microchannels to effectively deliver biofluid into a body via injection and the microfabrication approach is worth discussing because it can be utilized to create embedded microchannels in microcantilevers. Microcantilever-based hypodermic needles are sometimes referred to as in-plane microneedles since they are fabricated in the plane of a silicon wafer as contrasted to out-of-plane needles, where short microneedles are microfabricated normal to the plane of the wafer surface [108, 109]. Microcantilever-based needles have been fabricated using several structural materials such as silicon [110, 111], polysilicon [112] and metals [90, 113].

Micromachined pipette arrays were reported by Papautsky and coworkers [90]. They have integrated microchannels on cantilevers as well as dispensing apertures at the end of the cantilevers. The cantilevers were 1.5 mm long and 400  $\mu\text{m}$  wide, and the microchannels had an inner cross-sectional area of  $400 \times 30 \mu\text{m}^2$  ( $W \times H$ ). For fabrication, a (100) silicon wafer was doped with boron to form a 4–6- $\mu\text{m}$   $p^+$  layer, which later served as an etch stop. Then, a silicon nitride layer was deposited by plasma CVD to be used as a mask during the following anisotropic etching in KOH (Fig. 4.18a). Next, a palladium layer was selectively electroplated onto the silicon wafer to form the undersides of the needles (Fig. 4.18b). A thick photoresist layer (P4620) was deposited and photolithographically patterned as a sacrificial layer to define the inner lumen of the needles (Fig. 4.18c). A palladium layer was sputter-deposited to conformally cover the patterned thick photoresist layer, this was followed by the electrodeposition of a thin additional layer of palladium on top of the sputtered metal. The primary structural material was then electroformed to complete the top and side walls of the pipette (Fig. 4.18d). The sacrificial photoresist was dissolved by immersing the wafer in acetone (Fig. 4.18e). The  $p^+$  membrane was removed by plasma etching with  $\text{SF}_6$  gas from the reverse side to release the micropipettes (Fig. 4.18f).

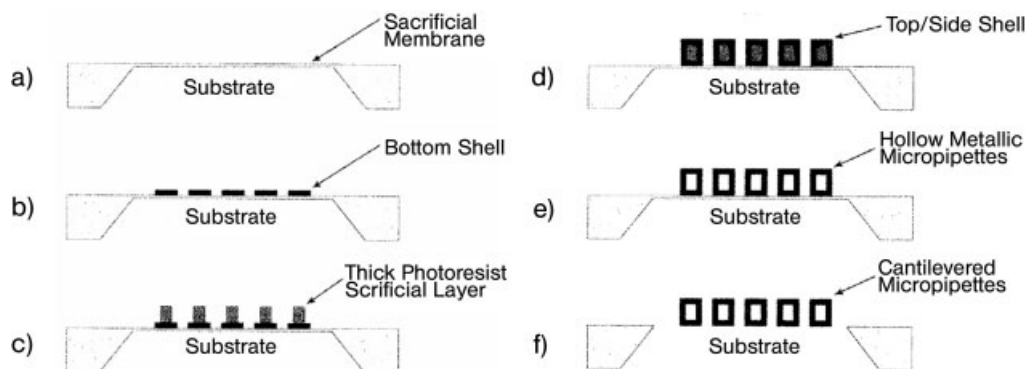

Figure 4.18. Fabrication steps for microneedle arrays [90].

The microfabricated microneedles were used for high lane density slab-gel electrophoresis. Capillary action was utilized to load samples into the microneedle. The samples were dispensed into wells of electrophoretic micro-gels using a syringe pump demonstrating a 2-fold increase in the number of theoretical plates and a 6-fold reduction in lane spacing compared to standard mini-gel separations. Although the micromachined pipettes were not intended for surface patterning, their closed microchannels demonstrated a means to effectively deliver biofluid by capillary action.

#### 4.3.5

##### NFPs

NFPs can be defined as microfluidic dispensing probes that incorporate a reservoir, continuously feeding the ink to the tip, which can write with sub-100-nm resolution [91, 114]. On-chip reservoirs were met in several applications already described. Apertured pyramidal tips incorporated a small reservoir at the hollow back of each tip [53]. Cantilever microspotters were capable of containing liquid samples in the split at the end of the cantilever [87], while SPTs had on-chip reservoirs for storing larger volumes of samples [88]. However, the minimum resolution of all those tools was limited by the size of the aperture or the width of the gap. It seemed to be challenging to make patterns in the sub-100-nm region. Also, the open microfluidic components in the aforementioned devices resulted in restricted control of evaporation and possible cross-contamination when multiple tips/inks are used. From such a point of view, nanopipette-based probes showed advantages [89]. Since nanopipettes are fabricated by individual glass capillary pulling, difficulties arise in fabricating arrays of uniform probes. Also, the minimum feature size patterned by nanopipettes is limited since it depends critically on the aperture size, which typically leads to a larger dimension of the patterns due to the formation of an external liquid meniscus around the pipette tip during patterning.

**Figure 4.19.** (a) Writing mechanism of the NFP device. A molecular ink drawn from an on-chip reservoir forms a liquid–air interface at the annular aperture of the volcano-like dispensing tip. Molecules are transferred by diffusion from the interface to a substrate and a water meniscus is formed by capillary condensation. (b) Liquid from the reservoir is

delivered to the dispensing tip via capillary force. (c) SEM image of a dispensing tip. (d) SEM image of an NFP chip showing cantilevers and an on-chip reservoir. (f) Frictional AFM images of features patterned by an NFP. Patterns with line widths as small as 40 nm have been successfully generated.

Both high-resolution patterning and continuous sample feeding through closed microchannels were achieved by NFP. Figure 4.19 illustrates a first-generation microfabricated NFP device and its molecular-writing results. A volcano-like dispensing tip was configured to have a ring-shaped aperture through which samples were dispensed to generate sub-100-nm lines on a routine basis. Features with a line width as small as 40 nm were patterned, which experimentally demonstrated high-resolution fountain-pen-mode writing, i.e. a writing mode in which ink is

transported from the on-chip reservoir to the substrate. An embedded microchannel and an on-chip reservoir continuously replenished the tip with liquid samples. Due to the unique volcano-like dispensing tip of the NFP, both continuous feeding and high-resolution writing were possible. The resolution of the NFP was controlled by the radius of the tip since it preserved the DPN-mode writing, compared to other techniques, where the aperture size or the gap width were considered as the dominant factors limiting the resolution. While the nanopipettes, apertured pyramidal tips and quill-type SPTs work by the formation of an outer meniscus between the probe and substrate, the NFP forms a meniscus between the ultra-sharp AFM-like tip and substrate, like traditional DPN.

The batch-fabrication processes developed for the NFP chips provided straightforward scaling-up to NFP arrays. Using standard microfabrication technologies, chips with five fountain-pen probes were batch-fabricated (Fig. 4.20). The fabrication steps started with the conventional tip formation process using a precursor cap defined by mask M1 (Fig. 4.20a). During the oxidation sharpening process, the precursor tip fell off (Fig. 4.20b). A silicon nitride film with a thickness of around  $0.3\ \mu\text{m}$  was deposited by LPCVD to form the floor of the channels. Mask M2 defined the space through which the on-chip reservoir would be connected to the channels. Layers of silicon oxide with a thickness of around  $0.5\ \mu\text{m}$  and silicon nitride with a thickness of  $0.3\text{--}0.5\ \mu\text{m}$  were deposited by LPCVD to form the sacri-

Figure 4.20. Microfabrication steps of NFP [114].

ficial layer and the ceiling layer of the microchannels, respectively (Fig. 4.20c). Lithography with mask M3 followed by RIE in  $\text{CF}_4$  plasma defined the in-plane geometry of the channels, where the channels follow the edges of the pattern comprised in mask M3. A buffered oxide etching (BOE) solution was used for a controlled underetching of the structures, to provide the lumen of the microchannels (Fig. 4.20d). Subsequently, the lateral openings of the channels were closed by bird's beak oxidation (Fig. 4.20e). Sealing of the channels followed using either an LPCVD silicon nitride layer or an electron-beam evaporated gold layer (Fig. 4.20f). Lithography with mask M4 was conducted to pattern the sealing layer with the geometry of the cantilevers and chip boundaries. The reverse-side nitride was lithographically processed with mask M5 and subsequently etched by  $\text{CF}_4$  RIE. Anisotropic etching in KOH solution formed the on-chip reservoir and the handling body (Fig. 4.20g). After the removal of the oxide, the chip remained suspended by small, easy-to-break silicon bridges, to provide good wafer-level maneuverability (Fig. 4.20h). After this step, a thin gold layer was deposited on the reverse side of the cantilevers to provide sufficient reflectivity for the optical beam-deflection sensing system of the AFM.

With the expansion to 1- or 2-D NFP arrays incorporating multiple on-chip reservoirs, simultaneous patterning of surfaces with multiple biological inks can be carried out. Potential applications include high-throughput manufacturing of nanosensors and nanoarrays. For example, in the DPN technique, a substrate was patterned with a MHA monolayer and subsequently antibodies were attached to be

**Figure 4.21.** Second-generation NFP chip. Left: reflected light optical micrograph of the top side of the chip, showing two reservoirs feeding each six microchannels on each side of

the chip. Right: transmitted light optical micrograph, showing the reservoir wells. Inset shows a SEM detail of the dispensing volcano-shape tip.

ready to sense antigens. With the NFP, most of the intermediate steps may not be necessary. It is also important to emphasize that NFP patterning does not require repeated dipping of the tip and specific treatment of the substrate for protein printing. A second-generation NFP device was recently fabricated by the same group, allowing two on-chip reservoirs, each feeding a linear array of six cantilevers with nanodispensing probes (Fig. 4.21). The new chip presents some advantages regarding channel sealing and fabrication, an increased uniformity and sharpness of the nanodispensing tips, a better control of the longitudinal and lateral bending stiffness of the cantilever and the possibility to add independent actuation of the probes and electrical contacts for conductive NFP lithography and voltamography.

#### 4.4 Applications

We now describe applications of cantilevers for patterning biomolecules, including DNA, protein and viruses.

##### 4.4.1 Patterning of DNA

Silicon nitride DPN tips created nanoscale patterns of oligonucleotides on both metallic and insulating substrates [14]. Hexanethiol-modified oligonucleotides were used as ink for DPN patterning on gold substrates with features ranging from 50 nm to several micrometers in size. The patterned surface was subsequently used to direct the assembly of complementary oligonucleotide-modified gold nanoparticles. The immobilization of the DNA was achieved by the covalent bonding between the hexanethiol group of the DNA and the gold surface. Prior to the patterning, the surface of the silicon nitride AFM cantilever was modified with 3'-aminopropyltrimethoxysilane in order to improve the coating of the DNA on the surface of the tip. The modified tip surface was readily wetted by the DNA ink solution when dipped. In addition to utilizing the gold-thiol immobilization for DNA patterning, modified silicon oxide surfaces were demonstrated to work as a DPN substrate. Since gold surfaces prevented the study of electrical or optical characteristics of the DPN-patterned nanostructures due to the conductivity and quenching, respectively, of the surface, the use of silicon oxide opened the door to such studies. The silicon oxide surface was treated with 3'-mercaptopropyltrimethoxysilane (MPTMS) and the oligonucleotides were modified with acrylamide groups in order to utilize the covalent link between the pendant thiol groups of the MPTMS and the acrylamide moieties of the DNA as an immobilization mechanism. The biological activity of the patterned oligonucleotides was confirmed in an ensuing hybridization process.

In DPN, functionalization of the tip surface is required to efficiently coat the DNA ink. However, the NFP did not need such tip modification due to the direct delivery of the DNA ink in suspension from the on-chip reservoir to the tip.

**Figure 4.22.** AFM topography image of an array of DNA dots patterned by fluidic spotting using an NFP probe.

Hexanethiol-modified oligonucleotides were deposited on a gold substrate in a fountain-pen fashion using the device presented in Fig. 4.21. An array of dots was patterned and verified by AFM topography scanned with a commercially available silicon nitride tip as shown in Fig. 4.22.

#### 4.4.2

##### **Patterning of Proteins**

DPN was used to fabricate a nanoarray for the HIV-1 immunoassay as a proof-of-concept DPN-based biodetection [15]. DPN-generated dots of MHA on a thin gold film were used to immobilize anti-HIV-1 p24 antibodies. When immersed into a sample containing HIV-1 p24, the nanoarray reacted with the antigens leading to a height difference of the MHA features due to the bound antigens. This height difference is not easily detectable by AFM. Hence, the height difference was amplified by gold nanoparticles that were functionalized with the same antibody. The DPN-generated nanoarray with the double-sandwich immunoassay demonstrated the capability to detect and measure antigens with unprecedented sensitivity. The important feature of this approach is the high number and small size of individual dots, which reduces the time necessary for antigens to travel and bind to antibodies, and also provides the necessary redundancy for a correct statistics.

An enhanced tool was introduced by Lynch and coworkers [115] for fast and large-area patterning. One of the improvements consisted of replacing the AFM piezotube with a piezoelectric inchworm stage capable of 20-nm resolution over 25 mm of  $xy$  travel. Although the stage did not provide as high lateral resolution as the piezotube, it performed better in terms of repeatable movements over several centimeters. A second improvement was the shortening of the tip–surface contact time for patterning by applying precisely timed bursts of wet or dry air directly to the tip–surface interface. With this scheme, protein transfer could be achieved in less than 100 ms, which was an improvement upon the  $250 \text{ s } \mu\text{m}^{-1}$  in DPN [15]. For patterning, a commercially available AFM probe was mounted on the tool for building protein nanoarrays. In demonstrated experiments, an array of antigen (mouse IgG) was spotted with approximately 700-nm diameter spots on

a pretreated substrate [115]. The specific binding of Cy3-labeled goat anti-mouse antibody was verified with minimal nonspecific background binding. It was demonstrated that nanoarray assays could be produced in a rapid fashion and the miniaturized size would lead to a reduced sample volume of the protein for bioanalysis. For example, each 1- $\mu\text{m}$  dot in the nanoarray would cover less than 1/1000 of the surface area of a conventional microarray dot while maintaining enough antibodies to provide a useful dynamic range [115].

#### 4.4.3

#### **Patterning of Viruses**

AFM was utilized to identify viruses utilizing type-specific immunocapture and the morphological properties of the capture viruses by Nettikadan and coworkers [116, 117]. Multiple virus-specific antibody capture domains were constructed on a chip using ink-jet protein arraying technology. The chip, termed ViriChip, was constructed with 600- $\mu\text{m}$  diameter antibody domains. The ViriChips were individually exposed to each of six group B coxsackieviruses [116]. Each of the six group B coxsackievirus types bound extensively to their specific ViriChip with little or no binding observed on the nonspecific chips. Counting of the number of bound viruses was performed using AFM inspection.

Substrates for the chips were prepared from diced silicon wafers ( $4 \times 4 \text{ mm}^2$ ). After ultrasonic cleaning in water and ethanol, metal films of 5-nm chromium and 10-nm gold were sequentially sputter coated. Target areas (600  $\mu\text{m}$  diameter) were created using copper electron microscopy grids as masks during sputtering. A SAM layer was coated by immersing the substrate in an alkanethiolate solution. The target areas were covered with recombinant Protein A/G followed by blocking the unreacted alkanethiol groups. The chip was completed by placing 1  $\mu\text{l}$  of antiviral antibody on the Protein A/G domain of a substrate, followed by incubation and rinsing. Each virus sample (1  $\mu\text{l}$ ) of the six group B coxsackieviruses was applied onto the antibody-coated domains. AFM scanning operated in tapping mode was used to obtain morphological and counting information on the viruses.

It was inferred that a reduction of the antibody domain size to 2–5  $\mu\text{m}$  should increase the sensitivity of the assay [116] based on the previous study on the phenomenon of analyte harvesting [23, 118]. Further, it was verified that the efficiency of virus capture increases dramatically with decreased sample volume. With microfluidic delivery of samples to the capture domain, the capture efficiency would likely be increased.

#### 4.5

#### **Conclusions and Outlook**

Since they have been used in AFM for imaging, microcantilevers have evolved to meet the requirements from many life sciences applications. Microcantilevers are fundamental tools for biopatterning and biosensing in SPM-based techniques. Dif-

ferent materials targeting the biochemical applications were integrated and used for fabricating the tips and cantilevers. Massive parallel arrays are being pursued in an attempt to increase the throughput. Efforts have been made to integrate microfluidics into microcantilevers, which include apertured pyramidal tips, miniaturized spotters with nib-type reservoirs, open and closed microchannels, on-chip reservoirs, and complex systems with several of the previously mentioned features. Microcantilevers may serve to create ultra-miniaturized bioanalytical devices and testing methodologies in which the efficiency relies on the higher detection speed, higher accuracy and increased statistical significance of the results.

## 5 Nanobioelectronics

*Ross Rinaldi and Giuseppe Maruccio*

### 5.1 Introduction

Nanobiotechnology has been boosted by the advancements in fabrication technologies, which enable the construction of artificial structures in the size range of biological entities. The fascinating world of the bio-self-assembly provides new opportunities and directions for future electronics, opening the way to a new generation of computational systems based on biomolecules and biostructures. Here, we review the advances in the field of nanobiomolecular electronics, starting from the description of a few selected bio-units up to the implementation of hybrid devices. Possible applications of bioelectronic devices to standard electronics, such as rectification, amplification and storage, as well as novel functionalities will be discussed on the basis of recent concept studies.

The chapter is organized as follows: Section 5.2 is dedicated to the motivations of nanobioelectronics research, Section 5.3 summarizes the fundamentals of bio-building blocks for nanoelectronics (DNA and proteins), and Section 5.4 deals with how to interconnect biomolecules and exploit their self-assembly properties for the implementation of nanobiodevices. Sections 5.5 and 5.6 are dedicated, respectively, to the investigation of DNA and proteins for nanobioelectronics applications. Finally, some conclusions are drawn and possible future research directions are forecast in Section 5.7.

### 5.2 Bio-self-assembly and Motivation

Moore's Law (Fig. 5.1), the 1965 prediction by Intel co-founder Gordon Moore that manufacturers would double the number of transistors on a chip every 18 months, with resulting declining prices and increasing performances, has been fulfilled for four decades by the semiconductor industry. However, the latest editions of the annual International Technology Roadmap for Semiconductors [1] – a joint effort of worldwide semiconductor industry associations predicting the main trends in the

**Figure 5.1.** Moore's law – number of transistors as a function of time (points refer to the various processors introduced by Intel: 4004, 8008, 8080, 8086, 286, 386, 486, Pentium, Pentium II, Pentium III and Pentium 4, respectively). The concomitant occurrence of some milestones of molecular electronics is also indicated. In 1965, Gordon Moore, co-founder of Intel, first observed and then predicted that the number of transistors per integrated circuit grew exponentially. So far, this prediction has been fulfilled thanks to the continuous advances in miniaturization driven by the

progress in lithographic techniques. However, it now seems to be in serious danger and modern electronics has to face the restrictions dictated by the laws of physics when the minimum feature size of a chip approaches 100 nm, at least with current technologies. Thus, gaining the nanometer scale and/or further enhancing the computational capabilities requires a turning point, a change in architecture and the development of conceptually new devices exploiting spin, quantum mechanics and/or molecular building blocks. (Adapted from Ref. [2].)

semiconductor industry spanning 15 years into the future – lists reasons for thinking that this may soon change.

The Roadmap explores “technology nodes” – advances needed to keep shrinking the so-called DRAM half-pitch, i.e. half the spacing between cells in memory chips. Currently, the industry is moving to a DRAM half-pitch of 90 nm, about 2/1000 the width of the proverbial human hair. Analyzing various aspects of chipmaking, the Roadmap forecasts that researchers should lower that figure to 35 nm by 2014, continuing doubling the number of transistors per integrated circuit. This miniaturization trend is expected to continue for another 15–20 years, but the down-scaling with the usual top-down approach (i.e. thanks to the improvement of the lithographic techniques) is becoming increasingly difficult because of physical limitations including size of atoms, wavelengths of radiation used for lithography, interconnect schemes, etc. Three fundamental limits exist [2]: (a) the energy needed to write a bit must be bigger than the average energy of the thermal fluctuations ( $kT$ ) to avoid bit errors (thermal limit), (b) the energy necessary to read or write a bit and the frequency of the circuits are limited by the uncertainty principle (quantum limit), and (c) a maximum tolerable power density exists (power dissipation limit).

Although minimum feature sizes in the few nanometers range have been demonstrated in various laboratories and a number of new lithographic solutions [such as extreme UV, X-ray proximity, and electron (EBL)- and ion-beam lithography (IBL)] have been proposed as post-optical techniques, to a large extent these tools are not suitable for mass production and/or capable of meeting the requirements of the Roadmap, and no known solutions currently exist for these problems.

Thus, the Roadmap underlines the pressing need for developing beyond-CMOS devices and post-optical lithographies, together with the necessity to engineer manufacturable interconnection schemes compatible with the new materials and processes recently proposed. Gaining the nanometer scale and/or further enhancing computational capabilities is expected to require a turning point, a change in architecture and the development of conceptually new devices [2–5].

One of the potential roadblocks to continue the scaling beyond the 50-nm node is molecular electronics. Having the final goal of using interconnected molecules to perform the basic functions of digital electronics, molecular electronics (for a review see Ref. [2]) has recently attracted much interest as a different approach to maintain the historical trend of reducing the cost/function ratio by around 25–30% per year. The concept of molecular electronics can be traced back to the Aviram–Ratner prediction [6] that molecules having a donor–spacer–acceptor structure would exhibit rectifying properties when placed between two electrodes.

A bottom-up approach is promising for building nanodevices from molecular building blocks instead of carving lithographically bigger pieces of matter into smaller and smaller chunks, since it provides a new solution to miniaturization. In fact, although it needs a cross-disciplinary effort (merging chemical, biological and physical expertise), the molecular approach offers important advantages of high reproducibility and small size of the molecular building blocks (naturally identical and with well-defined sizes and electronic levels), along with their thermodynamically driven self-assembly and self-recognition properties [7]. From this perspective, the fascinating world of biomolecules (accurately optimized by nature over billions of years of evolution) provides new opportunities and directions for further miniaturization. While engineers and scientists have long been aspiring to manipulate structures controllably and specifically at the micro- and nanometer scale, nature has been performing these tasks with great accuracy and high efficiency using highly specific biological molecules such as DNA and proteins. One of the biggest drivers behind nanotechnology's enthusiasm for biological systems revolves around the organism's impressive ability to manufacture complex molecules (like DNA and proteins) with atomic precision. However, the strongest motivation for using biomolecules as building blocks for the construction of artificial computational systems lies in their self-assembly properties, which open the way for a new generation of devices and fabrication strategies [8]. The self-assembly properties of biological units can be defined as “the self-organization of one or more entities without any external source of information about the structure to be formed as the total energy of the system is minimized to result in a more stable state” [9]. This process inherently implies (a) some mechanism driving movement

of entities like diffusion, electric fields, etc., and (b) the concept of “recognition” between different elements, or “bio-linkers”, that drives the self-assembly and results in binding of elements dictated by forces (electrical, covalent, ionic, hydrogen bonding, van der Waals, etc.), such that the final physical placement of the entities originates a state of lowest energy [10].

Researchers are now looking at biology as a source of inspiration, and working to join biology and nanotechnology, fusing useful biomolecules to man-made structures in order to fabricate devices that mimic nature in sensing [11], performing complex computational tasks [5], transferring electrons [12], relaying, processing and storing information and producing energy (e.g. biofuel cells exploiting enzymes that extract energy from compounds such as glucose to power life) [13], as well in creating multifunctional systems and molecular-scale motors [14] capable of performing mechanical movements. The result is a merger that attempts to blend biology’s ability to assemble complex structures with the nanoscientist’s capacity to build useful devices or the chemist’s ability to synthesize complex systems (up to hundreds of atoms in size) controlling the position of every atom without too much trouble or fusing useful biomolecules to chemically synthesized nanoclusters in arrangements that do everything from emitting light to storing tiny bits of magnetic data.

Over the last decade there have been dramatic advances toward the realization of molecular-scale devices and integrated computers at the molecular scale [2, 15]. First pioneering experiments were performed demonstrating that individual molecules can serve as nanorectifiers [16] and switches [17, 18], 1000 times smaller than those on conventional microchips. Very recently, the assembly of tiny computer logic circuits built from such molecular-scale devices has been demonstrated [19, 20]. Moreover, molecular electronics is expected to also develop nanodevices exhibiting new functionalities, which exploit peculiar properties of engineered molecules [21] or of biomolecules capable of performing efficiently a lot of different functions.

## 5.3

### Fundamentals of the Bio-building Blocks

#### 5.3.1

#### DNA

DNA is the basic building block of life. It has a double-stranded helical structure. The famous double-helix structure discovered by Watson and Crick in 1953 [22] consists of two strands of DNA wound around each other (Fig. 5.2). Each strand is about 2 nm wide, and has a long polymer backbone built from repeating sugar molecules and phosphate groups. Each sugar group is attached to one of four “bases”. The four bases – guanine (G), cytosine (C), adenine (A) and thymine (T) – form the genetic alphabet of the DNA and their order or “sequence” along the

**Figure 5.2.** (a) Diagram of the DNA double-stranded helical structure. (b) Possible interconnection of DNA fragment with two electrodes or an acceptor and a donor group for transport studies.

molecule constitutes the genetic code. Two single-strand (ss) DNA molecules can join together through hydrogen bonding to form a double-strand (ds) DNA. This process is called hybridization. The chemical bonding is such that an A can only pair with a T, while a G is always paired with a C. The base pairs look like the rungs of a helical ladder. Since the phosphate groups on the backbone are negatively charged, the DNA is usually surrounded by positive “counterions”. The negative charges produce electrostatic repulsion of the two strands, so that positive ions are needed to neutralize the negative charges and keep them together. DNA molecules have been proposed as molecular wires because some of the electron orbitals belonging to the bases overlap quite well with each other along the long axis of the molecule. Such so-called stacking interactions also underlie many one-dimensional (1-D) molecular conductors, including one of the most widely studied organic conductors – tetrathiafulvalene-tetracyano-*p*-quinodimethane (TTF-TCNQ).

### 5.3.2

#### Proteins

Proteins have a vital role in all living systems. The biological function of proteins is determined by the interaction with other molecules. The ability of proteins to interact with the outside world is based on their 3-D structure and conformational flexibility. Proteins are encoded by DNA. The primary structure of the protein determines how a protein will fold into a functional 3-D shape. A scheme concerning

Figure 5.3. Fundamentals of protein structure.

the fundamentals of protein structure is reported in Fig. 5.3. The folded (native-state) protein consists of hydrophilic (polar) residues on the inside and hydrophobic (nonpolar) residues on the outside. In solution, the polar residues are usually in contact with the solvent, whereas the nonpolar residues are protected from solvent in a hydrophobic core. The hydration shell in aqueous solution, where the  $\text{H}_2\text{O}$  molecules forms hydrogen bonds onto the protein surface, solvates the protein.

Proteins play a fundamental role in all biological processes, as they may have different functionalities such as enzymatic catalysis, ionic and electron transfer, coordinated moving, mechanical support, immunization, production and transmission of neuronal pulses, growth and transformation control, etc. Typical examples are hemoglobin that transports oxygen in the erythrocytes and myoglobin that plays the same role in the muscles, whereas iron is carried in the blood by the transferrin and is deposited in the liver by means of a complex with a different protein, ferritin.

In particular, proteins capable of charge transport can most likely be used for building bioelectronic devices. For example, blue copper proteins like Azurin from *Pseudomonas aeruginosa* and poplar plastocyanin are involved in the bacterial respiratory phosphorylation and in some steps on the photosynthesis of green plants, respectively. They show little differences in molecular mass (14 000–10 500) and in the structure of the copper active site (distorted trigonal bipyramid for Azurin and distorted tetrahedral for plastocyanin), which plays the role of an electron reservoir in the electron transfer process. Both of them are redox proteins whose functionality in physiological conditions consists of performing electron transfer between other metalloproteins [cytochrome  $c_{551}$  and nitrite reductase for Azurin and cytochrome *bf* and photosystem I (PS I) for plastocyanin].

## 5.4

**Interconnection, Self-assembly and Device Implementation**

To date, a fully biological device, presumably operating in a living (liquid) environment, is far from being realistic. An intermediate and necessary step is to fabricate hybrid devices in which the functionality of the biological molecules is exploited through the interconnection with a more conventional solid-state inorganic device. This is the case, for instance, of a field-effect transistor (FET) whose gate channel consists of a self-assembled biomolecular layer.

Although at the early stage, such technology is very fundamental for the understanding of biomolecular systems and for the exploration of their potentialities. The processes for the implementation of hybrid biodevices are based on two fundamental steps:

- The nanofabrication of a pattern which interconnects the bio-entity to the external world (load, power supply, circuit, etc.), following a typical “top-down” lithographic approach. This is a general issue concerning all molecular electronics (see Section 5.4.1).
- The self-assembling of the biomolecules (“bottom-up” fabrication) to immobilize the biosystem in the pattern. A possible systematic approach to build complex biomolecular devices is to start from well-characterized clean substrates [such as Si(100), SiO<sub>2</sub> or Au(111) single crystal surfaces] and deposit submonolayers of spatially isolated molecules or biomolecular functional units. The self-assembly of the biological units on the substrate can follow different pathways like (a) bulk (polymer) entrapment, i.e. absorption, (b) surface absorption (physisorption), (c) nondirected covalent binding to the surface (chemisorption), (d) electrostatic adsorption, (e) covalent binding at defined (molecularly engineered) sites of the biocompound or (f) binding by bio-specific interactions (Fig. 5.4) [23]. See Section 5.4.2 for further details.

**Figure 5.4.** Schematic of the different self-assembling mechanisms of biological units onto a substrate. (reprinted with permission from W. Göpel, *Biosensor and Bioelectronics* 1995, 10, 35–39. Copyright 1995 Elsevier Science Ltd.)

## 5.4.1

**Interconnecting Molecules**

A major challenge in molecular electronics is how to interconnect single molecules and probe molecular conductivity in real devices working at the nanoscale (both two- and three-terminal devices). This issue requires the fabrication of nanometer-spaced electrodes. Since optical lithography suffers from physical limitations (mainly related to diffraction effects), new techniques are needed for patterning below 100 nm. Even though none of the proposed methods equals the advantages of photolithography for low cost and high throughput, a number of lithographic solutions (extreme UV lithography [24], X-ray proximity lithography, and EBL and IBL) are available, and new techniques have been developed to produce very close electrodes. For instance, Reed and coworkers [25] have investigated charge transport through molecules of benzene-1,4-dithiol self-assembled onto the two facing gold electrodes of a mechanically controllable break junction fabricated by the gentle fracture of an electrode by means of mechanical deformation. Another possibility is to constrain molecules in free-standing junctions, which consist of suspended electrodes used to electrostatically trap molecules and/or nanoparticles by monitoring the current and interrupting the trapping fields at the first increase in conductivity. Among these various alternatives, planar nanojunctions – consisting of two facing metallic electrodes separated by an insulating medium and fabricated by EBL and lift-off processes – are ideal to implement molecular devices since they have a high process yield (typically more than 90% of the nanojunctions are good with an open-circuit resistance around 1 T $\Omega$ ) and provide the opportunity to perform transport experiments on molecules and/or nanostructures self-assembled at the surface of a solid, as well as to fabricate field-effect devices by adding a third electrode at the bottom of the device. Recently, Kervennic and coworkers [26] succeeded in producing pairs of platinum electrodes with a separation down to 3.5 nm by combining EBL and chemical electrodeposition. The separation between EBL-fabricated electrodes is reduced to atomic separation by monitoring the interelectrode conductance and stopping the electrodeposition process at predefined conductance values. In the particular case of DNA, the conductance has been measured using nanofabricated electrodes, atomic force microscopy (AFM), scanning tunneling microscopy (STM) and low-energy electron point source (LEEPS) microscopy. See Tab. 5.1.

Nanojunctions for devices	break junctions	free standing junctions	planar junctions

## 5.4.2

**Delivering Molecules**

Molecular-scale assembly of individual components in working devices is another challenge. In the last few years, great attention has been focused on the development of techniques capable of fabricating molecular layers and patterns [evaporation, spin-coating, Langmuir–Blodgett techniques, thermodynamically driven self-assembly (TDSA) and soft lithography] or to deliver molecules to specific locations (electrostatic trapping, dip-pen and related techniques, and optical tweezers). All these strategies have their own advantages and disadvantages. For example, evaporation usually is not suitable for delicate biomolecules, while spin-coating is fast and cheap, but films are strongly anisotropic and inhomogeneous. TDSA is particularly attractive for bioelectronics applications since it opens the way for the fabrication of engineered highly ordered layers, taking advantage of the specific reactivity of biomolecules having functional groups with affinity for specific surface atoms and/or molecular sites [7]. Although a detailed knowledge of the positions, identities and affinities of the functional groups is required in order to develop a reasonable linkage strategy, TDSA allows us to fully exploit all the intrinsic advantages of the biomolecular approach. Recently, soft lithographies (consisting of different fabrication techniques embracing imprint and stamping methods) have also been attracting considerable attention since they are biocompatible and allow us to create patterns on a surface of interest using a pattern-transfer element (a rigid stamp) made of an elastomer, a thermoplastic polymer network that deforms under an applied force and recovers its shape when the force is released.

In addition to these techniques (parallel and static), a number of scanning methods (serial or parallel) have been developed to place molecules in specific, well-established locations (e.g. in the gap between two nanoelectrodes). “Dip-pen” nanolithography (DPN), proposed by Mirkin’s group [27], is a powerful resistless nanopatterning technique allowing the delivery of molecules to a suitable substrate from a solvent meniscus. The concept of DPN is quite simple. A conventional silicon nitride AFM tip literally draws molecules of virtually any material from the solvent meniscus to a surface of interest (“paper”). The molecular “ink” consists of a chemically reactive material placed on the tip. The fine controls of the tip position and the chemisorption of ink molecules as the tip is scanned across the substrate enables the deposition of organic molecules in a nanometer-scale region. Using DPN it is currently possible to achieve high-resolution patterns (linewidths as small as 15 nm and less than 10-nm spatial resolution). The main parameters affecting the nanopatterning results are the diffusion and the relative humidity. When deposited onto solid surfaces, molecules diffuse out, therefore dramatically influencing the spatial resolution. The relative humidity controls the dimension of the naturally formed water droplet between the substrate and the AFM tip, and thus the effective contact area. Another limiting parameter is the tip radius of curvature. Due to the high resolution and the possibility to use the same apparatus to image and to write a pattern, DPN is a very powerful tool for molecular electronics. More recently, Mirkin’s group has also developed an eight-pen nanoplotter capable

of performing parallel DPN [28] using a dense array of AFM tips and has employed DPN to generate DNA-based templates capable of guiding the assembly of nanoscale building blocks [29]. This technique opens the way to placing molecules and/or nanostructures at established positions. Another interesting tool for molecular delivery is the optical tweezer where light is used to move matter and manipulate nanoscopic objects, exploiting photons momentum. For examples, nanoparticles can be trapped in the focus of a laser beam and serially moved. The force felt by the trapped particle is primarily given by the dipole and by the gradient force due to the interaction of a dielectric object with light and lies in the piconewton range, therefore allowing the manipulation of very fragile structures. Recently, MacDonald and coworkers have constructed 3-D trapped structures within an optical tweezers setup using an interferometric pattern between two laser beams. These results point towards the creation of extended 3-D crystalline structures [30]. Assembling functional molecular devices with this serial manipulation approach is, however, extremely slow, and thus technologically unattractive and not suitable for mass production. An alternative, promising strategy to produce large-scale functional circuits at the molecular level is so-called “molecular lithography” directly exploiting self-recognition and self-assembly of biomolecules on surfaces (a parallel process), as described in Section 5.5.

In particular, in order to attach single DNA molecules to metal electrodes, DNA oligomers have been functionalized with thiol groups (SH) [31] or other sulfur-gold interactions have been exploited [32–34], such as derivatizing oligonucleotides with disulfide groups. Electrostatic trapping has been also employed [35, 36] to align DNA molecules between the electrodes. See Tab. 5.2.

## 5.5

### Devices Based on DNA and DNA Bases

DNA plays a crucial role in biology as the carrier of genetic information in all living species. Recently, however, physicists and chemists have become increasingly interested in the electronic properties of the “molecule of life”, as demonstrated by the large number of fundamental and applied works published in the recent years, mainly concerning its charge transfer properties. Such considerable interest is largely explained by the number of possible applications ranging from electronic devices to long-range detection of DNA damage.

Despite the current hot debate, the subject is far from new. Soon after the Watson-Crick discovery of the double-helix structure of DNA in 1953, Eley and Spivey suggested that DNA could serve as an electronic conductor [37], as the result of interbase hybridization and  $\pi$ - $\pi$  interactions in the stacked base pairs of double-stranded DNA. If  $z$  is the direction of the DNA helical axis (i.e. perpendicular to the base plane), atomic  $p_z$  orbital can originate delocalized  $\pi$  bonding and  $\pi^*$  antibonding orbitals, enabling charge transport along the helical axis (similar stacked aromatic crystals, such as the Bechgaard salt, are indeed metallic). (Note that although DNA bases are also aromatic, there are important differences such as the nonperiodic nature of biological DNA and the expectation of Anderson localization for the electronic states. Moreover, the chemical surroundings and molecular vibrations have also to be taken into account in the case of DNA.)

The advent of measurements on single DNA molecules recently revived the field. In particular, measuring the fluorescence produced by an excited molecule, the Barton's group at the California Institute of Technology [38] found that it no longer emitted light if attached to a DNA molecule and ascribed this fluorescence quenching to the charge transfer from the excited donor molecule to a nearby acceptor molecule along the DNA strand. In other words, DNA would act as a conducting molecular wire, mediating long-range transport on fast timescales. Moreover, they reported a profound sensitivity of long-range charge transfer to stacking and a significant reduction of electron migration as the result of the presence of base mismatches or other stacking perturbations [38].

It is worth noting how these results could have deep implications in the fundamental understanding of important biological processes such as the mechanisms for sensing DNA damage in living organisms, which unlike the DNA repairing processes still present various open-points. For example, in response to DNA-damaging agents, cells induce the expression of DNA-repair enzymes, activate cell-cycle checkpoints, inhibit DNA replication and mitosis and promotes DNA repair, recombination, or, under some circumstances, undergo apoptosis (in the case of fatally damaged DNA, cells are triggered to self-destruct so that they cannot cause cancer). However, the mechanisms by which these cellular responses are activated are not completely understood. Proteins moving along the DNA could be responsible for DNA damage recognition, but in such case the screening of the genome would be quite inefficient since this process is expected to be highly time-consuming and very slow along, for example, the 2 m of DNA in the human

genome. However, if DNA is a conducting molecular wire, as reported by Barton and coworkers, the presence of damaged regions could be electronically detected exploiting DNA-mediated long-range charge transport, by two proteins (a transmitter and a receiver) working as a donor group at one end and an acceptor at the other end. If a damaged region intervenes between them, a significant reduction of charge transfer is expected and the transmitter could simply move along the DNA until the identification of the site of damage, which is then marked for repair [39].

After much initial controversy, the chemists studying charge transfer in DNA are now moving towards a common view [40, 41] and it is generally accepted that charge carriers can hop along the DNA over distances of few nanometres. On the contrary, the understanding of physicists investigating transport through DNA molecules is much less clear and the issue of DNA conductivity still presents some open-points, since the experimental results of different worldwide groups are surprisingly contrasting and range from an insulating [31–33, 42], semiconducting [35, 43] or ohmic [34, 36, 43–46] up to a proximity-induced superconducting behavior [47].

### 5.5.1

#### Charge Transfer in DNA

The process of charge transfer (intermolecular from one molecule to another or intramolecular from one end to the other of the same molecule) is one of the most fundamental in chemistry and materials science and has been extensively studied in extended molecules, like DNA, with a donor group at one end and an acceptor at the other end. Experimental and theoretical studies have shown that the electron-transfer reactions within such a single molecule can occur by two main mechanisms. The first consists of a single-step quantum mechanical tunnelling (QMT) from the donor to the acceptor, a coherent process since no energy is exchanged between the electron and the molecule during the transfer and the electron is never localized. QMT is quantitatively described by the Marcus theory [48] and characterized by a rate decreasing exponentially with the distance. As a consequence, it is possible only for short distances events, while for very long distances, it is expected to be insignificant. The second possible mechanism is thermal hopping, an incoherent process involving several uncorrelated events resulting in a random multi-step walk. In this case, the electron is localized on the molecule and exchanges energy with it. Hopping is predominant for long-distance electron transfer.

Shortly, the main factors influencing the electron transfer (ET) rate are [49]: (1) the distance between the donor and acceptor (in QMT the ET rate decreases exponentially with distance, whereas in hopping it is inversely related to the distance); (2) the nature of the micro-environment separating the donor and the acceptor (which mediates the virtual state or provides intermediate states, respectively); (3) the reorganization energy  $\lambda$ , i.e. the energy required for all structural adjustments (in the reactants and in the surrounding molecules) that are needed for the transfer of the electron [50]; (4) the driving force.

In the past, electron transfer in DNA was largely studied by means of various techniques. However, it was the important work of the Barton's group at Caltech [38] and the Turro's group at Columbia University [51] to revive the field, investigating its distance dependency and reporting the apparent coherent transfer over distances as long as 4 nm. As a result, DNA became a new paradigm for electron transfer, with possible applications as a molecular wire. In this respect, the extensive chemical variability of DNA (including differences in sequence, structures – kinks, bends, bulges and distortions – as well as the polyelectrolyte character of the double helix with the possible flow of positively charged counterions along the negatively charged phosphate backbone) opens large possibilities for tuning electron transport in DNA. On the other hand, the same variability is at the origin of the different results reported in DNA charge-transfer experiments. However, a common view about the basic mechanisms (coherent tunnelling and thermal hopping) involved in DNA charge-transfer was laboriously achieved in the last years thanks to extensive experimental and theoretical work.

To understand why the DNA sequence makes a difference, we have to compare the relative energies of the G-C and A-T base pairs obtained from computational models, photoemission experiments and electrochemical measurements. Since the thermal energy of the charge carrier is substantially smaller than the energy difference between these two base pairs, a hole will localize on G-C pairs while the A-T pairs act as barriers. Hole transfer is thus possible by tunnelling or hopping between G-C sites, with the second mechanism dominant for large distances due to the different distance dependencies.

Both the charge-tunnelling and the thermal-hopping mechanisms have been verified in experiments, notably by Bernd Giese and co-workers [52, 53]. In their experiment (Fig. 5.5), the charge transfer between G bases, separated by adenine-thymine  $(A \bullet T)_n$  bridges of various lengths, in double DNA strands was measured using gel electrophoresis. They found that from being a coherent superexchange charge transfer (tunnelling) process at short distances, the mechanism becomes a thermally induced hopping process for long  $(A \bullet T)_n$  sequences, where the adenines are involved as charge carriers (A-hopping). A switch between these reaction mechanisms occurs because the tunnelling rates decrease considerably as the distance increases. Therefore, in DNA strands where the guanines are separated by long  $(A \bullet T)_n$  sequences (more than three), endothermic transfer of the positive charge from a guanine radical cation ( $G^+$ ) to an adjacent adenine becomes faster than the direct transfer of this charge to the distant guanine. The subsequent migration of the positive charge between the adenines (A-hopping) is so rapid that the length of the  $(A \bullet T)_n$  sequence plays only a minor role. Note that charge transfer (and transport) in DNA strongly depends on the base-stacking characteristics, the dynamic structural distortion of the DNA, the base sequence and the different redox potentials of the bases (Fig. 5.6). In this scenario, having the smallest oxidation potential between the DNA bases, guanines (G) or sequences of guanines are easily oxidizable sites. Thus, once holes are created on the DNA chain, then the charge transport can occur among discrete G sites or delocalized GGG domains (e.g., polaron). This means also that they represent easy targets for many oxidizing

**Figure 5.5.** Electron transfer between a GGG sequence and a guanine radical cation, separated by  $(AT)_n$  base pairs. agents and guanine-rich regions of DNA could serve as “cathodic” protectors against oxidation for genes which are in electrical contact with them [54].

Meanwhile, Lewis and coworkers, at Northwestern University, have directly observed both thermal hopping and coherent transfer [55], while Barton and Zewail, at Caltech, also explained their fluorescence-quenching experiments using these two mechanisms [56]. For a more detailed description of the theory of charge transfer, see Ref. [57]. Most of the reported examples of charge transfer in DNA are in liquid environment.

### 5.5.2

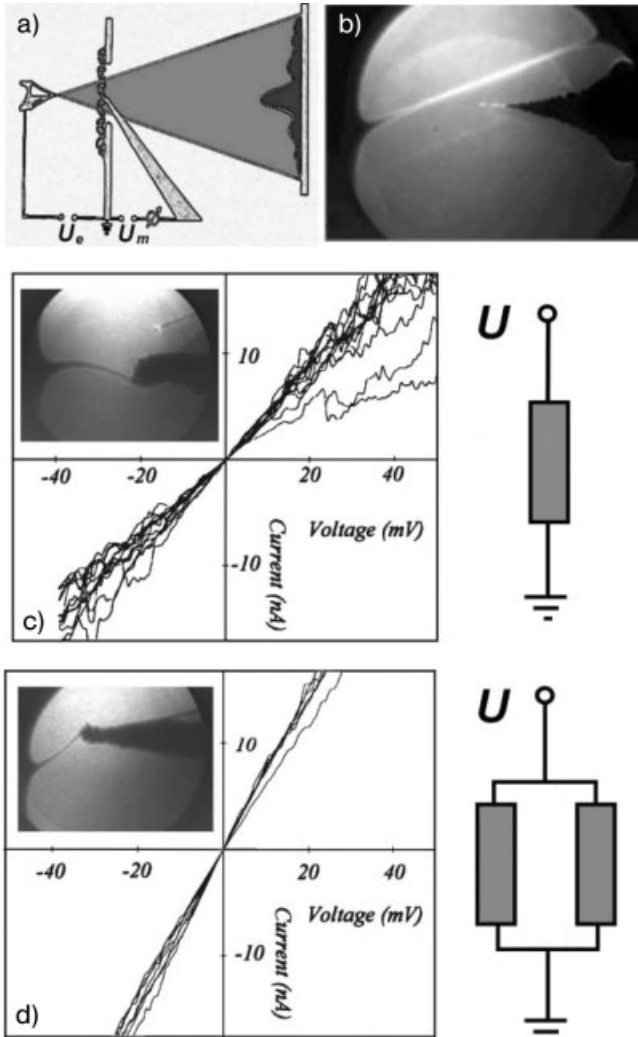

#### DNA Conductivity

While chemists are now converging towards a common view, among physicists there is still a hot debate about the issue of DNA conductivity due to the conflicting results yielded in direct electrical measurements by different groups worldwide. This is a quite new field which in the last years took advantage of the nanotechnology tools (such as electron beam lithography and scanning probe microscopy) to image samples at the molecular level and probe conduction in single DNA molecules by interconnecting them between two metal electrodes.

##### 5.5.2.1 Near-ohmic Behavior (Activated Hopping Conductor)

In 1999, Fink and Schönemberger at the Basel University [44] carried out the first direct electrical measurements on small bundles of DNA developing a special high-vacuum low-energy electron microscope able to image thin free-standing bundles of DNA stretched across a hole in a membrane. The molecules were placed onto a regular array of 2- $\mu\text{m}$  holes in a carbon foil by cast deposition of a drop of water containing 0.3  $\mu\text{g}/\text{ml}$  of  $\lambda$ -DNA onto the sample holder. This procedure usually resulted in  $\lambda$ -DNA networks spanning the sample-holder holes with DNA strands associated into a rope and only very occasionally individual DNA molecules were obtained. The DNA conductance was then measured in a vacuum environment ( $\sim 10^{-7}$  mbar) by touching the DNA bundles with an additional tip (Fig. 5.7) placed at an electrical potential  $U$  with respect to the grounded sample holder and used to achieve mechanical contact to a specific site of the DNA rope, to break the ropes at a certain distance from the rim of the hole, and to apply a voltage bias to one end of the ropes (while the other one is grounded). These manipulations were performed *in situ* while observing the projection images of the molecules on a TV monitor and the sample holder was covered with a gold layer to improve the electrical contact to the molecules. The result of this experiment was quite unexpected: a single DNA rope of 600 nm in length was found to behave like a ohmic conductor with a resistivity of the order of 1  $\text{m}\Omega\text{cm}$ , while two DNA ropes simultaneously interconnected behaved like two resistors in parallel (with the overall measured resistance reduced by a factor of 2). Contrarily, in the simplest picture one expects DNA to behave like a semiconductor with a large energy gap between the valence and conduction bands.

Results from the groups of Tran, Rakitin, Cai, Hartzell and Yoo [45, 43, 36, 34,

characteristics of an individual DNA rope and two DNA ropes in parallel. (reprinted with permission from H. W. Fink et al., *Nature* 1999, 398, 407. Copyright 1999 Macmillan Publishers Ltd.)

46] also suggested almost ohmic conductance at room temperature by means of very different experimental techniques. In all these studies DNA bundles, networks of bundles or supercoiled samples were investigated (see Tab. 5.3).

In particular, due to the numerous open points and difficulties concerning the contact effects and charge injection into DNA, Tran and coworkers measured the

temperature dependence of the AC conductivity in a contact-less configuration by evaluating the absorption in a microwave resonant cavity [45]. The measured conductivity was found to be only weakly frequency dependent and influenced by the environment of the double helix (with larger values in buffer). They interpreted the observed temperature dependence by means of a crossover between two transport

**Figure 5.8.** Temperature dependence of the conductance for poly(dA)–poly(dT) and poly(dG)–poly(dC). (reprinted with permission from Yoo et al., Phys. Rev. Lett. 2001, 87, 198102. Copyright 2001 American Physical Society)

mechanisms: ionic conduction due to the counterions at low temperatures and carrier excitations across single particle gaps or temperature-driven hopping transport processes at high temperatures. Notably, the same temperature dependence was observed by Yoo and coworkers (Fig. 5.8 [46]), which proposed an explanation in terms of a small polaron hopping model over the whole temperature range (the same model predicting a dependence of  $I \propto \sinh(bV)$  also fits their  $I$ – $V$  data very well).

Yoo and coworkers investigated transport in poly(dA)–poly(dT) and poly(dG)–poly(dC) DNA molecules and reported room-temperature resistances of 100 and 1.3 MΩ, respectively. Other interesting differences were observed like the much weaker temperature dependence for poly(dG)–poly(dC) and its behavior as a p-type semiconductor, while poly(dA)–poly(dT) acts as a n-type semiconductor under the effect of a gate voltage. Tran and coworkers reported a resistivity of 0.005 Ωcm for the dry λ-DNA, while Yoo and coworkers estimated a value of 0.025 Ωcm in the case of poly(dG)–poly(dC).

Other experimental results came from the Kawai group at Osaka University [36]. They used scanning probe microscopy and a conductive tip to inject current in DNA bundles connected to a metal strip at different positions in order to determine the length dependence of the current. The resistance was found to increase exponentially with the distance, from  $10^9$  ohm to  $10^{12}$  ohm (Fig. 5.9). Moreover, DNA made of C and G bases were more conductive than DNA with A and T bases [36] (estimated resistivity for poly(dG)-poly(dC) around 1 Ωcm). The increasing of the resistance with the length was attributed to the number of defect in the molecules, while they proposed that the more compact base-stacking structure of

**Figure 5.9.** Resistance versus DNA length for poly(dA)–poly(dT) and poly(dG)–poly(dC). (reprinted with permission from Cai et al., *Appl. Phys. Lett.* 2000, 77, 3105. Copyright 2000 American Institute of Physics)

poly(dG)-poly(dC) (crystal structure data indicates that the helical rises of residues are 2.88 Å and 3.22 Å for poly(dG)-poly(dC) and for poly(dA)-poly(dT), respectively [36]) can also contribute to its better conductance as compared to poly(dA)-poly(dT). In the same group, in a four probes current voltage measurement [58] the effect of oxygen doping was tested on poly(dG)–poly(dC) DNA and poly(dA)-poly(dT) DNA samples. The authors found that the conductance of the DNA samples increases by orders of magnitudes due to oxygen hole doping and that the poly(dG)–poly(dC) DNA samples behave like a p-type semiconductor, whereas the poly(dA)–poly(dT) ones are more likely n-type semiconductors. This difference was attributed to the lower oxidation potential of dG with respect to dA. In this experiment the spacing between the electrodes was varied from 100 to 200 nm.

Finally, Hartzell and coworkers [34] compared the conduction in nicked and repaired  $\lambda$ -DNA, showing a gap up to  $\pm 3$  V and almost ohmic behavior (it is worth noting, once again, the important possible implications in DNA damage recognition). Moreover, Kasumov and coworkers [47] reported proximity induced superconductivity in long  $\lambda$ -DNA, which in their experiment exhibits metallic behavior down to very low temperature (this would be the proof of the existence of true extended states). However, this result has not been independently reproduced and will not be further discussed here.

### 5.5.2.2 Semiconducting (Bandgap) Behavior

The role of the DNA sequence on transport was investigated at the nanoscale for the first time by Porath and co-workers at Delft University, who measured very short DNA molecules consisting of two strands containing only G and C bases, respectively, in order to probe the importance of G-C pairs in hole transfer through

DNA [35]. Using electrostatic trapping from a dilute aqueous buffer containing about one molecule per  $(100 \text{ nm})^3$ , Porath and co-workers placed individual double-stranded poly(G)-poly(C) DNA molecules between two nanoelectrodes only 8 nm apart. The DNA molecule was 10.4 nm long to span the two closely spaced metal nanoelectrodes as a linear, nearly stiff structure. After a DNA molecule was trapped from the solution, the device was dried in a flow of nitrogen and electrical transport was measured. On applying a voltage to the device, they first observed an insulating gap (i.e. no current) at low voltage followed by a conduction onset above 1 V. The low-current region widened as the temperature increased. Two different peaks were present in the differential conductance curves and suggested a molecular-band-mediated transport mechanism and a wide-gap semiconductor behavior, as expected for short DNA molecules if we assume that DNA bases have a rather large highest occupied–lowest unoccupied molecular orbital (HOMO–LUMO) gap (4 eV) and the metal work function lies in the gap. In this case, in fact, a very large electric field is needed to drive transport and allow charge carriers to enter the DNA by aligning the molecular energy bands with the energy levels in the electrodes. The reported  $dI/dV$  curve is thus a measure of the DOS, while the voltage gap (1–2 eV) can be related to the energy difference between the metal work function and the nearest molecular level available for conduction (either the guanine HOMO or the cytosine LUMO). Porath and coworkers [35] interpreted their results as reasonable evidence of the existence of coherent electronic states extended across the molecule. It is worth noting that, in this experiment, transport through DNA molecules only a few base pairs long is probed: the persistence length in dsDNA is about 100 base pairs at room temperature, thus the investigated molecules are reasonably free of the kinks and defects that would lead to an interruption of the  $\pi$ – $\pi$  interactions [57]. This experimental finding was confirmed by the model developed by Cuniberti and coworkers [59] on a similar DNA short sequence.

More recently, Watanabe et al. at Xerox in Japan [60] performed other experiments on single DNA molecules by means of a triple probe atomic force microscope in which two conductive carbon nanotube (CNT) electrodes were employed as source and drain electrodes to interconnect a DNA molecule and a third CNT (fixed to the AFM probe) served as the gate electrode. Due to the small drain-source distance (25 nm), also in this case only few base pairs were probed. Experiments were carried out under nitrogen atmosphere at room temperature and non linear  $I_{DS}$ - $V_{DS}$  characteristics with a non-conducting gap decreasing from 2 to 0.2 V with increasing  $V_G$  from 0 to 5 V were observed. Electrical measurements with drain-source distance of only 5 nm showed equally spaced steps in the  $I_{DS}$ - $V_{DS}$  curve with a period of 80 meV and a gap of 400 meV at  $V_G = 2$  V.

### 5.5.2.3 Insulating Behavior

The electronic conduction at length scales of 40 nm and longer was measured at Delft University by Storm and co-workers with different electrode shape [31]. They obtained clear AFM images of DNA molecules interconnecting the nanoelectrodes, but did not observe any conduction for such long lengths of DNA

with applied bias voltages up to 10 V and also with an additional gate voltage in the range between  $-50$  V and 50 V. They used both individual DNA molecules and small DNA bundles (mixed sequence and poly(dG)-poly(dC)) and employed a cast deposition technique to deposit the molecules between the electrodes. Although under their conditions DNA self-assembles into networks similar to those obtained by Cai and coworkers, Storm and colleagues measured a higher resistance in all their experiments of around  $1\text{ T}\Omega$ , which was observed to increase in a flow of dry nitrogen gas ( $>10^{13}\ \Omega$ , i.e.  $10\text{ T}\Omega$ ). Thus, they suggested that the observed conduction was due to the thin water layer on the hydrophilic mica. These findings clearly contrast with the Basel results (and other high-conductance reports), but they confirm earlier measurements by Braun and coworkers at Technion in Israel [32], who also observed insulating behavior for DNA over a scale length of about  $16\ \mu\text{m}$  in length, and results of de Pablo and coworkers [42], who measured the DNA conductivity using a scanning force microscopy (SFM) tip covered by gold (they reported a lower bound of  $10^6\ \Omega\text{cm}$  for the resistivity). The discrepancy between the Storm lower value ( $1\text{ T}\Omega$ ) and the conductivity reported by Cai and coworkers [about  $200\ \text{G}\Omega$  for bundles of poly(dG)-poly(dC) at a length scale of  $200\ \text{nm}$ ] is, however, not so large.

de Pablo and coworkers [42] also presented “first principles” electronics structures calculations for a double helix of infinite length in acidic dry conditions, which supported the picture of an insulating behavior for the  $\lambda$ -DNA. They started by considering a poly(C)-poly(G) sequence and then analyzed the effect of swapping guanine and cytosine bases in one of every 11 base pairs of their unit cell. This resulted in a dramatic change of the electronic structure of the chain and in a cut in the HOMO-state channel (more or less the same happens for the unoccupied band), as shown in Fig. 5.10. Thus, Anderson localization (over very few base pairs) and an exponential decay of the conductance with the length are expected in biological DNA, due to the nonperiodic nature of its base sequence. Residual conduction by hopping mechanisms (polaronic or not) is still possible, but it should exhibit a marked dependence on temperature and frequency [42]. Taking into account the electronic structure obtained for poly(C)-poly(G), de Pablo and coworker’s results could be consistent with those of Porath, but are strongly in contrast with those of Fink and Schonberger (whose resistivity is 10 orders of magnitude lower). An insulating behavior for a  $\lambda$ -DNA molecule on the micron scale has been also reported by Zhang and coworkers [33] (resistivity higher than  $10^6\ \Omega\text{cm}$ ).

#### 5.5.2.4 Discussion of DNA Conductivity

Despite the large worldwide efforts, the issue of DNA conductivity is, thus, still subject of intense debate and rather unsettled. Assessing and understanding DNA transport properties, with all their facets, it is crucial to gain a deep insight inside important life mechanisms (like DNA damage recognition and reparation) as well as for a variety of applications in molecular electronics and biotechnology, e.g. the implementation of DNA chips with an electronic readout. Microarrays for the de-

tection of nucleic acids (DNA chips) are widely used for DNA sequencing, disease screening and gene expression analysis since they allow us to obtain information on nucleic acid sequences in a manner that is faster, simpler and cheaper than traditional methods [61]. Currently, the readout schemes for such devices are optical and involve the use of fluorescent dyes, but the exploitation of DNA conductivity (if large enough, after hybridization, in well-stacked dsDNA as compared to floppy, insulating single strands of DNA) or of its self-assembly properties (for the delivery of conductive elements between pairs of electrodes in large arrays) could enable in the near future the development of an electronic readout which is expected to allow a significant increase in the number of different probe sites (whose density would be no more resolution limited) per unit area, and thus a potentially faster and more efficient sequence analysis.

The main difficulties in addressing the DNA conductivity lie in the complexity of the system and in making clean (i.e. fully controllable) experiments, due to three main issues:

- (a) Differences in the DNA molecules: sequence, length, character (single molecules or ropes).
- (b) Influence of the molecular environment (hardly controllable and possibly preparation dependent): water molecules, counterions, substrate, physisorbed/chemisorbed DNA. For example, the number of water molecules per base is believed to influence the DNA structure [62].
- (c) The detection scheme and the role (nature and quality) of contacts between electrodes and molecules. It is very difficult to have an ideal ohmic molecule-metal contact and the organic-inorganic interfaces usually produce tunnel barriers that can strongly influence the results. Only the metal work function is typically known.

Even theoretically, the situation is quite confused with the large unit cell limiting computational approaches [57], and a number of proposed transport models involving electrons, holes [63], polarons [64] and solitons [65].

However, recently, some progress in the analysis and understanding of the wide range of experimental results has been done [57]. We will try to provide a more unitary as possible discussion of the literature. As noted above, there has been only one group reporting proximity-induced superconductivity in long  $\lambda$ -DNA, thus these results will not be discussed here (Zhang and coworkers [33] proposed contamination from carbon or rhenium to explain such results).

Although the contact-less detection scheme of Tran and coworkers could detect very short dissipative regions embedded in an insulating DNA molecule [33] and de Pablo and coworkers [42] demonstrated that in Fink and Schonberger's experiment [44] the measured DNA conductivity was affected by the irradiation with the imaging electron beam of the LEEPS microscope (resulting in a contamination layer with subsequent increase of conduction), the different experimental evidence of conducting DNA molecules needs an explanation in a comprehensive framework, which also takes into account the observed semiconducting and insulating behaviors. In this respect, it is worth noting how all reports of near-ohmic behavior concern DNA bundles, networks of bundles or supercoiled samples, while insulating behavior was observed in single molecules and short molecules were found to be semiconducting.

The possible stabilization of floppy single DNA molecules by the bundles or condensed water and counterions trapped between the DNA molecules (leading to a different pathway for charge transport) could explain the observed near-ohmic behavior [57] and also the dependence of the conductance on humidity (the contribution of the alternative pathway to conduction would be of course strongly influenced by the water content, but the more regular structure of DNA at high humidity could also contribute) as well as the lack of anisotropy seen in films of oriented DNA molecules [62].

A 1-D pathway through stacked base pairs could be argued from the weak sequence dependence reported by Yoo and coworkers; however, this could also be related to the different helical rises of poly(G)–poly(C) and poly(A)–poly(T) DNA, which could lead to a different contribution from water and counterions. In this scenario, small molecules could easily exhibit a semiconductor behavior, as observed by Porath and coworkers. The effects of the water solvent on the electronic states are accurately discussed in [57].

#### 5.5.2.5 Other Applications of DNA in Molecular Electronics

The interest in DNA for molecular electronics, however, does not stop at its conduction properties, but also lies in its self-assembly ability. For example, in Rinaldi's group at the National Nanotechnology Laboratory, a single modified DNA base, the lipophilic deoxyguanosine, was adopted to fabricate electronic devices. Guanosine was chosen due to the lowest oxidation potential among the DNA bases, which favors transport, and its self-assembling properties related to its peculiar sequence of hydrogen-bond donor and acceptor groups [66]. Using this approach, Maruccio and coworkers [67], from the same group, succeeded in the fabrication of a prototype FET based on this modified DNA base (Fig. 5.11) with a maximum voltage gain of 0.76. Unlike other molecular electronics devices based on CNTs, this prototype FET is based on ordered and self-assembled layers, instead of a single molecule with tremendous interconnection problems [68]. The transistor was fabricated by cast deposition of a droplet of the deoxyguanosine derivative in chloroform solution between the source and drain contacts consisting of two EBL-fabricated chromium/gold electrodes separated by a distance of 20–100 nm, while the control electrode was a layer of silver deposited on the reverse of the Si/SiO<sub>2</sub> substrate. The guanosine-based FET operated at room temperature and ambient pressure, and exhibited a voltage threshold for the conduction which could be modulated by the gate voltage. The electrical characteristics were explained in terms of resonant tunneling, the threshold voltage being defined by the alignment between the molecular minibands and the Fermi level in the electrodes.

DNA exhibits a surprising range of structural forms and possible modifications. One interesting example is the replacement of certain hydrogen atoms in the base pairs of the DNA with metal ions (Zn<sup>2+</sup>) as reported by Rakitin and co-workers at Brown University in the US [43], in collaboration with researchers at the University of Saskatchewan in Canada. Specifically, they prepared and investigated four types of  $\lambda$ -DNA samples:

- (1) *B*-DNA in standard buffer at pH 7.5.
- (2) *M*-DNA where the imino-proton of each base pair was substituted with a metal ion (Zn<sup>2+</sup>).
- (3) *B*-DNA samples in which the sticky ends of the DNA were attached to surface-bound oligomers.
- (4) *B*-DNA at pH 7.5 with 0.1 mM of Zn<sup>2+</sup>, since at this pH *M*-DNA does not form but the contribution of DNA surface-bound Zn<sup>2+</sup> ions on the measured electrical characteristics can be determined.

**Figure 5.11.** (a) Self-assembly and cast deposition of dG(C<sub>10</sub>)<sub>2</sub> on the three-terminal device, consisting of two arrow-shaped Cr/Au electrodes on a SiO<sub>2</sub> substrate and a third Ag back electrode (not to scale). (b) High-magnification SEM image of two Cr/Au nanotips with a separation of 20 nm. (c) Characteristics of the FET at different gate voltages ( $V_G$ ). The dashed lines extrapolate

the voltage threshold  $V_T$  for any  $V_G$  value. By changing the gate voltage,  $V_T$  can be modulated since the alignment condition for resonant tunneling is modified due to a shift in the energy of the molecular band. (reproduced with permission from G. Maruccio et al., *Nanoletters*, 2003, 3, 479–483. Copyright 2003 American Chemical Society)

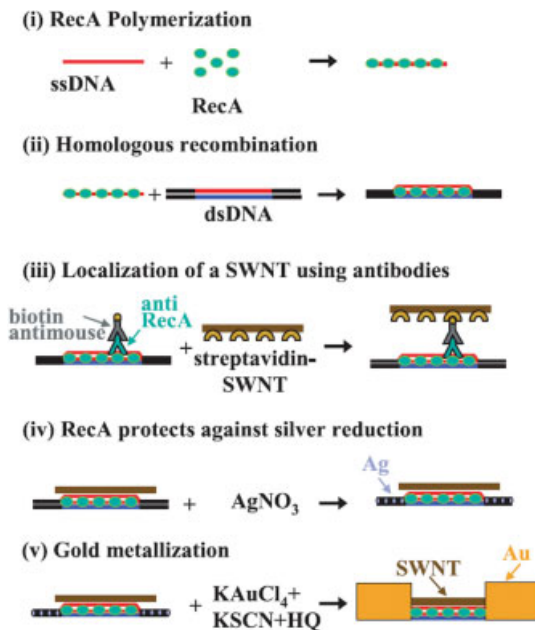

The subsequent exposure of the samples to “freeze-dry” methods could not rule out the ionic contribution because of the existence of salt bridges formed on the substrate surface between electrodes. To solve this problem a new design for the contact was implemented by placing DNA between two electrodes separated by a physical gap of width 1–30  $\mu\text{m}$  and practically infinite depth. A metallic-like con-

duction was observed in 15  $\mu\text{m}$  long *M*-DNA, while a semiconducting behavior with a few hundred meV band gap was obtained in the case of *B*-DNA before conversion into *M*-DNA. Finally, a decrease in the zero bias conductance of about three orders of magnitude with respect to *M*-DNA was found in sample (4). The possibility to achieve such drastic change in conductivity could have important applications in molecular electronics.

An entirely different use of DNA was proposed by Braun and co-workers at the Technion and is based on the exploitation of its unrivaled assembly properties [32]. In fact, a strategy for the assembly of integrated circuits is still missing in molecular electronics and in this respect the highly specific binding between DNA strands may provide a key tool to control the geometry and connectivity of future electronic circuits without the use of destructive lithography techniques. Inspired by this, the Braun group firstly assembled DNA between two electrodes adding sticky ends to DNA fragments and then replaced the counterions with silver ions demonstrating that DNA can be used as a linear template to grow a thin metallic wire. The same approach was followed by Richter at Dresden to build up highly conductive palladium nanowires on a DNA template [69]. Moreover, the group of Erez Braun developed also the so-called sequence-specific molecular lithography [8], an alternative and promising strategy to produce large-scale functional circuits at the molecular level exploiting self-recognition and self-assembly of DNA (a parallel process). The information encoded in the DNA molecules replaces the masks used in conventional lithography, while a RecA protein serves as the resist. This technique enables high resolution, the fabrication of three-way junctions (branch-points) and the sequence-specific positioning of molecular objects. More recently, Keren and coworkers [70] reported the fabrication of a carbon nanotube FET, self-assembled using a DNA scaffold molecule to provide the address for precise localization of the nanotube as well as the template for the extended metallic wires contacting it (Fig. 5.12). Besides DNA and proteins, genetically engineered viruses have also been employed to order nanostructures [71].

Recently Williams and coworkers at Delft joined the conducting properties of single-walled carbon nanotubes (SWNTs) with the specific molecular-recognition features of DNA by coupling SWNTs to peptide nucleic acid (PNA, an uncharged DNA analogue) and hybridizing these macromolecular wires with complementary DNA [72]. The oligonucleotide adducts imparted recognition properties, used to programme the attachment of SWNTs to each other and to the electrodes. This general approach can be exploited in the field of biosensors.

DNA can be also combined with specific chemical side groups, providing the basis for new functional devices and accurate biosensors. For example, nanocomposite structures made of gold nanoparticles covered with single-strand DNA fragments were prepared by the Alivisatos's group at Berkeley [73] and Mirkin and coworkers at Northwestern [74] with the spacing between the nanoparticles controlled statically (by using different sticky ends) or dynamically (by exploiting the melting properties of DNA with changes in temperature or solvent). Moreover, DNA has the potential for assembling intricate spatial structures and networks with a variety of geometries, as those produced by Seeman and co-workers at New

**Figure 5.12.** Assembly of a DNA-templated FET by molecular lithography. (i) Polymerization of RecA monomers on a ssDNA molecule, resulting in the formation of a nucleoprotein filament. (ii) Binding of the nucleoprotein filament at a desired address by homologous recombination. (iii) Delivery of a streptavidin-functionalized SWNT on the DNA-bound RecA by means of a primary antibody to RecA and a biotin-conjugated secondary antibody.

(iv) Incubation in an AgNO<sub>3</sub> solution and formation of silver clusters on segments unprotected by RecA. (v) Formation of two DNA-templated gold wires to contact the SWNT by electroless gold deposition (the silver clusters are used as nucleation centers). (reproduced with permission from K. Keren et al., *Science*, 2003, 302, 1380–1382. Copyright 2003 American Association for the Advancement of Science)

York University, including loops, knots, one- and two-dimensional arrays, three-dimensional cubes and nanolattices based on synthetic DNA structures [75].

As previously discussed, an important application of the assembly properties of DNA are the DNA chips which make use of many parallel DNA (single strands) probes to check whether certain genetic codes are present in a given specimen of DNA. Their read out schemes are currently optical, but an electronic read-out possibly exploiting the electron-transfer properties of DNA or using single-strands with sticky ends attached to electrically active molecular elements (such as metal clusters, fullerenes or certain molecular switches) could enable further miniaturization. The different electrochemical responses of single- and double-strand DNA molecules that attach to a surface can be also used in this frame [76].

Finally, concerning the applications of DNA self-assembly, we have of course to mention the DNA computation and its proof-of-concept by Adleman's group in 1994 [5], which demonstrated that the recombinant properties of DNA can be ex-

ploited to solve problems appropriately encoded into single DNA strands, using five simple operations: (a) synthesis of a large numbers of oligonucleotides, (b) annealing/hybridization of oligonucleotides to produce dsDNA molecules, (c) extraction of molecules containing a given sequence of bases, (d) detection of DNA molecules and (e) amplification of DNA molecules. The massive parallelism intrinsic in this approach allowed Adleman's group to solve a problem that had resisted conventional methods. The problem-specific technique of Adleman's group has been recently extended theoretically to more general Boolean operations.

In conclusion, although the advantages to use DNA as a molecular wire in electronic devices have probably to be evaluated in more detail, its unique assembly and recognition properties seem destined to be a major tool in molecular electronics.

## 5.6 Devices Based on Proteins

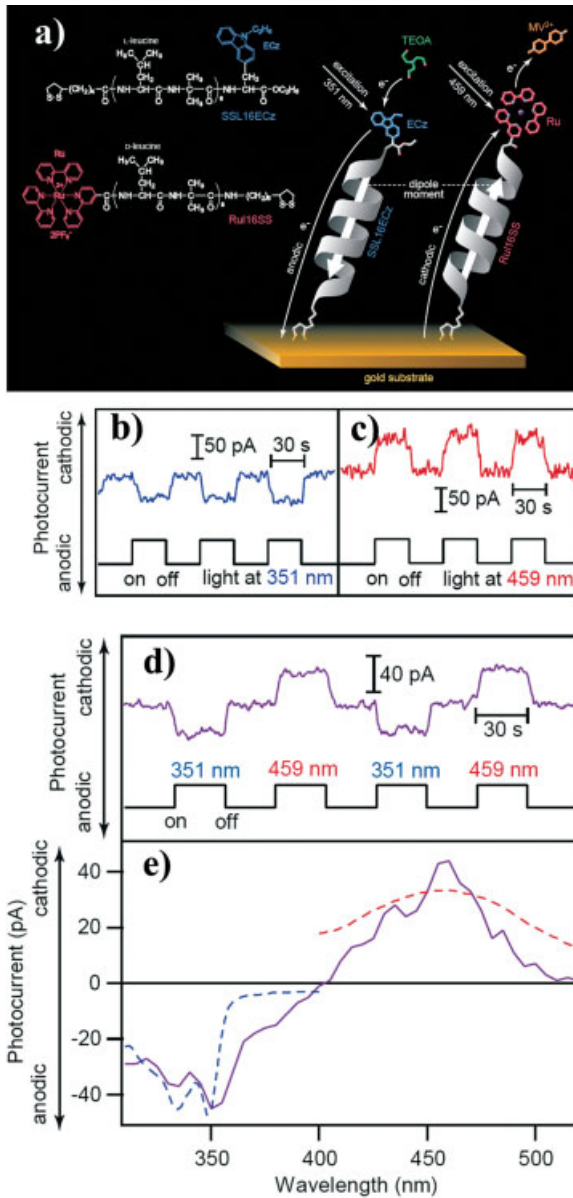

Besides DNA, proteins have been also intensively investigated in the last years for application in molecular electronics, molecular motors and biosensors, since their nature-tailored functions presents clear advantages for a number of specific applications. For example, the potential of photochromism has generated great interest in the synthesis of new photosensitive materials and in the development of new techniques for their use. Some biological systems, like bacteriorhodopsin and the green fluorescent protein (GFP) of the *Aequorea Victoria* jelly fish, offer naturally evolved optimized structures with unique properties that can further be tailored for specific applications by genetic engineering. The green fluorescent protein (GFP) is very interesting for optoelectronic applications since it exists in two distinct configurations (bright and dark) and has a very efficient fluorescence emission that makes possible also single-molecule detection. Moreover, genetic engineering allows producing mutants with modified spectral characteristics, enhanced brightness, photostability, quantum yield, and other properties tailored for specific applications. In particular, two GFP mutants – EGFP (enhanced GFP) and E<sup>2</sup>GFP (obtained by a single point mutation T203Y of EGFP) – were recently investigated by the Beltram group [77] who achieved optical control of transition between the bright and dark states in E<sup>2</sup>GFP by means of two laser beams with different wavelengths ( $\lambda = 476$  nm and 350 nm). Both the investigated proteins exhibited in solution absorption peaks at 400 and 515 nm, ascribed respectively to the protonated neutral and deprotonated anionic forms (states A and B) of the chromophore. A weak emission was observed for both mutants after excitation of state A and was ascribed to excited-state photoconversion from A to B. Moreover, the authors observed a reversible turning on and off (blinking) of the emission and its ultimate switching off (photobleaching) into a long-lasting dark state (C) within a few seconds after excitation at 476 nm. In the case of E<sup>2</sup>GFP mutants, it was possible to achieve a reversible photoconversion from state C back into state B by irradiation at 350 nm. Since unlimited optically controllable cycles between the bright

and dark configurations were reported, these results open the way to the use of the E<sup>2</sup>GFP mutant in memory devices by employing the states B and C to encode a (0, 1) bit. In fact, information can be stored and manipulated and the basic required operations (write, read and erase data) are performed at the single molecule level. According to the authors, one possible implementation is to use photoconversion from the dark to bright state by irradiation at 350 nm as WRITE step, fluorescence emission following weak excitation at 476 nm as READ step and photobleaching as ERASE step.

As discussed above, another interesting protein is the Bacteriorhodopsin (BR), a trans-membrane protein found in the cellular membrane of *Halobacterium salinarium*, which functions as a light-driven proton pump and thus is expected to be useful as photonic material. Due to its peculiar properties, its use as the active component in memory devices was investigated (for a recent review on Bacteriorhodopsin-based applications see [78]), in particular in holographic associative memories and branched-photocycle three-dimensional optical memories. More in detail, the proposed holographic associative memories were based on a Fourier transform optical loop and the real-time holographic properties of a BR films. On the other hand, in the branched-photocycle three-dimensional optical memories, parallel write, read, and erase processes were performed exploiting a sequential multiphoton process and an unusual branching reaction that creates a long-lived photoproduct. A very broad range of applications was proposed, from electronics to optoelectronics and computing including random access thin film memories, neural-type logic gates, photon counters and photovoltaic converters, artificial retinas, picosecond photodetectors, multilevel logic gates optical computing, and different kinds of memories (see [78] for further details).

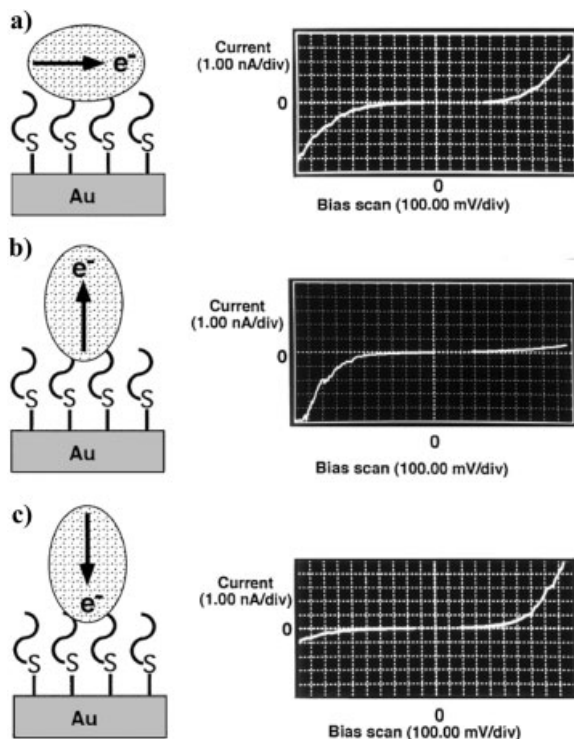

Then, very recently, Yasutomi and coworkers at the Kyoto University [79] reported the fabrication of a molecular photodiode that can switch photocurrent direction by changing the wavelength of an irradiating light (Fig. 5.13). Their device was based on bicomponent SAMs of two helical peptides carrying different chromophores (thus selectively activable) and having opposite direction of dipole moments (when immobilized on gold). Since at a certain range of the applied potentials the direction of the photocurrent is determined by the direction of the dipole moment, photocurrent can be switched from anodic to cathodic alternating photoirradiation at 351 nm and 459 nm. The optimum voltage for photocurrent switching was determined by investigating the dependence of photocurrents on applied potential for the unicomponent SAMs.

The Greenbaum group reported on the generation of exogenous photovoltages by the Photosystem I (PSI) reaction centers, nanometer-size robust supramolecular structures that can be isolated and purified from green plants. A diode laser at  $\lambda = 670$  nm was used to illuminate heterostructures composed of PSI and organosulfur molecules onto gold substrates, while the photovoltage was measured by Kelvin force probe microscopy. Under illumination, the potentials of the central region of the PSIs were found to be typically more positive than the periphery by 6–9 kT, where kT is the Boltzmann energy at room temperature [80]. Possible applications of the PSI to the implementation of artificial retina are currently under exper-

**Figure 5.13.** (a) Molecular structures of the two kinds of hexadecapeptides employed (SSL16ECz and Ru16SS) whose dipole moments (with opposite directions) determine the photocurrent switching from anodic to cathodic under selective photoexcitation of the sensitizer (an ECz or Ru group respectively) when the peptides are coassembled in a highly-ordered bicomponent SAM on a gold substrate via an Au-S linkage. (b-c) Periodic photocurrent generation by the SSL16ECz (Ru16SS) SAM upon photoirradiation at

351 nm (459 nm) in a 50 mM TEOA ( $MV^{2+}$ ) aqueous solution. (d) Time course of photocurrent switching upon alternating photoirradiation at 351 and 459 nm. (e) The action spectra (purple solid line) consists of anodic and cathodic photocurrent regions, which agree with the absorption spectra of SSL16ECz (blue dashed line) and Ru16SS (red dashed line) in ethanol, respectively. **Figure 5.14.** Orientation-dependent STS characteristics of individual PS I reaction centers. (a) If a PS I is oriented parallel to the electrode surface, a semiconductor-like behavior with a bandgap of around 1.8 eV can be observed. (b and c) If a PS I is anchored

perpendicular to the gold surface, a diode-like (current rectification)  $I$ - $V$  curve can be observed. (reproduced with permission from I. Lee et al., *Phys. Rev. Lett.* 1997, 79, 3294–97. Copyright 1997 American Physical Society)

imentation in the same group. Moreover, they also explored two-dimensional vectorial arrays of functional PSI reaction centers (prepared on atomically flat derivatized gold surfaces) by STS [12]. The nature and extent of PSI orientation were controlled by chemical modification of the surface derivative and checked by STS. When gold electrodes were treated with mercaptoacetic acid, 83% of the electron transport vectors were parallel to the electrode surface and a semiconductor-like  $I$ - $V$  curve with a band gap of  $\approx 1.8$  eV (corresponding to the first excited singlet state of chlorophyll) was observed (Fig. 5.14a). On the other hand, using 2-mercaptoethanol, 70% were oriented perpendicularly in the “up” position and only 2% were in the “down” position and current-rectification (i.e. diode-like behavior) was observed (Fig. 5.14b–c). Authors ascribed the asymmetry of the  $I$ - $V$  characteristics to either a difference in electronic energy (in analogy with a solid-state p-n junction) or a difference in the tunneling distance for each end.

A novel example of protein-based active electronic device has been recently dem-

onstrated by the group of Rinaldi and coworkers at NNL, taking advantage of the redox properties and of the functional groups of the blue copper protein Azurin, that, *in vitro*, is able to mediate electron transfer (ET) from cytochrome  $c_{551}$  to nitrite reductase from the same organism [81]. Azurin from *P. aeruginosa* is a 14.6 kDa blue-copper protein existing in two stable configurations – Cu(I) and Cu(II) – and its ET capability depends on the equilibrium between these two oxidation states by means of the reversible redox reaction  $\text{Cu}^{2+} + \text{e}^- \rightleftharpoons \text{Cu}^{1+}$ , which converts continuously the Cu(II) copper oxidized state into the Cu(I) reduced state and *vice versa*. A disulfide bridge (Cys-3-Cys-26) located at a distance of  $\approx 2.6$  nm from the copper site [82] allows the chemisorption of Azurin in oriented monolayers onto crystalline gold or other suitably functionalized surfaces [83, 84]. Since protein adsorption on surfaces may lead to denaturation, in their recent publication, Maruccio and co-workers [49] examined the integrity of proteins in dry monolayers after immobilization by non-contact atomic-force microscopy and by intrinsic fluorescence (the fluorescence of aromatic residues in proteins is strongly influenced by their microenvironment) concluding that neither the covalent binding to the functionalized  $\text{SiO}_2$  surface nor the application of strong electric fields induce gross denaturation and/or conformational transitions in Azurin. Their prototype device consists of a planar metal-insulator-metal nanojunction, fabricated by EBL [85] and connected by the self-assembled protein monolayer, and a silver back gate electrode in a field-effect transistor configuration. An oriented protein monolayer was formed in a two-step procedure involving (a) the self-assembly of 3-mercaptopropyltrimethoxysilane (3-MPTS) and (b) the reaction of the free thiol groups of 3-MPTS with the unique surface disulfide bridge of Azurin. The current-voltage characteristic ( $I_{\text{ds}}-V_{\text{ds}}$ ) exhibited a low-current plateau at low field and then rises up to hundreds of pA (see Fig. 5.15). The transfer characteristic exhibited a pronounced resonance centered at  $V_{\text{g}} = 1.25$  V. This feature gradually disappeared after some gate sweeps. From an electronic viewpoint, their device switches from a n-MOS FET behavior before resonance to a p-MOS FET after resonance. Although among all the fabricated nanodevices, only a limited group exhibited a clear gate effect over a number of gate sweeps (whereas the others failed during the first few sweeps – the ageing of nanodevices is a general issue of molecular electronics [16, 85, 87]), this is a key result because it would allow to exploit the advantages of a complementary logic, fabricating both p-type and n-type devices on the same chip.

The authors ascribed these results to the unique transport mechanism of their biomolecular devices. The transport of electrons through systems containing redox sites may occur via physical displacement of the redox molecules and/or electron hopping from one reduced molecule to an adjacent oxidized molecule [88]. The authors discarded the first mechanism since the proteins were covalently bound to the substrate. Thus, they ascribed electron transport in the Pro-FET to hopping from one reduced (Cu(I)) protein to an adjacent oxidized (Cu(II)) protein, which behave as a redox pair. For electrons to flow, therefore, both reduced and oxidized Azurins must be present and their relative proportion determines the ET rate. The authors proposed that the Azurin redox state is regulated by  $V_{\text{g}}$ : the higher is

**Figure 5.15.** Characteristic of the Pro-FET: 3-D plot of the drain–source current as a function of the drain–source bias ( $V_{DS}$ ) and gate bias ( $V_G$ ) measured in the dark and at room temperature. No leakage current was observed to flow between the planar electrodes and the back-gate (values as low as few picoamperes and a negligible variation with  $V_G$  up to 8 V).

A pronounced resonance centered at  $V_G = 1.25$  V is present (see also the transfer characteristic at  $V_{DS} = 5.5$  V in the projection). (Reproduced with permission from G. Maruccio et al., *Towards Protein Field-Effect Transistors: Report and Model of a Prototype*, *Adv. Mater.*, 2005, 17, 816–822)

$V_g$ , the greater is the fraction of reduced Azurins. At a particular value of  $V_g$  the fraction of oxidized molecules will equal that of reduced molecules and therefore ET will be maximal. In their model the change in the protein oxidation state was ascribed to the influence of the applied electric field on the redox energy levels of the proteins. To verify whether such model based on a hopping mechanism between neighbouring proteins was compatible with their experimental findings, they performed numerical simulations of the current flowing in the device as a function of the applied potentials. The basic features of the experimental curves were exhibited also in the results of their simulation. Moreover, the proposed model is also consistent with the interpretation of the redox peak in cyclic voltammetry curves and in electrochemical STM experiments [84, 89] performed on Azurins chemisorbed on Au(111) substrates. The key role of the copper atom in electron transfer was further supported by a comparison with the current-voltage curves measured in devices implemented with two Azurin variants (the first with the Cu atom replaced by a Zn atom, the second without metal atom), where the flowing currents were significantly lower and no modulation was observed between  $-6$  and  $6$  volts.

The same metalloprotein has been investigated also at Oxford, where Davis and coworkers acquired current–voltage characteristics by means of conductive-probe AFM and studied the dependence of the conductance from the force load, finding that forces larger than  $3$  nN were necessary to achieve a reliable contact to the protein [90].

Before concluding, we would also like to mention the work of Yu and coworkers, who succeeded in the construction of ordered neuronal networks by positioning neurons on a bioelectronic chips by means of a negative dielectrophoretic force [91].

## 5.7

### Conclusions

We have briefly discussed the present status of the research in the field of nanobioelectronics, with special emphasis on DNA- and protein-based devices.

Although this field is rather young and very open, the worldwide results obtained so far are promising, and deserve further studies to determine the actual potentiality of biodevices and to further investigate a number of important issues, such as:

- Interconnection of biomolecules and inorganic devices
- Molecular engineering and self-organization
- Transport mechanisms
- Reproducibility and ageing of biomolecular devices
- Biochemical driven implementation of fully biomolecular nanodevices

On the basis of recent progress in the field of nanobioelectronics we feel as though we are just at the beginning of a great journey that will have many unexpected findings. There is no turning back and we cannot even envisage the future developments of this field and where it will take us.

There is much work under way actively pursuing molecular and biomolecular engineering, and the building of composite materials at the nanoscale to be joined together, but there is still an enormous challenge ahead. Building materials from the bottom up requires a multidisciplinary approach. This arena is unquestionably in the nano-dimension, where all fields of science and engineering meet. New ideas will be fostered from collaboration among scientists with diverse backgrounds. As Francis Crick put it, “In nature, hybrid species are usually sterile, but in science the reverse is often true. Hybrid subjects are often astonishingly fertile, whereas if a scientific discipline remains too pure it usually wilts”.

### Acknowledgments

We are thankful for the invaluable support and exciting collaboration by various colleagues. We would like to thank Elisa Molinari, Rosa Di Felice, Francesca De Rienzo, Stefano Corni and Paolo Facci at S<sup>3</sup>-CNR-INFN research center in Modena (Italy), Gerard Canters and Martin Verbeet at Leiden University (The Netherlands), Salvatore Masiero, Tatiana Giorgi, Gianpiero Spada and Giovanni Gottarelli at University of Bologna (Italy), Roberto Cingolani, Valentina Arima, Adriana Biasco, Alessandro Bramanti, Franco Calabi, Stefano D’Amico, Eliana

D'Amone, Antonio Della Torre, Pier Paolo Pompa and Paolo Visconti at NNL-CNR-INFM research center in Lecce (Italy). Financial support by NNL-CNR-INFM, EC through SAMBA project and Italian MIUR (FIRB molecular devices) is gratefully acknowledged.

## 6

# DNA Nanodevices: Prototypes and Applications

*Friedrich C. Simmel*

### 6.1

#### Introduction

The unique biochemical and biophysical properties of DNA can be utilized to construct artificial, machine-like molecular structures which can perform simple mechanical or computational tasks, or both. This chapter gives an overview over the first prototypes of such “DNA nanodevices” as well as over recent developments towards functional DNA machines. In contrast to earlier review articles on this subject, particular emphasis is put on possible applications of DNA nanodevices in the life sciences – DNA devices interacting with proteins, as biosensors or as components of drug delivery systems.

The outline of this chapter is as follows. Section 6.2 gives a short introduction into the most important properties of DNA which make this molecule so interesting for nanoscale science and technology. Section 6.3 deals with “simple DNA devices” – prototype devices which can perform simple movements on the nanoscale. Section 6.4 focuses on more recent developments of “functional” nanodevices with an emphasis on possible applications in the life sciences. DNA-based molecular motors and automata will be discussed as well as the interaction of DNA devices with proteins. Section 6.5 deals with problems related to the construction of autonomous or “free-running” DNA devices and discusses a variety of different concepts to achieve such autonomous behavior. Section 6.5 closes the chapter with a few concluding remarks.

### 6.2

#### DNA as a Material for Nanotechnology

##### 6.2.1

#### Nanoscale Science

One of the main goals of nanotechnology is the manipulation of matter at the level of single molecules or atoms. Such ultimate control could lead to the development

of new functional materials and devices which obtain their functionality from the ordered assembly of components on the molecular scale. In the life sciences, such molecularly ordered systems could lead to extremely sensitive and even autonomous sensors and to intelligent drug delivery units.

One approach towards nanoscale control – often termed the “top-down” approach – is the manipulation of matter using macroscopic machines. Using scanning probe techniques, for example, the manipulation of single atoms or molecules has already been demonstrated during the last decade [1, 2]. Even though such examples show impressively the degree of control on the atomic level that has been achieved so far, it is not clear how scanning probe or other “top-down” techniques could be used for fast and efficient assembly of a large number of nanoscale components.

A different approach to molecular-scale engineering does not involve the “direct” manipulation of molecules and atoms with the help of a macroscopic device, but rather the utilization of self-assembly and self-organization principles. This approach is inspired by biological systems which often serve as “prototypes” for self-assembled nanotechnological structures.

In biological systems, complex and comparatively large structures are formed from smaller and simpler building blocks by “molecular recognition” events – usually the cooperative action of a multitude of weak bonds between two or more molecules which result in strong and highly specific interactions. Molecular construction is often assisted by “molecular machines” or enzymes – themselves self-assembled macromolecular complexes – which, among others, catalyze reactions, assist molecular transport or transduce signals. In addition, the molecules in a living cell are intimately linked within complex interaction networks which give rise to fascinating “emergent” properties.

Naturally, all these features would be highly desirable for artificial nanosystems. For these reasons, researchers in the field are trying to utilize the molecular recognition properties of biological molecules for the construction of nonbiological structures. Furthermore, first attempts have been made to construct artificial analogs of biological molecular machines and motors. One of the most interesting and most widely used biomolecules in this context is the famous molecule of heredity – DNA.

### 6.2.2

#### **Biophysical and Biochemical Properties of Nucleic Acids**

There are a number of good – and practical – reasons for the utilization of DNA in nanoscience (summarized in Fig. 6.1). The main feature of interest, of course, is the base-pairing interaction between complementary DNA bases which was discovered more than 50 years ago [3]. DNA molecules are composed of so-called nucleotides which themselves consist of a sugar unit (2'-deoxyribose) with a phosphate group and a “base” attached to it. The bases in DNA are the purines adenine (A) and guanine (G) and the pyrimidines thymine (T) and cytosine (C). In the Watson–Crick (WC) base-pairing scheme, the bases A and T bind together

**Figure 6.1.** The most important features of DNA for nanoscience. *Base-pairing:* The specific binding between adenine (A) and thymine (T), on the one hand, and guanine (G) and cytosine (C), on the other hand, is the basis of the unique molecular recognition properties of DNA. *Base sequence:* In ssDNA, nucleotides which consist of deoxyribose, phosphate and a base are linked together. The bases can be chosen arbitrarily and therefore large numbers of distinct DNA molecules with different base sequences are possible. *Programmability:* If two

DNA sequences are complementary, they may bind together to form a DNA duplex structure, i.e. sequence determines structure. *Nanoscale dimensions:* Under normal conditions DNA duplexes are right-handed double-helices with a diameter of 2 nm. *Mechanical properties:* On the nanoscale, DNA is a rigid molecule. The persistence length, i.e. the length over which the correlation between the tangential vector  $t(s)$  decays, is of the order of 50 nm or 150 base pairs.

via two hydrogen bonds, whereas G and C are connected via three such bonds. In DNA, the nucleotides are linked together by the phosphate groups which connect the 3' position of deoxyribose of one nucleotide with the 5' position of the sugar ring of the following nucleotide. This linkage endows the DNA strand with a “direction”, e.g. 5'-AG-3' and 5'-GA-3' (where the sequence is read from the 5' end of the first nucleotide to the 3' end of the last nucleotide) are two different molecules. If two DNA molecules with “complementary” sequences are brought together, they can bind to each other and form a DNA duplex. Here it is important that the two strands have opposite directionality, i.e. a DNA strand with sequence 5'- $N_1N_2 \dots N_{n-1}N_n$ -3' will bind to a strand with sequence 5'- $\underline{N}_n\underline{N}_{n-1} \dots \underline{N}_2\underline{N}_1$ -3', where  $\underline{N}_i$  denotes the WC complement of  $N_i$ . Under standard buffer conditions, the DNA duplex will adopt a double-helical structure with a diameter of 2 nm and a helix pitch of roughly 10.5 base pairs. The base pairs stack upon each other and

are “hidden” within the double helix. The planes defined by the base pairs are oriented roughly perpendicularly to the axis of the helix, whereas the sugar units with the negatively charged phosphates point radially away from it. The vertical distance between two subsequent base pairs is approximately 0.34 nm. The phosphate linkages make DNA a highly negatively charged polyelectrolyte. Due to the double-helical structure and this high charge density, duplex DNA is a relatively rigid molecule. In terms of polymer science, the persistence length  $L_p$  of double-helical DNA is of the order of 50 nm or 150 base pairs. This is a measure for how far one has to follow the contour of a polymer until the original orientation is lost – essentially this is a measure of its flexibility. More technically,  $L_p$  is the correlation length of the tangent vector of the polymer. In the worm-like chain (WLC) polymer model, we have  $\langle \vec{t}(s) \cdot \vec{t}(0) \rangle = \exp(-s/L_p)$ , where  $s$  is the coordinate along the polymer and  $\vec{t}(s)$  is the tangent vector at position  $s$ . An  $L_p$  of 50 nm makes DNA a considerably less flexible molecule than most synthetic polymers. For nano-construction, DNA can thus simply be regarded as a stiff molecular rod. At the same time, DNA is much more flexible than other biopolymers such as the cytoskeletal F-actin or microtubuli. It is therefore not straightforward to produce ordered micron-scale structures with DNA.

By the proper choice of DNA sequences, one can also *avoid* the formation of duplex structures. To this end, sequences have to be chosen in such a way that they are not complementary to any other DNA molecule – or to itself – over stretches of more than a few bases. In contrast to double-stranded (ds) DNA, single-stranded (ss) DNA is a much more flexible polymer with a persistence length on the order of 1 nm. By “programming” DNA molecules to form partly double-stranded and partly single-stranded regions, one can therefore construct molecular networks consisting of rigid and flexible elements.

Unlike the folding of amino acid chains in proteins, the formation of secondary and tertiary structure in nucleic acids is hierarchical and sequential [4] – the binding energies for base-pairing are much larger than the energies for other interactions between remote residues, and therefore DNA and RNA folding are dominated by secondary structure formation. The prediction of the formation of base-paired regions within one DNA molecule or those formed between several DNA molecules therefore represents a major step in accurate structure prediction for nucleic acids structures. In the absence of significant three-dimensional (3-D) interactions between distant sections of a DNA or RNA molecule, it is already the final step. This property makes the relation between DNA sequence and structure much more transparent than in proteins and therefore a “rational” design of DNA structures can be achieved much easier.

This rational design is also facilitated by the wealth of thermodynamic data available for nucleic acids structures. Based on these data, thermodynamic quantities such as the free energy of formation of DNA structures or useful experimental parameters such as the melting temperature of a given DNA duplex (the temperature at which half of the duplexes are dissociated into single strands) can be calculated relatively reliably. In a given set of DNA molecules, strands may also hybridize to each other in several alternative configurations and here thermodynamic calcula-

tions aid in the design of structures which mainly self-assemble into one specific, desired structure.

Maybe one of the most important practical features of DNA, however, is the availability of automated synthesis methods which allow the production of reasonable quantities of DNA with virtually any desired base sequence. A designed DNA structure can therefore be readily translated from a sequence on your computer to a real molecule.

### 6.2.3

#### **DNA Nanoconstruction**

The unique properties of DNA summarized in the previous section have indeed already been utilized for the realization of a number of impressive supramolecular constructions. Starting with the synthesis of a DNA molecule with the topology of a cube by Seeman and coworkers in 1991 [5]. DNA has been used to construct molecules with the structure of a truncated octahedron [6], DNA catenanes [7], tetrahedra and octahedra [8, 9], and other geometrical objects [10]. DNA has also been used to construct 2-D molecular networks from DNA branched junctions [11, 12]. When these networks fold back to themselves, they can also form DNA “nanotubes” [13–15]. Recently, such networks have even been utilized to arrange nanoparticles and proteins in two dimensions [16–18]. Attempts to extend these structures into the third dimension are currently being made in a number of laboratories.

## 6.3

### **Simple DNA Devices**

The biochemical and mechanical properties of DNA cannot only be used for the construction of static supramolecular structures, but they can also be utilized to achieve motion on the nanometer scale. So far, one can discern essentially two strategies. Some of the devices rely on conformational changes of the DNA molecules themselves which occur under certain buffer conditions. Other devices exploit the different rigidity of ssDNA and dsDNA, and switch back and forth between several structures by the addition or removal of DNA “fuel” or “set” strands.

### 6.3.1

#### **Conformational Changes Induced by Small Molecules and Ions**

The presence of multiply charged cations can lead to marked changes in DNA structure. DNA strands with a sequence of repeating CG residues, for example, may undergo a transition to the so-called Z form of DNA in the presence of cobalt hexammine. Z-DNA is a left-handed helical conformation of DNA and the transition from B form DNA (the “usual” right-handed double-helical DNA conformation) is therefore associated with a change in helicity of the molecule. In the “B–Z

device” [19], the B–Z transition has been utilized to produce nanoscale rotatory motion. To this end, the DNA sequence  $d(CG)_{10}$  which tends to undergo the B–Z transition, was flanked by two DNA supramolecular structures which do not. When the  $d(CG)_{10}$  sequence was switched into the Z form, the two flanking parts rotated with respect to each other. Experimentally this could be proved by fluorescence resonance energy transfer (FRET) measurements between two strategically attached fluorescent dyes. In FRET, excitation energy is transferred from one donor fluorophore to another chromophore in close proximity. The strong distance dependence of this effect in the nanometer range makes it extremely valuable for the characterization of nanoscale motions. Consequently, it is the most commonly used experimental technique – apart from gel electrophoresis – to characterize the operation of DNA nanodevices.

Another example where the presence of cations influences DNA structure is related to the phenomenon of DNA condensation – even though duplex DNA is highly negatively charged, two DNA helices can overcome their mutual electrostatic repulsion in the presence of multivalent cations such as  $Mg^{2+}$ , putrescine, cobalt hexammine, spermidine or spermine [20]. In Ref. [21], magnesium ions were utilized to switch a network of biotinylated DNA molecules linked by streptavidin from an uncondensed into a condensed structure, in which neighboring DNA duplexes formed supercoils. This was accompanied by a movement of the nodes of the network with respect to each other.

The presence of protons may also induce a DNA conformational change. At low pH values the DNA bases adenine and cytosine, for example, are protonated at their N6 or N4 positions, respectively. Protonated cytidine ( $pK_a = 4.2$ ) participates in a number of unconventional DNA secondary structures, e.g. the DNA “i-motif” and a DNA triplex structure. The i-motif [22] can form between DNA strands with repetitive stretches of cytosine residues and is held together by hemiprotonated cytosine pairs (Fig. 6.2a). The intramolecularly formed i-motif shown in Fig. 6.2(b)

**Figure 6.2.** Unusual DNA structures which form with protonated cytosine residues. (a) A hemiprotonated CC+ base pair. (b) A C-rich strand of DNA forms the so-called “i-motif” at low pH values due to intramolecular CC+ base-pairing. (c) Protonated cytosine also plays

a role in DNA triplex formation. Here, the lower two DNA strands bind to each other in standard WC mode, whereas the upper strand binds to the middle strand in the “Hoogsteen” mode. This is only possible when the cytosines are protonated.

has recently been utilized for a simple proton-driven DNA device [23]. Upon the addition of a small amount of hydrochloric acid to a solution of the DNA device strand 5'-CCCTAACCCTAACCCTAACC-3', the molecule folds into the *i*-motif. When the pH is subsequently raised by the addition of sodium hydroxide, the molecule unfolds again. At neutral pH, the DNA strand is available for hybridization and it can form a DNA duplex with its complement strand. During one operation cycle, the 5' and 3' ends of the device strand therefore move from a proximate position with a distance on the order of 1 nm to a position where they are separated by roughly 6 nm.

Under certain conditions DNA can also form triplex structures. In a triplex, two strands bind with each other in conventional WC mode while the third strand binds to the duplex via other base-pairing interactions. One such triplex structure is based on the binding of two homopyrimidine strands to one homopurine strand. In the example in Fig. 6.2(c), the homopurine strand contains the repetitive sequence  $d(GA)_n$ . One homopyrimidine strand [with the sequence  $d(TC)_n$ ] binds to the homopurine strand by WC base-pairing while the other homopyrimidine strand binds via “Hoogsteen” base-pairing [24]. The latter binding mode is only possible when the cytosine residues are protonated. One can therefore switch between a duplex and a triplex DNA structure by lowering or raising the pH value [25]. This duplex–triplex transition has already been utilized to drive the simple DNA mechanical device depicted in Fig. 6.3 [26]. Here, a long DNA strand L has been hybridized to two shorter DNA strands F and S. The strands F and L form a struc-

**Figure 6.3.** A proton-driven DNA nanodevice based on the duplex–triplex transition. The device consists of three DNA strands L, F and S. L and F form two rigid double-stranded “arms” connected by a flexible single-stranded hinge. Strand S is also hybridized to L and contains a DNA sequence which is able to form a triplex structure. The sequence which can bind to the duplex formed by S and L is contained in the unhybridized section schematically depicted as a “random coil” in the open

state. At low pH, the cytosine residues in this coil region are protonated and this section of L can bind to the S–L duplex in Hoogsteen mode, thereby forming a triplex structure. This closes the arms of the structure. The structure can be cycled between the open, duplex state and the closed, triplex state by changing the pH value of the reaction solution between pH 8 and pH 5. (Reprinted with permission from Ref. [26], © 2004, Wiley-VCH.)

ture characterized by two rigid arms connected by a short flexible hinge (very similar to the structure of other, hybridization-driven devices to be discussed in the next section). Strand S also hybridizes to a section of L, while a part of L remains unhybridized at high pH values. S contains a hompurine sequence and can form a triplex structure with L at low pH values. As shown in Fig. 6.3, in the triplex configuration strand L folds back on itself and therefore moves the two arms of the device with respect to each other.

Another (maybe the earliest) example of a DNA nanomechanical device, demonstrated by the Seeman group, was based on the influence of the intercalating dye ethidium bromide on DNA structure [27]. Here, the position of base pairs in a cruciform DNA junction embedded into a circular dsDNA construct could be shifted by applying torsional stress to the DNA circle via the incorporation of the intercalator.

One great disadvantage of the devices based on conformational changes caused by small molecules or ions is the fact that here DNA only plays a structural role – the DNA code is only utilized for the construction of the devices, but not for their control. Hence all of the devices in a reaction volume are affected by a buffer change simultaneously and they cannot be addressed individually. This issue is, at least in principle, resolved in hybridization-driven devices.

### 6.3.2

#### Hybridization-driven Devices

A very different operation principle underlies hybridization-driven DNA devices. Here, the conformational change of a DNA supramolecular structure is brought about by the hybridization of “fuel strands” with single-stranded “motor” sections. “DNA tweezers” were the first prototype of this kind of device [28]. Their operational principle is shown in Fig. 6.4. In the open state, the DNA tweezers consist of three strands of DNA. One 40-nucleotide long strand is hybridized to two other, 42-nucleotide strands in such a way that together they form two 18-base pair (6-nm), rigid duplex “arms” connected by a 4-nucleotide, single-stranded flexible “hinge”. In the open state, each of the 42-nucleotide strands still has 24-nucleotide (i.e. 42–18 nucleotides) single-stranded extensions available for hybridization. The addition of a 56-nucleotide “fuel” strand which is complementary to these extensions can then be used to close the tweezers structure, i.e. the two arms are forced together by the hybridization with the fuel strand. A “trick” is used to switch the device back to its original configuration. In the closed state, from the 56 nucleotides of the fuel strand, 8 nucleotides are deliberately left single-stranded. These 8 nucleotides serve as a “toehold” for another “anti-fuel” or “reset” strand which is exactly complementary to the fuel strand. A biochemical process known as “branch migration” unzips the structure, when fuel and anti-fuel try to bind with each other. After completion of this process, a stable 56-base pair “waste” duplex is formed and the DNA tweezers are in their open configuration once more. The device can be operated cyclically by the alternate addition of set and reset strands.

The same operation principle has since been used in many other DNA devices: a

**Figure 6.4.** Operation cycle of the DNA tweezers (*cf.* Ref. [28]). In the open state, the DNA tweezers consist of three DNA strands which together form a “tweezers”-like structure consisting of two double-stranded arms connected by a flexible single-stranded hinge. The arms have two single-stranded extensions to which a “set” or “fuel” strand can attach. The hybridization of the fuel strand with these extensions closes the tweezers structure. Another fuel strand which is completely

complementary to the first one can reset the tweezers to the open state. When the tweezers are in the closed state, the reset strand attaches to the single-stranded “toehold” region of the set strand (gray) and displaces the set strand from the tweezers by “branch migration”. After completion of this process, a double-stranded waste product is formed by the set and reset strand, while the open state of the tweezers is restored.

simple variation of the DNA tweezers is the DNA actuator device [29, 30] shown in Fig. 6.5. Here, instead of two single-stranded extensions, the arms of the tweezers were connected by a single-stranded loop. Depending on the sequence of the fuel strands, the device could either be closed similarly to the tweezers or stretched into an elongated conformation. Whereas the intermediate configuration is a rather floppy structure (like the open tweezers), the closed and the stretched configurations are much more rigid. The distance between the fluorescent dyes attached to the arms of the actuator is switched from roughly 2 nm in the closed state to approximately 14 nm in the stretched state.

A rotatory DNA device based on multiple crossover molecules (complex supramolecular DNA structures in which DNA strands are shared between two or more DNA duplexes) was demonstrated by Yan and coworkers [31]. Their DNA structure could be switched between a “paranemic crossover” (PX) conformation and a “juxtaposed” ( $JX_2$ ) configuration (Fig. 6.6). The PX motif is a four-stranded DNA structure in which two neighboring duplexes exchange strands of the same directionality at every possible site [32]. If parts of this motif are removed and replaced by DNA sections without crossover, molecules such as the juxtaposed  $JX_2$  structure result in which two helices are rotated with respect to the corresponding PX structure (Fig. 6.6). In the PX- $JX_2$  device, the central section of a supramolecular structure based on the PX motif was created with DNA molecules which could be removed by the same branch migration “trick” as used for the operation of the DNA tweezers. After removal, these molecules could be replaced by DNA strands which switched the device to a  $JX_2$  configuration. Again using branch migration, the device could be switched back to the original PX structure.

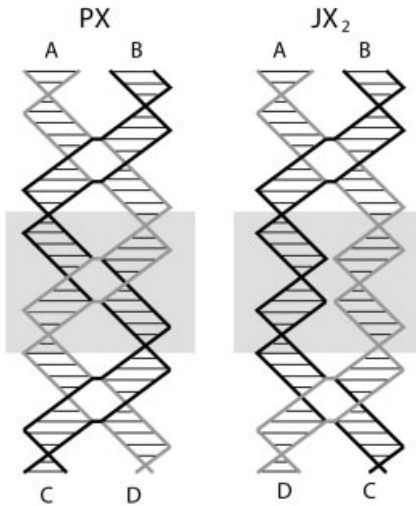

**Figure 6.5.** Operation cycle of a DNA actuator [30] switchable between three mechanical states. The actuator is similar to the tweezers and consists of two DNA strands (A and B) which hybridize together to form a circular structure as depicted in (a). By the addition of appropriate fuel or removal strands  $F_1$ ,  $\bar{F}_1$ ,  $F_2$  or  $\bar{F}_2$ , the device can be switched between a relaxed state (a), a closed state (b) and a stretched state (c). Removal strands can bind to the toehold sections depicted in gray of the fuel strands and remove them by branch migration. The ends of the arms (circular and triangular symbols stand for fluorescent dyes which are used for characterization) are switched from a short distance of a few nanometers in the closed state (b) to almost 14 nm in the stretched state (c). (Reprinted with permission from Ref. [30], © 2002, American Institute of Physics.)

Other devices utilizing branch migration were based on unusual DNA structures such as guanine quartets (“G quartets”). In a G quartet, four guanine bases bind to each other into a cyclical configuration via non-WC base-pairing interactions. In the experiments described by Li and Tan [33] and by Alberti and Mergny [34], ssDNA structures formed by several stacked intramolecular G quartets were switched to an elongated duplex structure by the addition of a complementary DNA fuel strand. This transition could be reversed by removing the fuel strand using branch migration. The overall effect was a detectable change in distance between the 5' and 3' ends of the device strand from about 2 nm in the quadruplex state to 7 nm in the duplex state.

#### 6.4 Towards Functional Devices

With the prototype devices described in the previous section it was established that it is possible to construct DNA structures which can perform movements on the nanometer scale. Except for their building material, these structures are nonbiological and completely “designed”. Their realization can therefore be regarded as an

**Figure 6.6.** The transition between the PX and the  $JX_2$  structure forms the basis of a nanomechanical device by Yan and coworkers [31]. Both structures are formed by two DNA duplexes which share common DNA strands. In the PX (paranemic crossover) structure, the two DNA double-helices exchange strands wherever it is possible, whereas in the  $JX_2$  (juxtaposed) structure strands do not cross over in the middle part of the structure. Note

that in the  $JX_2$  structure, the helices C and D have a different position than in the PX structure. In Ref. [31], Yan and coworkers managed to switch the inner section of these structures (gray) using removable DNA strands and branch migration. This leads to a switchable transition between the PX and the  $JX_2$  form. The corresponding “rotation” of the duplexes C and D with respect to each other can be observed.

important step towards the realization of complex artificial molecular machinery. However, the tasks these prototype devices could perform were not particularly “useful”. In fact, their movements (rotation or stretching) were mostly idle, i.e. the motion was just an internal rearrangement of parts. To lift DNA devices to the next level of complexity, it is important to design structures that can perform specific tasks and interact with their environment. There are a number of different approaches towards such functional devices. One is to achieve directed motion rather than idle movements with the goal to produce artificial molecular motors. Another possibility for functional devices is to couple DNA devices to nanoscale structures like other biomolecules or nanoparticles. Such hybrid structures could be particularly interesting for applications in biotechnology and the life sciences.

#### 6.4.1

##### Walk and Roll

Among the most fascinating biological molecular machines are molecular motors such as kinesin, dynein or the myosins [35]. Kinesin and dynein motors walk along cytoskeletal microtubuli, whereas myosin motors walk on supramolecular

tracks made from actin. Kinesin, dynein and certain kinds of myosin help to actively transport vesicles within cells. Myosin motors are also responsible for other kinds of active movement in eukaryotic cells, including muscle contraction in higher eukaryotes. Many other enzymes like DNA or RNA polymerases can also be regarded as biological molecular motors. Clearly, the ability to actively transport molecular components or to exert forces on a molecular scale would also be highly desirable for nanotechnological applications or in biotechnology. However, building an artificial molecular motor is not an easy task.

Molecular motors work very differently from macroscopic machines as all movements on the molecular scale are dominated by Brownian motion. The energies available for the operation of molecular motors are only slightly higher than the thermal energy and they are therefore subjected to large fluctuations. Research on biological molecular motors has shown that these tiny machines do not work against Brownian motion, but rather utilize it for their operation. In many cases, a “Brownian ratchet” mechanism seems to be at work, where an irreversible chemical step is utilized to “rectify” the undirected Brownian motion [36]. The general features of such biological motors now serve as a guideline for the construction of artificial DNA motors.

Three different concepts to achieve directional motion in DNA-based systems are depicted schematically in Fig. 6.7. They correspond to the DNA walkers by Shin and Pierce [37] and Sherman and Seeman [38], the molecular “gears” by Tian and Mao [39], and the enzyme-assisted walker by Yin and coworkers [40]. The first simple DNA walker was introduced by Shin and Pierce [37]. A double-stranded DNA scaffold with ssDNA “docking positions” attached to it serves as a track for the DNA walker. The walker itself is a DNA duplex with two single-stranded “feet”. As explained in Fig. 6.7(a), DNA fuel strands are used to connect the single-stranded feet to the docking positions on the track. The connector strands are equipped with single-stranded toehold sections and can be displaced from the device by removal strands via branch migration. The free DNA foot can then be connected to the next free position on the track. This can be repeated several times with the appropriate connector and removal strands to move the walker to arbitrary positions on the track.

A similar walking device based on more complex DNA structures was realized by Sherman and Seeman [38]. In their work, the walker consists of two DNA duplexes joined by flexible single-stranded linkers. The walker can be translocated along a track which consists of a triple crossover molecule (“TX”, three double helices connected by shared DNA strands) which contains single-stranded position labels. Similar to the walker by Shin and Pierce, the duplexes of the Sherman and Seeman walker also contain single-stranded “feet” and can be attached to the docking positions on the TX track via DNA linker molecules. Again, these connections can be removed by branch migration and the free foot can be connected to the next position.

As shown in Fig. 6.7(b), the same principle can be applied to achieve a different kind of unidirectional motion. In the “molecular gears” system realized by Tian and Mao [39], two DNA “circles” roll against each other driven by hybridization

**Figure 6.7.** Three examples for unidirectional motion realized with DNA devices. (a) A simple walker system. A walker, which consists of a DNA duplex (or a more complex structure) and single-stranded “feet”, can attach to a dsDNA track from which single-stranded binding positions or “footholds” extend. The attachment of the feet is achieved with DNA fuel strands  $F_1$  and  $F_2$ , which are partly complementary to the footholds and partly complementary to the feet. The connection between the walker and track can be broken again with removal strands which can remove the fuel strands by branch migration. Using a different fuel strand the free foot can be attached to another position on the track. This walking principle has been applied in Refs. [37, 38]. (b) Essentially the same principle as in (a) can be used to make two DNA circles roll against

each other. The two circles with single-stranded extensions can be connected to each other with one or two fuel strands. Using fuel and removal strands in the correct order, the circles can roll against each other (corresponds to the device in Ref. [39]). (c) An autonomous enzyme-driven “walker” (cf. Ref. [40]). The walker system consists of a dsDNA track with double-stranded position strands. Initially, the first two neighboring position strands have sticky ends which may hybridize with each other. The two position strands can be ligated together and cut with a restriction enzyme. This creates new sticky ends on the position strands. The net effect is the transfer of a few DNA bases from one position to the next (depicted in gray). Using two different restriction enzymes, transport of the bases can autonomously occur over a longer track with many positions.

and branch migration. The two circles consist of a closed single strand to which three strands are hybridized containing flexible hinges made of thymine residues and single-stranded extensions (“teeth”). The two circles can be connected by DNA linker strands which are partly complementary to one “tooth” of one circle and another tooth of the other circle. Due to the flexible hinges, two circles can be con-

nected by two linker strands simultaneously. As in the case of the walkers, the linker strands contain single-stranded toehold sections at which removal strands can attach and displace the linker strands from the device. By the alternate addition of linker and removal strands in the correct order, the two circles can be made to roll against each other in one direction.

A different concept to achieve unidirectional motion in a DNA-based system was demonstrated by Yin and coworkers [40]. In contrast to the other walkers, their system needs the help of DNA-modifying enzymes, but it walks “autonomously”. The basic idea is depicted in Fig. 6.7(c). Again, the walker (which now consists of only a few DNA bases) sits on a DNA track which consists of double-helical DNA with duplex position strands. These position strands have short, single-stranded ends. If the ends of neighboring strands are complementary, they can hybridize with each other and can then be ligated by a DNA ligase. The sequences of these duplexes are chosen such that in the ligated state the recognition sequence for a restriction endonuclease is formed. Upon the addition of the endonuclease, the connected neighboring position duplexes are cut and a new pair of sticky ends is produced. In this way, the DNA bases representing the “walker” are transferred from one to the next position. Using two different restriction enzymes, the system can be designed to unidirectionally transport the walker bases along a track without ever stepping back [40].

Quite recently, several improvements on these systems could be demonstrated. Turberfield and coworkers could realize an autonomous walker system similar to the system by Yin and coworkers, but now driven by the action of a nicking enzyme and branch migration [41]. In this new system, a longer DNA fragment is passed from one binding position to the next. In a different approach, Mao and coworkers could utilize the action of a DNA enzyme (*cf.* Section 6.5.1) to achieve autonomous unidirectional motion along a track [42].

The DNA walker systems demonstrated so far essentially belong to the “Brownian” type. The walkers diffusively find a binding position on a track and a chemical reaction (hybridization or enzymatic ligation, restriction, etc.) is used to fix the position. Directionality is introduced by the choice of the base sequence of the track positions and the walkers. So far, the walkers also move without load – so nothing can be said about the efficiency of these systems. It will be very interesting to see in the future how DNA walkers behave when they have to carry something, i.e. when they have to perform work.

#### 6.4.2

##### **Interaction with Proteins**

The numerous advantages of DNA mentioned in Section 6.1.1, i.e. its controllability, programmability and stability, allow us to rationally construct artificial molecular devices which are (by their very nature) “automatically” biocompatible. The life sciences should therefore be a particularly interesting and fruitful area for the application of ideas developed in the context of DNA-based nanodevices: moving molecular components, sensing, information processing, etc.

Exciting possibilities arise, for example, when DNA nanodevices are made to interact with proteins. This interaction can be achieved in a variety of different ways: proteins can be coupled to DNA chemically or biochemically, proteins may be utilized which naturally bind to DNA, and proteins can bind to “aptamers” – nucleic acids which fold into a specific structure in which they strongly bind to a protein.

Many interesting examples for biochemically coupled protein–DNA conjugates come out of the Niemeyer lab. One example, not directly related to DNA nanomechanical devices, is the utilization of DNA recognition in the so-called immunopolymerase chain reaction (PCR) technique [43]. Here biotinylated antibodies are linked to biotinylated DNA molecules via streptavidin. These DNA–protein constructs can then be used to detect a primary antibody–antigen recognition event by the amplification of the DNA fragment with the PCR. Another very interesting example for supramolecular constructs produced from biotinylated DNA and proteins is the assembly of bienzymic complexes from NADH:FMN oxidoreductase and bacterial luciferase [44]. NADH:FMN oxidoreductase reduces flavin mononucleotide (FMN) to FMNH<sub>2</sub>, which binds to luciferase. Luciferase in turn oxidizes an aldehyde to a carboxylic acid and emits blue light. As bacterial luciferase needs FMNH<sub>2</sub> for the reaction, holding the NADH:FMN oxidoreductase in close proximity greatly enhances its activity. Such a concept may allow one to tune biochemical activity by controlling the distance between enzymes in DNA-scaffolded multi-enzyme complexes.

There are also many proteins which naturally interact with DNA: nucleases, ligases, polymerases, recombination proteins, transcription factors, to name but a few. In many cases these DNA-binding proteins recognize specific DNA sequences and in some cases they also distort the structure of DNA. Seeman and coworkers demonstrated recently that DNA devices can be used to estimate the work performed by a DNA-binding protein when it distorts the double helix [45]. As protein, the *Escherichia coli* integration host factor (IHF) was used which bends the DNA double helix by more than 160°. The binding site for IHF was sandwiched between two DNA TX structures which were fluorescently labeled with a FRET pair (Fig. 6.8). The bending of the construct can be monitored with the FRET signal. To measure the work performed by the enzyme upon bending, cohesive ends of various lengths were also attached to the TX units. Upon bending the DNA, IHF also has to disrupt the duplex formed by these cohesive ends. The work can therefore be determined from the free energy of formation of the duplex. Interestingly, this concept is very similar to a recently demonstrated DNA-based force sensor [46], but here the “measuring device” itself is also on the molecular scale.

A different approach to DNA–protein hybrid devices is not to utilize proteins which bind to DNA, but rather to evolve specific DNA or RNA sequences which bind to proteins. Such so-called “aptamers” can be isolated in *in vitro* selection experiments (SELEX) for a large variety of proteins and also small ligands such as ATP [47]. Aptamers bind specifically to their targets and in many cases have comparable binding constants as antibodies with their antigens. The great advantage of aptamers as compared to antibodies is their simple preparation and their stability. In particular, once isolated, DNA aptamers can be easily synthesized using the

**Figure 6.8.** A DNA device that can be used to measure the work performed by a DNA-binding protein which distorts the double-helix. (a) The device consists of two connected triple-crossover (TX) constructs (left and right part; these are similar to the structures in Fig. 6.6, but with three interconnected double helices). The upper domains of the TX structures are connected by a DNA duplex which contains the recognition site for the DNA-binding protein IHF. The lower domains are connected by a

cohesive part which consists of two complementary single-stranded sections of DNA. (b) When IHF binds to its recognition site it distorts the DNA duplex connecting the TX structures. However, to be able to do so it has to perform additional work to disrupt the cohesive tract connecting the lower domains of the device. Using cohesive tracts of varying lengths one can estimate the maximum work the protein is able to perform. (Reprinted with permission from Ref. [45], © 2004, Wiley-VCH.)

automated DNA synthesis methods mentioned before. In the context of DNA nanodevices, one additional advantage is that they can be incorporated into DNA nanomechanical devices or supramolecular structures.

Recently, Dittmer and coworkers [48] applied the concept of switching a DNA device between two conformations using branch migration to a DNA aptamer structure. The operation principle of this device is explained in Fig. 6.9. The nanodevice is based on a DNA aptamer selected to bind the human blood-clotting protein, thrombin. The 15-base DNA sequence 5'-GGTTGGTGTGGTTGG-3' folds into a secondary structure consisting of two G-quartets, in the presence of potassium ions (Fig. 6.9). The device in its standard state binds thrombin. Release of the protein can be triggered by the addition of a single-stranded effector DNA containing a sequence that is complementary to a portion of the aptamer sequence, resulting in an unfolding of the aptamer to form a duplex, which is unable to bind the protein. The protein can be bound once again by the addition of another DNA strand, fully complementary to the previously added strand, which removes the effector by branch migration. The aptamer is thus allowed to return to its protein-binding quadruplex form. By the alternate addition of effector strands, the DNA device can repeatedly made to bind or release the protein – the device can therefore be thought of as a “nanohand”. In principle, similar devices can be constructed to bind other proteins and ligands if an appropriate aptamer exists.

**Figure 6.9.** A DNA device based on a DNA aptamer. The aptamer sequence 5'-GTTGGTGGTGGTGG-3' folds into a structure characterized by two stacked guanine quartets. In this structure, the aptamer binds strongly and specifically to the protein thrombin. To be able to switch this aptamer efficiently between a protein-binding and a non-binding conformation, it has been extended by a 12-nucleotide "toehold" section. In the folded state (I) the aptamer device A binds to the protein thrombin (T). In (II), the opening

strand Q attaches to the 12-nucleotide toehold section of the device and displaces the protein. In the stretched duplex conformation (III), the device cannot bind to thrombin. The removal strand R can attach to a second toehold section in strand Q and displace Q from A by branch migration. Strand A then refolds and binds the protein thrombin again. Alternate addition of Q and R strands allows repeated release and binding of the protein. (Reprinted with permission from Ref. [48], © 2004, Wiley-VCH.)

The examples mentioned in this section should give an impression of the potential of hybrid systems composed of DNA nanodevices and proteins. Such systems can have many interesting applications in the life sciences. DNA structures can be used to arrange proteins into certain geometries to fine-tune or study their interactions. DNA nanodevices can also be used as sensors which measure the work performed by DNA-binding proteins. Finally, DNA aptamers can be combined with

switchable DNA nanostructures to control the binding or release of molecules. This may find applications in biosensors or in intelligent drug delivery systems.

### 6.4.3

#### Information Processing

In biology DNA is used for the storage of genetic information. For artificial applications, this information-carrying nature of DNA has been utilized in the field of “DNA computing” for the solution of computational problems such as the “Hamiltonian path problem” [49], satisfiability problems [50–52] and many others. One more recent development in DNA computing is the construction of molecular automata which do not solve hard computational problems, but which can autonomously perform simple logical operations based on molecular inputs. This should be particularly interesting in the context of intelligent drug delivery systems. Here, one would like to construct autonomous molecular devices which can sense environmental information, perform a simple computation and decide which action to take, e.g. whether to release a specific molecule or not.

One approach towards autonomous information processing by DNA-based devices was taken by Benenson and coworkers [53–55]. In their work, the DNA-cleaving properties of the class IIS restriction endonuclease *FokI* were utilized to build the molecular realization of the computer-theoretical concept of “finite state machines” or “finite automata”. Finite automata are computing machines with a finite number of internal states which can undergo transitions between these states according to certain rules. A program for such an automaton consists of a series of such transitions. The operation of the automaton is based on the fact that the enzyme *FokI* cleaves a dsDNA substrate 9 and 13 nucleotides offset from its recognition, creating a 4-nucleotide sticky end. Hence, the states and input symbols for the automaton are represented by different 4-nucleotide sequences. In Ref. [53], *FokI* is used to sequentially cleave off pieces of a double-stranded program and thereby create a series of transitions between the various states of the automaton. Finite automata are related to Turing machines, but have limited computing power. In Ref. [53], Benenson and coworkers used their DNA automata to make simple decisions such as to determine whether a given input symbol occurs at least once. Keinan and coworkers recently used another class IIS endonuclease, *BbvI*, to perform similar molecular computations in a chip-based approach [56].

Benenson and coworkers, on the other hand, were able to demonstrate how their *FokI*-based DNA automaton could actually find application in autonomous diagnosis and drug delivery systems [57]. To this end, the transition molecules for a *FokI*-based DNA automaton were designed to be active only in the presence of specific mRNA molecules. With these transition molecules, a molecular computer was realized which could decide whether the levels of certain mRNA molecules were high or low. Depending on the decision, a short DNA strand was released as a “drug”. This DNA drug was chosen as an antisense molecule, which in principle could inhibit the synthesis of a cancer-related protein by binding to its corresponding mRNA.

A different approach towards autonomous computing with DNA is based on DNA enzymes. Similar to DNA aptamers, DNA enzymes are another example of DNA molecules which have functional properties in addition to their structural properties. They also fold into specific secondary and tertiary structures in which they exhibit catalytic activity. DNA enzymes (and their RNA counterparts, i.e. ribozymes) catalyze reactions such as RNA cleavage, ligation and even peptide bond formation. In Ref. [58], Stojanovic and coworkers realized several logic gates based on the action of the RNA cleaving deoxyribozymes E6 [59] and 8–17 [60, 61]. These DNA enzymes cleave RNA molecules or, alternatively, chimeric DNA/RNA hybrid molecules with an RNA base at the appropriate position, when these are bound to their substrate recognition sections. In Ref. [58], the recognition sequences are protected by self-hybridized stem–loop modules. By base-pairing with a DNA strand complementary to the loop sequence, the stem–loop modules can be opened. This makes the substrate recognition sequence accessible for the substrate, which is subsequently cleaved. By combining controlling and catalytic modules, Stojanovic and coworkers realized simple logic gates such as AND or XOR [58], a DNA half-adder [62] and a molecular computer which autonomously could play the game “Tic Tac Toe” [63]. A combination of autonomous DNA-based computers with aptamer-based molecular devices (as introduced above) seems natural. In fact, Kolpashchikov and Stojanovic recently introduced a molecular “robotic” system in which DNA logic gates controlled the binding state of a DNA aptamer for the chromophore malachite green [64].

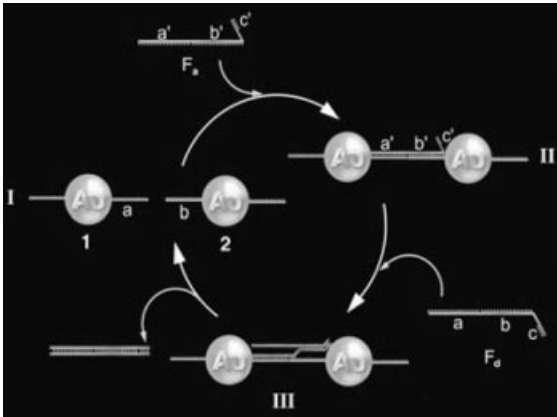

#### 6.4.4

#### Switchable Networks and Hybrid Materials

The properties of DNA nanomechanical devices may also be utilized to switch larger DNA nanostructures such as DNA-linked nanoparticle networks or DNA-based supramolecular networks between several states.

Yan and coworkers could show recently that the topology of large supramolecular DNA networks could be switched by nanomechanical actuators incorporated into these networks [65]. Again, switching between two different states was accomplished with DNA fuel strands and by using the branch migration mechanism. In a different publication, Yan and coworkers recently also demonstrated the incorporation of aptamer sequences into DNA supramolecular structures [18], which facilitated the spatial arrangement of proteins bound by the aptamers. Based on this work and ideas put forward above [44, 48], supramolecular structures are now conceivable on which several interacting proteins are held by different aptamer sequences and their distance (and hence their interactions) is regulated by actuating elements incorporated into the structures.

Similar structures can be realized which can switch the distance between inorganic nanoparticles rather than proteins. As a first example, Niemeyer and coworkers demonstrated a switchable network composed of gold nanoparticles and DNA molecules [66]. The experimental concept is displayed in Fig. 6.10. Two batches of gold nanoparticles are first tagged with thiolated oligonucleotides with

**Figure 6.10.** DNA can be used to reversibly control the aggregation of gold nanoparticles. Two species of gold nanoparticles (1 and 2) tagged with different single-stranded “address labels” can be connected using DNA strands  $F_a$  complementary to these labels. This leads to an aggregation of the nanoparticles which can be monitored, e.g. in the absorption characteristics of the sample. Removal strands  $F_d$

complementary to  $F_a$  can attach to the toehold section  $c'$  of  $F_a$  and remove the connecting strands from the aggregate by branch migration. This leads to a deaggregation of the DNA-linked nanoparticle network. By the alternate addition of  $F_a$  and  $F_d$ , the aggregation–deaggregation cycle can be performed many times. (Reprinted with permission from Ref. [66], © 2004, Wiley-VCH.)

different sequences. Two nanoparticles with different tags can then be connected by linker oligonucleotides which are partly complementary to the tags on one species of nanoparticle and partly complementary to the other. This leads to the formation of a crosslinked network of gold nanoparticles. To make the system switchable, the crosslinking oligonucleotides are equipped with a DNA “toehold” (as in the original “tweezers” system [28]) at which a DNA strand complementary to the crosslinker can attach. The crosslinker is then removed by branch migration and the nanoparticles are disconnected. By the alternate addition of crosslinkers and removal strands, the system can be driven through several operation cycles during which the mean distance between the particles is switched. In the case of metallic nanoparticles, the distance between the particles influences the coupling between surface plasmon excitations within the particles, and aggregation of the nanoparticles results in an observable shift in the absorbance of the reaction sample. This color change upon aggregation has already been applied in a variety of biosensors [67, 68] and such switchable networks may also find application in this area.

Apart from biosensing applications, switchable hybrid structures composed of DNA actuators and nanoparticles may also help to answer more fundamental questions regarding the coupling of excitations in nanoparticles, and to tune energy and charge transfer rates between them.

## 6.5

### Autonomous Behavior

Most of the devices described so far could not operate autonomously, with the exception of the autonomous walkers by Yin and coworkers [40], Bath and coworkers [41], and Tian and coworkers [42], and the computing devices by Benenson and coworkers [53] and Stojanovic and coworkers [63]. Usually, an external operator had to intervene at each step of the operation cycle of the devices and add DNA “fuel” or “effector” strands, or change the buffer conditions. While this may be no hindrance in simple applications, in many cases it might be desired to have free-running devices rather than “clocked” devices. For example, for applications in intelligent drug delivery or in nanofabrication, the devices should respond to environmental stimuli by a complex series of actions without guidance by an external operator.

#### 6.5.1

##### Driving Devices with Chemical Reactions

The successful concept of “fuel strands + branch migration” for the operation of DNA-based nanodevices has one drawback when it comes to autonomous operation: complementary fuel and removal strands cannot be added simultaneously to the reaction solution as they would immediately react with each other rather than driving a device through its states. A possible solution for this problem has been proposed by Turberfield and coworkers [69] based on the inhibition of hybridization between complementary strands by the formation of secondary structures. In Ref. [69] it is shown that the hybridization between two complementary strands can be slowed down considerably by forcing the strands into hairpin conformations using “protection strands”. Hybridization can be sped up again by DNA “catalysts” which can open these hairpin structures. To construct free-running devices using this concept, such catalyst strands would have to be incorporated into DNA nanomechanical structures. These would then be continuously driven through their states by the consumption of the metastable protected “fuel” strands. These fuel molecules could be added simultaneously as now the reaction with the DNA device would be much faster than a direct reaction.

Another realization of a self-running device was demonstrated by Chen and coworkers with a machine consisting of a DNA actuator [29] modified with an RNA-cleaving DNA enzyme [70] similar to the DNA enzymes used for computing by Stojanovic and coworkers. In its standard state, the DNA enzyme is in a compact form and the actuator assumes its closed state (Fig. 6.11). In the presence of its substrate (a DNA/RNA chimera), the enzyme extends to its catalytically active structure as it forms a duplex with the substrate and the arms of the actuator are pushed apart from each other. When the substrate is cleaved by the DNA enzyme, two short fragments remain hybridized to the device instead of one long substrate strand. The two short duplexes are thermodynamically less stable and the cleaved

**Figure 6.11.** An autonomous DNA device based on the action of a DNA enzyme. The sequence for an RNA-cleaving DNA enzyme has been incorporated into a DNA actuator similar to the one shown in Fig. 6.5. When a chimeric RNA/DNA substrate  $S$  binds to the DNA enzyme section  $E$ , the two arms of the device are pushed apart from each other. After

cleavage of the substrate the resulting shorter DNA fragments  $S^1$  and  $S^2$  unbind from  $E$ , and the device collapses into the closed state. This opening–closing motion can continue as long as substrate strands are available. (Reprinted with permission from Ref. [70], © 2004, Wiley-VCH.)

substrate is released from the device leading to the collapse of the enzyme section and thus an automatic closure of the actuator. The device will run through its operation cycle autonomously as long as the substrate is present. When using a noncleavable DNA substrate, the device can also be deliberately forced into a stalled configuration [71]. The recently demonstrated free-running walker by Tian and coworkers [42] is also based on this operation principle.

A different concept to autonomously operate buffer-driven DNA nanodevices has been demonstrated by Liedl and Simmel. It could be shown that the pH-sensitive conformational transition of a cytosine-rich DNA strand between a random coil conformation and the i-motif (Fig. 6.2b) could be driven by the oscillating proton concentration generated by a chemical oscillator [72]. In this system, the states of the DNA devices are synchronized by the dynamics of a nonlinear dynamical system rather than by an external operator.

### 6.5.2

#### Genetic Control

A very different possibility for the autonomous operation of DNA-based devices opens up when one considers the production of DNA or RNA effector molecules “on the run”. RNA molecules are produced, of course, when a gene is transcribed into mRNA by an RNA polymerase. It is therefore quite natural to think about

the utilization of genetic transcription for the operation of DNA nanomechanical devices.

It is well established that biochemical reaction networks have information-processing properties [73, 74]. This is particularly obvious in genetic networks which control the expression level of proteins through complex interactions between regulatory molecules and genes. The textbook example for a genetic switch is the *lac* operon in *E. coli* bacteria in which the expression of the protein  $\beta$ -galactosidase is regulated by the relative concentrations of lactose and glucose. Many other gene regulatory motifs with a variety of tasks and responsibilities have been found since the discovery of the *lac* operon and biochemical analogs of switches, oscillators, filters, components with memory functions and others have been identified [74].

Recently, the knowledge about these motifs has also been used to construct artificial genetic networks. By transferring circuit designs known from electrical engineering to artificial regulatory networks, such functions as a bistable genetic switch [75], a genetic oscillator [76], or a sender–receiver system [77] could be synthetically implemented in bacteria and similarly *in vitro* [78]. An overview of the developments in “synthetic biology” is given in Refs. [79, 80].

It is a tempting idea to use similar artificial genetic networks to drive DNA nanodevices through their mechanical states. One could imagine a genetic oscillator periodically producing RNA fuel strands which switch a DNA actuator from one conformation into another and back, possibly dependent on environmental variables which modulate the genetic activity. A first step in this direction was taken in Ref. [81] in which the DNA tweezers introduced in Section 6.2.2 were operated by an mRNA fuel strand which was transcribed from an artificial “fuel gene”. More recently, the transcription of fuel strands was also put under the control of simple gene regulatory mechanisms [82]. One example is shown in Fig. 6.12, where the closure of DNA tweezers by RNA fuel is controlled by the Lac repressor and the inducer IPTG. In the presence of the repressor protein LacI, fuel transcription is suppressed and the DNA tweezers are in their open state. When the inducer isopropyl-D-thiogalactoside (IPTG) is added to the transcription solution, it binds to LacI, which in turn cannot bind to the DNA substrate in this form. Consequently, fuel transcription is switched on and the tweezers close. In Ref. [82], the transcription of an appropriate removal strand has also been put under the control of a second repressor (LexA). Closed tweezers are opened by RNA fuel only in the absence of this repressor. To achieve genetic control over a series of movements, in the future the temporal order of the transcription events will have to be regulated using transcriptional cascades or feedback loops.

These initial steps demonstrate that it is indeed possible to control the action of DNA-based nanomechanical devices by gene regulatory mechanisms. It should therefore be possible to program DNA devices to perform a complex series of tasks in response to certain environmental influences. It is also conceivable to construct similar DNA or RNA structures which act in response to naturally occurring mRNA molecules. This again could be interesting in the context of biosensing or drug delivery. For example, one could construct aptamer-based devices which

**Figure 6.12.** Gene regulatory control of DNA devices. A gene construct contains the instructions to close opened DNA tweezers (close gene). Its transcription will lead to the production of a fuel mRNA strand which can close the tweezers. In the construct, the promoter of the gene is put under the control of the Lac operator directly downstream of the promoter.

When the repressor protein LacI binds to the operator, transcription extension by T7 polymerase is blocked. However, when the “inducer” IPTG binds to LacI, it cannot bind to the operator sequence. Then transcription is switched on, fuel mRNA is produced and the DNA tweezers are closed. (Reprinted with permission from Ref. [81], © 2005, Wiley-VCH.)

release their molecular load in response to the presence of specific mRNA molecules.

## 6.6 Conclusion

Apart from their original biological role, DNA molecules can be used as highly versatile building blocks for the construction of nanoscale structures and devices. The first simple prototype devices based on DNA could only perform simple movements such as stretching or rotation. Based on these prototypes and combining them with other concepts from nanotechnology and the life sciences, a variety of more functional DNA nanodevices has recently been demonstrated. The first examples of “DNA walkers” capable of unidirectional motion have been given; the interaction of DNA devices and proteins has been utilized for sensors, for the control of biochemical reaction rates and for the controlled binding and release of proteins; ideas from DNA computing have been integrated to logically control the action of DNA-based devices; and, finally, the action of DNA devices has been coupled to the genetic machinery.

These developments represent the first steps towards autonomous molecular-scale devices which can sense environmental information, perform computations and act independently as molecular motors, drug reservoirs or signal transducers.

As such, they are expected to have a significant impact on the development of advanced biosensors or as components for intelligent drug delivery systems.

## 7.1

### Introduction

Among membrane proteins, G-protein-coupled receptors (GPCRs) are of special importance because they form one of the widest groups of receptor proteins [1–6]. As they can be activated by a large variety of extracellular signals, such as light, odorant molecules, hormones, peptides, lipids, neurotransmitters and nucleotides, GPCRs mediate the sense of vision, smell, taste and pain [1–8], and are involved in an extraordinary number of physiological processes [1–8]. For the same reasons, GPCRs are also implicated in a number of pathologies and they constitute one of the most important classes of pharmacological targets [1–6]. Accordingly, many efforts in the field of nanobiotechnology are devoted to the realization of nanobiosensors based on a single or a few GPCRs and aimed at detecting the specific ligands [9–18]. In the cell, the detection and transduction process begins with the conformational change of the GPCRs associated with the capture of the specific ligand [1, 7]. This conformational transition then activates the so-called G-proteins, giving rise to a complex sequence of biological mechanisms which ends in the production of an electric pulse by neurons (action potential) [1, 7].

It must be noted that different ligands may induce and stabilize distinct conformational states among the various structures available, and thus promote different G protein activation and receptor desensitization/internalization [19–22]. Moreover, GPCRs can interact with other proteins through their C-terminal domains. They can also give rise to homodimers and heterodimers with other membrane-bound proteins involved in their function and pharmacology [23]. Of course, understanding these mechanisms is crucial for new drug design. However, the drug-discovery process and the research of novel GPCR-based therapeutics require a large body of data to allow the identification of new receptor ligands. Therefore,

there is an increasing need to develop genetic and chemical high-throughput screening (HTS) methods for an efficient sorting of compounds with pharmaceutical potential [3, 24–26]. In this context, the production of nanobiosensors based on GPCRs can provide a very useful tool.

In nanobiosensors, the detection process bypasses the complicated sequence of biological events which follows G protein activation; rather, the goal is to achieve sensitive and reliable monitoring of the conformational change by direct analysis of the optical or the electrical response of the nanodevice itself.

The first difficulty to be faced in developing such chip-based sensors is to prepare and immobilize the receptors in such a manner as to preserve their function, i.e. their ability of undergoing the appropriate conformational transition. The second difficulty consists in achieving sensitive and reliable monitoring of the conformational change, by analysis of the optical or electrical response of the device. Of course, this analysis requires the development of suitable tools, both experimental and theoretical.

This development represents a true challenge. In particular, here we discuss the possibility of studying the detection process of a single receptor device by direct measurement of its electrical properties [16, 17]. Actually, most of efforts in the literature focus on optical or atomic force microscopy (AFM) techniques to monitor the ligand detection process (see Section 7.3). Only a few attempts [16–18] based on electrical measurements have been made until now, as a consequence of the difficulty arising from the very low values expected for currents, which requires very advanced amplification techniques. Thus, the method adopted here and illustrated in this chapter represents a very innovative approach. Concerning this point, we further underline the novelty of the theoretical model that, uniquely in the literature, uses an impedance network for the description of the electrical properties of a single protein device.

It is important to note that all the members of the GPCR superfamily [1] share a common molecular topology consisting of seven transmembrane helical domains ( $\alpha$ -helices), connected by three intracellular and three extracellular loops (Fig. 7.1). This feature of the GPCR superfamily plays an important role in the development of theoretical and computational models of these receptors [1]. Actually, while the primary structure (amino acid sequence) is known for many GPCRs [27], the detailed atomic positions are available only in the case of rhodopsin, the rod cell photoreceptor that mediates light vision, where they can be measured by X-rays diffraction experiments performed in the protein crystalline state [27–31]. Indeed, the natural abundance and availability of rhodopsin, in contrast to other GPCRs, typically expressed at a very low level in the cell, results in the fact that only rhodopsin crystals have been obtained and studied at high resolution [27–33]. For all these reasons, rhodopsin is the best-studied GPCR, and it is often selected as a model protein for biological and biophysical studies of this kind of receptor [34–36]. Rhodopsin also serves as a pilot receptor for establishing biotechnological platforms for chip-based screening technologies, to characterize the function and interactions of GPCRs [37].

A three-dimensional structure for the activated state of rhodopsin, i.e. metarhodopsin II [19, 31, 37], was obtained at medium resolution by combining elements

**Figure 7.1.** Schematic drawing of a GPCR. The big dark-grey rectangular box represents the cellular membrane which separates the extracellular region (above) from the cytoplasmic region (below). The seven grey vertical rectangles show the seven transmembrane  $\alpha$ -helical domains of the receptor, while the loops and the two termini (N- and C-terminus) are shown by black lines. The three black circles represent the three subunits of the G-protein and, finally, the grey ellipse on the top shows a ligand captured by the receptor.

of secondary structure with experimental, long-range distance constraints inducing rigid body movements of secondary structures relative one to another. As a result, the metarhodopsin II state of the receptor exhibits a spatial organization different from the ground state rhodopsin [31].

In this chapter, we first briefly review some of the different techniques that have been previously developed to prepare and immobilize the receptors on the substrate. Then, we consider the detection process as characterized by the response of the device. In particular, we discuss the electrochemical impedance spectroscopy (EIS) technique, which is emerging as a very effective technique for the detection of biosensing events at the electrodes [38–42]. The largest part of this chapter is devoted to illustrating a recent theoretical model [17, 43–45] which studies the current response to an applied AC voltage of a nanodevice realized by a single GPCR embedded in its membrane and in contact with two functionalized metallic nanoelectrodes.

This model, based on a coarse-grained approach [17, 46, 47], describes the protein as a network [48] of elementary impedances. The model starts with the construction of a time-independent (static) network, corresponding to an ideally frozen protein, in which all the atomic positions are fixed at the equilibrium values [17]. The nodes of this static network correspond to the positions of the  $\alpha$  carbons ( $C_\alpha$ ) atoms of the rhodopsin amino acids, in the ground or in the activated state (metarhodopsin II), as taken from the protein data bank [27]. Then, an elementary impedance is associated with each link between a pair of amino acids, established according to a length cut-off criterion [46]. The elementary impedances, which mimic the electrical interactions among the protein amino acids, are taken dependent on the amino acid distance and on other parameters which account for the different physical and chemical properties of the amino acids [17]. The solution of the equivalent circuit determines the global impedance of the network itself. The

results of this static-network model, applied to the case of rhodopsin and OR-17 (rat olfactory receptor) [49], predict a detectable change of the global impedance associated with the conformational change of the receptor due to the sensing action [17, 45]. Afterwards, the frozen protein approximation is relaxed and the thermal fluctuations of the atomic positions are included in the model, first by adopting a single-force-constant approximation [43, 50, 51], as the simplest level of modeling, and then a two-force-constant approximation [44]. This last update in the model is introduced to describe the different flexibility of the atomic bonds within the  $\alpha$ -helices and within the loops [1]. The protein thermal fluctuations result in an impedance noise which is calculated as a function of the temperature. The implications of this impedance noise on the ligand detection process are then discussed.

## 7.2

### Preparation and Immobilization of GPCRs on Functionalized Surfaces

The first requirement to develop receptor-based nanobiosensors is the immobilization of receptors in such a manner as to preserve their function. Since GPCRs are composed of seven transmembrane  $\alpha$ -helices [1], they are extremely hydrophobic and require a lipidic or detergent environment to keep their native conformation and function. Generally, membrane receptors are expressed in heterologous cells, solubilized, and then purified in an appropriate detergent before being reconstituted in proteoliposomes and immobilized on a sensor surface [52–54]. Although many such successful procedures have been reported, the method requires substantial effort for purification of GPCRs prior to analysis. This cannot be considered for the majority of GPCRs because of their very low expression level, even in recombinant systems. Furthermore, the receptor function can be influenced by its lipidic environment as shown for rhodopsin [55] and  $\mu$ -opioid receptor [56]. Therefore, enormous care must be taken to avoid modification of the activity of the receptor during its solubilization and reconstruction.

The possibility of building bilayers harboring previously purified GPCRs on sensor surfaces has been demonstrated for rhodopsin [54, 57],  $\beta_2$ -adrenergic receptor [58, 59] and  $\mu$ -opioid receptor [60, 61]. On-surface reconstitution of rhodopsin in lipidic membranes has also been achieved from mixed detergent/lipid micelles, with a high density of functional receptors [15]. However, one of the most promising strategies for the preparation of GPCRs seems to produce lipid vesicles by breaking membranes where GPCRs have been expressed [18, 42]. Indeed, this procedure bypasses the difficulties implied in the purification of GPCRs and in their subsequent insertion into the reconstituted membranes.

For what concerns the immobilization of GPCRs, the self-assembled multilayer technique appears to be the most suitable and effective for the construction of well-ordered and ultra-thin organic films, since it allows the required control at a molecular level. Actually, starting from the pioneering works of Nuzzo and Allara [62], the field of self-assembled monolayers (SAMs) has experienced an explosive growth [63]. The simplicity in the production of SAMs, their adaptability and the

possibility of controlling the orientation of biomolecules on the surface ascribe to the SAM technique a central role in the construction of artificial biomolecular recognition surfaces, particularly in the development of biosensors [64–66]. The construction of self-assembled multilayers from biological components has been investigated intensively due to its potential application for biosensors [13, 14, 67, 68]. In particular, it has been found that the avidin–biotin system works very well as a bridge to anchor a bioreceptor, since the biotinylation of a biomolecule does not affect its biological activity. Furthermore, the noncovalent complex between avidin and biotin is characterized by a very high affinity constant of  $10^{15} \text{ mol}^{-1} \text{ L}$ . Once formed, the bond is stable even if the pH of the solution is changed and it can easily resist multiple washings [69].

In recent studies, a mixed SAM formed by 16-mercaptohexadecanoic acid (MHDA) and biotinyl-PhosphoEthanolamine, inserted and bound to MHDA, has been produced on gold electrodes [18, 42]. Neutravidin was then used to anchor biotin-labeled, receptor-specific antibodies. Such a multilayer system using biotin/avidin pairs acting as binding agents is of relevance for biosensor research, to immobilize a membrane receptor. Immobilization of the prototypical GPCR, rhodopsin, in its native membranes was thus achieved on functionalized surfaces [18, 42], which represents the first prerequisite for elaborating a GPCR-based biosensor. The rhodopsin membrane fraction preparations were obtained by simple sonication of the natural rod outer segments membranes. Negative-staining electron microscopy of the sample showed that the fragments are circularized into microsome, although unclosed membrane fragments are still present and the suspension is mostly constituted of vesicles with diameters of 40–100 nm. This procedure provides samples of rather uniform size, which fit the geometrical requirements of the nanobiosensor supports. Moreover, as the receptor remains at all times in its native environment, this procedure offers the advantage of avoiding the risks of altering or loosing receptor activity as a consequence of the purification and reconstitution of the GPCR in artificial membranes or liposomes. Furthermore, this specific immobilization methodology can be very useful to develop molecular arrays of other GPCRs that, in contrast to rhodopsin, are usually present in a low amount in the membrane fraction. Therefore, this form of *in situ* purification and immobilization on biostructured solid supports can overcome the difficulties usually encountered in studying most of the GPCRs and that arise from a low expression level.

### 7.3

#### Signal Techniques

Different techniques have been developed in recent years. A particularly important role in this field is played by optical techniques which, in most cases, make use of visible fluorescent proteins (VFPs) [70] and of confocal microscopy analysis, as in fluorescence resonance energy transfer (FRET) and fluorescence lifetime imaging (FLIM) techniques [71–73].

Other important tools for the investigation of this kind of system are offered by

surface plasmon resonance (SPR) [18, 54, 58] and AFM. This last technique, in particular, represents a very powerful tool for structural biology studies since it gives access to the molecular architecture [74, 75], and it can also be used to follow and characterize receptor immobilization on the selected biostructured surfaces.

EIS has become one of the most effective electrochemical techniques for the characterization of biomaterial-functionalized electrodes and of biocatalytic transformations at electrode surfaces; specifically, for the detection of biosensing events at electrodes [38–42]. Compared to other electrochemical techniques, one of the great advantages of EIS is the small amplitude of the perturbation from the steady state, which makes it possible to treat the response theoretically by linearized or otherwise simplified current–potential characteristics [38–42]. Therefore, EIS has been performed extensively to characterize the fabrication of biosensors and to monitor biomolecular recognition [12, 38–41, 76]. Very recently, electrochemical impedance measurements have demonstrated the sensitivity and selectivity of self-assembled multilayer systems for the specific grafting of the rhodopsin membrane fraction [18, 42].

#### 7.4

#### Theoretical Approach

The theoretical study of the electrical response to an external voltage of a GPCR-based device is a hard task. Thus, we limit ourselves to consider a “simple” two-terminal device, made by a single receptor embedded in a small portion of its native membrane and inserted between two ohmic electrical contacts (functionalized metallic layers) through which an AC voltage is applied. The device is placed within a physiological buffer solution, necessary to keep the protein in the correct conformation. This device is sketched in Fig. 7.2, where, without loss of generality,

**Figure 7.2.** Representation of a single receptor device: the receptor is contacted between two functionalized electrodes through which an external AC voltage is applied.

**Figure 7.3.** Schematic representation of the ground and activated states of OR-17 and rhodopsin.

a vertical configuration of the electrodes has been assumed (other configurations can also be considered).

As discussed before, the main mechanism by which GPCRs perform their biological functions is associated with the conformational transition undergone as consequence of the interaction and capture of the ligands [1, 9]. Thus, the main task of a theoretical study of the electrical properties of a GPCR-based device consists in estimating the magnitude of the difference of the electrical response to the external voltage in the two receptor conformations. The GPCR conformational transitions have been intensively studied [27, 31, 32, 46, 77–82], especially by experiments [27, 31, 32, 77–80], and it has been realized that the activation of the receptor involves a release of constraints in the transmembrane helix bundle, resulting in the opening of a cleft at its cytoplasmic end [19, 37], and in a net volume change of the protein [79]. In particular, a lot of information is available concerning the most stable light-activated state of rhodopsin, known as metarhodopsin II [27, 31, 32], where the available information also includes the coordinates of the atomic positions. To illustrate qualitatively the conformational change of GPCRs, Fig. 7.3 shows a schematic representation of the ground and activated states of rhodopsin and of the rat OR-17. Apart from these large-scale conformational transitions, it is well known that proteins are not rigid, but instead they sample a variety of conformations in the neighborhood of their native conformation [82]. These fluctuations within different conformations, all near to the equilibrium one, are called equilibrium fluctuations [82].

Both the complicated relationship between structure and functions of the proteins and the details of the molecular motion in the folded state can, in principle, be studied by molecular dynamics (MD) simulations and normal-mode analysis, by using classical MD or “*ab initio*” quantum MD, or even hybrid schemes [81, 83–85]. These last mix a quantum treatment of a limited number of atoms and a classical treatment of the remaining atoms, thus allowing the study of large biological molecules [81, 83–85]. However, the use of these atomic approaches becomes computationally very heavy and inefficient with increasing protein size [46].

Recently, alternative methods have been proposed, based on coarse-grained models of proteins and simplified force fields [50, 51]. Successively, many other studies have shown the success and the effectiveness of these kinds of models in describing protein dynamics, particularly for the case of large proteins composed by more than several thousands of amino acids [46, 47].

Therefore, in developing a theoretical model of the electrical properties of a GPCR-based device we have also followed a coarse-grained approach, by formulating it in terms of an electric network of impedances [17, 43–45] instead of the usual elastic network of springs, considered in the above cited works [46, 47, 50, 51]. In the following we illustrate in detail the procedure and we discuss the results for the case of rhodopsin. Moreover, we also show results concerning OR-17 [49]. However, it is important to note that, in addition its computational simplicity, an important advantage of this coarse-grained network approach [17, 46, 47, 50, 51] is given by the fact that, by focusing mainly on protein topology, it represents an appropriate tool for providing predictions for the other GPCRs, for which detailed information on the atomic positions is missing.

## 7.5

### The Impedance Network Model

We start by considering an ideally frozen bovine rhodopsin molecule, in which no fluctuation occurs and all the atoms occupy the equilibrium positions [17]. We describe this protein as a static network made of elementary impedances (in this context, a static network means a network made of time-independent elements). The network is built in the following manner [17].

First, we have to choose the nodes of the networks, i.e. we have to choose a reference position within each amino acid (residue). By following a choice largely adopted in the literature [46, 47, 51], we assume the  $C_\alpha$  atoms present in any amino acid as nodes of the network. Accordingly, we have taken the atomic coordinates of bovine rhodopsin from the Protein Data Bank (PDB) [27], where several sets of data from independent experiments are present in the standard PDB file format. We have used PDB with IDs 1F88 [28] and 1JFP [32] for the rhodopsin ground state, and the data set II (PDB ID 1LN6) [31] (engineered data) for meta-rhodopsin II. Then, we have extracted the spatial coordinates of the  $C_\alpha$  atoms of each amino acid (348 for bovine rhodopsin) from the PDB file.

We assume that the amino acids interact electrically between each other and that charge transfers between neighboring residues [78, 86] and/or changes of their electronic polarization [87] affect these interactions. Accordingly, a link is drawn between any pair of nodes,  $i$  and  $j$  separated by a distance  $l_{i,j}$  less than a given cut-off value,  $d = 2R_a$ , where  $R_a$  is an electrical interaction radius (Fig. 7.4). Moreover, we introduce two extra nodes (contact nodes) which mimic the electrodes. These contact nodes are linked to a given set of amino acids, depending on the particular geometry of the contacts in the real device (each electrode is linked at least to one amino acid). A representation of this interaction network for the case

**Figure 7.4.** A link is drawn between the nodes  $i$  and  $j$ , which stay at the positions of the  $\alpha$  carbon atoms  $C_{\alpha i}$  and  $C_{\alpha j}$  of the  $i$ th and  $j$ th amino acid, when their relative distance is less than twice the interaction radius  $R_a$ .

of a hypothetical protein made of 18 residues is shown in Fig. 7.5. We note that the solution and the membrane are not directly taken into account at this stage of the model (however, as the main effect of the membrane is to keep the protein in the folded state, this effect is implicitly accounted for by taking the coordinates of the  $C_\alpha$  corresponding to a given folded conformation of the protein).

The next step of the model consists of associating an elementary impedance  $Z_{i,j}$  with the link between the nodes  $i$  and  $j$  [17]. We take this elementary impedance as the impedance of a RC parallel circuit (the most usual passive AC circuit) and we denote as  $R_{i,j}$  and  $C_{i,j}$ , respectively, the resistance and the capacitance of the link between the nodes  $i$  and  $j$ . Different expressions can be adopted for  $Z_{i,j}$ . Here, we discuss three possibilities, corresponding to an increasing level of complexity. The first possibility, model (i), is the simplest one: all the impedances are taken to be equal:  $Z_{i,j} = Z_0$ . The second possibility, model (ii), consists of assuming that  $R_{i,j}$  and  $C_{i,j}$  are, respectively, the resistance of a simple ohmic resistor and the capacitance of a planar homogeneous capacitor. Thus,  $R_{i,j} \propto l_{i,j}$  and  $C_{i,j} \propto l_{i,j}$ . Consequently,  $Z_{i,j}$  takes the expression [17]:

$$Z_{i,j} = l_{i,j} \frac{\rho}{A(1 + i\rho\omega\epsilon\epsilon_0)} \quad (1)$$

**Figure 7.5.** Interaction network associated with a hypothetical protein made of 18 residues: the full circles show the nodes positioned at the  $\alpha$  carbon atom of each amino acid and the lines represent the links arising

from electrical interactions between a pair of amino acids with a relative distance shorter than a cut-off value. The open circles represent two extra nodes associated with the electrodes.

**Figure 7.6.** Modulus of the network impedance as a function of the interaction radius: the dotted curve is obtained from model (i), the dashed curve from model (ii) and the solid curve from model (iii). The impedance is expressed in arbitrary units and the interaction radius is in Ångstroms.

where  $A$  is the cross-sectional area of the capacitor and of the resistor,  $\rho$  is the resistivity,  $\varepsilon$  the relative dielectric constant,  $\varepsilon_0$  is the vacuum dielectric permittivity,  $\omega$  is the angular frequency of the external AC voltage. The third choice, model (iii), consists of taking the cross-sectional area of the resistor and of the capacitor equal to the area of the cross-section defined by the overlap of the two spheres pertaining to the given amino acids, as shown in Fig. 7.4. Thus:

$$A = \pi \left[ R_a^2 - \frac{l_{i,j}^2}{4} \right] \quad (2)$$

To compare these three models, we plot in Fig. 7.6 the modulus of the total network impedance,  $|Z|$ , calculated by using models (i), (ii) and (iii) as a function of the interaction radius  $R_a$ . The total network impedance  $Z$  is calculated by solving Kirchhoff's node equations. We note that in the case of an irregular network, with complex topology [48], the solution of the circuit by node equations is particularly convenient with respect to the use of loop equations. The systematic decrease of  $|Z|$  shown in Fig. 7.6 at increasing values of  $R_a$  reflects the increasing importance of parallel connections with respect to series connections. One can see that the curves of the first two models show a step-like behavior related to the sharp discontinuity in the value of  $|Z|$  when  $R_a$  becomes equal to  $l_{i,j}$ . However, the curve obtained by using model (iii) shows a continuous behavior. Furthermore, model (iii) appears to be more sensitive to a variation of the number of links in the networks.

Of course, an improvement in the description of the protein is expected if the physical and chemical properties of the different amino acids are accounted for in the expression of  $Z_{i,j}$ . At a simplest level, this can be done by considering  $\varepsilon$  and/or  $\rho$  as dependent on the indices  $i$  and  $j$ . For this purpose, we have taken [17] the following expression  $\varepsilon_{i,j} = 1 + g(\bar{\alpha} - 1)$  for the dielectric constant of the capacitor associated with the pair  $i$  and  $j$  of amino acids, where  $\bar{\alpha} \equiv (\alpha_i + \alpha_j)/2$  is the average

intrinsic polarizability of the pair, and  $\alpha_i$  and  $\alpha_j$  are the intrinsic polarizabilities of the  $i$ th and  $j$ th amino acid, respectively. Actually, by describing a protein in solution as a set of polarizable dipoles embedded in a dielectric medium of solvent molecules, Song [87] has calculated a set of values for the intrinsic polarizabilities of the 20 amino acids, portable for all the proteins in nature. Finally, we have chosen the value of  $g$  in the expression of  $\varepsilon_{i,j}$  in such a manner as to obtain the values of  $\varepsilon_{i,j}$  distributed between 1 and 80 (vacuum and water) proportionally to  $\bar{\alpha}$ . Thus, with the last update, model (iii) provides for  $Z_{i,j}$  the expression [17]:

$$Z_{i,j} = \frac{l_{i,j}}{\pi(R_a^2 - l_{i,j}^2/4)} \cdot \frac{1}{(\rho^{-1} + i\omega\varepsilon_{i,j}\varepsilon_0)} \quad (3)$$

In the following we will show and discuss results obtained by using this expression of  $Z_{i,j}$ .

An important feature characterizing the topology of a network is represented by the degree distribution, i.e. the distribution function of the node connectivity [48]. Figure 7.7 shows the degree distribution of the interaction networks of rhodopsin and OR-17 obtained for two values of the interaction radius,  $R_a = 4$  and  $5 \text{ \AA}$ . The degree distribution is found to be only roughly described by a Poissonian curve. Indeed, secondary peaks are present for both rhodopsin and OR-17. This behavior of the degree distribution characterizes a pseudo-random network [48]. We note that for the values of  $R_a$  considered in Fig. 7.7 the width of the distribution increases by increasing the interaction radius. The contrary will occur at the highest values of  $R_a$ . In particular, above a given maximum value of the radius,  $R_{a,\max}$ , of the order of the size of the receptor, each node will be connected with all the other nodes and the degree (number of links) of all the nodes will be become  $(N_{\text{am}} - 1)$ ,

**Figure 7.7.** Degree distribution (distribution function of the node connectivities) of the interaction network of rhodopsin and OR-17. The thin and thick solid curves are obtained in

the case of rhodopsin by taking  $R_a = 4$  and  $5 \text{ \AA}$ , respectively; the dot-dashed and the dashed curves are obtained in the case of OR-17 by taking  $R_a = 4$  and  $5 \text{ \AA}$ .

**Figure 7.8.** Total number of links in the network,  $N$ , and relative increment as a function of the interaction radius. The thin thick solid and the grey short-dashed curves show  $N$  for the interaction network corresponding to the

basic state of rhodopsin and OR-17. The thin solid and the grey short-dashed curves show the relative increment of  $N$ . The interaction radius is expressed in Ångstroms.

where  $N_{am}$  is the number of amino acids. Consequently, for  $R_a \geq R_{a,max}$  the degree distribution will become a  $\delta$  function independently of  $R_a$ .

Figure 7.8 reports the total number of links,  $N$ , existing in the network, as a function of the interaction radius. The data concerning the ground state of rhodopsin and OR-17 are shown by the thick solid and the grey dashed curves, respectively. We can see that for any value of  $R_a$ , the number of links in the interaction network of rhodopsin is higher than that existing in the case of OR-17. Moreover, the difference in the link number is rather significant (about 10%) for values of  $R_a \geq 8 \text{ \AA}$ . Figure 7.8 also displays as a function of  $R_a$  the behavior of the relative increment of the number of links,  $\Delta N/\Delta R_a$ , for the ground state of rhodopsin (black solid curve) and OR-17 (grey short-dashed curve). Thus, from Fig. 7.8 we can conclude that when  $R_a \sim 8\text{--}18 \text{ \AA}$  the connectivity of the network is very sensitive to the value of the interaction radius. On the other hand, by comparing the behavior versus  $R_a$  of  $N$  and  $\Delta N/\Delta R_a$  in the ground and in the activated state of rhodopsin, it has been found [17] that the range of values  $R_a \sim 8\text{--}18 \text{ \AA}$  corresponds to the maximum sensitivity of the network to conformational changes.

This statement is also confirmed by the analysis of the dependence of the total network impedance,  $Z$ , on the interaction radius in the case of rhodopsin and metarhodopsin, as shown in Fig. 7.9. Precisely, in Fig. 7.9 we report the difference of the impedance modulus,  $|Z|$ , calculated in the case of rhodopsin and metarhodopsin. This difference has been normalized to the impedance modulus of the rhodopsin network. We can see that when  $R_a \sim 8\text{--}18 \text{ \AA}$  the total network impedance depends strongly on the conformation of the protein. It must be noted that this

**Figure 7.9.** Relative difference of the values of the impedance modulus in the ground state (Rh) and in the activated state (MII) of rhodopsin as a function of the interaction radius ( $R_a$  expressed in Ångstroms).

sensitivity of the total network impedance to the conformational changes arises not only from the above discussed sensitivity of  $N$  to the protein conformation, but also from the fact that the elementary impedances  $Z_{i,j}$  are assumed to be functions of the distances  $l_{i,j}$ .

To provide a prediction of the expected electrical response of the GPCR-based nanodevice and to test our model in a direct comparison with the results of EIS measurements [38–42], we have calculated the network impedance as a function of the frequency of the applied AC voltage. Figure 7.10 shows the Nyquist plot of the network impedance calculated in the case of rhodopsin. Precisely, Fig. 7.10 displays the opposite of the imaginary part of the network impedance versus the real part, where both these quantities are calculated in the frequency range  $0 \div 1$  kHz. The three curves reported in Fig. 7.10 are obtained for  $R_a = 2$  Å (short-dashed curve),  $R_a = 5$  Å (long-dashed curve) and  $R_a = 12.5$  Å (solid curve). In all cases, we have taken  $\rho = 10^9 \Omega\text{m}$  while the amplitude of the applied voltage,  $V_0$ , is  $V_0 = 1$  V. Moreover, the real and the imaginary parts of the impedance have been normalized to the static value of the real part,  $\text{Re}[Z(\omega = 0)]$ , which takes the values  $\text{Re}[Z(\omega = 0)] = 302 \text{ G}\Omega$ ,  $11.2 \text{ G}\Omega$  and  $1.67 \text{ M}\Omega$ , respectively, for  $R_a = 2, 5$  and  $12.5$  Å. As a general trend, when  $R_a \geq 5$  Å, the shape of the Nyquist plot is indistinguishable from that corresponding to a single RC parallel circuit (semicircle). In contrast, when  $R_a < 5$  Å, the Nyquist plot deviates from this behavior. In particular, when  $R_a = 2$  Å, the degree of most of the nodes of the network is 2 (Fig. 7.7) and the series combination of elementary impedances  $Z_{i,j}$  becomes dominant in the network structure. In other terms, changes in the shape of the Nyquist plot are only detected near to the sequential limit. Of course, the value of  $\text{Re}[Z(\omega = 0)]$  depends on both  $R_a$  and  $\rho$ . Therefore, impedance spectroscopy measurements

**Figure 7.10.** Nyquist plot of the network impedance: the short-dashed curve corresponds to an interaction radius equal to 2 Å, the long-dashed curve to a radius of 5 Å and the solid curve to a radius of 12.5 Å. The real and the imaginary parts of the impedance are

normalized to the static value of the real part, which is 302 GΩ, 11.2 GΩ, and 1.67 MΩ, respectively, when  $R_a$  is 2, 5 and 12.5 Å. All curves correspond to the basic state of rhodopsin and are obtained by taking a resistivity of 1 GΩm.

could be a method which allows the identification of the values of the parameters to be used in the modelization of the receptor.

Figure 7.11 displays a comparison between the Nyquist plot corresponding to the rhodopsin interaction network and that corresponding to the activated state metarhodopsin II. Precisely, the solid curve is obtained for rhodopsin while the

**Figure 7.11.** Nyquist plot of the network impedance: the solid curve is obtained for rhodopsin by taking the interaction radius equal to 12.5 Å and a resistivity of 1 GΩm, the dot-dashed curve is obtained for metarhodopsin by taking the same values of the

parameters. The real and the imaginary parts of the impedance are normalized to the static value of the real part of the network impedance in the metarhodopsin state which takes the value of 2.04 MΩ.

dot-dashed curve for metarhodopsin II. In both cases we have taken  $R_a = 12.5 \text{ \AA}$ ,  $\rho = 10^9 \text{ } \Omega\text{m}$  and  $V_0 = 1 \text{ V}$ . The real and the imaginary parts of the impedance are normalized to the static value of the real part of the impedance in the metarhodopsin state:  $\text{Re}[Z(\omega = 0)] = 2.04 \text{ M}\Omega$ . Figure 7.11 shows that the conformational change of the receptor due to the detection of a photon implies a significant variation in the Nyquist curve, in principle detectable by impedance spectroscopy measurements. This result is of particular relevance also in view of the application of the model to other GPCRs.

## 7.6 Equilibrium Fluctuations

The above results have been obtained by considering an ideally frozen protein, in which no fluctuation occurs and all the atomic positions are fixed at the equilibrium values. However, as discussed in a previous section, proteins are not rigid, but they sample a variety of conformations in the neighborhood of the equilibrium conformation [46, 50, 51, 80]. These fluctuations of the atomic positions result in an intrinsic impedance noise which is present during an electrical measurement performed on such a nanodevice. The level of this noise turns out to be crucial to the actual detection of the ligand capture by the GPCR when compared with the impedance variation due to the conformational transition and with the electrode/amplifier noise.

Therefore, we have extended the previous model by relaxing the frozen protein approximation and by studying the effect of the fluctuations of the atomic positions on the electrical response to an AC field [17, 43–45]. For this purpose, we allow the nodes of the network to fluctuate around their equilibrium positions with an amplitude depending on the temperature [43, 44]. For the sake of simplicity and to get a first qualitative estimation, we describe the system of fluctuating nodes as a set of independent, isotropic, harmonic quantum oscillators, with common values of the force constant  $\gamma$  and of the proper frequency,  $\omega_0$ . The oscillators are assumed to be in contact with a thermal bath at temperature  $T$ . We denote with  $\vec{r}_{n,\text{eq}}$  and  $\delta\vec{r}_n = \vec{r}_n - \vec{r}_{n,\text{eq}}$ , respectively, the equilibrium position and the displacement from the equilibrium at the time  $t$  of the  $n$ th oscillator, and with  $\langle(\delta\vec{r})^2\rangle$  its mean square displacement. It can be easily seen that  $\langle(\delta\vec{r})^2\rangle$  is given by:

$$\langle(\delta\vec{r})^2\rangle = \frac{3}{2} \cdot \frac{k_B\theta}{\gamma} + \frac{k_B\theta}{\gamma} \cdot \frac{1}{\exp[\theta/T] - 1} \quad (4)$$

where  $\theta = \hbar\omega_0/k_B$ . Thus, when  $T \gg \theta$ , Eq. (4) simplifies as:

$$\langle(\delta\vec{r})^2\rangle \approx k_B T / \gamma \quad (5)$$

At an arbitrary temperature the wave function of the oscillator is a superposition of several excited states and its probability density cannot be expressed in a simple

form. Again, for simplicity, we take the following expression for the probability density of presence of the  $n$ th oscillator around its equilibrium position:

$$P(\delta\vec{r}_n) = \frac{3^{3/2}}{[2\pi\langle(\delta\vec{r})^2\rangle]^{3/2}} \cdot \exp\left[-\frac{3}{2} \cdot \frac{(\delta\vec{r}_n)^2}{\langle(\delta\vec{r})^2\rangle}\right] \quad (6)$$

where  $\langle(\delta\vec{r})^2\rangle = 3\langle(\delta x)^2\rangle$  and  $\langle(\delta x)^2\rangle = \langle(\delta y)^2\rangle = \langle(\delta z)^2\rangle$ . The fluctuations of the network impedance have been calculated by a Monte Carlo simulation which generates the position of all the nodes at each step according to the space probability given by Eq. (6). The calculations have been performed by choosing the value  $\gamma = 2.5 \text{ kJ mol}^{-1} \text{ \AA}^{-2}$  for the oscillator force constant, according to the literature [46, 50, 51]. This choice of  $\gamma$  provides  $\theta = 12 \text{ K}$ . Thus, the condition  $T \gg \theta$  is well satisfied at room temperature. The choice of a unique force constant for all the amino acids of the protein is a frequently adopted assumption [46, 50, 51], as in the previously mentioned Gaussian Network Models [46, 50].

However, it is also well known that  $\alpha$ -helices are much more stable under thermal fluctuations than loops and termini [1–4]. For this reason, we have also calculated the impedance noise by assuming two different force constants,  $\gamma_1/\gamma_2$  and  $\gamma_2 < \gamma_1$  for  $\alpha$ -helices and loops/termini, respectively [44]. The values of  $\gamma_1$  and  $\gamma_2$  have been chosen by taking the mean value of the force constant  $\bar{\gamma} = 2.5 \text{ kJ mol}^{-1} \text{ \AA}^{-2}$  and then by considering different values of the ratio  $\gamma_1/\gamma_2$ . The greater the value of this ratio, the more flexible the loops and termini are with respect to helices.

Figure 7.12 displays the values of the impedance modulus calculated as a function of the time for the case of rhodopsin. Similar data obtained for metarhodopsin

**Figure 7.12.** Calculated values of the impedance modulus versus time for rhodopsin. The impedance modulus has been normalized to its average value and the time is expressed in simulation steps. The grey and the black curves are calculated by taking the ratio  $\gamma_1/\gamma_2 = 1$  and 20, respectively.

**Figure 7.13.** Calculated values of the impedance modulus versus time for metarhodopsin. The impedance modulus has been normalized to its average value and the time is expressed in simulation steps. The grey and the black curves have the same meanings as in Fig. 7.12.

II are reported in Fig. 7.13. All the data in Figs. 7.12 and 7.13 have been normalized to their respective average values and refer to simulations performed at room temperature. In Figs. 7.12 and 7.13, the curves corresponding to  $\gamma_1/\gamma_2 = 1$  and 20 are reported, respectively, in grey and black. The comparison of the data shows that the metarhodopsin state is characterized by impedance fluctuations significantly wider than those in the rhodopsin state. This is particularly true when the force constant of the  $\alpha$ -helices is 20 times greater than the force constant of loops/termini. This result reflects the minor thermal stability of metarhodopsin with respect to rhodopsin, probably due to an expansion of the entire structure consequent to the conformational transition [35].

This conclusion is supported also by Figs. 7.14 and 7.15, which report the probability distribution function,  $\phi$ , of the impedance fluctuations for rhodopsin and metarhodopsin calculated at room temperature by taking the ratio  $\gamma_1/\gamma_2 = 1$  (open diamonds) and 20 (full circles). The probability densities have been obtained by analyzing  $Z(t)$  signals made of about  $5 \times 10^5$  data. Here,  $\sigma$  is the root mean square deviation from the average value of the impedance modulus  $\langle |Z| \rangle$ . This normalized representation has been adopted for convenience because it makes the distribution independent of its first and second moments [88]. In particular, Fig. 7.15 shows that for metarhodopsin the impedance fluctuations are non-Gaussian even when  $\gamma_1/\gamma_2 = 1$  (in contrast, in the case of rhodopsin the fluctuations are Gaussian). Moreover, strong non-Gaussian tails are present when  $\gamma_1/\gamma_2 = 20$  and, in particular, for metarhodopsin. This strong non-Gaussianity at room temperature for  $\gamma_1 \gg \gamma_2$  (and, in particular, for metarhodopsin) is due to the presence of big spikes corresponding to the loss of links that are crucial to ensure the connectivity of the network [48, 88].

**Figure 7.14.** Normalized PDF of impedance modulus fluctuations at  $T = 300\text{ K}$  for rhodopsin. Diamonds and full circles correspond to simulations performed by taking the ratio  $\gamma_1/\gamma_2 = 1$  and  $20$ , respectively;  $\sigma$  is the root mean square deviation from the average modulus. The solid curve represents the Gaussian distribution.

Finally, Fig. 7.16 reports the values of the relative root mean square fluctuation of the impedance modulus,  $\sigma/\langle|Z|\rangle$ , as a function of the temperature. We can see that once the higher flexibility of loops and termini is accounted for by taking two different values for the force constants  $\gamma_1$  and  $\gamma_2$ , the relative fluctuation of the impedance becomes strongly sensitive to the temperature. In particular, for  $\gamma_1/\gamma_2 = 20$ , the relative root mean square fluctuation of the impedance modulus for rhodopsin is about 15%, while for metarhodopsin it is about 35%. Such high levels of noise would make it problematic to detect the conformational change in terms of variation of the impedance of the nanodevice, being this variation roughly

**Figure 7.15.** Normalized PDF of impedance modulus fluctuations at  $T = 300\text{ K}$  for metarhodopsin. The solid curve, the diamonds and full circles have the same meanings as in Fig. 7.14.  $\sigma$  is the root mean square deviation from the average modulus.

**Figure 7.16.** Relative root mean square deviation of the impedance modulus as a function of temperature for rhodopsin and metarhodopsin. The data shown by full and open symbols are calculated by taking the ratio  $\gamma_1/\gamma_2 = 1$  and 20, respectively. The dashed lines represent the best fit of the data with an exponential law. The temperature is expressed in Kelvin.

of the same order [17]. However, the increase of the impedance noise itself in the rhodopsin  $\rightarrow$  metarhodopsin transition (more than a factor of 2 at room temperature) could in principle provide a way to detect this transition.

## 7.7

### Conclusions

We have considered the possibility of realizing nanobiosensors based on GPRCs. First, we discussed some of the main difficulties to be faced in developing such chip-based sensors, i.e. (a) the preparation and the immobilization of the GPCRs on functionalized surfaces in a manner suitable to preserve their function (to enable the conformational transition associated with the capture of the ligands) and (b) the signal techniques. In this regard, the problem consists of developing experimental and theoretical tools allowing a sensitive and reliable monitoring of the ligand capture and/or of the conformational transition by an analysis of the optical or the electrical response of the nanodevice. Focusing on this last approach, we discussed the EIS technique, which is emerging as a very effective technique for the detection of biosensing events at the electrodes [38–42]. Then, the largest part of this chapter was devoted to illustrating a theoretical model recently proposed for the study of the current response to an external AC voltage of a single-protein device. In particular, we have considered, as a prototype, a two-terminal device consisting of a GPCR (rhodopsin or rat OR-17) embedded in a lipid bilayer and contacted by two ohmic electrodes. A coarse-grain approach has been developed for the description of the electrical properties of the receptor which is modeled as a network of elementary impedances. The conformational changes of the receptor

induced by the capture of the ligand (photon or odorant molecule) are then translated into a variation of the network impedance. The role played by the different model parameters on the network structure and on the impedance spectral properties was analyzed. Furthermore, the study of the impedance noise associated with the equilibrium fluctuations of the protein showed that the conformational transition is followed by a significant increase of the impedance noise level, which, by itself, would offers an interesting possibility to detect the transition. Thus, the results obtained look promising for the practical realization of a GPCR-based nanobiosensor able to perform its sensing functions based on a change of its electrical properties.

# Protein-based Nanotechnology: Kinesin–Microtubule-driven Systems for Bioanalytical Applications

*William O. Hancock*

### 8.1 Introduction

Protein machines carry out tasks critical to cell function, including DNA replication, intracellular transport, ion pumping and cell motility. They have evolved incredible diversity, specificity, efficiency and precision, and a considerable proportion of research in modern biology aims to uncover the fundamental mechanisms underlying their function [1]. The cytoskeletal motors, kinesins, dyneins and myosins, constitute a subset of these protein machines and are notable in being able to convert chemical energy directly to mechanical work. In cells, these motors generate the force that drives muscle contraction, they transport intracellular cargo throughout cells and they drive the critical movements that underlie cell division.

With the ability to engineer devices and systems at the micron and submicron scales, and to synthesize nanoparticles with novel and powerful functionalities, there is a growing need to transport and organize material at submicron dimensions. Because cytoskeletal motors have evolved specifically to transport and organize material at these size scales, there is a current effort to integrate these molecular motors and their cytoskeletal tracks into engineered devices [2–10]. This interdisciplinary research, which involves biologists, bioengineers, chemists, materials scientists, electrical engineers and others, is part of a larger effort to integrate proteins with highly evolved functions into nanoscale engineered systems. For instance, proteins and peptides are also being used as tools to drive self-assembly of inorganic materials such as semiconductors into functional materials [11, 12]. Another example of protein-based nanotechnology is the push to create electronic devices based on proteins or ion channels [13].

Compared to pressure-driven microfluidic flow, active transport by molecular motors in microfluidic channels offers a number of advantages as components of bioanalytical systems or biosensors. First, because of the small size of the motors and cytoskeletal filaments, the channels can be scaled down to dimensions below 100 nm. Second, motor-driven transport can occur up concentration gradients and against fluid flows. Third, because energy for transport (in the form of ATP) is delivered and consumed directly at the site of transport, dense arrays of multiplexed

channels can be created without need for complex electrical connections. However, before biomolecular motors can be integrated into hybrid microscale and nanoscale engineered systems, there are a number of experimental hurdles that must be tackled. First, interfaces between the proteins and material surfaces must be optimized to attach proteins while maintaining their biochemical function. Second, the design of these microsystems needs to be optimized to best capitalize on the unique transport properties of these motors. Finally, to make analytical devices based on biomotors a reality, it is crucial to develop methods for attaching designated cargo to these proteins and to increase the stability of these proteins.

This chapter focuses on the integration of kinesin molecular motors and their microtubule tracks into microdevices for bioanalytical applications. A number of insightful reviews have been written on the molecular mechanism of motor proteins, in general [14, 15], and kinesin motors, in particular [16, 17]. There are also reviews on applications of biomolecular motors in nanotechnology [18, 19] and on applications of kinesin motors in microscale transport [4]. Finally, there is a parallel effort underway using actin and myosin for transport in microscale and nanoscale transport applications, [20–23], but that work is not discussed here.

This chapter is organized as follows. In Section 8.2, the relevant cell biology and biophysics of the kinesin–microtubule system is presented, including a description of the *in vitro* assays that have been developed to study kinesin function. Section 8.3 explores theoretical aspects of motor-driven microscale transport; in particular, the relationship between transport speeds and diffusion times for particles of various sizes. This analysis helps to frame applications in which kinesin-driven transport is best utilized. Section 8.4 discusses experimental approaches to interfacing motor proteins and microtubules with engineered surfaces. Section 8.5 reviews approaches that have been taken to control the direction of kinesin and microtubule movements. These studies provide the core work that needs to be accomplished towards integrating motor proteins into functional microscale devices. To create bioanalytical systems or biosensors driven by the kinesin–microtubule system, it is also crucial to develop strategies for attaching molecular or cellular cargo to microtubules or motors; these strategies are discussed in Section 8.6. Finally, Section 8.7 discusses higher-level design considerations for motor-driven devices, including ways to maximize the lifetime of motors and microtubules, and approaches for introducing minute samples into these devices and detecting low levels of analyte in microfluidic channels.

## 8.2 Kinesin and Microtubule Cell Biology and Biophysics

In eukaryotic cells, organelles, vesicles, chromosomes and protein complexes are actively transported throughout the cell by molecular motors moving along cytoskeletal filaments. This transport system consists of both kinesin and dynein motors moving along microtubule filaments, as well as myosin motors moving along

**Figure 8.1.** Structure and function of conventional kinesin. The two heads hydrolyze ATP and walk towards the “plus” end of microtubules. The kinesin tail binds to intracellular cargo. Microtubules, made from tubulin subunits, are 25 nm in diameter and tens of microns long.

actin filaments, but members of the kinesin family carry out the bulk of intracellular transport. Conventional kinesin, the founding member of the kinesin family, serves as a model protein for understanding the molecular basis of intracellular transport and for applications of molecular motors in nanotechnology. Conventional kinesin is a dimeric protein that contains three domains: the head or motor domain, the coiled-coil stalk that holds the two chains together and the tail that, along with two associated light chains, is responsible for binding cargo (Fig. 8.1) [24, 25]. Each motor domain contains both an ATP and a microtubule-binding site, and movement is achieved by a cycle in which each head alternately binds to the microtubule, undergoes a conformational change and releases from the track [16, 26–28]. Following the discovery of conventional kinesin [29], other members of the kinesin family were discovered based on sequence similarity in the motor head domain. The kinesin family can be divided into 14 classes based on sequence similarity and functional properties [30], and in the human genome there are 44 kinesin genes [31]. While almost all of the application work with kinesin motors has utilized conventional kinesin, because other kinesins have different motor properties, they may become useful in future applications.

Microtubules are cylindrical polymers of the protein tubulin that are 25 nm in diameter and up to tens of microns long. Tubulin dimers 8-nm long associate in a head-to-tail manner to make protofilaments, these protofilaments associate laterally to make sheets and the sheets close to make hollow cylinders that normally contain 14 protofilaments [32]. Because the subunits are asymmetric, microtubules have a structural polarity – the “minus” or slow-growing end is anchored near the center of the cell and the fast-growing “plus” ends extend to the perimeter of the cell. Experimentally, tubulin is normally isolated from cow or pig brains [33], which are large, inexpensive and rich in tubulin due to the neurons that require long-distance intracellular transport. Microtubules can be polymerized *in vitro* from purified tubulin, covalently modified with fluorophores or other functional groups and stabilized in polymer form with the drug taxol, making them stable for up to 1 week in normal buffers at room temperature [34].

**Figure 8.2.** Assays for studying kinesin motor function. (A) Schematic of the microtubule gliding assay, in which motors are adsorbed to the surface and microtubules are transported across the surface. (B) In the bead assay, in which microtubules are immobilized on the surface, motors are adsorbed to micron-scale beads and the beads are transported along the immobilized microtubules.

### 8.2.1

#### Kinesin Motility Assays

Nearly two decades of biochemical and biophysical experiments on conventional kinesin have resulted in a solid quantitative characterization of this molecular motor. Conventional kinesin motors walk along microtubules at speeds of nearly  $1 \mu\text{m s}^{-1}$ , taking 8-nm steps and hydrolyzing one ATP per step [27, 35, 36]. The motor speed decreases approximately linearly with applied load up to a single motor stall force of 5–7 pN [37, 38]. Kinesin movement *in vitro* is studied predominantly using two different assays – the microtubule gliding assay and the bead assay (Fig. 8.2) [39, 40]. In the microtubule gliding assay, motors are adsorbed to glass surfaces that have been treated with the blocking protein casein, and microtubules are observed landing on and moving over the motors, analogous to a rock star being passed over the hands of an eager crowd. Typically, these assays are performed in 20- $\mu\text{l}$  flow cells constructed from a microscope slide, two pieces of double-sided tape and a cover glass, which enables facile solution exchange by simply pipetting solution in one side and wicking out the other side using filter paper or tissue [41]. Using this geometry, the motor concentration on the surface can be varied and different solutions can be introduced to optimize movement characteristics [42]. Microtubule movements are visualized by covalently labeling the microtubules with a fluorescent dye, observing them under a fluorescent microscope coupled to a sensitive CCD camera and recording the movements on videotape or computer [41]. As the assay is relatively easy to perform and the filaments are transported long distances along the surface, this geometry has generated the most attention for microscale transport applications of the kinesin–microtubule system.

In the other commonly used assay, the bead assay, microtubules are immobilized on glass surfaces, motors are adsorbed to micron-scale beads and the beads

are transported along the microtubules. This system is analogous to the geometry found in cells, and one advantage is that optical tweezers can be used to grab the beads and measure displacements and forces generated by the motors to nanometer and piconewton precision [43]. For transport applications, the bead can in principle be replaced by functional nanoparticles or biomolecules like proteins or nucleotides. As the tail domain of kinesin motors can be deleted or significantly altered with no effect on the motor function [44], in theory antibody fragments, receptors, DNA-binding domains or other protein motifs can be fused to the motor tail and these motor–cargo complexes transported along microtubules.

Motor directionality is a key consideration for applications using either the gliding assay or the bead assay. In the gliding assay, microtubules diffuse out of solution and land on the motors, and the direction of microtubule transport is defined by the orientation of the filament (Fig. 8.3). Because the motors, which are immobilized, move to the microtubule “plus” end, the filaments move with their “minus” ends leading. The coiled-coil of conventional kinesin has a region of random coil that is thought to act like a swivel, enabling the heads to rotate freely and bind to filaments only in the proper stereospecific orientation [45]. As discussed below, a large portion of the work done to harness microtubule transport for nanoscale applications has involved finding ways to control the direction of microtubule transport. The bead geometry has its own directionality problems – the transport direction is determined by the orientation of the immobilized microtubules (Fig. 8.3). In theory, if a dense bundle of oriented microtubules could be immobilized on the surface, they would serve as ideal tracks to direct kinesin transport. However, as described in Section 8.5, achieving these oriented and aligned bundles has proven difficult [9, 46].

For applications using kinesin motors and microtubules, it is important to obtain sufficient amounts of protein and keep the proteins stable over time. As discussed above, tubulin can be purified from native sources following established protocols [33] or it can be bought from commercial sources (Cytoskeleton, Denver, CO). Conventional kinesin is generally bacterially expressed and purified [36, 44, 47], but it too can be purchased. One of the hurdles to using other motors in the kinesin family is that not all of them can be bacterially expressed [48, 49] and they can be more prone to denaturation or precipitation over time. Methods for extending the lifetime of kinesins and microtubules in engineered devices will be discussed below in Section 8.7. For more information and detailed protocols for kinesin and microtubule purification, and *in vitro* motility experiments, readers can consult the book *Kinesin Protocols* edited by Isabelle Vernos [50] or the Kinesin Home Page (<http://www.proweb.org/kinesin/>).

### 8.3 Theoretical Transport Issues for Device Integration

One of the main application goals for molecular motors to date has been active transport of analytes in microfluidic systems. There currently exist a number of ap-

**Figure 8.3.** Kinesin–microtubule *in vitro* motility assays. (A) Microtubule gliding assay, showing fluorescent microtubules moving over immobilized kinesin motors. Screens are 22  $\mu\text{m}$  wide and images are 2 s apart. As can be seen, many microtubules move over the surface and their directions are determined by their orientation when they land on the surface. (B) Bead assay in which 0.2- $\mu\text{m}$  diameter glass beads, to

which many kinesin motors are adsorbed, are transported along surface-immobilized microtubules. Screens are 10  $\mu\text{m}$  wide and images are 4 s apart. The direction of bead movement is determined by the orientation of the immobilized microtubules. Images in (A) are fluorescence and images in (B) are differential interference contrast microscopy.

proaches for moving fluids, analytes and particles through microscale geometries, such as pressure-driven convective flow, electrophoresis, dielectrophoresis and electro-osmotic flow. Rather than supplanting these methods, biomotor-driven transport should be thought of as a new approach that expands the toolbox. The best choice depends on the nature of the problem, and the hope is that in the future biomotor-driven transport will be combined with these other transport and separation approaches to make highly functional microscale devices.

It is informative to investigate from a theoretical perspective the range of particle sizes and transport distances where biomotor-driven transport is the most useful. Specifically, it is important consider the relative roles of diffusion (Brownian motion) versus motor-driven active transport. Small analytes (proteins and nucleotides) in aqueous solutions diffuse rapidly and any transport must overcome this diffusional mixing. For instance, as discussed below, an average protein can diffuse 1  $\mu\text{m}$  in 5 ms and even for distances of 100  $\mu\text{m}$  the average diffusion time is faster than the time it takes a kinesin motor moving at 1  $\mu\text{m s}^{-1}$  to get there. It should be remembered that active transport is unidirectional, while diffusion is random, but the quantitative comparison serves as a useful guide.

### 8.3.1

#### Diffusion versus Transport Times

In Tab. 8.1, diffusion times and motor-driven transport times are compared for a range of potential analytes from proteins up to eukaryotic cells. The Einstein rela-

**Tab. 8.1.** Theoretical diffusional and transport properties for a range of biological analytes

Particle	Diameter	$D$ ( $\mu\text{m}^2 \text{s}^{-1}$ )	1 $\mu\text{m}$		100 $\mu\text{m}$		Transition distance ( $\mu\text{m}$ )
			$t_{\text{Diffusion}}$ (s)	$t_{\text{Transport}}$ (s)	$t_{\text{Diffusion}}$ (s)	$t_{\text{Transport}}$ (s)	
Protein	5 nm	100	0.005	1	50	100	200
Nanoparticle	20 nm	25	0.02	1	200	100	50
Virus	100 nm	5	0.1	1	1,000	100	10
Bacteria	1 $\mu\text{m}$	0.5	1	1	10,000	100	1
Cell	20 $\mu\text{m}$	0.02	20	1	$2 \times 10^5$	100	0.05

Notes:

$$D = k_B T / 6\pi\eta r.$$

$$k_B T = 4.1 \times 10^{-21} \text{ Nm at } 25^\circ \text{C}.$$

$$\text{Viscosity } \eta = 0.89 \text{ cP at } 25^\circ \text{C} = 0.89 \times 10^{-3} \text{ Ns m}^{-2}.$$

$$t_{\text{Diffusion}} = x^2 / 2D \text{ (one-dimensional).}$$

$$t_{\text{Transport}} = x/v, \text{ where } v = 1 \mu\text{m s}^{-1} \text{ for kinesin.}$$

$$\text{Transition distance (when } t_{\text{Transport}} < t_{\text{Diffusion}}) = 2D/v.$$

tion is used to derive the diffusion constant,  $D$  based on the drag coefficient of the particle  $\gamma$ :

$$D = k_B T / \gamma \quad (1)$$

Where  $k_B T$  is Boltzman's constant ( $1.38 \times 10^{-23}$  Nm) multiplied by the absolute temperature [51]. From Stokes' law, the drag coefficient of a spherical particle in low Reynold's number flow is defined as:

$$\gamma = 6\pi\eta r \quad (2)$$

where  $\eta$  is the solution viscosity ( $0.89 \times 10^{-3}$  Ns m<sup>-2</sup> for water at 25 °C) and  $r$  is the radius of the particle [51, 52]. Combining these equations, we get the equation for the diffusion constant for spherical objects:

$$D = k_B T / 6\pi\eta r \quad (3)$$

For the particles in Tab. 8.1, approximate diameters are given and diffusion constants in aqueous buffers at 25 °C are calculated.

Using the diffusion constant, the average time it takes to diffuse a distance  $x$  in one dimension is defined as:

$$t_{\text{Diffusion}} = x^2 / 2D \quad (4)$$

and the time required for kinesin-driven transport is defined as

$$t_{\text{Transport}} = x/v \quad (5)$$

where  $v = 1 \mu\text{m s}^{-1}$  for conventional kinesin [36, 52]. In Tab. 8.1 these times are calculated for the different particles for distances of both 1 and 100  $\mu\text{m}$ . As can be seen, small particles diffuse rapidly and motor-driven transport outpaces diffusion only for distances over a few hundred microns, while large particles like bacteria and eukaryotic cells diffuse very slowly and motor transport is much faster for all distances. A helpful way to understand the utility of kinesins in microscale transport applications is to ask: at what transition distance does motor-driven transport outpace diffusion ( $t_{\text{Transport}} < t_{\text{Diffusion}}$ )? This distance, which gives a rough value for where motor-driven transport becomes useful, is calculated in the final column of Tab. 8.1. The important result is that for proteins and small particles like nanoparticles in the range of tens of nanometers, diffusional mixing is sufficient to get particles where they need to go for distances less than a few hundred microns. However, for larger particles like bacteria and cells, diffusion is inadequate at virtually all length scales. Hence, there is significant potential for these nanoscale motors to drive and control movement of micron-scale biological objects. As discussed in Section 8.6, drag forces for these relatively large objects are negligible compared to the forces kinesin motors can exert.

While it is insightful to compare diffusion and transport times, it is important to appreciate that while diffusion occurs in all directions, motor-driven transport is directional. Hence, even for short distances this transport can establish and maintain concentration gradients provided the transport flux is sufficiently high. Second, because binding these small cargo pulls the particles out of solution and eliminates their random diffusional movement, it reduces the number of degrees of freedom and achieves a significant level of positional control. Furthermore, increasing the solution viscosity either by adding solutes or by creating permeable hydrogels should be able to significantly slow diffusion rates without necessarily slowing motor transport. Finally, as the channels and sorters are fabricated using versatile photolithography techniques [2, 6, 53], there is ample opportunity for optimizing the design of these systems to maximize the utility of motor-based transport and minimize diffusional mixing.

## 8.4

### Interaction of Motor Proteins and Filaments with Synthetic Surfaces

A recurring technical hurdle in integrating functional proteins into engineered devices is the problem of interfacing synthetic materials with biological molecules. The problem of understanding and controlling protein–biomaterial interactions has been a major focus of the biomaterials field for decades [54, 55]. For instance, in the case of implanted biomaterials, the predominant approaches to maximizing biocompatibility are either to create surfaces that completely resist protein adsorption or surfaces to which proteins can adsorb, but not change their activities or otherwise produce an immune response. Due of the importance of this problem, there is a body of work on protein adsorption to biomaterials. However, there are no sure-fire techniques for (a) creating surfaces that bind proteins, but do not affect their function, or (b) creating surfaces that completely resist protein adsorption.

To harness the utility of motor proteins and their cytoskeletal tracks for nanotechnology and microscale transport applications, it is crucial to control the specific adsorption of these proteins to surfaces. Here, techniques for immobilizing motor proteins and cytoskeletal filaments are reviewed.

#### 8.4.1

##### Motor Adsorption

It can be argued that the discovery of conventional kinesin's motor activity [29] was a result of this motor's ability to bind to glass surfaces and retain its function. With proper surface passivation to reduce motor denaturation, conventional kinesin binds functionally to many types of glass as well as various oxides and other hydrophilic surfaces [7, 41, 56, 57]. The most reliable surface passivation is pretreatment of surfaces with casein, a protein found in milk. In solution, casein forms heterogeneous aggregates with diameters of the order of 10–300 nm [58].

The aggregation state of unproteolyzed casein is heterogeneous and depends on the  $\text{Ca}^{2+}$  concentration, pH, degree of phosphorylation and other factors [59]. For kinesin experiments, commercially bought casein is dissolved in buffer and passed through a submicron filter and/or centrifuged to remove aggregates [41].

It is clear that pretreatment of glass surfaces with casein greatly increases the activity of kinesin motors adsorbed to the surface, but the precise mechanism of action is not clear [41]. The working model is that casein aggregates tens of nanometers in diameter pack on the surface, the tail domains of the kinesin motors bind between the casein particles, and the motor heads stick into solution and interact with microtubules. It cannot be ruled out that the kinesin motors bind directly to the surface-adsorbed casein, but the fact that a great excess of casein in the motor solution does not compete with the surface-adsorbed casein (there is no reduction in the concentration of functional motors on the surface) argues against this. Also, it has been reported that casein has a chaperone-like function in stabilizing proteins against denaturation [60]. It cannot be ruled out that part of the enhancement of kinesin function by casein is due to stabilizing the motor protein structure.

One of the problems with the casein pretreatment described above is that it does not work for every motor protein. Apart from conventional kinesin, there are many other kinesin motor proteins (44 total in the human genome) that vary both in their motor properties and in their intracellular cargo [31]. These different motor characteristics – direction of movement along the microtubule, affinity for the microtubule and speed of movement – provide a rich toolbox for engineering hybrid devices based on these motors. However, while there is considerable structural consistency in the head domain, there is great divergence structurally and functionally in the tail domains [31, 61–63]. The result of this diversity is that techniques for attaching one motor to a surface do not necessarily work for other motors. To date, three generalizable approaches have shown promise. The first is to adsorb antibodies to the surface and immobilize the motors through these antibodies [64]. This approach has the advantage that antibodies complementary to virtually any motor can be made or, by attaching a universal protein tag (such as a hexahistidine tag) to recombinant motors, one reliable antibody to be used for a range of motors. A second approach for hexahistidine tagged motors is to functionalize the surface with a surfactant terminated with nitrilotriacetic acid (NTA), which chelates nickel ion. His-tagged proteins bind tightly to the surface through the immobilized Ni-NTA and the motors remain functional on these surfaces [65]. A third method is to attach motors to surfaces through biotin–avidin chemistry [66]. Streptavidin (or its equivalents avidin or neutravidin) can be directly adsorbed to surfaces or specifically bound to biotin-functionalized surfaces and biotinylated motors can be attached to this immobilized streptavidin. Motors attached by this means have been shown to be completely functional and the bond strong enough to not be pulled off by motor forces [67–69].

While a range of hydrophilic surfaces support kinesin-driven microtubule movements, hydrophobic surfaces do not. When glass surfaces are treated with the hydrophobic silane octadecyl trichlorethylsilane or other hydrophobic surface treat-

ments (with contact angles above  $60^\circ$ ) prior to casein and kinesin treatment, no microtubule binding or movement is observed [57, 70]. The interpretation is that motors denature on these hydrophobic surfaces and even casein pretreatment cannot prevent this motor denaturation. This property of surface chemistry-dependent motor function has been used to define where on microfabricated surfaces microtubules will be transported and where they will not (discussed further in Section 8.5).

#### 8.4.2

##### **Microtubule Immobilization**

For applications where microtubules are immobilized on surfaces and cargo-functionalized kinesins move along these filaments, a number of strategies have been developed for immobilizing microtubules. Microtubules will bind to clean glass or quartz microscope slides [71] and this immobilization is sufficient for some investigations into motor function. However, for transport applications, a more robust immobilization is generally required. One of the most common immobilization approaches is to functionalize glass surfaces with an amino silane compound (3-aminopropyltriethoxysilane) that confers a positive charge to the surface [39, 72]. Microtubules, which have a net negative charge at physiological pH, bind tightly to these surfaces and high microtubule densities can be achieved. By lithographically patterning silanes on silicon wafers, this approach has been used to pattern immobilized microtubules at microscale dimensions [73]. Polylysine-treated glass is another approach that uses electrostatic interactions to bind microtubules to surfaces [74].

Two other microtubule immobilization strategies have also been shown to work well. Microtubules can be biotinylated and attached to surfaces through streptavidin, either by adsorbing streptavidin directly to the surface or immobilizing another biotinylated protein (like biotinylated bovine serum albumin), and then using streptavidin as a glue between that protein and the biotinylated microtubule [37, 75]. In principle, self-assembled monolayers (SAMs) in which a portion of the groups are terminated with biotin could be patterned, and streptavidin and microtubules patterned by the underlying biotin. Other techniques for patterning biotin or streptavidin at micron or nanoscale dimensions that have been developed for DNA microarrays or nanoscale two-dimensional protein patterns could be applied to patterning biotinylated microtubules. The final immobilization strategy, in the “turning lemons into lemonade” category, involves using dysfunctional kinesin motors to immobilize microtubules [76, 77]. If kinesin protein is mishandled, e.g. stored at room temperature for days, or when problems arise during expression and purification of functional motors, the motors inactivate in such a way that they bind to microtubules, but do not move along them. When these “dead-heads” are adsorbed to surfaces, they act as an excellent adhesive to immobilize microtubules.

While the optimum immobilization approach depends upon the specific application, there are some general considerations that apply to all microtubule immobili-

zation techniques. First, approaches that permit patterning microtubules on the micron or submicron scale are helpful only if filament orientation can be controlled. For instance, even with narrow strips of adhesive, microtubules can simply lay across the lines, negating the pattern. Finally, from experiences in our laboratory and others, it is clear that from the perspective of kinesins, not all microtubule immobilization strategies are created equal. For instance, when microtubules are immobilized through aminosilanes on glass, motors rarely interact with microtubules that are tightly adsorbed to the surface through their entire length, while they interact much more frequently with microtubules that are more loosely tacked down and have regions that are not directly attached to the surface. Whether these problems are due to deformation of the microtubules when they are tightly adsorbed or to unfavorable motor–surface interactions is not clear, but these observations emphasize that the success of any immobilization strategy must include an analysis of motor function as well.

## 8.5

### Controlling the Direction and Distance of Microscale Transport

The key to harnessing the transport capabilities of molecular motors is controlling the direction of motion. For applications in microscale transport, it is this ability to direct the transport of a particle or analyte independent of fluid flows or concentration gradients that has generated the most interest in the field to date. Redirecting microtubule movements in the microtubule gliding assay has received the most attention because the filaments move long distances (detachment is not a concern), the filaments can be easily visualized by fluorescence microscopy and they can be functionalized to transport cargo. In this section, transport applications utilizing the filament gliding is covered first, followed by the opposite geometry, i.e. cargo-loaded motors moving along immobilized filaments.

#### 8.5.1

##### Directing Kinesin-driven Microtubules

Building on the standard microtubule gliding assay, the first directed transport investigations showed that micron-scale grooves deposited on glass surfaces either by shearing polytetrafluoroethylene (PTFE) or by microfabrication guide microtubule motions parallel to the grooves [2, 4, 7, 78, 79]. This redirection arises from the nature of microtubule movements along surfaces – the front of the filament searches out new motors to bind to as it is propelled along the surface and physical barriers that reorient this free end act to reorient the direction of filament movement (Figs. 8.4 and 8.5). Building on these initial demonstrations, a number of studies using more sophisticated fabrication approaches have amply showed that microtubules can be guided and redirected using surface features. A key advance, first shown by Hiratsuka and coworkers [6], was the demonstration that microtubules moving in microfabricated channels can be redirected by arrowhead-shaped “rectifiers” built into the channels that pass filaments traveling one direction, and buckle and

**Figure 8.4.** Physical model of a microtubule, propelled by immobilized kinesins, colliding with a wall and buckling. The length of filament that can buckle,  $L_B$ , is defined as the distance between the last motor and the wall. For the microtubule to buckle, the cumulative motor

forces must be greater than the minimum buckling force for approach normal to the surface, but can be less than that if the incident angle is less than  $90^\circ$ . (Reprinted with permission from Ref. [2] © 2003 American Chemical Society.)

redirect filaments traveling in the opposite direction. Later investigations extended this result using different fabrication approaches and a range of rectifier shapes (Fig. 8.6) [53, 80]. An important advance in this study was to identify photoresist materials that prevent adsorption of functional kinesin motors, such that when the photoresist is patterned on glass, functional motors are only found on the glass surfaces in the bottom of the channel. In both the work by Hiratsuka and co-workers and in a related study by Moorjani and coworkers [2], the key to containing the movement in the channels was not preventing protein adsorption to the walls, but rather the fact that motors that adsorbed to the photoresist denatured or otherwise inactivated. When the photoresist walls were treated to enable functional motor adsorption, the microtubules simply crawled over the walls [2].

One goal in achieving useful transport by this approach is minimizing the number of filaments lost due to detachment from and diffusion away from the surface. If filaments are transported along the surface by a population of motors that each cyclically attach and detach from the filament, there is a low probability that all of the motors are detached at the same time and so long transport distances can be achieved. However, when filaments are redirected by walls or crawl over walls of the channels, there can be significant filament loss if the channels are not enclosed on all sides [2, 79, 81]. This filament loss can be minimized by undercutting the walls of the channels to create overhangs that tend to trap the filaments in the

channels [3]. Also, by designing rectifying shapes and patterning gold on the bottom of the channel to maximize motor adsorption, and silanes on the sides of the channels to resist motor adsorption, high efficiencies of filament rectification have been achieved [80]. Experiments using this “open-top” configuration where motors are adsorbed to patterned and textured surfaces, and the top of the channels are left open to solution, have been instrumental in understanding the optimal channel design and surface chemistry for redirecting microtubule movements in microchannels. However, the best method for eliminating filament loss is to enclose these microchannels on all sides. For practical devices to emerge from this area of research, it is clear that enclosed microchannels will be required, together with apparatus for sample inputs and downstream detectors. As described below, there has been some initial progress toward these goals.

### 8.5.2

#### Movement in Enclosed Microchannels

Achieving directed movement in enclosed channels entails different design constraints than movement along topographically patterned surfaces. For instance, because microtubules are surrounded on four sides, detachment from the surface is less of a problem because subsequent rebinding is quite rapid. Furthermore, whereas guiding microtubules with open-top channels generally requires that the side walls are not populated with functional motors, in enclosed channels it is fine for microtubules to move along all four walls so long as they are moving down the channel in the desired direction. However, there are some important design constraints for creating enclosed channels for microtubule transport. First, because fluorescence microscopy is generally used to visualize microtubule movements in the channels, at least one side must be transparent and materials that autofluoresce (which includes many photoresists) need to be avoided. Second, as described in Section 8.7 below, polydimethylsiloxane (PDMS), which is regularly used in microfluidics work, can generally not be used because of its high oxygen permeability. Third, because the channels are initially filled and motor-functionalized by pressure-driven flow, the bond between the channels and the top enclosure must be sufficiently strong. Finally, the channel design must include fluidic connections for injecting motor and microtubule solutions into the channels.

Huang and coworkers recently succeeded in achieving kinesin-driven microtubule movements in enclosed microfabricated channels [57]. A number of channel designs were investigated, and a key breakthrough was creating hierarchical channels of decreasing dimensions such that solutions could be exchanged into small

←

**Figure 8.5.** A microtubule being redirected by a microfabricated channel wall. The channel is glass and the walls are 1.5- $\mu\text{m}$  high SU-8 photoresist. The microtubule moves from left to right in the channel, bumps into the photoresist wall and is redirected back into the channel. The scale bar at right is 10  $\mu\text{m}$ ; images are 12 s apart. 10 μm

channels 15  $\mu\text{m}$  wide and 5  $\mu\text{m}$  deep without large dead volumes. The channels were constructed in SU-8 photoresist patterned on glass, covered with dry film photoresist and topped with a silicon wafer or glass slide for mechanical stability. Microtubules moved long distances in the channels, indicating that the ATP fuel was not limiting in these enclosed volumes. Furthermore, the microtubules could move upstream in convective fluid flows, which means biomotor-driven transport can move against microfluidic transport [57]. Current work in this area aims to simplify fabrication processes and optimize the channel geometries to achieve ideal microtubule transport, concentration and redirection.

### 8.5.3

#### Immobilized Microtubule Arrays

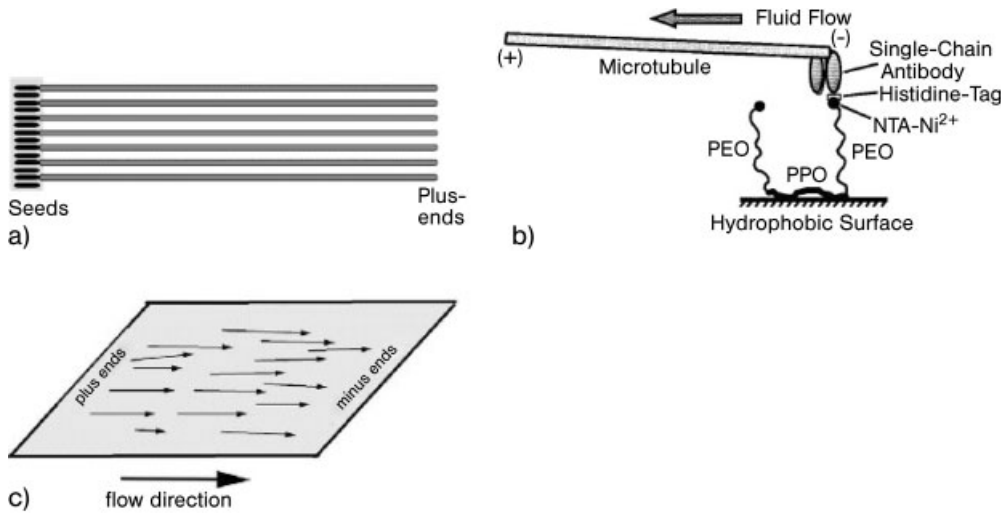

While most studies investigating transport applications of kinesins have utilized the microtubule gliding configuration, there has also been progress on immobilizing aligned microtubules and transporting motor-functionalized cargo along these filaments. Conceptually, binding motors to analytes and transporting this cargo along immobilized filaments is the simpler geometry and because of the ease with which motors can be engineered to contain diverse cargo binding domains in place of their tail, it has significant potential. However, the key hurdle to making this geometry work is immobilizing parallel and *uniformly oriented* filaments on surfaces. While filaments can be aligned in fluid flows, they are of mixed orientation and hence are of little use in transport applications. Current progress in obtaining arrays of uniformly oriented immobilized filaments is described below.

Brown and Hancock created an array of uniformly oriented microtubules by immobilizing short microtubule seeds at defined locations, growing filaments selectively off of the “plus” ends of these seeds, aligning the newly polymerized filaments by fluid flow and then immobilizing them on a surface (Fig. 8.7A) [46]. This process created aligned filaments, but the arrays were not the density needed for useful transport and the method is difficult to adapt to microscale environments. Limberis and coworkers used an elegant technique to bind and align microtubules [82]. Antibodies to the  $\alpha$ -tubulin subunit, which is exposed only at the “minus” ends of microtubules and not the “plus” ends, were immobilized on a surface and microtubules flowed in and allowed to bind end-on (Fig. 8.7B). Fluid flow was then used to push the filaments over and, although they were not immobilized in this study, a final immobilization step should not be difficult. A third technique, which may have the most potential, was demonstrated by Prots and coworkers,

**Figure 8.6.** Arrowhead-shaped structures in photoresist rectify microtubule movements. In this example, 1.5- $\mu\text{m}$  high SU-8 photoresist walls on glass create a rectifier with inlet and outlet channels. A microtubule can be seen moving upward inside the arrowhead, bumping into the photoresist wall and being redirected

back into the channel. Rhodamine-labeled microtubules and SU-8 channel walls were imaged using simultaneous fluorescence and differential interference contrast microscopy. (Reprinted from Ref. [53], with kind permission of Springer Science and Business Media.)

**Figure 8.7.** Three methods to create an array of uniformly oriented microtubules on a surface. (A) Brown and Hancock immobilized short microtubule seeds on an adhesive region, grew microtubules exclusively from the “plus” ends of these filaments, and then aligned and immobilized them. (B) Limberis and coworkers bound antibodies for  $\alpha$ -tubulin

to the surface, captured microtubule “minus” ends and then aligned the microtubules by fluid flow. (C) Prots and coworkers used fluid flow to align kinesin-driven microtubules and then immobilized these filaments on the surface. (Reprinted with permission from Refs. [46, 82, 83] © 2002 and 2001 American Chemical Society and 2003 Elsevier, respectively.)

who started with a field of microtubules moving over immobilized motors, aligned their direction of movement using fluid flow (over time all filaments move parallel and downstream to the flow) and then crosslinked the filaments to the motors using glutaraldehyde (Fig. 8.7C) [83]. Other experiments have shown that glutaraldehyde treatment does inhibit subsequent interactions of the microtubules with motors [84] and the authors showed that kinesin-functionalized beads move unidirectionally along these filament arrays [10].

One of the downsides of using kinesins moving over immobilized microtubules is that the transport distances are generally shorter than distances achieved by many immobilized motors moving long microtubules across surfaces. Single-molecule experiments have shown that during each encounter, conventional kinesin moves approximately 1  $\mu\text{m}$  along a filament before detaching [39, 85]. These motors can then reattach and move further; however, for long distance transport, longer run lengths are desired. Somewhat longer transport distances can be achieved by modifying the motors to increase the amount of positive charge in the “neck” region adjacent to the head [86] or by binding multiple motors to the desired cargo such that dissociation of one motor does not lead to dissociation of the entire cargo. These dissociation problems highlight the fact that if immobilized microtubules are used, they not only need to be uniformly aligned, but they need to be immobilized at high densities to maximize the rate of motor reattachment. To make this geometry feasible for analyte transport applications, more work needs

to be done to develop facile methods to create high density, uniformly oriented microtubule arrays.

## 8.6 Cargo Attachment

Another important hurdle for achieving useful transport from the kinesin–microtubule system is developing methods for selective and reversible attachment of cargo to the microtubules and/or motors. For microtubules moving in microchannels, the long-term vision is that the microtubules will pick up their cargo at one site and be transported along a channel, and the cargo will be deposited in a collection or analysis chamber. The question is: how is cargo attached to microtubules? Successful approaches and future ideas are reviewed here.

One problem with attaching cargo to microtubules is that, in contrast to motors, it is difficult to use the tools of molecular biology to modify tubulin sequences. Generally, tubulin for these applications is purified from cow or pig brain and it is currently prohibitively expensive to produce genetically engineered large animals for this purpose. *In vitro* expression of recombinant tubulin has been achieved [87], but it is technically demanding and yields are low. Hence, the primary route to modifying microtubules to enable cargo attachment has been to covalently link functional cargo attachment groups to the microtubules. By attaching reactive *N*-hydroxysuccinimidyl (NHS) groups to exposed amine residues on tubulin, microtubules have been covalently labeled with a number of fluorescent dyes and biotin [34]. Biotinylated microtubules have by far been the most widely used. Avidin (or its relatives streptavidin and neutravidin) contains four high-affinity biotin binding sites, enabling sandwich configurations where biotin-functionalized cargo can be attached to biotinylated microtubules [88, 89].

Proteins, single-stranded (ss) DNA or RNA molecules and cells represent three potential types of cargo that can be transported, separated and/or concentrated by the kinesin–microtubule system (Fig. 8.8). To date, all three types of cargo have been attached to microtubules through biotin–avidin chemistry. Biotinylated antibodies can be purchased from commercial sources or antibodies of interest can be biotinylated using amine-reactive biotin sold by Molecular Probes (Invitrogen,

**Figure 8.8.** Attaching cargo to a microtubule through biotin–avidin chemistry. Biotin molecules (black dots) that are covalently linked to tubulin subunits bind streptavidin protein (which has four biotin binding sites).

Biotin-functionalized antibodies (left), DNA oligonucleotides (center) or particles (right) can be linked through the streptavidin and transported by the immobilized kinesin motors.

Carlsbad, CA). These biotinylated antibodies can be attached to microtubules by incubating biotinylated microtubules first with neutravidin and then with the biotinylated antibody, but care must be taken not to overload the microtubule [89]. As the neutravidin binds to the same microtubule surface that the kinesin motors bind to, a portion of the tubulin subunits must remain unlabeled to enable motor binding. By attaching anti-GFP (green fluorescent protein) antibody to microtubules, we showed that microtubules can pick up and transport protein cargo along kinesin-functionalized surfaces [90]. This important proof of principle implies that microtubules could be modified to transport any protein for which a suitable antibody exists.

A second important cargo is nucleic acids. A possible application for a kinesin-based analytical device would be RNA analysis for examining gene expression in a small tissue sample or for detecting viruses. DNA microarrays are now widely used for expression profiling – determining what mRNA species are being expressed in a cell or tissue under certain conditions. However, if the sensitivity could be increased, smaller sample volumes could be used, ideally to the point where mRNA levels from individual cells could be analyzed. As this enhancement would remove any signal loss due to heterogeneity between different cells in a tissue biopsy, this is an active area of research. A kinesin-based transport device would be very valuable if it could bind selected mRNA from a cell lysate, transport these analytes down microscale channels, detect their presence and concentrate them in a collection chamber for later analysis such as sequencing or polymerase chain reaction (PCR) amplification (Fig. 8.9). To demonstrate the feasibility of nucleotide trans-

**Figure 8.9.** Diagram of a motor-based detection and purification scheme. Top panel shows an integrated system including a sample chamber containing microtubules and analyte, kinesin-functionalized microchannels through which cargo is transported, a LED excitation source and photodiode (PD) detector inte-

grated into the channels, and electrodes (E) to direct cargo-laden microtubules to the collection chamber. Bottom panel shows that kinesin-based transport that will drive the system. (Reprinted from Ref. [53], with kind permission of Springer Science and Business Media.)

port by microtubules, Muthukrishnan and coworkers bound ssDNA oligonucleotides to microtubules through biotin–avidin chemistry and then bound fluorescently labeled complementary DNA oligonucleotides to these microtubules. Like the protein cargo-functionalized microtubules, these DNA cargo-functionalized microtubules were faithfully transported across kinesin functionalized surfaces [88]. Diez and coworkers showed that kinesins can also be used to transport and stretch large pieces of DNA.  $\lambda$ -phage DNA attached to microtubules through biotin–avidin chemistry was transported along surfaces by immobilized motors and, when bound at one end to the surface or another microtubule, could be stretched by the motor forces up to its maximum contour length [91].

Another cargo attachment strategy that has been investigated is using cyclodextrins attached to microtubules [92]. These versatile molecules are cyclic oligosaccharides that contain a hydrophobic cavity that can be engineered to bind small molecules and proteins [93]. As they can be biotinylated, they can be attached to biotinylated microtubules through a streptavidin crosslinker and transported by surface-immobilized kinesins. Kato and coworkers reported that cyclodextrin-functionalized microtubules moved more than 10-fold slower than normal microtubules, indicating the attachment unfavorably altered the surface of the microtubule [92]. Hence, work needs to be done to improve this strategy, but it has the potential to be of significant utility. Other cargo-binding approaches can be envisaged such as designing RNA aptamers through directed evolution [94], and attaching these to microtubules through biotinylated bases, but no work has been published to date in this area.

### 8.6.1

#### Maximum Cargo Size

An important question for kinesin-based transport is: what is the size limit for cargo transported by kinesins and microtubules? To investigate the potential utility of kinesins in microscale devices, Limberis and Stewart attached kinesins to  $10 \times 10 \times 5\text{-}\mu\text{m}^3$  silicon microchips and found the chips moved at normal motor speeds along immobilized microtubules [56]. Similarly, Jia and coworkers attached clumps of gold nanowires  $6\ \mu\text{m}$  long to microtubules and found that they were transported at normal speeds along motor functionalized surfaces [53]. The fact that the viscous drag forces did not affect the motor transport speeds suggests that even larger objects can be transported. The theoretical maximum size of an object that can be attached to a microtubule and transported by kinesins is calculated below.

The theoretical size limit for spherical objects that can be attached to microtubules and transported by molecular motors can be calculated by comparing motor forces to viscous drag forces for a sphere in aqueous buffer. Individual motors can exert 5–8 pN of force [37, 38, 95]. Kinesin motors can be adsorbed on surfaces to densities of 1000 motors  $\mu\text{m}^{-2}$  or more, so it is reasonable to expect a long microtubule to be able to interact with hundreds of motors [42]. If motor forces sum (which has not been definitively shown, but is consistent with a number of experi-

mental observations), then it is possible that motor forces pushing a microtubule could approach 1 nN. The drag force on a particle moving in aqueous solution is equal to

$$F = \gamma v \quad (6)$$

where  $\gamma$  is the drag coefficient and  $v$  is the velocity [52]. For a microtubule moving cargo at  $1 \mu\text{m s}^{-1}$ , the drag coefficient,  $\gamma$ , that results in 100 pN of force, which would start to slow the microtubule, is  $10^{-4} \text{Ns m}^{-1}$ . The drag coefficient of a spherical object can be calculated from Stokes' law, given in Eq. (2) above. Solving for the diameter of a sphere that would start to slow down the microtubule – the result is 1 cm! Hence, the range of objects that can in principle be transported by this system has only begun to be explored.

## 8.7

### System Design Consideration

The development of biomotor-driven microscale devices has evolved in three phases: (a) recapitulating intracellular motility in *in vitro* experiments, (b) controlling microtubule transport using microfabrication, surface processing and other techniques, and (c) creating integrated functional devices. The first phase was completed by the early 1990s. The second phase has been the focus of considerable effort over the last five years and, although it will continue to advance, the progress will likely slow somewhat. It is now that researchers are turning to the third phase, i.e. device development. There are a number of issues that need to be resolved for this work to move forward, such as protein lifetimes, sample introduction, and analyte detection and processing. Progress to date in these directions and future efforts towards these goals are reviewed here.

#### 8.7.1

##### Protein Stability and Lifetime

As a tool in nanotechnology, there is a trade-off between the exquisite functionality of biomolecular motors and their robustness. For their small size, kinesins are able to achieve long-range transport of microtubules at appreciable speeds and generate significant forces. Due to their small size, they have the potential to be integrated into very microscale and nanoscale device geometries, enabling redundancy, multiplexing, minute sample analysis and minimal reagent costs. However, because they are proteins, they are much more fragile than most nanoscale materials. To assess their potential utility when integrated into analytical devices, and to investigate alternate design approaches, it is necessary to determine the lifetime of kinesin motors and microtubules under normal operating conditions, and then to find conditions that extend these lifetimes.

Under normal laboratory conditions, taxol-stabilized microtubules are stable at room temperature for roughly 1 week [96, 97], and kinesin motors are stable on the order of hours to days depending on their concentration, storage buffer, temperature and other variables. For experiments on motor fundamentals, as long as the motors are stable for a working day, there is no need to put the work in to extend their lifetime because each morning a new aliquot of protein can be thawed from the  $-80^{\circ}\text{C}$  freezer. Hence, it has been the interest in device integration that has driven experiments to uncover the mechanisms that limit the working lifetimes of kinesin and microtubules, and to extend these lifetimes.

In the kinesin–microtubule field, the most convenient technique for observing motor function is fluorescence microscopy. Microtubules can be visualized by differential interference microscopy, but for applications where motors and/or cargo are to be observed fluorescence is much more versatile. In the microfluidics field, a standard approach for creating channels has been PDMS molding and bonding to glass [98] and in a perfect world these two approaches could be combined. However, workers studying fluorescent microtubule movements in PDMS channels quickly ran into problems with photodamage [99]. In the standard microtubule gliding assay, the microtubule cocktail includes buffering salts, ATP to drive motility, and an antifade consisting of an oxygen-scavenging system and reducing agent [41, 45]. In the absence of antifade, exposure of the fluorescent microtubules to the high-intensity mercury arc lamp used for fluorescence excitation results in rapid photobleaching, loss of movement and microtubule depolymerization due to oxygen free radical damage. With antifade, the movement of rhodamine-labeled microtubules can be visualized for roughly 10 min under continual high intensity illumination. Without illumination or by shuttering the light, microtubule movement lasts for around 10 h or longer [100]. However, when the flow cell is enclosed with PDMS instead of glass, illumination leads to inhibition of motion and microtubule breakage or depolymerization after approximately 1 min [99, 100]. The cause of failure was traced to the high oxygen permeability of this silicone polymer, which overwhelms the antifade's ability to remove all of the soluble oxygen. PMMA enclosures also showed this same property. While these results do not rule out these materials as device components, if they are to be used they must be combined with another barrier to oxygen diffusion, increasing the complexity of fabrication.

A central concern in the feasibility of kinesin–microtubule powered devices is long-term storage: if hybrid biological/synthetic devices are manufactured, how long can they be preserved before use? Interestingly, this is a similar concern in the field of tissue engineering, where products like artificial skin that include live cells integrated into a polymer scaffold must be made at a manufacturing site, stored and shipped, and then unpacked and used by a doctor. The obvious first approach is freezing; kinesin motors, tubulin and even taxol-stabilized microtubules can be frozen on liquid nitrogen and stored at  $-80^{\circ}\text{C}$  for years with little loss in functionality. In theory, hybrid devices could be simply dunked in liquid nitrogen and thawed before use, but there are a number of possible problems with this approach, including mechanical problems due to unequal expansion coeffi-

cients of the various materials and the requirement for a deep freeze at every point of use.

There has been some recent work on novel methods for extending kinesin and microtubule lifetimes that has yielded interesting results. With the goal of identifying material-processing approaches that could be used to create hybrid devices, Verma and coworkers tested the stability of casein, kinesin motors and microtubules when exposed to various solvents and strippers used in materials processing and nanofabrication. Interestingly, kinesin motors survived when exposed to either pure isopropyl alcohol or acetone – two solvents commonly used to remove photoresist [101]. Microtubules were less robust than motors, but they did survive exposure to 1:4 dilutions of these chemicals in aqueous buffer and these diluted solvents retained their ability to strip photoresist. While not directly impacting device lifetime, these studies provide new approaches for device manufacture and they suggest that these proteins are more stable than may be indicated by their lifetimes in buffer at room temperature. In other work, it was found that drying immobilized kinesins by wicking the solution out of flow cells and storing them under different conditions resulted in longer kinesin lifetimes [102]. Hence, it is possible that instead of freezing hybrid devices, simply desiccating them and then reconstituting them may provide a simple alternative. These findings should lessen the constraints to hybrid device design.

### 8.7.2

#### **Sample Introduction and Detection**

Two future hurdles to creating kinesin-driven analytical devices are sample introduction and analyte detection. To date there is scant work in this area, but because these requirements are universal to virtually all sensor systems, ideas and modules will undoubtedly be borrowed from other disciplines. With respect to sample introduction, one design constraint is that these biomotors work in aqueous environments. As discussed above, kinesins can survive being dried or exposed to solvents, but for their proper function they must remain in proper buffer solutions. Hence, to detect airborne particles (e.g. viruses or bacteria), the samples would need to be concentrated (i.e. filtered) from the atmosphere and then transferred to the aqueous state. While not impossible, there are clearly a number of engineering problems to be solved for this application to become feasible.

An area where the strengths of kinesin-powered devices are maximized is the detection of proteins, RNA or small molecules in minute aqueous samples. As discussed above, detection of specific molecules from single cells is a holy grail of sorts for bioanalytical detection. Delivering the contents of single cells to kinesin-powered transport and detection machinery is a task in itself. Both convective flows and dielectrophoresis have been used to transport cells in microfluidic systems [103, 104]. Additionally, both optical and electrical methods have been developed to rapidly lyse cells, enabling their intracellular contents to be delivered to the microanalysis machinery [105, 106].

### 8.7.3

#### Analyte Detection and Collection

As in all analytical systems, analyte detection will be a key component to future kinesin-powered hybrid devices. The first choice for analyte detection is fluorescence, because it is sensitive and is the standard technique for observing microtubules moving in channels. Building on work guiding microtubule transport in microfluidic channels, analyte detection could be achieved by binding the analyte to the microtubule and observing the change in fluorescence. If the analyte (cell, protein or nucleotide) is fluorescent and has a different emission peak than the fluorophore labeling the microtubule, analytes could be detected by observing the microtubule fluorescence at one wavelength and measuring the analyte fluorescence at a second wavelength. In this case, the microtubule acts to both concentrate and to localize the analyte.

While this detection could be achieved using epifluorescence microscopy, there is potential for achieving much more utility and sensitivity by integrating the optical components into the microfluidic chips containing the motors and analyte. For instance, if an LED and photodiode are integrated into the microchannel containing the microtubule and bound analyte, the detector could be within microns of the sample (Fig. 8.9). This placement should maximize photon capture and reduce background signal due to extraneous signal. One advantage of using the kinesin–microtubule transport system for analyte detection is that the movement speed is stereotyped, so for low signal levels the time average of fluorescence as the analyte moves across the detector could be used to increase the signal-to-noise ratio.

## 8.8

### Conclusion

Due to the highly evolved properties of protein machines, there is incredible potential in integrating them into hybrid biological/synthetic devices. Their nanometer-size scales match well with emerging nanofabrication capabilities and novel functional nanoscale materials. A continuing struggle in nanotechnology is finding techniques to manipulate and organize molecules and nanoparticles in cases where self-assembly is not energetically favorable. As biomolecular motors have evolved to transport and organize biological materials on the nanoscale and microscale in cells, they have the potential to solve a number of these general problems in nanotechnology. This chapter reviewed the *in vitro* transport capabilities of kinesin motors, with an eye toward creating microfluidic devices for analyte detection. This application is one of the first envisaged for these particular protein machines and it is anticipated that as new approaches are developed for to gain ever more control over the kinesin–microtubule system, these biological machines will be applied to other nanoscale systems.

## Acknowledgments

The author wishes to thank members of his laboratory, especially Maruti Uppalapati, Gayatri Muthukrishnan, Zach Donhauser and Samira Moorjani, as well as collaborators and their students, particularly Tom Jackson, Lili Jia, Ying-Ming Huang, Jeff Catchmark and Vivek Verma. The author's research in this area is supported by the NSF and NIH/NIBIB, and by the Penn State Center for Nanoscale Science (NSF MRSEC DMR0213623).

# Self-assembly and Bio-directed Approaches for Carbon Nanotubes: Towards Device Fabrication

*Arianna Filoramo*

### 9.1

#### Introduction

Silicon-CMOS technology is the base of present hardware technology for information processing. Until now, its evolution has been governed by Moore's law (from the 1970s), stating that microprocessor performance (defined as the number of transistors on a chip) doubles every 18 months. However, the International Technology Roadmap for Semiconductors (ITRS) [1] predicts that the present CMOS technology will reach its fundamental limits in terms of miniaturization by 2010–2015, concurrently with a dramatic increase in the cost of the production units.

This prompts us to study and develop alternative nanofabrication technologies that will enable the production and manipulation of well-defined structures at the nanoscale level. Indeed, it is well accepted that conventional technologies based on the “top-down” approach are foreseen to experience experimental difficulties. This is due to the existence of various physical effects that do not down-scale properly and, most importantly, to the fabrication cost issues at the nanoscale dimension. At this scale, as also stressed in the IST Technology Roadmap for Nanoelectronics [2], self-assembly and, more generally, “bottom-up” approaches appear to be a more reasonable way to assemble nano-objects into circuits with a two- and/or three-dimensional layout. In particular, self-assembly is also identified as the most promising way to significantly reduce the fabrication costs compared to what is expected for standard top-down silicon-based devices. Indeed, the basic idea of self-assembly is to use a process involving the spontaneous self-ordering of substructures into superstructures. This spontaneous self-ordering is due to specific chemical or physical properties of matter and relies on the natural tendency of the system to search for a stable configuration. This chapter is not meant to be an exhaustive review of self-assembly techniques, but rather a focused discussion on the application of this concept to a particular nano-object – the carbon nanotube (CNT). At present there are several materials with potential for the fabrication of new-generation nanodevices. They vary from conventional semiconductors to conjugated molecules, but among them CNTs are one of the most interesting. This is

due to the wide range of physical properties they can show as a function of their shape and geometry.

CNTs have already been used to fabricate nanodevices, like field-effect transistors (FETs), with very interesting performance characteristics. In this chapter we describe their fabrication techniques, as well as their principal characteristics. The chapter also contains a more general discussion about these unique materials and their nano-applications. In this sense, we provide a discussion on the relevance of using CNTs as active elements in future nanoelectronic devices. We also critically consider the existing techniques that, by self-assembly, enable us to selectively place the nanotubes at specific locations on a substrate in a circuit configuration.

The self-assembly methods we will consider in this chapter are: *in situ* chemical vapor deposition (CVD) growth, the self-assembled monolayer (SAM) technique and the DNA-directed approach. We present their advantages, drawbacks and perspectives. In particular, we discuss in detail the DNA-directed approach. This bio-directed method constitutes a genuine and complete molecular-scale bottom-up method, since it relies on recognition properties inherent to biological entities and can be employed without using any standard lithography technique (a fingerprint of the top-down strategy). As well as the economically very appealing interest of a self-assembly technique is generated by the perspectives of important reductions in fabrication costs, DNA-directed self-assembly could in addition bring truly new technological perspectives by introducing a disruptive strategy and by stimulating the development of novel architecture paradigms, which could include concepts like self-repairing features, reconfigurability, three-dimensional design and massive parallel processing.

The chapter is organized as follows. Section 9.2 presents a brief review of the basic physical features of CNTs, their synthesis methods and the different families of CNT applications reported in the literature. Section 9.3 is devoted to the discussion of the techniques of fabrication of CNT transistors. Here, the interest in self-assembly is highlighted. The first self-assembly method to be detailed is *in situ* CVD in Section 9.4, whereas two post-growth approaches are extensively discussed in the following two sections: in Section 9.5 we review the SAM method and in Section 9.6 we discuss the different aspects of the DNA-directed self-assembly technique for nanotube electronic applications. Finally, we draw our conclusions in Section 9.7.

The scope of the chapter is to provide an introduction and an overview of the current state of the fabrication of devices made of CNTs by using self-assembly. Nonetheless the degree of maturity of the presented nanofabrication methods is variable; we provide a critical comparison of their perspectives and an analysis of the issues to be solved before they could be integrated to real-world applications. This aims to give to the reader the elements to think about the strategies to be conceived for the future developments of the different nanofabrication techniques. The focus of the chapter is more on the fabrication of devices by self-assembly methods than on the details of their functioning, which are left to the appropriate cited references. This chapter, with the help of the included references, will give

the reader the necessary tools to acclimate, evaluate and enter into this interesting field of research.

## 9.2

### CNTs: Basic Features, Synthesis and Device Applications

Since their discovery in the early 1990s by Sumio Ijima [3], CNTs have been a privileged subject of fundamental and applicative research due to their extraordinary physical properties [4]. For instance, their excellent resilience, tensile strength and thermal stability can be used for resistant car bodies, earthquake-resistant buildings or microscopic robots. More generally, the wide range of potential applications in vastly different domains is a result of the numerous and varied aspects of their physical, chemical, mechanical and electronics properties. Long-term exploitation of these unique properties is expected to allow the elaboration of a whole new family of valuable devices.

#### 9.2.1

##### Basic Features

CNTs can be divided in two classes: single-wall CNTs (SWNTs) and multiwall CNTs (MWNTs). A SWNT is basically a rolled-up shell of graphene sheet made of hexagonal carbon rings with half-fullerenes capping the shell ends. MWNTs were discovered first and are a stack of SWNTs of different diameters disposed in a concentric geometry (like Russian dolls). These two kinds of CNTs are schematically presented in Fig. 9.1.

Figure 9.2(a) shows a small part of the graphene lattice, with carbon atoms labeled according to the Dresselhaus notation [4]. The nomenclature  $(n, m)$ , with  $n > m$ , used to identify SWNT refers to integer indices of two graphene unit lattice vectors corresponding to a nanotube's wrapping index known as the *chiral vector*.

Figure 9.1. Schematic representations of a SWNT (a) and a MWNT (b).

**Figure 9.2.** The graphene sheet is a planar hexagonal lattice of carbon atoms (a). We can recognize the unrolled honeycomb lattice of a nanotube. SWNTs with different chiralities are

obtained by rolling-up parts of the graphene sheet along different axes: an arm-chair, a chiral and a zigzag (from top to bottom in b).

The chiral vector determines the direction along which the graphene sheet is rolled to form the nanotube. It is, by definition, perpendicular to the tube axis vector. The tubes of type  $(n, n)$  are commonly called armchair nanotubes because of their shape ( $\backslash \ / \ / \ \backslash$ ) perpendicular to the tube axis. They make a chiral angle of  $30^\circ$ . The tubes of type  $(n, 0)$  are called zigzag nanotubes due to their shape ( $\backslash \ \backslash \ \backslash$ ) perpendicular to the tube axis. They make a chiral angle of  $0^\circ$ . All the remaining tubes are called chiral nanotubes and have a chiral angle  $\theta$  with  $0 < \theta < 30^\circ$  (see Fig. 9.2b).

CNTs thus possess both nanometric (related to their radius) and microscopic (related to their typical length) characteristic. Correspondingly, most of their original physical properties result from this hybrid nature. For electronic purposes we are principally concerned with the transport properties of CNTs.

In this context, single-wall nanotubes are particularly interesting because of the

following singular physical property: a SWNT can show either metallic or semi-conducting behavior, depending on its chiral vector  $(n, m)$ . The general rule is that if the difference  $n - m$  is an integer multiple of 3 then the nanotube is metallic, whereas in all the other cases the nanotube is a semiconductor. As a consequence, if all chiralities are equiprobable, the metallic:semiconductor abundance ratio for SWNTs should be 1:3. Most importantly, one can envisage the realization of structures with specific transport properties by combining CNTs of different nature into the same device. For instance, nanotubes with different chiralities can be connected to obtain heterojunctions. Applications of SWNTs as electronic devices are discussed in a later section. Concerning MWNTs, the stacking of nanotubes with different chiralities can bring more unexpected results, as suggested by first-principles calculations. Indeed, the outcomes of such model calculations show that the interlayer coupling, which in most cases has little effect on the electronics properties of the individual tubes, can, under specific conditions of the relative positions of one tube shell with respect to the other, strongly modify their individual properties [5].

Finally, it is also important to recall that nanotubes have good elastomechanical properties and that they are thermally very stable. This is related to the fact that the two-dimensional arrangement of carbon atoms in a graphene lattice allows large out-of-plane distortions while the strength of carbon-carbon in-plane bonds keeps the graphene sheets exceptionally strong against distortions [6–8]. Experimental observations of distortions induced to a nanotube demonstrate this high elasticity and point towards its possible use as lightweight, highly elastic material [9–12]. Therefore, CNTs provide one-dimensional wires that enable the fabrication of different complete families of electronic devices.

### 9.2.2

#### **Synthesis of Nanotubes**

There are mainly three methods for the synthesis of nanotubes: arc-discharge [13–18], laser ablation [19–21] and CVD [22–26]. The first two are evaporation methods that employ solid-state carbon precursors as carbon sources for nanotube growth and involve carbon vaporization at high temperatures (in an oven at 1100–1200 °C) assisted, respectively, by an arc-discharge or laser ablation. In order to achieve nanotube growth some metal catalysts are added in the solid graphite source. The third method utilizes hydrocarbon gases as sources for carbon atoms. It also employs metal catalyst particles as “seeds” for nanotube growth, but the process takes place at relatively lower temperatures (500–1000 °C). More details about the CVD method are given in Section 9.4. These three methods have not been equally used in the literature.

Currently, the majority of the work published on the synthesis of CNTs (MWNTs and SWNTs) deals with different types of production by using the CVD route. A large variety of successful production approaches based on this method have been reported in recent years. Indeed, CVD processes are expected to be the solution for the mass production of CNTs.

The state-of-the-art synthesis achievements using CVD methods are: (a) production of centimeter-long CNTs [27, 28], (b) synthesis of CNTs along the direction of an applied electric field [29] and (c) very regular ordering of CNTs grown on templates [30]. The major problems of CVD-based approaches for SWNTs synthesis are: (a) the difficulty of producing CVD-SWNTs with a narrow diameter distribution and (b) the tubes produced generally have more defects. It is worth pointing out that although the best-quality SWNTs so far are produced by evaporation-related methods, the difference with CVD ones is becoming less and less significant.

It should be stressed that an important issue in the growth of SWNTs is the control of the tube diameter and of the chirality distributions. These two parameters are of prime importance in transport studies, since (a) as mentioned in Section 9.2.1, the chirality of a SWNT determines its intrinsic metallic or semiconducting properties and (b) the current of a nanotube transistor in its off-state is strongly dependent upon the nanotube bandgap, which is inversely proportional to the tube diameter  $d$  (the bandgap of a semiconducting SWNT  $\propto 1/d$ ). Despite the importance of having a good control of these distribution parameters, none of the three synthesis methods has yielded bulk materials with homogeneous diameters and chiralities. So far, evaporation techniques remain the best for the selective synthesis of SWNTs with a narrow diameter distribution [31, 32]. With respect to the chirality issue, two interesting reports should be mentioned: the first achievement concerns a preferential CVD growth of semiconducting SWNTs (with a yield of 90%) [33], while the second one concerns a postsynthesis method to separate metallic from semiconducting nanotubes [34].

### 9.2.3

#### Device Applications

A large number of studies on CNT applications have been reported in the literature [35]. They span from field emission electron sources [36–41], supercapacitors [42–44], artificial muscles [45–47], nanoelectromechanical systems [48–53], photoactuators [54], controlled drug delivery/release [55, 56], reinforcement of materials [12, 57–61], composite printable conductors [62], optical components [63, 64], nanoelectronic components [65], scanning probe tips [66–68], etc.

Here, we consider nanoelectronic device applications. In particular, we focus on transistors made of nanotubes and only briefly discuss their nanosensor applications. Indeed, it has been experimentally demonstrated that an individual semiconducting SWNT can be used as the channel of a CNTFET [69, 70]. In 2001, different achievements were accomplished: the demonstration of a room temperature single-electron transistor (SET) [71] and of nanotube transistors showing gain above unity [72], as well as the realization of logical gates mimicking CMOS ones (but with a lateral channel extension reduced to 1 nm) [72, 73]. Recent experimental [74–79] and theoretical [79–82] studies on CNTFETs showed that most of them work as Schottky barrier transistors. Their switching characteristics are limited by the Schottky barriers at the metal/nanotube junction that brings to the fore the

crucial role of interfaces in such a transistor. By optimizing the nanotube/electrode interface [74, 78, 83] and the gate coupling, the device characteristics can be improved both in the “on” and “off” states. Some CNTFETs [84, 85] already exhibit a level of performance comparable to state-of-the-art silicon MOSFETs (at comparable geometry).

It is worth pointing out that SWNTs are also an ideal material for nanosensor fabrication – their one-dimensional structure and their high specific area make the conductance of semiconducting SWNTs highly sensitive to very small amounts of molecules [86].

More precisely, in the context of sensor applications, the exceptional properties of nanotubes are exploited mainly in two ways. The first approach is based on the changes in electrical characteristic of a device constituted by an individual (or very few) SWNT in a transistor configuration. In this case the current in the device is modified by the interaction of the molecules with the semiconducting SWNT channel and/or with the electrodes of the transistor. In some cases the SWNT can be appropriately functionalized in order to enhance its interaction with and its sensitivity to the molecules to be detected. We can quote sensors of gaseous molecules [52, 87], proteins [88, 89], pH/glucose [90], aromatic compounds [91], humidity [92] and DNA hybridization with high sensitivity (concentrations as low as 6.8 fM solution) [93].

In the second approach, the CNTs are used as electrode materials in electrochemical cells [94]. Since their first application for the oxidation of dopamine [95], an increasing number of studies have been devoted to the CNT electrocatalytic behavior towards the oxidation of biomolecules. We can quote studies on dopamine [96–98], ascorbic acid [96], epinephrine [96, 98], 3,4-dihydroxyphenylacetic acid [99], homocysteine [100], thyroxine [101], glucose [102, 103], total cholesterol in blood [104] and DNA hybridization sensors [105–107]. The advantages presented by the CNT electrodes with respect to traditional carbon electrodes are better conducting characteristics, higher chemical stability, increased reaction rates, improved detection limit and reversibility. However, it should be noted that in most of these applications the nanotubes were utilized as a bulk material and not as an individual nano-objects. The nanotubes are generally dispersed in solution by chemical treatments, then incorporated in a matrix and deposited as (or onto) the electrodes. In some more recent reports the nanotubes are directly grown on the electrodes by CVD methods. A recent overview of this type of biosensors can be found in Ref. [108].

### 9.3

#### **Fabrication of CNT Transistors and Self-assembly Approaches**

The majority of the works reported on CNT transistors concern the study of their fundamental properties and performance. In this framework, the techniques that have been developed for the fabrication of such devices do not take into account yield/cost issue and are mainly based on random deposition methods.

Generally, the nanotubes are produced by an evaporation technique (laser ablation or arc-discharge) and, after a purification step, are dispersed in solution (typically in 1,2-dichloroethane). Then, they are deposited on an oxidized silicon substrate [69–78]. The result of this deposition is a completely spatially random distribution of the nanotubes on the substrate. Indeed, in this condition it is only possible to control the nanotube density on the surface by varying their concentration in the solution and not their positioning.

To connect some of these randomly dispersed nanotubes, they are first localized by atomic force microscopy (AFM) imaging with respect to some location marks fabricated on the substrate. Then, the best candidates (in terms of position) are chosen and a set of dedicated electrodes is fabricated. In some cases, a set of pre-patterned electrodes is already present on the substrate before the nanotube deposition and it is a matter of “luck” if the deposited nanotubes are correctly positioned on them. This is normally checked by AFM images of the sample. The same idea is followed if the nanotubes are randomly grown on the substrate by CVD. Indeed, after the growth, the nanotubes are imaged and the best candidates are electrically connected. Finally, it is also worth noting that each nanotube transistor does not always have its own gate electrode and that generally the conductive reverse side of the silicon substrate is used as a back-gate.

However, the possible use of CNTs as active elements in future nanoelectronics is closely related to the question of legacy/compatibility with present information technology. Indeed, it is quite unlikely that a system based on a new technology consisting of architecture with completely random disposition of such devices could be introduced and accepted. Therefore, to take full advantage of the unique electrical properties of SWNTs in device/circuit applications, it is desirable to be able to selectively place them at specific locations on a substrate with a low-cost, high-yield self-assembly-based technique.

Nowadays, the state-of-the-art of self-assembly of CNTs devices can be divided in two different classes of self-assembly methods: (a) *in situ* CVD growth, where the localization arises from the catalyst controlled positioning, and (b) post-growth localized deposition on a substrate. In the latter case, the nanotubes are first grown, handled in solution and only subsequently positioned on the substrate. Obviously, the technique chosen for selective placement of the nanotubes must not degrade the electrical characteristics of the devices and must leave open to all the possibilities of such interesting nano-objects.

The advantage of a post-growth deposition method is that, before deposition, CNTs can be purified and chemically treated in order to separate them by diameter [109–111], length [112] or chirality [34, 113, 114]. Moreover, in this predeposition step the nanotubes can also be chemically functionalized to add to their exceptional features other interesting chemical or physical properties [115, 116]. As discussed previously, the drawback to overcome in this case is mainly related to the deposition issue since it is generally random on the substrate. To solve this SWNT random deposition issue, two post-synthesis methods can be used.

The first one is to achieve a selective placement of SWNTs on regions of the substrate that are predefined by surface treatments. This post-growth selective place-

ment approach is based on the use of SAMs to modify the surface properties of certain regions of a substrate. This, in turn, affects the interactions between the sidewalls of a CNT and the surface, and the CNTs are preferentially attracted there.

The second approach could solve the deposition challenge using biological scaffolds, as DNA molecules, to realize site-controlled implementation of nanocomponents. Indeed, the unique intra- and intermolecular recognition properties of DNA have already been used to build-up scaffold structures and position nanoparticles [117–121].

These two post-synthesis methods are discussed Sections 9.5 and 9.6, while the *in situ* CVD approach is discussed in the next section.

## 9.4

### *In situ* CVD Growth

The *in situ* CVD method is based on the selective growth of CNTs on specified locations on the substrate. We now present the main aspects of this technique.

As previously mentioned, the first step of the CVD is the energy-activated decomposition of some hydrocarbon gas. The energy source can be either a plasma or a resistively heated coil and its function is to “crack” the gaseous molecules to provide reactive carbon atoms. Such carbon atoms diffuse towards the substrate, which is heated and coated with a transition metal catalyst. Then, the carbon atoms are fixed on the substrate and, if the appropriate conditions are fulfilled, CNT growth takes place.

The most commonly used gaseous carbon sources are methane, carbon monoxide and acetylene. Acetylene is widely used as a carbon precursor for the growth of MWNTs, which occurs at temperatures typically in the 600–800 °C range. Carbon monoxide or methane have proven to be more effective for the growth of SWNTs, since the temperature required is usually higher (800–1000 °C) and acetylene is not stable at these temperatures.

It should be noted that the CVD method has undergone dramatic and important developments over the past few years. The yield and average diameter of SWNTs were optimized by controlling the process parameters [122], and, although the diameter distribution is not as narrow as for laser ablation synthesis, impressive progress has been made in the optimization of this growth technique. For instance, as already quoted in Section 9.2.2, some reports have been found to move from the standard yield of 70% for semiconductor nanotube species [30] to a more interesting 90% [33].

Concerning the fabrication of CNT devices, the basic idea is to achieve the *in situ* localized growth of nanotubes by controlling the localization of the metal catalyst. Indeed, CVD CNT synthesis is essentially a two-step process consisting of an initial catalyst preparation step followed by the actual growth of the nanotubes, which starts at the places where the catalysts are present. Following this strategy, the first example of localized growth of SWNTs was realized in 1998 [86]. The authors produced individual SWNTs on silicon wafers patterned with micrometric islands of

catalytic material. Their synthesis procedure begins with the patterning of catalytic islands on silicon substrates by electron beam lithography (EBL). More precisely, they first use EBL to define micrometric square islands in a poly(methyl methacrylate) (PMMA) resist. Then, they deposit a liquid phase of the metal catalysts  $[\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}, \text{MoO}_2(\text{acac})_2]$  mixed with alumina nanoparticles. Finally, they obtain the catalyst islands by lift-off of the nonexposed PMMA resist. For nanotube growth, they used methane as carbon precursors and a temperature of about 1000 °C. Moreover, they limited the formation of amorphous carbon by limiting the CVD synthesis to short times (maximum 10 min). They found that all the grown nanotubes were rooted in the islands and that some of them bridged two metallic islands. Following this pioneering work, much activity on *in situ* CVD for CNT devices fabrication has taken place and transistor arrays have been fabricated [30].

However, there is an important issue to be solved before integrating such a CVD method with current CMOS technology. Indeed, for the direct growth by CVD of CNTs on silicon, the temperature regime for the growth of SWNTs and MWNTs must be compatible with CMOS integration. In this sense, substantial progress has been recently achieved by the use of a plasma-enhanced CVD (PECVD) method [33]. In this work, nanotube growth was carried out at 600 °C on  $\text{SiO}_2/\text{Si}$  wafers on which some discrete ferritin particles were randomly adsorbed to act as catalysts. The idea is that the plasma-assisted dissociation of  $\text{CH}_4$  into more reactive higher hydrocarbons and more reactive radicals must be favorable for efficient SWNT growth at lower temperatures. Moreover, the method uses a low-density plasma that propagates down and reaches the sample placed 40 cm from the plasma coil, thus preventing any local heating of the substrate. It should be noted that another advantage of lowering the CVD growth temperature is related to the diameter distribution and chirality issue. Indeed, it is likely that the size and shape of the catalytic nanoparticles should be more stable at lower temperatures, leading to a better control of the size and potential chirality of nanotubes.

In order to fully overcome the growth temperature issue and ensure compatibility with CMOS technology, a very interesting (but fundamentally different) solution can be envisaged. Indeed, these kinds of limitations can be completely avoided by preparing the nanotubes *ex situ*, functionalizing them and then selectively depositing the nanotubes into the CMOS circuit. This is the philosophy of the post-growth strategies, as discussed in the following sections.

## 9.5

### Selective Deposition of CNTs by SAM-assisted Techniques

The technique of localized deposition assisted by SAMs is nowadays the subject of large interest. It started with the pioneering works of the groups of Liu [123], Muster [124] and Choi [125]. It relies either on a local chemical functionalization of the surface [123] or on an electrostatic anchoring of surfactant-covered SWNTs on amino-silane functionalized surfaces [124, 125]. The basic idea beyond these pro-

cesses is the same, but the use of amino-silane surfaces has allowed the control of both deposition density and selective placement in predefined areas of the substrate of isolated SWNTs. Due to its great importance in the selective deposition of SWNTs, the SAM-assisted technique is discussed in detail in the following subsection.

### 9.5.1

#### Methodology and Key Parameters

This process can be summarized as follows [126–128]: the patterns (regions for future selective placement) are defined by performing EBL on a PMMA resist deposited on the  $\text{SiO}_2$  surface of a silicon substrate. After a cleaning step [reactive ion etching (RIE)], a monolayer of aminopropyltriethoxysilane (APTS) is deposited by CVD [129–131] to form a “sticky patch” in the regions opened in the resist (see schematic representation in Fig. 9.3).

Exposure to ethylenediamine (EDA) is used to increase both the surface concentration and the orientation of APTS [132], and consequently to improve interactions with SWNTs. It is likely that this EDA molecule plays the role of a catalyst during the chemical anchoring of APTS on Si-OH. Indeed, it blocks the hydrogen bond formation between the amino group and Si-OH [133]. As a consequence, at the end of the chemical reaction, each amino group is well oriented on the top of the monolayer and their density increases by around 50%. Gas deposition is chosen instead of silanization from an aqueous solution, since it yields a much better control of layer thickness [125]. Once the sticky patch has been formed, it is expected that the adhesion of SWNTs would be enhanced in the functionalized

**Figure 9.3.** Schematic vision of the fabrication of the APTS patterns on the substrate surface. The patterns are defined in a PMMA resist by standard electronic lithography. Then, the motifs are developed and, after a cleaning step (RIE), the sticky patches of APTS are deposited in vapor phase.

**Figure 9.4.** The sticky patches of APTS are exposed to the nanotube solution. In this case, to enhance placement selectivity, the residual PMMA resist is lifted off after nanotube deposition.

regions with the APTS “sticky patch”. Essentially, two ways can be chosen to selectively place SWNT.

The first method consists of working with an aqueous solution, where sodium dodecylsulfate (SDS) surfactant is used to disperse SWNTs. In this case, the sample is exposed to the SWNT suspension and then the resist is lifted off to enhance selectivity by removing any nanotubes that would have been adsorbed on the PMMA (see schematic representation in Fig. 9.4).

However, in this case, the following bottleneck has to be faced: the density of adsorbed tubes on the surface is too low for the realization of integrated circuits. It turns out that increasing the concentration of SWNTs in the solution leads mainly to the deposition of bundles on the surface. The two problems to be solved within this approach are (a) to improve the dispersion of SWNTs in the solution, and (b) avoid the competition, in the electrostatic anchoring on the amino-silane surface, between the SDS micelles present in the solution and the SDS-covered tubes.

In order to avoid these two drawbacks, a second approach has been developed [126, 127]. The main point is that nanotubes are dispersed not in an aqueous solvent, but in *N*-methyl pyrrolidone (NMP). It has been observed [134] that this solvent allows dispersing nanotubes without any kind of surfactant. Therefore, it can solve point (a) and eliminates point (b). However, due to NMP interaction with the PMMA resist, it has been necessary to modify the process as shown in Fig. 9.5.

**Figure 9.5.** After the formation of the APTS patterns, the residual PMMA resist is lifted off. Then the sample is exposed to the nanotube solution. In this case, the selectivity is ensured only by the different affinity of nanotubes with different (APTS/SiO<sub>2</sub>) surfaces.

The main difference with respect to the previous sequence (Fig. 9.4) is the reversed order of the last two steps. Thus, in the present case, the resist is removed before exposure to the nanotube solution. *A priori*, one would think that the selectivity of the placement would be partially lost; however, this is not the case, as shown in Refs. [126, 127].

The detailed studies reported in Refs. [126–128] have shown that each of the different steps in Figs. 9.3 and 9.5 play an important role in the selective placement, and that various parameters critically contribute to the success of the deposition process. Since these points are of particular importance in mastering the selective placement technique, we reconsider below the whole deposition process in much more detail. The discussion will follow Refs. [127, 128].

The nanotubes used in Refs. [127, 128] were obtained by the laser ablation technique [135]. The pristine SWNT samples first underwent a purification stage as described in Ref. [136]. Then, they were dispersed in NMP solvent. The solution was sonicated [137] and centrifugation was performed [126]. The SWNT concentration in NMP was varied from 0.1 to 0.005 mg mL<sup>-1</sup> and the variation of the density of deposited SWNTs was recorded. The substrates for that study consisted of 200-nm thick thermally grown SiO<sub>2</sub> on silicon, covered with a monolayer of APTS. The SWNTs in NMP solution were deposited on the surface for 1 min. Finally, the density of deposited SWNTs was quantified by AFM experiments. The main results of this study are presented below.

Before discussing the results concerning the selective placement, it is worth stressing the excellent deposition yield of the NMP-based approach. For the sake of comparison, Fig. 9.6 presents AFM images of APTS-treated substrates after exposure to either an aqueous SDS solution at 1.2 CMC (Fig. 9.6a) or to a NMP solution (Fig. 9.6b) for the same SWNT concentration and exposure time. Contrary to aqueous solvents, for the NMP solution the adsorption process on APTS seems to be independent of any charge effect (though they cannot be completely excluded [138]). Indeed, in the case of NMP, the NH<sub>2</sub> conversion of the silane group to NH<sub>3</sub><sup>+</sup> by exposure to HCl vapor does not seem to be relevant for the deposition yield. The adsorption is likely due to an interaction between the amine group of the APTS and the nanotube, as shown by Kong and Dai [139].

At a concentration of 0.1 mg mL<sup>-1</sup>, the density is 150 SWNTs on a 4-μm<sup>2</sup> area. This result is comparable to that of Liu and coworkers [123], with 240 CNTs on a 6.25-μm<sup>2</sup> area. Between 60 and 70% of the nanotubes on the recorded AFM images are less than 1.6 nm high, indicating individual SWNTs or small bundles. Therefore, the bundling problem observed with surfactants in aqueous solvents [point (a) above] seems to be much less significant in NMP.

The influences of several parameters on the deposition have been analyzed [126, 128], such as the deposition time, centrifugation speed, sonication time and SWNT concentration. The distribution of the nanotube diameter appeared similar for all concentrations (below 0.1 mg mL<sup>-1</sup>), indicating that there is no significant reduction of the bundles in diluted solutions. Concerning the centrifugation, the SWNT solutions were centrifuged for 10 min at different speeds up to 28 000 r.p.m. Unlike the case of SWNTs in aqueous solvents, the rotation speed seems to have no

**Figure 9.6.** AFM images of APTS-treated substrates after exposure to two kinds of nanotube solutions. (a) The substrate was exposed to an aqueous solution with SDS surfactant, while in (b) it was exposed to a

NMP solution. (c) A bare  $\text{SiO}_2$  substrate was exposed to the same NMP solution as in (b), note that in this latter case no nanotubes deposition is observed.

significant effect on the dispersion of nanotubes. Concerning the sonication, after 24 h the tubes were up to 1–2 μm long, but they were severely shortened to less than 400 nm length if sonicated for 36 h. Finally, as expected, by increasing the deposition time we observed, accordingly, an increase of the density of SWNTs deposited.

The principal aim of the study reported in Refs. [127, 128] was to achieve selective placement of CNTs. For that, the experiments were repeated on patterned substrates. As already mentioned, the resist was removed before SWNT deposition (Fig. 9.5). In this case, the selectivity is ensured only by the different behavior of

**Figure 9.7.** AFM image of a sample with a series of continuous APTS stripes 100 nm wide and spaced 1  $\mu\text{m}$  from each other. The stripes are defined by lithographic patterning of PMMA, then silanized and finally exposed to the CNTs in NMP solution.

the APTS-treated regions with respect to the nontreated regions. This point was checked by a preliminary experiment where a nonsilanized and a silanized substrate were exposed to the same nanotube solution. The results are reported in Fig. 9.6 [b (APTS-treated substrate) and c (nontreated substrate)]. It is clear from these figures that no deposition is observed for the nonsilanized sample.

An important parameter for the quality of the selective deposition is the geometry of the pattern. For the simple stripes geometry, the key parameter is the width of the stripes. Continuous stripes 500, 200 and 100 nm wide were patterned in PMMA, then silanized and exposed to the SWNTs in NMP solutions. Figure 9.7 shows the selective deposition obtained for the sample with 100-nm trenches. Suitable densities can be achieved for any width by varying the deposition time and/or the SWNT concentration in the solution within reasonable limits. For the same experimental conditions, the SWNT density increases roughly by a factor of 2 when the stripe width is increased from 100 to 200 nm. Moreover, was seen in this study that longer tubes (length  $\gg 1 \mu\text{m}$ ) are better aligned than shorter ones and that the quality of alignment is improved for narrower stripes, as already observed for aqueous solutions [125]. Finally, the use of 100-nm wide stripes represents the best way to limit the number of aligned SWNTs to one, which is crucial for the reliable study of electrical transport in individual SWNTs [127, 128].

Furthermore, in order to reliably control the fabrication of a large number of SWNT transistors on the same wafer, it is necessary not only to anticipate the statistics of deposition on a given pattern, but also the existence of any “proximity” effect, i.e. any effect on the deposition yield due to a possible combined interaction of patterned areas when they are in close vicinity to each other. SWNT deposition has been checked on groups of stripes 100 nm wide and 2  $\mu\text{m}$  long spaced by 1, 3

**Figure 9.8.** AFM images of two samples with APTS pre-patterned areas of different geometries, after exposure to a SWNT solution. (a) A single finite APTS stripe with one aligned nanotube. (b) A cross APTS pattern with two nanotubes aligned in each direction of the cross. No combing technique was applied during the nanotube deposition.

and 20  $\mu\text{m}$  on the same substrate. AFM observation showed a placement yield superior to 85% in all groups. The constant density of deposition obtained for all groups clearly indicated that no “proximity” effects were involved in the placement process. An additional test was performed with the realization of a crossed SWNT configuration. Finite size crosses 100 nm wide and typically with 750-nm long arms were submitted to SWNT deposition. Typical results for the deposition of SWNT on striped and crossed APTS motifs are reported in Fig. 9.8.

It should be stressed that this kind of result (in terms of yield and selective deposition) critically depends on the quality of deposited APTS, and can be obtained only if the monolayer is perfectly uniform, homogeneous and well ordered.

In conclusion, for SAM-assisted selective placement, the NMP-based method provides an excellent deposition yield for both unpatterned surfaces and substrates patterned with different geometries (single and groups of stripes, and arrays of crosses), and the feasibility of deposition of a limited number of aligned nanotubes per stripe (ideally one) has already been demonstrated.

The last step in the fabrication of SWNT transistors is the realization of contacts. The choice of depositing SWNTs by a selective placement approach considerably simplifies the subsequent contacting process. Indeed, since we define the deposition areas by EBL, the patterning of electrodes on top of precisely localized SWNTs is simple. No specific and tedious AFM imaging is required to locate SWNTs, as is the case for randomly deposited SWNTs. The transistor is fabricated by first selectively depositing the tubes on a silane pattern prepared on a substrate fitted with position markers. After nanotube deposition, the contact electrodes are patterned and made using standard lithographic techniques (see Fig. 9.9 for electrodes in the crossed and striped geometries).

**Figure 9.9.** AFM images of two connected samples with APTS areas of different geometries. (a) A single finite APTS stripe with one aligned nanotube connected by two electrodes (source and drain). (b) A 3-D view of a connected crossed device.

Altogether, these results obviously open the way for the controlled fabrication of a large number of SWNT devices by SAM self-assembly.

#### 9.5.2

##### **Performance of CNTFETs Fabricated by the SAM Method**

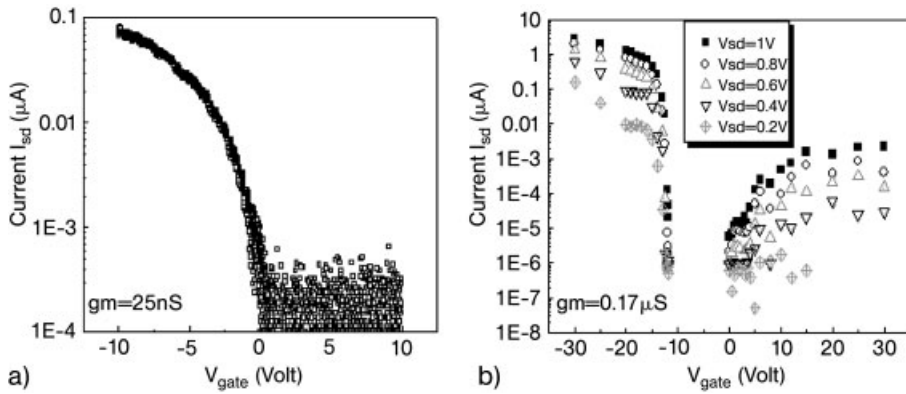

CNTFETs obtained by random deposition of nanotubes were introduced in Section 9.2.3. The present subsection is devoted to a comparison of the characteristics of transistors obtained by random and self-assembled depositions.

As already mentioned in Section 9.2.3, CNTFETs have been demonstrated to be Schottky barrier transistors. As a consequence, their transport characteristics can depend on the choice of the metal for electrode fabrication. One can check this point, e.g. by comparing the performance of devices obtained with the same tubes, but with different types of electrodes; this has actually been done for both randomly deposited [74] and self-assembled [83, 127] CNTFETs.

Figure 9.10 reports the characteristics of self-assembled CNTFETs in two configurations: (a) a “standard” configuration with 0.2-nm titanium/40-nm gold electrodes (Fig. 9.10a), and (b) an optimized configuration, hereafter called “TiC” (Fig. 9.10b), with deposition of 20-nm titanium/20-nm platinum electrodes and application of rapid thermal annealing (RTA). This RTA process took place at temperatures in the range 650–850 °C in inert ambient gas to convert the electrode contacts to titanium carbide (as in Ref. [74]). As the electrodes were fabricated on top of SWNTs deposited on 200-nm SiO<sub>2</sub> film grown on a silicon wafer, the wafer itself was used as the gate electrode (“back-gate” configuration). Electrical measurements were performed in vacuum.

“Standard” CNT field effect transistors behaved as p-type FETs, i.e. the dominant carriers are holes. As shown in Fig. 9.10(a), the transconductance ( $dI_D/dV_G$ ) for

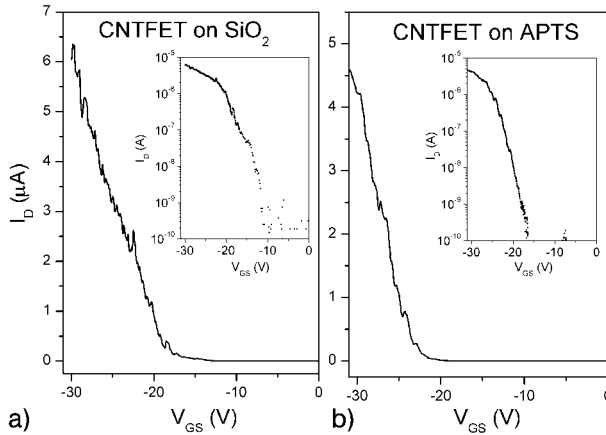

**Figure 9.10.** Transport characteristics of the “standard” (a) and “TiC” (b) devices. (a) Transfer characteristics at room temperature with source to drain voltage  $V_{SD} = 200$  mV;  $dI_D/dV_G = 25$  nA  $V^{-1}$ . The on/off current ratio

is  $10^4$ . (b) Transfer characteristics with source to drain voltage  $V_{SD} = [0.2 \text{ V}:1 \text{ V}]$ ;  $dI_D/dV_G = 0.17 \mu\text{A} V^{-1}$ . The on/off current ratio is  $10^7$ . (Adapted from Ref. [127].)

this kind of device is in the  $10^{-9}$  A  $V^{-1}$  range and the current modulation occurs through 4 orders of magnitude. “TiC” CNTFETs exhibited a drastic improvement of performance. According to several authors, “TiC” decreases the contact resistance for the injection of both p- and n-type carriers [74]. Indeed, the “TiC” CNTFETs in Fig. 9.10 are ambipolar, i.e. they carry a strong current at both negative and positive values of  $V_G$ .  $dI_D/dV_G$  increases by 2 orders of magnitude and results in the  $10^{-7}$  A  $V^{-1}$ , range while the current modulation occurs through 6–7 orders of magnitude, which is also 2 orders of magnitude better than “classical” devices.

The characteristic values of the self-assembled “TiC” devices are close to those obtained on similar back-gated devices fabricated by random deposition directly on  $\text{SiO}_2$  (e.g. as evidenced by the comparison of the results in Fig. 9.10 with those reported in Ref. [74] for a p-type device). Moreover, it has been shown that the transport characteristics of “TiC” CNTFETs obtained with both random and self-assembly techniques are strongly dependent upon the temperature of the annealing process, with an optimum around 800 – 850 K [74, 127].

The results clearly indicate that the electrical performance of self-assembled CNTFETs is mainly determined by the nanotube/metal contact interfaces and by their response to the applied electric fields. This obviously suggests that after RTA, the use of a SAM technique to direct the assembly of the nanotube does not perturb the transport characteristics of such fabricated CNTFETs. It is worth noticing the importance of this result, which validates the self-assembly approaches for large-scale production of nanotube-based electronics. Moreover, it should also be noted that the SAM-based process discussed above is fully compatible with the realization of top-gate devices [140] and/or low thickness and high effective dielectric constant oxide films [141]. In conclusion, this self-assembly technique allows con-

**Figure 9.11.** Transfer characteristics  $I_D(V_{GS})$  at  $V_{DS} = -1$  V of two CNTFETs with a gate oxide thickness of 200 nm. (a) CNTFET made by random deposition on  $\text{SiO}_2$ . (b) CNTFET made by the self-assembly technique. Insets show the same data in log-scale. (From Ref. [83].)

trolled and systematic fabrication of CNTFETs with performances reaching the actual state-of-the-art of CNTFETs as obtained by other techniques.

It should be also mentioned that the APTS monolayers are destroyed in the annealing process. Thus, it is still pertinent to question the role of the APTS monolayer on device characteristics when the RTA step is not performed, as it is the case of standard Ti/Au or Cr/Au electrodes. In order to elucidate this point, it is necessary to compare the performances of devices made by the APTS self-assembly technique (called CNTFETs on APTS) with those of CNTFETs made by random deposition (called CNTFETs on  $\text{SiO}_2$ ). A comparison is presented in Fig. 9.11, which shows the  $I_D(V_{GS})$  characteristics for the two kinds of devices. The measurements were performed at room temperature, in air, with the gate bias swept from the on- to the off-state [83]. We notice that their performances are very similar: on-state current up to around 5  $\mu\text{A}$ , on:off ratio of 4 orders of magnitude, transconductance of 0.4 – 0.5  $\mu\text{S}$  and subthreshold slope  $S = 2000 \pm 300$   $\text{mV dec}^{-1}$ . This means that, under typical atmospheric conditions, the performances are set by the quality of the contacts and the gate efficiency (set by the oxide thickness), independently of the placement technique. Note, finally, that the performances of the devices used in the comparative study shown in Fig. 9.11 are similar to the best performances of CNTFETs of comparable geometry reported in the literature and thus representative of the state-of-the-art of CNTFETs.

In conclusion, the chemical functionalization of  $\text{SiO}_2$  substrates by an APTS monolayer brings a relevant solution to the problems of (a) systematic placement of nanotubes in a transistor geometry and (ii) their subsequent connection to electrodes. Moreover, the use of the SAM deposition process not only does not deteriorate the device characteristics (as one may think), but it is also fully compatible

with the production of high-quality, state-of-the-art CNTFETs. Finally, more recent works have shown that it is possible to take even further advantage of the APTS monolayer to perform chemical optimization of CNTFETs [142]. Indeed, when compared to a CNTFET on SiO<sub>2</sub>, a CNTFET on APTS includes an additional, tunable, chemical interface (nanotube/APTS) to act onto.

In Sections 9.4 and 9.5 we have considered two approaches (CVD and SAMs) to perform selective placement of SWNTs. An important motivation was the development of a bottom-up technology for the implementation of nanodevices. However, standard top-down lithography techniques are still necessary in both two approaches. Indeed, even if the random deposition of nanotubes is avoided and large-scale fabrication can be envisaged, the patterns for the catalyst or for the APTS monolayer, as well as the electrodes, are realized by standard lithographic techniques. A real technological breakthrough in self-assembly would be to develop a complete molecular-scale bottom-up method. In this context, in the following section we discuss a promising technique based on the use of a DNA scaffold to realize nanoscale site-controlled implementation of nanocomponents.

## 9.6

### DNA-directed Self-assembly

Among the new methodologies based on bottom-up approaches for future nanotechnology, the exploration of bio-directed assembly for organizing nano-objects is one of the most promising. Indeed, the nanoscale is the natural scale on which biological systems build up their structural elements, and biological molecules have already shown great potential in the fabrication and construction of nanostructures and devices.

In this context, the DNA molecule is of particular interest, as highlighted by the increasing number of recent works devoted to the study of its physical properties and implementation in nanoelectronics. Indeed, the DNA molecule has already been successfully used to build up nanostructures [117, 143] or scaffolds for nanoparticle assembly [118–121]. Moreover, one can envisage its use for the assembly of devices. The key advantage in using DNA as a scaffold for these constructions is that its intra- and inter-molecular interactions are the most readily known, engineered and reliably predicted. The information contained in DNA sequences can be envisioned to code:

- The assembly of the scaffold.
- Its selective attachment on the surface microscale electrodes.
- The positioning of nano-objects or nanodevices on the scaffold.
- The realization of electrical connections and circuitry.

This idealized pathway to assemble circuit in two (or three)-dimensional geometry is very appealing, and, as we discuss in the following, some of the necessary steps have already been realized and reported in the literature, as well as a first mono-

device demonstrator [144]. In the following we discuss separately these four aspects of the use of DNA molecules for the realization of bio-assembled nanodevices and nanocircuits.

### 9.6.1

#### The Assembly of the Scaffold

In recent years, an increasing number of works have been devoted to the realization of nanostructured scaffolds with DNA molecules. The pioneering experiments concerned the assembly of sticky-ended linear DNA molecules [145]. Since then, a long way has been covered to evolve towards the vision, developed by Seeman and coworkers, of a construction with “smart bricks” made of DNA molecules. The main idea is based on the following simple scheme: the sticky ends of the envisaged DNA “smart bricks” would have the property to recognize each other and act as nanovelcro to realize the required assembly [146]. Obviously, such “smart bricks” must be more complex than linear DNA in order to realize a nanostructured two (or three)-dimensional scaffold. Therefore, in order to implement this scheme, synthetic molecules have been designed to produce branched motifs, taking inspiration from the natural phenomenon of reciprocal exchange crossover between DNA molecules [147]. Indeed, it is well known that natural DNA is not always in the linear configuration, but it passes, during its metabolism, through the configuration of an *unstable* branched molecule. The main idea of the method is to synthesize single-strand (ss) DNA molecules that self-assemble into *stable* macromolecular branched building blocks (called DNA tiles or “smart bricks”). Thus, the tip is to prepare synthetic oligonucleotides that break the homologous sequence symmetry of the natural branched molecules, avoiding in this way the instability due to the isomerization via branch migration [148]. Following this prin-

**Figure 9.12.** Schematic representations of various motifs constructed with DNA tiles: Holliday junction analogues, and DX and TX molecules. (From Ref. [148].)

ciple, various motifs have been fabricated, like Holliday junction analogues, double (DX) and triple (TX) crossover molecules, knots, and parallelograms (see Fig. 9.12).

The most interesting motifs in terms of scaffolds for nanotechnology purposes are those leading to a defined geometrical arrangement. In fact, simple branched junctions do not automatically lead to geometrical control [149, 150], essentially due to their lack of rigidity. The famous lattices reported by Seeman and coworkers rely on stiffer motifs, like the DX [151] or TX [152] tiles. More recent studies report the construction by biological recognition properties of a DNA-based nanostructure made of four four-arm junctions ( $4 \times 4$  tile, see Fig. 9.13) [153].

This programmed self-assembly gives rise to two distinct lattice morphologies: uniform-width nanoribbons and two-dimensional nanogrids that have been used to template protein and/or silver nanowires [153].

**Figure 9.13.** SEM and AFM images of different lattices constructed with DNA tiles. From left to right: (SEM image of) a DX, (SEM image of) TX and (AFM image of)  $4 \times 4$  lattices. (Adapted from Ref. [146].)

Another interesting approach has been developed by Bergstrom and coworkers, who used rigid tetrahedral linkers with arylethynylaryl spacers to direct the assembly of attached oligonucleotide linker arms into novel DNA macrocycles [154]. The main originality of this method consists in the use of rigid tetrahedral organic vertices and in the fact that a variable number of oligonucleotide arms serve as connectors for the design of more complex architectures.

### 9.6.2

#### Selective Attachment of the DNA Scaffold on the Surface Microscale Electrodes

Another important step in the pathway for the use of DNA-directed assembly of nanocircuits is the fixation/linkage of the DNA scaffolds on the substrate and its connection to external microelectrodes. The issue is to have some anchoring sticky-end points on the electrodes (or substrate) to selectively deposit the scaffold. In this context, the biochip community has made very strong efforts and different methods have been developed for DNA probe technology. The goal to achieve is to fix a specific sequence on each electrode of the chip. In present-day technology, the DNA probes are nearly always attached to inorganic substrates (silicon and glass are the most widely used) [155–157], while the presence of the electrodes is not always required. Nevertheless, the majority of the most advanced techniques proposed in the literature can be transposed to our electrode-specific linkage problem. The solutions that have been found are essentially of two types. The first is to label the surface with defined oligonucleotides sequences, by means of either (a) addressing by micro-nanospotting or (b) addressing assisted by an applied electric field. The second type of specific labeling is more exactly an *in situ* localized synthesis of the desired oligonucleotide sequence. These different techniques are briefly described below.

Historically, the micro-spotting technique was the first method developed. In this case, the immobilization is achieved passively either by covalent bonding or adsorption [158–161]. Nowadays, it is possible to find different variations of the same principle, like the robotic deposition on a prepared substrate [162] or the use of an ink-jet printer [161]. The more recent evolution of this technique is “dip-pen” nanolithography (DPN), which allows a lateral resolution of the order of 50 nm [163]. This technique is based on scanning probe technology, as described in the following. First, an AFM tip is “inked” with a solution of the material to be transferred to the surface. Then the AFM tip “writes” the desired pattern on the surface. However, although advances have been made by the introduction of parallel multipen approaches (by multicantilever AFM), this technique is still fundamentally slow and its throughput cannot compete with standard printing process.

Electrical addressing has also been intensively developed. As one example, Nanogen recently developed an electric-field-assisted DNA immobilization process [164], designed to give pixel-by-pixel selectivity. The Nanogen DNA chip (NanoChip™) uses affinity-based immobilization (noncovalent bonding of the capture probes to the surface). This technology uses the electrophoresis principle of migration of

**Figure 9.14.** Schematic representation of the *in situ* oligonucleotides synthesis process using a light-directed method. Adapted from Ref. [167].

the negatively charged DNA molecule: "... when a biotinylated sample solution is introduced onto the array, the negatively charged sample moves to the selected positive electrode, where it is concentrated and bounds to the streptavidin in the permeation layer. The array is then washed and another sample can be added. In this way, site by site, an array of [oligonucleotides] samples is assembled on the [electrodes] array" [165]. A more advanced method of selective attachment of DNA strands to an electrode, also based on electrical addressing, consists of the successive (electrochemically addressed) copolymerization of 5' pyrrole-labeled oligonucleotide and pyrrole. By this method, each electrode is covered by a conducting polymer (polypyrrole) grafted by an oligonucleotide [166].

The second solution concerns the *in situ* synthesis of the oligonucleotide sequence on the electrodes, using a light-directed method. Affymetrix commercializes this kind of array and the fabrication process can be schematized as follows (see Fig. 9.14) [167, 168]. A solid support is derivatized with a covalent linker molecule terminated with a photolabile protecting group. Light is then directed through a mask to de-protect and activate selected sites, and protected nucleotides couple to the activated sites. The process is repeated, activating different sets of sites and coupling different bases, allowing arbitrary DNA probes to be constructed at each site.

### 9.6.3

#### Positioning of Nano-objects or Nanodevices on the Scaffold

In order to position nano-objects on the scaffold, it is necessary to master their linkage to a DNA strand and then use the DNA recognition properties to insert

them on the scaffold. The approach can differ depending on whether the nano-object is inserted during the construction of the scaffold or linked to it successively. In any case, the linkage of the nano-object to the DNA strand is a key step of the process. Many works have been reported aiming to develop methods for functionalizing small inorganic building blocks with DNA and then direct their assembly into extended structures by using the molecular recognition properties associated with DNA. So far, DNA has already been used to functionalize gold nanoparticles [120, 169–172], semiconductor quantum dots [173] and CNTs.

Concerning the chemical derivatization of CNTs, end chemistry of oxidatively etched nanotubes has been largely investigated [174–177]. This functionalization method was mostly used to improve nanotube solubility by reacting the nanotubes with hydrophilic dendra, alkyl chains or polymers. Nonetheless, it is still not clear if this strategy leads uniquely to functionalization of the defect sites of the oxidized ends of the nanotubes or also their side-wall surface. Indeed, the oxidation step performed during the usual purification process of the SWNTs produces such defects in relatively low amounts (estimated to about 2–3%) [178, 179], but they are not specifically localized only at the nanotube ends.

Currently, most of the work performed on nanotube functionalization is based on side-wall chemistry. Both covalent and noncovalent routes have been developed. A series of covalent side-wall functionalizations has been reported recently, including the reaction of nanotubes with nitrene, carbene and radical compounds. These methods should open routes to a wide variety of new nanotubes derivative [180–182]. In contrast, noncovalent routes have been mainly used to wrap nanotubes with polymer to enhance solubility and form composite materials [183–188]. An interesting study about solubilization of SWNTs by means of noncovalent chemistry (peptide wrapping) has been recently reported. In this work the authors first solubilize the nanotubes in aqueous solution by peptide wrapping [189] and then they increase the stability of such solution by crosslinking the wrapped peptides to each other [190].

Most results reported on CNT–DNA linkage also deal with covalent chemistry based on carboxylic acid defect groups present on SWNTs [191–195]. In 2002, a work reported the covalent coupling of peptide nucleic acid (PNA) rather than DNA [195]. The authors chose PNA as an intermediate for the covalent chemistry before hybridizing it with a DNA strand. The reason of this choice was the higher robustness of PNA to environmental conditions, as compared to other oligonucleotides. Nevertheless, in this report, as in each of the other described methods for covalent grafting of DNA onto nanotubes, an additional aggressive oxidation was performed in order to increase the defect density [192–195] and no indication was given on the yield of DNA–SWNT linkages. Moreover, the effect of introducing a large number of defects along the nanotubes is still not clearly known, but is believed to strongly affect their original (mainly  $sp^2$ ) structure and electronic properties. Recently, the same type of covalent chemistry between ssDNA and nanotubes (MWNTs and SWNTs) has been exploited to form multicomponent structures including 150-nm gold nanoparticles [196]. Finally, there is an interesting report about the binding of DNA to nanotubes by photochemistry [197]. In this work,

the covalent linkage is not performed on a carboxylic defect, but by using acid photochemistry and *in situ* DNA synthesis.

Different works have also been reported on the association of biological molecules (DNA and/or proteins) with nanotubes by means of noncovalent chemistry. A strong interaction of DNA with the nanotube surface has been suggested for MWNTs [198] and more recently a demonstration of wrapping of SWNTs by well-defined ssDNA molecules has been published [34]. The great advantage of a noncovalent method is its independence of the presence of the carboxylic groups, so that the DNA binding can also be successfully achieved for completely defect-free nanotubes.

In terms of noncovalent methods, the attachment of streptavidin protein [199] to the nanotube is of particular interest, as we will discuss below. Streptavidin is a relatively small protein (60 000 Da) composed of four identical subunits. The mechanism that binds streptavidin to a  $sp^2$  nanotube surface is probably related to hydrophobic interactions [199]. Indeed, this molecule is known to bind to hydrophobic surfaces [200]. The streptavidin protein is particularly well studied for its various biochemical applications because of its high affinity to biotin. Indeed, each of the streptavidin subunits has an active binding site for biotin molecules and the streptavidin–biotin system has one of the largest free energies of association yet observed for noncovalent binding of a protein and small ligand in aqueous solution ( $K_{\text{assoc}} = 10^{14} \text{ M}^{-1}$ ). Moreover, these complexes are also extremely stable over a wide range of temperature and pH. Correspondingly, the simple idea that has been followed for the DNA–nanotube attachment process is to react a biotinylated DNA strand with a streptavidin-coated nanotube (see scheme in Fig. 9.15). In other words, this technique uses noncovalent chemistry through a biological recognition complex (streptavidin–biotin) in order to link DNA and nanotubes [201, 202].

One great advantage of this method is related to the yield and the robustness of the reaction, while its main inconvenience is its lack of site specificity. However, it is worth pointing out that none of the methods reported above, particularly those based on covalent binding, is genuinely site specific. In fact, it would be extremely naïve to think that the carboxylic defects are present only at the ends of the nanotubes. On the contrary, it is more likely to think that the chemistry on a side-wall defect will be extremely favored with respect to a reaction at the ends, due to the nanotube's particular cylindrical shape and geometry factor (diameter versus length). In order to avoid this unspecific site chemistry and ensure the effective-

**Figure 9.15.** Schematic representation of the linking process between a biotinylated DNA strand with a streptavidin-coated nanotube.

ness of a covalent reaction on carboxylic defects only at the ends, Willner and co-workers [203] developed a method to mask the nanotube side-walls by a wrapping. In this work the authors succeeded in performing real end chemistry and they were able to link covalently the flavin adenine dinucleotide cofactor only to the nanotube ends. It is thought likely that such a method could be extended/adapted to perform covalent end chemistry between nanotubes and DNA strands in solution.

#### 9.6.4

#### **Realization of Electrical Connections and Circuitry**

So far we have discussed methods to construct and position nanotubes on a DNA scaffold opportunely linked on the substrate microelectrodes. However, an essential step for electronic purposes is the electrical connection of such nanotubes. This latter relies on the transport properties of DNA molecules and has recently generated heated debate among scientists, as evidence both for and against the hypothesis of DNA as a conducting wire has piled up. While no full consensus has been reached, we feel that the extensive transport measurements carried out on single DNA molecules and DNA bundles strongly suggests that DNA in the dry state deposited on a substrate is a good insulator and thus not useful as a conducting element. We believe that in spite of its somewhat negative sense, such a conclusive statement is of great importance in defining strategies for implementing DNA-based technology. Indeed, it now becomes clear that to achieve an electrical connection using DNA strands, it is necessary to proceed to their metallization. During the past 10 years we have seen the development of numerous methods to metalize DNA scaffolds and a recent review of these metalization processes can be found in Ref. [204]. In the following we summarize the main aspects and results concerning this topic.

The feasibility of this biotemplating approach was first shown by Braun and co-workers [205]. The authors first immobilized a DNA strand between two electrodes. Then, they treated it with silver ions in order to perform an  $\text{Ag}^+/\text{Na}^+$  ion exchange and replace the natural sodium counterions of the DNA backbone with silver ones. Successively, these silver ions were subjected to a chemical reduction process by the reducing agent hydroquinone to form small silver aggregates. Finally, the silver nanoclusters fixed on the DNA strand were autocatalytically grown (using an acidic solution of hydroquinone and silver ions) to give a granular (100 nm width) nanowire contacting the two electrodes. The majority of DNA metalization processes follow the same principle and can be decoupled in terms of successive steps, as schematically shown in Fig. 9.16 and discussed below.

The first step consists of biomolecule activation – the metal ions or metal complexes bind to DNA, creating reactive metal sites (Fig. 9.16a). The activation can take place by an ion-exchange mechanism (as discussed above for silver [205]) on the DNA backbone or by insertion of the metal complexes between the DNA bases (like platinum or palladium complexes [206]).

In the second step, the bound seeds are usually treated with a reducing agent

**Figure 9.16.** Schematic representation of the different steps involved in the DNA metallization process. (Adapted from Ref. [204].)

(Fig. 9.16b). This converts the metal ions or metal complexes in metal nanoclusters fixed on the DNA strand. The more often used reducing agents are dimethylaminoborane [207, 208], hydroquinone [205] and sodium borohydride [209]. An interesting variant has been proposed by Keren and coworkers [210, 211], who fixed the reducing agent (glutaraldehyde) directly to the DNA strand in order to enhance specificity and reduce parasitic unwanted background metalization. At the end of these two steps, the DNA strand has some small metal nanoclusters fixed on it (as represented in Fig. 9.16c), which will successively act as “seeds” for the metalization of the DNA molecules.

The third step of the metalization process consists of autocatalytic growth of the fixed metal seeds on the DNA strand (Fig. 9.16d) by the addition of new metal ions (or metal complexes solution) and new reducing agent solution. The idea of this autocatalytic process is that metal complexes or ions from solution are preferably reduced on already reduced metal nanoclusters (the seeds) fixed on the DNA strands. It should be noted that this autocatalytic cluster growth can be generalized

to metal nanoclusters fixed on DNA strands by any other method. Indeed, effective metalization has been reported on *ex situ* prepared gold nanoclusters fixed on the DNA strand by appropriate chemical functionalization [212], by DNA construction [213] or simply by electrostatic interactions [214].

As mentioned above, different metals have been used in the metalization process. For the ion-exchange mechanisms on the DNA backbone we can quote silver [153, 205] or copper [215]. The results are quite convincing for the silver process, where a silver wire is formed consisting of a chain of contiguous 30- to 50-nm silver grains along the DNA backbone. However, the electrical measurements performed on the obtained silver necklace wire were not completely satisfactory. In a following work, the same group improved the process by replacing the silver clusters growth with an electroless gold coating of the silver-loaded DNA molecules [210]. In this way, using silver ions as catalysts, conductive gold DNA-templated wires with widths ranging from 50 to 100 nm were obtained. This procedure can be generalized and the final metal coating does not necessarily have to use the same metal as the seeding one [209, 210, 216].

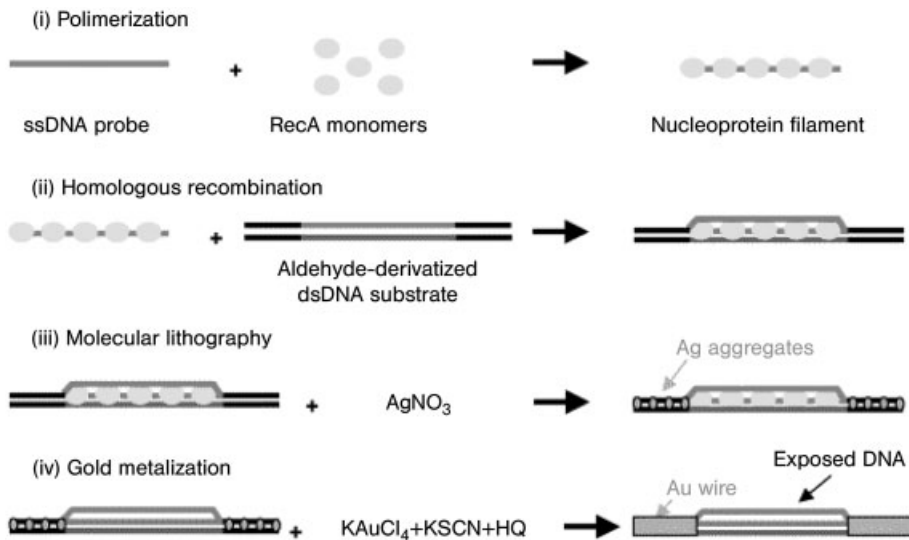

Concerning the intercalation mechanism of metal complexes between the DNA bases, palladium or platinum complexes have been the more extensively studied. Indeed, the binding process of Pt(II) complexes to DNA is well investigated in the case of cisplatin (*cis*-[Pt(NH<sub>3</sub>)<sub>2</sub>Cl<sub>2</sub>]), which is widely used as an anticancer drug [217]. It follows from these studies that when DNA is incubated with Pt(II) complexes such as cisplatin, the Pt(II) atom binds to one or two stacked DNA bases, forming monofunctional and bifunctional DNA–Pt(II) adducts, respectively. The most favorable binding site for cisplatin to the DNA is the N<sub>7</sub> position of guanine, followed by the N<sub>7</sub> position of adenine [217, 218]. Indeed, the bases A, G and C have exocyclic amine groups as well as ring amines, but it is the ring amines that act as Lewis bases. The Lewis base acidities differ from base to base, with the N<sub>7</sub> position of guanosine being the most basic. Other Lewis bases found in the nucleobases are N<sub>7</sub> of adenosine, N<sub>3</sub> of cytosine and the deprotonated N<sub>3</sub> of thymidine or uridine. The amines are all soft ligands and as such preferably complex to soft metals such as Pt(II), Pd(II) or Ru(II). When the DNA is in double-strand configuration, the arrangement of the basis is controlled by  $\pi$  stacking and then the Lewis base sites available for coordination to the metal (Pd, Pt, etc.) are limited to the exposed portion of the nucleobases found in the major groove (the N<sub>7</sub> position of guanosine and adenosine). It is commonly thought that, of these two sites, the N<sub>7</sub> of guanosine is the preferred one [219]. After these sites are occupied, the binding reaction proceeds more slowly and indiscriminately with other metal-binding sites of all bases [218–221]. Using this intercalation mechanism, palladium and platinum DNA-coated nanowires have been obtained. Generally speaking, these metalization processes of the DNA strands have been performed either (a) in solution and then the metalized DNA molecule is deposited on substrate for the characterization purpose or (b) on the DNA previously deposited on the substrate. The first case concerns the works reported by Ford and coworkers [209] and Mertig and coworkers [222], who showed the formation of tiny platinum nanocluster necklaces consisting of well-separated clusters of 3 – 5 nm diameter with a spacing from

one to several nanometers. On the contrary, Richter and coworkers [223], Deng and coworkers [224], Dupraz and coworkers [216] and Ongaro and coworkers [214] have metalized DNA strands already deposited on the substrate. In more detail, Richter and coworkers fabricated continuous palladium nanowires with average diameters of 60 – 100 nm on DNA strands aligned on interdigitated gold electrodes and obtained interesting transport properties. On the contrary, Deng and coworkers reported very granular 30-nm palladium nanowires without any data about their conduction properties [224]. Actually, both Dupraz and coworkers [216] and Ongaro and coworkers [214] started the metalization process in solution (seeds fixation), and successively stretched the metal-loaded DNA on the substrate. Then they completed the metalization process. They used, respectively, platinum and gold nanoparticles as catalytic seeds, but they both finished by a gold electroless plating process. They both obtained DNA-templated gold nanowires (average diameters about 20 – 50 nm) with estimated resistivities of between  $10^{-5}$  and  $10^{-4}$   $\Omega\text{m}$ .

However, among all the methods discussed above, only a few are really promising in nanocircuit applications. First, the more interesting procedure is the one where the DNA metalization occurs as one of the last steps. Indeed, after the metalization process all the recognition properties of the DNA molecule are completely lost, and the circuit architecture must be necessarily fixed and deposited on the substrate. Moreover, another important point is that some parts of the DNA scaffold must not be metalized to avoid shorts and preserve the device characteristics. In this sense, three convincing studies have been reported [210, 211, 213]. They are all based on the RecA protein properties. *In vivo*, the RecA protein is a central component in recombinational DNA repair pathways and homologous genetic recombination (in *Escherichia coli*). *In vitro*, RecA protein promotes the pairing and exchange of complementary DNA strands in reactions. The mechanism is as follows: RecA catalyzes the pairing of ssDNA with complementary regions of double-stranded (ds) DNA. The RecA monomers first polymerize to form a helical filament around ssDNA (Fig. 9.17a). Duplex DNA is then bound to the polymer (see Fig. 9.17b).

**Figure 9.17.** Schematic representation of the homologous recombination process that leads to binding of the ssDNA–RecA nucleoprotein filament at the complementary address on the dsDNA.

**Figure 9.18.** Mechanism of the sequence-selective metallization process. Thanks to the homologous recombination, the RecA protein acts as a sequence-specific resists for the creation of the silver seeds and successive gold metallization. (From Ref. [210].)

This particular feature has been used to differentiate a part of the sequence of the DNA strand in the metallization process. Indeed, it is clear that the targeted sequence is perfectly identified by the RecA polymerized ssDNA. The idea exploited is that the creation of the complex between the RecA–ssDNA polymer and the complementary regions of dsDNA acts as a mask for the metallization process. In the first report on sequence-specific metallization [210] it is shown that this complex avoids the Ag<sup>+</sup>/Na<sup>+</sup> ion exchange. This blocks the formation of the silver seeds on the targeted sequence of the DNA molecule and, consequently, the successive gold metallization (see Fig. 9.18).

In a successive work [211], the same team showed that sequence-specific lithography can also be achieved by sequence-specific patterning of the local reducing agent (glutaraldehyde). This patterning was performed both by hybridization between aldehyde-derivatized and underivatized DNA molecules and by sequence-specific protection against aldehyde derivatization using homologous recombination processes by the RecA protein. Then, the sequence-specific patterning of the reducing agent is reflected by the sequence-specific creation of silver metallization seeds and successive gold metallization.

The more recent report on selective metallization also uses the homologous recombination properties of the RecA protein and its originality is to employ a modified RecA to act as a “linking factor” for sequence-specific fixation of gold nanoparticles [213]. Then, these gold nanoparticles are used as “seeds” for the

metalization process. To be more specific, the authors use a genetically engineered cysteine derivative RecA protein (Cys-RecA) and, thanks to this derivatization, the gold nanoparticles can be fixed to the Cys-RecA–DNA filament. However, the gold nanoparticles are not fixed on unmodified RecA filament. Therefore, the strategy they developed to achieve selective metalization is to use separately cysteine derivatized RecA and unmodified wild-type RecA (RecA) to complex different sequences of the DNA strand. Then, the fixation of the gold nanoparticles respects the targeted sequences Cys-RecA–DNA and RecA–DNA, and the successive metalization presents a sequence specific gap corresponding to the unmodified RecA–DNA complex.

### 9.6.5

#### Fabrication of DNA-directed CNT Devices

Among the studies that use DNA to fabricate CNT devices [144, 225–227], the most impressive one is the report on the DNA templating of a CNTFET [144]. Indeed, in this work some of the crucial ingredients of the vision discussed in Section 9.6 were tackled and demonstrated, even if in a simple linear back-gate geometry. The authors employed (a) a selective placement of the nanotube on the DNA scaffold and (b) a sequence-selective metalization of the DNA strands. In this way, they were able to realize the electrical connection between the standard (lithographically defined) electrodes and the nanotube device. In both tasks (a) and (b) they exploited the sequence-specific homologous recombination of the RecA protein. They first anchored the SWNT in the desired part of the DNA scaffold and then, after deposition on a substrate, proceeded to the selective metalization process. The SWNT–DNA linkage was performed in buffered solution by the molecular recognition of a streptavidin-functionalized SWNT towards biotin and by the antibodies properties to link the biotin to the RecA–DNA filament, as schematized in Fig. 9.19.

**Figure 9.19.** Schematic representation of the sequence-specific binding of a streptavidin-coated SWNT. The homologous recombination process of RecA is used to target the binding site. The streptavidin-coated nanotube is fixed

to the DNA-bound RecA by using a complex antibodyRecA–biotin (a primary antibody to RecA and a biotin-conjugated secondary antibody).

Then, to fabricate the nanotube device, they stretched the SWNT–RecA–DNA assembly on a silicon substrate and performed the selective Ag/Au metalization process as described in Ref. [210]. One of the interesting features of this experiment is that, even in this more complicated configuration (i.e. presence of the SWNT, streptavidin, biotin and antibodies species), the masking properties of the RecA are preserved and the “protected” segment of the DNA strand is not metalized. Finally, the DNA-templated gold wires were connected by fabricating standard lithography electrodes and the device characteristics were recorded.

However, even if all the steps for DNA-directed self-assembly of a CNT device have been demonstrated and reported in literature, it should be noted that it is still missing a study where all these steps are combined. Indeed, in the work of Keren and coworkers [144] there is no selective attachment to the microscale electrodes. This implies that in order to fabricate these electrodes, the deposited SWNT–RecA–DNA strand must be localized by imaging, as for nanotube devices obtained by random deposition. On the contrary, in the report of Hazani and coworkers [226, 227], the SWNT–DNA complex is fixed to the electrodes by DNA hybridization, but no selective metalization is performed. In this case, it is likely that the contact between the nanotube and the electrodes is ensured by the fact that the DNA strands used are very short and the nanotube touches the metal anyway.

In conclusion, the demonstration of a completely DNA-directed self-assembled CNT device is, at the time of writing, still to be shown, as well as the realization of a more structured scaffold hosting more than one nanotube device in a circuit configuration. The knowledge and mastery of the different steps needed for the implementation of such a demonstrator have already been reported in literature, and it is now a matter of multidisciplinary will and teams to accomplish the task. Finally, for such a still open and exploratory research domain, new findings are expected to further enlarge the present vision and generate novel strategies for the short- to medium-term development of nanoelectronics.

## 9.7

### Conclusion

In this chapter we have presented a review on the self-assembly techniques for fabrication of CNT devices. First, we discussed their main physical features and sketched a few reasons why CNTs benefit from their present status as a serious potential candidate for future nanoelectronic applications. Then, we focused our attention on three methods to manipulate them by self-assembly. Indeed, this promising material could be envisaged to take part in the future nanoelectronic framework only if a cheap, massive parallel technology for fabricating nanotube devices is developed. The timing of this kind of research is particularly appropriate, as it results from an estimation of the ITRS roadmap [1]. From the analysis of this document it appears that, even if the scaling of CMOS device structures is a well-explored science, its limits will be reached in the near future due to various physical effects that do not scale properly, including quantum mechanical tunneling, the

discreteness of dopants, voltage-related effects such as subthreshold swing, fabrication costs and reliability related to very small size variation, built-in voltage and minimum logic voltage swing, and application-dependent power-dissipation limits. Self-assembly of new and interesting materials could bring some answers to these limitations. Indeed, it is extremely naïve to think that a non-CMOS device (based on nanotubes, molecules or other) that simply mimics a CMOS device can solve this scaling limit only because of its reduced size. Among the various issues that CMOS technology is facing, the power dissipation effect is the most serious one and it can actually apply also for any non-CMOS device. Based on this assumption, the study and implementation of non-CMOS devices cannot be motivated only by the scaling issue, but must present other kind of advantages like (a) performing a particular functionality not well covered by standard CMOS technology, (b) be economically very appealing with important reductions of fabrication costs, (c) really introduce a disruptive technology by presenting new physical effects or (d) be prone to the development of new architecture paradigms, which could include concepts like three-dimensional design, defect/fault tolerances, reconfigurability, self-repairing features and massive parallel processing. This is a strong reason to increase the investments in time and resources in studying alternative strategies like self-assembly and, in particular, bio-inspired technologies.

## 10 Nanodevices for Biosensing: Design, Fabrication and Applications

*Laura M. Lechuga, Kirill Zinoviev, Laura G. Carrascosa,  
and Miguel Moreno*

### 10.1

#### Introduction

There is increasing interest in obtaining biosensor devices based on nanotechnology developments which can detect, in a fast and selective way, any type of substance in air and liquid samples at very low concentrations – ideally at the single-molecule level [1]. Clinical diagnosis, genomics and proteomics are some of the fields where new laboratory analysis methods (faster, direct, more accurate, more selective, having a high throughput and cheaper than conventional methods) are in high demand. Due to their small size, ultra-sensitive transduction and the possibility of integration in “lab-on-a-chip” microsystems, biosensing devices fabricated with nanotechnologies are potential candidates for fulfilling all the above requirements.

In recent years several interesting nano-developments have been proposed as highly sensitive transducers for biosensing [as nanoparticles, carbon nanotubes (CNTs), photonic crystals, micro- and nanocatilevers, etc.], but few biomolecular interactions using such developments have been demonstrated. Many of those developments are still in their infancy, and further research and technological development is needed before real functional biosensing devices will be available. One of the main problems is the implementation. The path to connect such nano-developments to operations in real-world environments has not been paved, and large and complicated laboratory setups are still needed for signal acquisition and processing.

However, micro/nanobiosensor devices based on microelectromechanical systems (MEMS) and related (BIO)MEMS and (bio)nanoelectromechanical systems [BIO(NEMS)] technologies could provide a technological solution to achieve label-free devices which could be operated in stand-alone fashion outside from laboratory environment. For that reason, in this chapter we focus mainly on two important branches of nanodevices for biosensing: (a) nanodevices based on nanophotonics/optoelectronics and (b) nanodevices based on nanomechanics. Nanobiosensors based on optoelectronics and nanomechanics platforms are excellent examples of devices developed with microelectronics technologies, and constitute the platforms with more possibilities for being used in real applications in the near future.

The chapter covers the design, fabrication and testing of both types of biosensor nanodevices. Further integration of nanosensors, microfluidics, optical and electronic functions on a single sensing circuit could lead to a complete “lab-on-a-chip” technological solution which could be used in field applications and *in situ* analysis. Examples of fabrication, characterization and real applications of the devices will be discussed as well as the way of their integration. Although there are a number of reviews covering some aspects of the devices described here, this is the first summary and critical discussion of the developments based on the fields of photonics and nanomechanics, and the development of a new (nano)device combining both fields.

The chapter is organized as follows:

- An overview of the reasons for using nanobiosensors instead of the classical biosensor approaches.
- A brief overview of the immobilization techniques which could be employed for immobilization of the biological receptors in the transducers.
- A complete description of nanophotonic biosensors, starting from a general overview and showing one example, based in integrated optics, of the latest developments in this field.
- A complete description of nanomechanical biosensors, with an extensive overview of these devices, and showing some examples of design, fabrication and testing. One of the last developments in this field, combining nanomechanics and integrated optics, is presented for the first time.
- Finally, the future trends of this exciting nanobiosensor field are discussed.

## 10.2

### From Biosensor to Nanobiosensor Devices

#### 10.2.1

##### Overview

In addition to the excellent results obtained with existing biosensor technologies [2], there is still a need for devices able to detect, in a direct way, very low levels (picomolar to femtomolar and ideally at the single-molecule level) of a great number of chemical and biochemical substances in the areas of environmental monitoring, industrial and food processes, health care, biomedical technology, clinical analysis, etc. In addition to an extreme sensitivity, if we want to apply biosensor technology to real situations, we would need a high selectivity, short time analysis, and must be reversible, stable, simple to operate, robust, low cost and capable of multianalyte determination [2].

To achieve the above characteristics, the application of recent progress in micro- and nanotechnologies seem to be the most appealing alternative [3]. These technologies are already improving both the miniaturization and the sensitivity of the biosensor devices by using nanomaterials for their construction, allowing the intro-

**Figure 10.1.** Schemes and photographs of some nanodevices proposed for biosensing. (Reprinted with permission.)

duction of new signal transduction technologies. Due to their submicron dimensions, nanosensors, nanoprobes and other nanosystems allow simple and rapid analyses *in vivo*. We are assisting to the birth of new biosensor devices at the nanoscale which could be easily integrated in portable “lab-on-chip” platforms to perform “point-of-care” analysis and which in the future could even work inside the human body to detect, at the very early stages, the presence of cancer cells or infectious agents.

Several interesting biosensing developments based on nanotechnology have appeared in the literature during recent years, such as the use of semiconductor, metal or magnetic nanoparticles [4], localized surface plasmon resonance sensors (LSPR) [5], different types of CNT biosensors [6], probes encapsulated by biologically localized embedding (PEBBLE) [7] and many others [8] (Fig. 10.1). Although all of these developments are interesting from a scientific point of view, the real implementation of much of them will be hampered by several factors. Firstly, most of them still require using labels to detect the biomolecular interaction, which is undesirable for real applications (direct reading is much more precise). Secondly, the path to connect such nano-developments to the operation in a real-world environment has not been paved, and large and complicated laboratory set-ups are needed for signal acquisition and processing.

In contrast, micro/nanobiosensor devices based on microelectronics and related (BIO)MEMS/NEMS technologies could provide a technological solution for achieving label-free devices which could be operated in a stand-alone fashion outside of a
