#### 11.2.1

##### Nanostructures and Cells

Nanoparticles and nanowires have captured the interest of researchers because of their small size and unique characteristics. Materials in this size regime (i.e., <100 nm diameter [1, 2]) display properties that differ from their bulk counterparts. These properties, resulting from quantum confinement, include electron transfer, strong dipole moments, and size-tunable absorbance and fluorescent emission [1, 3]. Applications of these materials have been widespread, particularly in the electronics field, where there is a constant impetus to uphold Moore's law [4] and produce ever smaller electrical components. Nanoparticles have been integrated into LEDs, solar cells, and lasers [5], whereas nanowires have been used primarily to create electronic and computational components, including p-n diodes, field effect transistors, and logic gates [6].

Although the applications have not been as obvious, nanostructures also show great potential in the biological sciences [7]. Many of life's most basic functions occur in the nanometer regime. For example, the diameter of DNA is ~2 nm, of a cell surface receptor is ~10 nm, and of a virus is ~50 nm [8] (Fig. 11.1). Because of their similar size scales, nanocomponents easily interface with biological molecules [9], a feature that has already been exploited to create new sensing technologies, diagnostics, and therapeutics. Nanoparticles have been utilized as fluorescent dyes for cell labeling [10, 11], biosensors [12, 13], cell sorting aides [14], and chemotherapy alternatives [15]. Nanowires have been used for biological separations, biosensing, and gene therapy [16]. Thus, the combination of similar size scales with unique optical properties has produced several passive applications for biosensing. Future developments will likely exploit biological machinery to manipulate cells directly.

Nanostructures hold particular promise in the fields of cell and tissue engineering. In addition to possessing favorable size scales to many biological components, nanoparticles and nanowires can be manipulated in external optical [17], electric [1], and magnetic fields [18]. Their high surface to volume ratios present favorable sites for chemical reaction, and their optical properties allow for *in situ* monitoring of local structures and biochemistry [19]. Because of these capabilities, nanostructures provide some of the first opportunities to actively manipulate subcellular components. Some of this work has already been realized *ex vivo*. For example,

**Fig. 11.1.** Comparative diameters of a nanoparticle and selected biological molecules.

nanoparticles have been harnessed to kinesin and transported along microtubules [20]. However, most possibilities for nanostructures in cellular engineering have yet to be realized.

### 11.2.2

#### **Nanoparticle and Nanowire Synthesis for Biological Systems**

Nanostructures can be synthesized using various techniques, depending on the desired composition and properties. However, developing water-soluble, non-toxic nanostructures has been challenging. Most synthesis methods were originally designed for optical or electronic applications. Particles are commonly made under harsh conditions with high temperatures or organic solvents, incompatible with biological requirements. In fact, the nanomaterials themselves may be toxic (Section 11.2.5). Cadmium, a major component of semiconducting nanostructures, is known to interfere with DNA mismatch repair [21], can inhibit certain types of neuronal firing [22], and is a known carcinogen [23]. Carbon nanotubes and fullerenes can produce asbestos-like lesions in the lung [24]. Carbon [25–27], graphite [27], and iridium [28] particulates can damage tissues. The difficulties of making biological relevant, non-toxic nanostructures are great, yet several synthetic strategies have been developed.

##### 11.2.2.1 Nanoparticle Synthesis

Biologically active nanoparticles may be synthesized from semiconducting, metallic, or magnetic materials. Semiconducting particles, also known as quantum dots, are typically composed of CdX (where X is S, Se, or Te), and have been used primarily in optical applications, as a result of their high fluorescence quantum yields [19]. Metallic particles are usually made from gold. They have been used for bio-

sensing because they experience a color change with decreasing inter-particle proximity [13]. Additionally, they have formed the basis of several therapeutic treatments, as particles produce a temperature elevation with near-infrared excitation [15]. Magnetic particles are usually made from iron oxides [18]. Frequently, these particles are embedded in a micron-sized polymer matrix and used as MRI contrast enhancers and for cell and protein separation [18]. The variety of particles used has resulted in several synthetic techniques, each specific to the particle material employed.

**Semiconductor Nanoparticles** The most common method of semiconductor nanoparticle synthesis is high temperature precursor decomposition [29]. This procedure allows control of nanoparticle growth and nucleation, and thus size distribution. Depending on the reaction time and final temperature, particles synthesized using precursor decomposition can vary in size from 1 to 11 nm, with size distributions as narrow as 5% [29]. Regular size distributions are critically important for the creation of templated nanostructures, which form the basis of many cellular engineering applications (Section 11.3.2). These structures, created through the ordered self-assembly of nanoparticles, require uniform size distributions to develop patterns over large length scales.

Unfortunately, precursor decomposition utilizes organic solvents, presenting several difficulties to direct application in biology. Particles synthesized with the most common passivating ligands, tri-octyl phosphine (TOP) or tri-octyl phosphine oxide (TOPO), are soluble in chloroform and other organic solvents, but not in alcohols or aqueous solution [29]. Additionally, TOPO is a weakly bound ligand, which can disassociate from the particle over time, producing a cytotoxic product [30]. This loss of passivation exposes the particle core to oxidative attack, which can release toxic ions into the cellular environment [31], eventually resulting in particle dissolution. To protect the particle core from photooxidation and surface reactions, semiconductor particles are often modified with a shell of a wider band gap (i.e., more insulating) material. Most semiconductor particles employed in biological applications contain a shell, with the most common material used being zinc sulfide (ZnS) [32]. ZnS is an ideal shell material as it is substantially less toxic than cadmium, possesses a larger band gap than CdSe, and does not easily form alloys with CdSe [31, 33]. CdSe/ZnS capped particles are stable for months, even in the presence of oxygen and are less toxic than uncapped particles [31].

As an alternative to organic syntheses, nanocrystals have been produced in aqueous solvents through a process known as arrested precipitation. Bulk CdS is relatively insoluble in water ( $K_{sp} \sim 10^{-29}$ ) [34]. However, with the addition of aqueous thiols, nanometer-sized water-soluble colloids are produced. Briefly, upon thiol addition, complexes with cadmium ions are formed. Sulfur ions are added and crystal growth occurs, but it is hindered by the steric presence of the thiol compounds. Eventually, free sulfur anions cannot overcome these steric forces and particle growth is terminated. If the surface is well passivated, the crystals can remain suspended in water.

This process is controlled by many factors, including the reactant ratios, the thio-

lated ligand in question, and the pH of the reacting mixture; all of which contribute to nanoparticle size and uniformity [35, 36]. Aqueous syntheses are very flexible. Various materials can be used as reactants. The first CdS nanocrystals were produced using Cd(SO<sub>4</sub>) as a cadmium source [37], although Cd(ClO<sub>4</sub>)<sub>2</sub> [38] and CdCl<sub>2</sub> [35, 36] have also been used. Sulfur can be introduced through various mechanisms, and (NH<sub>4</sub>)<sub>2</sub>S [37], Na<sub>2</sub>S [38], and H<sub>2</sub>S [39] have all been investigated. Thiolated ligands can range widely, including mercaptoacetic acid, mercaptopropionic acid, mercaptoethylamine, and β-mercaptoethanol [35, 40, 41]. Although thiolated ligands are used most frequently, any ligand that binds to Cd<sup>2+</sup> ions and promotes water solubility of the particle may be employed.

Nanoparticles produced using aqueous syntheses offer many benefits for biological studies. For example, they can be manufactured using simple bench-top chemistry, requiring only a fume hood. Particle surfaces may be readily altered through the use of cysteine- or thiol-terminated biomolecules, or by performing post-synthetic conjugation chemistry on a ligand functional group. The main limitation of this procedure is the large particle size distribution, which can increase with time, developing a tail at larger sizes, indicating particle instability [42]. This is likely a result of Ostwald ripening, the growth of larger particles at the expense of the thermodynamically less stable smaller ones [41]. However, we have observed that only solutions of larger particles exhibit this behavior; solutions containing smaller particles (i.e., ~3 nm and less) can be stable in aqueous solution for months. Thus, the particles can exhibit remarkable stability, comparable only to silica-capped CdSe/ZnS [10, 43].

**Metallic Nanoparticles** Gold or silver nanoparticles, the most widely investigated, have a long history, originally being described by Michael Faraday in 1857 [44]. They are normally synthesized by the reduction of metal salts in citrate solution [45]. Similar to aqueous syntheses for semiconductor nanoparticles, various capping agents can be added to control particle surface properties and growth [46]. Gold nanoshells can also be created through the reduction of metal salts onto a pre-existing substrate [47]. Shell growth occurs by the formation of nanoparticles on a surface (i.e., gold [47] or silica [48]). As nanoparticle growth continues, particles coalesce to form a shell. These shells exhibit interesting plasmon resonance shifts, which can produce local heating in the presence of IR irradiation. As an alternative to aqueous routes, gold particles have also been produced in inverse micelle preparations [49]. In this synthesis technique, particle growth is limited by the size of the micelles formed. Unfortunately, most inverse micelle preparations utilize organic solutions, which may necessitate ligand exchange to create biologically stable particles.

Gold particles, in particular, have found application in the biomedical field because of their easily altered surface chemistry and optical properties. Gold readily binds thiol-containing molecules [50], offering a wide-range of surface chemistry options. Additionally, gold colloid solutions change color, from red to purple, upon particle aggregation [13], and particles can be deposited in self-assembled monolayers, facilitating integration into biosensors [51]. The presence of gold particles

can be detected using various methods, including optical and electron microscopy and Raman spectroscopy, and gold particles have been used in various diagnostic methods [46]. Finally, gold particles and nanoshells experience a temperature increase upon near-infrared irradiation that has been used for cancer therapy, e.g., hyperthermia (part of Section 11.6.2.2).

**Magnetic Nanoparticles** Most magnetic nanoparticles are composed of iron oxides. In general, particles are prepared by the addition of base to an aqueous solution of iron ions, forming iron oxide [18]. To prevent oxidation, particles are produced under nitrogen. For example, magnetite ( $\text{Fe}_3\text{O}_4$ ) may be prepared by Reaction (1) [18].

Crystal growth proceeds through nucleation of small complexes that grow as a result of Ostwald ripening. Particles formed range from 6–15 nm and consist of single magnetic domains. The strategy is very similar to aqueous syntheses for semiconductor and metallic nanoparticles described above. Reactions are controlled by passivating surface molecules, which take on an additional importance because particles are attracted to each other through their magnetic fields in addition to traditional electrostatic and van der Waals forces [18]. Passivating molecules can be added to the reactants, during reaction, which forms microemulsions, or after the reaction. A wide variety of natural and synthetic polymers, chemical stabilizers, and metallic coatings have been investigated. Typically, the passivating coating is not magnetic and can be as much as 20 nm thick, effectively doubling the diameter of the particle [52], which may prove problematic, depending on the application.

Magnetic nanoparticles are characterized by the nature of their magnetic properties. Nanoparticles may be ferromagnetic or superparamagnetic. In ferromagnetic materials, individual atomic dipole magnetic moments align to create permanent magnetization. This occurs because the internal thermal energy of the material is not sufficient to overcome the magnetic attraction of the individual dipoles. Particles in the micron-size range exhibit this behavior [18]. However, as particle size decreases, an interesting phenomenon is observed. Although the particle still possess insufficient thermal energy to overcome individual atomic magnetic attractions, the internal thermal energy of the particle is sufficient to alter the direction of all aligned dipoles. This produces a fluctuation of the magnetic dipole for the entire crystal, resulting in a net magnetic moment of zero. Particles below 15 nm exhibit this behavior [18], known as superparamagnetism. Although they are not “true” paramagnetic materials in that their atomic dipoles are aligned, the entire crystal exhibits paramagnetic behavior (e.g., temporary polarization).

#### 11.2.2.2 Nanowire Synthesis

Nanowires have been manufactured using various techniques, including templated synthesis, directed growth in solution, and vapor phase growth [3, 16]. Because of the range of methods employed, nanowires can be created from many substances, in-

cluding magnetic, semiconducting, and ceramic materials. In templated synthesis, nanowires or hollow nanotubes are grown inside a porous membrane using electrodeposition or sol-gel techniques. Using this method, magnetic [53], metallic [16], and ceramic [16] nanowires with aspect ratios of up to 250 have been manufactured. Templated synthesis has several advantages. Particles of varying composition can be created by changing the electric potential or electroplating solution. The presentation of nanowires may be varied. They can be constructed as supported arrays or, by dissolving the membrane, free-standing entities.

Solution phase synthesis proceeds through several mechanisms [3, 16]. In surfactant driven assembly, surfactants attach to a specific crystal face, limiting growth in those directions. Alternatively, chemical reaction may occur preferentially at a specific crystal face, and reduction at this surface produces nanowire growth and extension. Solution-phase synthesis has the advantage of being scalable (to gram quantities [3]) and occurring at modest temperatures, which are more amenable to biological components. The greatest limitation of this technique is that directed growth in solution is the not well understood and difficult to control.

Vapor-phase synthesis requires high temperatures to create gaseous reactants that are deposited on a substrate as nanowires or nanotubes. High temperature syntheses are primarily used to produce carbon nanotubes, but silicon and several other semiconductor nanowires have also been created using this approach [3, 6]. Nanowire formation is catalyzed by a metallic liquid droplet. As the temperature is increased, gaseous vapor of the desired component begins to form a eutectic mixture within the droplet, entering the liquid phase. Further increases in temperature raise the dissolved concentration, favoring formation of a pure solid composed of the desired component. The size of the droplet restricts crystal growth in a preferred direction and defines the diameter of the nanowires, with an average of 10 nm [6]. Nanowires produced are frequently contaminated by the seed crystal. Because many of the seed metals used (e.g., nickel) are toxic, the development of biocompatible nanowires may be hindered.

As with nanoparticles, surface functionalization is often required to produce biologically compatible, water-soluble nanowires. Many of the techniques employed are similar to those for nanoparticles, including the use of thiols, carboxylic acids, and siloxanes [16]. Because nanowires may be constructed of segments of alternating materials, several passivation strategies may be required. For example, metallic nanowires containing segments of nickel and gold can be labeled with distinct fluorescent agents using differences in surface chemistry (Fig. 11.2) [54]. Nanowires have also been functionalized with biological molecules including DNA and proteins [55, 56].

### 11.2.3

#### **Surface Passivation Strategies**

The main limitation of nanostructures produced in organic solutions is their lack of water solubility. Several techniques have been offered to correct this condition, all relying on modification of the nanostructure surface. This can be accomplished by altering the nature of the passivating ligands or augmenting the crystal with a

shell material that is biocompatible. These techniques have both been used to create nanoparticles employed for biological labeling [10, 11]. However, the process for transferring particles into water can be time-consuming and requires equipment outside the reach of most biological laboratories.

The most common method for rendering particles water-soluble includes an additional post-processing step known as ligand exchange. During ligand exchange, the existing chemical surface coating of the particle is replaced with one that can alter the solubility of the colloid [57]. There are several variations in the ligand exchange technique; however, the basic premise remains the same [29]. The particles are dried to remove unreacted ligand and the organic solvent, and are introduced into a solution containing a gross excess of the new ligand. After an incubation of several hours, exchange occurs. Exchange can be confirmed by altered solubility of the particles, or through analytical techniques like FTIR (Fourier-transform Infrared Spectroscopy) and XPS (X-ray Photoelectron Spectroscopy).

The most common ligand exchange used to produce biologically compatible quantum dots exchanges TOPO, bound to CdSe/ZnS core-shell particles, for mercaptoacetic acid (MAA = HS-CH<sub>2</sub>-COOH) [11, 57]. The binding of MAA occurs through the sulfur group at the molecule's terminus, which adheres to Zn atoms on the ZnS coating [57]. The carboxyl end of MAA provides water solubility. In addition to MAA, several other thiolated chemicals have been examined, including mercaptopropionic acid (MPA = HS-(CH<sub>2</sub>)<sub>2</sub>-COOH), mercaptoethylamine (MEA, HS-(CH<sub>2</sub>)<sub>2</sub>-NH<sub>2</sub>), and  $\beta$ -mercaptoethanol (MBE, HS-CH<sub>2</sub>-CHOH). In fact, any molecule that binds to the surface of the particle and is water-soluble can be used, thus allowing a range of surface chemistries to be explored. However, ligand exchange is a long, multi-step process spanning as many as three days. The particles are only stable in solution for 1–3 weeks [57], indicating possible loss of ligand coverage over time. If the ligands are toxic (e.g., MBE [58]) or bioactive (e.g., MEA [59]), desorption can have deleterious effects on cells exposed to particles.

Another method to create water-soluble nanoparticles alters the surface by applying a biocompatible shell material. An example of this technique, developed by Alivisatos et al. [10, 43], coats TOPO-capped CdSe/ZnS particles with silica. Particles were exposed to a gross excess of mercaptopropyltris(methoxy)silane (MPS), to which tetramethylammonium hydroxide (TMAH) had been added, producing a 2–5 nm silica shell [43]. This technique is versatile and could be applied to any TOPO-capped particle. Additionally, silica-coated particles meet several of the criteria for biological applications. Unlike particles that undergo ligand exchange, silica-coated nanocrystals exhibit stability for months [10, 43]. Also, biomolecules can be readily conjugated to silica using well-established techniques developed for chromatography. The only potential disadvantage of this technique is that silica is insulating and might alter the properties of the encapsulated particle.

#### 11.2.4

#### **Bioconjugation**

Once particles have been prepared for aqueous use, it may be desirable to attach biomolecules to their surface. The range of biomolecules that can be bound to

**Fig. 11.2.** Selective functionalization of multi-component nanowires can be achieved by taking advantage of the selective surface chemistry of the nanowire segments. (A) Reflection image of a two-segment nickel-gold nanowire. The brighter portion of the nanowire represents the more reflective gold surface. (B)

The corresponding fluorescence image shows a nanowire that was modified by coupling different fluorescent dyes to each segment, which allowed the Ni segment to emit green and the Au segment to emit red. (Photo courtesy of Gerald Meyer, Johns Hopkins University, Baltimore, MD.)

nanostructures is staggering, and this is one of the factors that have led to their broad appeal for biological applications (see Volume 1 of this series for more detail). There are several methods to link biomolecules to nanostructures [60], the simplest being physisorption on the nanostructure surface (e.g., Zhang et al. [61]). However, most nanostructures are charged, thus electrostatic attraction is more frequently used to mediate attachment. For example, DNA will bind to nanoparticles presenting trimethylammonium ligands [62], and layer-by-layer assembly has been used to create films of alternating-charged nanoparticles and biomolecules [63–65]. Additionally, binding affinities between materials have been exploited to link biomolecules to surfaces. Thiolated compounds bind strongly to Cd-based and gold nanostructures [50], and biomolecules containing cysteine can be attached to nanostructures in this way [66]. Nanostructures can also be functionalized with biomolecules through directed recognition. The avidin-biotin system has been well studied in this regard. Avidin and biotin display strong binding to each other. A molecule that has been modified with avidin can be linked to any biotin-labeled biomolecule. This technique has served as the basis for commercially available fluorescent quantum dot labels [10].

#### 11.2.4.1 Conjugation Strategies to Promote Non-specific Cellular Affinity

Once on a surface, biomolecule-conjugated nanostructures can be directed to a cell or tissue of interest. In some cases, this occurs on the basis of charge, resulting in non-specific adsorption. This recognition strategy is the most straightforward, requiring only adjustment of the surface charge, but has the least specificity. Particles cannot be directed to a specific part of a cell or a specific group of cells. This

method was first used by Alivisatos et al. [10], who investigated CdSe–CdS core–shell nanocrystals enclosed in a silica shell (Section 11.2.3) [43]. The shell conferred water-solubility on the particle, but also provided functional groups (e.g., aminosiloxanes) for bioconjugation. To demonstrate non-specific binding, the silica coating was modified with trimethoxysilylpropyl urea (urea =  $\text{NH}_2\text{-C-NH}_3^+$  at neutral pH), which binds negatively charged acetate groups ( $-\text{CH}_2\text{-COO}^-$  at neutral pH) in the cell nucleus. Nanocrystals introduced to cells were located in the nucleus, as evidenced through fluorescence microscopy measurements. Binding was suppressed with the addition of a negatively-charged reagent or sodium dodecyl sulfate (SDS), indicating that binding was primarily caused by non-specific electrostatic interactions.

#### 11.2.4.2 Biomolecular Recognition

Apart from electrostatic interactions, which are non-specific, particles can be directed to cells and tissue using biomolecular recognition, the strong and highly specific binding that exists between a receptor and its ligand target. This binding is not completely understood, but arises from a combination of electrostatic attractions, hydrogen bonding, and hydrophobic/hydrophilic interactions [67]. The cumulative interaction of these forces, which are individually weak, produces tight binding. Additionally, this affinity is unique to the ligand and its analogs, as only molecules with a certain conformation can access the binding site and form the appropriate bonds. Thus, the interfaces formed through biomolecular recognition are highly specific and controlled.

Several molecules have been identified as biorecognition elements, and can be used to connect small molecules to components of the cell. Typically, these fall into three classes: antibodies, proteins, and peptides [67]. Antibodies recognize components that are foreign to their host system, and can be produced for almost any cellular component. A wide range of antibodies are commercially available, and their large size and high number of functional groups allow for ready conjugation to many surfaces. Antibodies are by far the most commonly used biorecognition element in conjugate chemistry [68]. However, when antibodies cannot be applied, alternatives (e.g., proteins and peptides) may be employed. Because protein or peptide binding will produce a cellular response, these methods are often utilized to impose a specific cellular function (e.g., receptor-mediated endocytosis [11]) to the attached molecule. Proteins can be linked to these molecules through chemistry techniques, the success of which depends widely on the nature of the protein employed. For applications where an entire protein might be too large or expensive, protein fragments, known as peptides, can be employed. Peptides can be synthesized with additional amino acids to allow for conjugation to a chosen molecule.

#### 11.2.4.3 Conjugation Strategies for Antibody-mediated Recognition

Antibody binding is extremely useful for directing nanostructures to particular cell elements. A wide selection of antibodies is commercially available, and they may

be easily conjugated to nanostructure surfaces. Antibody–nanoparticle binding was first demonstrated by Nie et al. [11], using CdSe–ZnS core–shell particles. The particle surface was altered through mercaptoacetic acid ligand exchange, placing carboxyl groups on the surface. Using carbodiimide chemistry (i.e., EDC), carboxyl groups were conjugated to the reactive amines of IgG antibodies. Because aggregation is a side-effect of EDC chemistry, conjugates were examined with transmission electron microscopy and were found to be primarily single particles. Fluorescence optical microscopy confirmed that conjugated particles maintained their initial optical properties. To demonstrate biorecognition, IgG conjugates were shown to aggregate in the presence of a specific polyclonal antibody known to bind IgG fragments. Antibody recognition has also been demonstrated on live cells using aqueous CdS quantum dots conjugated to IgG secondary antibodies through EDC chemistry [66]. Primary antibodies recognized and attached to integrin receptors. Quantum dot–IgG conjugates were then able to bind and recognize the primary antibodies with no adverse cellular effects.

#### 11.2.4.4 Conjugation Strategies for Protein- and Peptide-mediated Recognition

Proteins and peptides (i.e., protein fragments) have also been conjugated to particles for cellular recognition. For example, phalloidin protein conjugated to silica-coated quantum dots was used to bind to actin filaments in fixed cells [10]. Phalloidin was attached to the nanoparticle surface using avidin–biotin chemistry. First, the silica coating of the nanocrystal was modified to include primary amines using 3-aminopropyltrimethoxysilane. Then, biotinamidocaproic acid 3-sulfo-*N*-hydroxysuccinimide ester was introduced. The NHS ester group of the activated biotin reacts quickly with primary amines to produce amide bonds, linking the nanocrystals to biotin molecules. The cells were exposed to a separate solution of biotinylated-phalloidin, which adhered to F-actin filaments in the cytoskeleton. Then, streptavidin was introduced, binding the biotin component of biotin–phalloidin. Finally, cells were incubated with the biotinylated-nanocrystals, which bound to the phalloidin–biotin–streptavidin complexes at avidin sites. Additionally, particles have been bound to transferrin, a surface protein that promotes uptake of iron molecules through receptor-mediated endocytosis [11]. EDC chemistry was used to mediate attachment to CdSe/ZnS particles. Transferrin-conjugated particles were incubated with living cells, and were found in intracellular vesicles, as would be expected following receptor-mediated endocytosis.

As an alternative to whole proteins, which can be bulky, a second approach utilizing peptides was developed. Peptides were attached to quantum dots as surface passivation molecules [66], providing a single-step technique for nanocrystal synthesis and bioconjugation. Aqueous CdS nanoparticles were attached to RGDS and YIGSR peptides, which bind to integrin receptors [69, 70] through thiolated ligand-binding using cysteine residues. Peptide–cell binding has several advantages to antibody- or protein-cell binding. The minimum peptide length for recognition depends on the protein selected, but can be as short as 3–5 amino acids (e.g., 1–1.5 nm) [69, 70]. Additionally, peptides can be manufactured to almost any length, with each amino acid roughly corresponding to 3 Å (0.3 nm) for a straight-

chain conformation [71]. Thus, the separation distance between the particle and the cell surface can be tuned through altering the length of the peptide. Their small size and tunable length make peptides ideal alternatives to large conjugation molecules. Given these factors, peptide bioconjugation presents a superior approach for forming close-range interfaces between semiconductor quantum dots and cellular receptors.

#### 11.2.5

##### **Toxicity (see also Volume 5 of this Series)**

Very few studies have examined the potential health risks of nanostructures. There is limited evidence that suggests risks are present, particularly through inhalation. A recently published report demonstrated that inhaled carbon nanotubes can produce asbestos-like lesions in the lung [24]. Among the highest dose group, the mortality rate was 55% ( $N = 9$ ) after only 7 days of exposure. Although these results were for pulmonary tissue, a separate set of studies examining carbon [25–27], graphite [27], and iridium [28] particulates established the ability of nanomaterials to damage other tissues, including the immune system [26] and brain [25, 27]. Particle effects on the brain included an increase in lipid peroxidation and damage to lipid-rich tissues [25]. The most troubling finding of these studies is that particle clearance proceeds slowly. A low level (i.e., 6% in lung) of particulates remained in tissue a full six months after exposure [28].

However, it is unclear if these results will apply to nanostructures used in biomedical applications. Most of these investigations examined toxicity through inhalation, but semiconducting, metallic, and magnetic particles are primarily produced in solution-phase. A more likely route of exposure is through ingestion or skin contact [72]. Additionally, the materials studied (i.e., carbon particulates and nanotubes) bear little similarity to the nanostructures reviewed here other than size. Several groups have employed semiconducting nanoparticles *in vitro* and *in vivo* without noticeable cell damage [73–78]; however, they did not specifically assess cell viability and function. To date, only a single study [31] has confirmed that semiconducting nanoparticles may be cytotoxic to cells when presented in aqueous solution. This was attributed to the release of free  $\text{Cd}^{2+}$  ions following oxidation of the particle core. Nanoparticles are susceptible to oxidation and photooxidation [1, 31, 79–82], particularly with UV exposure. Reaction of oxygen with group VI elements (e.g., S, Se, Te) produces oxides [1] that can disassociate from the particle surface. Free Cd atoms are left behind and may eventually enter solution. Elevated free cadmium levels have been reported for poorly-capped particles and particles exposed to prolonged UV excitation [31].

$\text{Cd}^{2+}$  ions have well-established health risks [83]. Cadmium is a known carcinogen, and has been linked to lung, testicular, adrenal, liver, and kidney cancer [23]. Although the exact mechanism of carcinogenicity is not understood, cadmium has been shown to interfere with DNA mismatch repair [21]. It also binds strongly to the sulfhydryl groups of mitochondrial proteins [84], and this is the believed source of toxicity observed for the primary hepatocytes studied previously [31]. Ad-

ditionally, cadmium is a commonly used blocking agent in patch-clamp studies that interferes with neuronal firing [22]. Given all of these factors, the stability of the nanoparticle core is of great concern. Modifying particles with a strongly-bound passivating ligand, an inorganic layer (e.g., ZnS), or a polymer coating can increase particle stability by preventing the entry of oxygen [31, 72]. Most recent reports on semiconducting quantum dot use for living systems utilize some coating of this nature [73–78].

Data for metallic nanoparticles and nanowires is even scarcer. Gold, in the bulk form, is fairly well-tolerated and has been used as an electrode coating in prosthetic implants for some time [85]. However, gold nanostructures have a dramatically higher surface area than bulk material. They are much more reactive and can potentially interfere with biochemical syntheses [86]. Reports on silver nanoparticles are conflicting. Although silver displays toxicity when employed in the nervous system, it has been widely used as a biomedical antimicrobial coating [87]. Silver nanoparticles employed in bone cement exhibited no overt cytotoxicity and a strong antibacterial effect at 1% loading [87]. However, mouse spermatogonia cells demonstrated a reduction in mitochondrial activity, increases in cell lysis and apoptosis, and changes in cell morphology when exposed to silver nanoparticles [88].

Uncapped iron oxide (i.e., magnetic) nanoparticles can also be cytotoxic, reducing cell viability by 20% at concentrations of only  $0.05 \text{ mg mL}^{-1}$  and 60% at higher concentrations (i.e.,  $2 \text{ mg mL}^{-1}$ ) [89]. Reduced viability may result from excessive particle internalization, producing apoptosis and limiting cell migration [90]. This behavior can be altered by the addition of a surface coating. For example, pullulan-conjugated nanoparticles showed no statistical difference in cell viability from control cells at  $2 \text{ mg mL}^{-1}$  concentrations [89].

Although the data on nanostructure toxicity is slim, it is apparent that coating the particles with a biocompatible shell (e.g., silica) or biomolecule (e.g., pullulan) reduces the risk of adverse reaction. This may result from isolation of a toxic core material, as in the case of Cd-containing particles, or from reduced protein adsorption, which limits particle endocytosis. The most effective coatings are likely those that reduce uptake through the endocytotic pathway [90], allowing the nanoparticle to remain in the extracellular environment as long as possible. As more research is performed, additional modifications to prevent toxicity will likely arise.

### 11.3

#### **Nanostructures to Modify Cell Adhesion and Migration**

An area of cellular engineering with great possibility for nanostructure use is the selective modification of cell adhesion. Cell adhesion is ideal for nanostructure-based evaluations because most of the salient events occur on the extracellular surface. Thus, nanostructure modifications for intracellular delivery (Section 11.4) are not required. Additionally, there is much to be gained from nanoscale investigations of cell adhesion and migration, as these processes are responsible for cancer metastasis [91], angiogenesis [91], tissue repair [92], and synapse formation [93].

Selective cell adhesion is also critical to the development of biocompatible implants and prostheses [94]. Integration with target cells is crucial to the function of the implant. However, in many cases this adhesion must occur while excluding undesirable cell types (e.g., immune cells, glia) that can interfere with device performance and tissue compatibility.

At the micron scale, cell responses to both chemical and physical cues are well established (for a review see Folch and Toner [95]). Surfaces with micron-sized pillars can influence cell adhesion and cytoskeletal protein distributions [96]. Cell extensions (e.g., neurites) are influenced by both the depth and width of surface grooves [97]. Chemical surfaces, containing adhesive islands, can confine cells to regions as small as 10  $\mu\text{m}$  [98]. As area decreases the number of adherent cells, degree of cell spreading, and even the signal for apoptosis (i.e., controlled cell death) can be controlled [99]. Physical and chemical patterns can produce a synergistic response. Neurons cultured on micropatterned substrates align their extensions with regions containing both cues (Fig. 11.3). These patterns have been incorporated into various applications. Physical patterns have been used in biosensors and implants to improve biocompatibility and tissue adherence [100]. Micropatterned adhesive regions can create ordered arrays of muscle cells [101, 102], and guide neurite extension for neural networks [103–106].

### 11.3.1

#### Cell Adhesion at the Nanoscale

Although the ability of cells to respond to micron-scale structures has been established, there has been doubt as to whether responses would extend into the nano-

**Fig. 11.3.** (A) PC12 cell micropositioned on PDMS microfabricated structure. The cross-shaped pattern was fabricated as a geometry to analyze neuron responses to multiple extracellular cues localized on the arms. In this case, microchannels 2  $\mu\text{m}$  wide and 500 nm deep were patterned on the right arm for stimulating the cell via contact guidance, as evidenced by the extension of an aligned neurite. (B) Rat embryonic hippocampal cell (E18) cultured on a PDMS substrate with

microchannels and immobilized NGF. Microchannels 2  $\mu\text{m}$  wide and 1  $\mu\text{m}$  deep were patterned in PDMS using replica molding from silicon masters. NGF was immobilized using arylazido photolinkers. The substrate provides a combination of physical and biochemical cues to accelerate polarization of the cell (i.e., determination of an axon). **Fig. 11.4.** Integrin binding to the ECM and cytoskeleton. Integrins embedded in the plasma membrane are used to form contacts with the extracellular matrix (e.g., collagen, laminin) and cytoskeleton (e.g., actin).

scale [2]. However, the environment surrounding cells is peppered with nanoscale cues. Cells are surrounded by a lipid bilayer  $\sim 5$  nm thick [8] (Fig. 11.4). Cell adhesion is mediated by 10 nm diameter integrins embedded in the bilayer [8]. These integrins cluster to create various nanoscale contacts (Table 11.1) [107, 108]. Integrins bind extracellular matrix (ECM) components, which are the primary elements of the basement membrane surrounding most tissues. Some of these components display heights of  $\sim 150$  nm and band widths of  $\sim 60$ – $80$  nm (Table 11.1) [2, 109], and fibrils and pores in ECM structures as small as 5 nm have been reported [109]. On the cell interior, integrins attach to nanometer-sized cytoskeletal elements, including microtubules, actin, and intermediate filaments (Table 11.1). These elements produce cell shape and structure, and may respond to external forces [110].

### 11.3.2

#### Cell Adhesion and Nanoscale Physical Topography

However, creating materials with dimensions that could explore these biomolecules has been challenging. Unlike microfabricated devices, patterning methods are just beginning to extend to the nanoscale. Using lithographic techniques, several features, including grooves, ridges, steps, pillars and pores, have been investigated (see Flemming et al. [109] for a review). Despite being several times smaller than a cell diameter (i.e.,  $\sim 10$   $\mu\text{m}$ ), cell responses were observed. Nanoscale physical features can create networks of aligned cells [111–113], induce macrophage spreading and phagocytotic activity [114], and guide neuronal growth cones [115].

For example, 350 nm wide nanogrooves have been used to evaluate smooth muscle cell (SMC) adhesion *in vitro* [113]. More than 90% of SMCs cultivated on this surface aligned to the grooves, and proliferation of the cells was significantly

**Tab. 11.1.** Cell–matrix contacts at the nanoscale. (Adapted from Ref. [107].)

Element	Dimensions	Description/purpose
Cell–matrix contacts [107, 198]		
Filopodium	20–200 $\mu\text{m}$ $\times$ 200–500 nm	Cell protrusion, actin bundle connected to syndecans (proteoglycans)
Focal contact	1.5 $\mu\text{m}$ $\times$ 250 nm	Cell contact, actin microfilaments connected to integrins, substrate adhesion
Hemidesmosome	150 $\times$ 40 nm	Cell contact, intermediate filaments connected to integrins
Podosomes	200–400 nm diameter	Cell contact, actin bundle connected to integrins
Microspike	2–10 $\mu\text{m}$ $\times$ 200–500 nm	Cell protrusion, actin bundle connected to integrins, NG2 (proteoglycans)
Cell exterior: extracellular matrix proteins [8]		
Collagen	1.5 nm triple helix, 10–300 nm fibers	Structural protein
Fibronectin	2–3 nm arms separated by 100 nm, fibrils 10–1000 nm	Adhesive protein
Laminin	30 $\times$ 100 nm	Adhesive protein
Cell interior: cytoskeletal elements [8]		
Actin	5–9 nm diameter	Muscle contraction, cell locomotion, vesicle transport
Microtubules	25 nm diameter	Organelle and protein transport, chromosomal separation, cell division, vesicular transport, primary components of cilia and flagella
Intermediate filaments	10 nm diameter	Mechanical strength, compose nuclear lamina

lower than those grown on control surfaces (Fig. 11.5). Additionally, in a wound healing assay, SMC microtubule organizing centers (MTOCs) were preferentially aligned with the cell axis for grooved surfaces, and the wound location for control surfaces. These studies demonstrate the importance of nanoscale features in guid-

ing cell extension and adhesion. Surfaces with smaller features have also been examined, most notably by direct application of nanoparticles. Silica nanoparticles with dimensions from 7 to 21 nm were deposited directly onto glass coverslips, producing amorphous nanoscale features [116]. Fibroblasts cultured on these surfaces formed clusters and were much less likely to adhere and spread when compared with plain glass controls.

Interest in the creation of nanoscale patterns has led to the development of a new technique, known as colloidal lithography, which uses arrays of ordered self-assembled nanoparticles as a resist (Fig. 11.6) [117]. Metal can be evaporated or sputtered through the colloidal resist, creating a pattern in the crevices between the particles. The shape and dimensions of this pattern can be varied by altering the size and packing of the nanoparticles in question. Particles used are commonly made of gold, silica, or polymers, with diameters on the order of 10–100 nm [118]. The structures formed can display order over length scales of several microns, with increasing order for assemblies of larger particles [51].

Colloidal lithography has been applied to cell adhesion only recently, with much of the work performed by the Sutherland and Curtis research groups (see Dalby et al. [119] for review). Using polystyrene beads roughly 100 nm, structures with

features ranging from  $\sim 50$  to 200 nm have been manufactured. Cellular responses to these patterns have been varied. Pancreatic epithelial cells [120] cultured on hemispherical titanium pillars of increasing width (i.e., from 60 to 170 nm) displayed less rounded morphologies and increased spreading with respect to flat control surfaces. However, fibroblasts on 160 nm high by 100 nm wide poly(methyl methacrylate) (PMMA) nanocolumns seemed to prefer smooth surfaces to nanostructures. Vinculin adhesions were smaller on nanocolumn surfaces than in the control group [121], and appeared similar to transient focal adhesion structures observed elsewhere in poor adhesive environments [122]. Cells cultured on nanocolumns contained fewer actin stress fibers [121] and displayed more filopodia per micron of cell perimeter [123] than the controls. These results suggest that the cells were unable to form solid attachments to nanocolumns and continued to explore the local environment (with filopodia) for suitable substrates.

The ability of titanium nanostructures to promote cell spreading, in contrast to PMMA, implies that cells respond not only to the dimensions but also the type of material used and is consistent with previous findings. In bulk conditions, endothelial cells adhere to bare titanium, whereas attachment to PMMA required preadsorption of ECM factors [124]. Adhesion to titanium also increases with surface roughness [125], consistent with the finding that cells preferred a rough nanopillared surface to the smooth control. Thus, in addition to physical properties, surface chemistry (e.g., metal vs. polymer) plays an important role in producing nanoscale cell adhesion.

### 11.3.3

#### Cell Adhesion and Nanoscale Chemical Patterns

Establishing nanoscale chemical patterns has proven more difficult than creating physical patterns. Many of the methods used at the micron-scale (i.e., microcontact printing) do not readily translate to nanometer dimensions [126]. Several inge-

nious techniques have been developed to overcome these obstacles. Clusters of adhesive peptide sequences, containing the RGD integrin binding fragment, have been attached to comb polymers with 2 nm monomer chain lengths. Cell adhesion increased with the number of RGD fragments per cluster and the overall density of the clusters [127]. Alternatively, arrays of protein-adsorbed spots have been created using dip-pen nanolithography [128]. An AFM-tip coated with thiolated proteins was exposed to a gold surface. Utilizing the strong attraction of thiols for gold surfaces, proteins are transferred to the gold substrate with tip contact. To examine cell adhesion, spots of the integrin binding protein retronectin 200 nm in diameter with 700 nm spacings were constructed against a non-adhesive background. Fibroblasts adhesion was demonstrated.

Nanoscale chemical patterning is just beginning to extend to nanoparticles. In a rather creative approach, polymer micelles containing gold precursors were used to create ordered arrays of gold nanodots. The micelles were deposited onto substrates and then exposed to oxygen plasma etch to remove the polymer. The remaining gold precursors formed nanodots *in situ*. Dots were then coated with cyclic RGD peptide fragments [108, 129]. RGD spots with diameters < 8 nm and spacings from 28–85 nm were created, with each dot theoretically large enough to accommodate only one integrin binding domain. Cell adhesion and focal contact formation was reduced for spacings > 73 nm, suggesting that integrin clusters separated by <70 nm are required for focal contact formation.

#### 11.3.4

#### Cytoskeletal Manipulation

Physical and chemical nanopatterns interact with cells passively. They are unable to directly probe specific cellular components. However, as a result of their unique optical, electrical, and magnetic properties, nanostructures *do* possess these capabilities. Most applications of direct cellular manipulation are still in the nascent stages. However, the use of magnetic particles for cell sorting and cytoskeletal manipulation has existed since the 1950s when it was pioneered by Crick (of DNA double helix fame) and Hughes [130]. Manipulation is accomplished using microspheres containing nanometer-sized magnetic colloids encapsulated in a polymer matrix, which are available from several commercial sources (e.g., Dynabeads, Dynal Corp., Brown Deer, WI) (Fig. 11.7).

The most common applications of this technology have been for cell sorting. Biomolecule-labeled magnetic microspheres can be used to isolate specific cells (for reviews see Chalmers et al. [14] and Zborowski et al. [131]), including rare cell lines [14, 132], which could be used for tissue engineering constructs or as a diagnostic tools. More recently, this technique has extended to magnetic nanowires. For example, magnetic nickel nanowires can be constructed using templated electrodeposition. Because of their large aspect ratios, the wires maintain residual magnetism (i.e., are ferromagnetic) in low magnetic field strengths. They can be used in sorting applications that traditional magnetite beads cannot, and in some cases, display superior performance [53, 133].

**Fig. 11.7.** Scanning electron microscopic image of a 10  $\mu\text{m}$  polystyrene particle labeled with Immunicon magnetic nanoparticles at magnifications of (A) 8000 $\times$  and (B) 50 000 $\times$ .

Note that the bound particles are on the order of 100 nm. (Photo courtesy of Jeffery Chalmers, Ohio State University, Columbus, OH.)

These cell sorting methods have been applied to tissue engineering. For example, magnetite ( $\text{Fe}_3\text{O}_4$ ) particles with an average diameter of 10 nm can be encapsulated into cationic liposomes [134]. These liposomes have been used to create tissue engineered cell sheets containing multiple cell types [135, 136]. Liposomes were exposed to cells, accumulating in the cytoplasm. Then, localized magnets were used to precisely position cells on a substrate. This technique has been used to create co-cultures of hepatocytes and endothelial cell [135], sheets of keratinocytes [137], and retinal pigment epithelium [138]. Similarly, nickel magnetic nanowires have also been used to control cell deposition on tissue engineered substrates [139]. Here, nanowires were coupled to cells through non-specific surface protein adsorption. Fibroblasts attached to the nanowires aligned with a magnetic field creating cell-cell chains.

Magnetic structures have also been used to investigate the effects of mechanical stress in cells. For example, the response of individual integrin receptors to external forces was examined using 5.5  $\mu\text{m}$  diameter magnetic spheres [140]. The spheres were coupled to RGD-peptide integrin binding motifs and incubated with cells to produce extracellular integrin binding. Then, spheres were exposed to magnetic fields, applying force to the cytoskeleton. Cytoskeletal stiffness was directly proportional to applied stress, demonstrating that integrins are mechanotransducers, modulating cell behavior in response to mechanical stress. This technique has also been expanded to allow manipulation of multiple cell culture dishes simultaneously, allowing for larger-scale biochemical analyses, including gene expression studies [141].

### 11.3.5

#### Future Applications of Nanostructures for Cell Adhesion and Migration

The potential for nanoparticles and nanowires to modulate cell adhesion is great, and many of the most exciting applications have not yet been realized. Most cur-

rent approaches manipulate whole cells rather than examining the effects of individual receptors and their ligands. Future methods may be able to compare cooperative and individual responses using micro- and nano-scale patterning techniques. Additionally, techniques will become increasingly active, directly manipulating cell receptors and proteins, as opposed to passive patterns on a substrate. These improvements will enhance understanding of the mechanisms for cell adhesion and migration, which may lead to new treatments for spinal cord injury, cancer, and vascular conditions. Increased knowledge of adhesion at the biomaterial–tissue interface will also provide improved prosthetic devices, implants, and tissue-engineered surfaces.

#### 11.3.5.1 Future Physical Nanostructures for Cell Adhesion

Most physical structures investigated to date have features  $>100$  nm. Although this is useful for investigating the cooperative action of cell surface proteins, it is not possible to explore individual receptors, with diameters of  $\sim 10$  nm, using these surfaces. Current technologies have been limited by the difficulty of creating regular, physical patterns that have structures on the order of 10 nm and repeat over several microns. Nanoparticle self-assembled monolayers offer several advantages to other physical patterning techniques at the  $<100$  nm length scale. Despite stacking faults, patterns display much more regularity than randomly oriented surfaces (e.g., Fig. 11.8), and at least short-scale order. Synthesis techniques to develop uniformly sized particles are well developed [51], and pattern roughness and dimensions can be easily changed by varying the particle diameter. Although more rigorous surfaces could be created using advanced lithography techniques (e.g., electron beam lithography), many of these techniques are expensive, difficult to reproduce, and inaccessible to the biologist, whereas many nanoparticles are now commercially available. Thus, in future applications, nanoparticle self-assembled monolayers will continue to be used in exploring cell adhesion either directly or as lithographic templates (Section 11.3.2). However, these techniques will probably emphasize directed self-assembly, allowing greater control of the pattern created.

For example, magnetic particles may be organized on a surface using magnetic fields to direct self-assembly [142]. This technique would allow much greater control of the resulting pattern than traditional self-assembly, which relies on thermodynamic forces to drive pattern formation [51]. When combined with techniques for specific cell placement (i.e., micropipette manipulation), magnetic assembly may allow for cells to be aligned with a specific pattern of interest. Extending these patterns to magnetic nanowires will bring further innovations. Because nanowires can be multifunctional, with domains of alternating materials, they offer a unique substrate for investigating cell adhesion. Nanowires produced using templated synthesis may have diameters from 10 nm to 1  $\mu\text{m}$  and lengths of up to 60  $\mu\text{m}$ . This compares favorably with receptor dimensions ( $\sim 10$  nm) and cell diameters ( $\sim 10$   $\mu\text{m}$ ) [53].

Other methods of directed assembly will also be explored. For example, Koo et al. [127] have demonstrated that star polymers can create structures with regularly-spaced adhesive peptides. The number of peptides bound and their spacing were

**Fig. 11.8.** Slow evaporation of an organic solvent containing monodisperse 11.5 nm iron nanocrystals results in the formation of extended regions of (a) monolayer or (b) multilayer superlattices. The superlattice structure can be tuned further through the co-assembly of two different sizes of nanocrystals, and provides a method to combine

nanocrystals with different functionality into ordered arrays. A binary nanocrystal lattice (c) with a rock salt (NaCl) structure is formed by evaporating a dispersion containing large iron nanocrystals (13.3 nm) and small gold nanocrystals (5.2 nm). (Photo courtesy of Brian Korgel, Aaron Saunders, University of Texas at Austin, Austin, TX.)

controlled by altering the number of monomers in the star and the monomer length. Similar techniques could be applied to nanostructures, and may employ new classes of polymers. For example, dendritic polymers are well-suited for attachment to spherical nanoparticles. Altering the length of the monomer could be used to control nanoparticle separation distance [143]. The use of various functional groups on the monomer exterior could also provide a method for directed assembly through electrostatic attractions or controlled crosslinking.

#### 11.3.5.2 Future Chemical Patterns for Cell Adhesion

**Applications in Cellular Engineering** The extension of the physical patterns discussed above to chemical patterning is straightforward. Colloidal lithography (Sec-

tion 11.3.2) could be used to produce patterned surfaces for chemical adsorption. Gold substrates, in particular, may be created through vacuum deposition and modified with thiolated chemicals and cysteine containing peptides. The dimensions of the pattern will be dependant on the size of the particles used and the method of their assembly. Alternatively, the nanoparticles themselves may be modified with biomolecules and assembled *in situ*. Nanoparticle arrays are an attractive substrate for cell adhesion studies because they provide the opportunity to investigate combined physical and chemical effects as the particles themselves provide shape, in addition to any chemical signatures.

One interesting possibility of nanoparticle arrays is the use of bimodal particle distributions. With a combination of small and large particles, ordered assemblies of alternating particle types can be created (Fig. 11.8) [144]. These assemblies would provide unique physical topography, but could also be used to create alternating adhesive and non-adhesive domains. For example, one particle size could be bound to RGD-containing peptide sequences, whereas another particle size could be passivated with cell resistant molecules (e.g., PEG [145]). Structures of this type would allow researchers to develop new understandings of the distribution requirements of adhesive sites. The greatest challenge in developing such assemblies will probably be controlling populations of particles that may be alternatively hydrophobic and hydrophilic. Micelles or lamellar sheets may be favored over monolayer particle structures. However, the use of amphiphilic peptides or particles of opposing charges may circumvent these difficulties.

**Applications in Tissue Engineering** Nanoparticles may also be incorporated into existing tissue engineering substrates to alter their chemical properties. Nanoparticles used in this context have the advantage of increasing the useful binding area without requiring a great deal of organic chemistry. One area where this would be of interest is the field of hydrogels. Some hydrogel materials possess good physical properties for tissue engineering, but are resistant to cell adhesion or migration [146, 147]. These substrates are modified through complicated bioconjugation strategies to contain adhesive binding sequences. The amount of biomolecule attached can be difficult to control and may be limited by the number of modifiable sites in the monomer. Scattered gold particles could be incorporated in the substrate to provide a thiol-mediated attachment point for biomolecules. Particles could be included directly in the uncured polymer mixture or could be deposited on the polymer surface and secured through annealing or covalent attachment. A similar approach has already been investigated using micron-sized particles [148]. Polymer templates composed of layer-by-layer assembled polyelectrolyte films were exposed to micron-sized, charged particles, which assembled on the pattern. These particles were then modified with RGD peptides and examined as substrates for cell adhesion.

Another exciting possibility is the incorporation of nanoparticles into smart-substrates. For example, gold nanoparticles have been used to create drug delivery substrates which expand upon exposure to radiation [17]. This technique could be adapted to produce active substrates for the evaluation of cell mechanics. For exam-

ple, a small number of fluorescent nanoparticles (e.g., CdSe) coupled to cellular integrin-binding domains could be introduced. Upon radiation (preferably in the IR to avoid cell damage), the substrate would expand. This expansion, and the cellular response, could be observed directly by monitoring the movement of the fluorescent particles. This approach has the advantage of potentially binding individual integrins. Expanding substrates might also aid researchers in constructing tissue engineering constructs for contractile tissue (e.g., muscle or heart) *ex vivo*.

#### 11.3.5.3 Active Investigation of the Cytoskeleton

To date, magnetic bead examinations of mechanical force in cells have primarily been confined to either the cell surface [140, 149] or to phagocytotic vesicles [150, 151]. However, as particles decrease in size and methods for intracellular delivery improve (Section 11.4.3), it may be possible to manipulate the cytoskeleton directly from the cytoplasm. This would greatly facilitate understanding of the role of the cytoskeleton in cell adhesion and cell mechanics. We already know that the cytoskeleton is a component of an elaborate mechanotransduction system and can influence cell differentiation, apoptosis, and polarity [110]. Many regulatory proteins are physically linked to the cytoskeleton, and changes in external force have been shown to influence local protein expression [110]. Several clinical ailments may have their basis in defective responses to mechanotransduction [110]. Intense study of the relationship between the cytoskeleton, external forces, and gene expression may lead to new treatments for these diseases.

A major challenge of this approach is the ability to develop sufficient magnetic force to manipulate objects. Microbeads encapsulate numerous nanometer-sized colloids that cumulatively generate enough force to produce changes in the cytoskeleton. It is unclear that single, nanometer-sized particles would produce measurable changes in cytoskeletal position, although there is some evidence that they will behave similarly to microparticles [152]. Additionally, cooperative action resulting from the attachment of multiple nanoparticles to the same structure can increase effective force. In some ways, nanoparticles may be particularly appropriate for investigation of the small structures of the cytoskeleton. Along with similar size scales, it is likely that smaller forces will be required to produce movement/tension as the size of the target structure declines (i.e., integrin vs. focal adhesion).

## 11.4

### Nanostructure Cellular Entry

Active cell manipulation requires methods to control nanostructure delivery and targeting. Whereas examination of the extracellular surface is straightforward, additional techniques are required to promote intracellular delivery. Nanostructures may be introduced to cells through endocytosis, but this is a passive technique. Most objects introduced into the endocytosis pathway are confined to lipid covered vesicles in the cell interior. Escape is difficult and materials are given little opportunity to interact with external proteins and biomolecules. Thus, direct delivery of

nanostructures is difficult. In this respect, the field of nanocomponent delivery shares many challenges with that of gene therapy, and many of the techniques introduced for the latter can be applied to nanostructures.

Controlled delivery is expected to have many applications. Fluorescent nanostructures could be used for real-time monitoring of intracellular features, which would greatly improve understanding of signal transduction, the endocytotic pathway, and intracellular transport. Magnetic and conducting nanoparticles could be used to control intracellular elements, potentially providing external control of cell adhesion, cell division, differentiation, gene expression, and apoptosis. Nanostructures could also be used as drug delivery agents for drugs, DNA, and proteins providing novel techniques for gene therapy, cancer treatments, and tissue engineering.

#### 11.4.1

##### **Biology of Molecular Delivery**

The cell plasma membrane is an effective method of excluding undesired components from the cell interior. This membrane is permeated with several transmembrane proteins, some of which serve as pores for small molecules to pass. However, despite their small size, nanostructures are still too large to enter the cell via this method (e.g., Rosenthal et al. [153]). Nanostructures are instead subject to endocytosis, a process through which objects are transferred from the local environment to the cell interior (Fig. 11.9). Endocytosis [8] is initiated by binding to the cell surface, followed by an invagination of the cell membrane. This membrane surrounds the foreign substance and pinches off from the bilayer, forming a vesicle in the cell interior, known as an endosome. After  $\sim 10$  min, the endosome migrates from the edge of the membrane to the Golgi apparatus. Endosomes are slightly acidic, with pH values near 6. Some proteins contain targeting sequences that are revealed in the acidic environment, allowing escape from the endosome. Other proteins, most notably membrane bound receptors, release their cargo and are returned to the surface by vesicle fusion. Yet other materials are delivered to lysosomes [8], which have an even lower pH (e.g., pH  $\sim 5$ ) and are filled with acid hydrolases. Lysosomes are the primary locations for digestion of proteins. Escape of foreign material from endosomes and lysosomes is exceedingly difficult. Endocytosis may be suppressed with temperature decreases (e.g.,  $4^\circ\text{C}$  [154]), but this affects other metabolic functions of the cell [155].

#### 11.4.2

##### **Nanostructure Endocytotic Delivery**

Internalization of foreign substances occurs through endocytosis, channel transport, or direct passage through the plasma membrane. However, channel transport is usually confined to ions [8], and, given current nanostructure surface treatments and size, it is unlikely that nanostructures could traverse the lipid bilayer unassisted. The endocytosis pathway, with an exclusion size of  $\sim 100$  nm [156], is the

**Fig. 11.9.** Endocytotic pathway: (A) Following binding, the cell membrane invaginates to encompass membrane-bound substances. The formation of these indentations in the cell membrane is driven by the binding of clathrin protein (red) on the cytoplasmic side. The membrane continues to fold until a vesicle is pinched off from the membrane bilayer. With intracellular entry, the clathrin coat is lost. Vesicles in this stage are known as early endosomes (B) and have a pH of  $\sim 6$ . They are

responsible for sorting vesicle contents, e.g., returning membrane-bound receptors (Y-shaped structures) to the cell surface. (C) Next, vesicles migrate toward the Golgi apparatus, where they merge with digestive proteins (black) and become late endosomes (pH  $\sim 5.5$ ). Late endosomes attempt to digest internalized matter. To complete this process, late endosomes merge with lysosomes (D), which have a pH of  $\sim 5.2$ .

most likely mechanism for nanostructure uptake, and using sugar-coated quantum dot aggregates [156], uptake of particles as small as 5 nm has been demonstrated. Endocytosis can be non-specific, resulting from adsorption on the cell surface, or receptor-mediated, occurring as a consequence of biomolecular recognition binding events between specific receptors and their ligands.

Nanoparticle internalization has been observed for both the non-specific [74, 157] and receptor-mediated [11, 31, 77, 156] pathways. Using the non-specific pathway, particles have been internalized directly from cell culture medium [158], the cell culture substrate [74], and following non-specific binding to the cell surface [76, 159–161]. Internalization likely results from electrostatic attraction between the particle surface and the cell membrane [160]. Interestingly, binding can occur regardless of surface charge, as the plasma membrane exhibits both anion and cationic domains [18]. Receptor-mediated uptake has been observed using the RGD-peptide integrin binding motif [160], epidermal growth factor [31, 162] and transferrin [11, 163]. Remarkably, endocytosis of nanostructures attached to a solid support (e.g., polymeric nanocolumns) has also been observed [164]. In fibroblasts, columns were surrounded by cell membrane and were located near newly-formed intracellular vesicles and clathrin pits. Macrophage-like phagocytotic vesicles, which increased disruption of the cytoskeleton, were also observed.

Regardless of the mechanism, internalization occurs within 30 min, unless specific steps are taken to inhibit internalization pathways (e.g., low temperature [154]). In studies of sugar-coated nanoparticles, the rate of endocytosis was higher

with increasing particle size, up to 50 nm. Endocytosis was not observed for aggregates larger than 100 nm [156]. Others have shown that macrophage phagocytosis increases with increasing material size, up to 1.1  $\mu\text{m}$  [165]. Particle endocytosis rates can also be modulated by local biochemistry. For example, uptake of 35-nm dextran coated iron oxide particles was enhanced by high concentrations of interferon-gamma (IFN- $\gamma$ ) and interleukin-4 (IL-4), whereas the application of lovastatin decreased particle uptake [161].

When nanostructures enter the cell, they are found in clathrin-coated pits [162], as would be expected for endocytosis. Co-staining experiments have confirmed that particles are confined to endosomes or lysosomes [159, 162, 163]. Generally, particles remain sequestered in these compartments [18], and are unable to escape. For example, particles internalized by vero cells accumulated in large storage vesicles, similar to those found in macrophages [159]. Vesicles appeared to pass to select daughter cells through asymmetric mitosis. Accumulation of particles can be a significant problem, as aggregations can potentially disrupt the cytoskeleton and cell membrane [166]. It is even possible to overload cells with particles, resulting in apoptosis [18].

Particle endocytosis has been utilized in several applications, the largest area being cell labeling and tracking. Nanostructures, particularly quantum dots, have several advantages in this application. Their fluorescent signals are resistant to bleaching and oxidation over long time scales [11]. Additionally, endocytosed particles remain fluorescent for weeks and are passed to daughter cells [76]. Internalized nanoparticles have been used to investigate several systems that organic dyes could not, including division of HeLa cells [76], formation of aggregate centers in starved *D. discoideum* [76], phagokinetic tracks and metastatic potential [74], as endosomal markers [159], and retrograde transport in filopodia [162]. Particles have also been used to monitor macrophages in atherosclerotic plaques *in vivo* [161].

However, for targeted delivery to cytoplasmic elements, endocytosis is an undesired event, as most nanostructures remain sequestered in lysosomes or endosomes. Endocytosis can be prevented. For example, particles attached to insulin or lactoferrin surface molecules were not internalized as frequently as unmodified controls [157, 167]. Most likely this resulted from binding to “fixed” molecules on the cell surface that are endocytosed at low rates. Also, endocytosis does not occur when particle non-specific binding is low. Mercaptoacetic acid-bound and commercially available streptavidin-conjugated CdSe/ZnS particles with low cell binding potential are not internalized [11, 162] whereas silanized CdSe/ZnS nanocrystals that have shown high cell binding affinities are [10]. Thus, surface chemistry can be used to alter the endocytotic potential of nanostructures. Differences have even been seen for particles with the same surface passivation, but different synthesis techniques (compare, for example, Gomez et al. [160] and Nie et al. [11]). These differences indicate that the most important method of preventing endocytosis is ensuring that the nanocrystal passivation chemistries do not permit non-specific binding to the cell surface. However, notably, methods to prevent endocytosis also prevent *any* cellular entry. Clearly, additional technologies will be required for targeted delivery of nanostructures to the cytoplasm.

## 11.4.3

**Other Methods of Cellular Entry**

To circumvent the difficulties associated with endocytosis, several methods of particle entry have been devised. Most of these techniques have been extrapolated directly from the field of gene therapy, the most popular method being the use of translocation peptides. Although there is still much debate as to the exact mechanism of these peptides [168–170] it appears that cell entry begins normally, through the endocytotic pathway. However, the peptides are able to disrupt the endosomal membrane, releasing its contents to the cell interior. This technique has been used with various outcomes. The pep-1 sequence, which forms complexes with quantum dots through its hydrophobic domain, was used to deliver particles to CHO-K1 hamster epithelial cells [171]. However, quantum dots appeared to remain isolated in vesicles, indicating that endosomal escape most likely did not occur. Other peptides have demonstrated greater success. Adenoviral nuclear localization and receptor-mediated endocytosis sequences were used to introduce gold nanoparticles to the cytoplasm [172]. Delivery did not occur unless both sequences were present, with particles targeting the nucleus as expected. Similar results were reported for iron oxide nanoparticles conjugated to the HIV tat peptide [173, 174]. Particles were distributed throughout the cytoplasm with some increase near the nucleus. Quantum dots conjugated to trichosanthin protein [175] and R<sub>11</sub>KC peptides [176] displayed nuclear targeting with aggregation near the nucleolus [175]. Mitochondrial targeting has also been demonstrated using the Mito-8 peptide [176].

Apart from translocation peptides, other approaches have been examined, with a rather elegant analysis conducted by Derfus et al. [177]. The researchers compared intracellular delivery of quantum dots using translocation peptides, cationic liposomes, dendrimers, electroporation, and microinjection. Of the chemical approaches, cationic liposomes offered the greatest degree of quantum dot delivery, with over 90% of fluorescence distinct from that of separately labeled endocytotic vesicles. In contrast, translocation peptides (i.e., pep-1 as Chariot, Active Motif) displayed fluorescence signals slightly lower than that of the unconjugated control, possibly indicating fluorescence quenching as a result of aggregation, and were localized almost entirely in endosomal compartments. These results are similar to those of Tkachenko et al. [172] who found that pep-1 like peptides produce particle accumulation in lysosomes/endosomes. Additional translocation peptides (i.e., TAT or HA-TAT) were not investigated and may yield different results (e.g., Tkachenko et al. [178]). All three chemical techniques yielded particle aggregates that were on the order of a hundred nanometers in diameter. These aggregates can diminish nanoparticle fluorescence, and may interfere with intracellular manipulation and targeting.

As an alternative, Derfus et al. also investigated physical delivery methods, including electroporation and microinjection [177]. Electroporation produced significant intracellular delivery to the cytoplasm, but particles displayed aggregates with diameters as high as 500 nm. This effect was not related to a loss of surface passi-

**Fig. 11.10.** Subcellular localization of quantum dots. A nuclear localization sequence (NLS) peptide was conjugated to the surface of PEGylated green quantum dots (emission maxima 550 nm). These particles were microinjected into the cytoplasm of 3T3 fibroblast cells, along with a 70 kDa rhodamine-dextran. After several hours, green emission from the quantum dots was observed in the nucleus of injected cells, while the red signal from high molecular weight dextran remained in the cytoplasm. (Photo courtesy of Sangeeta Bhatia and Austin Derfus, MIT, Boston, MA.)

vation, as highly crosslinked BSA coated particles exhibited similar results [177]. Similar aggregation has been reported with negatively-charged DNA plasmids [177], and may result from alterations of particle surface charge induced by the electric field. Alternatively, microinjection techniques delivered monodisperse particles that were not confined to endocytotic vesicles (Fig. 11.10) [177]. Previously, these particles were shown to pass to daughter cells during mitosis and retain fluorescence for up to 4 days [73]. The primary disadvantage of the microinjection technique is that it is difficult to scale-up to large populations, as injection is required for each cell.

#### 11.4.4

#### **Nanoparticle Intracellular Sensing**

A direct impact of intracellular delivery has been the ability to visualize internal components of a cell. Nanostructures have many optical properties that make them excellent candidates for intracellular labeling. For example, quantum dots display high quantum yields, narrow emission bandwidths, resist photobleaching, and can be readily modified with biomolecules to allow targeting [19]. Fluorescence persists for days [73] or weeks [76]. Additionally, magnetic nanostructures can be monitored with existing hospital equipment (e.g., MRI). Using nanostructures for sensing, it is possible that internal cell functions, including cell signaling and gene expression could be monitored in real time. This ability would represent a tremendous advance for diagnostics and treatment.

##### 11.4.4.1 **Semiconductor Quantum Dots**

Because of their unique optical properties, quantum dots have been widely used in sensing applications. Unfortunately, delivery of quantum dots to living cells has

**Fig. 11.11.** (A) Transmission images of lung cancer (H1299) tumor. (B) Fluorescence image of same tumor incubated for 1 h with MPA-PEG-capped CdTe nanocrystals injected intratumorally and imaged at an excitation wavelength of 545 nm. been challenging. Quantum dots can be introduced through endocytosis, and have been used to monitor cells during growth and development [76]. Particles introduced in this way remained in the cell for up to a week; however, targeting was non-specific, not directed to a particular intracellular component, and particles remained in endosomes. In another study, particles, introduced through microinjection, were used to follow development of *xenopus* embryos [73]. In this particular application, quantum dots were far superior to previous methods. Because quan-

**Fig. 11.12.** True-color fluorescence images of mesoporous silica beads (5  $\mu\text{m}$  diameter) doped with single-color quantum dots emitting light at 488 (blue), 520 (green), 550 (yellow), 580 (orange), or 610 nm (red). tum dots remained fluorescent in the daughter cell population for weeks, this technique allowed researchers to examine the fate of cells in the blastula, an achievement not possible using fluorescent dyes that photobleach in minutes. This technique was successful because only a few cells needed to be targeted for delivery; it would be difficult to use microinjection, a serial technique, in applications that require observation of multiple cells (e.g., organ labeling).

Both of these studies examined whole cells, and not specific targets. Most subcellular analyses have focused on extracellular targets, highlighting the difficulties of controlled intracellular delivery. For example, Dahan et al. [179] monitored the diffusion of glycine receptors in the synaptic cleft using semiconductor quantum dots. Quantum dots are particularly well-suited for this application because of their resistance to photobleaching. Traditional dyes only allow monitoring for short time periods, on the order of minutes, whereas quantum dots allowed receptor tracking for up to 20 min. Additionally, their small size allowed access to the synaptic cleft, a region that cannot be reached by microbeads (e.g., gold) that might be used in single particle studies. Alternatively, the diffusion of epidermal growth factor receptors (EGFR) was followed using quantum dots bound to EGF through avidin–biotin interactions [162]. Because of their resistance to photobleaching, receptor dynamics could be followed for long time periods, and a previously unreported mechanism of retrograde receptor transport was discovered. Quantum dots have also been conjugated to aptamers, DNA or RNA molecules that have been selected from populations for their specific binding affinities [180]. Aptamer-labeled particles were used to identify cancer cells *in vitro* and in lung cancer tumors (Fig. 11.11).

Applications for intracellular tracking are still in development. In particular, researchers are interested in creating tags that could be used for multiplexed intracellular measurements. Quantum dots are good candidates for these tags because they can exhibit a range of emission wavelengths under the same excitation, allowing for observation of multiple cues simultaneously (Fig. 11.12) [181]. These tags have great potential *ex vivo* as diagnostic tools and for high throughput screening. However, it may also be possible to observe the expression of several intracellular proteins concurrently through optical signals. In fixed cells, quantum dots conjugated to specific DNA sequences have been used to label the Y chromosome [182]. They have also been used to examine the intracellular expression of eNOS, a cardiovascular enzyme that converts nitrates into NO [183]. If successfully introduced into the cytoplasm, labeling of individual DNA strands or mRNAs may be possible. One limitation of quantum dots for intracellular tracking is the high blinking interval [184], which may prevent the tracking of intracellular components with a high diffusion rate. Nevertheless, with their persistent fluorescence and range of emission wavelengths, quantum dots will likely increase our understanding of intracellular signaling and could potentially revolutionize the field of diagnostics.

#### 11.4.4.2 Magnetic Nanoparticles

Magnetic nanoparticles have also been employed for whole cell labeling and intracellular tracking. Particles have been conjugated to the tat peptide, a nuclear local-

ization sequence, and utilized to determine the fate of stem cells [185]. With MRI, particles were visualized in blood and neuronal stem cells, allowing the location of those cells to be determined following injection in the rat tail vein. Alternatively, particles were coated with a combination of tat and Ha2 nuclear localization sequences and fluorescent dyes [174]. These particles responded to magnetic fields *in vivo* and were used to detect expression of the DEVD peptide, an apoptosis inhibitor. Particles have also been used for extracellular protein detection. For example, nanoparticles conjugated to transferrin have been used to monitor the expression of the transferrin receptor *in vitro* [186].

#### 11.4.5

#### Future Directions

##### 11.4.5.1 Nanostructure Intracellular Delivery

Existing methods of particle delivery have not yet yielded a technique for large-scale introduction of monodisperse particles. Biochemical methods can be used to evade endocytotic vesicles, but reports indicate [171, 172, 177] significant aggregation of particles. Alternatively, microinjection can produce disperse particle delivery, but is a serial technique, requiring cell-by-cell injections. Taking cues from research in gene therapy, researchers will continue to develop methods of particle delivery. Several new techniques are being explored as possible drug or DNA delivery methods, and could be extrapolated to nanoparticle delivery.

For example, polymersomes of PEG-polyester have been shown to foster endosome rupture and have been used to deliver two anti-cancer drugs [187, 188]. The low pH of endosomes encourages polymersome degradation. Soluble polymer components are then free to disrupt the lipid membrane, facilitating cargo escape into the cytoplasm. Similar polymersomes might be constructed to deliver nanoparticles to the cytoplasm. Likewise, fusogenic liposomes have been created to encapsulate polymeric nanoparticles [189]. Liposomes were created by encapsulating polymeric particles in traditional liposomes whose surface was modified by the addition of inactivated Sendai virus. The liposomes were able to deliver DNA to the cytoplasm, technology that could easily be adapted for delivery of magnetic or semiconducting nanoparticles.

Another potential delivery method uses carbon nanotubes to promote rupture of endocytotic vesicles [190] or directly penetrate the cell membrane [191, 192]. For example, nanotubes can be internalized through endocytosis, and then irradiated in the near-infrared to produce endosomal release. The primary limitation of this method is ensuring that heating levels remain low enough to prevent cell death. It is also possible that magnetic particles in a magnetic field could be used for this purpose (see, for example, Won et al. [174]), and a similar technique has been developed by Cai et al. using the Ni catalyst at a carbon nanotube tip for magnetic manipulation [192]. A rotating magnetic field allowed the nanotubes to penetrate the cell plasma membrane, where they remained. Soluble factors (i.e., DNA) bound to the surface were released from the nanotube surface through an unknown mechanism. Alternatively, carbon nanotubes functionalized with ammo-

nium permeate the cell membrane without the aid of magnetic fields [191]. The hydrophobic nanotubes can insert into the lipid bilayer of the plasma membrane, possibly transversing it. Any of these techniques might be adapted for nanostructure delivery; however, adjustment may be challenging as the surface chemistry and size of nanostructure cargos are significantly different from the DNA normally transported.

#### 11.4.5.2 Intracellular Sensing

An interesting possibility for sensing subcellular components is the use of fluorescence resonance energy transfer (FRET). This simple method for detection employs fluorescent molecules to produce an on or off signal upon binding. FRET occurs when an excited electron dissipates its energy by transferring it to a second molecule rather than through photon emission. This quenches the fluorescence of the first molecule. FRET is a distance dependant event. As the FRET donor and acceptor move away from each other, transfer no longer occurs and fluorescence in the donor is restored [193]. If a binding-induced conformational change separates two fluorescent molecules, e.g., attached to different portions of a protein, a fluorescent on/off signal can be produced.

This has been accomplished in several systems. A combination of gold quantum dots (which do not fluoresce) and organic fluorophores have been utilized to create DNA sensors [194]. Gold quantum dots were bound to single-stranded DNA sequences, which were terminated with fluorescent molecules, or fluorophores. The fluorophores formed an arched structure that interacted with the nanoparticle surface, quenching fluorescence (Fig. 11.13). However, when the complement DNA was introduced, binding occurred and the conformation changed. The fluorophore migrated away from the quantum dot surface and its fluorescence was restored. This technique is very accurate, the mismatch of a single base pair in a 30 amino acid DNA sequence could be detected [194].

A second, similar system utilized fluorescent CdSe/ZnS quantum dots to detect sugar binding [195]. The initial configuration contained cyclodextrin molecules

**Fig. 11.13.** Detection of DNA binding through FRET. (A) Fluorophore-conjugated single-stranded DNA is bound to a quantum dot, forming an arched structure with the nanoparticle surface. Fluorophore fluorescence is quenched through FRET with the nanoparticle. (B) When the complement DNA is added, the DNA structure changes, moving the fluorophore away from the nanoparticle and restoring fluorescence.

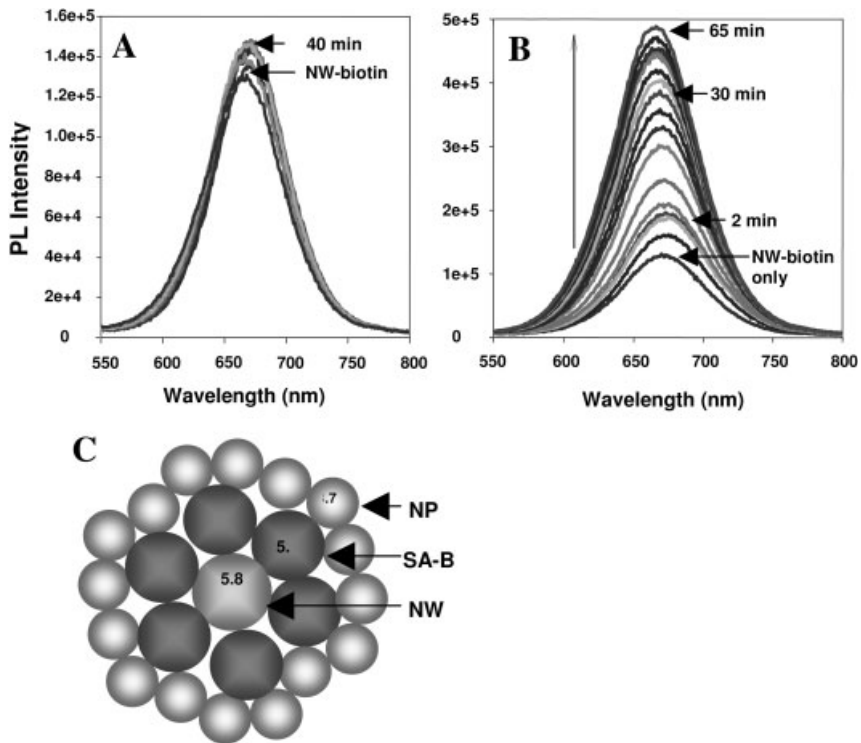

conjugated to a non-fluorescent FRET acceptor. The cyclodextrin adhered to maltose (i.e., sugar) binding protein, which was present on the quantum dot surface. FRET between the nanoparticle and the acceptor molecule quenched quantum dot fluorescence. However, when maltose was introduced, the cyclodextrin was displaced, restoring fluorescence to the quantum dot. Although maltose sensing was demonstrated, these sensors could eventually be adapted to detect glucose, a crucial molecule to monitor in the management of diabetes.

Finally, systems need not be hybrids, incorporating nanoparticles and fluorescent dyes; homogeneous systems have also been constructed [196, 197]. Two types of CdTe quantum dots were bound to model proteins. Red-emitting quantum dots were conjugated to bovine serum albumin (BSA), while green-emitting quantum dots were conjugated to an antibody that binds BSA (i.e., anti-BSA). When the two quantum dots were incubated together, the green fluorescence was quenched, as excited electrons transferred their energy to the red-emitting particles. Further, the red fluorescence was enhanced because energy transferred from the green-emitting quantum dots was dissipated through the red-emitting quantum dot. Similarly, the fluorescence of biotinylated-CdTe nanowires has been extinguished by the presence of streptavidin-coated gold nanoparticles (Fig. 11.14). Biotinylated-wires exposed to streptavidin alone displayed no change in fluorescence over time (Fig. 11.14A); however, upon addition of streptavidin-coated gold, fluorescence was increased in the CdTe acceptors (Fig. 11.14B).

FRET-based quantum dot sensing is elegant, and in theory can provide analyte detection of as few as 10 parts per trillion [196]. Additionally, the signal is easy to interpret: fluorescence indicates the presence of an analyte. FRET-based sensing can also provide quantitative information, as fluorescent intensity can be correlated to the number of molecule binding events. Although FRET systems could be constructed entirely from fluorescent dye molecules, quantum dots provide an excellent alternative. They display high quantum yield; and their acceptor energy and emission wavelengths can be tailored by changing the size of the particle.

## 11.5 Intracellular Transport of Nanostructures

Nanostructures that evade endocytosis have the potential to interact with intracellular structures, including components of the cytoskeleton. The cytoskeleton is responsible for the movement of proteins and vesicles through the cytoplasm, as well as cell mitosis, locomotion, and signaling. Nanostructures have been used to manipulate and interact with the cytoskeleton from the cell exterior (Section 11.3.4), but numerous additional possibilities exist for intracellular interactions. Perhaps the most intriguing potential application is the use of cytoskeletal elements to control intracellular nanostructure transport. This line of inquiry will not only improve biologists understanding of motion through the cell interior, but may aid in assembly of nanoscale structures *ex vivo*. To date, nanostructure-cytoskeleton research has focused on *ex vivo* applications, including sensing and molecular assembly.

**Fig. 11.14.** (A, B) Transient luminescence spectra of bioconjugated nanowires in solution. (A) Nanowire-biotin with streptavidin (without Au) monitored for 40 min after mixing, (B) Nanowire-biotin with streptavidin-Au monitored for 65 min. Excitation

wavelength for both (A) and (B) is 420 nm. (C) Cross section of closely packed model arrangement of CdTe nanowires and Au nanoparticles in the bioconjugate. (Photo courtesy of Nicholas Kotov, University of Michigan, Ann Arbor, MI.)

The primary focus has been on kinesin-microtubule structures, but actin–myosin interactions have also been examined. Direct translation of these methods to the clinic is not expected. However, the techniques developed for *ex vivo* studies might be adapted to nanostructures in the cytoplasm. The ability to perform cytoskeletal manipulations would allow researchers to explore internal mechanotransduction and manipulate intracellular transport, providing new insight to gene regulation, protein expression, vesicular transport and mitosis.

### 11.5.1

#### Biology of Intracellular Transport

The cytoskeleton is composed of a network that includes actin filaments, intermediate filaments, and microtubules [8]. Intermediate filaments, which are about 10

nm in diameter, provide the cell with mechanical strength and form the nuclear lamina, whereas motion primarily occurs along 5–9 nm actin filaments or 25 nm microtubules. Actin filaments interact with myosin proteins and are responsible for muscle contraction, cell locomotion, and vesicle transport [198]. Myosins contain heavy and light chains, with the heavy chain mediating attachment to actin filaments and the cargo. Motion is driven by the hydrolysis of ATP (i.e., adenosine triphosphate), which initiates conformational changes in the myosin protein, producing a stepping motion along the actin filament. Microtubules interface with kinesins and dyneins and are responsible for organelle and protein transport, chromosomal separation, cell division, vesicular transport, and are the primary components of cilia and flagella [198]. Microtubules are directional, continuously growing at their plus ends and slowly dissociating at their minus ends. Kinesin contains two heavy chains that include microtubule binding sites, whereas the structure of dynein is not well understood, but includes heavy chains and intermediate chains. Both kinesin and dynein movement occur through ATP hydrolysis. However, kinesin moves from the minus to plus end of the protein in discrete 8 nm steps, whereas dynein moves from the plus to minus end of the track [198]. Dyneins are primarily associated with cilia and flagella, cellular elements which produce cell movement.

### 11.5.2

#### **Actin-based Nanostructure Transport**

Movement in actin networks is initiated by ATP-binding to myosin proteins. The myosin II form, which is responsible for muscle contraction, is the most common, but myosin V may be the best suited for hauling cargo because of its processive motion [198]. Several nanostructure cargos have been attached to myosin. For example, quantum dots have been conjugated to myosin V heads [199]. Fluorescence signals from the particles allowed direct visualization of the “hand-over-hand” mechanism of myosin movement down the actin filament. Also, rabbit muscle myosin was conjugated to magnetic nanoparticles obtained from bacteria [152]. Using magnetic force, it was possible to alter the velocity of a myosin molecule along the actin filament. It is envisioned that such a system could be used to analyze single molecule interactions between myosin and actin filaments.

Alternatively, actin has been conjugated directly to nanostructures. Biotinylated phalloidin (which binds actin strongly) was attached to quantum dot surfaces and used to link nanoparticles to actin [200]. Proposed applications of this system include the creation of *in vitro* networks of actin filaments or delivery of specific cargos. Actin has also been attached to the surface of gold nanoparticles, a system used as a template for gold nanowire formation [201]. Gold nanoparticles bound to actin monomers could be connected to form nanowires on either side of an exposed actin protein core. Additionally, when placed on a myosin substrate, actin–myosin interactions directed nanowire movement. This technology is primarily intended for the creation of nanoelectronic networks, but might be used to assemble or transport nanostructures in cells.

## 11.5.3

**Microtubule-based Nanostructure Transport**

In contrast to actin filaments, microtubules have been more extensively studied for nanostructure transport, probably because they move a wider variety of natural cargos *in vivo*. Again, much of the work to date has been performed *ex vivo*, with proposed applications in nanoassembly and nanoelectronics. For example, microtubules have been organized in microfabricated channels using electric fields [202, 203] and their motion has been directed by absorbed kinesins [204]. Although this method does not apply directly to cellular engineering, many of the tools to adapt these techniques *in vitro* are in place. Silica microbeads were attached to kinesin as early as 1990 [20]. *Ex vivo* binding or transport of microchips [205], 1–10  $\mu\text{m}$  glass, gold, and polystyrene microbeads [206], CdSe quantum dots [207], CdSe nanorods [208], and gold nanowires [202] have all been demonstrated using the kinesin-microtubule system. The wide variety of cargos transported suggests that various nanostructures can be moved with ease. Techniques to control cargo motion have been developed. Photo-caged ATP can be activated with the application of light, permitting control of kinesin movement [209]. Collectively, these advances should allow for intracellular manipulation of the cytoskeleton in the near future.

## 11.5.4

**Future Directions**

Future research will focus on adapting *ex vivo* techniques to cell studies. For example, motor proteins without nanostructure modification have already been used *ex vivo* to transport and manipulate DNA [210]. The addition of nanostructures to these systems could provide the ability to control (e.g., magnetic manipulation) and monitor (e.g., fluorescent signal) biomolecule interactions *in situ*. Development of these assays would allow researchers to directly measure the force, speed, and dynamics of protein–cytoskeleton interactions. Additionally, nanostructure transport could be used for controlled delivery of drugs, proteins, vesicles, or even organelles (Section 11.6). A limitation of previous attempts to use nanostructures for this purpose has been the inability to control cargo release. One possibility is the use of photocleavable linkages [211]; however, the use of photo-caged ATP may limit the wavelengths available for this chemistry. An alternative approach might be to use the heat generated by excited magnetic particles to promote release of an attached biomolecule.

In addition to intracellular transport, cytoskeletal systems in whole cells may be harnessed to transport and manipulate objects. For example, the flagella of close-packed bacteria grown on a solid surface can be used to manipulate beads suspended in fluid [212]. Flagellated algae (e.g., *Chlamydomonas reinhardtii*) were used to move polymer beads through solution [211]. Algae were directed to specific locations using phototaxis, and bead attachment did not appear to significantly impede algae movement. It is unlikely that flagella or cilia could be harnessed directly to

nanostructures, as they are significantly larger ( $\sim 1 \mu\text{m}$ ). However, these whole-cell systems could be used for controlled delivery of nanostructures amongst a population of cells. For example, it might be possible to deliver toxic nanostructures to cancer cells using “safe” bacteria to transport particles into a specific organ.

## 11.6

### Biomolecule Delivery Using Nanostructures

One of the most promising applications of nanostructures is their use to deliver biomolecules to specific cells and cellular locations. Nanostructures with diameters from 10 to 100 nm can be introduced intravenously, and remain in the blood for significant periods of time [18]. Their surfaces may be modified with drugs, biomolecule cargos, and sequences to promote recognition by certain cell types (Section 11.2.4), resulting in specific targeting. The magnetic and heat-generating properties of nanostructures may be used to control biomolecule release. Nanostructures with these features have been incorporated into traditional drug delivery constructs to produce “smart” drug delivery devices (e.g., Sershen et al. [17]). Although much work has focused on extracellular delivery, intracellular delivery is also possible (Section 11.4). Nanostructure–DNA binding has been well-established [13], and gene therapy is a logical extension of this work. With their small size and flexible surface chemistry, nanostructures are ideal candidates for biomolecule delivery to cells.

#### 11.6.1

##### Biology of Controlled Delivery

###### 11.6.1.1 Drug Delivery

Therapeutic drugs typically display half-lives on the order of minutes to hours [213]. To control release and prolong the effectiveness of these molecules, drug delivery systems have been developed. Drug delivery devices may target any component of the cell interior or exterior and have been investigated as treatments for various conditions, including cancer [214], diabetes [215], and neurological disorders [216, 217]. In many cases, the desired treatment requires controlled release of a biomolecule over time, possibly many years [215]. Several systems have been developed to fine tune release, including polymer coatings and degradable hydrogels [218].

Drug delivery systems must operate *in vivo*, where the environment can be harsh. Introducing drugs targeted to specific cell types without direct implantation of a drug delivery system is difficult. Drugs may be administered orally or through direct injection, but the primary method is through intravenous injection [219]. Once inside the body, these molecules must evade the natural defense mechanisms of the body, including the reticulo-endothelial system (RES). Components that are too large ( $>200 \text{ nm}$ ) will be isolated in the spleen, whereas molecules that are too small ( $<10 \text{ nm}$ ) are removed from blood vessels by diffusion to sur-

rounding tissues or the kidneys [18, 145]. Some drug delivery applications require release to a specific target (e.g., gene therapy, cancer treatment), and achieving this is challenging. For example, the endocytotic pathway (Section 11.4.1) presents a significant barrier to controlled intracellular delivery (e.g., for cancer treatment). With their readily functionalized surfaces and small size, nanocomponents provide a unique method to address these issues.

#### 11.6.1.2 Gene Therapy

In contrast to most drug delivery applications, gene therapy focuses primarily on nuclear delivery of DNA in a one-time application. The concept behind gene therapy is straightforward. Many diseases result from defective copies of a particular gene. Gene therapy attempts to incorporate functional copies of those genes into the genome of affected individuals. For this to take place, the defective genes must be identified in the individual. New, working copies of these genes must be synthesized, delivered to the nucleus, and incorporated into the existing genome. This is usually achieved with the aid of transcription agents, which may use viral or non-viral mechanisms (for review see Johnson-Saliba et al. [220]). Viral vectors have been the most successful, but can provoke an immune response. Additionally, viruses do not infect all cell types equally, and targeting specific cell types can be difficult [221]. Non-viral delivery has been plagued by the difficulties of traversing the plasma membrane and directed targeting to the nucleus. Transfection efficiencies have remained low (0.01–10% [220]). Some of the greatest barriers to clinical gene transfection have been the long times required to achieve transfection and the low concentrations of available transfection agents [222]. For gene therapy to become a viable clinical option, these barriers must be surmounted.

### 11.6.2

#### Drug Delivery

Applications for nanostructures in drug delivery are vast (see Volume 10 of this series for more detail). Although usage of metallic and semiconducting materials has been more recent, nanostructured ferrofluids have been investigated since the early 1970s [223, 224]. Drug delivery systems have been envisioned to treat diabetes [215], cardiovascular diseases [225], and cancer [214]. As a result, this section will focus on several of the challenges facing drug delivery systems, and how nanostructures are poised to meet them. This will be illustrated with a few examples of targeted drug delivery applications, primarily in the area of cancer treatment. These applications are not intended to be comprehensive, but represent general cases where nanostructures improve upon existing technology.

##### 11.6.2.1 Cell Targeting *In Vivo*

For optimal control, nanostructures for drug delivery usually display three separate functionalities: a core material, drug or therapeutic element, and a targeting element [213]. The core material provides physical stability, controls size, and provides a template for drug attachment/encapsulation. In some cases, the core mate-

rial may serve multiple purposes, incorporating an additional targeting or sensing function. For example, magnetic particles may be manipulated with a magnetic field [18]; gold particles can be detected using Raman spectroscopy [47]; and quantum dots can be seen using fluorescence microscopy [19]. The drug or therapeutic element may be attached directly to the nanostructure, or encapsulated in its interior. Targeting molecules (e.g., biorecognition elements, see Section 11.2.4.2) can be added to the nanostructure surface to direct interactions with the cell of interest.

Many systems also include a component to increase circulation time and reduce RES recognition. Early efforts to use micro- or nano-sized particulates for drug delivery were plagued by short circulation lifetimes. Attachment to a carrier molecule can prevent these difficulties. For example, a significant improvement in delivery occurred with the addition of poly(ethylene glycol) (PEG) to particle surfaces [213]. PEG prevents the adsorption of proteins, which might be recognized by the RES [145]. Additionally, small nanoparticles (<10 nm) coated with specific targeting peptides accumulate in the tissue of interest while evading the RES [75]. Thus, particle surface modification can facilitate drug targeting and prevent RES clearance.

Nanostructures offer several advantages to traditional drug delivery systems. Nanostructures may be loaded with vast quantities of drug through encapsulation or binding to the particle surface. They can be further modified with specific targeting molecules. For each binding event, an entire nanostructure payload may be delivered, in contrast to the single molecules delivered using direct drug-biomolecule conjugation schemes [213]. Additionally, nanostructures can reach some target sites that are not accessible by therapeutic agents administered via traditional routes. For example, they have demonstrated the ability to cross the blood-brain barrier [213]. Unlike traditional systems, nanostructures can also be targeted to specific elements through external manipulation (e.g., magnetic fields), and those same signals can be used to trigger controlled release.

#### 11.6.2.2 Drug Delivery for Cancer Treatment

The possibilities for nanostructures in cancer therapy are staggering (also Volumes 6 and 7 of this series for more detail). Nanostructures can provide imaging capabilities, allowing detection of cancer in early stages [213, 226]. Therapeutics may be administered using nanostructure carriers [213]. If these particles are combined with imaging modalities, drug distribution can be monitored in real time. Delivery vehicles could be coupled to biorecognition elements that target only cancerous, and not healthy, cells [213]. Most research to date has focused on magnetic therapies to deliver cytotoxic agents; however, new materials and new approaches are beginning to be investigated. In some cases, the nanomaterial itself becomes the cytotoxic agent, activated by a remote optical source. Because of the ease of surface modification, size selection, and tunable optical, electrical, and magnetic properties, these drug delivery systems will likely become powerful additions to current clinical cancer treatments.

**Molecular Approaches** For recovery, cancer treatment requires complete removal of the cancerous cells [227]. In many cases, tumors cannot be fully excised surgi-

cally and traditional chemotherapy is either not possible or undesirable. Targeted cytotoxic drug delivery to the tumor provides one alternative to these standard treatments, and it was for this purpose that therapeutic nanostructures were first investigated [223, 224]. The concept is straightforward. Magnetic particles are conjugated to cytotoxic drugs. External magnetic fields are then used to concentrate the particles near the tumor. Particles are internalized, and the drug payload is released by physiological change (e.g., temperature, pH, enzymatic activity) [228].

Magnetic targeting has been used in many environments. Magnetic microspheres have been utilized to deliver drugs to the brain, with concentrations 100–400× higher than those of mice exposed to drug solution alone [229]. In brain tumor-bearing rats, similar systems administered 41–48% of the dose directly to the tumor, in comparison to 23–31% of dose in the absence of the magnetic field [230]. Particle localization in the vasculature has been controlled with magnetic targeting in a swine model [231]. Starch-coated particles, administered to rabbits intra-arterially, were concentrated in invasive squamous cell carcinomas following applications of magnetic fields up to 1.7 T [232]. Magnetic liposomes were delivered to osteosarcomas, suppressing tumor growth [233].

Nanostructure magnetic therapies have also been applied in the clinic. Lübbe et al. [227, 234] investigated the efficacy of magnetic particle bound-epirubicin to advanced tumors. Tumors were less than 0.5 cm from the magnet source and were subjected to magnetic fields of 0.5–0.8 T. No adverse reactions to the magnetic particles were observed, although toxicity was seen at high epirubicin doses. Results were mixed, as particle accumulation in tumors was not successful in 50% of patients [227]. Physiological parameters played a great role in this variability and must be addressed in future attempts to develop successful therapies.

One difficulty in implementing magnetic therapies is that magnetic field strengths high enough to overcome natural body forces (e.g., blood vessel flow) are difficult to develop and maintain, particularly for deep tissue targets [227]. In addition, optimizing particle size to provide the highest level of particle concentration at a tumor site is difficult. Magnetic susceptibility is inversely related to particle size, but larger particles are more likely to be removed from circulation by the RES [227].

Magnetic fields can be used to produce particle accumulation in a chosen tissue, but specific targeting sequences are required to promote selective internalization by cancerous cells. These surface agents are designed to prevent macrophage endocytosis (i.e., immune reaction), while increasing endocytosis in target cancer cells. Several coatings have been investigated. Poly(ethylene glycol) increased uptake in breast cancer cells, while reducing internalization by macrophages [235]. Modification with folate also produced selective internalization by breast cancer cells, but not other cell types [235]. Amino-poly(vinyl alcohol) (PVA) coatings encouraged endocytosis of magnetic particles by melanoma cells, whereas PVA, carboxylate-PVA, and thiol-PVA did not [236].

Once inside the cell, the drug must be released, enter the cytoplasm, and diffuse to its target (in most cases the nucleus or mitotic spindle). Drug release must be precisely controlled. Once the drug payload has detached from the magnetic

particle it can no longer be manipulated by a magnetic field. Drug escape from endosomal/lysosomal compartments is possible. The release of drug payloads from nanoparticles in lysosomal environments has been documented and correlated to observed cytotoxicity in breast and cervical cancer cells [237]. Additionally, oleic acid/pluronic coated-particles containing doxorubicin were internalized by prostate and breast cancer cells, producing dose-dependent cytotoxicity [238].

Apart from magnetic materials, researchers have investigated other nanostructures as nanochemotherapeutics, including colloidal gold [239] and silica [240]. Colloidal gold has been used to deliver tumor necrosis factor (TNF) [239] in a mouse model. Native TNF has been used as an anti-cancer therapy before but, however, was found to be toxic at therapeutic doses [239]. Particles bound to TNF, and containing PEG modifications to reduce RES clearance, accumulated in MC-38 colon carcinoma tumors and produced 50–90% reduction in tumor volume. Additionally, toxicity was drastically reduced. None of the animals examined demonstrated adverse reactions, whereas 25–100% of animals exposed to native TNF died. Development of silica nanoparticle carriers, though, is still in early stages. Silica has been attached to cefradine, a broad spectrum antibiotic [240]. Silica particles demonstrate drug release profiles that are likely tunable with particle size, but have yet to be tested *in vitro* or *in vivo*.

**Hyperthermia** Apart from their use as drug delivery vehicles, nanostructures can also provide the toxic moiety, treating cancer directly. Because of their unique optical properties, certain types of nanomaterials can produce local temperature elevations. This process, known as hyperthermia, has been investigated by several groups. As a result, this discussion is limited in scope, for more detailed information the reader is directed to recent review articles (e.g., Moroz et al. [241], Ramachandran et al. [242]). Hyperthermia is a result of particle Néel relaxation [243] in an AC magnetic field [228] (e.g., 5–30 kA m<sup>-1</sup> at 100–500 kHz [242]), producing a temperature elevation. When the temperature is maintained at 42 °C or higher for 30 min, cell death, primarily through necrosis, will occur [228, 242]. The exact mechanisms of cell death are not completely understood, but the effects of heat on DNA repair and protein expression are well-documented [244].

The use of magnetic particles to locally heat tumor tissue was first proposed in 1957 by Gilchrist et al. [245]. In that study, 20–100 nm magnetite particles were directly injected into the intestines of dogs. Since that time, several alternatives to direct injection have been developed [241]. Arterial embolization employs the tumor vasculature to deliver particles to the tumor interior. Particles may be surgically implanted, although this technique tends to focus on macroscopic structures (~1 mm) [241]. Finally, particles can be conjugated to appropriate biomolecules and may enter the cell (intracellular delivery).

The most limiting features of magnetic hyperthermia have been poor AC field control, temperature control, and cell targeting. High AC fields are not tolerated well, as they can lead to muscle response (e.g., spasms). The advent of nanometer-sized magnetic particles [246, 247] has allowed for the use of lower, more compatible AC fields [242], which may alleviate this concern. However, a clear understand-

ing of the relationship between AC field strength and the resulting temperature profile has not yet been obtained. Temperature control is critical because if body tissues are heated above 56 °C undesired tissue ablation results [242]. Modeling is helpful to address these concerns, but extensive modeling of magnetic hyperthermia systems has not been performed [242]. Additionally, it is difficult to target nanometer-sized particles to tissues of interest using magnetic fields. In this size regime, Brownian motion becomes dominant [242] and substantial force is required to manipulate particles to regions of interest. For this reason, biomolecular targeting may be a superior approach for directing magnetic particles to particular cells. In addition to these factors, magnetic hyperthermia must compete with other better established, approaches, including whole-body hyperthermia and thermistors, to deliver heat [244].

More recently an exciting new material, gold nanoshells, has demonstrated the potential to produce local hyperthermia (Fig. 11.15) [248]. These nanoshells exhibit unique optical properties, which are tunable, based on their size. Nanoshells absorb light in the near-infrared (NIR), and convert this energy into heat, primarily through vibrations of the crystal lattice (i.e., plasmon-resonance) [249]. Nanoshells offer several advantages to magnetic hyperthermia because of the excellent tissue penetration in the NIR and the small number of particles needed to produce a temperature increase [248]. Small particle size allows facile penetration of tumors through the vasculature [249], which is known to be more permeable in cancerous than healthy tissue. Particles introduced in this way may accumulate in tumors

**Fig. 11.15.** Side-by-side co-culture of SKBR-3 breast carcinoma cells and hamster dermal fibroblasts. Anti-HER2 (a tumor marker overexpressed on the breast carcinoma cells) targeted nanoshells were incubated with the co-culture. After rinsing, the cells were exposed to a near-infrared laser (808 nm, 1 min), then stained for viability with calcein AM (green),

indicating live cells, and ethidium homodimer (red), indicating cell death. The laser spot is indicated by the yellow circle. The targeted breast carcinoma cells were ablated while the “normal” cells were unharmed. (Photo courtesy of Jennifer West, Rice University, Houston, TX.)

non-specifically, or through direct, antibody-mediated targeting [250]. This effect has been used to create selective, local tissue ablation targeted specifically to tumors [249]. Additionally, the presence of nanoshells can be confirmed using optical techniques (e.g., using optical coherence tomography), allowing *in situ* monitoring of nanoshell targeting and therapy [15].

**Photodynamic Therapy** Another interesting application of nanomaterials in cancer therapy is the generation of cytotoxic singlet oxygen. In this process, known as photodynamic therapy (PDT), photosensitizers (PS) are encapsulated in or conjugated to the surface of nanostructures. Additionally, nanostructures can be conjugated to targeting molecules that direct them to local tissues. Upon absorption of light, the photosensitizers excite molecular O<sub>2</sub> to the singlet state, causing cell damage, most notably through disruption of cellular membranes [251]. Singlet oxygen can also cause tissue damage through disruptions of the vasculature, resulting in tissue starvation [251]. Although application of nanomaterials to PDT is recent, several materials have been investigated, including silica, gold, and quantum dot nanoparticles.

Silica nanoparticles are easily modified to allow encapsulation of PS, which are largely hydrophobic. For example, native silica was modified with aminosilanes to promote encapsulation of meta-tetra(3-hydroxyphenyl)-chlorin PS [252, 253]. When excited, the PS-silica nanoparticles produced more singlet oxygen than free PS [253], possibly as a result of increased PS concentration. Silica nanoparticles have also been used to entrain 2-devinyl-2-(1-hexyloxyethyl) pyropheophorbide (HPPH) PS [252]. When exposed to cells, nanoparticles entered the cell interior, most likely through endocytosis. Upon excitation singlet oxygen was produced, resulting in cell death.

Similarly, gold nanoparticles have been prepared as carriers for PS; however, in this case the molecules are linked to the particle surface rather than entrained in particle pores. Using the strong binding affinity between gold and thiol groups, mercaptoalkyl-modified phthalocyanine PS were tethered to the surface of gold nanoparticles [254]. Singlet-oxygen generation was enhanced when compared with that of free phthalocyanine, possibly as a result of the phase transfer agent (i.e., tetraoctylammonium bromide) also tethered to the nanoparticle surface.

An interesting possibility for PDT is the use of semiconductor quantum dots [255]. CdSe quantum dot surfaces (~5 nm) conjugated to Pc4 PS produced excitation and singlet-oxygen generation through fluorescence resonance energy transfer (FRET) [256]. Additionally, unconjugated CdSe quantum dots produced singlet oxygen [256]. Although the efficiency of singlet oxygen generation through this mechanism was very low (5% quantum dots vs. 43% Pc4 PS), quantum dots are extremely resistant to photobleaching and could potentially produce singlet oxygen over longer time periods than traditional PS [255]. The greatest effects on cell viability appear to occur when quantum dots are combined with tethered traditional PS [e.g., trifluoperazine (TFPZ), sulfonated aluminum phthalocyanine (SALPC)] [257]. The exact mechanism for the loss of cell viability in the presence of quantum dots is unclear. It may be attributed to the generation of reactive species, including

singlet oxygen, but could also result from the liberation of Cd ions, which are cytotoxic [31, 257].

### 11.6.3

#### Gene Therapy

Gene therapy can be thought of as a specific subset of drug delivery. The agent delivered is DNA, instead of a pharmaceutical; and the release of the agent occurs one time rather than at a controlled rate. The ability of nanostructures to bind DNA is well known and was initially investigated for sensing and high throughput screening applications [13]. Recently, several investigators have expanded this research to examine potential applications in gene therapy. There are several potential advantages to nanostructure-based vectors. Like other non-viral systems, they can minimize adverse immune responses. Additionally, nanostructures can be readily modified with biomolecules to promote targeting and uptake. Some nanostructures can also be targeted using external fields and monitored optically.

Initially, nanoparticles were investigated as passive carriers. Silica nanoparticles and gold nanoparticles, in particular, have been examined because of the numerous surface modification strategies available. These systems use nanoparticles to increase presentation of DNA to the cell surface and to couple transfection agents with targeted recognition molecules. Conversely, magnetic nanoparticles have been used as active transfection agents, with magnetic fields directing cell targeting.

##### 11.6.3.1 Silica Nanocarriers

Silica nanocarriers are good candidates for DNA delivery because they are biocompatible, present concentrated DNA to the cell surface, and are easily synthesized. Normally, silica nanoparticles are negatively-charged and will not interact with DNA, which is also negatively-charged. However, their surfaces may be modified with aminosilanes to provide cationic surfaces, and zeta potentials of up to ~50 mV have been observed [258]. These surfaces bind up to 90% of available DNA, primarily through electrostatic attraction [259], and have produced transfection efficiencies 30% as high as those of polyethylenimine (PEI) (60 kDa), a standard cationic carrier. Successful transfection has also been demonstrated *in vivo* (e.g., in the brain), with transfection efficiencies equivalent to those of some viral vectors [260]. Additionally, silica nanocarriers demonstrate far less toxicity than cationic delivery systems [261] or viral vectors [260].

Apart from improvements in biocompatibility, it has been suggested that nanoparticles may enhance transfection efficiencies by concentrating DNA near the cell surface [222]. Traditional transfection systems rely on diffusion to initiate contact between the DNA carrier and cell membrane. Many transfection agents are toxic to cells, and contact time must be limited. Most of the DNA complexes in solution never reach the cell membrane. Because of their increased bulk, nanostructures can overcome these difficulties. In one study, dense silica nanoparticles, coupled to dendrimer transfection agents, sedimented on cell surfaces, increasing transfec-

tion efficiencies by almost eight-fold over traditional dendrimers [222]. In another study, the chain length of the dendrimer transfection agent used could be reduced when coupled to silica particles. This is advantageous because long chain (e.g.,  $G > 5$ ) dendritic polymers have been found to be effective gene transfection agents; however, they are difficult to synthesize and isolate [262]. When coupled to mesoporous silica, short-chain (i.e.,  $G_2$ ) poly-amidoamine (PAMAM) dendrimers were able to deliver gene with transfection efficiencies of 35% [262], comparable to unconjugated long-chain variants.

#### 11.6.3.2 Gold Nanocarriers

Like silica, gold nanocarrier surfaces can be readily modified, in this case using thiolated molecules. However, much smaller sizes can be obtained with gold than silica nanocarriers (e.g., 1–10 nm vs. ~30 nm). Smaller nanocarriers potentially increase complex internalization and DNA cargo release [263]. Transfection efficiencies of DNA bound-gold nanocarriers are dependant on the surface charge or hydrophobicity and the chain length of the surface coating. The most successful nanocarriers display efficiencies up to  $8\times$  that of PEI (60 kDa) [263].

Gold particles also enhance the efficacy of existing agents. For example, PEI (2 kDa)-bound gold displayed an eight-fold transfection increase over PEI alone [264]. When combined with chemically modified PEI treatments, transfection of up to 50% of cells was possible [264]. The mechanism for this enhancement is uncertain. Physical concentration of DNA molecules through increased sedimentation may play a role, as hypothesized for silica particles [222]. However, the efficiencies of gold nanocarriers are much greater than those of silica (30% of PEI vs. 800% of PEI) despite being almost an order of magnitude smaller. Thus, additional factors likely contribute to transfection enhancements. Studies of endocytosis have shown an increase in internalization for particles in the 50 nm region [156], and it is possible that the smaller size of DNA-gold complexes enhances their uptake.

#### 11.6.3.3 Magnetic Nanocarriers

By far the most widely studied non-polymeric nanocarriers have been magnetic particles. Magnetic particles can improve the effectiveness of traditional vectors by promoting specific targeting to the cell surface, and possibly the cell interior [265]. In a technique similar to that used for cell sorting, magnetic nanoparticles have been used to concentrate retroviral vectors, which were isolated in concentrations up to 4200 times that of the control [266]. Using a magnetic field, these particles were then directed to certain portions of a cell culture dish, producing extremely efficient, patterned *in vitro* transfection. In a more comprehensive study, cationic magnetic nanoparticles were examined with non-viral (i.e., PEI, AVET, lipofectamine, geneporter, and DOTAP-cholesterol) and viral (i.e., recombinant adenovirus and a retrovirus) transfection agents *in vitro* and *in vivo* [265]. Using magnetic fields, transfection could be confined to specific regions of a cell culture plate, in agreement with Hughes et al. [266].

The application of a magnetic field produces an extraordinary reduction in transfection times, from 2–4 h to as little as 10 min [265]. This is most likely explained

by an increase in vector concentration near the cell surface, resulting from direct magnetic targeting and increased sedimentation [221, 222]. As many vectors demonstrate chronic toxicity in cell culture, a reduction in required transfection time is an important innovation. Additionally, the required DNA dose declined, potentially allowing the use of retroviral transfer agents, which are difficult to isolate in high concentration. Further, targeting of magnetic nanocarriers is extremely specific. Few receptors for the transfection agents employed were required, allowing transfection of cell types that previously did not respond to the viral vectors investigated. A modest increase in transfection was evident for viral agents bound to magnetic particles, and transfection drastically increased (e.g., 20× that of control) the presence of a magnetic field.

Magnetotransfection also shows great promise *in vivo*. Magnetic particle-bound viral agents produced transfection in the gut and stomach, normally inhospitable environments for viral agents and DNA [265]. Transfection has been achieved in primary endothelial cells (i.e., human umbilical vein endothelial cells) that normally display remarkable resistance to DNA and might be used as stem cells [267]. Magnetic nanospheres conjugated to the vascular endothelial growth factor (VEGF) gene have been examined as a treatment for limb ischemia [268]. Using magnetotransfection, overexpression of VEGF was produced, resulting in an increase in capillary formation. This treatment method offers great improvements over either systemic delivery of VEGF or delocalized gene therapy. Systemic delivery has not been very successful because the VEGF half-life is very short, whereas traditional untargeted vector delivery does not target the limb in question and can produce unwanted angiogenesis in alternative locations. Although these studies used external magnets to guide particles, existing MRI technology may also be used for this purpose, reducing one barrier to clinical implementation.

#### 11.6.4

##### Future Directions

###### 11.6.4.1 Drug Delivery

Nanostructures offer several advantages that will encourage their future use in drug delivery. One benefit is the ability to encapsulate large amounts of drug in a small space. Recent work has highlighted the increased storage potential of magnetic nanotubes/wires in particular. Nanowires possess many of the size advantages of nanoparticles, while having an increased length along which diffusion can occur or drug can be encapsulated. Electrospun nanofibers containing magnetic particles have been manufactured, providing potential MRI targeting ability while increasing available drug storage area [269]. Alternatively, magnetic nanoparticles were deposited on the inner surface of silica nanotubes using templated synthesis, and the controlled release of ibuprofen, 5-FU, and 4-nitrophenol drugs was evaluated [270].

Another interesting system to increase storage is the use of hollow polymeric nanospheres. In a technique similar to colloidal lithography (Section 11.3.2), nanoparticles may be used as templates to self-assemble nanometer-sized degradable

polymer shells [271]. Known as layer-by-layer assembly, this technique systematically adds oppositely charged molecules [e.g., polyelectrolytes, including poly(sodium styrenesulfonate) and poly(allylamine hydrochloride)] to a surface through electrostatic attraction. Once the shell is assembled, the core material, usually a polymer nanoparticle (e.g., polystyrene latex [271] or poly(lactic acid)/poly(lactic acid-co-glycolic acid) [272]), can be dissolved. Permeability of the resulting shell is dependant on the polyelectrolytes selected and on the solution pH [272], allowing for specific drug release in pH-altered environments (e.g., endosomes, gut, and stomach). As well as drug, shells can also encapsulate nanostructures, including magnetic particles [273, 274], CdTe [275, 276], Cd<sub>x</sub>Hg<sub>1-x</sub>Te [276] and HgTe [276] semiconductor quantum dots, and gold-cobalt nanoparticles [277]. The shells provide a protective coating that may facilitate intracellular delivery of nanoparticles and their cargos.

Nanostructures also provide ideal drug delivery agents because their surfaces may be altered with multiple agents: drugs, targeting molecules, and chemicals to facilitate intracellular delivery. For example, one system, conceived by Ferrari [213], would use nanoparticles to treat large tumor masses. Traditionally, drugs must access the tumor from its periphery. However, in Ferrari's system, elaborate mechanisms are used to avoid these barriers. First, the nanoparticle encapsulates actin monomers and myosin-bound therapeutic agents. The nanoparticle surface would be bound to molecules that target appropriate cells (e.g., endothelial cells forming the neovascular tumor barrier). The nanoparticle would also be attached to molecules that enhance permeation of the endothelium, allowing nanoparticle access to the tumor interior. Once inside the tumor, the nanoparticle would release its actin cargo, forming filaments along which the myosin-bound drug payload can travel. The drug would then be delivered to tumor cells beyond the tumor periphery.

Nanostructures can also be used to create "smart" delivery vehicles, with triggered release produced by an environmental change. For example, the polymeric nanospheres described above can encapsulate nanoparticles that alter their permeability, actuating release. Au-coated cobalt nanoparticles were able to disrupt polymeric capsules in the presence of a magnetic field, releasing FITC molecules [277]. Another example of selectively triggered release is the use of CdS nanoparticles as capping agents for mesoporous silica storage spheres [278]. CdS nanoparticles were used to block surface pores of mesoporous silica. Upon addition of chemicals that disrupt disulfide bonds, the CdS particles were removed, allowing controlled release of the drug cargo. Alternatively, gold nanoshells have been encapsulated in thermoresponsive hydrogels [17]. When the nanoshells are exposed to infrared light, the temperature increased [Section 11.6.2.2 (Hyperthermia)], causing the polymer to collapse and release its drug cargo.

Future nanoscale drug delivery devices will likely incorporate many of these techniques. Nanocavities, as found in nanotubes or polymeric nanospheres, may provide space for increased drug storage. Nanostructure surfaces may be altered to target release to a specific location. Additional adaptations may allow for safe passage of molecules through tissue barriers and into the cell interior. Once in place, optical

or magnetic excitation may be used to actuate drug release. Ultimately, these systems will provide heretofore unseen control in drug delivery.

#### 11.6.4.2 Gene Therapy

**Multifunctional Systems** Similar to drug delivery, multifunctional systems will likely form the cornerstone of improved nanostructure–DNA delivery. Nanostructures can be attached to several types of biomolecules, creating modular DNA delivery systems that include DNA, cell membrane transporters, and endosomolytic agents. For example, researchers have combined hybrid viruses conjugated to nanoparticle surfaces with magnetic force to create novel gene delivery systems [279]. Previously, the envelope of the hemagglutinating virus of Japan (HVJ) was modified to transfer DNA through cell fusion; however, efficiency remained slow and untargeted. To improve transfection, the virus was coupled with magnetic particles modified with either protamine sulfate or heparin. Successful transfection was achieved using protamine sulfate *in vitro*, whereas heparin was needed to maximize transfection *in vivo*. It is unclear whether these factors enhance direction by promoting cell binding through specific receptors, or simply by altering the zeta potential of the particle surface. In another example of composite systems, researchers combined DNA-covered gold nanoparticles with electromigration and electroporation to enhance delivery. Up to 82× the amount of DNA was delivered when gold particles were subjected to electric fields, promoting electromigration and subsequent electroporation. Although not compared directly with electroporation of free DNA, it is probable that the addition of conductive gold particles enhanced delivery. Although much work is in the early stages, combination approaches can, clearly, merge two mediocre delivery systems to create powerful transfection systems.

**Nanorods** Polymeric microparticles are by far the most common nanostructures studied for gene therapy. However, nanorods offer some distinct advantages as combination transfection agents. Metallic nanorods can be constructed from alternating material segments (Section 11.2.2.2). Through specific surface chemistry interactions, these segments can be chosen to promote selective attachment of biomolecules to each element [280]. For example, rhodamine dye and DNA were attached to segments of Au–Ni nanorods, respectively. The rhodamine was used to locate nanorods, which were found in acidic organelles, probably cytoplasmic vesicles. Alternatively, DNA and transferrin were attached to nanorods, and transfection efficiencies improved by 2–3-fold [280]. This method represents an advantage to nanoparticle-based systems, which attach multiple elements to the same molecule. In single material systems, kinetic considerations may favor binding of one molecule over that of another.

Another advantage of nanotubes is their potential ability to penetrate the cell membrane directly, reducing dependence on the endocytotic pathway for vector delivery. There is some evidence that magnetic particles may be forced through the cell membrane under the influence of a magnetic field [221]. Also, carbon nano-

tubes with a magnetic cap can penetrate the cell in a magnetic field [192]. This system was examined as a method of gene delivery, with up to 85% of cells displaying the gene of interest. Transfection was not evidenced in the absence of the magnetic field, demonstrating that the mechanism of infection was active spearing, and not passive diffusion of vectors to the cell surface. However, both rotating and static fields were required for optimal gene delivery. Because of their surface modifiable segments and high aspect ratios favorable for cell penetration, nanotubes may prove to be superior materials for forming composite delivery systems.

**Frontiers of DNA Delivery** One of the greatest difficulties in assessing *in vivo* gene therapy success is ascertaining whether the intended target has been transfected. Magnetic particles have been used for some time as diagnostic agents in magnetic resonance imaging (MRI). The combination of magnetic particles as gene delivery agents and imaging modalities may allow researchers to monitor transfection *in vivo* [281, 282]. In addition, it may be possible to monitor gene *expression*. Genes that encode for ferritin formation have been used to synthesize metallic particles directly inside cells [283]. If linked to a transfected gene, ferritin molecules could serve as reporter molecules, indicating the transcription level of the gene of interest. Using existing MRI systems, these exciting developments could allow external observation of transfection and subsequent gene expression *in vivo*.

Also, the potential ability of nanostructures to deliver large quantities of DNA is creating new possibilities for therapeutic treatment. The initial focus of most gene therapy approaches has been delivery of a working copy of a deficient gene. However, in many cases the gene in question *overexpresses* a protein, and it would be desirable to “turn-off” the gene. It has been proposed that complimentary oligonucleotides may bind mRNA, preventing protein synthesis [284]. However, as opposed to the one-shot delivery of vectors, silencing genes will require large amounts of DNA to be delivered continuously. Initial reports indicate that transfection using magnetic particles may provide high levels of these oligonucleotides [285]. Ammonium-modified gold nanoparticles bound DNA, preventing RNA polymerase attachment and subsequent DNA transcription [62]. Reversible hybridization has also been demonstrated on a gold nanocrystal platform [286]. DNA conjugated to gold nanoparticles denatured in the presence of a radio-frequency magnetic field. When the magnetic field was removed, DNA appeared to return to the native configuration. Although the exact mechanism is uncertain, it is likely that heating effects produced by the presence of a magnetic field [Section 11.6.2.2 (Hyperthermia)] caused the loss of hybridization.

## 11.7

### Protein Manipulation

Another potential therapeutic use of nanostructures is the active manipulation of proteins. Enzymes and proteins can be directly conjugated to a nanostructure surface, and, in many cases, activated or deactivated through optical or magnetic ef-

fects. Alternatively, substrate molecules can be linked to nanostructures, and used to indirectly manipulate bound proteins, including cell surface receptors or ion channels. Although the applications of nanostructures in this field of cellular engineering are the least developed, they offer the ability to directly control cellular signaling pathways and responses. As techniques continue to advance, nanoscale protein manipulation will lead to new therapies, a greater understanding of cell function, and external systems for large-scale biochemical synthesis.

### 11.7.1

#### **Biology of Protein Manipulation**

Most cell functions, including signaling, replication, and metabolism, are dictated by proteins. Most proteins are globular structures containing positively- and negatively-charged hydrophobic and hydrophilic residues [8]. Upon folding, the hydrophobic residues are confined to the center of the protein, producing secondary structure. The secondary structure frequently contains an active site, a series of charged residues that recognize and bind substrates. Protein–substrate binding affinities result from a combination of electrostatic, hydrogen bonding, and van der Waals interactions [8]. Substrate binding often produces a conformational change in the protein, which activates a signaling pathway or catalyzes a chemical reaction [8].

Proteins may be free or bound to the cell membrane. Proteins embedded in the membrane usually contain several hydrophobic residues, arranged in alpha helices, which span the membrane [8]. These proteins contribute to intercellular signaling, cell motility and adhesion, and the flow of components into and out of the cell. Ion channels, in particular, represent one class of membrane-bound proteins that can respond to electrical, mechanical, or chemical signals [8], and therefore are an interesting target for nanostructure manipulation.

### 11.7.2

#### **Manipulation of Free Proteins: Enzymes**

Nanostructures can be bound to free proteins using many of the techniques discussed previously (Section 11.2.4). The most widely-studied nanostructure system for enzymatic manipulation consists of mesoporous silica containing enzymes immobilized in the particle matrix. This technique has been used to entrap butyrylcholinesterase, an enzyme that cleaves ester bonds, with retention of over 90% of activity [287]. Enzymes bound to silica were more resistant to temperature changes, preserving 100% of activity versus an 85% decrease for free enzyme in solution. Enhanced stability most likely resulted from enzyme interactions with the nanoparticle support, as others have found that enzyme–nanoparticle binding lowers kinetic barriers for conformational rearrangements that may prevent denaturation [288]. Enzymes have also been encapsulated in hollow silica nanoparticles; however, these systems were less successful. Enzyme activity was reduced when compared with free enzyme, most likely as a result of diffusion limitations [289].

Control of the amount of enzyme encapsulated has been obtained using layer-by-layer techniques. Films or shells containing alternative layers of electrolyte and silica nanoparticle or enzyme have been constructed [290, 291]. The amount of enzyme incorporated is controlled by adjusting the number of layers constructed. This technique can also prevent unanticipated enzyme desorption from the particle [292]. Although most of the envisioned applications of this technique are for biosensing or the development of large scale reactors [293], it is possible that layer-by-layer assemblies could be used to construct prosthetic elements that contain a missing or inactive enzyme in the patient.

In addition to silica particles, other materials have been investigated. Trypsin enzyme has been linked to dextran-modified gold through supramolecular interactions [294], and chymotrypsin has been bound to mixed-monolayer protected gold clusters through electrostatic interactions [295]. For chymotrypsin, binding was designed to occur at the active site, and inhibited the enzyme completely with a 1:5 nanoparticle to chymotrypsin ratio. Chymotrypsin has also been attached to CdSe quantum dots with varying surface functionalities. Capping ligands terminated with hydroxyl groups did not interact with enzyme, whereas carboxyl-terminated ligands inactivated enzyme [296]. Enzymes have been coupled to magnetic particles as well, which have the potential benefit of targeting using magnetic fields; however, these are most commonly used in bioreactors, not living systems [297].

Also, nanoparticles have been trapped in the pore of certain proteins, chaperonins, which are responsible for repairing defects in protein folding [298]. Normally, these proteins encompass misfolded proteins, providing a permissible environment for reconfiguration. After folding has been corrected, the protein is released in an ATP-driven process. CdS nanoparticles were complexed with chaperonin proteins with the aid of dimethylformamide. Particles displayed unusually long-lived fluorescence, indicating that chaperonins were able to shield nanoparticles from adverse reactions (e.g., oxidation) in much the same way that misfolded proteins are protected. Further, upon ATP addition, colloids were released and could be isolated through centrifugation.

### 11.7.3

#### **Manipulation of Bound Proteins: Receptors and Ion Channels**

Utilizing nanostructures to manipulate cell surface receptors and ion channels is in many ways easier than the manipulation of free biomolecules. The exterior of the cell is much more accessible than its interior, and introducing nanostructures to an extracellular *in vitro* or *in vivo* environment is straightforward. Although endocytosis may still be an issue, particularly if nanostructures are designed to remain on the cell surface for long periods, performing experiments at low temperatures can alleviate these concerns [154]. This section focuses primarily on nanostructure manipulation of cell surface receptors and ion channels, as nanostructure cytoskeletal manipulation was discussed previously (Section 11.3.4).

Nanoparticle binding to cell surface receptors can influence cell function, particularly the internalization of substances. Magnetic nanoparticles, conjugated to in-

sulin, prevented endocytosis and increased cell proliferation and viability [167]. Gold nanoparticles bound to certain glycoproteins, may inhibit cellular HIV virus transmission [299]. CdSe quantum dots attached to serotonin were used to inactivate serotonin transporters [153], a class of receptors that remove excess transmitter from the extracellular environment following a synaptic event. The particles inhibited serotonin in a dose-dependant manner, most likely because transporters became obstructed when attempting to internalize serotonin-bound nanoparticles.

Nanoparticles have also been employed to investigate ion channels, proteins responsible for signaling in nerve cells. Collagen- and laminin-coated magnetite particles were used to non-specifically coat cell surfaces. When exposed to a magnetic field, an increase in intracellular calcium was observed [300]. These increases result from activation of mechanosensitive ion channels, found often in cardiac tissue. Alternatively, nanoparticles were bound to neuron cell surface receptors, near ion channels of interest. CdS nanoparticles conjugated to integrin-binding peptides were used to explore the potential of electrically exciting ion channels with nanoparticle electrical fields [66, 301]. Ion channels have even been directly linked to nanoparticles. For example, ion channels entrained in silica nanoparticles displayed activity for over a month [302].

#### 11.7.4

##### **Future Directions**

The potential of nanostructures to manipulate biomolecules continues to emerge. For example, it is possible that nanostructures could be used to investigate prion proteins, which have recently been identified as potential sources of transmission for mad-cow disease. Defective prions propagate by converting normal prions into the abnormal structure, forming structures similar to amyloid complexes found in Alzheimer's and Parkinson's disease [303]. Gold nanoparticles have been linked to prions, which were used to create self-assembled arrays [304]. Although the main focus of this work was to create stable nanowires, it may be possible to use nanostructures (e.g., magnetite) to manipulate prions and prion propagation, forming a basis for therapeutic treatment. At the very least, manipulation of this new class of biomolecules could provide valuable insight into structure, folding, and prion-prion interactions.

Additionally, future nanostructure-protein systems will expand the ability to manipulate ion channels. For example, organic dyes have been linked to a mechanosensitive channel in such a way that the channels become activated with light [305]. Given their optical and magnetic properties, it is likely that a similar design could be constructed with nanostructures. Although this system was constructed *ex vivo*, it demonstrates the possibility of direct cell manipulation using optical and mechanical elements. Along these lines, gold nanotubes have been used to create artificial ion channels [306]. Nanotubes were embedded in an artificial plasma membrane, composed of polymers, and linked to a DNA molecule. The DNA molecule was used to provide rectification (e.g., on and off states), and was electrophoretically driven to block the mouth of the pore, preventing ion flow. It is

likely that nanostructures will continue to be used in this way, possibly being integrated into cells for control of ion flow, signaling, and protein binding.

## 11.8 Summary and Conclusions

### 11.8.1 Summary

Nanostructures present several advantages for biological research. They are of similar size to many biological materials. Nanostructure surface areas are high and easily altered through various surface chemistry techniques, allowing for easy biomolecule addition and presentation. Combined with the unique optical and electrical properties of nanostructures, these features have heightened interest in the use of nanostructures for biological investigation. Nanostructures may be composed of many different materials, including semiconductors, metals, and magnetic materials, and may be fashioned into particles, wires, tubes, and shells. Synthesis techniques vary depending on the material employed and the desired shape, but generally include solution-phase synthesis, templated electrodeposition, and deposition from the vapor phase. Once manufactured, nanocomponents can be modified with a range of biomolecules using physisorption, electrostatic attraction, material specific affinities, or biomolecular recognition. These bioconjugates can be used to attach nanostructures to specific components of cells. Although there is some evidence that nanostructures may be cytotoxic, these risks can be mitigated through the application of surface coatings, and nanostructures have already been employed successfully in several *in vivo* and *in vitro* applications.

Nanostructures can be used easily for external investigation of cells. For example, they are ideal for the exploration of cell adhesion, migration, and mechanics, primarily as a result of their small size, similar to that of many components that mediate cell attachment. Interactions with physical topography have chiefly been achieved using structures created through optical lithography. However, colloidal lithography offers a facile technique to create nanostructures much smaller than those produced previously. Additionally, nanoparticles themselves may be organized in self-assembled sheets to create roughened physical surfaces with nanoscale dimensions. Chemical patterns can be produced using many of these same methods. For example, gold-thiol binding affinity may be exploited to assemble proteins on nanoparticles or surfaces created through colloidal lithography. In addition to these passive investigations, magnetic nanostructures can be used to directly manipulate cells. These methods have been implemented for cell sorting and to construct tissue engineering substrates. Also, direct cytoskeletal manipulation is possible, and magnetic nanostructures have been utilized to study the role of integrins in mechanotransduction. Future work will likely focus on integrating physical and chemical cues into multifunctional devices, as well as the creation of active substrates to directly manipulate cells.

Whereas it is straightforward to interface nanomaterials with external structures that govern cell adhesion and migration, controlled intracellular delivery of nanostructures is difficult. Materials can be introduced easily through endocytosis, but remain sequestered in endosomes or lysosomes and are unable to interact with the intracellular environment. Several techniques have been developed to elude this fate, including the addition of translocation peptides, liposomes, dendrimers, electroporation, and microinjection. However, most of these techniques produced significant particle aggregation, which can reduce optical signals and impede interactions with subcellular components. Among these techniques, only microinjection has produced discrete intracellular delivery, but this is a serial technique, difficult to adapt to large numbers of cells or *in vivo* delivery. Despite the limited techniques, several researchers have successfully delivered nanostructures to the cell interior. The primary applications have been for cellular and subcellular tracking. Future research will likely concentrate on improving targeting and delivery of nanostructures, perhaps using biomimetic rather than natural methods.

If controlled delivery can be achieved, it presents the opportunity to directly manipulate internal cellular components, including the cytoskeleton. The cytoskeleton is responsible for cell division, signal regulation, transport, and mechanical properties. Movement along the cytoskeleton is mediated by transport proteins, which bind to specific components, including actin filaments and microtubules. It is possible to conjugate nanostructures to both cytoskeletal components and transport proteins, providing a method for nanostructure movement. These systems have been demonstrated *ex vivo*, primarily for self-assembly and electronics applications; however, it is possible that these techniques may also be explored *in vitro*. Future work will likely adapt *ex vivo* methods for *in vitro* studies. If successful, nanostructures could be used to manipulate the cytoskeleton, increasing understanding of mechanical stimuli in cell signaling and division. Additionally, nanostructures may be transported along cytoskeletal elements, providing a method for directing nanostructures to an organelle of interest, with potential applications in drug delivery and gene therapy.

Additionally, internalized nanostructures could be used for controlled cellular delivery of biomolecules, with applications in drug delivery and gene therapy. The half-lives of drugs are very short, and in many cases, sustained long-term delivery is required for optimal therapeutic effect. Several polymeric release systems have been designed, but these lack targeting ability to specific cells or cell components. Also, many delivery agents are quickly removed from the body through the reticulo-endothelial system. Because nanostructure surfaces can be modified easily, they can surmount these challenges. Biorecognition molecules can be added for selective cell targeting; stealth molecules, e.g., poly(ethylene glycol), can be added to increase particle circulation times.

The greatest immediate potential impact lies in the field of cancer therapy, where discrimination between healthy and diseased cells is essential for treatment. Nanostructures have been used for direct molecule delivery, primarily through magnetic targeting. However, they have also been used for triggered release, actuated by an external event or environmental change. For example, gold and magnetic nano-

structures experience temperature elevations in the presence of near-infrared irradiation. This effect, hyperthermia, can be used to produce local tissue damage. Alternatively, nanostructures have been linked to photosensitizers for photodynamic therapy. In response to optical excitation, these chemicals catalyze the reaction of nearby molecules to create cytotoxic substances.

Nanostructures have also been used for gene therapy, which is in effect a subset of the field of drug delivery. Nanocarriers for DNA delivery have been created using silica, gold, and magnetic particles. Even in passive systems, increases in transfection efficiency were seen. Improvements most likely resulted from the density of the nanostructures, which promoted sedimentation on the cell surface, concentrating DNA presentation. However, increases were also seen for smaller nanostructures, indicating that the small size of nanocarriers may enhance cellular uptake. The addition of active targeting (e.g., magnetic field) further enhanced DNA delivery.

Future systems for drug and DNA delivery will likely incorporate multiple functionalities. Carriers may contain the cargo, targeting molecules, agents to enhance permeation, and means for optical detection. Many carriers include an intrinsic targeting capability (e.g., magnet or electric field response) that can be incorporated to maximize release. The use of nanorods will likely be investigated, as their larger surface area increases available storage for cargo. Also, there is some evidence that magnetic nanorods can directly penetrate the cell membrane, evading the endocytotic pathway. These enhancements will provide delivery vehicles that can control the location and time of release.

Finally, internalized nanostructures may be used to directly manipulate proteins, an area of huge potential, still in initial stages of investigation. Free proteins, including enzymes, can be encapsulated in or attached to nanostructures, and these composite systems can be used to control enzymatic activity. Most of this work has focused on the creation of biochemical reactor devices, but may serve as the basis for the creation of prosthetic elements, which replace a missing enzymatic function. Additionally, nanostructures may be linked to substrates and used to manipulate membrane-bound proteins. These interactions can modulate the internalization of substances and ion channel activity. Future research will likely continue to examine new classes of proteins (e.g., prions) and expand research in ion channel manipulation.

### 11.8.2

#### **Conclusions**

Nanostructures provide scientists with exciting opportunities to manipulate cells directly. They possess similar sizes to many biological components, including DNA, proteins, peptides, and organelles. Nanostructures are easy to synthesize and can be composed of metallic, semiconducting, ceramic or magnetic materials (in addition to carbon, polymeric, and peptide materials discussed elsewhere). Their surfaces are readily modifiable with a range of biomolecules, which provide a direct means to interact with the cell and its environment. Although there is

some concern that certain nanostructures may be cytotoxic, they have nonetheless been employed in several *in vitro* and *in vivo* applications.

Because of their unique optical and electrical properties, nanostructures can be used to manipulate and visualize components of the cell exterior and interior. Most of these investigations have been passive. However, as technologies, particularly for controlled delivery, continue to advance, experiments will shift to more active manipulations of cells and their components. This ability will allow scientists to examine intracellular function with increased control. Additionally, these developments will likely lead to new diagnostic and therapeutic applications, particularly for gene therapy and cancer treatment.

# Nanoengineering of Biomaterial Surfaces

*Ashwath Jayagopal and Venkatram Prasad Shastri*

### 12.1

#### Introduction

Cells sample their environment through sensory elements that can discern minute changes in chemical composition and surrounding mechanical forces. These sensory elements are on the order of tens to hundreds of nanometers, and include lamellopodia that aid in cell locomotion, and receptor tyrosine kinases that can bind growth factors. Nanoscale interactions mediated by these elements lead to the activation of signaling pathways that influence cellular processes at different levels, ranging from mRNA synthesis and cell cycle progression to apoptosis. Therefore, it comes as no surprise that biomaterial surface characteristics, namely chemistry and topography, have a profound influence on the elicited cellular response of a tissue engineering construct. Early biomedical devices rarely incorporated nanoscale surface engineering as part of the design paradigm. However, this has changed in light of the growing biological evidence that has elucidated potential therapeutic avenues made possible by the nanoscale presentation of information. New approaches seek to reconstruct the natural tissue environment replete with biochemical and topological cues for the optimum restoration of function. In this chapter, we review the unique contributions and key examples of traditional and rapidly-emerging surface engineering techniques directed toward the progression of biomimetic tissue engineering. As various fundamentally different techniques are discussed, we have grouped biomaterial surface engineering strategies by their primary enabling features, from which some similarities can be drawn, such as the utilization of chemically-based or instrument-guided approaches. We discuss the amenability of these techniques for achieving micro- and nanoscale surface features, the applicability toward hard and soft materials and three-dimensional (3D) geometries, and the future implications of each technology concerning the development of clinically-relevant cellular and tissue engineering devices.

## 12.2

### Conventional Photolithography

The demand for miniaturization strategies in microelectronics long preceded the need for micro- and nanoscale features in tissue engineering devices prompted by the elucidation of extracellular matrix (ECM) proteins and signaling mechanisms, and thus many biomaterial surface engineering strategies are convenient adaptations of these well-established methods. An example is photolithography. The resolution limit of this technology is generally the wavelength of the light used for irradiation, so given the availability of UV excitation sources, photolithography has been frequently utilized to create organized cellular or biomolecular patterns upon nanoscale features engineered on planar surfaces. In the conventional scheme, a patterned photomask is used to control the light-induced decomposition of a spin-coated photoresist on the substrate, exposing defined regions of the substrate. These regions can be etched to create topographical features such as grooves, and can be chemisorbed with compounds such as organosilanes, which promote adhesion to proteins, as well as compounds that resist adsorption. The surface can then be utilized to site-specifically pattern cells and biomolecules. This photoresist-based photolithographic technique was employed for the micropatterned, cocultivation of hepatocytes and fibroblasts, and cell placement was spatially-controlled by the patterning of collagen to the glass surface [1]. The topographical features produced by photolithographic processes have generated potent cellular responses, such as cell alignment and parallel cytoskeletal filament orientation along grooved features, as well as several other responses, as reviewed by Fleming et al. [2].

Photolithography-based surface engineering techniques can be modified such that the biomolecule itself, not the surface, is the photoactivatable conduit for biopatterning. Variations of photolithography include the use of photoreactive chemicals conjugated to a biomolecule, such that irradiation directly mediates site-specific biomolecular immobilization to the surface. Commonly used strategies based on this principle include arylazide, diazirine, benzophenone, and nitrobenzyl photochemistries [3, 4]. In the first three methods, UV irradiation results in active groups that insert themselves within chemical bonds, enabling photoimmobilization of the species attached to the photolabile moiety. The first two chemistries have been successfully applied to the attachment of cell adhesion peptides (RGD-containing) [5, 6] and/or proteins, such as biotin and antibodies [6, 7]. Benzophenone chemistry was applied to covalently attach a laminin peptide fragment [4]. Thus, these photochemical surface engineering techniques can be employed to recreate ECM-like environments that are most supportive of natural cellular proliferation and migration patterns. Nitrobenzyl chemistries have been successfully applied towards the photobiotinylation of polymer surfaces [8].

Photolithographic and photochemical techniques can reproducibly produce nanoscale features that are critical for influencing cellular behavior. The technology is well characterized, and facilitates the surface engineering of chemistry, through adsorption of compounds containing functional groups or biomolecules, and also

provides a conduit for producing certain topographies. However, several elements of this technology are generally not satisfactory for tissue engineering applications. First, photolithography is not suitable for patterning nonplanar surfaces, and is associated with costly, specialized equipment, often using solvents not suitable for cell and protein patterning [9]. Thus, it is difficult to utilize photolithography for the ultimate goal of tissue engineering, which is the 3D biomimesis of the natural tissue environment. Furthermore, for photoreactive chemistries, extensive biomolecule conjugation to the photoactivatable adduct may be involved, UV irradiation must be used, which is damaging to biomolecules, and most processes cannot be carried out in aqueous media, all of which complicate tissue engineering device fabrication strategies that make use of this technology [10]. In addition, illumination is conventionally conducted through photomasks that do not alter the intensity of incoming light; thus, illumination is said to be “all-or-none”, making it difficult to produce features of non-uniform height. This is a primary limitation in adapting photolithographic techniques for producing 3D features.

To address shortcomings of photoresist-based photolithographic techniques, several modifications in techniques and materials have been reported that have reinforced the utility of these methods in modern tissue engineering, in which biomolecule and cellular sensitivity to the processing environment is of critical importance. One approach has been the development of biocompatible photoresists. To expand on the applicability of photoresist-based techniques for protein and cell patterning, a “bioresist” based on a copolymer of methyl methacrylate and vinyl pyrrolidone was applied for the alignment of fibroblasts, obviating the need for potentially-denaturing solvent development steps used to remove photoresist [11]. Another biocompatible photoresist, based on poly(*t*-butyl acrylate), was utilized to pattern a polystyrene tubular support with antibodies, with only mild resist removal steps (specifically, 60 °C and exposure to basic media) that were tolerated by the biomolecules. Features of this technique were comparable with the high resolution of photolithographic techniques, with the patterning of 0.13 μm lines with protein arrangements <10 μm [12–14]. The feature of non-denaturing conventional photolithography is an important step in the transition from established microelectronics processes to tissue engineering micro and nanofabrication procedures that do not necessitate the use of biologically-incompatible solvents in processing steps. To address the all-or-none limitation inherent in the photomask used, several strategies involving what is called gray-scale photolithography have been utilized. In this approach, the mask itself contains tunable features, mainly varying light transmission levels, which control the site-specific degree of photoresist irradiation. In one approach, dye-filled microfluidic channels within an elastomeric mask consisting of varying concentrations of dye were successful in producing 3D features in resist, using standard equipment, with resolution in the single micron range [15].

Recent developments in photochemistry have introduced the possibility of photoconjugating biomolecules, and perhaps cells without the use of UV irradiation and dry environments. Furthermore, complex bioconjugation techniques used to attach photoactivatable compounds such as caging compounds to the bioactive agent are

**Fig. 12.1.** Schematic for photoimmobilization of biotin-4-fluorescein to a bovine serum albumin (BSA)-coated glass surface using visible-light laser irradiation through a photomask. Photobleaching of the fluorescent dye initiates a singlet-oxygen-mediated binding reaction. (Reproduced with permission from Ref. [10].)

no longer the only option for utilizing light-guided patterning strategies. Holden et al. have reported a method for the fluorophore-mediated attachment of biomolecules such as enzymes to electron-rich surfaces in aqueous, neutral media, using visible light that is not harmful to proteins [10, 16] (Fig. 12.1). The technique uses the well-known fluorescein photobleaching reaction to immobilize biomolecules in patterns as arranged by photomasks and fluorescence illumination. Fluorescein and similar organic dyes used for patterning are commonly conjugated to proteins using simple, rapid laboratory techniques [17], thus making the technology accessible to most biological laboratories. One can envision the application of photochemical techniques such as this one for the patterning of biomolecules on complex geometries, simply by controlling the localization of laser irradiation in the  $x$ - $y$ - $z$  plane for site-specific radical-mediated immobilization, although this has not been explored to any significant degree. In another approach that obviates the need

for UV-activatable groups, Luebke et al. described a Trp-containing peptide or protein crosslinking system based on blue excitation light and a ruthenium complex for specific cell patterning on a poly(ethylene glycol) (PEG)-coated glass surface, with single-cell resolution enabled by the use of digital micromirrors [18, 19]. These methods, like the advancements in biocompatible photoresists, also facilitate the use of non-denaturing chemistries in the photolithographically-mediated controlled patterning of tissue engineering scaffolds and implants.

By judicious selection of biomaterials, surface engineering of 3D cellular matrices can be accomplished by photolithographic and photochemical techniques, thus potentially addressing, at least in part, the difficulties of nonplanar patterning with conventional approaches. As an example, PEG-diacrylate hydrogels, known to photopolymerize in the presence of an initiator, were conjugated to nonspecific and specific cell adhesion peptides and exposed through a transparency-based photomask to create 3D layered hydrogel patterns, upon which dermal fibroblasts were specifically attached in specific cell adhesion peptide-defined regions [20] (Fig. 12.2). The study demonstrated that photolithographic methods can be used for the surface engineering of complex 3D cell and biomolecule spatial arrangements, with minimum expense, as the mask was printed on a transparency sheet by laser printer. A photochemistry-based technique for the 3D surface engineering of agarose hydrogels was demonstrated by Luo and coworkers, who conjugated

**Fig. 12.2.** Site-specific adhesion of human dermal fibroblasts to RGDS-immobilized PEG-diacrylate (PEGDA) hydrogels. (a)–(c) Hydrogel patterned with RGDS generic cell adhesion peptide. (d) Hydrogel patterned with

RGDS and REDV (nonspecific) peptide. In all images, HDF-binding is limited to RGDS-patterned regions only. Scale bar = 250  $\mu\text{m}$ . (Reproduced with permission from Ref. [20].)

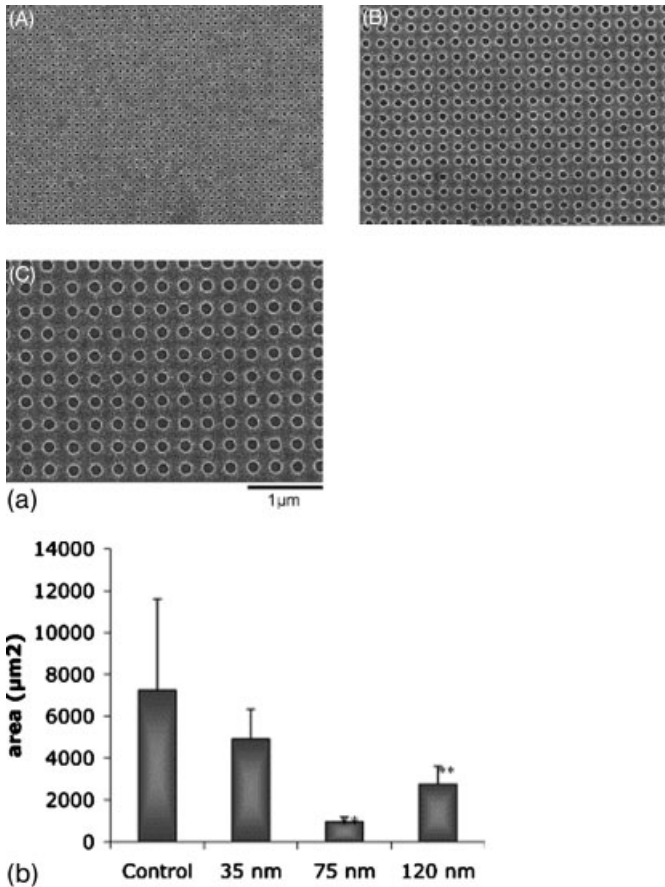

photolabile nitrobenzyl-Cys groups to the hydrogel [21, 22]. Upon UV exposure, exposed sulfhydryl functional group channels were then exploited to site-specifically conjugate RGD-containing cell adhesion peptides, which were patterned to guide neurite outgrowth. In work by Revzin et al., 3D PEG hydrogels could be engineered to bear immobilized fluorescent proteins, supporting the possibility of incorporating ECM-signaling cues within hydrogel microstructures [23]. These findings demonstrate the potential of techniques based on conventional photolithographic and photochemical approaches to construct, with high-resolution and reliability, complex 3D environments based on tissue-like hydrogels to be potentially applied towards the controlled organization of functional tissue. Thus, photolithography and photochemistry, often suggested to be incompatible for tissue engineering applications, may actually be a potential route to the fabrication of 3D tissue constructs using a well-established technology.

### 12.3

#### Electron-beam Lithography

As previously discussed, we have found that nanoscale interactions are paramount to the optimization of a desired cellular response. To this end, nanofabrication techniques used in high-density storage media and electronics might be extended for purposes of patterning sub-10 nm features for tissue engineering applications, given the appropriate material and chemical conduits to enable such an approach. Electron beam lithography (EBL) is a technology capable of achieving such a high resolution, and initially has been shown to be potentially applicable to tissue engineering applications. In this technology, in a manner similar to photolithography, electron beams rather than light are used to irradiate polymer resists (e-beam resists), such as poly(methyl methacrylate) (PMMA). The resist can then be developed to produce several nanotopographies. The current resolution limits of this strategy are as low as 5 nm in the *X-Y* plane and 1 nm in the *Z* plane [24], thus warranting applications of EBL in tissue engineering device fabrication.

Given the advantage of high-resolution, biological applications of EBL have only recently emerged. While EBL is currently being utilized to first study in detail such nanoscale interactions between cells and their surrounding chemistry and topography [25–27], it seems plausible that such a technology could be also directed towards the precise fabrication of complex tissue engineering scaffolds. The potential of EBL to create high-resolution protein patterns on conventional substrates, such as silane-coated silicon wafers, has been demonstrated [28, 29]. In one example, EBL-patterned 1  $\mu\text{m}$  PMMA grooves were seeded with collagen to control lung fibroblast orientation and patterning [30]. Hippocampal neuron perpendicular alignment was influenced heavily by EBL-etched nanoscale grooves [31, 32]. In another application, an EBL method capable of producing 20 nm features surface engineered with poly(caprolactone) (PCL) [33], a biodegradable polymer used in biomedical implants, was used to study the filopodial extensions of fibroblasts in response to different nanotopographies [34] (Fig. 12.3). Thus, as we elucidate the

**Fig. 12.3.** (a) Scanning electron micrographs of nanopit topographies produced by electron-beam lithography, nickel die fabrication, and hot embossing. Diameters: (A) 35, (B) 40, (C) 120 nm. (b) Average number of filopodia per cell on planar and nanopit-containing surfaces. Results are mean  $\pm$  SD;  $P < 0.05^*$ ,  $P < 0.01^{**}$  (student's *t*-test). (Reproduced with permission from Ref. [34].)

specific geometries capable of optimizing tissue organization and function, EBL, at least on a limited amount of materials, is a candidate for creating such features. Three-dimensional surface engineering features, while not explored in depth with EBL, have been at least demonstrated to be achievable, using EBL-enabled amino-functionalization of a gold surface templated with a self-assembled monolayer (SAM), upon which proteins are sequentially layered [35]. These preliminary findings suggest the potential utility of EBL in the surface engineering of tissue engineering devices, provided the materials and biological agents are compatible with the process.

Given the biocompatibility of PCL and PMMA substrates (discussed above for EBL applications) in tissue engineering, EBL has initially been demonstrated to

be relevant to the surface engineering of biomaterials, and it is likely that, in conjunction with other fabrication techniques, EBL-based nanopatterns can be plated on other polymeric and metallic biomaterials as well. However, this has yet to be extensively investigated in a true cellular and protein surface engineering context, especially since most patterning for tissue engineering applications has been primarily explored on the microscale, where high-resolution EBL was not necessary. This might be addressed by investigating more biomaterials for their potential utility as e-beam resists. Furthermore, this highly-specialized technique can be both costly and time-consuming, with the serial drawing nature of the technology, and the extensive effort (computationally and physically) that is necessitated by patterns of increasing complexity. Similar to light-based techniques, EBL can require extensive optimization of process parameters, such as beam current, scan mode, and diameter, as well as resist properties [36]. Pattern reproducibility and resolution, as well as feature width, can be problems with this technology under various conditions. Nevertheless, the high resolution achievable by EBL warrants its further investigation concerning the surface engineering of biomaterials, and the method can still be utilized as an *in vitro* tool to study the fundamentals of cellular responses to varying topographies on the order of single nanometers, since that is the scale of cell plasma membrane features.

## 12.4

### Soft Lithography

The enhanced specialization of biomaterial surfaces required for realistic functional tissue arrays has necessitated the development of new surface engineering techniques. Photolithography and EBL technologies, for instance, in general are not suitable for patterning on nonplanar surfaces. As a result, the diversity of biomaterials available to accommodate specific tissue structures may not be suitable fabrication platforms using these technologies. Furthermore, these techniques are time-consuming, can involve denaturing solvents, and require costly equipment and clean-rooms not accessible to biological laboratories [9, 37, 38]. For biomaterial surface engineering to complement advances in our knowledge base of optimal cellular environments, a family of micro- and nanofabrication technologies known as soft lithography have been developed that are suitable for patterning cellular and biomolecular arrays, with resolutions comparable to those of photolithography [9, 39–41].

Soft lithographic approaches, such as microcontact printing (uCP), microfluidic patterning [micromolding in capillaries (MIMIC)], membrane-based patterning (MEMPAT), and laminar flow patterning [38, 39, 41, 42], are related by the use of elastomeric stamps or channels for patterning, typically based on the silicone rubber poly(dimethylsiloxane) (PDMS). The polymer is cast against a patterned master mold generated by conventional photolithography to create a stamp with various features. PDMS stamps have been used effectively in the patterning of biomolecules and cells through uCP, in which the patterned stamp is coated or “inked”

with a functional chemical substance, such as a self-assembled monolayer (SAM), normally consisting of alkanethiols, and transferred by brief contact to another surface, such as gold, glass, or polymeric materials [37]. Self-assembled films on the target surface can then be used to create patterns in the nanoscale regime [43–45]. MIMIC involves the use of elastomeric channels, a support (e.g., glass, gold, polymer, metal), and a liquid polymer of low viscosity, to form patterned layers by capillary action [42]. In MEMPAT and related techniques, a thin elastomeric lift-off membrane with circles and square-shaped features are used to constrain cell and protein seeding [39, 46, 47]. Laminar flow patterning takes advantage of the low Reynolds' number, parallel non-mixing fluid streams of molded capillary channels to selectively pattern cells and their biomolecular environment [48, 49]. Other novel techniques involve multilayering schemes for the development of 3D elastomeric devices such as microfluidic on/off valves [50]. The variety of soft lithographic techniques provides significant versatility in surface engineering applications.

Soft lithographic procedures incorporate versatile materials and procedures that are readily accessible to biologists [51]. The key component of these technologies, PDMS, is a biocompatible, inexpensive, oxygen-permeable material that can be utilized for cell culture [52], and, due to its elastomeric nature, it can readily assume the shape of nonplanar structures, and is a robust material that can be reused as a stamp for the same application, without leaving residual polymer on the targeting surface. Furthermore, while PDMS is hydrophobic and non-functional for bioconjugation, surface oxidation or polymer grafting procedures can be utilized to make the surface hydrophilic and surface functionalized [53–55]. A previous drawback in soft lithography was the photolithographic step used to generate the original stamp. However, this potentially time-consuming and costly step has been modified with the development of rapid prototyping (RP) steps that use less expensive materials and processing equipment, such as transparency-based photomasks [56] and inexpensive computer-aided design and printing tools [57]. Generally, soft lithography is a low-cost technique that does not necessitate specialized accommodations such as clean-rooms. Hence, the attractive features of soft lithography are versatility in the type of surface that can be patterned (including some 3D applications), low cost compared with other methods, micro- or nanoscale resolution appropriate for tissue engineering applications, and biocompatibility.

Soft lithography is a significant example of a technique that complements the need to fabricate complex cellular and biomolecular arrays for tissue engineering. The appeal of this technology for the engineering of surface chemistries and topologies on biomaterials can be illustrated through several examples. Nanoscale features of varying shape such as lines and circles can be achieved by uCP with certain modifications [58–60]. Alkanethiol SAMs terminated with fibronectin-adhesive and resistant groups were patterned by uCP on gold and silver surfaces to control endothelial cell adsorption on the microscale [61, 62]. uCP techniques have been used to pattern cells and proteins on gold, silver, glass and polymer substrates. Using SAMs with certain specificities toward a given biomolecule or cell, control is provided over cell–cell interactions, as well as cell confinement and

migration within a microscale area, which is critical to the goal of biomimesis. For example, by patterning biomolecules in a tight distribution on the nanoscale, subsequently a high density of protein-based information is created, which makes it possible to mimic the same density of information in living systems, such as integrin clustering. Findings that are a result of the patterning of cells using uCP techniques include the correlation of geometrical and biomolecular surface information with several biologically important events, such as cell growth and differentiation, cell cycle, cytoskeletal arrangement, and cell polarization [9, 37, 40]. For the fabrication of more complex structures, 3D channel networks can be harnessed by using MIMIC to fabricate multiple patterned arrays of protein gradients and cells, on a diverse pool of surfaces, such as biodegradable polymers (PLGA, PEG), glass, gold, and silicon [9, 37, 42]. Laminar flow patterning, due to its ability to deposit multiple cells or proteins in separate streams, adds significantly to this functionality, as streams containing distinct information (cells, growth factors, serum) can be rapidly patterned without the placement of physical implements to separate the streams. Furthermore, patterning directly over cell cultures, or even certain regions of cells, is possible with this technique, which is perhaps its major distinguishing feature. For example, Takayama et al. were able to demonstrate selective labeling of mitochondrial subpopulations, as well as the disruption of actin filaments in specific cell regions, using a technique known as partial treatment of cells using laminar flows (PARTCELL) [49, 63] (Fig. 12.4). Thus, soft lithographic patterning can be utilized to specifically influence cellular organization and function, with the added functionality of biochemical and physical manipulation on the single cell level, which could be useful for developing regions within a tissue construct, whereby different cells would require certain nutrients at distinct spatial and temporal intervals.

Biomaterial surface engineering techniques based on soft lithography have been shown to provide controlled cellular environments with various biochemical cues for optimum tissue function and organization. Fundamental information concerning the influence of such signals on cellular phenotype and function have been made possible by these methods, which can employ SAM and direct cellular and/or protein patterning strategies to present complex biochemical information with high resolution. To translate the past decade of patterning cells and biomolecules on mostly planar surfaces toward work to develop functional tissues and organs, increased attention is needed regarding the amenability of these approaches on other biocompatible substrates. The investigation of other elastomeric materials as

stamps with varying properties may enable new approaches. The most commonly used material currently, PDMS, is a hydrophobic polymer, and thus is susceptible to protein adsorption unless surface-modified, and can slowly recover hydrophobicity even in that case [64]. Also, in addition to the hydrophobic properties of the material, the ability to produce quality patterns on the stamp, as well as the quantity of different nanopatterns to be produced using the same stamp, are major factors affecting reproducibility of the pattern and the scope of application of the technique. In addition, the true nanoscale resolution limit of most of these technologies has not been ascertained. However, as there is no wavelength-imposed limit as in other technologies, it is likely this limit will be suitable for nanoscale feature patterning, if not already suitable. The usefulness of soft lithography for presenting topological information has not been explored for the most part, although PDMS is easy to mold and could be used in studies of cell–substrate interactions in such a context. In addition, soft lithography could potentially be combined with other nanofabrication techniques to produce desired features such as grooves if necessary. Even though some questions the technology may raise, this family of methods is still a low-cost method of producing quality patterns of cells and proteins at potentially nanoscale resolutions on nonplanar substrates. Furthermore, improvements have been demonstrated in extending the types of materials that can be used for pattern transfer. Patterned agarose hydrogel stamps have been used in inking/stamping procedures, such as in the method employed by Stevens et al. to transfer osteoblasts to hydroxyapatite scaffolds [65]. Thus, soft lithography pattern transfer can be accomplished with wet stamps which enhance cell viability, likely without sacrificing much control over patterns produced. Further work will likely improve the resolution provided by rapid prototyping methods, and continued efforts concerning multilayered, multifunctional surfaces that present structurally-favorable cellular microenvironments using these techniques, especially laminar flow patterning of biomolecules and cells using parallel nonmixing streams, are capable of facilitating the development of novel tissue engineering devices.

## 12.5

### Polymer-demixed Nanotopographies

As discussed previously, highly specialized EBL techniques provide for the reproducible topological patterning of biomaterial surfaces, with biologically-relevant features such as grooves. However, such methods are time-consuming and expensive, and candidate surfaces and materials for EBL are limited. Accessible techniques for the high-resolution nanopatterning of biomaterial topographies at low cost are thus necessary to facilitate the progression of surface engineering strategies in tissue engineering fabrication. Recently, methods in surface engineering have been developed that exploit the bulk interactions between polymeric domains to produce a desired surface feature upon a substrate. By manipulating these phenomena, it has been demonstrated that surface *topologies*, in addition to surface

chemistries, can be patterned upon a surface. Here we discuss a concept known as polymer demixing, whereby the inherent immiscibility of a binary polymer system, when cast upon a surface, results in phase separation-induced surface features [66]. Polymer demixing is a process tunable by polymer selection, relative polymer proportions and solubilities within the common solvent, and solvent selection, and can be utilized to produce nanoscale topographies such as pits and hills of tunable height and depth on the 10s of nanometers. Polymer blends initially explored with this strategy include poly(styrene) (PS) and poly(methyl methacrylate) (PMMA), PS and poly(4-bromostyrene) (PBrS), and poly(n-butyl methacrylate) (PnBMA) [66–69].

Surface engineering strategies of high tunability are highly desirable in the field for achieving specific, reproducible surface features. With polymer demixing, polymer fraction composition is a determinant of the type of topology produced, whereas polymer concentration in the solvent mixture is the parameter governing topology size. For example, by varying a 60/40 blend of PS/PBrS in total concentrations of 0.5–5% in toluene, nanoscale island features of heights from 13 to 95 nm were produced [67]. Interestingly, this study showed that positive-phenotyped human endothelial cells elicited nanoisland height-specific cytoskeletal and morphological responses, with the slightest grade (13 nm) eliciting the most rapid cellular spreading, relative to flat surfaces and higher features of the same polymer blend. Filopodia were observed to be in contact with the nanoislands, and cell shape was arcuate, in agreement with *in vivo* morphologies, suggesting that nanofeature-presenting surfaces may provide a more natural cell phenotype than flattened surfaces, such as the tissue culture polystyrene commonly employed. The 13 nm features produced by this method were also tested for fibroblast response, and again a greater cellular response was observed on the nanoisland-laden surface compared with the planar surface of the same composition. In addition, gene expression as assessed by microarrays was significantly enhanced for hundreds of signals in response to the nanoislands, with the timing of upregulation being consistent with focal adhesion formation upon the surface structures [69]. As an extension to tissue engineering approaches utilizing tubular constructs, polymer demixing was recently applied to the inner lining of nylon tubing to develop nanoislands of 40 and 90 nm, which had profound effects on cell spreading and cytoskeletal organization [70]. Thus, the application of polymer demixing could have implications for the development of neural growth cone elongation conduits and vascular grafts, for the control of cell adhesion and morphology, as well as gene expression. In these preliminary studies it is apparent that nanotopologies on the 10s of nanometers directly influence cell shape, proliferation, and signal transduction. Collectively, polymer demixing studies complement EBL studies on cell–biomaterial surface interactions in reinforcing the importance of nanoscale surface information on cellular response. Also, this work demonstrates that topography as the dominating feature, rather than chemistry as the primary mechanism, can be tuned to control cellular adhesion and signaling.

New strategies to present tunable nanoscale topological features will undoubtedly be useful in tissue engineering device fabrication as the knowledge base

concerning optimum cell growth and function conditions is expanded to include in-depth nanoscale interactions. However, as technologies such as EBL and, in this case, polymer demixing are rather in their infancy in terms of biological applications there is considerable uncertainty of the extent of application of these technologies. The utility of polymer demixing in tissue engineering applications will depend on the number of biocompatible polymeric blends that can be induced by phase separation to form the desired structural features at the necessary resolution. If the ribbon and hill nanopatterns cannot be generated upon well-characterized biomaterials, it is unlikely that polymer demixing techniques can be utilized for tissue engineering, other than for the detailed study of cell–surface interactions in tissue engineering-like 3D constructs. However, phase separation techniques based on some different principles, such as *temperature*-induced phase separation (TIPS) [71], have been reported for developing relevant biomaterial constructs, in this case porous biodegradable polymer architectures. Therefore, additional parameters other than polymer–polymer and polymer–solvent interactions should be investigated for families of polymers to identify more relevant phase separations. In addition, future studies than address the combination of surface chemistries with these nanotopographies would be helpful and likely provide new insight on detailed nanoscale biochemical interactions, and also enable added features to this platform. For instance, while tall features were shown to be relatively inhibitory to cell adhesion, the grafting of cell adhesion peptides to the same feature might evoke a drastically different response in terms of cell spreading and growth rate. Nevertheless, polymer-demixed surfaces provide an interesting platform towards the study of nanotopography and its influence on cellular responses. The capability of reproducing *in vivo*-like cell phenotypes on an *in vitro* platform, as suggested by the arcuate morphology and structural changes of endothelial cells and the molecular expression profiles of fibroblasts on nanofeatures produced by this technology, could establish this technique as a correlative study tool to predict, for example, post-implantation responses. Of significance in this technology is the data gathered from cellular growth patterns on structures of varying height, which has some relevance should the same cells be patterned on 3D arrays in tissue engineering applications.

## 12.6

### Star-shaped and other Novel Polymer Structures

In addition to phase separation strategies, novel properties resulting from alterations in the polymeric structural configurations themselves have been of significant benefit in surface engineering approaches. Since polymers can be tailored to present functional groups on their surface, the density of that information on a given surface can be of critical importance to the evoked tissue engineering response, in the form of cell adhesion or spreading, for example. Star polymers, for example, are such a structure. They consist of a central core from which multiple branches of varying physicochemical properties emanate. By incorporating star-

shaped polymers onto biomaterial surfaces, the multivalency of the polymer can be exploited to present multiple surface chemistries, with a tunable number of branches and branch length, while the central core can impart its characteristic properties upon the whole surface.

Star-shaped architectures have been investigated in studies appropriate to tissue engineering applications. A promising application can be found in PEG-star architectures within hydrogel constructs. Initial studies by the Peppas laboratory concerning the utility of PEG star polymer hydrogels, for example, indicated that swelling properties of the construct could be adjusted by branch length, as well as the incorporation of acrylate moieties within the structure [72, 73], thus suggesting the utility of this approach in developing controlled-release tissue engineering surfaces, perhaps for the timely release of growth factors to encourage functional tissue development prior to or following implantation. In another example, star PEG coatings on titanium were explored for their utility of resisting nonspecific adhesion while promoting site-specific attachment of cells through a branch-conjugated RGD sequence [74], which illustrates the benefit of this approach in conferring added functionality upon titanium-coated implants in enhancing interactions and tissue integration with the surrounding environment, and reducing the adsorptive capacity of titanium for proteins, while also taking advantage of its mechanical stability in bioimplants. In other work to highly-tune cell adhesion on bioimplant surfaces, Griffith and coworkers investigated the utility of a “comb” copolymer consisting of a PMMA backbone with PEO branches, conjugated with varying RGD peptide densities. Surface film clustering of comb-presenting films either modified or unmodified with the peptide was demonstrated to be tunable for controlling cell–surface interactions [75–77]. The multifunctionality of star and comb polymers allows for incorporation of adsorption-resistant and adhesive surfaces within the same construct, and parameters such as the number and length of branches, and backbone/branch polymer composition, can be tuned, albeit with some difficulty, depending on the desired configuration, to develop complex surface arrangements of optimum density and spacing.

The degree of tunability of star-shaped polymer configurations appears to be very extensive, and the approaches used to make such modifications are diverse. In one example, such modifications are used to reversibly change the surface properties of a self-assembled film. Using a heteroarm star block copolymer of poly(2-vinylpyridine) and polystyrene, a self-assembled “brush” developed that could be tuned by solvent and pH-induced environments to present core–shell micelles with one of the two polymers on the surface. In addition to unimicellar interactions, lateral phase segregation was also observed for the monolayer, creating “dimple” and “ripple” morphologies, thus illustrating the development of an intelligent polymer coating with tunable, switchable surface chemistries and morphologies [78]. In another application, an amphiphilic diblock copolymer consisting of polystyrene and poly(ethylene oxide) (PEO) was synthesized in various star-shaped configurations, resulting in relative spreading and compaction of each polymer along the surface that were different than the linear form of the copolymer [79]. An exciting tuning approach highly relevant to star-shaped and dendrimer-branching poly-

mers is the concept of molecular imprinting. In this process, the polymerization step is accompanied by a “templating” step, in which the polymer and template, such as a biomolecule or metabolite-binding probe, are crosslinked. Extraction of the template, for example by hydrolysis, creates highly-specific complementary binding sites for the templating structure. The presence of multiple surface functionality sites on star and other multibranched polymers thus facilitates this approach to developing highly-sensitive recognitive networks, and has been exploited in the specific imprinting of porphyrin and glucose-based recognition systems [80, 81]. These works are interesting precursors to the development of smart multifunctional biomaterial surface constructs that are responsive to the changing conditions of the microenvironment. While molecular imprinting is generally considered a technology for drug delivery and biosensor applications, it is conceivable that such imprinting technologies incorporated into hydrogels could serve as specific biomolecule-recruitment devices that sort out serum proteins to capture the proper growth factors for the cells that are entrapped within the construct. Alternatively, such a technique could be used to recruit specific endogenous stem cells within a construct to generate new tissue *in vivo*, although the technology is in its infancy. Nevertheless, the versatility of star and other hyperbranched, nonlinear polymers makes them promising candidates for several tissue engineering applications in which the presentation of surface chemistries on the nanoscale level is required. Manipulation of the biomaterial itself in this manner may avoid the time-consuming optimization of process parameters used in other methods to achieve desired surface chemistries within biomaterial constructs.

## 12.7

### Vapor Deposition

In tissue engineering scaffolds or cellular and protein arrays for biosensor applications, patterns have been generated using the aforementioned photolithographic and soft lithographic techniques. These approaches may have limitations in the equipment and procedures involved, and/or the range of biomaterials that can be patterned. For instance, photolithographic equipment can be expensive, and soft lithographic fabrication techniques have been carried out primarily on gold and silicon substrates. Furthermore, PDMS, a common building block of microfluidic devices, nonspecifically adsorbs proteins via hydrophobic interactions, and does not express native functional groups for bioconjugation techniques [54, 55]. Thus, techniques adapted from the semiconductor industry have evolved that permit the thin film deposition of a wide variety of materials. Chemical vapor deposition (CVD) and related strategies, for example, are essentially a family of techniques that involve the chemical transformation of volatile gaseous precursors into thin films upon a substrate. The highlights of CVD that are relevant to biomaterial surface engineering are the capability of this technique to deposit various coatings (including multiple surface functionalities) on several substrates of varying composition and geometry. The process can be performed without catalysts and poten-

tially-denaturing solvents at room temperature. These advantages have encouraged the exploration of CVD technologies in the patterning of defined chemistries on substrates of complex geometries that might be considered candidate tissue engineering constructs.

We now illustrate the versatility of CVD-based approaches for the patterning of surface chemistries on various biomaterial surfaces. Lahann and coworkers have employed CVD polymerization of poly(2-chloro-para-xylylene) to homogeneously coat metallic stents, which permitted subsequent plasma treatments to significantly reduce platelet adhesion [82]. In addition, polymer deposition enabled the immobilization of a thrombin inhibitor on the stent to further reduce thrombogenicity [83]. This process addressed several shortcomings with previous attempts to coat Nitinol-based stents with polymers, such as the use of solvent-based defects, and the difficulty of evenly coating thin films below the micron scale. Thus, CVD is a potentially powerful technique for the coating of potentially thrombogenic or non-biocompatible metal surfaces with stable, evenly distributed functional polymer coatings for improving the performance and expanding the scope of application of existing materials. In other work by Lahann, CVD polymerization of functionalized poly(xylylenes) was applied for the thin film coating of steel, glass, gold, silicon, Teflon, and polyethylene surfaces, and, in conjunction with uCP, layer by layer (LbL) self-assembly was permitted for the controlled deposition of endothelial cells [84]. Therefore, the synergy of CVD with other patterning techniques for the spatial patterning of surface information is particularly of interest, as the benefits of soft lithographic pattern transfer techniques can be combined with the ability of CVD to pattern chemical functionalities on various surfaces. As further support that soft lithography and CVD polymerization can complement each other in the development of novel tissue engineering constructs, PDMS-based microfluidic devices themselves were functionalized on the luminal surface with the same functionalized paracyclophanes [85]. Reactive or nonreactive polymeric coatings of sub-100 nm thickness were homogeneously-deposited within the luminal surface of both straight and curved PDMS microchannel geometries [86] (Fig. 12.5), suggesting the potential of this technique in the ultrathin patterning of biofunctional groups within complex tissue constructs.

In addition to the capability of CVD techniques to deposit a given material on various substrates, the properties of the materials and surface chemistries that can be patterned are diverse as well, and are highly-relevant to bioimplant and tissue engineering applications. As a first example, by the CVD-based deposition of a photoactivatable surface chemistry upon a microfluidic channel, a template was provided for the spatially-controlled functionalization of both hydrophilic (PEG) and protein coatings in discontinuous arrangements [87]. In a second example, CVD-based thin film formation of poly(2-hydroxyethyl methacrylate) (HEMA), a biocompatible polymer with extensive biomedical applications, was observed to be a swelling property-tunable process by adjusting the partial pressure of a cross-linking agent incorporated into the vapor phase [88]. As a result, the deposited film had tunable crosslinking properties and could function as a hydrogel. Recently, the utilization of CVD for the deposition of thin films with chemically-tunable top-

Fig. 12.5. Chemical vapor deposition (CVD) of straight and curved PDMS microchannel geometries of a hydrazide-reactive coating. The channels were exposed to biotin-hydrazide followed by TRITC-streptavidin. Channel depth is  $75\ \mu\text{m}$ , channel width is  $100\ \mu\text{m}$ . (Reproduced with permission from Ref. [86].)

ographies suitable for biological applications was demonstrated by the fabrication of aligned carbon nanotube arrays on a silicon substrate for the promotion of fibroblast growth [89]. This example suggests that CVD can serve as the patterning method for powerful, exciting nanotechnologies, to allow exploitation of their unique properties, and thus CVD can play an important role in the fabrication of complex 3D architectures for tissue engineering scaffolds.

CVD techniques provide a mechanism for the homogenous deposition of thin films presenting surface chemistries for the specific patterning of cells and biomolecules. While its application has primarily been directed towards *in vitro* diagnostic assays, the variety of compatible substrates and deposition candidate materials suggest the substantial applicability of CVD for biomaterial surface engineering for *in vivo* devices. While many of the polymer coatings investigated for CVD of stents

and cellular patterning surfaces have not been associated with apparent cytotoxicity, more extensive *in vivo* studies would be welcomed concerning the biocompatibility of deposited polymer coatings, particularly with metallic stents, given the better characterized nature of that application. Given the well-deserved appeal of hydrogels in tissue engineering applications, it would also be desirable to attempt to expand the list of candidate polymer films that can be tuned to behave as hydrogels using CVD processes with suitable co-polymerization agents. The versatility of CVD for the solvent/catalyst-free deposition of multiple coatings and surface chemistries on various materials and geometries make it an attractive option for surface engineering applications, either alone or in conjunction with other known techniques such as photopatterning and soft lithography.

## 12.8 Self-assembly

We have discussed the utility of soft lithography in the patterning of cells and proteins on complex geometries. A technology that has facilitated this application (as well as photolithographic approaches) is the use of self-assembled monolayers (SAMs), namely alkanethiols, for patterning on gold and silver surfaces. These SAMs are known to pack onto a gold surface with nearly crystalline density. Thus, the properties of the SAM itself are assumed by the new surface, allowing for chemical tuning of the biomaterial. For example, through organic synthesis modifications, alkanethiols can be modified to present bioconjugation sites, such as carboxylic acid, or protein-resistant sites, based on the hydrophilic PEG moiety. Using uCP, alkanethiols have been patterned with resolutions of 200 nm [90]. uCP techniques have been routinely used to create alternating patterns of ECM proteins and cells, with adsorption-resistant surfaces in between them conferred by PEG groups. The surface properties of SAM-adsorbed surfaces can be analyzed by a host of techniques, such as ellipsometry, X-ray photoelectron spectroscopy, electron microscopy, and quartz crystal microbalance, thus enabling many standard quality control procedures in the development of biosensors and cell/protein arrays. In addition to nanoscale resolution, when combined with the molding properties of PDMS stamps, SAMs can be utilized in conjunction with soft lithography and other standard techniques to produce complex features of varying chemistry and topology [61].

Despite the highly-useful features provided by SAMs on these substrates, the overall utility in tissue engineering applications is unclear. While chemisorption of alkanethiols on gold is useful in studying fundamental interactions of proteins and cells on the nanoscale, there is limited application in using SAMs to produce patterns on other surfaces that are not noble metals. Furthermore, organic synthesis techniques are complex, with each functional group requiring its own set of synthesis protocols. Other SAMs, such as alkylsilanes on hydroxyl-presenting surfaces have been applied, but their synthesis is especially complex and its use is far less than alkanethiols for biological surface engineering applications. However,

the biocompatible aspects of gold make it suitable in several tissue engineering applications, and should a host of biomaterials, such as titanium, be modified with gold surfaces where needed for SAM-assisted surface engineering, then SAM associated-strategies can conceivably be employed to create high-definition patterns for *in vivo* applications.

The nanoscale assembly of cells, proteins, and biomaterials such as polymers achieved by multiple nanofabrication processes has been also accomplished by the exploitation of alternating layers of materials containing opposing charges or hydrogen bond donor–acceptor pairs. Layer by layer (LbL) assembly techniques have emerged as low-cost nanopatterning strategies upon which various surface chemistries and topographies have been patterned. The method is simple, can be used to pattern stable films upon various hard and soft surfaces of varying geometries, and can bear biological information at varying heights within the film, without disturbing the overall assembly of the LbL network [91]. The use of electrostatically-complementary building blocks has also facilitated the use of other nanofabrication technologies, such as soft lithography, by enhancing pattern transfer from a stamped mold.

Several examples indicate the potential utility of LbL for the development of complex tissue engineering devices. In a co-culturing application, negatively-charged hyaluronic acid (HA), deposited by lithography, and the adhesive protein fibronectin were co-adsorbed to a glass substrate, followed by the specific attachment of cells to the fibronectin. A second adsorption medium consisted of positively-charged poly(L-lysine) (PLL), which bound electrostatically to the non-cell-coated HA layer to “switch” the originally non-adhesive chemistry to a cell-adhesive moiety that was permissive for the attachment of a secondary cell type, thus demonstrating the simplicity of LbL for patterned co-culture applications [92]. In another application, discrete, multiprotein regions were patterned within the same substrate using LbL in conjunction with photolithography, demonstrating the utility of LbL for facilitating hierarchical assemblies of distinct information [93]. Another LbL-based technology, colloidal lithography, has shown to be a promising, versatile application. In this technique, nanospheres are self-assembled on any number of surfaces, and can be the template for lithographic or vapor deposition processes, or themselves can contain functional groups for patterning. Since the nanoparticles are highly uniform and size-tunable, and can be tightly-packed if needed, they are highly-versatile materials for several surface engineering applications in a tissue engineering context. Additionally, the capability of this technology for the simultaneous presentation of surface texture and chemistry has been demonstrated. Shastri et al. investigated a functionalized nanoparticle-based system for simultaneously modifying surface chemistry and roughness (topology) without altering bulk substrate properties, on hard and soft materials such as titanium and polyurethane [94]. In another study involving microparticles electrostatically adsorbed on multilayer polyelectrolyte films, adjustments involving RGD peptide density on the microparticles and the packing density of the microparticles on the film surface, a function of the patterning area, were used to tune surface chemistries and roughness, with profound effects on cellular morphology [95].

LbL-based approaches obviate the need for substrate-specific bonding agents, such as SAMs based on alkanethiols and organosilanes [96]. The compatible materials, be it the thin film to be deposited or the substrate, are endless due to the availability of oppositely-charged polyelectrolytes, and with colloidal assemblies, both surface chemistry and surface texture can be presented to the cellular environment on microscale dimensions. This is a rare feature in biomaterial surface engineering techniques, which typically can present surface chemistry or surface topology, but not both simultaneously. The technique can be inexpensive compared with existing nanofabrication techniques, and/or can complement them. The size of nano/microparticles chosen for the application can be selected to modify thickness and surface area available for bioconjugation. Surface chemistries can be confined to different depths of a 3D multilayered construct, which enables the development of complex environments needed for tissue engineering applications as the library of matrix biology expands to define ever more complicated cell–ligand signaling processes.

The self-assembly phenomena observed for alkanethiols and polyelectrolytes on surfaces can also be observed for biomolecules. Here, the monomeric building blocks of the biomaterial surface chemistry and topology are peptides or proteins, which associate with each other through various non-covalent interactions. This has been very useful for biological surface engineering, since proteins do not have the same biocompatibility issues associated with polymers or other synthetic materials. Furthermore, protein structure and alignment is of great interest to the biological community, and the fact that this field has developed extensively will enable tissue engineering applications that take advantage of protein structural morphology to present high-resolution information to cells. Proteins themselves are the nanoscale messengers of information to cells, providing signals in the form of chemistry and topology, and thus techniques that directly apply this information to surfaces are desirable.

Nanoscale features from biomolecules can be created by hierarchical, irreversible systems, such as those based on avidin–biotin stacking systems, or interchangeable complexations. Such strategies have been used to develop beta-sheet monolayers [97, 98], as well as peptide-based nanotube architectures [99, 100]. Spontaneous formation of porous networks by a set of peptide families yielded filaments of 10–20 nm, with pores 50–100 nm in size, with complex geometries [101]. Thus, various nanoscale chemistries and topologies are achievable with this strategy. Self-assembling peptides can be patterned using uCP, to control cell–cell interactions by modulating the peptide sequence and surface density. The self-assembled peptides may be further conjugated to cell-signaling peptides, such as RGD for example, to allow for methods that are focused on presenting a surface topology and chemistry simultaneously. As an alternative to hydrogels based on synthetic polymers, Mi [102] and colleagues have developed RGD-incorporated hydrogels by the self-assembly of proteins with the included sequence, in a process dictated by temperature and pH. The RGD incorporation enabled the binding and spreading of fibroblasts on the surface. While this is a feat achievable by other approaches, this work illustrates that it is possible to encode biological signals within proteins

that naturally assemble into modules, each consisting of similar or varying information. One can envision the modular construction of natural self-assembled polymeric architectures on a host of biocompatible surfaces to direct multiple processes such as cell proliferation, migration, and cytokine secretion, at the same time. Further tuning is possible, such as the mechanical properties of the self-assembled species, and the degree of self-assembly. For example, a peptide-amphiphile complex on the order of 6 nm developed by Hartgerink and coworkers have provided for a pH-tunable (and reversible) self-assembly mechanism, with reversible crosslinking of the complex tunable by disulfide bridges [103]. These features enabled the mineralization of hydroxyapatite on the complex surface in an orientation that resembled the collagen–hydroxyapatite alignment in bone. thus illustrating the advantage of using biomimetic structures based on biomolecule-based monomers.

As the enabling technology in this mode of self-assembly are the peptides themselves, then there is no particular substrate specificity. Any surface that allows the desired nanoscale self-assembly is then a candidate substrate for this approach, which makes the scope of application potentially quite extensive in tissue engineering applications. The ease with which biologists can synthesize recombinant proteins and peptides with functional domains, all without an appreciable reduction in normal protein function, makes self-assembled biomolecule arrays an exciting prospect that is also readily accessible.

In general, nanoengineering of surfaces based on self-assembly can be a very convenient approach. Ambient temperatures, no need for organic solvents, and the use of well-characterized films or biofilms for predictable, reproducible results are all potential features of this technique. As the number of bioactive agents that influence cellular and tissue function are elucidated, the number of potential biomolecular self-assembling candidates will likely expand as well. Future studies that investigate the synergistic effect of bioactive agents and surface topology (as initially achieved with colloidal-based approaches above) are warranted, as is the transition from protein patterning to viable tissue engineering constructs by extensive *in vivo* studies.

## 12.9

### Particle Blasting

An important challenge of surface engineering strategies for biomaterials is the modification of a surface to achieve sufficient surface free energies that are required for adequate cell adhesion, motility, and proliferation. Surface engineering of implants, commonly in the orthopedic and dental implant arenas, often employ sandblasting technology for the attainment of certain tunable surface morphologies. By varying the physical properties of the blast material itself, and the pressure with which it is ejected, surface topographies can be achieved for modulating various biological responses similar to those observed for topographies produced by

other methods. These techniques are generally applicable to a wide variety of biomaterials, and are relatively inexpensive.

Sandblasting techniques, while simple, can be readily applied to several well-characterized biomaterials and biomedical applications to modulate their biological response. An example can be seen with the sandblasting of PMMA, a widely-used material in bone cements and ocular applications, with alumina microparticles [104]. Compared to smooth PMMA, vascular and corneal cell adhesion was higher on roughened PMMA surfaces. The simplicity of sandblasting can also be applied toward the deposition of films in addition to surface texturing. By loading a sandblaster with hydroxyapatite powder, Ishiwaka et al., produced a high-strength bond between the powder and the titanium surface that was higher than titanium coated by electrochemical and electrophoretic deposition processes [105].

These examples illustrate the principle that surface roughness alone, whether patterned by the previously-mentioned techniques, or randomly distributed by simple sandblasting techniques, has a profound influence on the affinity of cells for biomaterial surfaces. Furthermore, to generate such topology to evoke the desired cellular response in terms of adhesion and organization, it may not be necessary to employ expensive, time-consuming steps, if simple and rapid techniques such as sandblasting can achieve the same effect. However, this technology is generally not suitable for advanced tissue engineering applications that require precise control of biomolecule and cell placement, since it does not provide for surface chemistry modifications, is random in topography distribution, and has not thus far offered fine nanoscale resolution. Furthermore, blasting particles can be embedded within the target surface, which may complicate biological applications. Nevertheless, there is utility of sandblasting for creating microscale surface topography at room temperature, without the need for chemical modifications (although acid etching steps often accompany it), and surface chemistry can also be deposited onto a surface using this technology. While its main applicability is directed toward orthopedic and implant dentistry techniques, and has not been extensively performed on most biomaterial surfaces not relevant to those fields, it is conceivable that particle blasting could be utilized for a broad range of tissue engineering devices. For example, controlled-release microspheres could be used as the blast material for a deformable hard substrate, to serve as a cell-supportive nutrient reservoir during cell seeding on titanium or polymer-coated implants, thus potentially providing both surface roughness and chemistry in the form of released biomolecules or surface functionalities (e.g., RGD).

## 12.10

### **Ion Beam and Plasma-guided Surface Engineering**

These are surface engineering techniques that provide mechanical and chemical alteration of a biomaterial surface, without negatively affecting the overall bulk properties of the original material. For decades, ion beam-related technologies,

such as ion implantation, plasma immersion ion implantation, and ion beam-assisted deposition, have been highly reproducible techniques for the modification of surface properties due to the degree of control provided over the process. Furthermore, these techniques and variations on these techniques have been utilized to modify the properties of many biomaterials in many ways, including the overall response of the biomaterial to *in vivo* environments. A plasma is generally defined as a mixture of gas in a reactor containing one or more charged and uncharged species, which can be energized/accelerated with an applied electric field. Ion implantation involves the bombardment of a surface with accelerated ions from an excited plasma. Superficial layers of the target material (generally  $<1\ \mu\text{m}$ ) are disrupted by the ions, and a host of physicochemical modifications occur as a result, depending on process parameters and intrinsic material and ion properties. The modifications generally do not “strip” material off the surface as may chemical treatment-based approaches or reactive ion etching, which makes this technique useful for enhancing biomaterials selected for their intrinsic properties. The ion-polymer interactions can strengthen the resultant material properties by the formation of crosslinks. Similarly, for metallic biomaterials, ion implantation can strengthen the original material without bulk modifications by the formation of alloyed species, such as that produced by titanium modification by nitrogen.

A main application of ion implantation strategies has been directed toward the improvement of titanium implants for integration with bone, a major tissue engineering arena. Titanium has long been utilized as a biomaterial due to its rigidity and biocompatibility. Several techniques such as those discussed previously have been carried out to enhance the bone-Ti interaction, such as with hydroxyapatite deposition. These endpoints can also be achieved with ion implantation methods. For example, implantation into Ti with sodium ions resulted in a complex that enhanced hydroxyapatite precipitation from a pretreatment solution, which led to improved cell densities relative to untreated surfaces [106]. An alternative route to hydroxyapatite deposition has been realized with ion implantation for enhancing osteointegration. Implantation of carbon ( $\text{C}^+$ ) and carbon monoxide ( $\text{CO}^+$ ) ions into titanium dental implants significantly improves bone integration, with stronger contacts between bone and implant made possible by covalent bonds not observed in the standard titanium oxide-bone interface [107]. Ion implantation techniques are also suited to the enhancement of other biomaterial interactions. Vascular smooth muscle cells seeded on fluorine-treated polystyrene was observed to have improved adhesion and survival characteristics. Ion implantation has also improved the endothelialization properties of polyurethane, polystyrene, and poly(ethersulfones) for the construction of vascular grafts [108–110].

Other related technologies are useful for surface engineering of biomaterials, by other mechanisms. Ion beam-assisted deposition (IBAD) directs the acceleration of ions toward a simultaneously-generated, vapor-deposited thin film on the surface. The deposited film then reacts with the ions, resulting in modified properties such as film density, texture, interfacial properties, and stress. This technique has been utilized to deposit bacteriostatic silver films on catheters, as well as sealant and

electrode coatings on polymeric substrates [111]. In response to the “line-of-sight,” serial modification limitations imposed by conventional ion beam technologies, a technique called plasma immersion ion implantation (PIII) was developed in the 1980s. This method enables the rapid implantation of complex geometries, and has been used to enhance the hydrophobicity of various polymers such as poly(tetrafluoroethylene) (PTFE), PDMS, and polyurethane, and to improve material properties of various metals [112–117]. Another technology, reactive ion etching (RIE), utilizes both ions and chemically-reactive species, to impart a chemical component to the primarily physical process. When the reactive species formed by the chemical component and the substrate surface is created, the byproduct can be removed by various means, such as the physical ejection of atoms from the substrate. For surface patterning applications, inductively-coupled plasma reactive ion etching (ICP-RIE) was utilized to etch 3D features in PMMA blocks for protein patterning and modification of the surface to resist nonspecific binding, thus obviating a nonspecific adsorption blocking step [118]. This variation on RIE allows for independent control of ion density and ion energy, to address the tradeoff between substrate damage and etching efficiency. RIE allows for tuning of both chemical and physical components, which are generally isotropic and anisotropic, respectively, to influence the detail of the etching process. Other plasma-based techniques for the etching, sterilization, and surface property modification of biomaterials are extensively reviewed elsewhere [119]. Of note are tetrafluoromethane plasmas for hydrophobic treatment of a surface, and oxygen and nitrogen plasmas for enhancing surface hydrophilicity.

Plasma-based techniques are a versatile method for the modification of many biomaterials, and are suited for developing new surface properties without substantially changing those of the background material, due in general to the low penetration of the bombardment species. Processes can be performed in dry conditions without harsh chemicals to tailor to a specific tissue engineering application, and the engineer has multiple tunable process parameters that can be modified to achieve desired surface properties. The technique is applicable to metals, ceramics, and polymers that may be used as biomaterials; in general, plasma treatments can enhance the biomaterial surface in terms of biocompatibility, biochemistry, tissue function, and mechanical properties, and are thus a key technology. However, caution must be exercised in process parameter optimization, such that undesired stripping of the surface and underlying layers does not occur. This is especially the case with new technologies such as deep RIE, which have etch rates far beyond single microns. In addition, these processes can be both expensive and hazardous, due to the equipment needed and the plasma compositions (e.g.,  $\text{Cl}_2$ ), respectively. Furthermore, ion interactions with a surface create a chemically-different species that must be independently evaluated (from the original polymer) for typical features, such as biocompatibility, etc. Nevertheless, this technology, due to the myriad of tunable parameters and candidate substrates, makes plasma-based treatments important for the development of biomaterial surfaces with novel properties.

### Sol–Gel Technology

In addition to a biomaterial featuring certain metrics, such as satisfactory biocompatibility criteria and appropriate tissue interactions (cell adhesion, low thrombogenicity, etc.), in many cases the porosity of the structure within specific macroporous and mesoporous ranges are critical to the success of the bioimplant. Cells and tissues require specific porous architectures characteristic of their *in vivo* environment for tissue ingrowth and fully functional regeneration. For bone tissue regeneration, long a main focus of tissue engineering, specific porous architectures are essential for cellular migration and vascularization with a steady influx of nutrients and molecular cues to facilitate the process. Sol–gel technology has served as a promising route to achieving such structures for various tissue engineering applications. This processing technique can be utilized to enhance the biocompatibility of biomaterial surfaces, can readily coat a number of surfaces, and forms chemically-stable coatings in physiological environments. Of particular interest are the sol–gel derived bioactive glasses. Several incorporations of sol–gel processes are described elsewhere in detail, but they generally involve the gelation of a nanoparticulate suspension into a continuous network. Following an “aging” step, the gel is dried to produce a glassy solid. The process enables the synthesis of materials with various physical properties, made possible by allowing the mixture of organic and inorganic materials within the same process.

Several applications of bioactive glasses illustrate the importance of this technique in creating mechanically stable, highly-functional tissue engineering constructs. Scaffolds based on bioactive glasses were shown to have compressive strength similar to trabecular bone, with pore diameters within the microscale sufficient to allow vascularization of regenerated tissue, as well as cell migration [120]. Furthermore, it was determined that the sintering temperature of the process was a determinant of mesoscale pore size, which had profound effects on the dissolution rate and hydroxyapatite layer formation, as well as the compressive strength of the material. The tuning of surface area, and thus dissolution rates, in tissue engineering scaffolds for bone is highly powerful, as it allows for a mechanism of tuning the implant to the natural bone resorption rate in the body. In another example, sol–gel processing was utilized to develop bioactive foams presenting amine and mercaptan groups to allow for biomolecule incorporation with similar mesoscale and macroscale porosity as the previous application [121]. Thus, these networks supportive of natural tissue ingrowth and vascularization can also be biofunctionalized to allow for appropriate molecular signaling throughout the interconnected matrix. In other applications, sol–gel processing has provided a method of making conventional biomaterial surfaces more biocompatible. Titanium surfaces coated with hydroxyapatite sol–gel layers were shown to exhibit a higher activity of osteoblast-like cells compared with bare titanium, with tunable surface dissolution rates achievable by the incorporation of fluor-hydroxyapatite [122]. Other coatings, such as PLGA and titanium oxide, have also been patterned on titanium

substrates using sol-gel processes, with cell adhesion on the sol-gel coated hydroxyapatite layer being higher than the plasma-sprayed substrate [123].

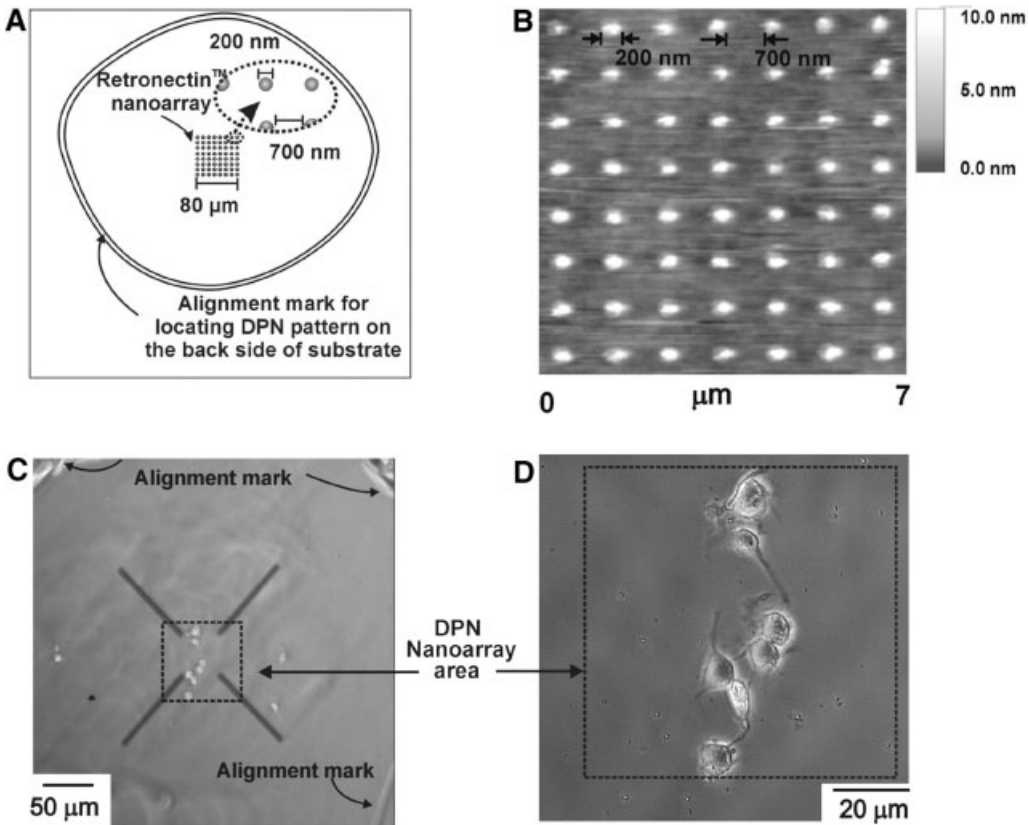

The low cost, favorable mechanical properties, and tunable nano and macroporous architectures made possible by sol-gel technology using a wide blend of organic and inorganic materials make it a promising surface engineering technique. With the added advantage of introducing chemical functionalities within the sol-gel processing steps, bone tissue engineering devices that utilize bioactive glasses and other sol-gel derived materials will benefit from the advances in bone tissue biology, which are already elucidating key molecules such as bone morphogenic protein (BMP-2), which have spatial and temporal distribution profiles that could be tuned by an implant for optimum tissue regeneration [124]. However, tissue engineering applications utilizing sol-gel processes would be enhanced by more extensive studies of the effects of process parameters on porosity of manufactured architectures for various composites. Further studies should also investigate the type of chemical functionalities that can be incorporated within porous architectures produced by sol-gel processes.

## 12.12

### Nanolithography

A family of surface engineering technologies has been developed to produce high-contrast and high-resolution nanoscale patterns for the purpose of readily integrating this information within novel BioMEMS and tissue engineering applications. Collectively known as nanolithography, these strategies include soft lithography, which has been discussed previously, as well as dip-pen lithography (DPN) and nanoimprint, or nanoindentation lithography (NIL). In DPN, an atomic force microscope (AFM) scanning probe is “inked” analogous to a PDMS stamp with specific information, in the form of SAMs, peptides, oligonucleotides, or other biomolecules, and patterned upon a solid substrate by capillary transport, to produce features as low as 30 nm [125]. Substrates tested with DPN have primarily included silicon and gold, with multiple inks. The major advantage of DPN is not only its nanoscale resolution appropriate for biology, but also its direct-writing capability inherent in the probe-based technology, which allows for single cell and potentially single biomolecule manipulations.

DPN is not an old technology, and thus direct tissue engineering applications have not yet been reported at the time of this writing. Most studies are focused on determining the species that can be successfully patterned using DPN, and have been reviewed by Mirkin et al. [126]. Of particular interest is the development of SAMs that function as DPN-sensitive resists for forming features on solid substrates as low as 25 nm. Proteins have been successfully patterned with DPN, with features as small as 45 nm, and cells have specifically-adhered to patterned protein recognition sites [127, 128] (Fig. 12.6). To address the serial nature of the process inherent in other techniques, several studies are in place to develop mul-

**Fig. 12.6.** Fibroblast adhesion to dip-pin lithography (DPN)-patterned retronectin (cell adhesion protein) arrays. (A) Fibroblasts were adsorbed onto a retronectin-patterned area of 6400  $\mu\text{m}^2$ . (B) Retronectin protein array. (C, D) Optical images of intact cells adsorbed on retronectin-patterned area. (Reproduced with permission from Lee et al. [126].)

tiprobe arrays for higher throughput DPN. While these developments are exciting for semiconductor and biosensor applications, the applicability of this technique for the surface engineering of biomaterials is not clear. However, gold-plated biomaterials, such as Au pits within titanium implants, can be readily manufactured using previously discussed techniques, thus enabling AFM probe access if an application is found. Also, it seems likely, based on the variety of inks that can coat an AFM tip, that DPN could conceivably be utilized to pattern living tissues or tissue scaffolds to construct cell–protein arrays with nanoscale precision. If such a feat was achieved, then single biomolecules and cells could be manipulated and oriented toward appropriate functional locations within a tissue engineering construct, not unlike that achieved with LGDW as discussed previously. Regardless of whether such a transition is made, further investigations concerning the dynamics of inking and ink transfer to a substrate are warranted to optimize the technol-

ogy. Various parameters govern this process, not limited to chemistry and geometry, which allow for some tunability in the process. However, the specialized equipment and conditions necessary to apply the technique will limit its accessibility to biological laboratories seeking patterning tools for hypothesis testing, although the embracing of DPN by industry carries with it the potential vision of developing high-throughput, accessible DPN methods for nanofabrication on order.

Similar to DPN technology, NIL is capable of resolutions down to 10 nm [129, 130]. In this technology, a silicon template generated by conventional patterning techniques serves as the template for a polymer (e.g., PMMA) elevated beyond its glass transition temperature, such that it is elastically deformable. Following a cooling step, the polymer assumes the pattern transferred by the mold. Several features make this technology very attractive over existing techniques, including DPN. The technology is not limited in resolution by beam parameters, requires no expensive equipment, and can be utilized in high-throughput processes for reproducible quality patterns. This was furthered by the development of air cushion press (ACP) technology to create more uniform pressures during mold imprinting (Nanonex Corp.). Furthermore, NIL is not as time-consuming as DPN and other beam-based serial technologies, and, like DPN, it is conceivable that single biomolecules could be manipulated with this technique. Thus, NIL is generally a user-friendly biocompatible technology that can be readily applied to surface engineering applications. Applications have included nanoscale protein patterning with preserved activity and high signal to noise ratios [131]. NIL has been combined with further processing steps such as self-assembly and RIE to create defined bioactive regions, thus demonstrating the synergy of NIL with various existing techniques [132]. Given the ultimate resolution of 10 nm for this technique, it could replace electron beam lithography for tissue engineering applications on a cost and biomaterial flexibility basis alone. However, not all materials can be manipulated by NIL, and until the full scope of candidate molding materials is investigated the true utility of the technique will not be fully realized. Furthermore, stamp fabrication can be a tedious process; in addition, the 10 nm resolution limit has not yet been realized for biological applications, and its suitability for most biomaterials has not been determined. Nevertheless, the NIL technique promises to be a flexible, low-cost, high-throughput technique for producing nanoscale features.

### 12.13

#### Laser-guided Strategies

The wide range of technologies discussed thus far have been associated with their own unique advantages and limitations, as there is no one size fits all approach in biomaterials surface engineering, in terms of patterning any surface with reproducible chemistries and topologies of perfect resolution for the application of interest. For example, EBL, plasma/ion beam, and photolithography are constrained by specialized equipment costs and lengthy procedures, whereas sandblasting techniques generally do not produce precisely repeatable features. We now discuss a

family of technologies based on lasers, which is a promising alternative to the above techniques for the tuning of various biomaterial surface properties. Potential advantages of this approach include high reproducibility, the potential for automated guidance systems, and various sources to choose from of different excitation wavelengths and power densities, which immediately suggests the potential of generating patterns of varying intensity in a manner not unlike a “maskless” grayscale photolithography. The wide availability and familiarity with lasers is also an enticing aspect in incorporating this technology in tissue engineering applications, as well as the potential to incorporate into existing methods, recalling the method of Holden et al. for laser patterning of multiple dye-labeled biomolecules using photomasks [10]. Lasers have been successfully applied to the surface texturing and patterning of polymers, biomolecules, and even cells, to a host of material surfaces.

The generation of surface topologies is possible with multiple laser types, due mainly to the material properties of the target surface. First, since many substances absorb strongly in the ultraviolet range of the spectrum, UV-emitting lasers can thus be used to successfully modify biomaterial surfaces without altering bulk properties, since the penetration depth is limited by the high surface absorption of energy. This feature enables two surface modification routes: (a) the etching of material through photoablation and (b) the nanopatterning of topologies, made possible by the low UV wavelengths of the lasers. Photomasks can be incorporated in patterning steps if necessary to facilitate the formation of certain surface features as described elsewhere. Technically, this process could be performed on any geometry, since the only requirements of this technology is that the laser beam is in contact with the surface to be patterned, and that the surface has chemical bonds that are photolabile at the illuminating wavelengths. Excimer lasers have been used for the photoablation of polymeric surfaces for over two decades [133, 134], and thus an extensive library is available concerning candidate materials and their responses to texturing. Other (higher-emitting) lasers for the patterning of either non-polymeric or low UV-absorbing materials have also been employed. An example is the Nd:YAG laser texturing of titanium surfaces [135]. In general photoablation does not require chemicals or specialized equipment other than the laser to achieve the basic task, although the technology seems capable of incorporating multiple added functionalities, such as computer guidance (discussed below), complex masks, and incorporation into device fabrication assembly lines for rapid, simultaneous patterning of multiple features. Despite the scope of applicability of photoablative techniques, recent studies have demonstrated that they do not possess the resolution necessary for BioMEMs applications when compared with dry etching methods [136], and thus, as with any technique, the geometrical features required of the application must be assessed for suitability with the method used to pattern them.

The same ablative nature of laser irradiation of surfaces has also been exploited to deposit polymer and other biomaterial films, using pulsed laser deposition (PLD) techniques. Laser light is directed inside a vacuum chamber, and several process parameters such as wavelength, power, and duration can be tuned to con-

control the vaporization of the surface material. Potential advantages of this technique are similar to those for texturing/etching using photoablation, such as the broad range of materials that can be ablated with laser irradiation. Furthermore, the tunability of process parameters and the high resolution (small spot size of irradiation) provides for an important control mechanism over the vaporization process. No chemicals or other catalysts (such as exogenous heating of substrate) are needed for PLD. This approach has been successfully applied to the layering of PTFE (Teflon) [137] and PMMA films [138, 139]. In addition, using protective detergent capsules, thin films of glucose oxidase were also formed by PLD, with preservation of activity [140]. While PLD provides for some biomaterial surface engineering applications, especially with polymer thin film deposition on complex geometries, it is difficult to extend its applications to keep up with the need for different scaffolds and bioimplants. Each PLD specimen requires optimized process parameters such that heating of the substance is not too substantial such that the polymer architecture is irreversibly damaged. Even more caution is required in the PLD-based manipulation of biomolecules and cells, and it is unlikely protective substances can safely encapsulate all such species while facilitating high-quality surface patterning. The lack of compatibility between biomolecules and UV irradiation is a limiting aspect. Nevertheless, the laser positioning outside of the vacuum chamber may provide for a favorable alternative to other film deposition techniques, in that the source orientation can be adjusted as needed, in addition to the other previously discussed process parameters that are user-tunable.

Recent approaches have been developed to circumvent some of the limitations of PLD. To improve laser-assisted film deposition methods, a technique called matrix-assisted pulsed laser evaporation (MAPLE) and its related direct-write counterpart (MAPLE DW) were devised, whereby the material to be deposited is dissolved in a judiciously-selected solvent and frozen; the complex is then irradiated to deposit the film of interest with removal of the solvent *in vacuo* [141]. With this system, exposure to laser irradiation is generally limited to the solvent capsule, which aids in preserving the integrity of the dissolved species. As an example, PEG films, which were damaged by direct UV irradiation, deposited using MAPLE were of favorable structural integrity for typical applications [142]. Interestingly, by encapsulating cells in a glycerol-based matrix, successful deposition with acceptable cell viability can be achieved with features  $<10\ \mu\text{m}$  [141]. In a fundamentally different approach to enhance the biocompatibility of laser-based processes with cells without the use of UV light, the exploitation of optical forces have been used to laser-guide cells to specific locations on substrates. Near-infrared light irradiation can exert tiny forces on the cells, the net effect of which is for cells to move toward the center of the beam and away from the light source. This technique, called laser-guided direct writing (LGDW) is capable of single-cell resolution patterning, and has been employed for the co-patterning of endothelial cells and hepatocytes within Matrigel constructs to create self-assembled 3D constructs with similar morphology to hepatic sinusoids [143] (Fig. 12.7). This technique has the advantage of “point and shoot” control of single cells to create multicellular arrays without a compromise in cell viability, as the irradiation source is not ultraviolet. Further-

**Fig. 12.7.** Laser-guided direct writing (LGDW) of cell patterns approximating liver sinusoids *in vitro*. (A) HUVECs deposited by LGDW. Cell elongation along the pattern was observed. (B) 24 h post-deposition, added hepatocytes surrounded HUVECs to form sinusoid-like structures. (Green – albumin, red – CD31 staining; bar = 200  $\mu\text{m}$ .) more, optical trapping could likely pattern cells on multiple surface types, provided there is an aqueous medium to support light guidance. Although the method is time-consuming, involving a cell-by-cell manipulation technique, theoretically, multiple laser arrays could be utilized for the guidance of multiple cells at once to form hierarchical organization of tissue. This method could be incorporated into advanced schemes that seek to optimize tissue structural and functional properties, for instance by the enhanced migration of a slow-moving cell type by added optical guidance.

Future applications of lasers in biomaterial surface engineering could potentially be in areas in which scale-up for mass production is necessary. Laser-based approaches could be exploited for the capability of modifying surface texture with one laser type, and performing film and biomolecule deposition with other wavelengths, in an assembly line-style fashion. This readily-accessible technology has already been successfully applied to the surface engineering of biomaterials with promising results in producing nanoscale and microscale features. However, a much more detailed investigation of the interface between lasers and biological materials/environments is necessary to expedite such a transition.

#### 12.14 Rapid Prototyping Techniques

The future of biomaterial surface engineering for tissue regeneration and bioimplant applications is highly dependent on the development of procedures for the nanofabrication of 3D cell-protein arrays that can be scaled-up for mass production. Early techniques that constituted the primary methods of scaffold fabrication, such as salt/porogen leaching, fiber bonding, and gas foaming, were not capable of

high-throughput, reproducible construction of multilayered, highly interconnected porous architectures of consistent structural and morphological characteristics [144, 145]. To this end, several rapid prototyping (RP) or solid freeform fabrication (SFF) techniques, some of which have already been described (such as MAPLE DW), have emerged to meet the need for high-throughput, reproducible construction of functional tissue architectures. Various RP approaches are related by the use of computational design and fabrication guidance, using CAD-based software. The 3D model of interest is designed on computer using CAD software, and linked instrumentation translates this data into a physical model on a layer-by-layer basis. The building blocks can be powders, liquids, or crystalline materials, depending on the instrumentation employed. RP, if proven to be (a) flexible in the candidate biomaterials that can be used, (b) reproducible in the patterns produced, and (c) capable of achieving tissue engineering-relevant features, will undoubtedly constitute one of the most significant milestones in the field, as it will enable the application of numerous designs and concepts gathered from decades of multi-disciplinary research into clinical practice using high-throughput, reliable manufacturing processes. Here, we discuss four interesting RP technologies that in initial stages have demonstrated utility in their potential to recreate useful tissue architectures: stereolithography (SLA), selective laser sintering (SLS), three-dimensional printing (3DP), and fused deposition molding (FDM).

Computer-guided manufacturing of tissue engineering devices has been explored for some time as the need to not simply design devices but to manufacture them was anticipated by many groups. One route to this goal has been achieved through laser-mediated technologies. For example, Mikos et al. have adapted commercial stereolithographic (SLA) technology for the 3DP of a scaffold using servomotor controlled, laser-based crosslinking of a polymer-photoinitiator composite layers upon a movable stage [146]. While the features produced were on the order of hundreds of microns, nevertheless the utility of CAD-CAM approaches for the manufacturing of clinically-useful biodegradable tissue scaffolds was demonstrated. SLA (and its improved-resolution derivative technology  $\mu$ SLA) has been applied with promising results in the manufacture of scaffolds incorporating polymers (e.g., PCL) [147] or ceramics [148] with improved microscale resolution, although the use of lasers presents potentially degradation problems as discussed below. Another laser-based commercial manufacturing technology applied to biomaterial surface modification is SLS. In this technology, a laser is directed upon a thin layer of powdered polymer. The heat generated at the surface, which is elevated beyond the polymer's glass transition, is capable of particle fusion, with some control over the pattern and microstructure generated. The 3D model within the CAD software contains slice-by-slice information that guides the laser rastering, scan speed, and intensity, while fresh powders are deposited above the fused layer for the formation of a new one. Early results concerning the use of SLS for polymeric scaffolds are mixed. SLS (as well as SLA) is a laser-based technique and, thus, the same issues concerning polymer degradation observed in laser applications discussed previously are equally applicable here. Degradative effects can include chain scission as well as photo-oxidation. Degradation was observed in the

application of SLS for the manufacturing of polyethylene (PE)-based implants [149]. However, SLS has yielded useful results in the fabrication of ceramic and hydroxyapatite-based devices [150]. For example, SLS process parameters such as laser scan speed and laser intensity were tuned to successfully fabricate polyetherketone (PEEK)–hydroxyapatite constructs for bone tissue engineering applications [151]. Thus, while the same precautions necessary in other laser-based nanoengineering strategies are applicable to SLA and SLS, the flexibility of the technique in accommodating a wide variety of materials and substrates is of particular significance, as well as the potential of the technique to be incorporated in computer-automated high-throughput and high-reliability manufacturing of tissue engineering scaffolds. For this technology to be successful in the surface engineering of biomaterials for clinical usage, work to study the influence of laser tuning parameters on the resulting morphology (e.g., porosity) and mechanical characteristics of the construct produced is necessary. The resolution of the technique will be limited by the wavelength of the laser used, and thus optimization of laser choice should be carried out to achieve the necessary spatial control during the production process. Additionally, the compatibility of these processes with existing methods to engineer surface chemistries is unclear, and should be addressed in future work. It seems feasible, however, to layer functionalized polymer microparticles as needed, or to possibly surface engineer functionalized moieties using other methods as each layer is constructed. The ability of the laser to not only crosslink polymers but to also initiate chemical reactions should be useful in developing SLS and SLA-based processes that incorporate biofunctionalization into scaffold construction. A potential advantage of this technique, which would allow such possibilities, is the amenability of this method for constructing tissues layer-by-layer, using local heating of the polymer in a room temperature environment, thus avoiding heating chambers, although “part bed” temperature is an adjustable parameter as needed [151]. Furthermore, organic solvents used in casting procedures are not necessary by this technique, which needs only a steady supply of deposited polymer microparticles as the starting material. The applicability of these techniques for manufacturing using the broad spectrum of biocompatible polymer-based biomaterials (i.e. those that can be synthesized in a powder form), followed by extensive *in vivo* investigations of scaffold performance, is certainly warranted given the promising results in preliminary work.

Another RP method that can be utilized in ambient temperatures is 3D printing (3DP), which uses essentially a specialized inkjet printer to deposit a binding solution layer-by-layer upon pre-deposited powder beds. Thus, any material that can be obtained in a powder form is a candidate for this technique if a compatible binder can be identified. Upon drying of the bed, unbound powder is removed. Key process control parameters in this technology are the size of the deposition nozzle and polymer microparticles (which dictate layer thickness), the type of binding solution utilized (biocompatibility, hydrophilicity), as well as the resolution step of the printer head. The binding material can be biocompatible, although several studies have used organic solvents as the binder [152]. Early work demonstrated the potential utility of 3DP for the manufacturing of biodegradable, functional polymeric

scaffolds for cell adhesion [153]. A multilayered osteochondral scaffold intended for tissue engineering of articular cartilage based on PLGA, PLA, and CaP was fabricated using 3DP with bone and cartilage-like regions of suitable porosity and layer mechanical characteristics within acceptable ranges for hard and soft tissues [154]. This study demonstrates the benefits of a high-throughput multilayering approach for building hierarchically-organized hybrid materials, with sections delegated to specific functions. A problem with 3DP that is especially relevant to the creation of porous scaffolds has been a difficulty with removing internally-embedded compounds, and due to incomplete fusion of polymer particles during the process, undesired micropores can develop that compromise the resulting integrity of the construct [152]. However, future investigations into optimal binders and polymers will likely overcome these issues. The success of 3DP technologies for the surface engineering of biomaterials will depend on work to study the capability of the technique to accommodate micro- and nanoscale features as needed for multiple applications, such as bone tissue engineering (for ingrowth, cell migration, and vascularization), as well as elucidation of polymers (and binder materials) that are compatible with this technique in a tissue engineering context. As with SLS, traditional surface chemistry modifications could be performed after the deposition of each layer to impart bioactivity or mechanical characteristics within the model, but efforts to incorporate such steps during 3DP would be welcomed. Also, as with SLS, the polymers must be supplied in powder-form to be compatible with the process. However, in contrast to SLS, because the whole process is performed without heat, it is possible that bioactive molecules or cells could be incorporated within the constructs, although this has not been extensively investigated. The capability of cell or protein co-deposition will depend on the use of biocompatible binders. This young technology has been licensed to several companies (<http://web.mit.edu/tdp>), and will certainly yield therapeutically useful constructs of sufficient mechanical and biochemical properties should the scope of compatible biomaterials be expanded.

Reproducible, porous scaffold architectures have also been generated by a related nozzle-based technique known as fused deposition molding (FDM). In this technology, a thermoplastic material is pumped through a heated nozzle to fabricate the device layer-by-layer. A z-axis stepper facilitates the process, and the nozzle diameter as well as the polymer melt thickness influences thickness (z-resolution). An advantage of this technique is the ability to deposit architectures that are porous in three dimensions by adjusting the horizontal distance between deposited filaments (fill gap). Initial studies are supportive of the utility of the approach. FDM was used for the fabrication of 3D interconnected porous and resorbable PCL scaffolds, with satisfactory biocompatibility and mechanical properties [155, 156]. Furthermore, tissue formation was demonstrated with osteoblast-like cells and fibroblasts within the construct, and the mechanical properties and porosity were controllable by process parameters. Similar positive results have been obtained with PCL/CaP and other polymer hybrid systems [157, 158]. However, the scope of FDM is limited by the amount of biomaterials that can be deposited in the manner described. Compatible materials must have the proper melt character-

istics that allow it to be extruded through the nozzle. Furthermore, FDM likely cannot be used to simultaneously deposit proteins or cells due to the melting process, as well potential viscosity modifications and nozzle clogging that would make the application very difficult. Z-resolution, as mentioned, is limited by the size of the extruded polymer filament. Nevertheless its application for PCL-based scaffolds warrants its further investigation, due to the favorable aspects of the polymer, such as its FDA-approved status and numerous tissue engineering applications that have already been investigated.

While each RP/SFF approach has its characteristic advantages and disadvantages, they each constitute major steps in the effort to rapidly and reliably produce functional tissue architectures. Given the wide variety of synthetic polymeric constructs that are compatible with these processes, the next step is to integrate these methods with natural polymers, such as ECM, which is underway in several laboratories. Furthermore, as many modifications such as surface chemistry are performed post-processing, the technology would greatly benefit from methods to incorporate such steps within the process itself when possible. Lastly, the further integration of SFF with established nanoengineering approaches discussed in this chapter will expand the capabilities of the constructs produced, especially if such nanoengineering can be performed following the deposition of each layer to develop highly-customized architectures. If these steps can be incorporated to some extent within these processes, the result will be a highly-tunable system for the development of “made to order” tissue engineering constructs that can be fabricated using CAD-based modeling that incorporates features specific to the patient’s needs.

## 12.15

### Conclusions

We have described both established and emerging biomaterial surface engineering technologies for the molecular-level presentation of information to cells. Each approach makes an overall contribution to the tissue engineering field by serving as a potential tool to tune the interfacial characteristics of a biomaterial for the optimal reconstruction of the tissue environment. The future will witness further advances in the effort to construct functional tissues with nanoscale precision through integrative strategies that control biochemical and topographical signaling, as nature-inspired developments in materials science continue to adapt to the criteria imposed by biology for recreating complex living systems.

# Nanomaterials for Medical Diagnosis and Therapy

## Contents

**Foreword** VII

**Preface** XXI

**List of Contributors** XXVII

<b>1</b>	<b>Nanotechnologies for Diagnosis – Present and Future</b>	<b>1</b>
	<i>Gareth A. Hughes</i>	
1.1	Introduction to Patient Diagnostics	1
1.2	Nanotechnology and Patient Diagnostics	2
1.3	Optical	9
1.3.1	Fluorescence	9
1.3.2	Quantum Dots	11
1.3.3	Surface Plasmon Resonance (SPR), Nanoparticles and Nanoshells	14
1.3.4	Fiber Optic Biosensors	19
1.4	Electrical	19
1.4.1	Nanomaterials for Enhanced Electron Transfer	20
1.4.2	Electrochemical Biosensors	24
1.5	Magnetic	28
1.6	Mechanical	30
1.7	Imaging Diagnostics	33
1.8	Nanotechnology-enhanced Tools	34
1.8.1	Analytical Tools	35
1.8.2	Raman Spectroscopy	35
1.8.3	Mass Spectrometry	36
1.8.4	Genetics	37
1.8.5	Immunoassays	39
1.9	Nanotechnology and the Future of Patient Diagnostics	40
1.9.1	Multifunctional Platforms	40
1.9.2	Real-time Monitoring	40
1.9.3	Multiplexed Diagnostic Assays	40
1.9.4	Point-of-care Diagnostics	41
1.9.5	Regulations, Risks and Ethics	42
	References	44

<b>2</b>	<b>Superparamagnetic Nanoparticles of Iron Oxides for Magnetic Resonance Imaging Applications</b>	<b>51</b>
	<i>Jean-Marc Idee, Marc Port, Isabelle Raynal, Michel Schaefer, Bruno Bonnemain, Philippe Prigent, Philippe Robert, Caroline Robic, and Claire Corot</i>	
2.1	Introduction	51
2.2	Physicochemical Characteristics	53
2.2.1	Physicochemical Properties of the Crystal	54
2.2.2	Hydrodynamic Particle Size and Charge	54
2.3	Pharmacology and Metabolism	56
2.3.1	Role of Physicochemical Parameters	57
2.3.2	Mechanism and Consequences of Interaction with Macrophages	58
2.3.3	Pharmacokinetics	59
2.3.4	Nanoparticle Vectorization	60
2.4	Current Clinical Uses and Future Developments	61
2.4.1	Gastrointestinal Tract Imaging	61
2.4.2	Liver and Spleen Diseases	63
2.4.3	Lymph Node Metastases	64
2.4.4	Blood Pool Characteristics	66
2.4.5	Characterization of the Atheromatous Plaque	67
2.4.6	Other Potential Uses	68
2.4.6.1	Stroke	68
2.4.6.2	Cerebral Tumor Characterization	68
2.4.6.3	Multiple Sclerosis	69
2.4.6.4	Arthritis	70
2.4.6.5	Infection	70
2.4.6.6	Kidney Imaging	71
2.4.6.7	Acute Cardiac Transplant Rejection	72
2.4.6.8	<i>In Vivo</i> Monitoring of Cell Therapy	72
2.4.6.9	T-staging of Uterine Neoplasms	73
2.4.6.10	MRI-detectable Embolotherapy	73
2.5	Conclusion	75

3.1	Introduction	85
3.2	Chemical Functionalization of CNTs	86
3.2.1	Noncovalent Functionalization	86
3.2.1.1	$\pi$ - $\pi$ Stacking Interactions	86
3.2.1.2	Hydrophobic Interactions	88
3.2.2	Covalent Functionalization	89
3.2.2.1	Defect Functionalization	90
3.2.2.2	Sidewall Functionalization	91

3.3	CNTs in Diagnosis	96
3.3.1	CNTs in FETs	97
3.3.1.1	Fabrication	97
3.3.1.2	FET Biosensors	98
3.3.2	CNT-based Electrodes	100
3.3.2.1	Fabrication	101
3.3.2.2	Nanoelectrode Biosensors	102
3.4	CNT Cell Uptake	105
3.5	CNTs as Delivery Devices for Antigens and Adjuvants	107
3.5.1	Interaction of <i>f</i> -CNTs with CpG Motifs and Potentiation of their Immunostimulatory Activity	107
3.5.2	Presentation and Immunogenic Potential of Peptide Antigens Attached onto <i>f</i> -CNTs	109
3.6	CNTs for Drug Delivery	111
3.7	CNTs for Gene Transfer	115
3.7.1	Interaction with DNA and RNA	115
3.7.2	Delivery and Expression of Gene-encoding DNA and RNA	116
3.8	Health Impact of CNTs	118
3.8.1	Parameters of CNTs Related to Health Impact	119
3.8.1.1	Purity	119
3.8.1.2	Solvents	123
3.8.1.3	Surface of CNTs	123
3.8.1.4	Length	123
3.8.2	<i>In Vitro</i> Effect of CNTs	123
3.8.3	<i>In Vivo</i> Effects of CNTs	125

## Preface

From the time the human mind emerged, about fifty thousand years ago, our understanding of the human body and of ways and means to protect ourselves better from both natural degradation as well as diseases has been continuously growing. The human mind has been responsible for triggering creative technological breakthroughs at different intervals, significantly improving our quality of life at each of these stages. We are again standing on the threshold of yet another technological mastery with the ability to create nanomaterials akin to natural sub-micron biomolecules for the protection of our body and to prolong its life. The purpose of this book, *Nanomaterials for Medical Diagnosis and Therapy*, is to reveal for the first time how man-made nano-sized materials are being judiciously combined with biological molecules in order to find hitherto unimaginable, superior diagnostic tools and novel therapeutic approaches to alleviate human suffering. Most of what you will read here will provide you with a broader perspective to how nanotechnology is going to revolutionize medicine in the close future. You are unlikely to get such a perspective reading individual articles from the scientific journals. This is the final volume in the ten-volume series on *Nanotechnologies for the Life Sciences (NtLS)* and in a way reflects the ultimate goal of all life scientists, with the other nine volumes as guide posts, to improve our health and quality of living. The book has sixteen chapters, covering all aspects of medical diagnosis and therapy except cancer as this subject is covered in volumes six and seven. With over 700 pages, it is the largest of all the ten volumes. Before I go ahead with giving you details of individual chapters in this final volume, I would like to take this opportunity to provide you glimpses of the information contained in the first nine volumes, which many of you may have already read.

The first volume in the series *Biofunctionalization of Nanomaterials*, with eleven chapters, dealt with various approaches to attach biomolecules to nanomaterials for applications in the life sciences, and the second volume *Biological and Pharmaceutical Nanomaterials*, with twelve chapters, focused on natural nanomaterials that are relevant to the life sciences. The ability to characterize systems in nanoscale is pivotal to the success of nanotechnology, and the third volume *Nanosystem Characterization Tools for the Life Sciences*, with eleven chapters, is a useful source of information both for life scientists interested in nanoscale systems and for characterization specialists interested in applying their tools in biological systems. The

fourth volume of the series, *Nanodevices for the Life Sciences*, contains thirteen chapters and is a compendium of the exciting possibilities that exist in the world of tiny devices. The fifth volume, entitled *Nanomaterials – Toxicity, Health and Environmental Issues*, reviews some of the critical risk assessment issues, which are crucial in life sciences, that are currently being investigated by the health & environmental nano researchers, and has twelve chapters. The sixth and the seventh volumes, *Nanomaterials for Cancer Therapy* and *Nanomaterials for Cancer Diagnosis*, with a total of twenty-two chapters, captured nanotechnological approaches for the treatment of cancer and their utility in developing tools and materials for sensitive and early diagnosis of this serious affliction. While the eighth volume, *Nanomaterials for Biosensors*, containing thirteen chapters, touches upon biomolecular sensing using a variety of Nanomaterials, the ninth volume *Tissue, Cell and Organ Engineering* with its twelve chapters is an encyclopedia on nanotechnological approaches to the engineering of biologically functional matter capable of serving as tissue or organ replacement. The ten volume series on *Nanotechnologies for the Life Sciences* with 122 chapters contributed by about 150 researchers across the globe totaling some 4600 pages comes to conclusion with the publication of the tenth volume.

This tenth volume begins with the chapter entitled *Nanotechnologies for Diagnosis – Present and Future*, which is a contribution by Gareth A. Hughes of Zyvex Corporation in Richardson, Texas, USA. In this chapter, a general discussion on various aspects of diagnostics including *in vitro* diagnostics (IVDs), implantable sensors and imaging techniques is presented in addition to touching upon regulatory and ethical considerations. Moving to a more specific diagnostic tool, authors lead by Jean-Marc Idée from Guerbet, Aulnay-sous-Bois, France, brings out the importance of Superparamagnetic Iron Oxide Nanoparticles (SPIONs) as contrast agents in Magnetic resonance Imaging. The chapter, *Superparamagnetic Nanoparticles of Iron Oxides for Magnetic Resonance Imaging Applications*, is a comprehensive source of information on the unique capability of SPIONs as contrast agents for MRI of the gastrointestinal tract, liver & spleen, lymph node, blood pool, and atheromatous plaque.

The third chapter, *Carbon Nanotube-based Vectors for Delivering Immunotherapeutics and Drugs*, reviews the application of carbon nanotubes in drug delivery and biosensing. Alberto Bianco and co-workers from the Institute of Molecular and Cellular Biology in Strasbourg, France, have done a commendable job in delineating the pros and cons of utilizing the unique property of CNTs, the penetration ability with capacity for high loading, for innovative medical diagnosis and therapies. The team lead by Soon Hong Yuk from Hannam University in Taejeon, Korea, contributed the fourth chapter, entitled *Core-Shell Nanoparticles for Drug Delivery and Molecular Imaging*. In this chapter, the authors focus on core-shell nanoparticle architecture with a layer of polymeric materials surrounding an organic or inorganic nanoparticle core, and demonstrate that such architectures provide improved stability and a sustained release pattern of protein drug and decreased cytotoxicity. In the fifth chapter, *Nanotechnologies for Targeted Delivery of Drugs*, various aspects of targeted delivery utilizing different types of nanomaterials are highlighted. Authors Pavel Brož and Patrick Hunziker from the Medical Inten-

sive Care unit of Basel University Hospital in Switzerland present successful targeting strategies employed that use both 'natural nanostructures' (such as bacteria and viruses) and 'artificial nanostructures' (lipid-based ones such as liposomes and micelles, protein-based ones such as dendrimers, and polymer-based ones such as nanoparticles, nanospheres and nanocontainers) in areas other than cancer.

The sixth chapter, *Nanoporous and Nanosize Materials for Drug Delivery Systems*, written by Yoshinobu Fukumori, Kanji Takada and Hirofumi Takeuchi from Kyoto Pharmaceutical University, Japan, covers application of a number of inorganic, organic and natural nanoporous materials in general and nanoporous silica-based materials in particular for medical therapy. Continuing on the theme of core-shell nanoparticles as described in a general way in the fourth chapter, Yoko Yamaguchi and Rie Igarashi from the Institute of Medical Science of St Marianna University in Kanagawa, Japan, present their efforts in the seventh chapter towards the development of a specific non-spherical core-shell product, NanoEgg<sup>TM</sup>, for dermatological applications. The chapter, *NanoEgg<sup>TM</sup> Technology for Drug Delivery*, describes the commercialization of these particles for overcoming the limitations of classical ATRA (all-*trans* retinoic acid) treatment through controlled release.

Polymeric nanomaterials have been receiving a lot of attention as materials of choice for both drug delivery as well as diagnostic tools due to their unique physicochemical characteristics that allow for controlling the fate of a drug within the patient. Three chapters, 8, 9 and 10, have been dedicated to bring out comprehensively the information present in the literature on different facets and types of polymeric nanomaterials for application in medical diagnosis and therapy. The eighth chapter, *Polymeric Nanomaterials – Synthesis, Functionalization and Applications in Diagnosis and Therapy*, a contribution from the laboratories of Rachel Auzély-Velty from the Centre de Recherches sur les Macromolécules Végétales (CERMAV) in Grenoble, France, focuses on 'frozen', non-dynamic polymeric nanomaterials, where an exchange between individual polymer chains and polymer chains of the nanoobject cannot take place, unlike the dynamic systems such as micelles and liposomes. On the other hand, the ninth chapter, *Polymeric Nanoparticles for Drug Delivery*, authored by P. Kallinteri and M. C. Garnett from the School of Pharmacy of Nottingham University, UK, brings out the physiology and anatomy underlying the diseases which may be treatable using polymeric nanomaterials and the way these are handled by the body. In the tenth chapter, *Solid Lipid and Polymeric Nanoparticles for Drug Delivery*, the authors José Luis Pedraz and co-workers from the University of Basque Country in Vitoria, Spain, present a comparative analysis of solid lipid nanoparticles (SLNs) and polymeric nanoparticles with reference to their production processes, characterization, and a wide ranging therapeutic applications.

Chapter eleven by Zach Hilt from the University of Kentucky in Lexington, USA, explores the relatively underdeveloped field of hydrogels. In this chapter aptly titled as *Intelligent Hydrogels in Nanoscale Sensing and Drug Delivery Applications*, the author has done a great job in providing an up-to-date review on the application of intelligent hydrogels such as ionic and temperature-responsive, biohybrid and imprinted hydrogels in micro/nanoscale sensing and drug delivery. In the twelfth chapter, *Nanoshells for Drug Delivery*, a layer-by-layer self assembly approach to

nanoshell formation is described in addition to the utility of nanoshells in controlled release of pharmaceutical ingredients. Authors Melgardt M. De Villiers and Yuri Lvov from the University of Wisconsin and Louisiana Tech University respectively, compare in a systematic fashion two types of nanoshells – metallic nanoparticles composed of a dielectric core (e.g. silica) coated with an ultra thin metallic layer (e.g. gold) and nanoshells formed by electrostatic layer-by-layer molecular self-assembling (E-LbL) for drug delivery applications. L. Andrew Lee, Hannah N. Barnhill and Qian Wang from University of South Carolina provide an overview on the topic of the programming of the Bionanoparticles (BNPs) and current research on their biomedical applications in the thirteenth chapter entitled *Bionanoparticles and their Biomedical Applications*. This chapter is a must-read for all those interested in BNPs and how they can be exploited for generating novel biotemplates in the nanometer range for a myriad of biomedical applications.

As we reach the end of the book, the last three chapters assume special importance. While chapter fourteen contributed by Hironori Nakagami, Yasuhiko Tabata and Yasufumi Kaneda from Osaka University, Japan, reiterates the importance of nanotechnologies in gene therapy, the fifteenth chapter, written by S. M. Moghimi from the University of Brighton, UK, cautions about the possible toxic effects of a well-known gene transfer vector. The titles of the two chapters are *Nanotechnology for Gene Therapy – HVJ-E Vector* and *Nanotoxicology of Synthetic Gene Transfer Vectors: Poly (ethyleneimine) – and Polyfectin-mediated Membrane Damage and Apoptosis in Human Cell Lines*, respectively. The final chapter by Gang Liu and Ping Men from the University of Utah in Salt Lake City, USA, entitled *Nanoparticles for the Treatment of Alzheimer's Disease: The Theoretical Rationale, Present Status and Future Perspectives* indicates that nanotechnology has potential to treat Alzheimer's disease (AD), the most devastating neurodegenerative disorder with progressive and irreversible damage to thought, memory and language. I am very confident that the information that is presented in these sixteen chapters in this tenth volume will help in furthering the utility of nanotechnological approaches in medical diagnosis and therapy. I am, as always, very grateful to all the authors for their scholarly presentations of their topics, providing timely inputs and corrections in making the final volume in this series a reality.

As I conclude this ten-volume series, I would like to reinforce some of the comments that I made in my preface to the first volume. As I said, nanotechnology's greatest gift to mankind, in my view, is its ability to promote lateral thinking amongst not only scientists, but all those who are associated with this new approach, the so called 'nano thinking' to problem solving. On behalf of all the authors who have made contributions to this exciting series, it is my privilege to play the role of a catalyst in inculcating this new thinking by providing a multi-pronged base of knowledge in nanotechnologies for the life sciences. It is my hope that this book series will help in stretching the limits of thinking in all those who come in contact with it.

It is yet another opportunity for me to convey my thanks to each and every person (unfortunately due to lack of space I am unable to mention all the names) with whom I had the privilege of interacting and who have helped me directly or in-

directly during the course of the publication of the whole series. I would like to express my gratitude to the following people for their support and assistance. My employer and colleagues at the Center for Advanced Microstructures and Devices, graduate advisor Prof. N.R. Krishnaswamy who laid the foundation to my career, family and friends, and the Wiley-VCH publishing team, Martin Ottmar, Esther Döring, Nele Denzau and Eva Wille, with whom I had great pleasure in working.

Finally, my special thanks to you, the readers, for ensuring that the knowledge base provided in this book series will be a building block for further understanding of nanoscience. I do realize that there is a lot of scope for improvement and need to add new topics to this book series. I am hoping that I will be able to, with your comments and suggestions, take this series to a new level in the near future.

October 2006, Baton Rouge

*Challa S.S.R. Kumar*

## Nanotechnologies for Diagnosis – Present and Future

Gareth A. Hughes

### 1.1 Introduction to Patient Diagnostics

This chapter highlights the capabilities of nanoscale materials and devices for patient diagnostics. Current state-of-the-art diagnostic applications in development are reviewed with an extensive list of references provided for further investigation. The chapter is broken down into four major areas: *in vitro* and *in vivo* diagnostics (optical, electrical, magnetic, mechanical), imaging diagnostics, nanotechnology-enhanced analytical tools and techniques for diagnostics, and the future for patient diagnostics. In comparison to other published chapters on the subject of nanotechnology for diagnostics, this chapter covers the gamut of diagnostics including *in vitro* diagnostics (IVDs), implantable sensors and imaging techniques. Finally, in addition to covering a variety of diagnostic tools and methods where nanotechnology can be implemented, regulatory and ethical considerations are briefly discussed, providing a foundation on which to build scientifically responsible nanotechnology developments for life sciences.

Patient diagnostics involves more than analyzing the symptoms of disease. Diagnostic tools and assays are used to determine tissue type prior to organ transplantation, to determine blood type for patients requiring blood transfusions, and to monitor the progression of disease and the effects of therapy. Diagnosing a patient prior to onset of any symptoms would be ideal. Catching a disease early would allow the patient to take appropriate precautions to slow, halt or possibly reverse the progression of the ailment. The ability to combine diagnostic testing with patient profiling such as a genetic screen could open up the possibility of personalized therapy. Table 1.1 lists examples of applications for patient diagnostics.

A variety of techniques and testing protocols are available for performing patient diagnostics. Many times, a combination of techniques or tests are performed to provide accurate diagnosis. Current diagnostic techniques include immunoassays, genetic-based tests, cell-based assays, tissue or histological tests and medical imaging. Immunoassays are used for numerous diagnostic applications including monitoring levels of endocrine hormones such as estrogen, cortisol and prolactin, detecting biomarkers following myocardial infarction such as troponin and myoglobin, diagnosing hepatitis A–E, and searching for various biomarkers for cancer.

**Tab. 1.1.** List of diagnostic applications.

---

Diagnose disease susceptibility, risk assessment
Infectious disease assessment
Tissue typing for organ transplants
Screening for blood transfusions
Monitor therapy activity
Check disease progression
Personalized medicine
Genetic screening

---

Genetic-based diagnostics involve a variety of analytical techniques and gene expression profiling to determine susceptibility of disease. Cell-based assays involve high-throughput cell sorting along with intracellular imaging techniques. Two of the major focus areas for tissue-based testing are in cancer detection and in tissue typing for transplant patients. A variety of medical imaging tools exist ranging from magnetic resonance imaging to ultrasound. Imaging methods provide non-invasive means to diagnose disease.

There are also numerous specialized diagnostic techniques that are used when symptoms exist that warrant the use of a particular test. Specialized diagnostic techniques include electromyography (EMG) for monitoring nerve and muscle activity, electroencephalograph (EEG) to assess electrical activity of the brain, electrocardiography (ECG or EKG) to monitor electrical activity of the heart, tonometry for measuring internal eye pressure and spirometry to measure lung function. A summary of examples for testing protocols and techniques which are used in diagnostics are listed in Tab. 1.2. A comprehensive resource for diagnostics is the *Merck Manual of Diagnosis and Therapy* [1].

## 1.2 Nanotechnology and Patient Diagnostics

This chapter will summarize diagnostic applications of nanotechnology currently being development. Life science and medical applications of nanotechnology are numerous, ranging from tissue engineering, drug discovery to drug delivery and diagnostics [2, 3]. Nanotechnology is enabling a variety of diagnostic methods, including optical, electrical, magnetic, electrochemical and mechanical, and is enhancing established methods such as biomedical imaging techniques and spectroscopic methodology [4–22]. Handheld, wearable and implantable diagnostic tools for real-time patient monitoring can be manufactured when comprised of devices and materials precisely fabricated at the nanoscale [23].

Functionalized nanoparticles can enable multiplexed bioassays for simultaneous diagnostic screening of multiple diseases [24, 25]. High-capacity screening and combined molecular and immunological diagnostics will play a role in establishing

**Tab. 1.2.** Examples of techniques and testing protocols used in patient diagnostics.

Diagnostic type	Tool or technique used	Example applications
Immunoassay	enzyme-linked immunosorbent assay (ELISA)	cancer detection allergy tests, immunoglobulin (IgA, IgE, etc.) levels hormone levels C-reactive protein (CRP) infectious diseases autoimmune diseases diabetes assays prion disease diagnosis pancrease function tests
	bead-based assays	multiplexed assays cytokine levels cystic fibrosis testing blood typing metabolic disorders
	radioimmunoassay (RIA)	hormone levels liver function tests viral detection
	fluorescence polarization immunoassay (FPIA)	kidney function tests homocysteine levels
Genetic	single nucleotide polymorphism (SNP) analysis	sickle-cell cystic fibrosis testing p53 mutation detection metabolic disorders pharmacogenomics drug efficacy
	DNA chips and microarrays	multiplexed assays cancer detection tuberculosis drug efficacy
	polymerase chain reaction (PCR)	DNA amplification infectious diseases inheritable diseases
	Northern blot	mRNA detection gene regulation analysis
	Southern blot	DNA detection inheritable diseases restriction fragment length polymorphisms (RFLP) for prenatal diagnostics

	electrocardiography (ECG or EKG)	heart electrical activity
	tonometry	glaucoma
	spirometry	evaluate lung function

a broader range of testing capabilities that will allow diagnostics to be not disease-specific, but patient-specific and support the development of pharmacogenomics [26, 27]. Ultimately, smart nanostructures such as nanoparticles, nanotubes and dendrimers could be fabricated with both targeting capability and therapeutic moieties enabling site-specific delivery of therapy and personalized medicine [28]. Table 1.3 lists diagnostic techniques enhanced or enabled by nanotechnology which will be described in further detail in this chapter.

Nanoscale entities are abundant in biological systems. Viruses, proteins, small molecule drugs and fluorescent dyes are all less than 100 nm, as shown in Fig. 1.1. Through the manipulation of organic and inorganic materials at the atomic level, novel materials, structures and devices can be realized. Thermal, optical, electrical and mechanical properties of materials can be enhanced. Novel properties, not observed in the bulk form of materials, can be harnessed. Chemical activity of substances can be tailored to a desired end use such as improving biocompatibility of implantable materials and developing artificial receptors for targeted analyte binding. Surface properties of materials, such as adhesion, can be modified. Properties of materials at the nanoscale can be quite different than bulk material properties. Due to greater surface area per unit volume, nanomaterials can exhibit higher chemical reactivity, increased mechanical strength, and faster electrical and magnetic responses.

The field of nanotechnology brings about the necessary convergence of technical disciplines such as physics, chemistry, engineering and computer science with the biological disciplines of molecular and cell biology, genetics, neuroscience, biophysics, and biochemistry. Through the convergence of all these disciplines, the field of nanotechnology is poised to create many breakthroughs across all industries. Medical applications show particular promise, including building blocks of

Tab. 1.3. Diagnostic techniques enabled or enhanced by nanotechnology.

Technique	Applications
Optical	enhanced fluorescence quantum dots surface plasmon resonance (SPR) nanoparticles nanoshells bio-barcodes Probes encapsulated by biologically localized embedding (PEBBLEs) fiber optics

Genetics	nanopore sequencing
Immunoassays	luminescent nanoparticles

nucleic acids as structural components as binding agents similar to antibodies rather than typical genetic maps, nanostructured biosensors for implantable patient monitoring and nanoparticles as imaging contrast agents.

Patient diagnostics can be broken down into three major modalities: assays, biosensors and imaging. Nanotechnology plays a role in improving these modalities and also creating novel diagnostic methods. *In vitro* assays are used extensively for diagnostics. Three commonly used assay formats are enzyme-linked immunosorbent assays (ELISAs), polymerase chain reaction (PCR)-based genetic assays, and staining assays such as Giemsa and Gram for viral and bacterial diagnostics. While many diseases and infections can be diagnosed with such assays, most of these assays require laboratory equipment. Point-of-care diagnostics are typically not possible using these assays. Samples are usually shipped to laboratories that

Figure 1.1. Scale of things, from atom to embryo.

specialize in performing these *in vitro* assays. Nanotechnology can improve these assays by increasing throughput for rapid diagnostics or by enhancing sensitivity which could enable catching a disease earlier.

Biosensors provide the ability to perform diagnostics at point-of-care and enable real-time diagnostics in the form of implantable devices. The general format of a biosensor, shown in Fig. 1.2, comprises of a biologically receptive site which binds specifically to the analyte in question and a transducer that translates the binding event into a measurable signal, which can be optical, electrical, magnetic or mechanical. Nanostructures can be used to enhance any of these transduction mechanisms. For example, nanoscale semiconductor materials (quantum dots) can be used in optical biosensors. In comparison to traditional organic fluorophores, quantum dots are much more photostable, have greater quantum efficiency and have much narrower emission. Such advantages could be used to develop highly sensitive optical biosensors and multiplexed assays. Due to high surface area, nanowires and nanotubes can greatly enhance charge transfer in biosensors based on electrical mechanisms. Functionalized magnetic nanoparticles can be targeted to desired analytes and detected with miniature magnetic sensors, creating portable diagnostics. Finally, nanocantilevers, modified with antibodies or other biological receptors, can be sensitive enough to detect a single biomolecule such as an individual viral particle.

Aptamers make up one particular class of biological receptor structures which show increasing potential for use in diagnostics. Aptamers are oligonucleotide sequences that are structured for high affinity and specificity towards a desired ligand, similar to antibodies, but formed from nucleic acids rather than amino acids. Since their discovery in the early 1990s [30] through the use of an *in vitro* technique named systematic evolution of ligands by exponential enrichment (SELEX),

Figure 1.2. Major components of a biosensor.

many aptamers have been developed that bind various targets including thrombin, platelet-derived growth factor (PDGF) and keratinocyte growth factor (KGF). Recently, an anti-vascular endothelial growth factor (VEGF) aptamer was introduced as a new treatment for macular degeneration. Developing therapeutic applications for aptamers is an expanding area of research.

Aptamers have several advantages over monoclonal antibodies which have likewise generated much interest in therapeutics. Aptamers are fully processed *in vitro*. Antibodies require an animal model as a starting point. Therefore, tight process control and scale-up are much more achievable for aptamer production paving the way for lower cost therapeutics. Aptamers, especially DNA aptamers, are much

Figure 1.3. Synthetic noradrenaline receptors [42]. Reproduced with permission from J. Am. Chem. Soc., Vol. 127, S. Kolesheva et al., Selective detection of catecholamines by synthetic receptors embedded in chromatic polydiacetylene vesicles, p. 10000–10001. © (2005) American Chemical Society.

more stable than their antibody counterparts, which are large protein molecules that can readily degrade if appropriate storage conditions are not used. Even if the aptamer does denature, the structure can be easily regenerated. Furthermore, aptamers have not shown any appreciable evidence of toxicity or immunogenicity. These same properties show promise for aptamers in the field of diagnostics, both *in vitro* and *in vivo* [30–38].

One strength of aptamer-based diagnostic sensors over antibody- or enzyme-based techniques is the ability to denature and regenerate the aptamer. This ability could enable reusable biosensors that match the affinity and specificity of antibody and enzyme sensors [37, 38]. Combining aptamer recognition with nanoscale sensing capability such as optical, electrochemical or magnetic transduction methods will enable development of highly sensitive, portable and, eventually, implantable diagnostic tools [39–41].

Medical imaging for diagnostics comes in a variety of forms including X-ray imaging such as computed tomography (CT) scans, magnetic resonance imaging (MRI), positron emission tomography (PET) scans, ultrasound and more recent optical techniques such as optical coherence tomography (OCT). The advantage of imaging over assays and biosensors for diagnostics is the elimination of the need for a patient sample, such as blood or tissue. In the case of implantable biosensors, imaging has the advantage of being noninvasive. However, most medical imaging equipment is expensive and requires trained personnel to both operate and interpret. Furthermore, the low resolution of most of these techniques limits sensitivity. Nanoparticles as contrast agents can be used to increase sensitivity which may allow earlier diagnosis of diseases. If sensitivity is greatly increased using contrast agents, then less-powerful imaging components, such as magnets for MRI, may be used reducing size and cost.

## 1.3

### Optical

#### 1.3.1

##### Fluorescence

Fluorescent tags, such as fluorescein isothiocyanate (FITC) and rhodamine, have been used extensively as optical markers for a variety of biological assays. Traditional fluorophores have a broad user base and are available in many forms such as voltage-sensitivity dyes, membrane-specific chemistries and pH-sensitive structures. However, traditional fluorophores typically have broad emission spectra, exhibit short emission lifetimes and are susceptible to photobleaching. With the desire for greater sensitivity, multiplexed assays, single-molecule detection and *in vivo* diagnostics, enhancement of traditional fluorophores and the development of novel markers are transforming optical detection methods.

Fluorescent tags can be improved by conjugation with receptor molecules, with coatings for improved photostability, and by combining with metals for greater emission. Figure 1.3 shows three synthetic receptors for noradrenaline which

**Figure 1.4.** Synthetic receptor embedded within a phospholipid/polydiacetylene membrane [42]. Reproduced with permission from J. Am. Chem. Soc., Vol. 127, S. Kolusheva et al.,

Selective detection of catecholamines by synthetic receptors embedded in chromatic polydiacetylene vesicles, p. 10000–10001. © (2005) American Chemical Society.

provide sensitive fluorescent assays when embedded with phospholipid/polydiacetylene membrane assemblies [42]. By embedding the synthetic receptor within the phospholipid/polydiacetylene membrane (Fig. 1.4), single micromolar detection of catecholamines in urine samples was achieved producing a 1000-fold improvement over existing synthetic receptor-based catecholamine detection systems. Such a sensitive method could provide an earlier diagnostic for Parkinson's disease. Also see Fig. 1.5.

Nanoparticle platforms consisting of surface-functionalized, silica-coated nanospheres can be used for bioimaging applications [43, 44]. Silica coating enhances aqueous dispersion of nanoparticles, and allows surface functionalization of peptides and nucleic acids for specificity. Fluorescence emission can be tuned by controlling the size of the nanoparticle. A range of nanoparticle sizes can be used simultaneously for multiplexed assays due to each size of nanoparticle emitting a different color. Due to little to no autofluorescence, the signal-to-noise ratio can be quite high, enabling highly sensitive bioimaging techniques for early diagnostics.

Dendrimers are highly branched, monodisperse polymers that have well-defined size and chemical functionality. Voids and channels within the dendritic structure can be carriers for drug molecules. Size, composition and morphology of dendrimer composites can be precisely controlled by pH, temperature and concentration. In addition to drug molecules, metal ions can be entrapped within dendrimer voids creating novel fluorescent nanoparticles [45]. Silver/dendrimer composites absorb in the 300- to 400-nm range with emission from 400 to 500 nm. By using low concentrations of silver/dendrimer composite (below 1  $\mu\text{M}$ ) to minimize cytotoxicity, intracellular fluorescent assays can be performed due to cellular uptake of nanoscale dendrimer structures.

**Figure 1.5.** Example of assay using nanoparticle tags [48]. Reproduced from *Nanotechnology*, Vol. 15, P. Huhtinen et al., Europium (III) nanoparticle-label-based assay for the detection of nucleic acids, p. 1708–1715, © (2004), with permission from Institute of Physics and P. Huhtinen.

Fluorescence can also be enhanced using metallic nanostructures such as silver or gold nanorods and nanospheres [46, 47]. Such phenomenon is termed metal-enhanced fluorescence (MEF). When a fluorophore is exposed to a nearby metallic surface, quantum efficiencies can increase due to interactions of the excited-state fluorophore with free electrons in the metal. At short distances between fluorophore and metal (less than 5 nm), quenching can occur. Highly sensitive *in vitro* diagnostic assays may be realized using MEF. Other metals that exhibit enhanced fluorescence are the Lanthanide series of metals or the “rare earth” elements such as europium, samarium and terbium [48, 49].

### 1.3.2

#### Quantum Dots

Quantum dots are nanometer-size crystals in which electrons are confined in all three directions. Electron energies are quantized within the nanocrystalline quantum dot enabling an array of emission wavelengths to be produced depending upon the band gap of the crystalline material and quantum dot size as shown in Fig. 1.6. Common quantum dot materials include CdSe which emits blue, InP which emits green and InAs which emits red [50]. Typical quantum dot cores are 3–4 nm in diameter; however, due to water insolubility and possible toxicity of typical cores, polymeric or silica coatings are added to make them water-soluble and biocompatible [51, 52]. ZnS is also a commonly used coating for CdSe core quantum dots for protection against photooxidation [53].

Coatings can increase quantum dot diameter to greater than 30 nm in some cases, creating a tag much larger than standard fluorescent dyes which poses challenges for intracellular delivery and creates potential alterations of the very biological activity that one may be investigating [55]. In addition to water insolubility and large size, quantum dots exhibit thermoquenching where emission decreases as temperature increases. For isothermal bioanalytical applications, thermoquenching poses no problems. However, for *in vitro* assays and, possibly, *in vivo* imaging

**Figure 1.6.** Emission wavelength as function of quantum dot size [54]. Reused with permission from H. Mattoussi, *J. Appl. Phys.*, 83, 7965 (1988). Copyright 1998, American Institute of Physics.

applications, where temperatures may fluctuate, thermoquenching effect must be taken into account.

Another limitation of quantum dots is their susceptibility to intermittent emission (“blinking”). Due to their high quantum efficiencies and the use of multiple quantum dots per typical assay, the effects of intermittent emission are negligible. However, where the “blinking” phenomenon becomes a limiting factor is with fluorescence intensity studies, single-molecule spectroscopy and flow cytometry where temporal data is necessary [53, 56, 57].

Despite the larger size, quantum dots are being used for multiplexed *in vitro* assays and *in vivo* imaging applications due to brighter and narrower emission, broader absorption spectra, and high photostability. Quantum dots have much narrower emission spectra (around 30 nm at half maximal emission) in comparison to organic dyes (50–100 nm), such as fluorescein and rhodamine. Due to their narrow emission and the capability of achieving emission over a broad excitation range, multiple quantum dots of different color can be imaged simultaneously using a single excitation source [58–60]. Typical organic dyes limit the ability to perform multiplexed assays because of their overlapping emission spectra and their limited absorption capability, requiring multiple excitation sources to be used when multiple fluorophores are desired.

Through surface functionalization by covalent, noncovalent and chemisorption modifications, quantum dots can be used in protein and DNA immunoassays. Biotinylated, streptavidin-conjugated and antibody-conjugated quantum dots are now readily available, enabling a variety of sandwich-based assays. It is the ability to functionalize quantum dots that make them attractive for diagnostic applications.

By encasing the core quantum dot nanocrystal with a biocompatible, hydrophilic, readily functionalized coating such as silica or polymer and modifying the coating with biologically specific entities such as antibodies, enzymes and nucleic acids, sensitive fluorimetric assays and biosensors can be realized. Assays and biosensors based on quantum dots are being developed for diagnosing breast and prostate cancer, for simultaneously detecting multiple toxins, and for sensing levels of acetylcholine [61].

For *in vivo* applications, it is desirable to have quantum dots that emit in near-infrared (NIR) range of 700–1550 nm, where such energy absorption in tissue is minimal. Example nanocrystalline materials for NIR quantum dots include CdTe, InP and InAs. CdTe-based quantum dots consist of a CdTe core with a CdSe shell which have lower quantum yields and weaker NIR absorption than InP and InAs quantum dots. InP quantum dots are larger (above 6 nm) than most other nanocrystalline structures which, after coating, limits their use for *in vivo* applications. InAs quantum dots are much smaller (below 2 nm), but have limited absorption capability in the NIR due to their small size [62]. Alloys and core–shell structures comprised of nanocrystalline materials improve NIR absorption capability while keeping the quantum dot to a functional size. Figure 1.7 shows the size distributions for InAsP, InP and ZnSe alloys, and core–shell quantum dot structures.

Figure 1.8 shows emission spectra for InP, InAs and InAsP alloy quantum dots. With increasing percentage of arsenic in the alloy, greater NIR luminescence is observed. Figure 1.9 shows the effect of the core–shell structure on emission. As the InAsP alloy core is coated with shell material, first with InP and finishing with ZnSe, the emission of the quantum dot is pushed further into the NIR range.

Another interesting phenomenon of quantum dots is the observation of fluorescent downshift (“blue” shift) when bound to bacterial surfaces [63]. By conjugating antibodies or aptamers to quantum dot surfaces, specific bacteria can be targeted. Upon binding of antibody- or aptamer-conjugated quantum dots to bacterial surfaces, shifts in fluorescent emission peaks ranging from 60 to 140 nm have been

observed which can be readily optically detected. This method could be used to determine the presence of bacteria in a sample.

### 1.3.3

#### Surface Plasmon Resonance (SPR), Nanoparticles and Nanoshells

Molecular-recognition molecules immobilized using self-assembled monolayers (SAMs) coupled with SPR sensing create sensitive, label-free biosensors [64–74].

Figure 1.10. Typical set-up for SPR [68].

A typical SPR set-up is depicted in Fig. 1.10, with main components consisting of a sensor substrate (chip) coated with a thin metal film (typically gold or silver), a polarized light source and an optical detection unit. Polarized light is directed toward the sensor chip at an angle such that an evanescent wave is created on the surface of the metal film. Changes in the dielectric constant of the adjacent medium shift the intensity of the evanescent wave, resulting in a change in angle of reflection from the metal surface. The angular shift is detected with a photodetector [70].

By modifying the metal film for biological specificity, the SPR sensor can be tailored to respond to a desired analyte. Upon binding of the analyte to the molecular-recognition site of the modified metal film, the index of refraction changes at the sensor surface, which results in an angular shift of the reflected light. The metal surface is typically first modified with alkane thiol or alkyl siloxane chemistry. Subsequent modification defines the biological specificity of the SPR sensor and can consist of streptavidin for biotinylated analytes, biotin for streptavidin-conjugated analytes or sandwich assays using free streptavidin followed by biotinylated analyte, antibodies for antibody–antigen interactions and enzymes or aptamers for affinity assays.

Using metal nanoparticles and nanoshells with SPR phenomena creates localized SPR (LSPR) which enables field-portable, lower-cost SPR systems with improved capability to detect small molecules, all of which could pave the way for greater use of SPR in patient diagnostics [69, 71–74]. An example of a LSPR set-up using gold-coated silica nanoparticles and a fiber optic probe for excitation and detection is shown in Fig. 1.11.

Optical properties of nanoparticles depend highly on size, shape and local environment. When the nanoparticle diameter is much smaller than the wavelength of light, then the optical interaction of nanoparticles can be described by Mie theory

**Figure 1.11.** LSPR biosensor set-up [71]. Reproduced with permission from Analytical Chemistry, Vol. 77, T. Endo et al., Label-free detection of peptide nucleic acid-DNA

hybridization using localized surface plasmon resonance based optical biosensor, p. 6976–6984. Copyright (2005) American Chemical Society.

of electromagnetic radiation scattering stated in Eq. (1) [69, 75, 76]. SPR occurs when  $\epsilon_r = -\chi\epsilon_m$  and  $\epsilon_i$  is small:

$$E(\lambda) = \frac{24\pi N_A a^3 \epsilon_m^{3/2}}{\lambda \ln(10)} \left[ \frac{\epsilon_i}{(\epsilon_r + \chi\epsilon_m)^2 + \epsilon_i^2} \right], \quad (1)$$

where  $E(\lambda)$  is the optical extinction (sum of absorption and scattering),  $N_A$  is the areal density of nanoparticles,  $a$  is the radius of nanoparticles,  $\epsilon_m$  is the dielectric constant of the medium,  $\lambda$  is the wavelength of the absorbing radiation,  $\epsilon_i$  is the imaginary portion of the nanoparticle dielectric constant,  $\epsilon_r$  is the real portion of the nanoparticle dielectric constant and  $\chi$  is the aspect ratio of nanoparticles ( $\chi = 2$ , for a sphere).

Probes encapsulated by biologically localized embedding (PEBBLEs) are optical nanosensors which can be used to monitor intracellular conditions such as pH and

**Figure 1.12.** Diagram of PEBBLE nanosensor [79]. Reproduced with permission from Analytical Chemistry, Vol. 76, Y.-E. L. Koo et al., Copyright (2004) American Chemical Society. Real-time measurements of dissolved oxygen inside living cells by organically modified silicate fluorescent nanosensors, p. 2498–2505.

calcium ion levels [77–79]. Fluorescent molecules are entrapped within a permeable polymer gel creating PEBBLE nanoparticles typically ranging from 20 to 200 nm, as represented in Fig. 1.12. The polymer gel coating protects the internal fluorophore from nonspecific protein binding and reduces cytotoxicity. Due to the porosity of the polymer coating, small ions such as calcium, oxygen and hydrogen can penetrate the coating, and reach the entrapped fluorophore. Therefore, pH- and calcium-sensitive dyes can be encapsulated while maintaining their desired function.

Single base-pair mismatches in a sequence of DNA can be detected using colorimetric assays comprised of electrostatic absorption of DNA onto colloidal gold nanoparticles [80–83]. Such assays eliminate target labeling and do not require any covalent modifications of DNA or substrate surfaces. Furthermore, sensitivity is high enough to obviate the need for DNA amplification such as PCR. Color detected is dependent upon degree of aggregation of gold nanoparticles. Due to the ability to perform the assay in less than 10 min, RNA degradation is minimized and, therefore, RNA sequences can also be determined.

Another technique which results in high sensitivity without the need for target amplification is the Bio-Barcode Assay (Fig. 1.13), which can be used for both nucleic acid and protein analysis [84–89]. The Bio-Barcode Assay uses both gold nanoparticles and magnetic microparticles functionalized with the same antibody specific for the particular analyte to be detected. Antibody-functionalized gold nanoparticles are further modified with oligonucleotide strands of a known sequence, giving the gold nanoparticles a unique identity or barcode. When exposed to the target analyte, both gold nanoparticles and magnetic microparticles bind to the analyte creating complexes of gold nanoparticle–analyte–magnetic microparticle.

**Figure 1.13.** Bio-barcode assay [6]. Reproduced from *Clinical Chimica Acta*, Vol. 358, K. K. Jain, *Nanotechnology in clinical laboratory diagnostics*, p. 37–54, Copyright (2005), with permission from Elsevier.

After the complexes are magnetically separated and washed, the barcode DNA is dehybridized and released from the gold nanoparticles into solution. The single-stranded barcode DNA is then collected and bound to a microarray containing oligonucleotides complementary to half of the targeted barcode DNA. Gold nanoparticles functionalized with oligonucleotides complementary to the other half of targeted barcode DNA are then hybridized to the microarray-captured DNA. Finally, the gold nanoparticles are coated with silver for amplification and the microarray is read using light scattering intensity measurements. The Bio-Barcode Assay enables detection of molecules down to attomolar sensitivity.

Aptamer-conjugated gold nanoparticles can bind desired protein targets forming gold-tagged proteins for subsequent analysis [90]. The bound gold nanoparticles can be enlarged in catalytic solution of gold chloride resulting in higher absorbance at 540 and 650 nm as the size of gold nanoparticles increases. An example using thrombin as target protein is shown in Fig. 1.14. A greater concentration of protein binds more aptamer–gold nanoparticle conjugates, which provides a greater surface density for catalytic solution to deposit more gold. Observed absorbance then is a function of protein concentration. Sensitivity down to single nanomolar protein concentrations have been achieved with this method.

**Figure 1.14.** Aptamer-functionalized gold nanoparticles for binding assay amplification [90]. Reproduced with permission from J. Am. Chem. Soc., Vol. 126, V. Pavlov et al., Aptamer- functionalized Au nanoparticles for the amplified optical detection of thrombin, p. 11768–11769. Copyright (2004) American Chemical Society.

#### 1.3.4

#### Fiber Optic Biosensors

Fiber optic biosensors show potential use in intracellular assays and *in vivo* applications [91–95]. Modifying the distal tip of the optical fiber to create a biologically active surface allows for binding events or reactions at the distal tip surface to be monitored optically through fluorescent or spectroscopic (IR and Raman) methods. An example of a modified optical fiber tip is shown in Fig. 1.15. Due to containment of the reactive species to the fiber tip surface, localized detection of the desired analyte can be achieved. Furthermore, highly sensitive diagnostic devices could potentially be developed by combining fiber optic biosensors with nanoparticles or nanoshells for amplification of optical response (i.e. LSPR or surface-enhanced Raman spectroscopy).

### 1.4

#### Electrical

Electrical methods to measure analytes include amperometric, conductimetric and potentiometric techniques (Fig. 1.16) [96]. Amperometric techniques utilize a working electrode containing chemistry, typically an enzyme, specific to the analyte being monitored. A voltage potential is set up between the reference electrode and the working electrode. Products from the binding of the analyte to the surface chemistry of the working electrode become oxidized or reduced depending on the voltage potential between the electrodes. Electrical current is measured at the work-

**Figure 1.15.** Surface modification of optical fiber distal tip [95]. Reproduced with permission from *Analytical Chemistry*, Vol. 77, T. Konry et al., Optical fiber immunosensor

based on a poly(pyrrolebenzophene) film for the detection of antibodies to viral antigen, p. 1771–1779. Copyright (2005) American Chemical Society.

ing electrode providing a method to determine the presence and concentration of the analyte. Conductimetric techniques measure the conductance of the analytical solution as a function of the analyte concentration. Measurement electrodes can be modified with biological receptors concentrating the analyte near the electrode surfaces. Potentiometric techniques are based on field effect transistor devices in which the current flowing between source and drain is affected by analyte concentration. Voltage is monitored as the current is affected providing a method to measure analyte concentration.

#### 1.4.1

#### Nanomaterials for Enhanced Electron Transfer

Nanomaterials, such as nanotubes and nanoparticles, can enhance electron transfer and can be readily modified for biological specificity [97, 98]. Integrating nanomaterials with microfabricated electrodes and circuits, enable portable, miniature instrumentation. Using electrical methods of detection eliminates the need for enzymatic amplification techniques typically used in optical detection assays. Due to the use of electronics, amplification and signal conditioning can be integrated within the assay substrate.

**Figure 1.16.** Electrical detection methods [96]. Reproduced from *Advanced Drug Delivery Reviews*, Vol. 56, R. Bashir, *BioMEMS: state-of-the-art in detection, opportunities and prospects*, p. 1565–1586, Copyright (2004) with permission from Elsevier.

Multiwalled carbon nanotubes (MWNTs) can be functionalized with single-stranded DNA. When exposed to the complementary DNA, after target hybridization, charge conductance through the carbon nanotube changes indicating binding of the cDNA [99]. MWNTs can be selectively grown on electrode surfaces coated with nickel catalyst. A conformal  $\text{SiO}_2$  layer passivates the exposed substrate between MWNTs. Ethylene glycol-modified siloxanes can be deposited onto the oxide surface to inhibit nonspecific binding. Finally, siloxanes can be selectively removed

from the MWNTs through electrochemical etching, exposing the MWNT surface for subsequent functionalization with single-stranded DNA (Fig. 1.17). The cycle of siloxane removal from selected MWNTs followed by single-stranded DNA functionalization provides a method to produce dense arrays of different single-stranded DNA probes.

Target DNA, extended with additional guanine bases, is exposed to the MWNT array and allowed to hybridize. The additional guanine produces a small current when electrochemically oxidized. The current generated is transferred to the MWNTs, which transfer the charge to the underlying electronic circuit for eventual signal acquisition. Due to generation of a very small current, electrocatalytic amplification of guanine oxidation current can be achieved using polypyridyl complexes of ruthenium (Fig. 1.18) or osmium.

Nanowires fabricated from semiconducting single-wall carbon nanotubes (SWNTs), silicon and zinc oxide can be integrated into field effect transistors (FETs) [100], and functionalized for biological specificity enabling rapid, label-free, detection of small molecules [61, 65, 101, 102]. The ability of FET devices to sense

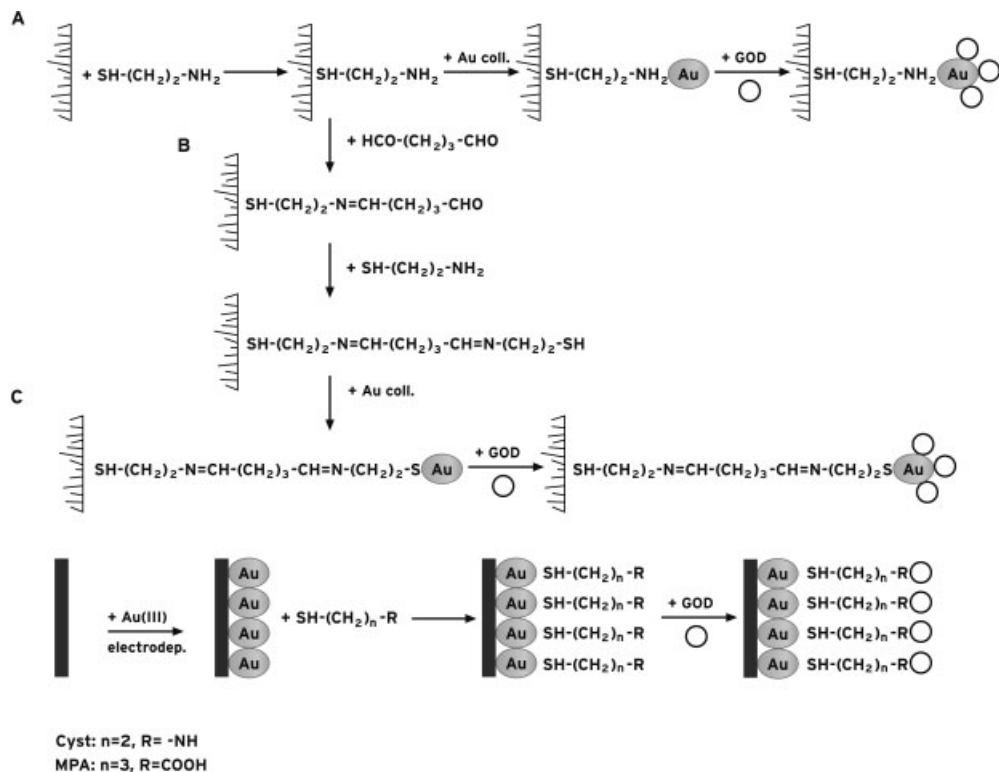

**Figure 1.18.** Electrochemical detection of nucleic acids with electrocatalytic amplification by ruthenium-polypyridyl complex [99]. Reproduced from *Clinical Chemistry*, Vol. 50, J. E. Koehne et al., Minutized multiplex label-

small molecules is due to a change in surface charge upon adsorption onto the gate material of target molecules. Nanowire FETs consist of functionalized nanowires as the gate material deposited or placed between transistor source and drain (Fig. 1.19). Such a physical arrangement produces devices highly sensitive to electrical changes. Due to the high surface area to volume of nanowires, extremely minor surface charge changes may be monitored, possibly enabling detection of single molecules.

biosensors, P. Yanez-Sedeno and J. M. Pingarron, Fig. 1. © (2005) with kind permission of Springer Science and Business Media.

#### 1.4.2

##### Electrochemical Biosensors

Low-cost, portable, fast-response diagnostic systems can be realized with electrochemical biosensors [103]. Glucose biosensors based on glucose oxidase are one of the most common diagnostic tools currently available. Electrochemical DNA analysis has also been widely investigated [104]. Aptamers can also be immobilized onto electrode surfaces and be used in electrochemical sensing systems [105–107]. To enhance charge transfer and to improve immobilization of enzyme or target, nanostructures such as carbon nanotubes and metallic nanoparticles can be used in conjunction with immobilized enzymes to form high specificity and high sensitivity biosensors. Due to their large surface area, nanoparticles provide enhanced adsorption of DNA and enzymes over flat surfaces which are typically used in microarrays and immunoassays [108, 109]. Biosensors can be created by linking silica or gold nanoparticles carrying immobilized DNA or specific enzyme onto gold electrodes. Electrochemical impedance analysis can be used to monitor hybridiza-

**Figure 1.21.** PMP complex [110]. Reproduced from *Current Applied Physics*, Vol. 5, T. Haruyama et al., *Bio-, nano-technology for cellular biosensing*, p. 108–111, Copyright (2005), with permission from Elsevier.

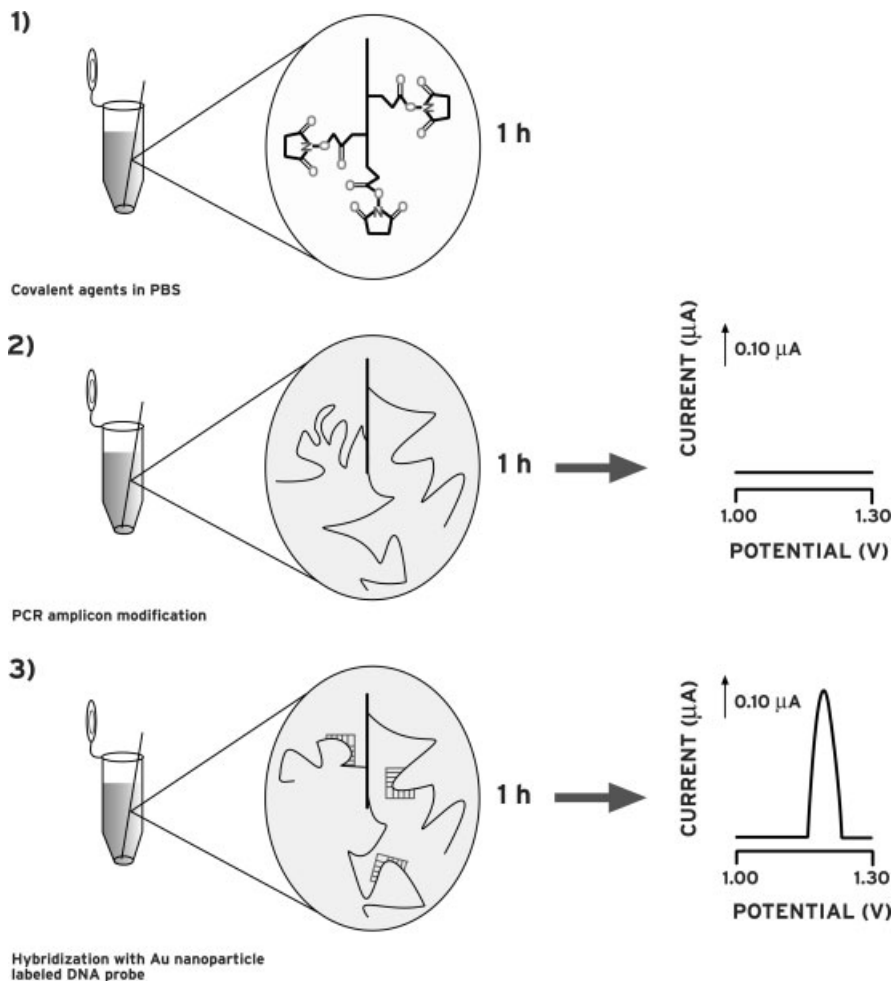

tion of cDNA or enzyme activity. Several methods for using gold nanoparticles to enhance enzyme-based diagnostic assays are shown in Fig. 1.20.

Through self-assembly of two or more different polymers with metal ions, thin films with nanoscale cavities can be formed (Fig. 1.21). These polymer–metal–polymer (PMP) complexes can be tailored for biochemical specificity and be used as amperometric transducers for electrochemical assays [110]. PMP complexes can be readily spin coated onto metal electrodes for biosensor formation. Another advantage of PMP films is their cellular compatibility. Cells can be cultured directly on the surface of PMP film allowing for cell-based diagnostics to be performed.

Electrochemical detection of DNA hybridization opens up the opportunity for low-cost gene mutation and single nucleotide polymorphism (SNP) analysis. The portability of such genetic sensors (genosensors) provides exciting possibilities for clinical use. Multifunctional gold nanoparticles is one platform that can be used in electrochemical genosensors [111]. First, target single-stranded DNA is immobilized onto the working electrode, such as a pencil graphite electrode (PGE), of the electrochemical cell. Thiol-terminated oligonucleotides, of the sequence to which the target DNA is to be compared, are then added to solution containing gold nanoparticles. The DNA-immobilized working electrode is immersed into the solution which now contains oligonucleotide-functionalized gold nanoparticles and gold oxidation is measured using differential pulse voltammetry which produces an electrical current depending on degree of hybridization (Fig. 1.22). A perfect match produces the highest current. A single point mutation is discernible due to lower current being generated. The absence of hybridization still produces some current, but much less than the single point mutation.

Many electrochemical reactions can be enhanced through electrocatalytic amplification using electron-transfer mediators. These mediators help transfer of

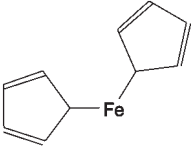

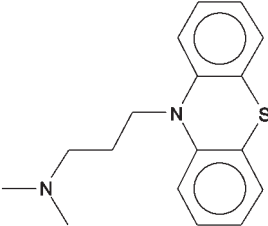

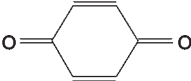

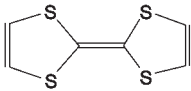

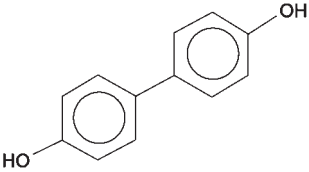

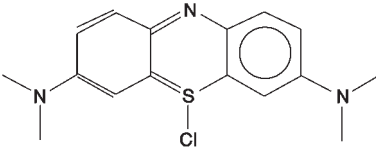

**Figure 1.22.** DNA hybridization detected electrochemically with gold nanoparticle probes [111]. Reproduced with permission from *Analytical Chemistry*, Vol. 75, M. Ozsoz et al., Electrochemical genosensor based on

colloidal gold nanoparticles for the detection of Factor V Leiden mutation using disposable pencil graphite electrodes, p. 2181–2187. Copyright (2003) American Chemical Society.

electrons between the working electrode and the enzymatic reactants, essentially creating a molecular conduit to shuttle electrons. Without electron-transfer mediators, many of the electrons produced by enzymatic activity may be lost due to diffusion. Methods utilizing electron-transfer mediators involve coimmobilizing them with the enzyme in a conductive polymer matrix, inorganic sol-gel or carbon paste [112–115]. Several frequently used electron-transfer mediators are listed in Tab. 1.4.

Precision assembly of materials is routinely achieved in biological systems through use of proteins. One particular nanostructure formed by bacteria is a monolayer of crystalline proteins called an S-layer. These crystalline proteins can

Tab. 1.4. Examples electron-transfer mediators.

be removed from the exterior of bacteria, resuspended in solution and allowed to self-assemble on solid support surfaces such as silicon, metal or polymer. The self-assembled S-layer monolayer can be modified with enzymes or antibodies for analyte specificity. Optical or electrical measurements can then be used to detect the presence of binding analyte. One such diagnostic tool is an S-layer dipstick shown in Fig. 1.23 [116–118].

**Figure 1.23.** Filtration membrane modified with protein A immobilized on S-layer for antibody functionalization.

## 1.5 Magnetic

Ferrite nanoparticles can be coated with gold (Fig. 1.24) or silica which can then be functionalized with targeting molecules. Antibody-conjugated magnetic nanoparticles can be used to tag proteins for magnetic immunoassays [119]. Using magnetic methods to report binding could enable multiplexed assays to be performed on chip-based substrates.

Genomagnetic nanocaptors are silica-coated, magnetic nanoparticles functionalized to bind with RNA or DNA [121]. Molecular beacons, e.g. loop–stem structures of single-stranded oligonucleotides, can be bound to magnetic nanoparticles to enable capture of single-base mismatched DNA and target mRNAs for intracellular gene expression analysis (Fig. 1.25) [120, 122]. In comparison to linear single-stranded DNA typically used in hybridization assays, the loop–stem structure of molecular beacons provides greater discrimination between perfect match and single-base mismatched DNA [123].

Combining molecular beacons with magnetic nanoparticles, single-base mismatched DNA can be magnetically separated (Fig. 1.26). Genomagnetic nanocaptors (GMNCs) colabeled with molecular beacons perfectly complementary and single-base mismatched to target DNA can be dispersed within a mixture of sample DNA to be analyzed. Both perfectly complementary DNA and single-base mismatched DNA will bind to the molecular beacons on the surface of the GMNCs which can be magnetically separated from solution. Due to the differences in melting temperature for each of the DNA complexes, complementary DNA can be separated from single-base mismatched DNA.

For intracellular applications, magnetic nanoparticles can be coated with cell-penetrating peptides [124]. One class of protein which has been used for efficient cellular internalization is membrane translocating signal (MTS) protein which include HIV-1 tat protein and VP22 herpes virus protein. Other cell-penetrating peptides include penetratin and transportan. These cell-penetrating peptides and proteins show promise as effective carriers to transport impermeable nanoparticles

across cell membranes. Functionalized magnetic nanoparticles may also be internalized through magnetofection – the application of external magnetic to attract magnetic nanoparticles into the cell (Fig. 1.27) [125–127].

Similar to chip-based electrical methods for biological analysis, sensors based on magnetic nanoparticles could also be used for benchtop and handheld diagnostics. For instance, arrays of DNA probes can be immobilized on surfaces as in DNA chips. Biotinylated complementary target DNA can then be hybridized with the DNA probes on the chip followed by washing of the substrate to remove unbound DNA. Streptavidin-functionalized magnetic nanoparticles can then be exposed to the chip, resulting in the capture of magnetic nanoparticles to target cDNA [120]. The capture sites can be detected with underlying magnetoresistive, spin valve or magnetic tunnel junction sensors which produce signals based on changes in the magnetic field [128]. The magnetic field above the sensor is perturbed due to the presence of bound magnetic nanoparticles. See Fig. 1.28.

## 1.6 Mechanical

Biosensors based on mechanical transduction methods include cantilevers [129–133], surface acoustic waves (SAWs) [38] and quartz crystal microbalances [134]. These mechanical structures can be mass-produced using combination of photoli-

**Figure 1.27.** Magnetofection [126]. Reproduced from *Biological Chemistry*, Vol. 384, C. Plank et al., The magnetofection method: using magnetic force to enhance gene delivery, p. 737–747, Copyright (2003), with permission from Walter de Gruyter GmbH & Co. KG and C. Plank.

thographic, micromachining and thin film techniques. As the capabilities of these techniques continue to be improved, nanoscale mechanical structures, such as nanocantilevers, can be fabricated. The advantage of making mechanical structures with nanoscale dimensions is their resulting ability to respond to extremely small mechanical stimuli such as molecular binding. For example, nanocantilevers can be used to detect subfemtograms of material. A single viral particle on a nanocantilever produces a measurable response.

Biosensors based on nanocantilever structures can be fabricated by modifying the cantilever surface with biological receptors such as antibodies, aptamers and complementary DNA. Upon target binding, the cantilever will deflect if operating in static mode or its resonant frequency will shift if operating in dynamic mode. Deflection of the cantilever is typically monitored optically by focusing a laser onto the cantilever and measuring deflection with a photodetector (Fig. 1.29), similar to an atomic force microscope (AFM). Although static mode cantilevers perform better than the dynamic mode due to mechanical damping of the resonating cantilevers, as the cantilevers are reduced to the nanoscale measuring the deflection becomes challenging while resonant cantilevers become much more sensitive to mass loading. Therefore, most nanocantilever biosensors operate in dynamic mode.

**Figure 1.28.** Biosensor based on magneto-resistive arrays [120]. Reproduced from *Materials Today*, Vol. 7, P. Gould, Nanoparticles probe biosystems, p. 36–43, Copyright (2004), with permission from Elsevier.

In dynamic mode, the resonant frequency of the nanocantilever can be monitored with optical methods as described above or with electrical methods such as capacitive or piezoelectric. The binding of additional mass results in a downshift of the resonant frequency as indicated by:

$$\frac{1}{f_1^2} - \frac{1}{f_0^2} = \frac{\Delta m}{4\pi^2 k}, \quad (2)$$

where  $f_0$  is the initial cantilever resonant frequency,  $f_1$  is the resulting cantilever resonant frequency after binding,  $\Delta m$  is the mass of analyte bound to the cantilever and  $k$  is the spring constant of the cantilever. The spring constant for a rectangular cantilever is expressed by:

$$k = \frac{Ewt^3}{4L^3}, \quad (3)$$

**Figure 1.29.** Typical optical measurement of cantilever deflection [130]. Reproduced with permission from Nickolay V. Lavrik, *Review of Scientific Instruments*, 75, 2229 (2004). Copyright 2004, American Institute of Physics.

where  $E$  is the Young's modulus of the cantilever,  $w$  is the cantilever width,  $t$  is the cantilever thickness and  $L$  is the cantilever length.

Using techniques based on semiconductor fabrication methods, nanocantilevers can be batch-fabricated in large volumes (hundreds to thousands per substrate) establishing potential for low-cost manufacturing. Nanocantilevers can be individually functionalized such that arrays can be formed providing multiplexing capability. With the use of electrical readout methods instead of optical methods, low-power portable cantilever-based diagnostic systems could be realized.

## 1.7 Imaging Diagnostics

Medical imaging diagnostics include MRI, PET, CT, OCT, optoacoustic or photoacoustic tomography (OAT or PAT) and NIR imaging. Nanoparticles containing hundreds of contrast agents can greatly enhance the sensitivity of these imaging methods [24, 122, 135, 136]. Examples of MRI contrast agents include gadolinium-diethylene-triamine-pentacetic acid (Gd-DTPA) and superparamagnetic iron oxide particles (SPIOs). Ultrasound contrast agents are designed to affect the propagation of sound waves in the surrounding sample area by altering the acoustic properties. Liquid perfluorocarbon nanoparticles and liposomes are examples of ultrasound contrast agents. Due to the small scale of nanoparticle contrast agents, the body does not quickly clear them, which prolongs the time that can be taken during imaging for a more thorough diagnosis.

Noninvasive detection at the single-cell level may be possible with nanocarriers loaded with contrast agent and functionalized with biological receptors specific to the desired cell. Such sensitivity could greatly improve early disease detection.

Nanocarriers could include liposomes, dendrimers or porous polymeric nanoparticles. Multifunctional nanocarriers combine biological specificity with the ability to use multiple imaging modalities. For instance, crosslinked iron oxide (CLIO) nanoparticles have branched structure which facilitates complexing with targeting entities such as enzymes or aptamers in addition to attachment of fluorophores or quantum dots [137]. Therefore, magnetic nanoparticles which function as MRI contrast agents can be modified to target a specific cell type and can be simultaneously monitored optically due to addition of optical tags.

An advantage of optical imaging methods over MRI, PET and CT is the potential of manufacturing lower cost imaging equipment. Lasers and optical (for OCT and NIR) or acoustic (for OAT/PAT) detectors are relatively inexpensive in comparison to large magnets and X-ray machines. One drawback of optical imaging is tissue absorption and reflection of photonic energy. Nanoparticle contrast agents that possess greater absorption than surrounding tissue or produce enhanced luminescence when irradiated can help alleviate tissue effects. Another advantage of using optics for imaging is the ability to guide the optical path with fiber optics, as in endoscopy, enabling internal imaging of vasculature, deep tissue and possibly the brain.

Optoacoustic or photacoustic tomography uses optical irradiation to induce localized thermal perturbations in the absorbing tissue [138]. Thermal vibrations produce acoustic waves which propagate from the underlying tissue to the skin surface. Acoustic detectors on the surface of the skin pick up the resulting acoustic waves. Optically absorbing gold nanoparticles can be used as contrast agents for optoacoustic imaging [139]. By controlling shape and structure, nanoparticles can be designed to optimally absorb at a desired wavelength. Simultaneously using optically absorbing nanoparticles of various designs that are each targeted to different cell or tissue types could provide a means for multiplexed bioimaging.

Gold nanoparticles as small as organic fluorophores can be irradiated with NIR and produce luminescence from lower excitation intensities than typical bioimaging fluorophores. Gold nanoparticles are also highly photostable (an advantage over organic fluorophores) and do not produce significant blinking (an advantage over semiconductor quantum dots). Furthermore, gold nanoparticles are easier to fabricate than quantum dots, can be readily modified for biological specificity and exhibit very low toxicity. All of these characteristics show promise for gold nanoparticles as an enabling technology to achieve single-molecule *in vivo* imaging for early diagnostics [140].

## 1.8 Nanotechnology-enhanced Tools

Although nanotechnology promises to develop novel diagnostic methods, current tools and methods can also benefit. Analytical instrumentation such as IR and mass spectrometers are widely used tools which are breaking into patient diagnostics. Enhancements of these instruments and techniques using nanotechnology should further this potential. Genetic-based techniques such as PCR, sequencing and gene chips are being made more affordable and more portable. Even standard

immunoassays can be improved upon using multivalent nanoparticles to improve the signal-to-noise ratio.

### 1.8.1

#### **Analytical Tools**

Analytical chemistry techniques such as IR and Raman spectroscopy and mass spectrometry are widely used in life sciences – from pharmaceutical process monitoring to drug discovery. Due to the versatility of these techniques, diagnostic applications are being developed. As discussed earlier, IR spectroscopy, especially in the near IR region, is being used in diagnostic imaging. Raman spectroscopy, with its ability to perform analysis in aqueous samples and less-stringent requirements on sample preparation, is especially promising for diagnostics with the potential for single-molecule detection using Raman enhancement techniques. Finally, mass spectrometry as the gold standard in analytical chemistry and proteomics is already being investigated for use in breath diagnostics and shows potential for diagnosis progression of disease based on protein profiles.

One drawback with using IR, Raman or mass spectroscopy for diagnosis is the need for specialized equipment and trained personnel to operate the equipment. Such equipment is typically situated in separate laboratories, requiring samples to be shipped for analysis. Lower-cost and easier to use equipment may open up the possibility of having analytical spectroscopic techniques at the patient bedside. One advantage of these techniques over biosensor or assay-based diagnostics is their nonspecialization. Biosensors and assays are typically formulated to detect a particular analyte of interest. Enzymes, antibodies, aptamers and complementary DNA strands are all used in biosensors and *in vitro* assays, making the sensors or substrates specific to the target in question. This specificity limits the ability of such diagnostics to detect a multitude of targets unless an array of sensors or substrates are prepared, each with their own specificity. Furthermore, one needs to have an idea of what to target for the biosensor or assay to be useful. Spectroscopic techniques are not target specific, but provide a fingerprint, or spectral signature, based on the chemical profile of the sample. The resulting fingerprint is compared to a database to find matches which delineate the chemicals that exist in the sample. This provides a powerful mechanism to analyze unknown samples and to simultaneously detect a multitude of analytes.

### 1.8.2

#### **Raman Spectroscopy**

One of the challenges using Raman spectroscopy is the weak Raman signal that is generated from the sample being interrogated. The use of more powerful lasers for excitation combined with sensitive detectors has helped Raman spectroscopy become more widespread. For diagnostic use, powerful lasers are not always practical, so another way to improve the Raman signal is to enhance the interaction between the optical excitation and the sample. Two techniques used to enhance

Raman signal are surface-enhanced Raman spectroscopy (SERS) and tip-enhanced Raman spectroscopy (TERS) [141–147].

For SERS, gold or silver nanoparticles are most commonly used to amplify the Raman signal. These nanoparticles can be used within living cells to amplify weak Raman signals from intracellular moieties, enabling the tracking of such entities without the need for fluorescent tags. Nanostructured tips, typically less than 50 nm in tip radius, are used in TERS. These tips can be AFM cantilever tips or scanning tunneling microscope (STM) tips coating with thin gold or silver film. SERS and TERS techniques amplify the Raman signal by establishing resonance between the applied optical field propagating through the sample and the surface plasmon waves propagating through the metallic nanostructures. The potential for single-molecule detection within living cells using SERS or TERS could open up the opportunity for early detection of disease.

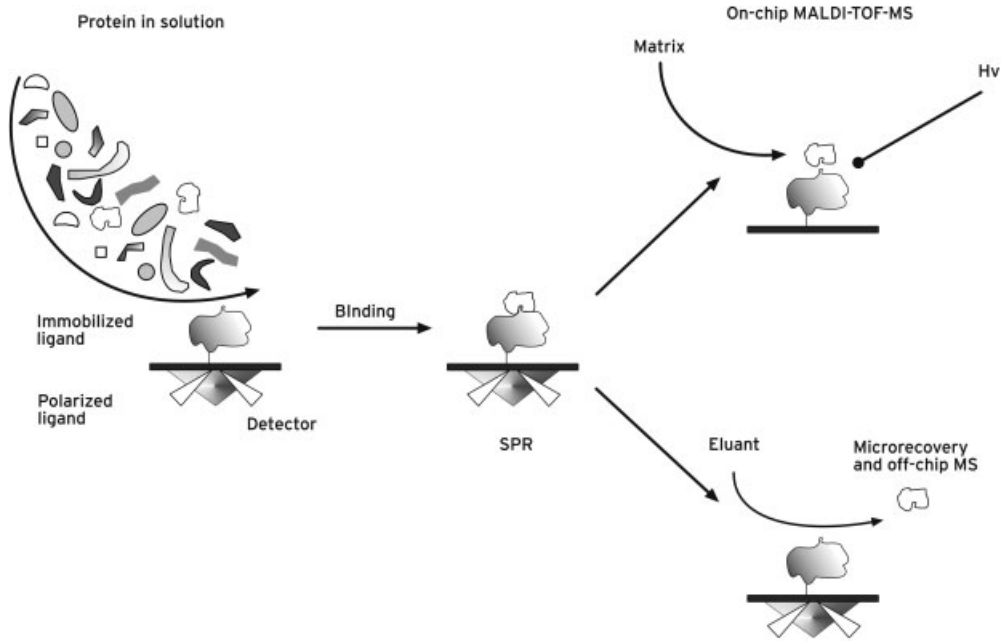

### 1.8.3

#### **Mass Spectrometry**

Two of the challenges of using mass spectrometry for diagnostics are sample delivery and sensitivity. For mass spectrometer analysis, samples must be analyzed in an ionized, gaseous form. Therefore, biological samples must be prepared prior to delivery. Two methods are predominantly used for biological sample preparation and delivery with mass spectrometers. The first method involves spotting of the sample onto a substrate. A laser is used to desorb and ionize the sample which is then passed into the mass spectrometer. Matrix-assisted laser desorption and ionization (MALDI) and surface-enhanced laser desorption and ionization (SELDI) are the two commonly used substrate-based techniques. The second method involves use of a fine capillary to deliver the liquid sample towards electrodes situated near the tip of the capillary. The liquid sample aerosolizes upon emission from the capillary and a high field across the electrodes ionizes the aerosol, which travels into the vacuum chamber of the mass spectrometer and transforms to vapor phase.

Nanostructured materials and surfaces can help enhance MALDI and SELDI techniques. By enabling smaller spot sizes, dense arrays could be nanofabricated, helping increase the throughput of MALDI and SELDI systems [148]. Nanoscale surfaces functionalized with an array of biological receptors could be used to bind with desired targets within the protein population of the sample providing a pre-sorting mechanism prior to mass spectrometry analysis. Many proteins of clinical relevance are overshadowed by more abundant proteins and can be difficult to detect. Nanoparticles specific for these lower-abundant proteins could be used as harvesting agents in preparation for mass spectrometry analysis [149].

Finally, protein quantification and binding analysis can be performed in conjunction with fingerprinting and structural elucidation by combining binding-based assay with mass spectrometry. One technique amenable to coupling with mass spectrometry is SPR (Fig. 1.30) [150]. Using immobilized receptors on the SPR substrate, binding of targeted proteins can be detected. Once SPR detection is complete, the substrate can be coated with matrix and used for MALDI mass spectrometry or microfluidics could be used to draw the sample from the SPR sub-

**Figure 1.30.** SPR mass spectrometry [150]. Reproduced from *Trends in Biotechnology*, D. Nedelkov and R. W. Nelson, Surface Plasmon resonance mass spectrometry: recent progress and outlooks, p. 301–305. Copyright (2003) with permission from Elsevier.

strate for electrospray ionization (ESI) mass spectrometry. An enhancement of this combination technique would be the use of nanoparticles establishing localized SPR to increase the sensitivity of quantifying low-abundance proteins prior to mass spectrometry.

#### 1.8.4

##### Genetics

Traditional bacterial diagnostics involve culturing followed by identification and often another confirming step which can take days to weeks for results to be achieved. ELISAs can provide faster results due to higher sensitivity so that fewer cells are required for analysis. However, immunoassays do not necessarily provide information on the particular strain of a pathogen. Here is where strain-specific tests are performed using genetic-based assays. Such assays typically involve amplification of the nucleic acids, such as PCR, to provide enough genetic material to perform the assay. Nanotechnology is enabling even quicker results by speeding up the PCR process or even by obviating the need for amplification altogether.

One nanostructure being investigated is the nanopore for DNA sequencing [151–154]. Nanopores fabricated from organic materials, such as proteins, or inor-

Figure 1.31. DNA nanopore.

ganic materials, such as semiconductors, could be designed to allow only single-stranded DNA to file through (Fig. 1.31). Electrical or optical methods could be used to detect each DNA base as it transcends through the pore, providing a direct readout method for sequencing without the need to amplify the DNA. The resulting sequence can then be analyzed to determine mutations for genetic screening or can be compared to pathogen sequences for diagnosing infections.

Nanopores can be machined within semiconductor materials using focused ion beam (FIB) milling [155]. With FIB milling, a high-energy ion beam is finely focused onto the sample to be machined. Arrays of nanopores can be machined by manipulating the sample stage and alternating the ion beam on and off. Isolated organic structures may also have the capability of nanopore sequencing. One particular biological structure that has an internal pore diameter of 1.5 nm, which will allow only single-stranded DNA to pass through, is the  $\alpha$ -hemolysin ion channel shown in Fig. 1.32.

Figure 1.32.  $\alpha$ -Hemolysin ion channel, approximately 10 nm long with 1.5 nm internal pore diameter.

## 1.8.5

**Immunoassays**

Immunoassays are routinely used for diagnostics due to their high sensitivity and high selectivity. With the growing desire for smaller sample sizes and earlier disease capture, improvements in immunoassays would be welcome. One method to enhance sensitivity of immunoassays is through the use of antibody-conjugated nanoparticles [156]. For instance, lanthanide-based chelate complexes can be attached to antibody-conjugated nanoparticle carriers creating dense luminescent particles with biological specificity. Lanthanide ions, such as Eu(III) and Tb(III), exhibit narrow emission spectra in the visible wavelength range. Therefore, increasing the density of the chelate complexes by nanoparticle immobilization will produce greater emission to enhance sensitivity. A capture probe can be immobilized onto the substrate surface which targets the desired analyte. The detection antibodies conjugated to the nanoparticle carrying the Lanthanide complexes then bind to the captured analyte, if present. Luminescence is then measured to determine the presence of the analyte. Other small molecule dyes could also be used if nanoparticle immobilization of such dyes could be achieved. See Fig. 1.33.

## 1.9

### Nanotechnology and the Future of Patient Diagnostics

#### 1.9.1

##### Multifunctional Platforms

An area of future impact of nanotechnology for patient care is the development of *in vivo* modular, multifunctional platforms to target, detect and react [157–160]. Dendrimers, due to their highly branched structure, are potential multifunctional nanostructured platforms. Crosslinking to two or more different types of nanoparticles could also create a multifunctional platform. For targeting, biological receptors such as aptamers or antibodies could be immobilized onto the nanostructured platforms. Reporting moieties such as quantum dots or contrast agents could be attached to a separate branch within the dendrimer or attached to or embedded within the crosslinked, nontargeting nanoparticle. This will allow for tracking of the multifunctional platforms with noninvasive imaging methods. Therapeutics could be harbored within the dendrimer core or coated onto the nontargeting nanoparticle enabling targeted drug delivery in conjunction with imaging for combination diagnosis and therapy.

Figure 1.34 shows a multifunctional dendrimer carrying folic acid as a targeting agent, fluorescein as a reporter and methotrexate as the therapeutic. Folic acid, or folate, has a high affinity for folic acid receptors which many cancer cells overexpress. FITC is a widely used fluorophore. Methotrexate (MTX) is an effective anti-cancer drug, but with high toxicity. By adding targeting capability to drugs such as MTX, less amounts of drug should be necessary for therapy. Also, systemic side-effects should be minimized. The use of a multifunctional carrier platform not only enables transport of the drug to its desired destination, but also allows for tracking with the addition of reporter entities.

#### 1.9.2

##### Real-time Monitoring

Implantable sensor technologies that can be remotely monitored enable on-demand and real-time patient monitoring. *In vivo* nanoscale sensors may also provide feedback, based on physiological status, as part of replacement biological systems, such as an artificial kidney or pancreas [161]. Due to the ultraminiature form factor, identical sensors may be implanted for redundancy as a safeguard against sensor failure. Multiple sensors for different targets may also be implanted to simultaneously monitor patient condition.

#### 1.9.3

##### Multiplexed Diagnostic Assays

Nanoscale sensing platforms combined with microfluidic systems for sample delivery offer the potential to simultaneously perform large numbers of analyses and increase sample throughput [162–164]. Also, biomimetic molecular constructs,

**Figure 1.34.** Fifth-generation dendrimer simultaneously functionalized with MTX, folic acid and FITC [157]. Reproduced with permission from Molecular Pharmaceutics, Vol. 2, X. Shi et al., Capillary electrophoresis of

(poly)amidoamine dendrimers: from simple derivatives to complex multifunctional nanodevices, p. 278–294. Copyright (2005) American Chemical Society.

such as peptide or aptamer structures, have the potential to be derived with high affinity for numerous analytes [165]. Being able to analyze a single sample for a number of disease biomarkers at one time could lower the cost of diagnosis and enable a more accurate assessment of the patient's condition.

#### 1.9.4

##### Point-of-care Diagnostics

Bringing the diagnostic tool to the patient, i.e. point-of-care, as opposed to sending samples to a laboratory has the potential to benefit everyone in the healthcare chain. The doctor or nurse will be able to perform quicker diagnoses. The healthcare institution may reduce operating costs due to less need to take and process patient samples. The insurance company or other third-party payer may reduce their costs due to fewer reimbursable events that are typically involved in diagnostic procedures, such as drawing patient samples, using laboratory time and purchasing diagnostic reagents. Finally, the patient should also benefit from faster, more accurate and less-costly diagnosis.

Sample handling is one technical hurdle that must be overcome for point-of-care diagnostics to truly reach the clinic. Micro/nanofluidics will likely play a major role in delivering the patient sample to the sensing portion of the diagnostic tool. However, sample delivery is only one of the challenges in getting a sample, such as blood, to the biologically sensitive area of the tool. For instance, in the case of blood analysis, the sample may need to be filtered and desired analytes separated out, all automatically within the portable diagnostic tool. Without filtering and separation, the sensor surface may quickly become saturated with nonspecific proteins.

### 1.9.5

#### **Regulations, Risks and Ethics**

Although a thorough discussion is beyond the scope of this chapter, the risks and benefits of nanotechnology for patient diagnostics must be carefully addressed. Nanotechnology enables the construction of materials and devices that can intimately interact with biological systems. Such interaction has its benefits, as exhibited by the various opportunities described in this chapter and from numerous other sources. However, we must proceed diligently to understand the effects of artificial nanostructures on biological systems. The benefits of nanotechnology must be understood along with the risks. Early and close interaction with regulatory agencies, such as the Food and Drug Administration (FDA) and the Environmental Protection Agency (EPA), should be part of the technology development process [166, 167].

Currently, additional or special regulatory handling of biomedical nanotechnology products is not being anticipated, although new toxicological testing and standards may need to be developed. For regulatory purposes, the FDA defines nanotechnology as “research and technology or development of products regulated by FDA that involve all of the following:

- (1) the existence of materials or products at the atomic, molecular or macromolecular levels, where at least one dimension that affects the functional behavior of the drug/device product is in the length scale range of approximately 1–100 nm;
- (2) the creation and use of structures, devices and systems that have novel properties and functions because of their small size; and,
- (3) the ability to control or manipulate the product on the atomic scale.”

With the potential of multifunctional capability, many biomedical nanotechnology products will likely not fall into a single FDA category, but may be handled as combination products [168]. Examples of existing combination products are listed in Tab. 1.5. To regulate combination products, the FDA established the Office of Combination Products (OCP) in 2002. As defined by the FDA in Section 3.2(e) of 21 CFR (Code of Federal Regulations) Part 3, a combination product includes:

- (1) A product comprised of two or more regulated components, i.e. drug/device, biologic/device, drug/biologic or drug/device/biologic, that are physically, chemically or otherwise combined or mixed and produced as a single entity.

**Tab. 1.5.** Examples of combination products.

---

Drug-eluting stents  
 Catheter with antimicrobial coating  
 Antibody combined with therapeutic  
 Transdermal drug delivery patches  
 Orthopedic implant with growth factors

---

- (2) Two or more separate products packaged together in a single package or as a unit and comprised of drug and device products, device and biological products, or biological and drug products.
- (3) A drug, device or biological product packaged separately that according to its investigational plan or proposed labeling is intended for use only with an approved individually specified drug, device or biological product where both are required to achieve the intended use, indication or effect and where upon approval of the proposed product the labeling of the approved product would need to be changed, e.g. to reflect a change in intended use, dosage form, strength, route of administration or significant change in dose.
- (4) Any investigational drug, device or biological product packaged separately that according to its proposed labeling is for use only with another individually specified investigational drug, device or biological product where both are required to achieve the intended use, indication or effect.

For nanotechnology diagnostic products used *in vitro*, the FDA Office of *In Vitro* Diagnostic Device Evaluation and Safety has regulatory control. As defined by the FDA in 21 CFR 809.3, an *in vitro* diagnostic product includes:

*In vitro* diagnostic products are those reagents, instruments and systems intended for use in diagnosis of disease or other conditions, including a determination of the state of health, in order to cure, mitigate, treat or prevent disease or its sequelae. Such products are intended for use in the collection, preparation and examination of specimens taken from the human body.

Scientists must not only weigh the health risks, but also the ethical risks. Scientists should be concerned with public perception and ethical issues of nanotechnology [169–175]. With the potential to perform highly sensitive, multiplexed and rapid diagnostics, guidelines and protocols should be established to aid clinicians and patients to make sense of all the data and proceed with the most appropriate course of action. A diagnostic test may be developed and used to which no counter treatment is available. If patients are willing to take such tests, then they should be made well aware of the possible quandaries.

Nanotechnology has the potential to revolutionize medicine as we know it today. Nanostructured materials and devices may make possible the ability for targeted drug delivery, real-time patient monitoring, high-resolution noninvasive imaging, high-throughput screening and multiplexed diagnostics. Such an arsenal of tools

and techniques could enable the ability to capture a disease at its earliest onset, specifically target the diseased site and rapidly treat the patient before any physiological damage is done and without any detrimental side-effects.

## 2 Superparamagnetic Nanoparticles of Iron Oxides for Magnetic Resonance Imaging Applications

*Jean-Marc Idee, Marc Port, Isabelle Raynal, Michel Schaefer,  
Bruno Bonnemain, Philippe Prigent, Philippe Robert,  
Caroline Robic, and Claire Corot*

### 2.1 Introduction

Superparamagnetic nanoparticles of iron oxides have become a major tool for medical imaging with a wealth of applications. This chapter will first describe their physicochemical characteristics, which are of paramount importance for their interaction with macrophage-like cells and, more broadly, for their biodistribution. The general pharmacological properties of these nanoparticles (including their interaction with macrophages and pharmacokinetic behavior) will subsequently be reviewed. Nanoparticles of iron oxides are currently marketed or undergoing clinical trials for cancer imaging applications, which will be described, but also for indications related to their blood pool characteristics and their unique potential for interaction with inflammatory cells. Since inflammatory infiltrates are found in a vast number of diseases (from atheromatous plaques to degenerative diseases such as multiple sclerosis), it appeared of clinical interest to numerous researchers to investigate the relevance of nanoparticles in such indications. The results of these studies will be presented for each of these potential new indications. Last, the noninvasive tracking of stem cells with superparamagnetic nanoparticles, which has attracted much attention in both neurological and cardiologic research over recent years, will be detailed.

For nearly 20 years, research in the field of magnetic resonance imaging (MRI) contrast agents has been oriented towards the study and development of superparamagnetic nanoparticles. These are iron oxides – magnetite ( $\text{Fe}_3\text{O}_4$ ), maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ) or other ferrites that are insoluble in water. Unlike ferromagnetic substances and because of their size, superparamagnetic agents have no magnetic properties outside an external magnetic field [1]. These nanoparticles have in common their specific uptake by macrophages, explaining why, even if they are not entirely captured by the liver and spleen, they are widely evaluated as MRI markers for diagnosis of inflammatory and degenerative disorders associated with high macrophage phagocytic activity.

**Figure 2.1.** General structure of USPIO nanoparticles.

Superparamagnetic agents are highly effective in MRI as they are strong enhancers of proton relaxation.

Superparamagnetic nanoparticles are small coated crystals of iron oxides (Figs. 2.1 and 2.2), characterized by a large magnetic moment in the presence of a static external magnetic field. This large magnetic moment is caused by a crystal ordering (spinel) which induces a cooperativity between the individual paramagnetic ions constituting the crystal. Consequently, the magnetic moment of superparamagnetic particle is greater than the sum of each paramagnetic ions constituting the crystal. These small superparamagnetic crystals are smaller than a magnetic domain (approximately 30 nm) and, consequently, they do not show any magnetic

**Figure 2.2.** Transmission electron microscopy images of USPIOs (iron oxide crystals diameter: 5–7 nm) (Guerbet, unpublished data).

remanence (i.e. restoration of the induced magnetization to zero upon removal of the external magnetic field), unlike ferromagnetic materials. The interaction between surrounding protons of water molecules and the magnetic moment of superparamagnetic particles results in an increase in longitudinal  $r_1$  and transverse  $r_2$  relaxation rates.

The T1 relaxation of superparamagnetic particles has been explained by various models, and Roch and coworkers [2] have proposed a model introducing the anisotropy energy to explain the relaxivity at low magnetic fields while the relaxivity at high fields is mainly related to the outer-sphere Curie relaxation mechanism. The nuclear magnetic relaxation dispersion (NMRD) profile of contrast agents shows the relationship between their relaxivity and the proton Larmor frequency. The NMRD profile of these particles has been obtained, and shows that the magnetic field applied has a considerable and nonlinear influence on the signal [3]. These authors have proposed a new theory which takes account of the magnetic moment of the monodomains and the saturation of the macroscopic magnetization. This fact should be taken into consideration when analyzing the imaging data.

In most situations, it is the significant capacity of superparamagnetic nanoparticles to reduce the spin–spin T2 relaxation time and thus reduce the MRI signal that is used, and such molecules are mostly employed because of their negative enhancement effect on T2-weighted sequences. This drop in signal intensity is related to the field gradients produced by the magnetic particles that dephase nearby diffusing protons and shorten T2/T2\*. This effect is rationalized by outer-sphere relaxation (Ayant and Freed's theory).

This predominant effect on the T2 relaxation time does not prevent these agents' properties from being put to use on the T1 relaxation time if the imaging sequences are chosen appropriately [4]. This is why their use in increasing the signal in the myocardium tissue [5] and in magnetic resonance angiography has been proposed [6].

The multiple components which govern the efficacy of these agents require them to be characterized as accurately as possible by information such as the size of the iron oxide crystals, the charge, the nature of the coating, the hydrodynamic size of the coated particle, etc. These physicochemical characteristics not only affect the efficacy of the superparamagnetic particles in MRI, but also their stability, biodistribution, opsonization and metabolism as well as their clearance from the vascular system.

## 2.2

### Physicochemical Characteristics

The synthesis of superparamagnetic nanoparticles is a complex process because of their colloidal nature [7]. Consequently, a full set of analytical methods should be used in order to characterize the efficacy (in terms of magnetization and relaxivity) and purity of nanoparticles and the reproducibility of the synthesis process. Moreover, since the size, the geometry, the composition of the crystals as well as the

Tab. 2.1. Size of iron oxide nuclei (nm) [8].

	X-ray diffraction	Transmission electron microscopy
Ferumoxides	$4.96 \pm 0.14$	$4.8 \pm 1.9$

Ferumoxytol	$6.76 \pm 0.41$	–

charge of the particles and the nature of the coating strongly influence the physicochemical and biological behavior of the particles, an accurate description of the physicochemical properties of these nanoparticles is crucial in establishing any structure–activity relationship [8, 9].

### 2.2.1

#### Physicochemical Properties of the Crystal

The size of the crystals varies from agent to agent, but also depends on the measurement technique. The core size is generally between 4 and 10 nm (Tab. 2.1). The size of the crystal can be appreciated by transmission electronic microscopy (TEM) and needs to be measured on a statistically significant number of crystals. Moreover, the sample preparation can induce aggregation of the colloids and the TEM measurements may consequently not reflect the crystal size in solution. The size of the crystals can also be measured by X-ray diffraction (XRD) by analyzing the X-ray line broadening. Moreover, XRD can provide information concerning the crystal composition and structure. A detailed characterization by TEM and XRD analyses of new nonpolymeric-coated  $\text{Fe}_3\text{O}_4$  nanoparticles has been recently described by Cheng and coworkers [10].

Composition of the crystal can also be analyzed by Mössbauer spectroscopy. The magnetic properties of the nanoparticles can be studied by the behavior of the magnetization according to the applied magnetic field (magnetometry) which confirms the superparamagnetic property and gives the magnetization at saturation (MS). Of course, the magnetic properties can also be studied by recording the NMRD curve. According to the relaxivity theory developed by Roch and coworkers [2], the fitting of the NMRD curves can provide information on the relaxometric size and the magnetization at saturation.

### 2.2.2

#### Hydrodynamic Particle Size and Charge

The hydrodynamic size of the nanoparticles [i.e. the global size of the particle comprising one or several magnetic crystal(s) surrounded by the coating molecules] is

usually measured by photon correlation spectroscopy (PCS), which analyses the quasielastic light diffusion of nanoparticles when illuminated by a monochromatic laser beam. The intensity of the diffused light is modulated by the Brownian motion of the particles in solution. Different mathematical analyses of the PCS data can provide an estimation of the hydrodynamic size and the polydispersity of the nanoparticles. However, the values obtained by PCS dramatically depend on the mathematical models and weighting parameters used (unimodal or multimodal distribution, distribution in number, volume or intensity). Consequently, the hydrodynamic size measurements described in the literature for different nanoparticles are very difficult to compare, and any relationship between size and biodistribution should be made with caution.

The size of the particles themselves with their coating varies even more and the measurement method contributes significantly to this variability (Tab. 2.2).

It is currently agreed that two main categories of superparamagnetic agents must be distinguished [9]:

**Tab. 2.2.** Size and coating agent of the nanoparticles currently marketed or under clinical investigation.

Brand name or common name	Company	Other names	Coating agent	Size (laser light scattering) (nm)
Endorem <sup>®</sup> / Feridex <sup>®</sup>	Guerbet Advanced Magnetics	Ferumoxides AMI-25	dextran	120–180

<sup>a</sup>At 20 MHz (0.47 T).

- Superparamagnetic iron oxides (SPIOs), the hydrodynamic size of which including coating is greater than 50 nm.
- Ultrasmall superparamagnetic iron oxides (USPIOs) which are less than 50 nm in size.

This difference in size is reflected by significant differences in the ratio of relaxivity constants  $r_2/r_1$  (Tab. 2.3), but also by a significant difference in plasma half-life and biodistribution.

Another fundamental characteristic of these agents is the nature and charge of the particle coating. The charge on the surface of the nanoparticles is usually appreciated by the  $\zeta$  potential measurement deduced from the measurement of electrophoretic mobility. Unfortunately, the value of  $\zeta$  potential of superparamagnetic nanoparticles is rarely described in the literature. Although most superparamagnetic particles are covered by dextran or dextran derivatives (e.g. carboxy-dextran), they have occasionally been coated with other molecules such as starch, siloxane, arabinogalactose, amino-functionalized polyvinyl alcohol (PVA), citrate, etc.

Therefore, when referring to superparamagnetic agents, these must be properly characterized and their characteristics compared with the other agents by using the same measurement methods. The relationship between the structure, the composition and the charge of nanoparticles and their potential in terms of efficacy, biodistribution and safety is not yet well understood.

### 2.3 Pharmacology and Metabolism

Iron oxide nanoparticles are internalized into macrophages (Fig. 2.3) and other phagocytic cells following intravenous administration.

**Figure 2.3.** Intracellular localization of the USPIO ferumoxtran-10 ( $7.1 \text{ mmol L}^{-1}$ ) following a 24-h incubation with activated THP-1 human monocytes. Iron staining with Prussian blue and counter-staining with eosin (Guerbet, unpublished data).

### 2.3.1

#### Role of Physicochemical Parameters

The size and physicochemical surface properties of SPIOs and USPIOs strongly interfere with their capacity to be internalized into macrophages or other phagocytic cells following intravenous administration.

Ferumoxtran-10, which has a small hydrodynamic diameter (15–30 nm, see Tab. 2.2), shows a long blood residence time, which allows it to easily access macrophages located in deep and pathologic tissues (such as lymph nodes, kidney, brain, osteoarticular tissues, etc.). Indeed, these tissues are far less accessible than well-vascularized tissues such as the liver or spleen.

Other USPIOs such as ferucarbotran or very small superparamagnetic iron oxide particles (VSOPs) have a higher macrophage uptake. This is associated with a faster blood clearance and, consequently, a more limited access time to the deep compartments [11, 12]. For example, the elimination half-life of VSOP-C184 in healthy volunteers is only 0.5–1.5 h after bolus injection [13]. Conversely, feruglose (Clariscan<sup>®</sup>), because of the pegylation of the coating starch, can be regarded as “stealth nanoparticles” which are hardly recognized by the macrophage–monocytic system and probably not suitable for macrophage imaging [14].

It has recently been shown that superparamagnetic nanoparticles with an amino-functionalized PVA coating can interact with human melanoma cells with-

out any cytotoxicity. This interaction of the nanoparticles with melanoma cells was found to be active, energy-dependent and saturable [15]. It also depended on the amino-PVA:iron oxide ratio – the increased uptake in the presence of amino groups is consistent with the well-known uptake of cationic liposomes, mainly for transfection purposes.

A recent study compared anionic nanoparticles (AN) (coating: meso-2,3-dimercaptosuccinic acid, hydrodynamic diameter 24 nm) with ferumoxtran-10 [16]. *In vitro* uptake by the human prostatic adenocarcinoma cells PC3 was found to be superior with AN than with ferumoxtran-10. In mice grafted with PC3 cells, the iron concentration inside tumors reached two peaks: first one at 1 h (ferumoxtran-10 > AN) and second one at 12 h (ferumoxtran-10 = AN). Imaging studies showed tumor brightening on T1-weighted images with ferumoxtran-10 and darkening on T2-weighted images with both compounds. With ferumoxtran-10, an early peak at 1 h on T2 imaging and a second peak at 12 h on T1 imaging suggested an initial intravascular distribution and, possibly, a secondary extravasation in the interstitium (or, alternatively, some intracellular uptake) at 12 h [16].

### 2.3.2

#### Mechanism and Consequences of Interaction with Macrophages

According to their coating (negative charges and hydrophilicity), nanoparticles display different degrees of uptake by macrophage-like cells, as previously mentioned.

The macrophage is a specialized host defense cell with endocytic properties. Its involvement in the pathogenesis of numerous diseases is well known and makes it a very interesting pharmaceutical target.

It has been shown *in vitro* that ferumoxides endocytosis by mouse peritoneal macrophages was dose-dependently inhibited by polyinosinic acid and fucoidan, suggesting that a scavenger receptor SR-A mediated endocytosis is involved for this contrast agent [17].

On the human activated monocyte THP-1, ferumoxide was shown to undergo a higher macrophage uptake compared with ferumoxtran-10, probably because of its larger size [17]. This result was confirmed in another study [18] which also showed that, apart from particle size, the phagocytic uptake is dependent on the surface properties of the nanoparticles since, both for SPIO or USPIO categories, ionic carboxy-dextran coating leads to a higher uptake than nonionic dextran coating [18].

Another study also found a higher cellular uptake (on hematopoietic progenitor, mesenchymal fibroblast and epithelial HEP-G2 cell lines) with the SPIO ferucarbo-tran than with the USPIO SHU-555C (hydrodynamic diameter 30 nm) [19].

Rogers and Basu recently showed that the hydroxymethyl glutaryl coenzyme A (HMG-CoA) reductase inhibitor lovastatin dose-dependently reduced the uptake of the SPIO ferumoxides by a murine macrophage-like cell line (J774A) [20]. The mechanism of this effect is unclear, and may be explained by a downregulation of class A types I and II receptors, or, alternatively, by interference of lovastatin in macrophage–receptor binding, reduced receptor recycling or at the level of

scavenger receptor mRNA expression. The clinical relevance of such *in vitro* data for the detection and characterization of atheromatous plaques with USPIOs in patients treated with HMG-CoA reductase inhibitors remains unclear.

The same authors also demonstrated that the pro-inflammatory cytokine interferon (IFN)- $\gamma$ , but also the anti-inflammatory cytokine interleukin (IL)-4 increased SPIO uptake at relatively high concentrations [20].

Another study has investigated the biological consequences of the rat macrophage labeling with the citrate-coated nanoparticles VSOP [21]. Cell growth and viability were minimally affected. However, transient oxidative stress was evidenced by an acute increase in both malonyldialdehyde and protein carbonyls.

In addition to their phagocytic properties, macrophages also possess a high secretory capability leading to the release of growth factors and cytokines. Very low IL-1 release (comparable to negative control) was observed after incubation of macrophages with ferumoxides or ferumoxtran-10, even at a high concentration ( $500 \mu\text{g Fe mL}^{-1}$ ), thus suggesting a low pro-inflammatory potential for these nanoparticles [17].

### 2.3.3

#### Pharmacokinetics

Ferumoxtran-10 is completely degraded in the macrophage lysosomal compartment within 7 days [22]. The plasma elimination half-life is strongly species dependent. It is 2 h in rats (after intravenous injection of a 30 or  $45 \mu\text{mol kg}^{-1}$  dose), approximately 6 h in rabbits whereas it is around 24–36 h in humans following intravenous administration [11, 23]. In both rats and rabbits, increasing the dose caused a longer half-life because of the progressive saturation of uptake by liver and spleen.

Since the access of USPIOs to deep compartments is favored by prolonged blood residence time, animal imaging experiments are generally performed using high doses of USPIO ( $200\text{--}1000 \mu\text{mol kg}^{-1}$ ) compared to the human clinical dose of  $45 \mu\text{mol kg}^{-1}$  [11].

It has been shown that the age of rats significantly influences the half-lives of the signal intensities in vessels and in the liver following injection of VSOP-C43. In the younger animals, the intravascular signal decrease was about 50% of the value seen in older animals [24]. This suggests a higher macrophage uptake in younger animals. Since pharmacokinetic data are classically obtained during phase I clinical studies in young healthy volunteers, caution seems necessary when it comes to extrapolating imaging window to elderly patients.

The iron contained in SPIOs and USPIOs is bioavailable, and is incorporated into the normal body iron pools, such as hemoglobin [25]. This is consistent with the increase in ferritin levels reported in several articles with various USPIOs [13, 26]. Ferritin is the physiologic storage form of iron. Actually, it is believed that K upffer cells degrade dextran-coated iron oxide nanoparticles by incorporating most of the iron they contain into ferritin and/or hemosiderin (when the intracellular concentration of ferritin becomes relatively high) before exocytosis [27].

The USPIO ferumoxtran-10 (Sinerem<sup>®</sup>/Combidex<sup>®</sup>) is currently under clinical trial for the detection of nodal metastases (see Section 2.4.3). After intravenous infusion, USPIO nanoparticles are distributed to the lymph nodes by two distinct pathways: (i) direct transcapillary passage through venules into the medullary sinuses of the lymph node, followed by phagocytosis by macrophages, and (ii) non-selective, endothelial transcytosis into the interstitial space in the body, followed by uptake of the nanoparticles by draining lymphatic vessels and transport to the lymph nodes via afferent lymphatic channels [28, 29].

Several routes of administration have been suggested for SPIOs and USPIOs. The SPIO ferumoxides (Endorem<sup>®</sup>/Feridex<sup>®</sup>) is administered using slow intravenous infusion, ferucarbotran (Resovist<sup>®</sup>) is injected as a bolus. Clinical studies on ferumoxtran-10 have so far used slow intravenous infusion but preclinical studies have shown that this USPIO can also be directed to specific lymph nodes via subcutaneous injections at distinct sites [30]. In human volunteers, it was shown that interstitial administration of ferumoxtran-10 ( $0.28 \text{ mg Fe kg}^{-1}$ ) increases the number of lymph nodes that can be adequately detected with MRI.

The site of injection in the pelvis influenced the location of visualized lymph nodes, with the largest number of nodes visualized with periprostatic injection. This interstitial approach may also allow a reduction of the dose when compared with the intravenous route [31].

The optimal temporal window for imaging lymph nodes with ferumoxtran-10 is 24–36 h after intravenous infusion [29].

#### 2.3.4

#### Nanoparticle Vectorization

Although it has a good temporal and spatial resolution, MRI displays a relatively low sensitivity (about three to six orders of magnitude less than that of isotope techniques). It therefore requires amplification to enable its use in molecular imaging. Molecular imaging includes a large array of applications (study of tissular blood flow changes, spectroscopic quantification of metabolite concentrations, generation of pH maps, studies of vascular volume or permeability, pharmacokinetic studies of chemotherapeutic drugs, denoting of gene expression, specific imaging of molecules that are overexpressed in pathological states, etc.) [32]. A promising option for local signal amplification is vectorization of nanoparticles to enable them to reach their biological target [33]. Several strategies have been selected to vectorize nanoparticles. One example is the oxidative conjugation producing aldehydes on the dextran coating of the particles, at the expense of a substantial loss of the biological activity of the protein. To reduce this effect, the protein that binds the biological target has been linked to the iron oxide nanoparticles through a linker molecule [34].

Nonoxidative strategies have become an interesting alternative method: epichlorohydrin is first coupled to the hydroxyl groups of the dextran coating to provide a terminal halogen derivative which can subsequently be used to link any molecule containing an amine function (peptide, protein, antibodies, etc.) [35]. As an exam-

**Tab. 2.4.** Functionalized USPIOs: some examples.

Biological target	Type of functionalized USPIO	Experimental model	Reference
Acute inflammation	MION-IgG	rat model of myositis	38

ple, vectorizing groups [such as the connecting segment-1 fragment of fibronectin, the peptide GRGD (Gly-Arg-Gly-Asp) or a nonpeptidic small-molecular-weight RGD mimetic] have been grafted with the dextran coating of USPIO previously coated with epichlorhydrin [36].

Another approach uses 2,3-dimercaptosuccinic acid (DMSA) and *N*-succinidyl 3-(2-pyridylthio)propionate (SPDP) [37]. Recent examples of functionalized USPIOs used for experimental molecular imaging are shown in Tab. 2.4 [38–43].

## 2.4

### Current Clinical Uses and Future Developments

#### 2.4.1

##### Gastrointestinal Tract Imaging

As in computed tomography (CT) scanning, it is clinically necessary to improve the differentiation between the gastrointestinal tract and surrounding organs. Para-

**Figure 2.4.** Signal suppression of the gastrointestinal structures in pyelography. MRI prior (A) and after (B) oral administration of 500 mL ferumoxsil (courtesy Dr A. Blandino, Policlinico G. Martino, Messina, Italy).

magnetic contrast agents, which increase the gastrointestinal tract signal, may also increase movement artifacts. Specific superparamagnetic contrast agents have been developed for this reason. A first agent, ferumoxsil (AMI-121), has been tested in clinical trials by oral administration at 600–900 mL [44–47] and is licensed in Europe as Lumirem® (or Gastromark® in the USA).

This product is composed of iron oxide particles coated in a layer of inert silicon and its diameter is 300 nm (Tabs. 2.1 and 2.2). After oral administration, it significantly improves the definition of organ boundaries such as the uterus and lymph nodes [47] (Fig. 2.4). Other agents have been developed for the same application: WIN-39996 [48], oral magnetic particles (OMPs), also referred as to ferristene (Abdoscan®) (polystyrene coated) [49–53].

Ferumoxsil has also been used as well in MR enteroclysis in 60 patients with Crohn's disease [54]. Aliquots of 600 mL of ferumoxsil associated with 2.5 L of tide water and methylcellulose were instilled through a transjejunal tube, in order to reduce the signal intensity of the lumen. Additional rectal instillation of water for positive contrast improved the distension and identification of large bowel and terminal ileum.

Similarly, an Italian team [55] used a double-contrast method for evaluating the inflammatory activity in patients with Crohn's disease, after darkening the lumen of the bowel with oral administration of Lumirem®, the gadolinium contrast agent was injected. Parameters such as wall thickness, wall T2-weighted signal, wall con-

trast enhancement, amount of fibroproliferation and T2-weighted signal of fibrofatty proliferation on fat-suppressed images were evaluated.

These negative contrast agents for gastrointestinal imaging are generally well tolerated, with mild side-effects such as nausea, vomiting (1–5% of patients) or flatulence [56]. Oral SPIO are generally administered over 30–60 min, with a volume of 900 mL for contrast enhancement of the whole abdomen and 400 mL for the upper abdomen [57].

#### 2.4.2

#### Liver and Spleen Diseases

The first clinical indication for iron oxide nanoparticles was hepatic imaging. Following intravenous injection, SPIOs are rapidly taken up by hepatic Kupffer cells and the spleen (marginal zone and red pulp) macrophages, resulting in a drop in magnetic resonance signal intensity, and therefore in hypointense images, mostly because of a susceptibility effect.

Since Kupffer cells are exclusively located in the healthy hepatic parenchyma [58], SPIOs increase the contrast between healthy and diseased tissue devoid of Kupffer cells. The first agent to be developed (and marketed in Europe more than 10 years ago under the name Endorem<sup>®</sup>) was ferumoxides (or AMI-25) (Feridex<sup>®</sup> in the US). These are T10-dextran coated particles and their hydrodynamic size is 120–180 nm (Tabs. 2.1 and 2.2). Many preclinical and clinical trials have demonstrated the efficacy of ferumoxides in the detection of the focal lesions of the liver as well as for their characterization [59–64] (Fig. 2.5).

The same product has been studied in terms of its capacity to detect lesions of the spleen [65, 66]. The most common side-effects reported with ferumoxides are

**Figure 2.5.** Liver imaging prior (A) and after (B) injection of ferumoxides (HASTE sequence) allowing a better depiction of a cholangiocarcinoma which does not uptake the nanoparticles and appears in isosignal

intensity pre/postinjection while the signal of the normal parenchyma becomes dark. (courtesy Dr C. Matos, Erasmus Hospital, Brussels, Belgium)

lower back pain (4%), flushing (2%) and various combined gastrointestinal complaints (5.6%) [67].

Another product was subsequently developed for this clinical application in MRI: ferucarbotran (SHU-555A) (Resovist®), the particles of which are coated with carboxy-dextran and are approximately 60 nm in diameter [19, 68]. Safety data obtained during phase I–III trials of this compound revealed a total of 162 side-effects in 1053 patients, of which 75 (7.1%) were possibly, probably or definitely drug related. The majority of events occurred within the first 3 h [69].

Chondroitin sulfate iron colloid (CSIC) has also been put forward [70] as well as MDL (liver-directed nanoparticles) [71], but these particles have not been marketed. Furthermore, other hepatocyte-specific agents were evaluated but not marketed either: asialofetuin-coated USPIO or arabinogalactan-coated USPIO, which are particularly well recognized by the asialoglycoprotein receptor (ASGPR) present on the surface of normal hepatocytes [72]. ASGPR is of interest for hepatocyte targeting in that it is prototypic of the class of receptors that constitutively enters cells and allows delivery of molecules to the intracellular compartments [73]. In addition to their ability to assess focal hepatic lesions, these agents can be used to assess hepatocyte function [57].

In addition to SPIOs, USPIOs such as ferumoxtran-10 can be located in several compartments of the liver (extracellular space, reticuloendothelial cells and possibly hepatocytes). In the rat, ferumoxtran-10 acts mainly as an extracellular agent for at least 1 h (increase in liver signal intensity on T1-weighted images) and is taken up by cells from the reticuloendothelial system at later time points [74]. A subsequent rat study showed that the USPIO feruglose induced an hepatic T2\* effect at late (up to 133 days after injection for 5 mg Fe kg<sup>-1</sup>) time-points when the concentrations of iron oxide nanoparticles in the liver were below method detection limits. This effect is probably a result of nanoparticle breakdown products [27].

In a clinical study comparing the SPIO ferumoxides with the USPIO ferumoxtran-10 in patients with focal hepatic diseases (hepatocellular carcinoma, metastases, hepatocellular adenoma and focal nodular hyperplasia), Mergo and coworkers observed that, although both compounds had similar T2 effects (comparable loss of hepatic signal intensity in their study conditions) and improved the lesion-to-liver contrast when compared with non-contrast-enhanced images, the USPIO allowed more in-depth characterization of the lesions, because of its additional blood pool effect [75].

Further studies are needed to better understand the potential utility of USPIOs for assessment of hepatic vascular structures and clinical benefit in the characterization of focal hepatic lesions, notably by optimizing the USPIO injected dose and the chronology of MRI.

### 2.4.3

#### Lymph Node Metastases

Nodal disease is an independent adverse prognostic factor in many types of cancer. The only widely accepted method for assessing nodal involvement by means of

imaging so far is measurement of the node size. This preoperative staging will influence the oncologist's decision to use neoadjuvant therapy or the surgeon's decision to perform nodal dissection [76]. Superparamagnetic agents which can be taken up by normal nodes following intravenous or subcutaneous injection have raised great interest. The first agent, and that on which most research has been carried out, is ferumoxtran-10 (or AMI-227). Its iron oxide core is surrounded by a 8- to 12-nm layer of T-10 dextran coating [23], leading to a final size of around 30 nm (Tabs. 2.1 and 2.2). It has similar physicochemical properties to the monocrystalline iron oxide nanocompounds (MION) which have a monocrystalline crystal core with an approximate diameter of 4 nm and a dextran coating resulting in a hydrodynamic diameter of 17 nm [77].

Numerous studies on ferumoxtran-10 have shown its efficacy in metastatic lymph node imaging [78–81] (Fig. 2.6). Schematically, as previously mentioned,

**Figure 2.6.** MRI (T2\* sequence) of lymph node metastases prior (A) and after (B) ferumoxtran-10 injection in a patient with head and neck cancer (courtesy Dr M. Mack, University Hospital, Frankfurt/Main, Germany).

USPIO slowly extravasate from the vessels into the interstitial space, from which they are transported into the lymph nodes through lymphatic vessels [28, 29, 82]. Upon USPIO administration, normal lymph nodes will appear dark on the MR images, while tumor metastases remain isointense with the precontrast image (i.e. before USPIO uptake by lymph node macrophages). In eighty patients with presurgical clinical stage T1, T2 or T3 prostate cancer who underwent lymph-node resection or biopsy, MRI was done before and 24 h after the intravenous injection of 2.6 mg kg<sup>-1</sup> of ferumoxtran-10. Sixty-three lymph nodes, from 33 patients, had histopathologically detected metastases. Of these, 45 (71.4%) did not fulfill the usual imaging criteria for malignancy. However, the ferumoxtran-10-enhanced MRI correctly identified all patients with nodal metastases. Nodal metastatic infiltration measuring 5–10 mm were identified [81].

Several phase III clinical trials using USPIO ferumoxtran-10 for the detection of lymph node metastases, especially in the head and neck and pelvis regions, are currently in their final stages. Promising results have also been published for rectal cancer [76].

#### 2.4.4

#### Blood Pool Characteristics

Uptake of ferumoxtran-10 and the MIONs or other USPIOs by the liver and the spleen is quite low because of their physicochemical characteristics. They consequently remain in the blood circulation for a very long time. With their long blood half-life and T1-shortening effect, these agents have been evaluated as blood pool agents for indications such as measurement of cerebral perfusion [83, 84], myocardial or renal perfusion [85], angiography [6], or detection of vascular hepatic lesions [86]. These compounds are classically referred to as slow-clearance blood pool agents. Whereas these agents are confined to the vascular compartment, their molecular volume only allows a slow “sieving” through the glomerular fenestrae. Their renal clearance is consequently much lower than the normal glomerular filtration rate.

These blood pool characteristics provide a much longer time window for data acquisition during radiological procedures, with little loss of intravascular signal intensity.

The potential clinical indications related to these properties are:

- *Cerebral imaging*: measurement of the cerebral blood volume [87] and functional imaging [88]. The MR evaluation of stroke and its functional consequences may benefit from the use of blood pool agents. Even if emergency treatment of cerebral vascular accidents is currently limited, there is reason to believe that a diagnostic aid which precisely defines the cerebral shadow zone would demonstrate the value of better managed care, as was the case in myocardial ischemia.
- *Cardiac imaging*: quantification of the hypoperfused zones and MR coronary angiography.

- *First-pass angiography* [89, 90].
- *Tumor imaging*: detection and characterization of the lesion-associated microvascular environment. These agents would enable prediction of the treatment efficacy by evaluating the endothelial permeability and size of neovessels (calculation of blood volume and vessel size index) [91, 92].
- *Optimization of hyperpolarized  $^3\text{He}$  gas MRI* [93].

#### 2.4.5

#### Characterization of the Atheromatous Plaque

The composition and stage of atherosclerotic plaque are clinically more relevant than the severity of stenosis for evaluation of the risk of acute ischemic events. Atherosclerosis is basically an inflammatory disease [94]. Monocytes adhere to the vascular endothelium and accumulate in lesion-prone arterial sites. This adherence is facilitated by the endothelial expression of adhesion molecules. Adherent monocytes are subsequently enticed into the arterial intima where they differentiate into macrophages [95]. Macrophage-rich areas are more frequently found in the atheromatous plaques of patients with unstable angina and non-Q-wave myocardial infarction [96]. This suggests that macrophages are a marker of unstable atherosclerotic plaques and that specific targeting of these cells may lead to the characterization of atheromatous plaques prone to rupture.

Animal studies have clearly shown that USPIO induce focal signal intensity decreases in the aortic wall of atheromatous rabbits [97, 98] or apolipoprotein E (ApoE) knockout mice [99].

Interestingly, the exposure period of atherosclerotic plaque to circulating USPIO seems to be critical for the uptake of nanoparticles: in a comparative study in hyperlipidemic rabbits, the *in vivo* MRI signal intensity was found to be significantly higher with the long half-life agent ferumoxtran-10 than with another USPIO of similar size, ferumoxytol ( $T_{1/2} \sim 6$  h), whereas *in vitro* macrophage phagocytosis was greater with the latter compound [100].

Preliminary clinical studies or case reports using ferumoxtran-10 have also shown USPIO-induced signal loss in aorta and pelvic arteries [101] or in carotid atheromatous plaques [102–104]. In one of these clinical trials [102], histological analysis showed USPIO in 27/36 (75%) of the ruptured or rupture-prone plaques and 1/14 (7%) of the stable atheromatous lesions. Postcontrast images should systematically be compared with corresponding precontrast images in order to exclude USPIO-induced signal reduction from other effects such as plaque calcification (which can also lead to strong susceptibility effects).

Given the heterogeneity of plaque formation and progression mechanisms, the macrophages which have endocytosed USPIO could be activated macrophages derived from activated blood-borne monocytes, activated macrophages derived from smooth muscle cells or foam cells which correspond to macrophages at a later stage [11]. Further studies are definitely required to better understand the precise mechanism of USPIO-uptake by atheromatous plaques. Obviously, such preliminary data open very interesting prospects for clinicians.

#### 2.4.6

#### Other Potential Uses

Given the wide spectrum of inflammatory diseases, it is evident that these nanoparticles have a huge clinical potential. Some clinical applications of high interest are discussed below.

##### 2.4.6.1 Stroke

Ischemic focal lesions are associated with a strong inflammatory local response that involves microglial cell activation as well as infiltration of hematogenous leukocytes, mostly monocytes [105, 106].

Ischemia-associated inflammation plays a major role in the pathogenesis of neurodegeneration associated with stroke. Activated macrophages produce numerous cytokines which exacerbate the ischemic tissue damage [107]. Consequently, non-invasive imaging of inflammation associated with subacute ischemic stroke lesions could be of predictive value and helpful for the development of cytoprotective drugs.

When injected in Fisher rats 5.5 h after permanent occlusion of the middle cerebral artery, the USPIO ferumoxtran-10 was shown to allow MR visualization of macrophage infiltration associated with focal ischemic lesions [108].

However, this technique did not allow determination of the specific contribution of microglia and blood-borne macrophages to USPIO accumulation. These results were confirmed by a subsequent study in rats where cerebral infarction was induced by photothrombosis of cortical microvessels. In this study, ferumoxtran-10 was injected 5 days after the induction of the cerebral ischemic lesions. Magnetic resonance imaging performed 24 h later displayed a rim-like signal loss around the lesion, which was in full spatial agreement with the histological data [109].

In a clinical phase II study, this USPIO was administered at the end of the first week after symptom onset in a series of 10 consecutive patients with ischemic stroke [110]. Two follow-up MR scans were performed 24–36 and 48–72 h after infusion. Vessel-associated changes were noticed (as signal loss on T2/T2\*-weighted images) and decreased from the first to second scan. This effect was most likely related to the blood-pool effect of the USPIO. In addition to this effect, a parenchymal enhancement was noticed, mostly on T1-weighted images. This effect increased over time and matched with the expected distribution of macrophages. Larger clinical studies are clearly needed to demonstrate the clinical benefit associated with the use of USPIOs as a MRI surrogate markers for brain inflammation.

##### 2.4.6.2 Cerebral Tumor Characterization

As mentioned above, according to their physicochemical properties, USPIOs can have a long blood half-life and therefore be found into the vascular compartment before being progressively endocytosed by tissue macrophages. Therefore, the nanoparticles can be used both for imaging tumor-associated microvessels during the early vascular equilibrium phase and, later, as a macrophage imaging agent for the characterization of the tumor-associated inflammatory lesion.

Preliminary clinical data [11, 111] have shown that there are distinct contrast enhancement mechanisms between early  $Gd^{3+}$  nonspecific contrast agent-based imaging, early USPIO injection, and late (24 h postinfusion) USPIO imaging. This could be of value for brain tumor characterization. USPIO nanoparticles do not cross the ruptured blood–brain barrier at early postinjection stages. This may prove helpful for the assessment of tumoral microvascular heterogeneity. Interestingly, in this preliminary study, the late USPIO-induced tumoral enhancement was found to be higher in high-grade than in low-grade glioblastomas [111].

In a preliminary study comparing the SPIO ferumoxides to the USPIO ferumoxtran-10 in 20 patients with primary and metastatic intracranial tumors, it was found that ferumoxtran-10, in contrast to ferumoxides, can be used as an intravenous contrast agent for MRI of intracranial tumors. Tumor enhancement was found to be comparable to but more variable than that observed with a nonspecific  $Gd^{3+}$  chelate. Histological examination showed similar distribution of the USPIO to be similar to that seen on MR images, i.e. primarily at the tumor margin, with less central localization. Most of the staining within the tumor was found in parenchymal cells with fine fibrillar processes, thus suggesting an astrocytic or microglial derivation [112].

#### 2.4.6.3 Multiple Sclerosis

Multiple sclerosis, an idiopathic inflammatory disease of the central nervous system, is characterized pathologically by demyelination and subsequent axonal degeneration. It is currently accepted that MRI with  $Gd^{3+}$  nonspecific contrast agent, especially during or following a first attack, can be helpful in providing evidence of lesions in other parts of the brain and spinal cord [113]. Edema formation is detected by T2-weighted MRI, and a second MR scan could be useful at least three months after the initial attack to identify new lesions and provide evidence of dissemination over time [113]. Furthermore, magnetization transfer imaging or T1-weighted imaging can also be used for investigation of the demyelination process.

However, these parameters can only provide information on the consequences of the inflammatory process, but not on inflammation itself.

Some USPIOs (ferumoxtran-10, MION-46L) have been shown to be useful for *in vivo* macrophage activity imaging on experimental autoimmune encephalomyelitis (EAE) – a commonly used animal model that mimics human multiple sclerosis in several aspects [114, 115]. Post-USPIO sensitivity was found to be better than either pre-USPIO or post-nonspecific  $Gd^{3+}$  chelate-enhanced images [114].

A phase II pilot study investigated inflammatory lesions in 10 patients with definite relapsing-remitting multiple sclerosis who were included during one relapse episode. MRI with T1-weighted,  $Gd^{3+}$ -enhanced, T2- and T2\*-weighted images was performed before and 24–48 h post-ferumoxtran-10 infusion. Nine out of the 10 patients studied showed multiple sclerosis lesion enhancement with USPIO. Some lesions enhanced up to 3 days after USPIO infusion. Seven patients showed multiple sclerosis lesion enhancement with the  $Gd^{3+}$  chelate.

Several patterns of enhancement were described when comparing USPIO- and  $Gd^{3+}$  chelate-induced enhancement: lesions enhancing with both contrast agents

**Figure 2.7.** Multiple sclerosis: phase II clinical trial – ferumoxtran-10: (A) T1-weighted MRI images before injection and (B) T1-weighted MRI images 24 h postinjection of ferumoxtran-10. (courtesy Professor Vincent Dousset, Pellegrin Hospital, Bordeaux, France)

( $n = 31$  lesions), with  $Gd^{3+}$  chelate only ( $n = 24$ ) or with USPIO only ( $n = 2$ ). Interestingly, the enhancement with USPIO was not superimposed on that related to the  $Gd^{3+}$  chelate [11, 116]. One example of USPIO-enhanced plaque is shown on Fig. 2.7.

#### 2.4.6.4 Arthritis

Arthritis is characterized by infiltration of  $CD4^+$  T cells, B cells and macrophages that sometimes organize into discrete lymphoid aggregates with germinal centers [117]. In a rabbit model of unilateral arthritis, MRI at 1.5 T was performed before and 24 h after intravenous injection of the USPIO ferumoxytol. Significant T1 and more predominantly T2\* and T2 effects were evidenced in the synovium of all arthritic knees. Conversely, no significant changes in MR signal characteristics were found in the nonarthritic control knees. Histologic examination confirmed iron uptake in the macrophages within the hyperplastic synovium of the arthritic knees [118]. USPIO nanoparticles have also been found in macrophages located in synovial inflammatory infiltrates in a rat model of osteoarthritis (unpublished data) (Fig. 2.8).

#### 2.4.6.5 Infection

Macrophages are activated during infection and migrate to the site of microbiotic invasion, thus providing a theoretical rationale for testing USPIO in such an indi-

**Figure 2.8.** Representative photomicrographs of Perl's staining of iron oxide in macrophagic cells located in rat inflammatory synovium: (A) low- and (B) high-power magnification view (unpublished data).

cation. An experimental model of infection was developed in rats (unilateral deep calf muscle abscess following intramuscular injection of a *Staphylococcus aureus* suspension). Animals were imaged before and 3, 24, 48 and 72 h after intravenous injection of the USPIO ferumoxtran-10. Visualization was more sensitive with a T2\*-weighted gradient echo sequence. The T2\* effect was most prominent 3 h after ferumoxtran injection because of the high amount of intravascular USPIO at this time-point. A significant decrease in T2\* relative signal intensity was found at 24 h, reflecting the intracellular iron accumulation within macrophages. Only a slight decrease in T2\* signal intensity was found at 48 and 72 h. Local signal intensity changes were correlated with macrophagic uptake of the USPIO [119].

In fact, signal intensity characteristics of abscesses on T1- and T2\*-weighted sequences obtained 24 h following USPIO injection strongly depend upon the administered dose. At low dose ( $50 \mu\text{mol Fe kg}^{-1}$ ), T1 effects were stronger than T2\* effects [120].

#### 2.4.6.6 Kidney Imaging

Intravenous injection of puromycin amino-nucleoside (PAN) in the rat is a good model of nephrotic syndrome secondary to glomerular epithelial cell lesions associated with glomerular and tubulointerstitial infiltration by macrophages. In nephrotic rats, the USPIO ferumoxtran-10 injected intravenously ( $90 \mu\text{mol kg}^{-1}$ ) induced a significant decrease in signal intensity in all compartments of the kidney in the PAN group, whereas the signal from the control group did not vary 24 h postinjection. This effect was correlated with the presence of macrophages with iron oxide nanoparticles at histology [121]. Interestingly, the same USPIO was also found to decrease signal intensity in the cortex in a model of nephrotoxic nephropathy (by injection of sheep anti-rat glomerular basement membrane serum). In this model, equivalent to Goodpasture's syndrome in humans, inflammatory lesions were exclusively located at the level of glomeruli. Conversely, in a rat

model of obstructive nephropathy, which is known to induce diffuse interstitial lesions with macrophage infiltration in all kidney compartments, the USPIO induced a decrease in signal intensity in all compartments [122].

Renal allograft rejection is associated with a massive inflammatory infiltration [123]. In a rat renal allograft model, USPIO, when injected on the fourth day following transplantation, induced a decrease in MR signal intensity at 24 h in some rejecting allografts, whereas isografts and allografts with immunosuppressant treatment had no signal reduction [124]. Promising results were obtained in a preliminary clinical study performed in seven patients with suspected proliferative glomerulonephritis and five with suspected renal graft rejection imaged 72 h following injection of ferumoxtran-10. USPIO-enhanced MRI may allow acute tubular necrosis to be distinguished from other acute nephropathies in native and transplanted kidneys and may also allow active proliferative nephropathies to be differentiated from chronic ones [125]. Of course, such preliminary clinical data, obtained in a small number of patients, need to be confirmed by other studies. Dextran-coated USPIOs serving as blood pool agent were also used to evaluate renal perfusion in dynamic MRI in normal and transplanted rat kidneys.

A good agreement between renal graft perfusion and histopathological changes associated with graft rejection suggests that USPIO-enhanced dynamic MRI may be used to evaluate acute allograft rejection [126].

Iodinated contrast agents can be nephrotoxic in at-risk patients by inducing medullary hypoxia [127]. Intravenous injection of USPIO has been used in rat models of contrast nephropathy to assess renal lesions induced by the iodinated contrast agent [128] as well as their reversibility [129].

#### 2.4.6.7 Acute Cardiac Transplant Rejection

In addition to kidney graft evaluation, USPIO may be used to noninvasively detect inflammatory changes associated with cardiac graft rejection as elegantly shown in two studies involving intravenous administration of either dextran-coated USPIO (27 nm in diameter) [130] or feruglose (NC100150) [131] in rats with heterotopic heart transplantation. Feruglose was used for its blood pool properties in dynamic T1 MRI whereas the dextran-coated USPIO was used for its ability to be captured by macrophages. However, it is worth mentioning that macrophagic infiltration may be associated with other pathophysiological situations such as reperfusion injury or myocardial infection.

#### 2.4.6.8 *In Vivo* Monitoring of Cell Therapy

Recent progress in the field of stem and progenitor cells suggests that their use to correct or replace defective cell populations may soon become a clinical reality. Clinical applications are numerous and promising, both for the central nervous system-related diseases (spinal cord injury, Parkinson's disease, myelin disorders, Huntington's disease, etc) and regeneration of the myocardium. Renal and hepatic pathologies may also benefit from the progress of cell therapies. It is therefore crucial to track the location and *in vivo* distribution of these cells in a noninvasive manner [132].

For this purpose, stem cells must first be magnetically labeled *in vitro* before being administered to a living organism [132].

Several approaches have been described to optimize the internalization process [132], including linking the nanoparticles to the highly cationic HIV *tat* peptide [35] or the use of an anti-transferrin receptor monoclonal antibody covalently linked to nanoparticles (MION-46L) [133].

In fact, it is more convenient to use commercially available and registered nanoparticles. Several studies have shown that ferumoxides or MION-46L can be internalized after mixing with a transfection agent (such as dendrimers, high-molecular-weight poly-L-lysine, lipofectamine, protamine sulfate, etc.) [132, 134] or without such agents [135]. Actually, unmodified SPIOs or USPIOs have been successfully used, at high concentrations, to label cells (fluid phase mediated endocytosis) in the absence of transfection agents [12, 135]. However, it is worth mentioning that SPIO particles, with a diameter of about 100–150 nm were found to be more efficient for cell targeting than were USPIO nanoparticles, which have average hydrodynamic diameters of 20–40 nm [135]. This is probably related to the fact that phagocytic and endocytic uptake increases with increasing particle diameter (at equivalent coating thickness).

Uptake of the nanoparticles increases with time, but cell viability decreases with increasing incubation time. An incubation time of 2–4 h has been considered an acceptable compromise in the case of hematopoietic progenitor cells [135].

There is ample preclinical literature showing that MRI tracking of stem cells is feasible. Some recent examples are shown in Tab. 2.5 [136–139].

Due to the high anatomical spatial resolution of MRI, its potential for quantification, the low cytotoxicity of superparamagnetic nanoparticles and the promising studies currently available, MR monitoring of cell therapy seems to be a technique with a good future.

#### 2.4.6.9 T-staging of Uterine Neoplasms

USPIO ferumoxtran-10, evaluated for MR lymph node staging in uterine carcinoma, was serendipitously found to induce a significant decrease in signal intensity of both myometrium and cervical stroma, thus allowing improved delineation of uterine neoplasms.

A clinical study involving 17 patients subsequently confirmed that the contrast-to-noise ratio between tumor and myometrium and between tumor and cervical stroma was significantly higher on USPIO-enhanced images compared with unenhanced images [140].

#### 2.4.6.10 MRI-detectable Embolotherapy

Embolization is frequently used for the treatment of cancer, but it is so far difficult to locate the injected embolic material and to monitor changes in its structure over time.

SPIOs embedded in polyglucosamine (chitosan) (100–150  $\mu\text{m}$  in diameter) were detected by MRI after selective embolization of a renal artery in rabbits [141]. How-

Tab. 2.5. Animal models of cell tracking: some examples.

Animal model	Stem cells	Nanoparticle used	Result	Reference
Experimental myocardial infarction in pigs	swine mesenchymal stem cells	ferumoxides + poly-L-lysine; intramyocardial injection	successful imaging at 1.5 T and correlation with histology	136
<i>mdx</i> mice (murine model of Duchenne's muscular dystrophy)	multipotent, muscle-derived stem cells	ferumoxides + poly-L-lysine; intramuscular injection	Successful sequential imaging and correlation with histology	137

ever, although they are derived from nanoparticles, such objects can no longer be considered as being nanoparticles.

## 2.5

### Conclusion

The use of superparamagnetic nanoparticulate agents in MRI has been a major development in the range of tools available to clinicians. The efficacy of these agents has led to their being proposed in gastrointestinal tract and hepatic lesion imaging. The prospects for increased use in lymph node and functional imaging look very promising. These nanoparticles are also potential disease-specific agents. This potential depends on improved knowledge of the fundamental mechanisms of the interaction of the superparamagnetic agents with the MR signal and also on the control of the pharmacokinetic behavior of these molecules. In terms of effect on the MR signal, the use of the dose-dependent effect of the nanoparticles on the T1 relaxation time will undoubtedly be an increasingly widely studied research topic in the near future. The importance of the  $r_2/r_1$  ratio as a function of the magnetic field is also emphasized in studies establishing the most appropriate sequences for the molecules under clinical development. In terms of pharmacokinetics, research into preventing the iron oxide particles from being taken up by the liver and spleen reticuloendothelial system by appropriate selection of particle charge, size and coating is of major interest.

The chemical coating of these nanoparticles may also allow them to be linked to molecules (“pharmacophores”) capable of specifically targeting a specific area such as an organ, a disease or a particular biological system such as macrophages or stem cells. This opens major research avenues with important potential clinical consequences.

Nanoparticulate molecules can also behave as blood pool contrast agents for MR angiography at both first-pass and equilibrium. Here, again, clinical applications are numerous. Furthermore, the ability for such nanoparticles to target inflammatory lesions offers major and very exciting prospects for the characterization of numerous inflammatory and degenerative diseases.

Last, but not least, nanoparticles used for medical imaging purposes are also at the interface with targeted therapies and can be expected to have the potential to contribute to the follow-up of such treatments.

In addition to the intravenous route, local administration may also be envisaged (aerosol, interstitial, subcutaneous injection, etc). This opens up an important research field into more specific agents adapted to clinicians’ needs. Fundamental research is needed to better understand the toxicity issues potentially associated with nanoparticulate molecules in general and particularly their interaction with the immune system.

A bright future can be anticipated for nanoparticulate contrast agents provided their development is based on a rational design through a thorough understanding of their physicochemistry and biological environment.

## Carbon Nanotube-based Vectors for Delivering Immunotherapeutics and Drugs

*Alberto Bianco, Wei Wu, Giorgia Pastorin, Cédric Klumpp, Lara Lacerda, Charalambos D. Partidos, Kostas Kostarelos, and Maurizio Prato*

### 3.1

#### Introduction

Administration of drugs is very often limited by problems of insolubility, inefficient distribution, lack of selectivity and side-effects raising health concerns. Currently, most of these problems are the subject of very intense studies, aiming to improve efficiency, availability and toxicity profiles. In addition, cell membranes that act as barriers can pose a problem in drug delivery by selectively allowing only certain structures to pass based on hydrophilicity:hydrophobicity ratios. Among the currently available delivery systems, which include liposomes, emulsions, polymers and microparticles [1–3], carbon nanotubes (CNTs) have recently gained high popularity as potential drug carriers, therapeutic agents and for applications in diagnosis [4–10].

CNTs possess a unique and fascinating one-dimensional nanostructure, which imparts intriguing properties to the nanomaterial, such as tremendous strength [11], high thermal conductivity [12] and amazing electronic properties ranging from metallic to semiconducting [13–16]. These all-carbon hollow graphitic tubes with high aspect and nanoscale diameter [17] can be classified by their structure into two main types: single-walled CNTs (SWNTs), which consist of a single layer of graphene sheet seamlessly rolled into a cylindrical tube, and multiwalled CNTs (MWNTs), which comprise multiple layers of concentric cylinders with a space of about 0.34 nm between the adjacent layers (Fig. 3.1) [18].

Several techniques, e.g. arc-discharge [19], laser ablation [20], chemical vapor deposition (CVD) [21] or the gas-phase catalytic process (HiPCO) [22], have been used to synthesize CNTs. However, up to now, the CNTs prepared by all currently known methods are mixtures of different tubes with a broad distribution in diameter and chirality, and often contaminated by impurities (mainly including amorphous carbon and catalyst particles). Various methods have been developed to purify CNTs, such as oxidation of contaminants [23–28], microfiltration [29], chromatographic procedures [30, 31] and microwave irradiation [32–34].

**Figure 3.1.** Molecular structures of defect-free SWNTs (left) and MWNTs (right) with open ends.

One important feature of CNTs is that this material is practically insoluble in both aqueous and polar/nonpolar organic solvents. Although this characteristic has hindered their chemical manipulation and potential applications in many fields, it has stimulated research in their chemical and physical functionalization.

A great effort has been invested in the search for new ways to chemically derivatize the CNTs. Although their tips are very reactive, similar to fullerenes, their sidewalls are much more inert toward chemical reagents. For this reason, there are not so many methods exhibiting general applicability.

Both covalent and noncovalent functionalization approaches are currently known that are very helpful in disentangling the CNT bundles, but which have different impacts on their electronic properties.

## 3.2 Chemical Functionalization of CNTs

### 3.2.1 Noncovalent Functionalization

The methods of functionalization of CNTs based on noncovalent interaction can be performed without destroying the intrinsic  $sp^2$ -hybridized structure of the nanotube sidewall, so that the original electronic structure and properties of CNTs can be preserved. Different kinds of noncovalent functionalization have been explored.

#### 3.2.1.1 $\pi$ - $\pi$ Stacking Interactions

The noncovalent functionalization of CNTs could be achieved by  $\pi$ - $\pi$  stacking interactions between conjugated molecules and the graphitic sidewall of CNTs. Compounds with the pyrene moiety, e.g. *N*-succinimidyl-1-pyrenebutanoate (Fig. 3.2), could be adsorbed irreversibly onto the surface of SWNTs through  $\pi$ - $\pi$  interaction [35]. Furthermore, via the succinimidyl ester group on this bifunctional anchor,

**Figure 3.2.** Typical molecules that can noncovalently modify CNTs via  $\pi$ - $\pi$  stacking interaction.

various molecules with primary or secondary amines [such as ferritin, streptavidin (SA) or biotin-polyethyleneoxide-amine] were covalently attached to the activated pyrene by nucleophilic attack of the amino group [35]. Using a similar strategy, some other biomolecules (e.g. protein and DNA) [36–38] and gold nanoparticles [39] were also coupled to CNTs.

Through the  $\pi$ - $\pi$  stacking interactions, other classes of molecules, including phthalocyanines [40–42], porphyrins [43–53] and their derivatives, have been immobilized onto the surface of CNTs (Fig. 3.2). It was demonstrated that this kind of composite could display photoinduced charge transfer from the dye molecules to CNTs [42, 45]. The selective interaction between the porphyrin derivative and CNTs was also discovered [46]. The use of Raman spectroscopy, near-infrared (NIR) absorption and buck conductivity has shown that porphyrin derivatives could be selectively adsorbed onto semiconducting nanotubes in a solubilized sample. This is a convenient method to separate the semiconductive CNTs from metallic CNTs.

Polymers with conjugated structures could also be coupled to CNTs by  $\pi$ - $\pi$  forces (Fig. 3.2) [54–75]. The strong interaction between the conjugated polymer and the nanotube remarkably increased CNT dispersibility [54, 61, 66–68]. Some conjugated polymers have been used to purify CNTs by efficient phase separation from the main impurity, consisting of amorphous graphitic shells [62, 64, 65]. In this way, amorphous carbon impurities tend to sediment out of solution, whereas the nanotubes stay in suspension. In addition, this kind of composite has potential applications in the optoelectronic field because of energy transfer from the excited conjugated polymer to the nanotubes [55–60, 63, 66, 69–75].

**Figure 3.3.** Typical molecules that can noncovalently modify CNTs via hydrophobic interactions.

### 3.2.1.2 Hydrophobic Interactions

Another method of noncovalent functionalization of CNTs involves association of CNTs with amphiphilic molecules through hydrophobic interactions in aqueous media. In this system, the amphiphilic molecules interact noncovalently with the aromatic surface of CNTs using their hydrophobic parts, while exposing the hydrophilic parts to the aqueous solution to minimize the hydrophobic interface between the nanotubes and their polar environment.

Through hydrophobic interactions, water-soluble polymers polyvinylpyrrolidone (PVP) and polystyrenesulfonate (PSS) (Fig. 3.3) wrapped helically around the surface of SWNTs helped to dissolve the nanotubes in water [76]. The association between the polymer and SWNTs, which is reversible by changing the solvent system, was very robust, independent of the presence of excess of polymer in solution and uniform along the surface of the nanotubes.

Surfactants were also conjugated to CNTs via hydrophobic interactions. So far, various anionic, nonionic and cationic surfactants have been used to suspend CNTs in aqueous medium (Fig. 3.3) [77–81]. Among them, bile salt surfactants such as deoxycholic acid (DOC) and taurodeoxycholic acid (TDOC) have been found to be very efficient in solubilizing SWNTs. This is because the aggregation was further prevented by the coulombic repulsion between surfactant-coated SWNTs [81]. In addition, if aromatic moieties in the hydrophobic part of the amphiphilic molecule were present, particularly strong interactions between the molecule and the CNTs could be established. This kind of aggregates forms additional  $\pi$ – $\pi$  stacking between the aromatic part of the molecule and the graphitic sidewalls of CNTs while exposing the hydrophilic groups to the aqueous solution. As an example, sodium dodecylbenzene sulfonate (SDBS) presented an increased ability in suspending CNTs in water [80]. Some of the surfactants including so-

dium dodecyl sulfate (SDS), SDBS, DOC or TDOC were found to be very effective in dispersing individually SWNTs [79–81]. This provided the possibility to study the properties of individual SWNTs and further manipulate single tubes [82–86].

Hydrophobic interactions were also used to couple biomolecules to CNTs. In particular, an amphiphilic peptide was wrapped around the SWNT surface. The peptide was able to adopt an  $\alpha$ -helical structure in aqueous solution, exposing the hydrophobic face of the helix to the nanotube surface [87, 88]. Atomic force microscopy (AFM), transmission electronic microscopy (TEM), and absorption and Raman spectroscopy proved that the SWNTs were debundled by the peptide. The peptide-coated nanotubes were assembled into macromolecular structure through charged peptide–peptide interactions between adjacent peptide-wrapped nanotubes. The size and morphology of the supermolecular structure can be regulated by controlling the factors that affect peptide–peptide interactions. It was also demonstrated that the ability to disperse individual SWNTs increased with increasing the amount of aromatic residues inside the peptide sequence [89]. In a similar manner, different proteins have also been adsorbed onto the surface of SWNTs and uptaken by mammalian cells (see Section 3.4) [90].

Another interesting approach involved the conjugation of single-stranded DNA with SWNTs resulting in helical wrapping around the surface of the tube exposing the hydrophilic sugar-phosphate backbone towards the exterior [91, 92]. Using this strategy, individually dispersed nanotubes in solution were obtained. CNT wrapping by single-stranded DNA was strongly dependent on the DNA sequence. Moreover, the dependence of the electrostatic properties of the DNA–CNT hybrid on the tube diameter and electronic properties enable nanotube separation by anion-exchange chromatography.

In addition to a direct interaction with CNTs, biomolecules have also been attached to SWNTs via amphiphilic molecules as a bifunctional linker. For instance, phospholipid molecules with phospholipid (PL)–poly(ethylene glycol) (PEG) chains and terminal amine (PL–PEG–NH<sub>2</sub>) were noncovalently conjugated to SWNTs. PL alkyl chains were adsorbed to the surface of SWNTs via hydrophobic interactions while the PEG chain extended into the aqueous phase for SWNTs dispersion. After incorporation of a heterobifunctional crosslinker sulfosuccinimidyl 6-(3'-[2-pyridyldithio]propionamido)hexanoate (sulfo-LC-SPDP), the functionalized SWNTs (*f*-SWNTs) were coupled with DNA and RNA via disulfide linkage. The complexes were subsequently delivered to cells (see Section 3.7) [93].

### 3.2.2

#### Covalent Functionalization

The characteristics of CNTs such as low curvature, low solubility and bundling tendency make these carbon nanomaterials relatively inert to chemical treatment. So far, a number of routes to covalent functionalization of CNTs have been developed. According to the location of the functional groups, the strategies to covalently functionalize CNTs can be classified into two main types: (i) defect functionalization,

and (ii) sidewall functionalization. The covalent functionalization of nanotubes is more robust and better controllable compared to functionalization based on non-covalent methods.

### 3.2.2.1 Defect Functionalization

CNTs synthesized by any available method are not free of defects. The intrinsic defects include five- or seven-membered rings called Stone–Wales defects,  $sp^3$ -hybridized defects and vacancies in the  $sp^2$ -hybridized six-membered ring carbon structure of the sidewall [94, 95]. A limited number of defects can be tolerated by CNTs without losing their macroscopic electronic and mechanical properties [96–98]. In addition, the tips of the tubes, forming a hemispherical fullerene, have stronger reactivity than the sidewalls because of their higher curvature [99, 100]. When treated with strong oxidizing agents such as nitric acid,  $KMnO_4/H_2SO_4$ ,  $O_2$ ,  $K_2Cr_2O_7/H_2SO_4$  or  $OsO_4$ , CNTs could be opened and cut into short tubes. In the meantime defects were introduced around the CNT surface [28, 95, 100, 101]. Moreover, oxygenated functional groups such as carboxylic acid, ketone, alcohol and ester groups were generated by the oxidization process to the ends and the defect sites of the nanotubes [102]. These functional groups were very important to further functionalize CNTs. Sonication could also produce defects on the sidewall of CNTs that were eager for further chemical reactions [103–106].

Using the nanotube-bound carboxylic acid groups introduced by oxidization treatment, further functionalization was performed via amidation, esterification or the zwitterionic  $COO^-NH_3^+$  formation. Before covalent modification, the carboxylic acids are often activated by thionyl chloride, carbodiimide [e.g. *N*-(3-dimethylaminopropyl)-*N'*-ethylcarbodiimide (EDC) or *N,N'*-dicyclohexylcarbodiimide (DCC)] or *N*-hydroxysuccinimide (NHS), to get highly reactive intermediate groups (Scheme 3.1). Esterification was achieved by the nucleophilic substitution reaction of nanotube carboxylate salt with alkyl halides [107]. The functionalization of CNTs via nanotube carboxylic acids, located at the ends or pre-existing defects of CNTs, preserved the essential features of the CNT electronic structure as well as the bulk properties of the material [102, 108].

The first shortened soluble SWNTs were obtained through carboxylic amidation using octadecylamine [102]. Since then, various lipophilic and hydrophilic dendrons have been attached to CNTs via amide or ester linkages, which significantly improved the solubility of CNTs in organic or aqueous solvents [109]. These groups could be subsequently removed under basic or acidic hydrolysis conditions [110]. In addition, following this functionalization process, CNT bundles were largely exfoliated into individual nanotubes [96]. This enabled further manipulation and investigation of the spectroscopic properties of individual SWNTs.

Via amidation or esterification, polymers like poly-propionyl-ethylenimine-co-ethylenimine (PPEI-EI), poly-*n*-vinylcarbazole (PVK-PS) and PEG were grafted to the surface of CNTs [111]. Another approach called “graft from” was developed to attach polymer to CNTs. The polymerization initiators were first covalently bound to CNTs and then the nanotube-based macroinitiators were exposed to monomers to accomplish the polymerization. In particular, polymer poly-*n*-butyl methacry-

**Scheme 3.1.** Typical CNT carboxylic acid derivatization routes.

late (PnBMA), poly-methyl methacrylate (PMMA) and copolymer PMMA-*b*-poly-hydroxyethyl methacrylate (PHEMA) have been coupled to CNTs via atom transfer radical polymerization (ATRP) [112, 113].

Defect functionalization was used to link biological molecules to CNTs via stable covalent bonds. For example, *f*-SWNTs and *f*-MWNTs with bovine serum albumin (BSA) were synthesized via diimide-activated amidation at ambient condition. It was found that the protein bound to nanotubes remained active [114]. SA (a protein with potential clinical applications in anticancer therapy) was complexed to SWNTs prefucionalized with biotin through EDC activated amidation [115]. Similarly, using the biotin–SA interaction, a biotinylated DNAzyme was covalently attached to MWNTs prefucionalized with SA via amide linkage. The nanotube-bound DNAzymes displayed highly active and classical enzymatic behavior [116].

DNA was also bound to CNTs via amide linkage [117, 118]. DNA–CNT conjugates were hybridized with their complementary sequences and this hybridization was apparently reversible upon a denaturation process. The derived single-strand DNA–CNTs could be reused in a second-round of hybridization. In another case, DNA recognition was achieved by peptide nucleic acid (PNA) *f*-SWNTs, in which PNA was attached to SWNTs via NHS activated SWNTs [119].

### 3.2.2.2 Sidewall Functionalization

The sidewalls of CNTs have an aromatic, six-membered ring structure. So far, various kinds of reactions of the sidewall have been developed such as fluorina-

tion, radical addition, nucleophilic addition, electrophilic addition and cycloaddition [120]. There are two principal sources of molecular strain that affect the reactivity in nonplanar conjugated molecules: (i) pyramidalization of the conjugated carbon atom and (ii)  $\pi$ -orbital misalignment between adjacent pairs of conjugate carbon atoms. Unlike fullerene, in which the strain is primarily from pyramidalization,  $\pi$ -orbital misalignment is the main source of the strain for the sidewalls of CNTs. Since  $\pi$ -orbital misalignment, as well as pyramidalization, scales inversely with nanotube diameter, nanotubes with a smaller diameter display a higher chemical reactivity [99]. Differing from defect reactions, sidewall reactions disrupted the conjugated structure of CNTs, as monitored by Raman or absorption spectroscopy. In the Raman spectrum of pristine SWNTs, three main characteristic modes were disclosed: (i) the radial breathing ( $\omega_r$ ) below  $350\text{ cm}^{-1}$ , (ii) the tangential ( $\omega_t$ ) mode at  $1550\text{--}1600\text{ cm}^{-1}$  and (iii) the disorder ( $\text{sp}^3$ ) mode at  $1250\text{--}1450\text{ cm}^{-1}$ . The radial breathing mode was demonstrated to be in strong relationship with the diameter of the nanotube [121]. The relative intensity of the disorder mode was related to the amount of  $\text{sp}^3$ -hybridized carbon atoms in the SWNTs and thus provided direct information of the extent of sidewall functionalization, in which the carbons linked to functional groups were converted from  $\text{sp}^2$ -hybridized into  $\text{sp}^3$ -hybridized carbon [122]. The absorption spectrum reflected the sidewall covalent modification of SWNTs. The disruption of the conjugated structure caused by the reaction led to the loss of optical transitions between van Hove singularities in the electronic density of state (DOS) of CNTs, which was detected as the loss of the structure of the absorption spectrum [123].

**3.2.2.2.1 Fluorination** The fluorination of SWNTs was accomplished through the reaction of SWNTs with elemental fluorine at temperatures ranging from  $150$  to  $600\text{ }^\circ\text{C}$  [124]. By controlling the reaction conditions such as temperature and time, the stoichiometry could be regulated. In some cases, a stoichiometry of  $\text{C}_2\text{F}$  was obtained (see Scheme 3.3). The investigation of absorption and Raman spectra indicated the electronic perturbation of fluorinated SWNTs. The fluorination allowed exfoliation of SWNTs bundles into individual nanotubes and remarkably improved the solubility of SWNTs in tetrahydrofuran (THF), dimethylformamide (DMF) and various alcohols [125]. The C–F bonds were very sensitive to the treatment with hydrazine, which allowed almost complete recovery of the conductivity and the spectroscopic properties of the pristine SWNTs [124]. It was demonstrated that the Fermi energy level of fluorinated SWNTs, as well as the conduction band energy, were significantly shifted to lower values compared to those of the pristine SWNTs. This revealed that fluorinated CNTs were better electron acceptors than pristine nanotubes, and thus displayed higher chemical reactivity to strong nucleophilic reagents like Grignard, alkyllithium reagents and metal alkoxides (Scheme 3.2). The same result was reached by exploiting the eclipsing strain effect that weakened the C–F bonds in fluorinated CNTs relative to the C–F bond in alkyl fluorides [126, 127]. It was proposed that the substitution of fluorine by nucleophilic reagents proceeds via a concerted allylic displacement [126].

**Scheme 3.2.** Fluorination of CNTs and further modification routes.

**3.2.2.2.2 Radical Addition** The addition of radicals to SWNTs was carried out using different radical sources including perfluorinated alkyl radicals photoinduced from perfluoroalkyl iodide [128], aryl radicals generated by one-electron reduction of the diazonium salt [129–131], radicals produced by decomposition of benzoyl peroxide in the presence of alkyl iodides [132], or directly produced by decomposition of benzoyl or lauroyl peroxide [133].

The functionalization of SWNTs with diazonium reagents was achieved by three different methods: electrochemical reaction [119], thermochemical reaction in solvent [130] and using a solvent-free system [131] (Scheme 3.3). The resultant SWNTs displayed very high degree of functionalization. It was also demonstrated that metallic SWNTs showed higher reactivity in these types of reactions than semiconductive SWNTs, which would allow CNT separation [134].

R = halogen,  $\text{CO}_2\text{CH}_3$ ,  $\text{NO}_2$ , *tert*-butyl,  $\text{COOH}$ ,

**Scheme 3.3.** Example of a strategy to functionalize SWNTs with diazonium compounds. ODCB = orthodichlorobenze.

**3.2.2.2.3 Nucleophilic and Electrophilic Addition** Due to the high electron affinity imparted by the curvature of sidewall [135], CNTs were reacted with strong nucleophilic reagents such as nucleophilic carbene [128], *sec*-butyllithium [136], polymeric carbanions [137] and Birch reduction reagents (lithium/1,2-diaminoethane [108] or lithium/ammonia [138]) to form various *f*-CNTs (Scheme 3.4).

**Scheme 3.4.** Reaction of SWNTs with nucleophilic carbene.

In addition, the electrophilic addition was also achieved by the reaction of chloroform with the sidewall of CNTs in the presence of Lewis acid [139].

**3.2.2.2.4 Cycloaddition** Various cycloaddition reactions to CNTs have been developed, including [2 + 1] cycloaddition of dichlorocarbene [108], nitrenes [128] and bromomalonates under Bingel reaction conditions [140], [4 + 2] Diels–Alder cycloaddition of *o*-quinodimethane performed under microwave irradiation [141], [3 + 2] cycloaddition of azido groups under ultraviolet (UV) irradiation [142], and azomethine ylides [143]. The 1,3-dipolar addition of azomethine ylides is particularly versatile for the functionalization of CNTs [143–145]. This strategy is suitable for different types of CNTs (e.g. pristine and purified SWNTs or MWNTs), and involves the *in situ* generation of an azomethine ylide through the decarboxylation of an immonium salt derived from condensation of a  $\alpha$ -amino acid and an aldehyde in the presence of CNTs. This afforded functionalization of CNTs with the 2-substituted pyrrolidine (Scheme 3.5).

**Scheme 3.5.** 1,3-Dipolar cycloaddition reaction of azomethine ylides to SWNTs.

The CNTs modified by this method possessed a very high degree of functionalization and improved solubility in organic or aqueous solvents [143, 146]. The disruption of the aromatic structure of the sidewalls of the *f*-SWNTs was proven by absorption spectroscopy [143]. This functionalization technique was also used to purify CNTs [147]. Protected amino groups were introduced onto the surface of CNTs via 1,3-dipolar cycloaddition of azomethine ylides [143, 148]. For instance, *f*-CNTs with N-protected glycine were achieved using N-protected amino acid, which were subsequently used to link biomolecules (e.g. bioactive peptides) by fragment condensation or selective chemical ligation (see Section 3.5) [148, 149].

**3.2.2.2.5 Multifunctionalization of CNTs** The first multifunctionalization of CNTs was achieved using a vertically aligned MWNT membrane. One method involved the protection of the sidewalls of CNTs with polystyrene in the process of plasma oxidation that produced carboxylate derivatization. Under this process, aligned MWNT membranes functionalized with carboxylic acid groups at the terminal parts were obtained. Thereafter, bifunctional CNTs with thiol groups on one end and carboxylic groups on the other end were accomplished by floating on top of a 2-aminoethanethiol reaction solution one side of the oxidized CNTs membrane [150]. Another approach was carried out by floating directly one side of an aligned MWNTs membrane on 3'-azido-3'-deoxythymidine (AZT) solution in ethanol under UV irradiation and, after removal of absorbed AZT molecules by washing with ethanol, laying the unmodified side on the surface of a perfluorooctyl iodide solution in 1,1,2,2-tetrachloroethane (TEC) under UV irradiation. Thus, bifunctionalized MWNTs with AZT molecules and perfluorooctyl chains were obtained [151].

These two methods of CNT bifunctionalization are quite complicated and limited to aligned MWNTs. Using a different method, Wu and coworkers introduced an orthogonal protecting methodology into the chemical modification of nanotube to achieve the multifunctionalization of CNTs [152]. In particular, diaminotriethylene glycol chains mono-protected by phthalimide were linked to the carboxylic acids of oxidized MWNTs. In a second step, a suitable N-substituted glycine with a diaminotriethylene glycol chain mono-protected by *tert*-butyloxycarbonyl (Boc) was introduced via 1,3-dipolar cycloaddition (Scheme 3.6). Since the phthalimide is stable to harsh acidic conditions and orthogonal to the Boc, the selection and control of attachment of different molecules was possible [152]. In this case, CNTs containing both fluorescein and amphotericin B (AmB) were prepared, and bioactivity of the conjugates was studied (see Section 3.6) [152]. This method of bifunctionalization is general and suitable for different types of CNTs.

In summary, the functionalization and consequent applications of CNTs have been dramatically increased in the last few years. The chemical modification of CNTs cannot only endow these intriguing nanomaterials with various functions, but also extend their potential applications to different fields of research.

**Scheme 3.6.** One of the routes to the bifunctionalization of CNTs. (a) Neat  $(\text{COCl})_2$ ; Pht-N $(\text{CH}_2\text{CH}_2\text{O})_2\text{-CH}_2\text{CH}_2\text{-NH}_2$ , dry THF, reflux; (b) Boc-NH- $(\text{CH}_2\text{CH}_2\text{O})_2\text{-CH}_2\text{CH}_2\text{-NHCH}_2\text{COOH}/(\text{CH}_2\text{O})_n$ , DMF, 125 °C; (c) hydrated  $\text{NH}_2\text{-NH}_2$ , EtOH, reflux; (d) FITC, DMF; (e) HCl 4 M in dioxane;

### 3.3 CNTs in Diagnosis

A biosensor can be defined as the spatial combination of a biological recognition element and a transduction process into an electrical signal [153]. One of the most used recognition element, due to its high chemical specificity and inherent biocatalytic signal amplification, is an enzyme. Other elements like antibodies, nucleic acid and aptamers are also commonly incorporated into biosensing devices. An important issue in the elaboration of new sensors for application in living systems is to avoid invasive tools, which may cause trauma [154]. In this context, the development of electrical instrumentations has paved the way for miniaturization of noninvasive biosensors. This type of device requires an electronic conductor and a binding agent for recognition [155]. Due to their particular structure [156, 157], CNTs are very promising for the development of new alternative biosensors. The

aromatic carbon structure of CNTs is characterized by a  $(m, n)$  lattice vector in the graphene plane. The two indices determine the diameter and chirality of the nanotubes. When  $n = m$ , the rolling process leads to an armchair tube with a metallic behavior. When  $n - m = 3i$ , where  $i$  is an integer, the nanotubes adopt a zigzag conformation and behave as semimetallic species. Finally, when  $n - m \neq 3i$ , the resulting nanotubes are chiral and semiconductor. Semiconducting nanotubes represent about two-thirds of the SWNTs, whereas metallic tubes represent about one-third. These properties could be exploited for the fabrication of new electronic devices containing CNTs such as field-effect transistors (FETs), nanoelectrode arrays (NEAs), nanoelectrode ensembles (NEEs) or screen-printed electrodes (SPEs) [158–167]. FET devices need semiconductor-type nanotubes. Currently, no method of production permits us to obtain a specific type of nanotubes. Some studies were carried out on the separation or selection of semiconducting and metallic nanotubes [168–171].

This section will describe the utilization of CNTs in FETs and in modified electrodes (NEAs, NEEs and SPEs). Initially, the methods of preparation of the devices will be addressed and then their applications in the field of biosensing will be illustrated.

### 3.3.1

#### CNTs in FETs

The FET is a transistor that relies on an electric field to control the shape and hence the conductivity of a channel in a semiconductor material. Basically, two metal electrodes called the source and drain are connected by the channel, and a third component (the gate) is separated from the channel by a thin insulator film. The latter, usually made up of Si, is replaced by semiconducting SWNTs in CNT-based FETs [158, 164]. There are two types of FETs: (i) p-type and (ii) n-type. If a negative charge is placed on the gate and the applied voltage exceeds a certain threshold, then a hole current flows in a p-type system. For a n-type FET, the current flows when a positive charge is present on the gate and the voltage exceeds the threshold [166].

##### 3.3.1.1 Fabrication

As CNTs are still emerging in the field of electronic devices, the protocols for their preparation are not yet optimized. A CNT-based FET was built by positioning a semiconducting SWNT between two metal electrodes. Typically, as-prepared SWNTs were purified by acid treatment to remove metal particles, which can interfere with the electronic properties of the nanotubes. Other, more elaborate techniques to obtain highly pure nanotubes (up to 95% wt) consisted of heating as-grown HiPCO SWNTs in wet air in the presence of  $H_2O_2$ , followed by acid treatment, magnetic fractionation and vacuum annealing [168]. Subsequently, the nanotubes were dispersed in an organic (dichloromethane) or aqueous solution with a surfactant like sodium dodecyl benzene sulfonate [164, 168]. The suspension was then deposited on a substrate constituted of a degenerately doped, oxidized silicon

**Figure 3.4.** A typical CNT-based FET. The nanotube serves as a semiconductor between the source and the drain electrode. The silicon wafer in this case is used as a back gate.

wafer. An alternative technique consisted on the growth of SWNTs directly on the SiO<sub>2</sub>/Si wafer by chemical vapor deposition (CVD) [36, 172–176]. Once the SWNTs were deposited, the electrodes were fabricated with electron beam lithography, followed by thermal evaporation and lift-off. The degenerately doped silicon was used as back gate electrode. At this stage, the channel was composed of a simple SWNTs or a small bundle with properties ranging from semiconducting to metallic behavior (Fig. 3.4). To select only semiconducting SWNTs, a source-drain current  $I$  was applied at different bias voltage  $V_b$  and gate voltage  $V_g$ . Typically, the  $I$ – $V_g$  curve at low voltage bias shows a low source–drain resistance and almost no gate response for metallic nanotubes [168]. These types of CNT FET devices behave as p-type FETs with holes as dominant carriers. However, by using a network of SWNTs between the drain and the source, the network exhibited a semiconductor-like conductance as semiconducting SWNTs represented about two-thirds of the tubes [176]. Efforts have been made to improve them, thus now they can be built with a  $g_m$  transconductance of  $2300 \mu\text{S } \mu\text{m}^{-1}$  whereas a  $g_m$  of  $650 \mu\text{S } \mu\text{m}^{-1}$  was obtained for the same device based on silicon. Moreover, the parasitic contact resistance changed from more than 1 to 100 k $\Omega$  or above [166]. In addition, a method to select semiconducting SWNTs by current-induced electrical breakdown was developed. This technique permitted a direct current-induced oxidation only at the metallic SWNT component of the CNT bundle by previously depleting semiconducting SWNTs with the gate [177].

Even at this early stage of development, CNT-based FETs have been shown to outperform the corresponding Si-based devices. Their applications in sensing can therefore offer considerable improvements.

### 3.3.1.2 FET Biosensors

CNTs have already been successfully employed for sensing chemical species. In fact, molecules were adsorbed onto the surface of nanotubes. The fringing electric field radiating from the CNT surface polarized the molecules, increasing the capac-

ity of the system. Different chemical vapors including  $\text{NO}_2$  and  $\text{NH}_3$ , and a wide range of chemicals were detected [35, 160, 178–181]. A more sophisticated system based on a single-strand DNA-SWNT-FET was designed. The source–drain current was a function of the chemical environment and was modulated by the DNA sequence. In fact, depending on the DNA sequence covering the nanotube, the response for a same gas can be different in both sign and magnitude. Thus, the selection of a DNA sequence can enhance the detection of a specific gas and can serve for the design of “molecular noses” able to detect one molecule in a strong and variable background. The sensor had a rapid response and was also self-regenerating as it could undergo 50 gas exposure cycles [174].

In the field of biosensing, CNT-based FETs appeared as promising devices. Glucose biosensors are particularly requested. In industrialized countries, about 4% of the population is prone to diabetes. Thus, the selective determination of blood glucose is of crucial importance. *In vivo* monitoring requires a biosensor with long-term stability, selectivity and sensitivity in the millimolar range. Usually, the sensor for this type of application requires to couple the enzyme glucose oxidase to the electrochemical transducer. In the case of a CNT-based FET, it was possible to link noncovalently the enzyme via a pyrene moiety [35]. 1-Pyrenebutanoic acid succinimidyl ester was adsorbed onto the nanotube surface by strong van der Waals interactions. The enzyme was subsequently reacted with the active ester, thus forming a covalent linkage. The quantity of enzyme deposited on the CNT support was about one enzyme molecule every 12 nm of nanotube. Such FET allowed the detection of pH changes down to 0.1, by measuring the difference of conductance. Similarly, the CNT sensor could detect the activity of the enzyme in the presence of glucose down to 0.03 mM [36]. This technique was also applied to the recognition of proteins by using biomimetic sensors. One example concerned the sensing of thrombin via an aptamer [172]. An aptamer is an artificial oligonucleotide that can bind any kind of entity (e.g. metal ions, small organic molecules, proteins and/or cells). The affinity, selectivity and specificity are equal or superior to those of antibodies. Practically, the immobilization of thrombin aptamer was achieved by first covering the nanotube in the FET with carbodiimidazole (CDI)-Tween. Tween possess a hydrophobic part, which bound noncovalently to the tube, while the CDI moiety allowed covalent fixation of the aptamer. The measurement of the conductance permitted the detection of thrombin in the millimolar range. The selectivity appeared very high in comparison to elastase. Elastase is another serine protease with an isoelectric point ( $pI$ ) and molecular weight similar to thrombin. However, no changes in the conductance were observed in its presence. Although the specificity and selectivity could be very high, the mechanism of electrical conductance changes is still not well understood. Dai and coworkers fabricated three different types of devices to better comprehend this phenomenon [175]. The first device consisted of a system with unmodified CNTs and Pd/Au electrodes. The second had a methoxy(PEG)thiol covering the metal electrodes to block nonspecific protein adsorption. The third tool was modified at the electrode and the nanotube was coated with Tween 20. The conductance measurements were performed in the presence of different proteins including BSA, human serum albumin (HAS), human cho-

ronic gonadotropin (hCG),  $\alpha$ -hCG, human immunoglobulin G (hIgG) and avidin. Unspecific binding led to a decrease of conductance on the first device, a change was detected only for avidin on the second and any change at all was observed on the third. All the proteins used have a  $pI$  around 5–7, meaning that at physiological pH they are neutral or slightly charged. Avidin was an exception, because its  $pI$  is between 10 and 11, highlighting the importance of the positive charges. The advanced hypothesis for the mechanism of conductance modifications was that the variation originated from the metal–tube contact. These p-type devices always exhibit a decrease upon protein adsorption. This behavior was similar to a reduction of the work function of a metal. In the case of Pd electrodes, the Schottky barrier to the valence band of the nanotubes is mainly zero. The biomolecular adsorption increased this barrier. However, in the case of avidin, the charges on the CNT surface exerted gating effects or charge transfer causing variations in the electrical conductance.

The CNT-based FETs have also been used in an antibody-based sensor [175]. For example, the hCG– $\alpha$ -hCG antigen–antibody system is currently used for clinical pregnancy tests. The hCG protein could be adsorbed and detected onto the nanotube FET. A signal was observed upon the addition of  $\alpha$ -hCG. This biosensor was capable of detecting species in the nanomolar range. The same comparison was done by using antibody-specific binding onto the tubes [176]. CNTs were first covered by Tween. Then U1A RNA splicing factor was linked to the Tween after activation with 1,1-carbonyldiimidazole. U1A is a prominent autoantigen target in systemic lupus erythematosus. The measurements revealed the binding of the monoclonal antibody 10E3, which recognizes U1A specifically, at a concentration of 1 nM or below. CNT-based FETs were also functionalized with hemagglutinins (HAs) [173]. Instead of binding the proteins directly to the nanotubes, they were attached on the reverse side of the silicon wafer (Fig. 3.5). The silicon wafer was oxidized with  $H_2SO_4$  for the fixation of a dithiothreitol linker. Next, the introduction of a maleimide linker permitted the coupling of HA. The  $I-V_g$  curves measured in the presence of various concentrations of an antibody anti-HA showed a detection limit of approximately of  $5 \times 10^{-8}$  mg mL<sup>-1</sup>. Comparing these results to the same experiment with an enzyme-linked immunoadsorbent assay (ELISA), the FET increased the limit of detection by three orders of magnitude.

Therefore, the preliminary results on CNT-based FETs displayed an increase in the sensitivity as well as better detection limits. The great advantage of these new FETs stems from their small size, because miniaturization is an important parameter for the development of biosensors able to work at the single-cell level.

### 3.3.2

#### CNT-based Electrodes

The construction of nanoelectrodes is a great challenge to create miniaturized sensors. Reducing the size will enable us to detect species in microenvironments with high sensitivity. Thus, the utilization of nanomaterials is highly recommended. CNTs can be considered ideal candidates.

**Figure 3.5.** CNT-based FET functionalized on its reverse side. The silicon wafer is oxidized on the reverse side to allow the linkage with HA. The current is measured in air by applying a voltage to the back gate facing the reverse side.

### 3.3.2.1 Fabrication

Several techniques were used to prepare CNT-modified electrodes. One approach consisted on the covalent linkage of oxidized nanotubes to a metal electrode (usually Au) [182, 183]. The purification of nanotubes by acid treatment shortened the nanotubes leading to free carboxylic functions mainly at the tips. An Au electrode was functionalized with a mixture of cysteamine and 2-thioethanol. The CNT coupling reaction was performed in the presence of an activator of the carboxylic groups (EDC or DCC). 2-Thioethanol was used to avoid nonspecific adsorption of the nanotubes onto the electrode surface as well as to prevent accumulation of the nanotubes on it. The obtained CNT array was further functionalized with any biological species to finalize the elaboration of the electrode (Fig. 3.6).

Another technique was based on the deposition of a metal film (usually Pt or Cr) on a Si wafer to serve as an electrical contact for the nanotubes. Then, a Ni catalyst was deposited on the top of the metal film and the nanotubes were grown by CVD [165, 184]. The forest-like vertically aligned nanotube array was encapsulated by a dielectric film ( $\text{SiO}_2$  or Epon 828 epoxy-based polymer), dramatically increasing the mechanical strength of the nanotube array, so that a chemical mechanical polish-

**Figure 3.6.** Nanoelectrode made of CNT arrays. The CNTs are disposed in a forest-like structure. The carboxylic groups on their tips are not hindered and can be easily functionalized.

ing process could be applied. This treatment oxidized the exposed end of the tubes and allowed control of the quantity of available nanotubes. Again, the nanotubes were ready to be further functionalized to create the nanoelectrode sensor (Fig. 3.7). A third approach to fabricate the electrodes was based on the utilization of the SPE technique [185, 186]. The working and the reference electrodes were made of carbon paste. Three masks were used to form: (i) sliver conducting lead wires, (ii) the carbon film for electrochemical reactions and (iii) the insulating film. In the reaction compartment, the carbon paste film was modified by CNTs. Oxidized CNTs were dropped with a solution of *N*-cyclohexyl-*N'*-( $\beta$ -[*N*-methylmorpholino]ethyl)carbodiimide *p*-toluenesulfonate (CMC) to afford a hydrophilic polymer layer after drying in hot air. Alternatively, oxidized CNTs were dispersed in DMF and then incubated with EDC and NHS to be activated for the coupling of the bioactive molecule.

### 3.3.2.2 Nanoelectrode Biosensors

As mentioned for CNT-based FETs, the environment around the tubes changes their conductance. The measurement of the current will give direct information of the medium. A modified glassy carbon electrode was constructed to detect hydrogen peroxide. Nanotubes were first suspended in Nafion, which possess ion-exchange, discriminative and biocompatibility properties [187]. The suspension was then simply deposited onto the electrode. In this case, cyclic voltammograms displayed oxidation and reduction currents, whereas in comparison no redox activity was observed for a simple glassy carbon electrode. Nevertheless, the preparation of biosensor required the immobilization of a biological entity. This can be done by linking the molecule to the free carboxylic groups of the nanotube tips. To control

**Figure 3.7.** A nanoelectrode ensemble. The nanotubes are grown directly on the metal film via a catalyst (usually nickel). After deposition of the dielectric film, the number of nanotubes

tips present on the surface can be selected by polishing. A weak polishing lets only the longest tubes appear with a low-density nanoelectrode array.

the specificity of the binding location, it is crucial to avoid any nonspecific absorption. Some reports described the interaction of proteins with nanotubes [188, 189]. For example, SA strongly bound to nanotubes [188]. Hence, the protection of the sidewall of the tube can be performed by wrapping a polymer like Triton X co-adsorbed with PEG [189]. This provided an efficient barrier against protein adsorptions. As a consequence, specific immobilization of glucose oxidase at one tip of the nanotube was achieved via reconstitution of the apo-flavoenzyme glucose oxidase with the flavin adenine dinucleotide (FAD) cofactor [183]. The free amine of the FAD was coupled to the carboxylic end by activation with EDC. After addition of the apo-glucose oxidase, the glucose enzyme was reconstituted at the top of the tubes. The turnover rate of electrons transferred to the electrodes was 6-fold higher than for the active site of the glucose oxidase to its natural  $O_2$  electron acceptor. By controlling the length of the tubes in the array, the measurements of the current revealed that the electrons could be transported along distances greater than 150 nm. Evidently, a shorter length enhances the electrocatalytic current. Another method used the nanoelectrode ensembles where the carboxylic end-groups of the nanotubes were directly coupled to the glucose oxidase [184]. This glucose sensor showed high selectivity towards the substrate. Indeed, a negligible signal was observed for ascorbic, uric acid and acetaminophen. The nanoelectrode gave a linear

response up to 30 mM glucose. For practical use, the required linear response is 15 mM. The detection limit of the system was 0.08 mM. These types of sensors could be extended to other enzymes, like microperoxidase MP-11 [182].

The utilization of nanotubes also permitted the development of nucleic acid sensors [165, 185]. The free carboxylic functions on the carbon nanoelectrode were used to covalently link different 5'-amine modified oligonucleotides. In this manner, the oxidation of guanine bases could be monitored to detect DNA hybridization. Several ways were explored to construct this type of sensor. Initially, the sensors exploited the utilization of oligonucleotide probes in which guanines were replaced by nonelectroactive inosines to eliminate the redox background [165]. The complementary DNA sequence was instead modified with a 10-base polyguanine at the 3' position. However, the background noise remained high because of the low oxidative current resulting from the small number of guanines. To circumvent this problem, a  $\text{Ru}(\text{bpy})_2^{3+}$  mediator was introduced to transfer the electrons from the base to the electrode. Polymerase chain reaction (PCR) amplicons were then detected. An improvement of at least 30 times was obtained in comparison to the use of the same kind of technique with a silane-modified electrode. In a similar approach, hybridization was observed with the single-strand binding (SSB) protein, which plays an important role in DNA replication [185]. The SSB protein binds specifically to the single-strand DNA, while it has almost no affinity toward double-strand DNA. The protein sequence comprises four tyrosines and four tryptophans. The electrochemical oxidation of these residues was measured when the protein was immobilized onto the electrode. Then, specific detection of single-strand DNA in the medium was monitored by signal changes upon binding. At this stage of development, the performances of the biosensor remained constant for 1 week, but decreased 10-fold after 1 month and vanished after 2 months. A third technique of fabrication was applied to carbon nanoelectrodes for monitoring total cholesterol in blood [186]. Cholesterol oxidase, peroxidase, potassium ferrocyanide and threhalose dissolved in a buffer were deposited onto the reaction area of the electrode. Then, a hydrophilic polymer was applied to coat the rest of the electrode. Finally, cholesterol esterase, threhalose and Triton X in a phosphate buffer were deposited. The enzymatic cascade led to the formation of hydrogen peroxide, which was reduced by the ferrocyanide. The resulting current was recorded at various concentrations of cholesterol. While a nonlinear relationship was obtained between the cholesterol concentration and the current response for an unmodified electrode, an almost linear response was observed for a CNT-modified electrode. Moreover, the CNTs provided almost double the sensitivity, an acceptable repeatability over three consecutive assays, no interference effect from ascorbic and uric acids, and a stability at room temperature over 2 months.

In summary, CNTs are endowed with appropriate characteristics for the elaboration of biosensors. They possess high electronic conductivity and nanometric size. Miniaturization is an important parameter in the conception of more efficient sensors, which could be used to control biochemicals at the single-cell level. The current performance of nanotube-based biosensors has already overtaken the other sensors, but optimization still needs to be reached. Glucose biosensors are very

**Figure 3.8.** Molecular structure of FITC– (left) and fluorescent peptide–CNT (right) conjugates.

promising. However, numerous other oxidases exist and can be employed for the design of novel CNT-based biosensors. A bright future awaits these new sensors for pharmaceutical and clinical use.

### 3.4 CNT Cell Uptake

CNTs started to develop as new drug delivery systems because of their capacity to penetrate cell membranes and distribute into the cytoplasm and/or the nucleus.

**Figure 3.9.** Confocal image of HeLa cells incubated with the fluorescent peptide–CNT conjugate.

This behavior was observed for the first time in 2004 by Pantarotto and coworkers [190]. The amino groups of *f*-CNTs were coupled either to fluorescein isothiocyanate (FITC) or to a peptide bearing FITC on the side-chain of a lysine (Fig. 3.8).

Subsequently, fibroblasts were incubated with the fluorescent nanotubes. It was found that these tubes were easily internalized by the cells and could be detected in the cytoplasm and the nucleus using epifluorescence and confocal microscopy [190]. This penetrating capacity was also observed in other types of cells (Fig. 3.9).

The mechanism of uptake of this type of *f*-CNTs was energy independent and nonendocytotic. Indeed, the incubation of the fluorescent tubes with different types of cells in the presence of sodium azide or 2,4-dinitrophenol, well-known endocytosis inhibitors, did not block the penetration capacity of the tubes. The reduction of the temperature of incubation from 37 to 4 °C again did not affect cell uptake to a significant extent.

When the CNTs were devoid of the fluorescent moiety, they could be detected in the cells using transmission electron microscopy (TEM) [191]. Ammonium *f*-CNTs were incubated with HeLa cells. After washing, staining and fixing, the cells were embedded into a polymer that was cut into thin slices of 90 nm thicknesses using a diamond microtome. Each slice was deposited on a TEM grid and observed under the microscope. Functionalized nanotubes were visible in the cytoplasm and the nucleus. The tubes were also identified at the level of the cellular membrane in the process of crossing this barrier [191]. The shape of the tube was elongated, suggesting a behavior as a nanoneedle, capable of piercing the lipid bilayer of the membrane without provoking cell death. This mechanism, which can be defined as nanopenetration, was observed by Cai and coworkers, who developed an efficient molecular delivery technique called nanotube spearing [192]. In this case, CNTs filled with magnetic particles were cultured with MCF-7 cells. Under the action of a magnetic field, the suspended tubes were put in rotation to spear the cells. A second static magnetic field was applied under the plate where the cells were grown to pull the tubes through the cell membrane into the cytoplasm. Scanning electron microscopy showed the nanotubes crossing the cell membrane like tiny needles.

NIR fluorescence microscopy could be also used to detect CNTs in the cells [193]. Macrophages were able to phagocytose pristine CNTs without apparent toxic effects. Subsequently, the tubes were tracked into the cells by irradiation at 1100 nm and recovery of a fluorescence signal. This technique seems very promising since it could be extended to the visualization of CNTs in the tissue and the organs. However, only non-*f*-CNTs were used in this study and concerns are emerging about their toxicity once injected into a body (see Section 3.8).

An alternative pathway of penetration of CNTs into the cells was reported by Dai and coworkers. Oxidized CNTs were initially functionalized with biotin and then complexed to a fluorescent SA [115]. The protein–nanotube conjugates were taken up in an endocytosis-mediated mechanism, as they were localized into the endosomes. This behavior was also confirmed by complexing different proteins or nucleic acids to the nanotubes via noncovalent interactions [90, 194]. HeLa and HL-60

cell lines were treated with fluorescent BSA or SA, and a fluorescent 15-mer oligonucleotide at low temperature and in a adenosine triphosphate (ATP)-depleted environment [194]. Preincubation of the cells with sodium azide or cell culture performed at 4 °C clearly influenced nanotube uptake. In addition, it has been demonstrated that the endocytosis was clathrin dependent. To assess the role of clathrin, experiments were carried out in the presence of sucrose and potassium-depleted medium to disrupt the clathrin-coated vesicles. Under these conditions, the level of nanotube cellular uptake was drastically reduced. In parallel, it has also been demonstrated that the nanotubes were not internalized through the caveolae or lipid-raft pathway. In this case the cells were treated with filipin and nystatin, known to perturb the cholesterol distribution on the cell membrane, which is implicated in the lipid-raft mechanism. The two drugs did not hamper the uptake of the CNTs. Therefore, it could be concluded that *f*-CNTs complexed to proteins and nucleic acids penetrate following a clathrin-dependent endocytotoxic process. Elucidation of the different mechanism of cellular entry is crucial for the development of CNTs as delivery system for therapeutic molecules.

### 3.5 CNTs as Delivery Devices for Antigens and Adjuvants

The development of new delivery systems for the successful and effective administration of vaccines and immunotherapeutics still remains a great challenge. The listing of “delivery” among the top 10 biotechnologies required for improving global health has recently reinforced this view [195]. Among the novel delivery options, CNTs have emerged as a promising option for biomedical applications. This is because CNTs can enter into the cells and can be functionalized (see Section 3.4) [148, 190]. The later property makes them soluble, nontoxic and permits modification of their surface [7]. Moreover, these molecules in the nanometer size range offer the control that modern drug delivery and targeting demands – control of the chemical nature of the carrier, control of the surface and, important in targeting, control of dimensions. CNTs can serve as vaccine delivery and adjuvant vehicles by virtue of their nanoparticulate nature. The hydrophobic nature of CNTs contributes to vaccine delivery capability by facilitating the interaction of CNTs with antigens or immunostimulatory molecules and uptake of the vaccine particles by immunocompetent cells.

#### 3.5.1 Interaction of *f*-CNTs with CpG Motifs and Potentiation of their Immunostimulatory Activity

Immune responses to vaccine antigens are normally enhanced by immunostimulants called adjuvants. Recently, synthetic oligodeoxynucleotides (ODN) containing immunostimulatory CpG motifs (ODN CpG) have been considered as candidate adjuvants for vaccines or immunomodulators for therapeutic applications against

tumors, allergy or to combat bioterrorist threats [196–199]. CpG motifs are unmethylated sequences that derive from bacterial DNA. The activation of the immune system by CpG motifs is a highly evolved defense mechanism, whose actual aim is to detect the microbial nucleic acid [200]. This can be achieved through the Toll-like receptor 9 [201], which belongs to the Toll family of pattern recognition receptors, conserved during the evolution in species from insects to humans [202]. CpG motifs induce B cell proliferation, antibody secretion and activate antigen-presenting cells (APCs) to express costimulatory molecules and secrete cytokines including, interleukin (IL)-12 and tumor necrosis factor (TNF)- $\alpha$  [200, 203]. In particular, the increased production of IL-12 promotes interferon (IFN)- $\gamma$  production by natural killer (NK) cells and T cells, and enhances the antigen-specific T cell proliferation and differentiation of naive T cells towards the T helper ( $T_h$ ) 1 phenotype [200, 203]. The triggering of the Toll-like receptor 9 by the ODN CpG is a critical event for the activation of innate immune system [203]. This requires the entry of ODN CpG into the cell for recognition by its receptor, which is expressed in endosomal compartments. Despite the potent immunostimulatory properties of ODN CpGs, their effect is short-lived because of their low uptake by the cells. In order to increase their biological properties, delivery of CpG using CNTs was explored. Therefore, ODN CpGs were first complexed with *f*-CNTs and their interaction analyzed [204], and then the immunostimulatory properties of the complexes were tested *in vitro* [204].

Cationic CNTs lend themselves as vectors for delivery because of their ability to form complexes with ODN CpG. Surface plasmon resonance (SPR) help in the understanding of the interaction that occurred between a *f*-CNT and ODN CpG to form complexes in real time, and gave an insight of how these molecules were bound [204]. Three types of *f*-CNTs were selected in the first series of experiments (Fig. 3.10).

Each *f*-CNT was attached onto the sensor chip by forming a stable amide bond between the amino groups on the tubes and the carboxylic functions on the chip's carboxylated dextran matrix, activated in turn with EDC and NHS. Following attachment, the increase in mass due to the interaction of *f*-CNTs with the ODN CpG 1668 present in the fluid phase was measured using the Biacore 3000 system.

Figure 3.10. Molecular structures of ammonium *f*-CNTs for ODN CpG complexation.

Although there were no significant differences between the affinity of binding between the two SWNT preparations and the ODN CpG 1668, the ODN CpG 1668 bound to the MWNT-NH<sub>3</sub><sup>+</sup> formulation with much lower affinity. This difference was probably due to the relative dimensions and charge distributions of the two types of *f*-CNTs. Both SWNT-Lys-NH<sub>3</sub><sup>+</sup> and MWNT-NH<sub>3</sub><sup>+</sup> displayed the same amount of positive charges. However, there must be an avidity effect, resulting from a double electrostatic interaction per ODN CpG molecule after their binding to SWNT-Lys-NH<sub>3</sub><sup>+</sup> where the two ammonium groups on each lysine residue are in close proximity with respect to the single ammonium on the MWNT-NH<sub>3</sub><sup>+</sup>.

Following the demonstration of complexation of the ODN CpGs with *f*-CNTs, their immunopotentiating effect was tested [204]. SWNTs were the CNTs of choice since they bound to ODN CpG 1668 with higher affinity than the MWNTs. After incubating the SWNT-Lys-NH<sub>3</sub><sup>+</sup> at various excess ratios with a minimal immunostimulatory dose of the ODN CpG 1668, the complexes were added to a culture of naive mouse splenocytes. Complexes of SWNT-Lys-NH<sub>3</sub><sup>+</sup> at 18:1 and 9:1 ratios over the ODN CpG 1668 increased its immunostimulatory properties by 58 and 45%, respectively. There was no significant effect on immunostimulation when lower ratios of SWNT-Lys-NH<sub>3</sub><sup>+</sup>/ODN CpG were tested. Although the mechanism of this immunopotentiating effect is not quite clear, it could be argued that the high excess of SWNT-Lys-NH<sub>3</sub><sup>+</sup> over the ODN CpG 1668 had a neutralizing effect of its negative charge. As a consequence, the repulsion forces by the negatively charged cell membrane were presumably reduced and therefore, the cellular uptake of ODN CpG 1668 was increased.

These preliminary findings pave the way for future *in vivo* experiments using animal models of disease or vaccination protocols to test the therapeutic or adjuvant potential of such complexes. Moreover, further studies will need to address whether serum proteins can alter the surface potential of CNTs, their size, the stability of complexes and the formation of aggregates.

### 3.5.2

#### **Presentation and Immunogenic Potential of Peptide Antigens Attached onto *f*-CNTs**

Peptides representing selected regions from the amino acid sequence of a protein antigen (epitopes) can be used as immunogens to induce peptide- and pathogen-specific B cell and CD4<sup>+</sup> (T<sub>h</sub>) or cytotoxic CD8<sup>+</sup> [cytotoxic T lymphocyte (CTL)] T cell responses. Activated CD4<sup>+</sup> T cells help B cells to produce antibodies that neutralize viruses and bacterial toxins [205], enhance the magnitude of cytotoxic T cell responses to clear virus-infected cells [206], and regulate the immune responses to foreign antigens on the basis of the cytokine profile they secrete [207]. CD8<sup>+</sup> T cells are the main effector cells responsible for the clearance of viral infections [208]. The development of such peptide vaccines requires a basic knowledge of the role of the various antigens of the pathogen in infection and immunity, the use of a cocktail of epitopes able to induce a broad range of protective antibody and T cell responses, and a delivery system for presentation of these epitopes to immunocompetent cells.

B cell epitopes are mainly located on the surface of a protein antigen. Therefore, the native structure of the antigen is critical for recognition by antibodies. Immunization with flexible peptides normally induces a diverse set of antibody specificities that bind several different conformations of the peptide [209]. However, a subset of these antibodies can cross-react with the native protein, presumably because these peptides adopt a conformation similar to the native epitope [209]. Therefore, for a synthetic peptide vaccine to elicit a protective antibody response it is important the B cell epitope to be presented to the immune system at a conformation mimicking the native structure. The ability of *f*-CNTs to present a covalently linked synthetic peptide representing a neutralizing and protective B cell epitope from the foot-and-mouth disease virus (FMDV) corresponding to the 141–159 region of the VP1 viral envelope protein was tested [210]. SWNTs-NH<sub>3</sub><sup>+</sup> and SWNTs-Lys-NH<sub>3</sub><sup>+</sup> modified with a maleimido group were used. This functionality allowed linking the FMDV peptide bearing an additional cysteine at the N-terminus necessary for a selective chemical ligation (Fig. 3.11).

To elucidate the structural and functional relationship between *f*-CNTs-linked peptide and peptide-specific polyclonal and monoclonal antibodies, the ELISA test and SPR were used. Both methods demonstrated that the SWNTs-linked peptide retained the structural features required for recognition by anti-FMDV peptide monoclonal and polyclonal antibodies [148, 211].

Since the FMDV peptide was not immunogenic (i.e. not capable of eliciting an immune response) in BALB/c mice (T cell help is required) [212] an immunization protocol that has been previously shown to overcome the requirement of coupling nonimmunogenic peptides to carrier proteins or T<sub>h</sub> epitopes was employed [213]. To this end, the SWNT-linked FMDV peptide was coimmunized with a protein antigen that provided T cell help, like ovalbumin (OVA) in a Freund's emulsion. After two injections, strong antipeptide antibody responses were induced that had significantly higher virus neutralizing capacity than the antibodies elicited after coimmunizing the free peptide with OVA [211]. This finding highlights the potential of *f*-CNTs to act as a delivery system capable of presenting critical epitopes at an

Figure 3.11. Molecular structures of FMDV peptide *f*-CNTs.

appropriate conformation to elicit antibodies with the right specificity. Moreover, no antibody responses were induced against the *f*-CNTs, which could potentially hamper the successful outcome of the immunization procedure, particularly when several administrations are required [214].

Although the application of CNTs in the field of vaccine delivery is in its infancy, CNTs offer several attractive features, including the control one has over the primary nature of the system. They provide a platform for the attachment of adjuvants and antigens. Their potential use as vaccine delivery and adjuvant vehicles is likely to have a significant impact on the route that vaccines will be administered in the future and the required dose, conferring a competitive advantage in the market place. Obviously, their immunogenicity, toxicity, biodegradability, stability, biocompatibility, cost and consistent GMP manufacturing with readily scalable production processes has to be studied for each system and each application. These challenging issues should not inhibit research in examining the potential of CNTs to deliver vaccines since the most interesting and valuable delivery systems are yet to come.

### 3.6

#### CNTs for Drug Delivery

Drug delivery systems are necessary to improve the pharmacological profile and the therapeutic properties of administered drugs [1]. Among the wide variety of available delivery systems, CNTs may represent a promising alternative [215]. The application of *f*-CNTs as new nanovectors for drug delivery became possible soon after the demonstration of cellular uptake of this new material. However, only a few examples of delivery of therapeutic agents using CNTs are currently reported in the literature. Dai and coworkers have shown the potential of CNTs to transport proteins into the cells [90]. Single-walled CNTs were shortened to a length between 20 and 100 nm using strong acid conditions. This treatment also allowed the generation of carboxylic groups at the terminal parts of the tubes and at their defect sites. The carboxylated tubes were complexed with different types of proteins including SA, protein A, BSA and cytochrome *c* (Fig. 3.12).

Mammalian cell lines were incubated with the complexes to study the capacity of CNTs to drive the adsorbed proteins into the cells. The complexes were localized in the endosomes and released into the cytoplasm by addition of chloroquine (a molecule able to destroy the endosomes). In the case of cytochrome *c*, it was verified that the protein exerted its biological function after liberation from the endosomal trap. Indeed, the cells entered into apoptosis. At the same time, it was shown that CNT-protein complexes were biocompatible by measuring cell proliferation.

In a different approach, Wu and coworkers used *f*-CNTs with AmB – one of the most effective antimycotic molecules for the treatment of chronic fungal infections (Fig. 3.13) [152].

MWNTs were treated with strong acid conditioned to reduce their length to about 180–940 nm. The carboxylic groups were coupled with a phthalimide

**Figure 3.12.** Molecular model of the complex between a shortened CNTs and SA.

mono-protected triethylene glycol diamine. Subsequently, the tubes underwent the 1,3-dipolar cycloaddition reaction to introduce a N-functionalized pyrrolidine ring on the external walls of the tubes. A second Boc-protected amino group was therefore introduced on the nanotubes. The two protecting groups are orthogonal and permitted to modify the tubes with a fluorescent probe to follow the cell internalization of the conjugate and the active drug AmB to exert its antifungal activity. It

**Figure 3.13.** Molecular structure of CNTs functionalized with FITC and AmB.

has been shown that AmB–CNTs were rapidly internalized into Jurkat cells in a dose-dependent manner. The process was nonendocytotoxic since the incubation of the cells at 4 °C or in the presence of sodium azide did not completely block the uptake. The drug was internalized into mammalian cells with a remarkable reduction of toxicity. Indeed, AmB is widely used, but it suffers from high toxicity. At the highest dose, more than 40% of cells died by the effect of free AmB, while all cells remained alive following the treatment with AmB covalently conjugated to CNTs. Very interestingly, AmB preserved its high antifungal activity once linked to the nanotubes. Different types of pathogens including *Candida albicans*, *Candida parapsilosis* and *Cryptococcus neoformans* were treated with AmB–CNT conjugates, and the activity was in some cases higher than the drug alone. Although only some hypotheses on the action of the AmB linked to the tubes could be formulated (increase of the solubility of the drug, multipresentation of the drug by CNTs that favor interaction with the fungal membrane), the conjugation of AmB to the tubes modulated its therapeutic effect by decreasing mammalian toxicity and increasing the antifungal activity.

Using another strategy, Hosmane and coworkers prepared SWNTs with a carborane cage for boron neutron capture therapy (BNCT) [216]. CNTs were functionalized with a substituted  $C_2B_{10}$  carborane derivative via nitrene cycloaddition. Following treatment with sodium hydroxide, a water-soluble CNT conjugate was obtained (Fig. 3.14).

Then, the biodistribution study on different tissues showed that carborane nanotubes were concentrated more in tumor cells than in blood, liver, lung or spleen when administered intravenously. However, the mechanism for this it is not yet understood. The results are preliminary, although promising for future applications of CNTs on delivery of boron-based agents for effective BNCT treatment of cancer, provided that cytotoxicity and more complete biodistribution studies prove the biocompatibility of this system. Another application of CNTs in cancer therapy was shown by Kam and coworkers [217]. The property of CNTs to adsorb NIR irradiation was exploited to kill cancer cells. Pristine SWNTs were wrapped with PEG modified with a PL moiety on one side and folic acid (FA) on the other side. As

Figure 3.14. Molecular structure of CNTs functionalized with a carborane cage.

**Figure 3.15.** Molecular structure of CNTs functionalized with FITC and methotrexate.

tumor cells are known to overexpress folate receptors, the PL-PEG-FA/SWNT construct was mainly taken up by cancer cells, which were then destroyed by using a laser wavelength of 808 nm. Laser pulses induced local heating and consequently death only of those tumor cells that had internalized the CNTs.

Pastorin and coworkers have developed an alternative method to exploit CNTs in cancer [218]. CNTs were doubly functionalized using 1,3-dipolar cycloaddition reaction. Two orthogonally protected amino groups were introduced on the sidewalls and the tips of the tubes. After selective deprotection, an anticancer molecule [methotrexate (MTX)] and a fluorescent probe (FITC) were linked to the tubes (Fig. 3.15).

MTX is a drug widely used against cancer, but it displays a reduced cellular uptake. Therefore, the limited capacity of MTX to cross the cell membrane could be overcome by its conjugation to CNTs, which are able to enhance cell uptake of linked moieties. The presence of fluorescein provided the optical signal for imaging CNT-drug into the cells. Jurkat cells were incubated with different doses of MTX-CNT and the fluorescent tubes were localized around the nuclear membrane in a dose-dependent manner. Preliminary studies have shown that MTX conjugated to the CNTs had the same cytotoxic activity of the drug alone.

Another class of carbon nanomaterials very similar to CNTs called carbon nanohorns were found to be effective systems for delivery of anticancer agents. Single-walled carbon nanohorns (SWCHs) are spherical aggregates of graphitic tubes with dimensions in the nanorange scale. These nanostructures were loaded with dexamethasone [219]. Binding and release of the drug were subsequently evaluated using two types of nanohorns. It was found that oxidized nanohorns were able to adsorb more dexamethasone than as-grown horns. The analysis of activation of glucocorticoid response in mouse bone marrow cells and induction of alkaline phosphatase in mouse osteoblasts confirmed the biological activity of the drug released from the carbon support. Similarly, carbon nanohorns were used to encapsulate cisplatin (another anticancer agent) [220]. Again, the structure of the drug was preserved into the aggregates. Cisplatin was slowly liberated into water and it was effective in blocking the growth of human lung cancer cells. Unloaded oxi-

dized carbon nanohorns were instead not active. Therefore, this type of carbon material is potentially useful as a carrier of anticancer agents.

In view of the overall results, functionalized carbon nanostructures represent an emerging and new class of delivery tools for the transport, encapsulation and release of molecules into mammalian cells. However, it will be important in the near future to assess the metabolism, biodistribution and clearance from the body of nanotubes for further development and complete integration in living systems.

## 3.7

### CNTs for Gene Transfer

#### 3.7.1

##### Interaction with DNA and RNA

In the quest for a useful nonviral gene transfer system, the interaction between a cationic component (liposome, polymer, nanoparticle) and the negatively charged nucleic acids to be delivered is critical for the eventual effectiveness of the gene transfer construct. CNTs have very recently been explored for the first time as novel materials for the complexation and delivery of gene-encoding nucleic acids [191, 221]. However, the physicochemical interactions between CNTs and DNA have been studied under different contexts for much longer, particularly in attempts to disperse non-*f*-CNTs, and for the construction of sensors, nanocircuits, nanocomposites and gene delivery vectors.

Theoretical predictions of DNA interactions with CNTs by molecular dynamics simulations have shown that single-stranded DNA spontaneously inserts into non-*f*-CNTs through a combination of van der Waals and hydrophobic forces [222]. However, a recent molecular modeling simulation has demonstrated that double-stranded DNA can also wrap around non-*f*-CNTs or, in the case of positively charged CNTs in an aqueous environment, DNA molecules could electrostatically adhere onto the CNTs surface [223].

Experimentally, a range of different techniques has been used to understand the CNT–DNA interactions and the ensuing supramolecular structures between the two components. However, most studies agree that the nature and mechanism of such interactions will be highly dependent on the type of CNTs surface functionalization and the characteristics of the nucleic acids.

UV and IR spectroscopy have both been used to show that non-*f*-SWNTs and double-stranded DNA interact through hydrogen bonds [224, 225]. Changes in the electronic levels in the nucleotide bases of the DNA molecule were found in these studies and the DNA acquired a chaotic sphere conformation upon interaction with CNTs.  $\pi$ – $\pi$  interactions between the CNT sidewalls and the nucleic acid bases have been proposed as the mechanistic basis for this wrapping effect. Moreover, the ability of DNA to wrap around the CNT surface has been described for both double-stranded DNA [226, 227] and single-stranded DNA [91], and has been utilized to disperse CNTs in solvents of varying polarity.

As described earlier in this chapter, CNT surface characteristics can be altered through organic and defect functionalization. By strong oxidation, OH and C=O defects are introduced at the tips and sidewalls of CNTs. Several studies describe that these oxidized CNTs (CNT-ox) covalently bond DNA-NH<sub>2</sub> in a controllable assembling process [38, 118, 228, 229] or are helically wrapped ( $\pi$ - $\pi$  interactions) by double-stranded DNA and single-stranded DNA [230–232]. An alternative functionalization reaction described by Georgakilas and coworkers produces positively charged ammonium-*f*-CNTs (CNT-NH<sub>3</sub><sup>+</sup>) [146]. The interaction of CNT-NH<sub>3</sub><sup>+</sup> with plasmid DNA (pDNA) was studied in detail in our laboratories [221, 233]. We have found that these *f*-CNTs interact with pDNA to form complexes primarily through electrostatic forces and that the pDNA was condensed around the CNT-NH<sub>3</sub><sup>+</sup>. Moreover, these studies have indicated that the total available surface area and the surface charge density of CNTs were critical parameters in the interaction and complexation of pDNA.

With regard to interactions between RNA and CNTs, to our knowledge there has only been one published report describing the interaction between non-*f*-SWNTs and RNA polymer poly(rU) [234]. In this study the RNA polymer poly(rU) was observed in a blob-like conformation when bound at the surface of CNTs as imaged by scanning electron microscopy, resembling the condensation of pDNA strands. These authors suggested that the binding occurs through  $\pi$ -stacking and hydrophobic interactions; however, no detailed mechanistic study has been published so far describing how the CNT–RNA interactions occur.

### 3.7.2

#### Delivery and Expression of Gene-encoding DNA and RNA

The development of water-soluble CNTs automatically renders them compatible with the biological fluids and milieu. The complex formation between CNTs and nucleic acids in combination with the improved CNT biocompatibility recently achieved allowed for exploration of the hypothesis that CNTs can be used as gene-delivery systems. So far, the intracellular translocation and expression of gene-encoding nucleic acids (DNA and RNA) involving CNTs have been shown for mammalian cells to bacteria *in vitro*. The following is a comparative description of the different techniques used to deliver nucleic acids to cells through CNTs.

The first ever study to demonstrate CNT-mediated gene delivery and expression of marker gene-encoding nucleic acids was carried out in our laboratories. Pantarotto and coworkers reported that CNTs covalently functionalized with ammonium groups (CNT-NH<sub>3</sub><sup>+</sup>) were able to associate with pDNA through electrostatic interactions [191]. Transmission electron microscopy images of the supramolecular complexes showed the pDNA attaining a condensed globular conformation at the surface of the CNT-NH<sub>3</sub><sup>+</sup>. The delivery of pDNA and expression of  $\beta$ -galactosidase (a marker gene) in CHO cells was found to be approximately 10 times higher than naked pDNA. An endosome-independent penetration mechanism was proposed for the complex uptake based on evidence of spontaneous cellular uptake of the *f*-CNTs alone. Similar to other nonviral gene delivery systems based on the elec-

trostatic supramolecular complex formation between a cationic macromolecule or nanoparticle and nucleic acids, the charge ratio (+/−) CNT-NH<sub>3</sub><sup>+</sup>:pDNA was found to be a critically important factor determining the level of gene expression.

A similar approach was later followed by Liu and coworkers, which reported a noncovalent association of pDNA onto the surface of CNTs functionalized with polyethylenimine (PEI) – a polymer with high density of terminal amine groups [235]. The complexes were tested at different charge ratios in different cell lines (293, COS7 and HepG2 cells) and the level of gene (pCMV-Luc) expression was found to be much higher than those of DNA alone. This study suggested that the uptake mechanism of the CNT-PEI-pDNA conjugates was took place by endocytosis.

Kam and coworkers later used two distinct methods to deliver nucleic acids via CNTs into HeLa cells. In a first study [217], CNTs functionalized with Cy3-labeled single-stranded DNA through noncovalent adsorption were used. These CNTs were excited with NIR light. The release and nuclear translocation of the single-stranded DNA was reported by confocal microscopy only in the case of NIR treatment. In the absence of cell illumination by NIR, the Cy3-DNA was seen by Kam and coworkers to remain in the cytoplasm. This group also suggested an endosome-mediated cellular uptake.

In a subsequent study by the same group [93], CNTs were functionalized by non-covalent adsorption of PL molecules, which contained a PEG chain terminating in an amine (CNT-PL-PEG-NH<sub>2</sub>) or maleimide (CNT-PL-PEG-maleimide) group. Then a thiol-containing SH-DNA-Cy3 was covalently linked to the CNTs via a disulfide bond by a heterobifunctional cross-linker. In this way, a complicated CNT-PL-PEG-single-stranded DNA-Cy3 complex was formed, sensitive to enzymatic cleavage upon endocytosis and translocation to the lysosomal compartments. It was reported in that study that nuclear localization of Cy3-DNA was possible only in the presence of the disulfide linkage. However, in this study gene-encoding nucleic acids were not used therefore no gene expression was reported at all.

A very different strategy to introduce exogenous pDNA into mammalian cells was described recently by Cai and coworkers [192]. The pDNA was immobilized on the CNTs, which contained Ni particles (CNT-Ni) enclosed and suspended with the surfactant Nanospere AQ. Then, with a magnetic spearing technique (exposure to an external magnetic field followed by centrifugation) the complexes were added to Bal 17 cells, mouse splenic cells and a primary culture of mice cortical neurons. The expression of the enhanced green fluorescent protein (*EGFP*) gene was evaluated by fluorescence microscopy and flow cytometry. Gene delivery through CNT-Ni produced 80–100% fluorescent cells, while CNTs deprived of Ni particles did not produce any fluorescence signal. In this way, another illustration of the possibility to use CNTs to transport intracellularly gene expressing nucleic acids was seen. However, such techniques are only appropriate for *in vitro* or *ex vivo* gene transfer.

The delivery of exogenous genes by CNTs has been shown to be also possible in bacterial cultures. Rojas-Chapana and coworkers have demonstrated that oxidized, water-dispersible CNTs deliver pDNA into *Escherichia coli* through temporary nano-

channels across the cell envelope [236]. The pUC19-transformed bacteria were examined by optical microscopy, and an efficient transformation between 9 and 32 transformants was observed. The authors achieved that by an electroporation technique using microwave-activated CNTs, which apparently orient their tips in a conformation perpendicular to the bacterial cell membrane.

CNTs have also been shown to transport RNA into mammalian cells. Lu and coworkers have studied the cellular uptake of CNT–RNA polymer poly(rU) hybrids formed through nonspecific binding. MCF7 cells were examined by confocal microscopy after addition of the hybrids, and their translocation in cellular and nuclear membranes reported [237]. In agreement with these findings, Kam and coworkers, in more a recent report, used a complex CNT–small interfering RNA (siRNA) conjugate linked with disulfide bonds (as described above for single-stranded DNA) and have shown preliminary observations of siRNA-mediated gene silencing [93].

All of these studies have been initiated by our initial observations that it was indeed feasible to use *f*-CNTs to complex, deliver and express gene-encoding nucleic acids. The most recent study in this exploratory exercise has been very recently published using GFP-encoding pDNA condensed with *f*-CNTs carrying positive charges [238]. In this way our initial reports and observations were indeed substantiated and reproduced in an independent study. The development of CNTs as delivery systems for nucleic acids is still in its exploratory stage, and many more studies are needed to determine the advantages and limitations offered by these novel materials.

### 3.8

#### Health Impact of CNTs

Nanotechnology has been rapidly developing due to the possibility of engineering at nanometer scales. The resulting nanoproducts display physicochemical characteristics that confer electrochemical, mechanical and thermal properties that are very useful in the medical, scientific, commercial and environmental fields. However, it is too early to say whether the “nanostructures” will wean the world from dirty technologies or if they will definitely backfire, basically because the laws of chemistry or physics are different when particles get down to the nanoscale. Even substances that are normally innocuous can trigger intense chemical reactions and biological anomalies as nanospecies [239].

For this reason, there is a heated debate between the desire of introducing nanomaterials in everyday life and the moralistic tendency of blocking the nanotech factory until the risks will be better understood. Currently, available information concerning the relative environmental and health risks of manufactured nanoparticles or nanomaterials is severely absent and defective. In fact, most of nanomaterials (fullerenes, nanoparticles, nanofibers and nanotubes) are made of carbon atoms, with distinct geometries, different surface areas, and diverse physical and chemical

properties. The existence of such variables produced a lot of contrasting evidence. Doses, effects and cell viability of different carbon nanomaterials are summarized in Tab. 3.1. For example, Adelmann and coworkers have studied the *in vitro* effect of fullerenes on alveolar macrophages, prepared in an arc between two graphite electrodes [240]. A 60% reduction in macrophage viability and increased levels of some inflammatory cytokines were found, suggesting that such structures had similar toxicity to quartz particles. Moreover, it was discovered that stable solutions of C<sub>60</sub> nanoparticles (nano-C<sub>60</sub>) displayed a high toxicity against bacteria at a concentration of 0.4 μg mL<sup>-1</sup> [241]. Other highly water-soluble nanofullerenes (13–100 mg mL<sup>-1</sup>) showed also a remarkable cytotoxicity both in fibroblasts and in liver carcinoma cells at very low concentrations (50 μg mL<sup>-1</sup>) [242]. It could be deduced that such behavior conveys a common toxicity of all C<sub>60</sub> materials [243]. On the contrary, it was observed that the lethal doses varied by seven orders of magnitude, strongly depending on the functionalization of the fullerene surface [242]. Therefore, the further modification at the surface deeply influenced the toxicological profile of the nanomaterials [244].

In contrast, some *in vivo* studies on fullerene showed that intraperitoneal injections of amounts of C<sub>60</sub> up to 2.5 g kg<sup>-1</sup> in mice and rats had neither lethal effects nor acute toxicity [245, 246]. What was evident was only a hypertrophy of livers and spleens, which could be ascribed to the high amount of compound injected that had exceeded the absorption capacity of the animal. Similarly, mice subcutaneously implanted with Hat-stacked carbon nanofibers did not show severe inflammatory responses such as necrosis or degeneration after 4 weeks of incubation [247]. However, these encouraging results are not exhaustive in representing the reduced harmfulness of all the different nanomaterials.

### 3.8.1

#### Parameters of CNTs Related to Health Impact

The data reported above suggest that, in general, carbon nanoparticles can be considered as dangerous as quartz, only on the basis of the common “starting material”, i.e. carbon. In particular, CNTs represent a class of substances which are, at the same time, intriguing (for their characteristics) and doubtful. In fact, they revealed unusual toxicological properties, because their shapes can be both fibers and nanoparticles, and they are often characterized by the presence of metallic components even after their purification. CNTs, both single and multiwalled, are classified as “synthetic graphite” by the National Occupational Safety and Health Administration, on the basis of the same hexagonal/honeycomb pattern. However, such extrapolation might not be protective for exposure to CNTs, because they show physicochemical properties that are often influenced by several variables.

##### 3.8.1.1 Purity

CNTs generally show different levels of purity, which are strictly dependent on the methods employed for their production. The impurities are essentially made up of

Tab. 3.1. Doses, effects and cell viability of different carbon nanomaterials.

Type of nanomaterial	Amount/ concentration	Cell/animal target	Effect	Possible causes	Ref.
Fullerenes	not specified	alveolar macrophages	60% reduction on cell viability; inflammatory cytokines (IL-6, IL-8)	intrinsic toxicity	240
Nano C <sub>60</sub>	0.4 µg mL <sup>-1</sup>	bacteria	growth inhibition		241
Nano C <sub>60</sub>	50 µg mL <sup>-1</sup>	fibroblast; liver carcinoma cells	decreasing cytotoxicity with increasing functionalization and solubility	oxidative stress; surface effect	242
Functionalized gold nanoparticles	250 µM	leukemia cells	no remarkable cell death; rapid internalization		244
C <sub>60</sub>	2.5 g kg <sup>-1</sup>	mice and rats	no acute toxicity; hypertrophy	too high amount	245, 246
Hat-stacked carbon nanofibers (H-CNF)	not specified	rats	no toxicity		247
SWNTs, MWNTs, fullerenes	≥1.41 µg cm <sup>-2</sup>	alveolar macrophages	20% reduction on cell viability (SWNTs)	low purity	248
Pristine SWNTs	0.1–10 µg mL <sup>-1</sup>	HaCaT cells	increased cell death	oxidative stress or solvent (DMF)	249
<i>f</i> -SWNTs	3 µg mL <sup>-1</sup> – 30 mg mL <sup>-1</sup>	HDF	cell death 50% or below		252
MWNTs (220 and 825 nm)	50–500 ng mL <sup>-1</sup> ( <i>in vitro</i> )	leukemia cells THP-1	inflammation (especially with 825-nm samples)	length	253
	0.1 mg mL <sup>-1</sup> ( <i>in vivo</i> )	mice	granulomatous inflammation		253
HiPCO, CVD- SWNTs and CVD- double-walled CNTs	0.62–2.5 mg	red blood cells	complement activation	C1q activation	254
Arc-SWNTs and CVD-H-CNF	10 µg mL <sup>-1</sup>	leukemia cells THP-1; mouse spleen cells	immune response	Induction of TNF- $\alpha$	255

Tab. 3.1 (continued)

Type of nanomaterial	Amount/ concentration	Cell/animal target	Effect	Possible causes	Ref.
<i>f</i> -SWNTs	<5 $\mu\text{M}$	fibroblasts	no remarkable cell death (90%); rapid internalization		190
<i>f</i> -SWNTs and <i>f</i> -MWNTs + plasmid DNA	1 mg mL <sup>-1</sup>	HeLa cells	no remarkable cell death; efficient delivery		191
MWNT-PEI + DNA	<5 $\mu\text{g mL}^{-1}$	HEK293 cells	below 40% reduction on cell viability	increased PEI weight	235
SWNT-CpG ODN	5 ng-5 $\mu\text{g}$	mouse splenocytes	no remarkable cell death		204
SWNT-RNA	$\leq 1$ mg mL <sup>-1</sup>	breast cancer cells (MCF7)	efficient delivery		237
SWNTs	1-250 $\mu\text{g mL}^{-1}$	embryo kidney cells (HEK293 cells)	apoptosis; 20/30-kDa protein secretion	downregulation of genes for adhesion; upregulation of genes involved in apoptosis	256
Pristine MWNTs	0.1-0.4 mg mL <sup>-1</sup>	embryo kidney cells (HEK293)	inflammation	production of IL-8	257
Pristine and oxidized MWNTs	400 $\mu\text{g mL}^{-1}$	T lymphocytes	40% reduction on cell viability (pristine) 80% reduction on cell viability (oxidation)	better dispersion of oxidized tubes	258
MWNTs	0.5, 2 or 5 mg	rats	upregulation of pro-inflammatory and profibrotic mediators	biopersistence in the lung	259
Raw, HiPCO and arc-SWNTs	0.1 or 0.5 mg per mouse	mice	granulomas	intrinsic toxicity	260
Pristine SWNTs	1 or 5 mg kg <sup>-1</sup>	rats	pulmonary inflammation, with non-dose-dependent granulomas	blockage of upper airways	261

Tab. 3.1 (continued)

Type of nanomaterial	Amount/ concentration	Cell/animal target	Effect	Possible causes	Ref.
Fullerenes and CNTs	0.2 mL (not specified)	four albino rabbits and 40 human volunteers	no remarkable skin irritation or allergen risks		262 263
Carbon fiber particles	not specified	341 workers	contact dermatitis	exposure to organic solvents or to carbonaceous particles	264 265
Pristine HiPCO–SWNTs	0.06, 0.12 or 0.24 mg mL <sup>-1</sup>	HaCaT cells	alteration of cell morphology and surface integrity	transition metal catalysts	266
Pristine HiPCO or laser ablation SWNTs (aerosol)	15.5 mg	cotton gloves	deposition on individual gloves ranged from 217 to 6020 µg (aerosol below 53 µg m <sup>-3</sup> )	ultrafine powders	267

residual catalysts and amorphous carbon. Their high amount might enhance the toxicity. In this context, Jia and coworkers investigated the cytotoxicity caused by nanostructures such as SWNTs, MWNTs and fullerenes on alveolar macrophages (AM) [248]. The different carbon particles, all with a purity superior than 90%, were suspended in RPMI medium using a Dounce homogenizer and sonicated for 20 min. In this way, a stable suspension was obtained and immediately used to measure the phagocytic ability of AM after a 6-h exposure to carbon materials. The amount of materials used was expressed as µg cm<sup>-2</sup>, because CNTs are characterized by a wide length distribution. As expected, the tested samples exhibited different cytotoxicity to AM. At low doses (1.41 µg cm<sup>-2</sup>) SWNTs showed a high cytotoxic effect, corresponding to above 20% inhibition of cell growth with a dose-dependent trend. MWNTs and fullerene were instead much less toxic. One possible reason for such a major difference could be attributed to the purity level of SWNTs that was lower than the other samples. Indeed, residual amorphous carbon and trace amounts of metallic catalysts, such as Fe, Ni and Y, were present in SWNT samples. These impurities, even at a low level, can influence cell viability, so ultrapure material should be employed; in any case, human and environmental health evaluations of different carbon nanomaterials must be considered individually.

### 3.8.1.2 Solvents

Any kind of cell evaluation needs a medium to dissolve the sample. Physiological solutions, with the addition of nutritional elements, are the most appropriate, but sometimes the low solubility of the carbon material requires the use of polar, organic solvents. Manna and coworkers investigated the essential mechanism involved in the toxicity of SWNTs [249]. Human keratinocytes (HaCaT cells) were exposed to concentrations between 0.1 and 10  $\mu\text{g mL}^{-1}$  of nanotubes, displaying increased cell death. This observation was attributed to the excess of oxidative stress within the cells and to the associated activation of transcription factor NF- $\kappa$ B. However, DMF was used to dissolve the samples and might have induced some alterations of the results. In fact, DMF is a solvent known to be toxic and thus it should be avoided in cell manipulation.

### 3.8.1.3 Surface of CNTs

Until now, the size cut-off below which particles are surely toxic has not been demonstrated. However, there are at least two main reasons that render CNTs potentially harmful: (i) their large surface area and (ii) the reactivity or intrinsic toxicity of the surface [250, 251]. The smaller the particles, the more toxic they become. This is due to the fact that there is more surface area per mass unit. As a consequence, any intrinsic toxicity of the surface will deeply influence the toxicological profile of the samples. For example, Sayes and Ausman investigated the effect on human fibroblasts (HDF) of some water-dispersible SWNTs [252]. It was found that cytotoxicity of compounds decreased significantly with the increased degree of functionalization on the surface. In addition, although a dose–response relationship of toxicity in the considered range of concentrations (0.003–30  $\text{mg mL}^{-1}$ ) was observed, cell death did not exceed 50%, apart from in one case in which 1% surfactant was employed. This could be justified by the fact that surfactant was coated on the surface of the nanotubes in a noncovalent, reversible way, whereas the functional groups were covalently bound and were not removed in the conditions of the biological tests.

### 3.8.1.4 Length

Another parameter that was found to influence the toxicity profile of CNTs is their length. Sato and coworkers separated MWNTs of 220 and 825 nm using controlled strong acid conditions [253]. During a short incubation time, clusters of both samples were shown to be surrounded by macrophages as a consequence of the activation of innate immunity. The shorter tubes displayed a lower inflammatory response. In both cases, no severe effects, such as necrosis or degeneration, were observed around CNTs throughout the experimental period of 4 weeks.

## 3.8.2

### *In Vitro* Effect of CNTs

SWNTs were investigated to verify if they affected the immune system through the activation of complement [254]. For this purpose, SWNTs in concentrations be-

tween 0.62 and 2.5 mg were tested in rabbit red blood cells. They displayed a dose-dependent potency in complement activation comparable to that of the known, potent activator zymosan. In particular, it seemed that such activation followed the classical pathway, but with high selectivity. This was confirmed by the demonstration of a direct binding of CNTs to the main complement subunit C1q. On the contrary, chemical modifications at the surface of CNTs reduced or even eliminated the complement activation, but further investigations are necessary to confirm this observation.

In a parallel study, SWNTs were evaluated in terms of their capacity to activate mouse spleen cells [255]. Since different cell types (monocytic leukemia THP-1 and spleen cells) and incubation times were employed, it was difficult to compare the obtained results. It has been confirmed that SWNTs induced an immune response, although the stimulating activity resulted to be lower than that of microbial systems.

The effect of functionalized, water-soluble CNTs on cell viability was also analyzed by Pantarotto and coworkers during the study of translocation of bioactive peptides across the cell membrane [190]. 3T6 and 3T3 fibroblasts were treated with 1–10  $\mu\text{M}$  concentration of fluorescent SWNTs. The cytotoxicity was evaluated by flow cytometry, using the markers Annexin V and propidium iodide as indicators of apoptosis and necrosis, respectively. It was observed that below 5  $\mu\text{M}$  almost 90% of the cell population remained alive, indicating a nontoxic behavior of *f*-CNTs. Low toxicity was not only a characteristic of SWNTs functionalized with peptides. Both *f*-SWNTs and *f*-MWNTs, regardless of cell subtypes, are nontoxic on their own [90, 220]. HeLa cells, incubated for several hours with about 1 mg mL<sup>-1</sup> of CNTs mixed with plasmid DNA in different charge ratios, did not demonstrate signs of apoptosis [191]. In addition, *f*-CNTs complexed to different types of nucleic acids including plasmid DNA, RNA and oligodeoxynucleotides CpG sequences were not toxic for cells like breast cancer cells (MCF7) or splenocytes [204, 235, 237].

Apart from the investigation of the effect of CNTs on cells, it is also important to understand the mechanism involved in their interaction with biological systems. Cui and coworkers evaluated the activity of human embryo kidney cells (HEK293) during 5 days treatment with SWNTs in concentrations between 1 and 250  $\mu\text{g mL}^{-1}$  [256]. It was found that SWNTs were able to inhibit the proliferation of HEK293, and to induce apoptosis in a dose- and time-dependent way. The most interesting finding was that cells actively responded to SWNTs, secreting a series of 20- to 30-kDa proteins able to aggregate and wrap this unknown material, regardless of the uniformity of the starting samples. The possible mechanism for this phenomenon was attributed to a stimuli induced by SWNTs attached at the cell surface, followed by a downregulation of the genes responsible for adhesion. It was also envisaged that SWNTs could determine an upregulation of the genes associated with apoptosis and secretion of small proteins as protection for cells that were preserved from the contact with the tubes. This phenomenon presents a double advantage, since it allows us to investigate the rules at the basis of this interaction and, at the same

time, it offers the possibility to consider these secreted proteins as potential targets in future medical therapy.

The same type of cells was also used to verify if bigger material, like MWNTs, was able to cross the external membrane and to affect the cell functions. It was shown that unmodified MWNTs were able to enter HEK293 cells and to induce the release of the pro-inflammatory cytokine IL-8 [257]. In addition, it was demonstrated that they were less toxic towards T lymphocytes than chemically functionalized tubes [258]. This was attributed to the fact that oxidized MWNTs were better dispersed in aqueous solution, determining higher weight/volume concentrations and, thus, a deeper impact on toxicity. At the dose of  $400 \mu\text{g mL}^{-1}$ , oxidized tubes killed more than 80% of cells in 5 days, while pristine MWNTs decreased the cell viability of less than 40%. However, although it is obvious that CNTs toxicity does not depend only on concentration, the dose used in this study was very high and the same experiments with concentrations below  $40 \mu\text{g mL}^{-1}$  did not affect the function of T cells [258].

### 3.8.3

#### ***In Vivo* Effects of CNTs**

Apart from *in vitro* experiments, some CNTs were implanted at the subcutaneous level in rats to study their effects *in vivo*. Sato and coworkers demonstrated that coagulated MWNTs of 825 nm determined granulomas, since they were not easily phagocytosed by macrophages in comparison to MWNTs of 220 nm length [253].

MWNTs were also administrated intratracheally to rats to evaluate their respiratory toxicity due to their biopersistence in the lungs [259]. The results clearly showed that, once they reach the lung, MWNTs have the capacity to induce an overexpression of pro-inflammatory and profibrotic mediators. However, there might be some artifacts on the experimental strategy, since the method of administration presents several limitations, such as the formation of big aggregates that could remain entrapped in the airways. A different mode of administration (e.g. inhalation) and the real ability of these materials to translocate from the respiratory system to other organs would give more reliable data.

Other *in vivo* studies were conducted by Lam and coworkers [260] and Warheit and coworkers [261] to investigate the pulmonary toxicity of SWNTs in rodents. In particular, Lam and coworkers evaluated histopathological alterations in mice at 7 and 90 days after exposure to three differently manufactured SWNTs that contained varying amounts of residual catalytic metals: (i) raw nanotubes (RNT) and (ii) purified nanotubes (PNT), both iron-containing HiPCO products from Rice University, and (iii) CarboLex's Ni-containing electric-arc nanotubes (CNTs). Carbon black and quartz were employed as low and high pulmonary toxicity controls, respectively [260]. The experiments indicated that the three types of tubes induced dose-dependent lung lesions characterized by interstitial granulomas, regardless of the amount of metal impurities inside the samples. Even the product containing very low quantities (2% by weight) of iron produced granulomas, suggesting that

CNTs themselves are toxic. However, the methods employed for this study were somehow ambiguous, since the suspension was obtained by briefly shearing and short sonication to avoid any alteration of the nature of SWNTs, but the instillation was performed through a plastic catheter placed in the trachea. Thus, further studies would be needed to elucidate the cause of death. However, it was clear that mice treated with 0.5 mg of nanotubes showed the formation of granulomas, containing macrophages laden with black particles, few lymphocytes, neutrophils, eosinophils and other inflammatory cells. Interestingly, it was encouraging to observe that the lowest dose (0.1 mg per 30 kg) determined no evident clinical signs. The same (5 mg kg<sup>-1</sup>), or even a lower (1 mg kg<sup>-1</sup>), amount of SWNTs was employed in the study of Warheit and coworkers, in which histopathological evaluation of lung tissue was conducted after 24 h, 1 week and 3 months postinstillation [261]. In these experiments, SWNTs and graphite particles, together with the corresponding controls (carbonyl iron and quartz particles) were prepared in a volume of 1% Tween 80 surfactant and phosphate saline buffer subjected to polytron dispersion. Rats, intratracheally instilled with carbonyl iron or graphite, did not present adverse effects, while no dose-dependent multifocal granulomas were visible after exposure to SWNTs, even if they did not progress beyond 1 month. In 15% of the rats, the highest dose induced mortality, but the main reason for that was due to mechanical blockage of the upper airways and not to the inner toxicity of SWNTs particulate. The death index was somehow incorrect, because the nanotubes tended to form nanoropes instead of being individually dispersed. A proof was the observation that the surviving animals appeared normal through the whole 3 months. In addition, studies on chemotaxis concerning quartz treatment showed a reduced motility as a consequence of a deficiency in macrophages after 1 week. This phenomenon was not observed in the case of SWNTs, which differed from quartz also in the formation of granulomas in a non-dose-dependent manner.

Additional studies by Huczko and coworkers have contributed to understanding further the impact of nanomaterials on health. They tested the effect of fullerenes and CNTs on skin irritation and allergen risks [262, 263]. There is only some evidence of contact dermatitis caused by exposure to carbon fibers [264, 265]. The authors applied two protocols that are commonly employed for testing skin irritation, i.e. a patch and a Draize rabbit eye test. In the first case, 40 people showing predisposition to irritation and allergy were treated with a patch of Whatman filter paper saturated with a water suspension of CNTs, and then they were examined for 96 h. In the second method, four albino rabbits were administered with 0.2 mL of CNT aqueous suspension, and observed after 24, 48 and 72 h. The absence of adverse effects seemed not to be dependent on the time of exposure nor on the type of material used, since there were no differences in comparison with the reference material (which did not contain CNTs). On the whole, the encouraging results in all experiments on skin irritation suggested that no specific precautions should be adopted while handling such nanomaterial [262, 263].

In general, the manufacturing of carbon nanomaterial is based on the use of transition metal catalysts. Therefore, the eventual health hazards are potentially connected with carbon and metals. In fact, free iron or nickel and transition metal

complexes are known to produce reactive radicals, which could induce radical oxidation and enhance oxidative stress. In order to investigate this aspect, Shvedova and coworkers identified and quantified the reactive species that were produced during the manipulation and evaluated the effects of pristine SWNTs on human epidermal keratinocytes (HaCaT) [266]. SEM and TEM allowed us to verify that oxidative stress, caused by treatment with SWNTs, caused a change in the morphology of cells, besides altering surface integrity. These unwanted effects were reduced by the subsequent use of an iron chelator that displayed a protecting role towards HaCaT cells and, thus, confirmed that cytotoxicity of SWNTs was mainly correlated with iron catalytic effects.

A parallel study investigated the adverse effects recorded by aerosol release obtained through mechanical collisions of as-produced SWNTs with bronze beads [267]. The results were somehow ambiguous, since the production of ultrafine powders was not very efficient and it was not possible to discriminate if such particles were made up mainly of nanotubes or of catalyst. Moreover, although nanotubes tended to agglomerate into nanoropes, thus reducing the formation of an appreciable respirable aerosol, it was possible that such nanoparticles remained in the mouth and nasopharyngeal region, causing a potential health risk.

On the whole, CNTs have shown uncommon and interesting physicochemical properties, which increase their possible biomedical applications; however, at the same time, they might persist in biological systems and, consequently, be responsible for adverse health effects and environmental safety. It is imperative that a clear understanding of what really happens to nanoparticles months and years after their release is needed, since some encouraging evidence is not exhaustive in guaranteeing complete innocuous behavior. For all these very important reasons, further studies are required to investigate if CNTs can be widely used for their useful characteristics as well as if they safely represent a promising beginning of the so-called “next industrial revolution”.

### 3.9

#### General Conclusions

Although still debatable, the use of CNTs in drug delivery and biosensing is acquiring more and more substantiating evidence for efficient development. It is clear that many important issues have to be faced before CNTs can be proposed for clinical trials. However, CNTs show unusual carrier properties, with a very strong tendency to pass cell membranes and seem to perfectly fit into the new discipline of nanobiotechnology. Although the first toxicological reports on pristine CNTs were very discouraging, labeling CNTs as very dangerous species, it is becoming widely accepted that *f*-CNTs are by far less toxic than non-*f*-CNTs. Therefore, the combination of penetration ability with high loading achievable with CNTs makes these new carbon species promising candidates for innovative therapies. Another aspect that should not be disregarded is that other functions can be introduced on CNTs by using different functionalization methods.

In conclusion, we do hope that, in a few years, *f*-CNTs will be considered as valuable building blocks for pharmaceutical uses.

### Acknowledgments

The authors are deeply indebted to all their coworkers who have partly contributed to the development of the research described in this chapter and whose names are cited in the references. This work has been supported by the CNRS, MRNT (Gen-Homme 2003), University of Trieste and MIUR (PRIN 2004, prot. 2004035502). G. P. and W. W. are recipients of a fellowship from MNRT. C. K. is grateful to the Università Italo-Francese/Université Franco-Italienne (VINCI Programme 2003) for financing his international PhD.

## Core–Shell Nanoparticles for Drug Delivery and Molecular Imaging

*Sung Kyun Han, Ree Sun Kim, Jin Ho Lee, Giyoong Tae, Sun Hang Cho, and Soon Hong Yuk*

## 4.1

### Introduction

Core–shell nanoparticle structures, in which a layer of polymeric materials surrounds an organic or inorganic nanoparticle core, have been investigated both as a means to improve the stability of the core nanoparticle and as a way of accessing unique physical properties that are not possible from one nanomaterial alone. This chapter describes the preparation method and characterization of a novel protein delivery system and molecular imaging agent composed of core–shell nanoparticles with the variation of core materials such as lipid, polymeric or inorganic nanoparticles.

With rapid advancements in the field of biotechnology/genetic engineering, a growing number of protein drugs have been produced [1, 2]. Although they show potent and specific physiologic actions in small doses, most of them are difficult to administer clinically. Although a wide variety of delivery systems have been designed and characterized, the parenteral route has been most widely selected for the efficient delivery of protein [3–7]. However, the problems still remain in the parenteral delivery of protein because most proteins have a short half-life in the physiological condition. Loss of biological activity and change in immunogenicity as a result of protein aggregation or denaturation are the most important challenges faced in the delivery of protein drugs [8–10]. Hence, they cannot be utilized effectively in conventional dosage forms. For such active agents, new types of drug delivery systems must be developed to deliver the drug more effectively. Among the various approaches investigated, extensive research has been conducted on the ability of colloidal systems such as liposomes and polymeric nanoparticles as an optimal delivery system for protein drugs. A wide variety of drugs such as hydrophilic drugs, hydrophobic drugs, proteins, vaccines and biological macromolecules can be delivered using colloidal systems via a number of routes [11–15]. They can be formulated for targeted delivery to the lymphatic system, brain, arterial walls, lungs, liver or spleen, or made for long-term systemic circulation [16–18]. There-

fore, numerous protocols exist for colloidal systems based on the type of drug used and the desired delivery route.

A number of liposomal formulations have been reported as drug delivery vehicles for sustained release of protein drugs and some have been evaluated for clinical applications [19–21]. Most of the previous studies involved traditional liposomes (unilamellar [22, 23] or multilamellar vesicular systems [24, 25]) and multivesicular liposomes (DepoFoam) [26–29]. However, the liposomal system shows a mechanical instability under physiological conditions, which results in a total release of the internal aqueous content (burst effect). As each multivesicular liposome is composed of discontinuous internal aqueous chambers, bounded by a continuous, nonconcentric network of lipid membranes with a higher aqueous volume:lipid ratio, the multivesicular liposomes have exhibited an improved stability. This enables us to design the sustained release form of encapsulated protein drug since, unlike unilamellar vesicular systems, a single breach in the external membrane of a multivesicular liposome will not result in a total release of internal aqueous content containing protein drug. They have been evaluated with recombinant human insulin [30–32], leuprolide (a 9-amino-acid peptide analog of luteinizing hormone releasing hormone) [33–35], met-enkephalin (an endogenous opioid peptide of 5 amino acids) [36, 37] and octreotide (a cyclic octapeptide analog of somatostatin) [38, 39]. However, the sustained release formulation of protein drugs using multivesicular liposomes still remains a major challenge, achieving high drug loading with high drug recovery and controlling the release pattern over a prolonged period.

Recently, polymersome (polymer vesicle) has been prepared by the molecular assembly of an amphiphilic diblock copolymer composed of poly(ethylene glycol) (PEG) and polyesters or polycarbonates [40, 41]. Biodegradable diblock copolymers based on PEG and poly(lactide) have been used to prepare carriers such as micelles, nano/microparticles and gels for controlled or targeted delivery. However, the formation of polymersomes has been reported and suggests a promising application in drug delivery system for water-soluble drugs and protein drugs; similar advantages and disadvantages founded in the liposomal system are observed in the polymersome.

Polymeric nano/microparticles are the most suitable and preferred systems in the delivery of protein drugs by the parenteral or nonparenteral route. Due to the large amount of toxicological and chemical data available, biocompatibility/histocompatibility, predictable biodegradation kinetics, ease of fabrication, and variety in copolymer ratio and molecular weight, polyesters have been found the most widespread use as a major component of polymeric nano/microparticles and they have been approved in clinical applications [42, 43]. Despite many advantages, polyesters like poly(lactide-co-glycolide) (PLGA) also have some inherent shortcomings. Due to the hydrophobic nature of the polymer compared to most of the protein drugs to be encapsulated, the serious problems associated with protein activity were observed during storage or *in vivo* release. Since hydration and degradation of PLGA are prerequisites for the release of protein drugs during the bioerosion phase, this results in an acidic microenvironment due to the formation of lactic

acid and glycolic acid, which leads to denaturation (hydrolytic degradation and aggregation) of protein drugs. Although improvement of protein drug compatibility has been investigated by coencapsulating buffer salts and stabilizer for protein drugs and modification of polyesters, it still remains challenging.

With the significant progress in the treatment of diseases and diagnosis, the importance of molecular imaging as well as that of drug delivery has increased tremendously. The prerequisite for efficient molecular imaging is to prepare the magnetic nanoparticles with a narrow size distribution. Information technology which has been used in data storage devices now enables us to prepare magnetic (metal) nanoparticles with such a narrow size distribution. However, as such particles have a strong tendency to agglomerate due to their large specific surface area, various methods have been studied in order to stabilize the nanoparticles. For this purposes, many attempts have been made to establish the preparation method of magnetic nanoparticles coated with a biocompatible polymer (core-shell nanoparticles with metallic core) to improve the stability and biocompatibility under physiological conditions.

As described previously, there are number of studies on the protein delivery system and molecular imaging agent using a single nanomaterial system. However, these systems showed major drawbacks in terms of the stability, release pattern and cytotoxicity. Recently, a number of investigations have been devoted to understanding the formation of core-shell nanoparticles [44, 45] and much interest has been focused on developing core-shell nanoparticles as an effective means of delivering bioactive materials [46–50]. Due to their distinct geometry, numerous applications have evolved, and core-shell nanoparticles with a variation of core materials have been designed and characterized as drug delivery systems based on the type of drug used. In this chapter, a new type of protein delivery system and molecular imaging agent will be introduced using core-shell nanoparticles, which exhibit the improved stability, a sustained release pattern of protein drug and decreased cytotoxicity.

## 4.2

### Core-shell Nanoparticles with a Lipid Core

As an effective oil-soluble drug carrier, lipid and mixed micelles have been developed. However, lipid-based drug carriers composed of a single lipid phase have several inherent problems, including the burst effect and difficulty in achieving zero-order release. To overcome these difficulties, core-shell nanoparticles with drug-loaded lipid core were prepared (see Fig. 4.1). For the formation of the polymeric shell, drug-loaded lipid cores were usually freeze-dried in the aqueous solution containing polymers used for the shell material. Freeze-drying of vesicular structure and subsequent recovery of the very same structure on the microscale is simple and straightforward [51, 52]. However, with the vesicular structure on the nanoscale, the situation is more complex [51]. A solution to the problem that allows the recovery of vesicular structure on the nanoscale was found to be the inclu-

**Figure 4.1.** Schematic description of the advantages gained with the formation of core–shell nanoparticles.

sion of relatively high concentrations (around 30 wt%) of cryoprotectants such as trehalose, sucrose, mannose or glucose. The role attributed to these cryoprotectants is replacement of structure-stabilizing water-based hydrogen bonds at the liposomal surface, which are lost in the process of drying [53].

Another approach to cryoprotection, which does not require the inclusion of additives such as the sugars listed above, has been made by chemical modification of phospholipid with hydrophilic polymers, surfactants or block copolymers [54].

A novel method for the preparation of core–shell nanoparticles with a lipid core was designed and characterized (see Fig. 4.2). The lipid core is composed of lecithin, which forms a spherical supramolecular structure (multilamellar vesicles) in the concentrated state [55]. The polymeric shell is composed of pluronics [poly(ethylene oxide)–poly(propylene oxide)–poly(ethylene oxide) triblock copolymer, F-127]. In this study, a F-127/trehalose mixture was used to stabilize the drug-loaded lipid core in the form of core–shell nanoparticles. With the combina-

**Figure 4.2.** Schematic description of core–shell nanoparticles with drug-loaded lipid cores.

tion of F-127 and trehalose, the concentration of cryoprotectant can be reduced into approximately 5 wt% and chemical modification of lipid to improve the stability of vesicular structure on the nanoscale was not required.

First, the core-shell nanoparticles with a drug-loaded lipid core were prepared for a lipophilic drug. A drug suspension composed of 90/10 (w/w) [Tween 80/paclitaxel (model drug)] mixture was prepared in which the oil phase was subsequently dispersed. The oil phase was composed of 40 wt% aqueous solution of lecithin from soy bean oil. The obtained drug dispersion and oil phase were mixed in equal amounts, and were then subjected to sonication in an ice bath for 3 min to prepare the drug-loaded lipid core using a probe-type ultrasonic wave homogenizer (Branson Sonifier Model 185). The solution mixtures composed of 90/10 (w/w) (F-127 aqueous solution/drug-loaded lipid core) were prepared to induce the formation of the polymeric shell on the surface of the drug-loaded lipid core. F-127 aqueous solutions were prepared with or without trehalose to observe the preservation of integrity of the core-shell structure of nanoparticles during the freeze-drying.

Aqueous concentrated lecithin mixtures show typical lamellar liquid crystalline behavior and the individual lamellae tend to form a spherical supramolecular structure [55]. Figure 4.3 shows the particle size distribution of 5 wt% lecithin aqueous solution, which exhibits the formation of a spherical supramolecular structure with a diameter of 45.6 nm. The size, polydispersity and surface charge of nanoparticles were determined using an electrophoretic light-scattering spectrophotometer equipped with a 10 mW He-Ne laser (632.8 nm) (ELS-8000; Otsuka Electronics, Japan). Based on this, paclitaxel solubilized in Tween 80 was added to 40 wt% lecithin aqueous solution and subjected to sonication leading to the complete dissolution of paclitaxel. This is a universal principle for all drugs that are

**Figure 4.3.** Size distribution of 5 wt% lecithin in aqueous medium with 5 wt% Tween 80. (From Ref. [48].)

**Figure 4.4.** Size distribution of paclitaxel-loaded lipid cores in the aqueous medium. (From Ref. [48].)

poorly soluble in the water phase of emulsions and simultaneously in the oil phase, but possessing a suitable lipophilicity to interact with the lecithin molecules in the interfacial layer [56]. Of course, the incorporation capacity of an oil-in-water (o/w) emulsion is not unlimited. At a certain stage, the interfacial layer is saturated with paclitaxel, leading to the formation of nondissolved small drug crystals in the dispersion. As shown in Fig. 4.4, paclitaxel-loaded lipid cores dispersed in 10 wt% F-127 aqueous solution exhibit a stable emulsion with diameter of 99 nm.

Freeze-drying was performed for the formation of a polymeric shell composed of F-127. As shown in Fig. 4.5(A), significant aggregation was observed to show that the spherical supramolecular structure was disintegrated during the freeze-drying process. This phenomenon is usually found in the freeze-drying of protein solution. With freeze-drying, the protein activity is significantly decreased due to the disintegration of supramolecular structure. It has been reported that trehalose, a naturally occurring osmolyte, is known to be an efficient stabilizer of proteins and helps the activity of enzymes in solution as well as in the freeze-dried state [57]. This led us to use trehalose as a stabilizer of the spherical supramolecular structure of core–shell nanoparticles. Note that exposure of freshly collected oocytes to a concentration of trehalose between 0.5 and 1.0 M for up to 10 min had no significant effect, indicating that trehalose is not toxic [58]. With adding 5 wt% trehalose in F-127 aqueous solution, freeze-drying was performed to induce the formation of the polymeric shell. As shown in Fig. 4.5(B), nanoparticles with diameter of 267.4 nm were observed, indicating minimal disintegration of spherical supramolecular structure.

A cryogenic transmission electron microscopy (cryo-TEM) image was obtained for the verification of the formation of core–shell nanoparticles. For the measure-

**Figure 4.5.** (A) Size distribution of nanoparticles formed from 10 wt% F-127 aqueous solution without trehalose. (B) Size distribution of nanoparticles formed from 10 wt% F-127 aqueous solution with 5 wt% trehalose. (From Ref. [48].)

ment, the samples were prepared as a thin liquid film (less than 0.25  $\mu\text{m}$  thick) supported on cryo-grid. These were quenched into liquid ethane at its freezing point and stored under liquid nitrogen. They were later transferred to a Tecnai 12 electron microscope (Philips, The Netherlands). Direct imaging was carried out at a temperature of approximately  $-170^\circ\text{C}$  and with a 120 kV acceleration voltage, using the images acquired with a Multiscan 600 W CCD camera (Gatan, USA). With the nanoparticles formed from 10 wt% F-127 aqueous solution, the formation of core-shell nanoparticles was observed as shown in Fig. 4.6.

In this study, lecithin was used as the main component for the preparation of nanoparticles (self-assembled aggregates). The addition of other substances, espe-

cially surfactants and drug, may result in the alteration of the original structures. Differential scanning calorimetry (DSC) was used to characterize the lipid core with addition of surfactant, F-127 and drug as shown in Fig. 4.7. Although a minimal peak was observed with 15 wt% F-127 aqueous solution, no characteristic peaks

**Figure 4.8.** The release pattern of paclitaxel from nanoparticles formed as a function of the concentration of F-127 aqueous solution.  $N = 3$  experiments. (From Ref. [48].)

were observed with lecithin and Tween 80 mixed with paclitaxel. However, the characteristic peaks were observed at 105.5 and 111.9 °C with paclitaxel-loaded lipid cores (loading amount: 4 wt%) and with paclitaxel-loaded lipid cores in the presence of F-127 and trehalose, respectively. A similar peak was observed at 104.9 °C with the freeze-dried nanoparticles resuspended in water. This indicates that the original structure of the paclitaxel-loaded lipid core was maintained in the presence of F-127 and trehalose during the freeze-drying, resulting in the formation of core-shell nanoparticles with a drug-loaded lipid core.

For application as a drug delivery system for lipophilic drugs, core-shell nanoparticles with paclitaxel-loaded lipid core were prepared and the release behavior of paclitaxel was observed as shown in Fig. 4.8. Without the polymeric shell (0 wt% of F-127 aqueous solution), a significant burst effect was observed, resulting in the precipitation of paclitaxel into the release medium. This is due to the poorly solubilized paclitaxel in the lipid phase and its poor solubility in aqueous media. With the formation of the polymeric shell, released paclitaxel from the lipid phase diffused through the polymeric shell (F-127 phase), resulting in a significant decrease in the burst effect and an almost zero-order release pattern was observed with nanoparticles formed from 10 wt% F-127 aqueous solution.

Based on the formation of core-shell nanoparticles, the application has evolved in the area of protein delivery. Figure 4.9 shows the chemical structure of lecithin used as a core material. Due to its low isoelectric point (below 3.5), zwitterionic lecithin shows anionic characteristics under physiological pH as presented in Fig. 4.9.

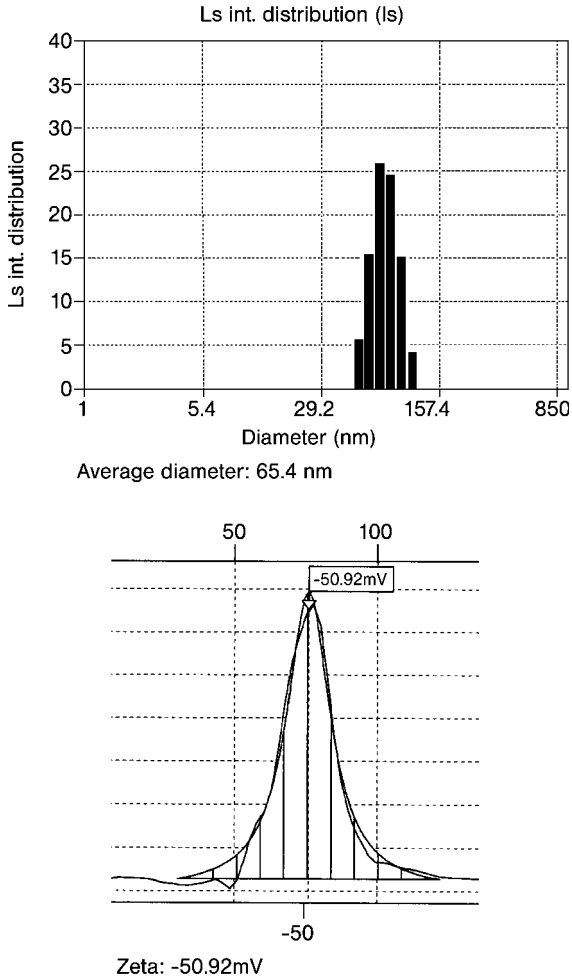

**Figure 4.9.** Chemical structure of lecithin used as a lipid core.

With a proper choice of protein drug with a higher isoelectric point (above 7.4), the ionic interaction between lecithin nanolipid and protein drug can be achieved as presented schematically in Fig. 4.10.

Vascular endothelial growth factor (VEGF) was used as a model protein drug. VEGF is a potent mitogen in embryonic and somatic angiogenesis with a unique specificity for vascular endothelial cells [59, 60]. VEGF has been considered as a potential treatment for stroke due to its angiogenic and direct neuroprotective action [61]. One potential mechanism for the treatment of stroke is the induction of angiogenesis with increasing oxygen availability. The extent of newly formed vessels is probably an important factor in determining the improvement in the blood flow, culminating in the recovery and repair of neurons, and a reduction in the ischemic damage.

**Figure 4.10.** Schematic description of the formation of protein-loaded core-shell nanoparticles.

**Figure 4.11.** The size distribution and  $\zeta$  potential of lecithin nanoparticles.

The medical product related to VEGF is being developed for the treatment of coronary artery disease [62]. As a result of blocked arteries in the heart, patients with coronary artery disease typically experience severe, often immobilizing, pain from minimum physical activity such as walking. This product is intended to improve blood flow in the heart through the formation of new blood vessels, a process known as angiogenesis, with the delivery the angiogenic protein, VEGF-121. In this approach, the product is directly injected into the heart wall by an endocardial injection catheter and this enables the sustained, controlled production of VEGF-121 protein in the area of the heart with poor blood flow. It was reported that there were no VEGF-related serious adverse events or dose-limiting toxicities.

**Figure 4.12.** The size distribution and  $\zeta$  potential of core–shell nanoparticles with a VEGF-loaded lecithin core.

The core–shell nanoparticles are utilized as a delivery vehicle of VEGF with a sustained release pattern. For the preparation of the protein-loaded core–shell nanoparticles, a similar process to that described previously was employed. For efficient loading of protein drug, complex formation was induced between lecithin and VEGF, and this complex was mixed with F-127 aqueous solution containing 5 wt% trehalose. Freeze-drying was conducted to form the polymeric shell on the surface of the complex composed of lecithin and VEGF (see Fig. 4.10).

In the freeze-drying process, trehalose used as a cryoprotectant plays two roles. One is to preserve the core–shell structure of nanoparticles, which is very important for the accomplishment of the sustained release pattern of VEGF. The other is to preserve the activity of loaded VEGF. It has been reported that globular proteins invariably show higher melting (denaturation) temperatures in the presence

of sugars (in dilute solution) and concentrated sugar systems confer textural consistency that prevents microbial attack in foods. It is not clear, however, whether these two different types of stabilization have a common physicochemical origin; in particular, whether water-sugar interactions are the only basis of both phenomena. Among all the sugars, trehalose has received the greatest attention, both because of its wide role in nature and its potential use as a highly efficient natural preservative [63].

Figure 4.11 shows the  $\zeta$  potential and size distribution of lecithin nanolipid. The size of lecithin nanolipid was approximately 65.4 nm and a negative value of the  $\zeta$  potential was observed, indicating that anionic lecithin nanolipid is suitable for the immobilization of cationic VEGF. After freeze-drying of VEGF/lecithin nanolipid complex in the F-127 aqueous solution containing 5 wt% trehalose, the obtained powder was resuspended in water and characterized with a particle size analyzer. As shown in Fig. 4.12, the diameter was approximately 270 nm and the magnitude of the negative value of the  $\zeta$  potential was decreased. With the formation of the polymeric shell, the size of the nanoparticles was increased and the negative charge of the lecithin nanolipid was decreased. The cryo-TEM image clearly demonstrates the formation of core-shell nanoparticles as shown in Fig. 4.13.

The release of VEGF from the nanoparticles was measured as shown in Fig. 4.14. A VEGF-loaded nanoparticle suspension (0.2 mL) was subsequently put into a dialysis tube. The dialysis tube was placed into 15 mL PBS containing 2.0 mM sodium azide and 0.1% (w/v) bovine serum albumin (BSA), and kept in reciprocal shaking water bath (Sangwoo Scientific, Korea) at 37 °C and 35 r.p.m. At each time-point, the whole medium was taken and replaced with the fresh release medium.

**Figure 4.13.** Cryo-TEM image of core-shell nanoparticles with a VEGF-loaded lecithin core.

Figure 4.14. The release of VEGF from the core–shell nanoparticles.

The amount of released VEGF into the release medium was determined by ELISA analysis (Neogen, USA). The sustained release pattern was observed up to 10 days, releasing about 16% of the initial loading and this indicates that a 1-month period of VEGF release can be achieved with core–shell nanoparticles.

With the adsorption of F-127 on the surface of lipid core by freeze-drying, the stabilized core–shell nanoparticles were formed in the presence of trehalose. This indicates that trehalose, which is generally used as a protein stabilizer, preserves the integrity of the spherical supramolecular structure of the lecithin core during the freeze-drying. Due to the distinct geometry of core–shell nanoparticles with a lipid core, the lipophilic drug can be loaded in the lipid core and protein drugs can be loaded in the polymeric shell.

### 4.3

#### Core–Shell Nanoparticles with a Polymeric Core

PLGA micro/nanoparticles have been designed and characterized for the delivery of a couple of proteins. Biodegradable microspheres containing recombinant human erythropoietin (EPO) were prepared from ABA triblock copolymers, consisting of hydrophobic PLGA A blocks and poly(ethylene oxide) (PEO) B blocks [64]. Using excipients with known protein stabilizing properties, such as BSA, poly(L-histidine), poly(L-arginine) or a combination of poly(L-arginine) and dextran, the EPO aggregate content was significantly reduced to below 5% of the encapsulated

EPO. In particular, the microspheres composed of ABA triblock copolymer (35 mol% PEO; 30 kDa) in combination with 5% BSA yielded both an acceptable level of EPO aggregate and a continuous release profiles under *in vitro* conditions for up to 14 days. Pharmacokinetic characterization of VEGF controlled release microspheres composed of PLGA was performed using a rat model. The microspheres were administered subcutaneously to the rat and the pharmacokinetic parameters were compared with those of VEGF solution [65]. The subcutaneous administration of protein solution resulted in rapid clearance from the tissue, with high plasma concentrations as expressed by rapid absorption and elimination. However, the subcutaneous administration of VEGF microspheres produced low plasma concentrations and high subcutaneous concentrations over a period of 7 weeks.

However, because of the hydrophobic character of PLGA, the loading of protein into PLGA micro/nanoparticles with a minimal decrease of protein activity still remains challenging. In addition, nanoparticles have a further advantage over larger microparticles because they are better suited for intravenous delivery. The smallest capillaries in the body are 5–6  $\mu\text{m}$  in diameter. The size of particles being distributed into the blood stream must be significantly smaller than 5  $\mu\text{m}$ , without forming aggregates, to ensure that the particles do not form an embolism.

The rapid removal of intravenously administered colloidal drug carrier by the mononuclear phagocytic system, comprising mainly the Kupffer cells of the liver and the macrophages of the spleen, has been identified as the major obstacle to the efficient targeting of colloidal carriers to target sites such as the circulation itself, tumor, sites of inflammation and bone marrow. Various studies have been carried out for the successful avoidance of these difficulties. One of the related studies reported that the *in vitro* interaction with isolated macrophages and the biodistribution of model polystyrene nanospheres after modification of the particle surface using PEO/poly(propylene oxide) (PPO) block copolymers of the poloxamer (Pluronic) poloxamine series and the presence of PEO on the surface of nanospheres decrease the extent of phagocytosis [66]. It was also verified that poloxamer and poloxamine copolymers are bound to the nanosphere surface by hydrophobic interaction of the PPO chains, whereas the hydrophilic PEO chains protrude into the surrounding medium to create a steric barrier and this barrier prevents or decreases the adsorption of plasma proteins onto the particle surface, resulting in the decreased recognition by the liver and spleen macrophages [67–69]. Similar results have been reported with PLGA nanoparticles coated with Pluronic [70]. In particular, the size of nanoparticles and coating layer thickness were measured using photon correlation spectroscopy, indicating the presence of a hydrogel layer on the surface of nanoparticles. These results enable us to design PLGA nanoparticles with a hydrogel layer on the surface, which are utilized as cores in the formation of core–shell nanoparticles with a polymeric core.

#### 4.3.1

##### **Hyaluronic Acid (HA)-functionalized PLGA Nanoparticles**

A novel preparation method for core–shell nanoparticles with a hydrophilic polymeric shell was designed and characterized based on the preparation method of

hydrophilized PLGA nanoparticles with Pluronics described previously. The core is composed of PLGA and polymeric shell is composed of Pluronics (F-127) and HA. The role of the core is to provide the nucleus for the stable formation of the hydrophilic polymeric shell by physical adsorption and that of the polymeric shell is to provide the hydrophilic network for protein loading. Specifically, HA was used as one of the components for polymeric shell to induce the ionic interaction between protein and HA for the efficient loading and sustained release of ionized and hydrophilic protein. For the characterization of core-shell nanoparticles as a drug carrier, lysozyme, which was used as a model protein drug, was loaded into the nanoparticles, and the loading amount and release pattern was observed with the variation of the composition of the polymeric shell.

In the previous study, PLGA nanoparticles were prepared based on the temperature-induced phase transition in the F-127/PLGA mixture without solvent [71]. This method provides F-127-coated PLGA nanoparticles (hydrophilized nanoparticles) used as a core. Figure 4.15 describes the preparation method of nanoparticles used as a polymeric core schematically. F-127 is in a flaky state and PLGA is in a powdery state at room temperature. The mixtures were prepared individually by weighing 85 mg of polymers with 0.2 weight ratio of (PLGA/F-127) and 3 mg of Tween 80 into 20 mL vials, which were immediately put into a vacuum oven at 60 °C. Within 30 min, both polymers were liquidized completely to form a transparent polymer solution. The melted mixtures were transferred to vacuum oven at 25 °C to induce the phase transition (the solidification of liquidized polymer mixture). With the phase transition, PLGA formed the phase-separated domain with a spherical form and F-127 formed the continuous phase as shown in Fig. 4.16. Following the equilibration period for 3 h, the solidified mixture was withdrawn from the vacuum oven and immersed in distilled/deionized water for 3 days to solubi-

**Figure 4.15.** Schematic description of the method of preparation of PLGA nanospheres. (From Ref. [71].)

**Figure 4.16.** SEM image of phase-separated (8:2) (w/w) F-127/PLGA mixture. (From Ref. [71].)

lize F-127 using a dialysis bag (molecular weight cut-off range: 40–50 kDa; Fisher Scientific, USA), replacing the distilled/deionized water every hour. This aqueous solution containing PLGA nanoparticles was centrifuged for 20 min and filtered through the 0.45- $\mu\text{m}$  filter membrane. The obtained PLGA nanoparticles were freeze-dried. In the final stage for preparing PLGA nanoparticles, Pluronic was removed from the phase-separated aggregate. However, the complete removal of Pluronic was impossible due to the hydrophobic interaction between the PLGA and the PPO domain of F-127, resulting in the formation of Pluronic-adhered PLGA nanoparticles. Due to the presence of F-127 on the surface of PLGA nanoparticles, stability in aqueous medium was significantly improved as shown in Fig. 4.17.

For the preparation of core–shell nanoparticles with a hydrophilic polymeric shell, the formation of a gel layer was induced. First, PLGA nanoparticles prepared previously were suspended in HA/F-127 aqueous solution with a variation of the weight ratio of HA/F-127. Subsequently, this aqueous solution mixture was subjected to freeze-drying to induce the formation of the polymeric shell.

Figure 4.18 describes the formation of core–shell nanoparticles with a hydrophilic polymeric shell and the protein-loading process [49]. F-127 forms a spherical micelle at low concentration. In this low micellar concentration regime, micelles are well-separated and the solution is an isotropic fluid. At higher concentrations, the micelles approach close packing and ordered domains, consisting of cubic packing of spherical micelles, are induced resulting in the gelation. With the freeze-drying process in this study, the concentration of F-127 aqueous solution was increased with the evaporation of water and gelation was induced to form a polymeric shell. With the evaporation of water by freeze-drying, F-127 was adsorbed (gelled) into F-127-coated PLGA nanoparticles and HA might be adsorbed

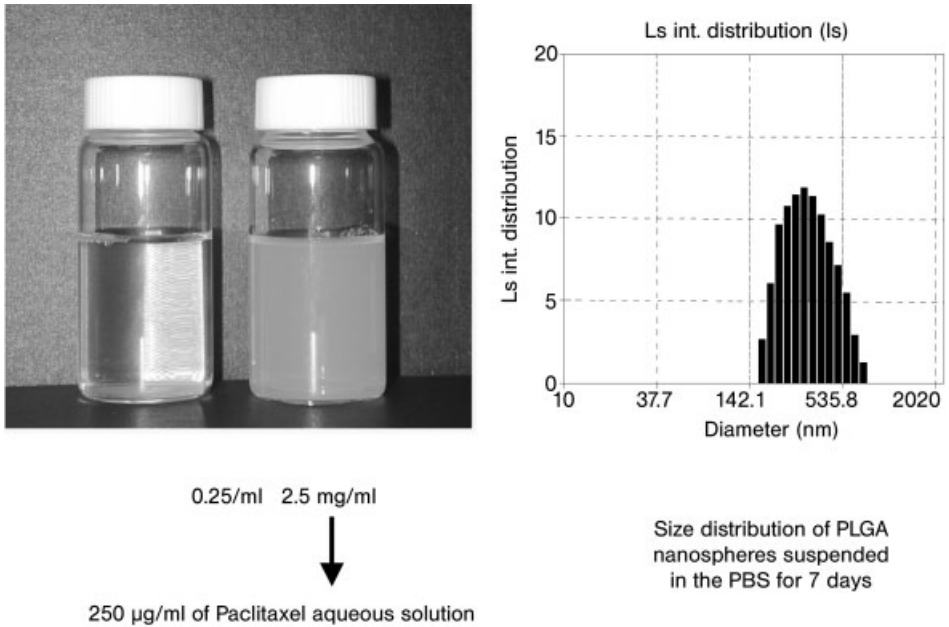

Figure 4.17. The enhanced stability of F-127-coated PLGA nanoparticles in aqueous media.

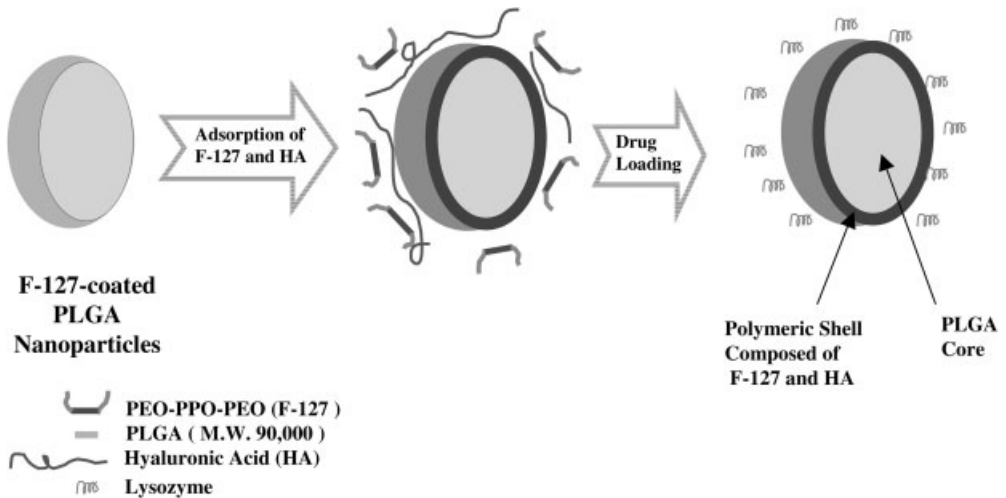

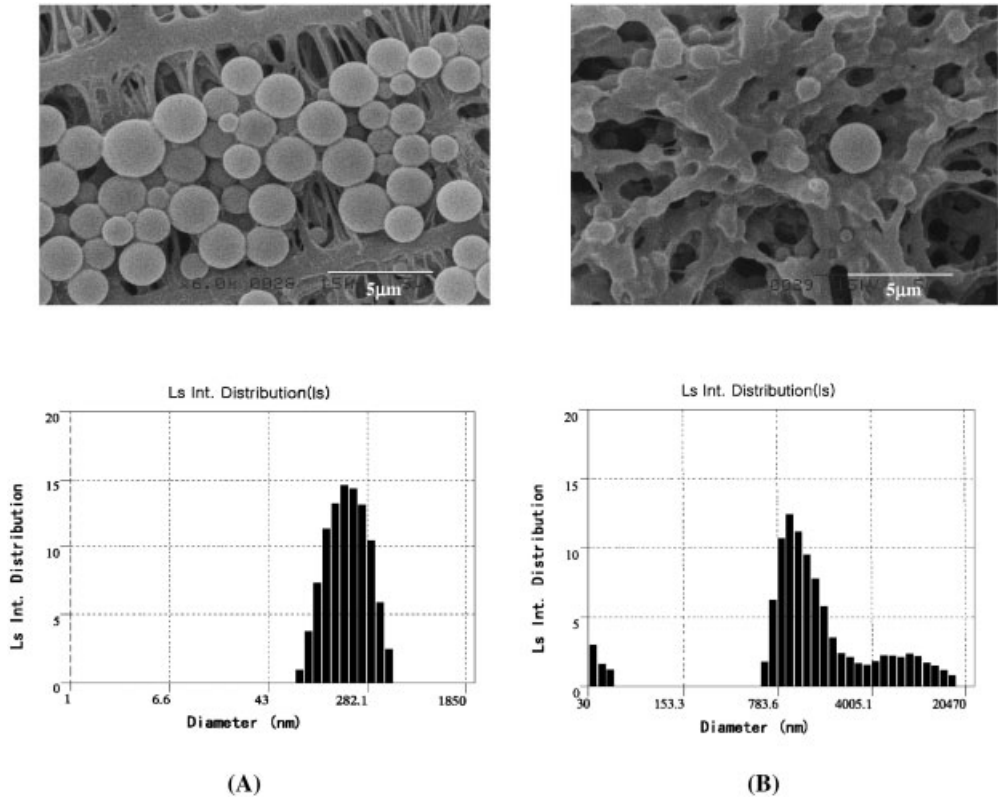

Figure 4.18. The formation of core-shell nanoparticles with a hydrophilic polymeric shell and the protein loading process. (From Ref. [49].)

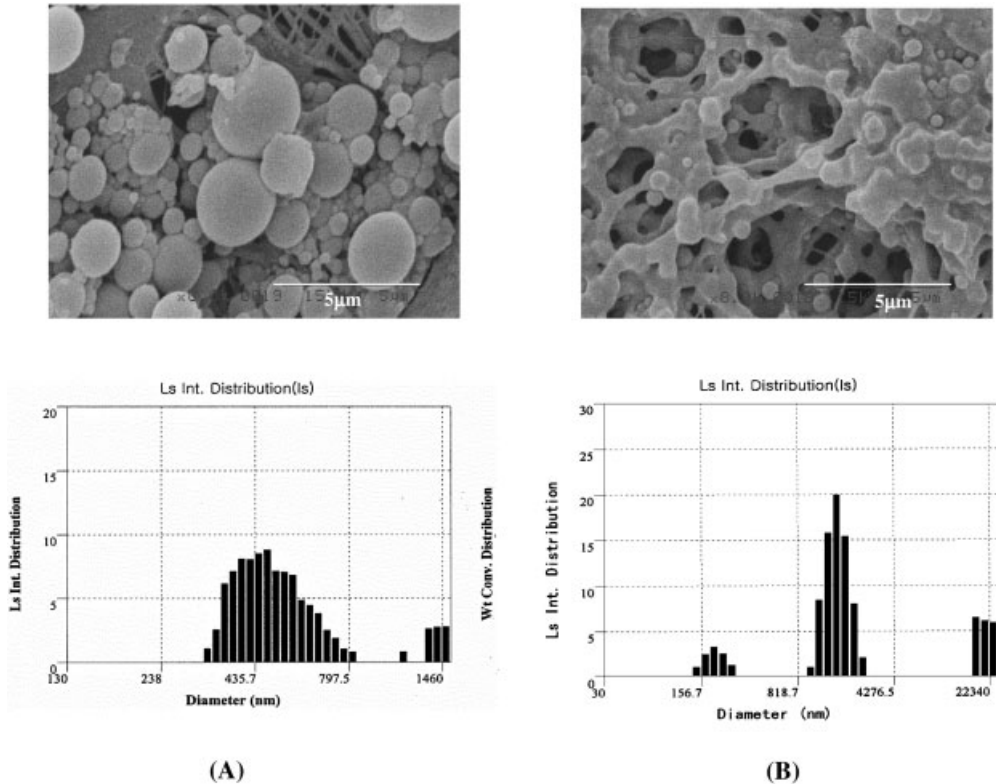

**Figure 4.19.** (A) SEM image and size distribution of core–shell nanoparticles formed from 5 wt% F-127 aqueous solution. (B) SEM image and size distribution of core–shell nanoparticles formed from 10 wt% F-127 aqueous solution. (From Ref. [49].)

into F-127-coated PLGA nanoparticles with F-127, resulting in the formation of a polymeric shell composed of F-127/HA composite.

The shape of core–shell nanoparticles formed at different concentrations of F-127 in the absence of HA was examined by scanning electron microscopy (SEM) to observe the optimum concentration of F-127 for the stable formation of the polymeric shell. As shown in Fig. 4.19, the aggregation of nanoparticles was observed at core–shell nanoparticles formed as 10 wt% F-127 aqueous solution. This is due to the formation of a polymer network between free F-127 (which was not adsorbed on the surface of the PLGA nanoparticle). However, aggregation was not observed at the core–shell nanoparticles formed at 5 wt%, indicating that most F-127 in the aqueous media was adsorbed on the surface of PLGA nanoparticles. Therefore, the concentration of polymeric shell material was fixed at 5 wt% throughout the experiment. Note that the fibrous structure in the background of Figs. 4.19(A) and 4.20(A) is from the filter paper.

**Figure 4.20.** (A) SEM image and size distribution of core–shell nanoparticles with 0.2 weight ratio of HA/F-127. (B) SEM image and size distribution of core–shell nanoparticles with 0.4 weight ratio of HA/F-127. (From Ref. [49].)

For the efficient loading of cationic lysozyme (isoelectric point: 11.1) under physiological conditions, anionic HA was incorporated into the polymeric shell by co-adsorption with F-127. Core–shell nanoparticles were prepared with the variation of the HA/F-127 weight ratio. As shown in Fig. 4.20, the aggregation of nanoparticles was observed at 0.4 weight ratio of HA/F-127. This is due to the formation of a polymer network between free HA (which was not incorporated into the polymeric shell). In the adsorption of F-127 and HA on the surface of F-127-coated nanoparticles, the main driving force forming the polymeric shell is the hydrophobic interaction between F-127. As HA does not have intermolecular interactions with F-127 or PLGA nanoparticles, it is embedded physically in the F-127 network within the range of 0–0.3 weight ratio of HA/F-127. However, the formation of the HA/lysozyme complex without the PLGA core could be possible due to unstable embedding of HA in the polymeric shell. This property should be improved for

**Figure 4.21.** The variation of the  $\zeta$  potential of core–shell nanoparticles as a function of the weight ratio of HA/F-127. (From Ref. [49].)

the exact manipulation of loading lysozyme (or negatively charged proteins under physiological conditions).

Figure 4.21 shows the variation of the  $\zeta$  potential of core–shell nanoparticles with the variation of weight ratio of HA/F-127. The negative value was observed with the increase of weight ratio of HA/F-127, indicating that anionic HA is embedded in the polymeric shell and that the polymeric shell is suitable for the immobilization of cationic lysozyme.

Figure 4.22 shows the change of loading amount with the variation of weight ratio of HA/F-127. Lysozyme was loaded into core–shell nanoparticles by sorption method. Samples of 100 mg of dried core–shell nanoparticles were suspended in 100 mL of PBS containing 10 mg of lysozyme and stored at 25 °C to induce the ionic interaction between lysozyme and HA in the polymeric shell. After equilibrium for 12 h, this aqueous solution was centrifuged for 20 min and filtered through a 0.45- $\mu$ m filter membrane. The obtained lysozyme-loaded core–shell nanoparticles were freeze-dried. The amount of unloaded lysozyme in the aqueous media was analyzed by high-performance liquid chromatography (HPLC) to measure the amount of drug loaded. Lysozyme was determined by reversed-phase HPLC using a Shodex RSpak RP 18-415 column and trifluoroacetic acid/ acetonitrile (0.1/99.9, v/v%) mobile phase at a flow rate of 1 mL min<sup>-1</sup>. The elute was monitored by UV absorption at 220 nm. The amount of drug loading is defined as the ratio of the amount of drug in the nanoparticles/total weight of nano-

**Figure 4.22.** The variation of loading amount of core-shell nanoparticles as a function of the weight ratio of HA/F-127. (From Ref. [49].)

particles. The loading amount was increased up to 7 wt% with the increase of HA content in the polymeric shell. Due to the ionic interaction between cationic lysozyme and anionic HA in the PBS (pH 7.4), stable immobilization of lysozyme into the polymeric shell was induced and this led to the increase of the loading amount.

Figure 4.23 shows the release pattern of lysozyme from the core-shell nanoparticles formed as a function of weight ratio of HA/F-127. To measure the release pattern of lysozyme from the nanoparticles, 5 g of freeze-dried core-shell nanoparticles was put into 500 mL of PBS (pH 7.4). Temperature was maintained at 37 °C and stirring was maintained at 600 r.p.m. At given time intervals, 5-mL aliquots were withdrawn from release medium (PBS). HPLC analysis can then be performed as previously described. To maintain the sink condition in the release medium, 5 mL of fresh PBS was added to release medium after sampling. Without HA in the polymeric shell, a significant burst effect was observed. With the formation of the polymeric shell composed of F-127 and HA, the release rate was reduced significantly and an almost zero-order release pattern was observed at nanoparticles with 0.2 weight ratio of HA/F-127. Although HA is embedded in the F-127 network within the range of 0–0.3 weight ratio of HA/F-127 as shown in Fig. 4.21, it does not have intermolecular interactions with F-127 or PLGA nanoparticles and this leads to the release of HA from the polymeric shell. As lysozyme is ionically bound to HA, lysozyme and HA release together with the formation of

**Figure 4.23.** The release pattern of lysozyme from the core–shell nanoparticles. (From Ref. [49].)

an ion complex. To verify the release of HA from the polymeric shell, the variation of the  $\zeta$  potential was measured as a function of time for equilibrium in the release media. Figure 4.24 shows that the  $\zeta$  potential of core–shell nanoparticles with 0.2 weight ratio of HA/F-127 was increased with the increase of equilibrium time. This indicates that HA is released from the polymeric shell during the release of lysozyme and the sustained release of lysozyme is due to the release of the ionic complex composed of HA and lysozyme, which has a higher molecular weight compared with free lysozyme.

The specific enzyme activity of lysozyme in the release media after the 1-week release experiment was measured. For lysozyme activity assay, a suspension of  $0.1 \text{ mg mL}^{-1}$  *Micrococcus lysodeikticus* was prepared in PBS ( $37^\circ\text{C}$ ). To  $2.95 \text{ mL}$  *M. lysodeikticus* suspension,  $0.05 \text{ mL}$  lysozyme solution was added and mixed immediately. The turbidity of the suspension was measured at  $450 \text{ nm}$  by a Shimadzu UV-1601 spectrophotometer. One unit of activity corresponds to a decrease in turbidity of  $0.001 \text{ min}^{-1}$  at  $450 \text{ nm}$  [72]. In comparison to the activity of native lysozyme, 81.3% activity was preserved and this indicates that the activity of lysozyme was preserved during the freeze-drying process.

Core–shell nanoparticles with a composite polymeric shell composed of F-127 and HA have been prepared based on the hydrophobic interaction between PLGA and the PPO domain of F-127. Although HA does not have intermolecular interactions in the polymeric shell, the formation of the polymeric shell composed of F-127 and HA within the range of 0.3 weight ratio of HA/F-127 was observed.

**Figure 4.24.** The variation of the  $\zeta$  potential of core-shell nanoparticles as a function of the time for equilibrium in PBS. (From Ref. [49].)

Due to the ionic interaction of cationic lysozyme and anionic HA under physiological conditions, the efficient loading and sustained release of lysozyme were accomplished. This enables us to prepare charged nanoparticles with a core-shell structure for the delivery of protein drug.

#### 4.3.2

#### Heparin-functionalized PLGA Nanoparticles

A new, facile method to prepare heparin-functionalized PLGA nanoparticles for the controlled release of growth factors has been developed [73]. This system is composed of PLGA as a hydrophobic core, F-127 as a hydrophilic surface layer (polymeric shell) and heparin as the functional moiety. Nanoparticles were prepared by a solvent-diffusion method without chemical modification of the components.

Heparin is a highly sulfated, anionic polysaccharide composed of repeating disaccharides of 1-4-linked glucosamine and uronic acid residues. Heparin is best known for its anticoagulant properties that are mediated through a pentasaccharide sequence that binds antithrombin III (AT-III) and subsequently complexes thrombin [74]. Heparin also interacts with a variety of proteins that have heparin-binding domains, including various growth factors, e.g. fibroblast growth factor (FGF) family [75], VEGF family [76], platelet-derived growth factor (PDGF) family [77], transforming growth factor (TGF)- $\beta$  family [78] and glial-derived neurotrophic factor (GDNF) [79]. This binding between growth factor and heparin or heparan

sulfate proteoglycans enables the growth factors to crosslink their receptors, and the association stabilizes the growth factor and protects it from proteolytic degradation [80, 81].

Based on the high specific binding of heparin for various growth factors, several heparin-containing systems have been developed for the controlled release of the growth factors. Edelman and coworkers encapsulated heparin-conjugated and basic FGF (bFGF)-loaded Sepharose beads in calcium alginate microspheres and demonstrated the controlled release of bFGF [82]. Sakiyama-Elbert and coworkers incorporated heparin-binding peptide 5 domains into a fibrin gel to bind heparin, which was then used to load and release bFGF [75] or  $\beta$ -nerve growth factor (NGF) [83]. Wissink and coworkers grafted collagen matrices with heparin and the sustained release of loaded bFGF was observed [84]. Tanihara and coworkers cross-linked alginate and heparin with diamine using carbodiimide activation to construct a hydrogel which showed sustained release of loaded bFGF [85]. Seal and coworkers covalently attached heparin-binding peptides to multi-arm PEGs, which were then physically crosslinked with heparin [86]. Among the heparin-binding growth factors, VEGF is of particular interest in tissue engineering due to its proangiogenic properties [87, 88]. So far, PLGA microspheres have been generally adapted for the particle-type sustained release system of growth factors [89, 90]. However, the encapsulation of proteins into hydrophobic PLGA cores has easily denatured proteins to aggregate and adsorb on the degrading PLGA surface [91–94], and also the presence of a water/organic solvent interface during protein loading has been identified as a major cause of protein denaturation and aggregation [95–97]. Alginate has also been used to encapsulate growth factors [98–100]. Even though there is no interfacial problem when proteins are encapsulated in alginate beads, rapid release and an initial burst of encapsulated proteins, as well as irreversible complexation with alginate were reported [100, 101]. Growth factor delivery by gelatin microspheres is very similar to the case of the alginate system [102, 103]. The main interaction between protein and gelatin is polyion complexation and the conformational change of the gelatin molecule is also followed. In addition, even though alginate and gelatin are natural polymers, growth factors do not have any binding domains on these polymers, thus limiting the binding events to the proteins with net positive charges [104]. Several heparin-based micelles or nanoparticles have also been developed as drug carriers [105–107]. However, all these systems employed chemical modifications of the functional group sequence of heparin to attach with either hydrophobic polymers or the low-molecular-weight hydrophobic moiety, thus reducing the bioactivity of the heparin, as represented by antithrombic activity [108].

The nanoparticles were prepared by a spontaneous emulsion solvent diffusion method as follows (Fig. 4.25). Samples of 40 mg of PLGA were dissolved in 2 mL DMSO at room temperature. The organic phase was then slowly added to 30 mL of deionized water containing 1.5 g of F-127 and a fixed amount of heparin with vigorous stirring. The amount of heparin was varied to control the entrapped heparin on the nanoparticles. The nanoparticles formed in the aqueous solution were col-

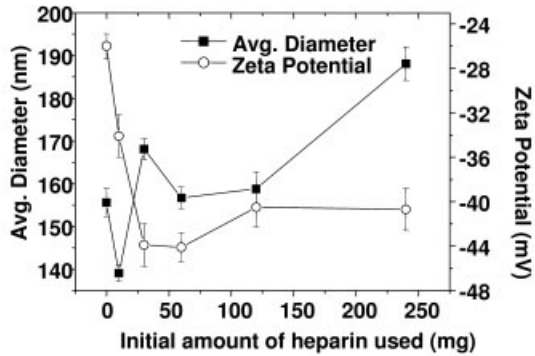

**Figure 4.25.** Schematic representation of heparin-functionalized PLGA nanoparticle preparation and chemical structures of the components. (From Ref. [73].)

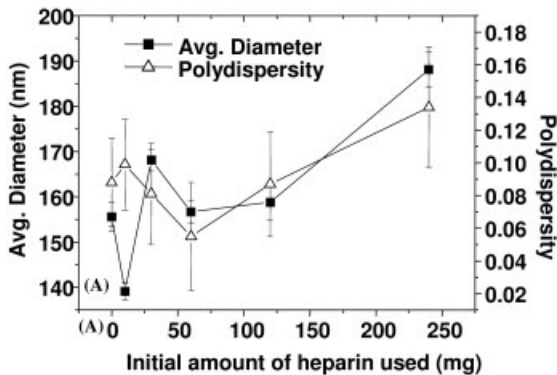

lected by high-speed centrifugation (Hanil Science Industrial, Korea) at 12 000 r.p.m. for 1 h and resuspended in 0.5 mL of PBS solution containing 1.0% (w/v) Tween 80.

The size, polydispersity and surface charge of the nanoparticles were characterized by varying the amount of heparin in the aqueous phase. For the nanoparticles prepared from the aqueous solution containing no heparin, monodispersed nanoparticles with an average diameter of  $156 \pm 3$  nm and polydispersity of  $0.09 \pm 0.03$  were obtained. The surface charge from the  $\zeta$  potential measurement was  $-26.0 \pm 1.1$  mV (Fig. 4.26). By increasing the amount of heparin in the aqueous phase during the preparation of nanoparticles, the  $\zeta$  potential value decreased significantly, whereas the size and the polydispersity of nanoparticles varied little. However, when the amount of heparin in the aqueous phase was increased to 240 mg, both the size and the polydispersity of the nanoparticles increased noticeably to  $188 \pm 4$  and  $0.13 \pm 0.04$  nm. Thus, it can be concluded that heparin molecules were entrapped in the nanoparticles, maintaining their monodisperse distribution when the amount of heparin in the aqueous phase was less than 240 mg.

To obtain specific information about the amount and distribution of heparin in the nanoparticles, the anti-factor Xa (FXa) assay of the nanoparticles prepared at various conditions was carried out. Anti-FXa assay (Chromogenix Instrumentation Laboratory, Italy) on nanoparticles was carried out to calculate the amount of heparin in nanoparticles. The principle of this assay is that the amount of neutralized FXa binding with a heparin-antithrombin (AT) complex is proportional to the

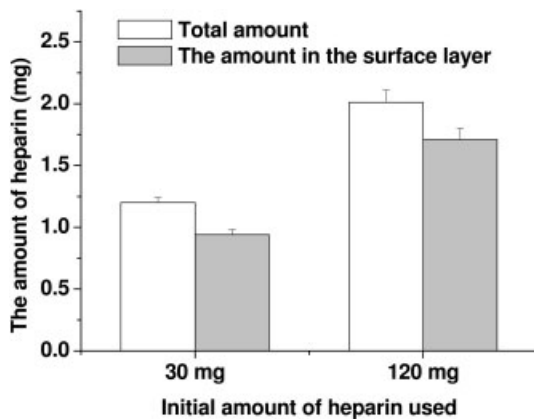

(A)

**Figure 4.26.** The size, surface charge and polydispersity of heparin-functionalized PLGA nanoparticles obtained by varying the amount of heparin in the aqueous phase during preparation.  $N = 6$  experiments. (From Ref. [73].)

amount of heparin. In order to measure the total amount of heparin in nanoparticles, the lyophilized nanoparticles were dissolved in methylene chloride to extract PLGA and F-127, and then the precipitated heparin was collected. On the other hand, the amount of heparin available on the nanoparticle surface was directly measured using the nanoparticle-AT complexation. In this assay, the activity of heparin distributed in the nanoparticle surface layer was measured using the diluted nanoparticle suspension and the heparin activity was increased by increasing the amount of heparin in the aqueous phase during the nanoparticle preparation. The activity of total heparin both in the nanoparticle core and surface layer, measured by extracting the entire heparin molecules entrapped in the nanoparticles, was a little higher than the heparin activity in the surface layer. The heparin activity was converted to the amount of heparin by using the anti-FXa activity of the heparin sodium used. The amount of heparin in the surface layer and the core of the nanoparticles, obtained by subtracting the amount in the surface layer from the

**Figure 4.27.** The amount of heparin in heparin-functionalized PLGA nanoparticles determined by the anti-FXa assay.  $N = 3$  experiments. (From Ref. [73].)

total amount, revealed that heparin molecules were mainly distributed in the nanoparticle surface layer and only a relatively small amount of heparin was in the nanoparticle core (Fig. 4.27).

$^1\text{H}$ -nuclear magnetic resonance (NMR) analysis of nanoparticles was performed to obtain the mole ratio between F-127 and PLGA in the nanoparticles. The  $^1\text{H}$ -NMR (JEOL JNM-LA300WB FT-NMR Spectrometer, Japan) analysis was performed to calculate the molar ratio between PLGA and F-127 in the nanoparticles. The suspension of nanoparticles was freeze-dried and then dissolved in  $\text{CDCl}_3$ . The molar ratio was calculated using the integral of separate peaks of CH (5.1 p.p.m.) of PLGA and  $\text{CH}_3$  (1.1 p.p.m.) of F-127 (Fig. 4.28).

The weight percentage of the heparin entrapped in the nanoparticles was 0.0, 2.4 and 4.7 for the nanoparticles prepared from an aqueous phase containing 0, 40 and 120 mg of heparin, respectively. Thus, the proposed method can manufacture the monodisperse nanoparticles containing heparin up to 4.7 wt% in total (4.0 wt% at the surface layer) and the amount of heparin can be controlled by adjusting the amount of heparin in the aqueous phase during preparation. The localization of F-127 molecules to the PLGA cores during particle formation is probably due to the hydrophobic interaction between the PPO block of F-127 and PLGA. The interaction between heparin and PEO blocks of F-127 may also contribute to localization of heparin on the nanoparticles, resulting in a high concentration of heparin in the nanoparticles. A similar observation has been reported between alginate and Pluronic F-127; the formation of crosslinks between the carboxyl group of alginate and PEO blocks of PF-127 leads to the formation of a three-dimensional network, resulting in improved shear stress.

Lysozyme was selected as a model protein for the *in vitro* release experiments using the heparin-functionalized PLGA nanoparticles. To load lysozyme into the nanoparticles, the resuspended nanoparticles were mixed with 0.1 mL PBS

**Figure 4.28.**  $^1\text{H}$  NMR analysis to calculate the molar ratio between PLGA and F-127 constituting the heparin-functionalized PLGA nanoparticles by comparing  $^1\text{H}$  from CH of PLGA (5.1 p.p.m.) and  $^3\text{H}$  from  $\text{CH}_3$  of Pluronic F-127 (1.1 p.p.m.). (From Ref. [73].)

containing 1 mg of lysozyme and then incubated at 4 °C overnight with gentle rotation, which yields the loading of 1 mg of lysozyme into 43.3 mg of heparin-functionalized PLGA nanoparticles. Then, lysozyme-loaded nanoparticle suspension (0.6 mL) was subsequently put into a dialysis tube. The dialysis tube was placed in 100 mL PBS containing 2.0 mM sodium azide and kept under the same conditions as described previously.

Lysozyme can interact electrostatically with the heparin because lysozyme is net positively charged (the isoelectric point of lysozyme is pH 11.1). The average diameter and size distribution of nanoparticles after loading lysozyme were not changed after loading, and there was no aggregated complex among lysozyme-loaded nanoparticles. Figure 4.29 shows release profiles of lysozyme from three kinds of nanoparticles with different heparin contents of 0.0, 2.4 and 4.7%, respectively. In the case of the nanoparticles with no heparin, over two-thirds of the total lysozyme loaded was released within 3 days. In contrast, the nanoparticles with heparin contents of 2.4 and 4.7% showed linear and complete release profiles without any initial burst up to 10 and 19 days, respectively which shows net positively charged lysozyme was well bound in the negatively charged surface layer of the nanoparticles. To characterize the deactivation of lysozyme released from the heparin-functionalized nanoparticles, the concentration of the released lysozyme was analyzed based on the bioactivity of the released lysozyme on *M. lysodeikticus* cell walls using a lysozyme assay kit and compared with the concentration of the total

**Figure 4.29.** Cumulative lysozyme release from three kinds of heparin-functionalized PLGA nanoparticles with different heparin contents.  $N = 3$  experiments. (From Ref. [73].)

protein measured using the Micro BCA protein assay (Fig. 4.30). There were no differences between the total protein concentration and the bioactive lysozyme concentration at each time-point, showing that no denaturation of lysozyme occurred during loading into the nanoparticles and release from them.

Nanoparticles with a heparin content of 4.7% were selected as a VEGF release system, based on the result of the lysozyme release experiment. First, the release experiment was performed with loading 250 ng of VEGF into 14.4 mg of the nanoparticles. To load VEGF into the nanoparticles, both one-third and one-tenth of re-

**Figure 4.30.** Comparison of the concentrations of lysozyme released from heparin-functionalized PLGA nanoparticles measured by the bioactivity on *M. lysodeikticus* cell walls using a lysozyme assay kit and the total protein concentration using a Micro BCA protein assay.  $N = 3$  experiments. (From Ref. [73].)

**Figure 4.31.** Cumulative VEGF release from heparin-functionalized PLGA nanoparticle with 4.7% w/w of heparin for two different loading amounts.  $N = 3$  experiments. (From Ref. [73].)

suspended nanoparticles were mixed with 25  $\mu\text{L}$  PBS containing 250 ng of VEGF and 75  $\mu\text{L}$  PBS containing 750 ng of VEGF, respectively, and then incubated at 4  $^{\circ}\text{C}$  overnight with gentle rotation, which yields loading of 250 ng of VEGF into 14.4 mg of nanoparticles and 750 ng of recombinant human VEGF into 4.3 mg of nanoparticles.

After loading, no aggregation among the protein-loaded nanoparticles was observed. The stability of VEGF in the release medium (PBS solution containing 0.1 wt% BSA) was conformed by comparing the concentration of VEGF in the release medium incubated at 37  $^{\circ}\text{C}$  for 24 h. The release of VEGF from the nanoparticles showed a linear profile without any initial burst up to day 37, releasing about 85% of the initial loading amount, and then the release rate was slowed down (Fig. 4.31). This release pattern was similar to the case of lysozyme; however, a much more prolonged release pattern was obtained. To elucidate whether the prolonged release was responsible from the decreased loading amount of the protein or the more specific interaction between VEGF and heparin than that between lysozyme and heparin, the loading amount of VEGF to the nanoparticles was increased 10-fold. The relative release rates (percent of the total amount) were almost same in both cases. Thus, the prolonged release pattern was mainly due to the more strong and specific interaction between VEGF and heparin than that between lysozyme and heparin.

Nanoparticles with heparin molecules on the surface were prepared by solvent diffusion without any chemical reaction. Monodispersed nanoparticles containing heparin up to 4.7 wt% in total (4.0 wt% at the surface layer) were manufactured and the amount of heparin was controlled by adjusting the amount of heparin in the aqueous phase during preparation. The release of lysozyme from the nanoparticles with 4.7 wt% heparin showed a linear and complete release profile with-

out any initial burst over 2 weeks, and the released lysozymes maintained their bioactivity. The release of VEGF from the nanoparticles showed a linear and more prolonged profile without any initial burst over 1 month, mainly due to the stronger and more specific interaction between VEGF and heparin than that between lysozyme and heparin. Thus, the heparin-functionalized PLGA nanoparticles can be employed a growth factor delivery component in tissue engineering scaffolds as well as a sustained release system for various heparin binding growth factors.

#### Core–shell Nanoparticles with a Metallic Core

Core–shell nanoparticles with a metallic core have been studied intensively for application in the biomedical areas such as for magnetic resonance contrast agents [109], targeted drug delivery [110], and cancer diagnosis and treatment [111]. With the formation of core–shell nanoparticles with a metallic core (polymer-coated magnetic nanoparticles), a magnetic resonance contrast agent with enhanced stability and biocompatibility under physiological conditions can be achieved. Previously, iron oxide nanoparticles were stabilized with the formation of a polymeric layer on the surface of iron oxide nanoparticles using dextran, starch, albumin, silicones or PEG [112, 113]. The coprecipitation of iron salts in a polymeric coating solution by the microemulsion method [114] or and laser-induced pyrolysis [115] was used to prepare polymer-coated iron oxide nanoparticles. However, the wide size distribution remains still challenging with regard to the formation of a polymer shell on the surface of magnetic nanoparticles.

Recently, PVP-coated iron oxide nanoparticles with a narrow size distribution were prepared [109] based on the thermal decomposition presented previously [117–125]. First, 1 g of PVP was dissolved in 3 mL of DMF and this solution was purged with nitrogen to remove oxygen in a three-neck, round-bottom flask. The resulting mixture was heated to around 160 °C under vigorous mechanical stirring and  $\text{Fe}(\text{CO})_5$  was injected into the mixture. The reaction mixture was stirred for 2 h at 160 °C. During this process, the initial orange color of the solution gradually became a brownish black colloid solution. The colloid solution was cooled at room temperature and dialyzed for the removal of excess unreacted PVP at 37 °C for 2–3 days whilst being continuously stirred. For the characterization of PVP-coated nanoparticles, the dialyzed colloidal solution was freeze-dried.

Figure 4.32 shows the X-ray diffraction (XRD) data of pure PVP and PVP-coated iron oxide nanoparticles to confirm the crystallinity of the PVP-coated iron oxide nanoparticles. The characteristic patterns of the spinel phases  $\text{Fe}_2\text{O}_3$  and  $\text{Fe}_3\text{O}_4$  were observed, and this showed that iron oxide nanoparticles in PVP-coated iron oxide nanoparticles were mixtures of  $\text{Fe}_2\text{O}_3$  and  $\text{Fe}_3\text{O}_4$ .

The hysteresis loop of PVP-coated iron oxide at in room temperature is shown in Fig. 4.33. The magnetic properties of PVP-coated iron oxide nanoparticles were measured at room temperature with  $|H| \leq 20$  kOe using Quantum Design MPMS 5 superconducting quantum interface device (SQUID) magnetometer. The mass

Figure 4.32. XRD pattern of PVP-coated iron oxide. (From Ref. [109].)

magnetization is defined as the magnetic moment per total mass of sample measured. The PVP-coated iron oxide nanoparticles produced were characterized by a high magnetic moment in a high magnetic field (generally, about 5–90 e.m.u.  $g^{-1}$  of metal oxide) and a negligible magnetic moment in the absence of an applied field. Such behavior is characteristic of superparamagnetic particles. From the results, 3- and 50- to 100-nm PVP-coated iron oxide nanoparticles exhibited superparamagnetic properties. The saturation magnetization of 3-nm particles was 34 e.m.u.  $g^{-1}$  Fe and the saturation magnetization of 50- to 100-nm nanoparticles was 90 e.m.u.  $g^{-1}$  Fe. These results showed that bigger iron oxide nanoparticles had larger mass magnetization.

Figure 4.34 shows a TEM image and particle size analysis of PVP-coated iron oxide nanoparticles prepared in DMF. The TEM image shows that the diameter of nanoparticles is 50–100 nm with a spherical shape. Following resuspension of nanoparticles into aqueous media, the size distribution analysis demonstrates that the colloid has the diameter of 200 nm. A similar process was applied to PVP-coated iron oxide nanoparticles prepared in Carbitol as shown in Fig. 4.35. Nanoparticles of 3 nm diameter were observed in the dried state and those of 100 nm diameter were observed in the aqueous media with a narrow size distribution. These size differences are due to the swelling of PVA on the surface of the iron oxide nanoparticles (metallic core); this indicates the formation of PVP-coated iron oxide nanoparticles.

(A)

(B)

**Figure 4.33.** Magnetization curve of PVP-coated iron oxide nanoparticles of (A) 3 and (B) 50–100 nm at room temperature. (From Ref. [109].)

Fourier transform IR (FTIR) spectra of pure PVP and PVP-coated iron oxide nanoparticles are presented in Fig. 4.36. With the increase of PVP/ $\text{Fe}(\text{CO})_5$  molar ratios, the C=O absorption bands were shifted from 1670 to  $1653.56\text{ cm}^{-1}$ . The results showed that iron oxide was coordinated through the carbonyl group of PVP,

**(A)****(B)**

**Figure 4.34.** (A) TEM image and (B) size distribution of PVP-coated iron oxide nanoparticles prepared with DMF as solvent. (From Ref. [109].)

**(A)****(B)**

**Figure 4.35.** (A) TEM image and (B) size distribution of PVP-coated iron oxide nanoparticles prepared with Carbitol as solvent. (From Ref. [109].)

**Figure 4.36.** FTIR spectra of pure PVP and PVP-coated iron oxide nanoparticles. (From Ref. [109].)

and the interaction between PVP and iron oxide was increased with the increase of the particle size.

For further confirmation of coordination between iron oxide and the carbonyl group of PVP, X-ray photoelectric spectroscopy (XPS) spectra were observed as shown in Fig. 4.37. Correction of the energy shift due to the static charging of the samples was accomplished with the C 1s peak at 284.6 eV as a reference. The accuracy of the reported binding energies was  $\pm 0.1$  eV. The photoelectron peaks at 711.3 and 726 eV are the characteristic doublets of Fe 2p from iron oxide. The N

**Figure 4.37.** XPS spectra of PVP-coated iron oxide nanoparticles. (From Ref. [109].)

**Figure 4.38.** Viability of cells exposed to a solution containing PVP-coated iron oxide nanoparticles at various iron concentrations. (From Ref. [109].)

1s peak centered at 399.6 eV indicates that the nitrogen is influenced by the iron oxide. The O 1s peak at 531.8 eV is shifted toward to higher binding energy compared with pure PVP (530.3 eV), implying the decrease of electron density around O atoms in the carbonyl group of PVP, probably due to the interaction between iron oxide and O atoms in PVP [126].

Figure 4.38 shows the viability of cells exposed to the solution containing PVP-coated iron oxide nanoparticles at various iron concentrations for 4 h. To test whether the PVP-coated iron oxide nanoparticles had biocompatibility, a 5-dimethylthiazol-2-yl-2,5-diphenyl tetrazolium bromide (MTT) assay was performed. Cell viability is expressed as the mean  $\pm$  SE of percentage of absorbance of controls where 100% equals viability of untreated control cells. Although the iron concentration increased, cell viability did not decrease. Following the formation of the PVP layer on the surface of iron oxide nanoparticles, a significant increase in the biocompatibility was observed.

With the administration of 40  $\mu\text{mol}$  PVP-coated iron oxide intravenously into the rabbit, T2-weighted magnetic resonance imaging (MRI) images were observed as shown in Fig. 4.39. Samples 0.24 g of PVP-coated iron oxide nanoparticles were added to 1.4 mL distilled water and this solution was administered to rabbits weighing 4 kg. The concentration was equal to the concentration of commercially available Resovist (40  $\mu\text{mol Fe kg}^{-1}$ ). *In vitro* MRI test were performed with a 3.0 T MRI system (Philips, The Netherlands). The T2-weighted MRI images of prepared and commercial samples were observed. The sequence parameter was T2-weighted images; fast gradient echo with repetition time (TR) = 9.6 ms, echo time (TE) = 4.6 ms, flip angle = 8.0°, field of view = 10  $\times$  5 cm<sup>2</sup>. The images are T2-weighted MRI images before injection of contrast agent (left) and after injection

**Figure 4.39.** T2-weighted MRI images before injection of contrast agent (left) and after injection of PVP-coated iron oxide nanoparticles (right). (From Ref. [109].)

of PVP-coated iron oxide nanoparticles (right). This showed a profound negative enhancement of the liver after injection of PVP-coated iron oxide, indicating that the iron oxide contrast agent improved the detection of the liver lesions significantly.

#### 4.5

#### Conclusions

With the variation of core materials, various types of core-shell nanoparticles are being introduced. Although numerous studies and applications have been made using single-phased nanoparticles mainly composed of lipid, polymer or metal, there remain a number of problems to be solved. With the formation of nanoparticles with a core-shell structure, a significant improvement has been accomplished in the stability of nanoparticles, and the activity and release profile of loaded model drugs. The core-shell nanoparticles discussed in this chapter may be one of the leading examples of biocompatible polymer systems for drug delivery and molecular imaging purposes. Associated considerations may include the characterization in the *in vivo* models and retaining more appropriate physicochemical properties for practical applications in pharmaceuticals.

## 5 Nanotechnologies for Targeted Delivery of Drugs

*Pavel Brož and Patrick Hunziker*

### 5.1 Introduction

Targeting specific tissues, cell types or specific cellular targets such as membrane proteins and intracellular organelles in the body is desirable in modern medicine for improved diagnosis and treatment. Usual therapeutic concepts in somatic medicine involve either targeted mechanical changes of pathological tissues, cells or processes (e.g. cancer surgery, interventional cardiology and orthopedics), or the untargeted application of therapeutic agents (drugs) with an automated function. Both methods have their own limits, which we will highlight to create a common background of understanding that is essential for this chapter.

While modern, minimally invasive (e.g. endoscopic interventions) surgery has increased therapeutic precision and decreased the quantity of negative side-effects to healthy tissues, there still are natural limits to the morphological scale, which direct “human-controlled” (in contrast to automated or self-controlled processes) action can reach. Due to the natural limits of senses, it is most unlikely that we will be able to perform surgical operations at cellular or even subcellular dimensions without the help of nanometer-sized tools with an automated functionality.

On the other hand, medicine knows a huge stockpile of different pharmaceutical agents such as cardiovascular drugs, antibiotics and steroids, which are usually administered on an oral or intravenous route and find their desired therapeutic target (such as cancer cells, bacteria or pathologically altered tissue) on their own or with the help of cellular transport systems. This method allows reaching even subcellular targets such as specific receptors inside or outside the cell for a therapeutic purpose; however, this strategy obviously bears specific problems. Since most of the drugs are transported with the blood flow or bound to plasma proteins, they reach every part of the human body and targets other than just the desired ones. As a result, negative side-effects such as loss of hair, vomiting, diarrhea and destruction of fast growing cells in the bone marrow occur when using cytotoxic anticancer drugs. Some drugs can even lead to fatal complications during the therapeutic process. For further information about adverse drug effects [1], refer to Figs. 5.1 and 5.2.

**Figure 5.1.** Incidence of adverse drug events (data from Ref. [1]). More than 30 000 elderly patients (mean age 74.7 years, 58.7% female, mean prescription drug dispensing over 12 months 21.1!) treated at a Medicare institution were monitored for adverse drug events over a period of 12 months. Observed drug events were rated from significant to fatal. The results show the high impact of adverse drug events

on healthcare systems and on patients taking multiple drugs. Even though about one-third of the events may have been prevented by the physician, two-thirds of all adverse drug events are not preventable and have to be explained by unselective drug targeting, which influences physiologic processes other than the expected target process in a negative way.

Modern highly active drugs with strong therapeutic potency that were introduced to medicine in recent years try to overcome these problems of side-effects and unwanted interactions by reaching higher target specificity than older drugs. Examples are therapeutic monoclonal antibodies (e.g. rituximab for non-Hodgkin's

**Figure 5.2.** Frequency of types of adverse drug events (data from Ref. [1]). In the same study as in Fig. 5.1, adverse drug events were differentiated according to the type of event (organ, physiologic function). One adverse drug event may manifest itself as more than one type; the value gives the probability for an

adverse drug event to influence the mentioned organ/physiologic function. Most common events are nausea, vomiting, diarrhea, constipation, electrolyte disorders, renal malfunctioning, bleeding and allergic manifestations.

lymphoma, trastuzumab for breast cancer), which can even bear certain functionality such as (i) a radioactive isotope (e.g. tositumomab, an antibody linked with  $^{131}\text{I}$  used for treatment of non-Hodgkin's lymphoma), (ii) monoclonal antibodies for active cancer vaccination (e.g. mitumomab for small cell lung cancer) or (iii) artificially designed agents that can block certain types of intracellular proteins such as kinases (e.g. imatinib inhibits a pathological tyrosine kinase in chronic myeloid leukemia). However, even though these drugs create a much higher therapeutic potency, there are still the known problems with side-effects, even though they tend to be milder than the side-effects of standard anticancer therapy (surgery, chemotherapy and radiotherapy).

Another important area of medicine that will be changed by nanometer-sized tools is diagnostics. Diagnostics can be defined as every method that allows the doctor to assess a certain characteristic or development inside or on the surface of the human body that they cannot assess with their own sensory. This vast area ranges from common techniques such as X-ray imaging, blood cell counting, plasma analysis, drug level measurement, anatomic imagining of certain parts of the body by computed tomography (CT) or magnetic resonance imaging (MRI) and histological inspection of tissue samples to more specialized techniques such as protein assays, gene expression assays and receptor expression studies.

Common to all of these new methods is the trend to miniaturization, small sample measuring, and diagnostics at cellular and subcellular dimensions. Tools such

as microchip assays, target-specific contrast agents for imaging and small-sample diagnostics are some of the now commonly used techniques.

Clearly, nanotechnology will be able to introduce even more ground-breaking diagnostic and therapeutic methods to medicine in the years to come, which will contribute to a better detection of pathological processes and to better therapeutic options for sick people. A central problem which nanotechnology has to overcome is the difficulty of targeted delivery as described above. The idea is to increase the diagnostic signal or the therapeutic impact on the desired target with a small range of negative side-effects.

This chapter will highlight some basic problems for targeted delivery of nanometer-sized structures and will present successful targeting strategies employed by both “natural nanostructures” (such as bacteria and viruses) and “artificial nanostructures” (lipid-based such as liposomes and micelles, protein-based such as dendrimers, and polymer-based such as nanoparticles, nanospheres and nanocontainers) in areas other than cancer. The main goal of this chapter is to present different facets of the enormous field of targeted delivery, to present the main literature dealing with targeted delivery and to show the high level of interdisciplinarity. Only by combining parts of scientific disciplines such as pharmacology, microbiology, immunology, chemistry, physics and medicine will it be possible to build nanotechnological devices for targeted delivery.

The chapter is mainly suitable for physicists and chemists working in this research area and showing interest in the biomedical and pharmacological part of targeted delivery to the human body. Nonetheless, it is also written for people with a general interest in “nanomedicine” [2, 3] that share the belief that it will be possible to compose nanostructures with a complex and automated functionality for the benefit of humanity.

Section 2 describes some pharmacological basics and special pharmacological problems concerning targeted delivery of macromolecules and chemically complex carriers. In Section 3, we will discuss strategies for targeted delivery used by microorganisms such as bacteria and viruses, and by the “natural nanoparticle” prion. In Section 4, we will review targeting strategies for site-specific delivery of artificial nanotechnological carriers. In Section 5, we will sum up the main messages of the chapter and try to give an outlook into the future of targeted delivery. The reader is referred to the given references for a deeper insight into a certain topic.

## 5.2

### Basic and Special Pharmacology

#### 5.2.1

##### Outline

Pharmacology is the scientific discipline that describes and examines the effect of chemical substances on biological systems such as the human body and their use as therapeutic agents. The subspecialty of drug delivery concentrates on the development of new therapeutic systems with high target specificity, low side-effects

and controlled release of active substances with complex functionality. The toolbox of nanotechnology has revived this research area and is trying to develop new therapeutic concepts.

In this section, we will first discuss some basic characteristics of drug input and disposition that are essential for a deeper understanding of targeting strategies. In the second part of this section, we will point up specific hurdles for targeted delivery.

For more details about this topic, see Refs. [4–6].

## 5.2.2

### Basic Pharmacology

When giving a drug to the body there exist several steps the chemical substance has to go through before it can unfold its specific effect and other steps before it can be removed from the body. The most important ones are absorption, bioavailability, distribution and elimination. We will discuss these four steps to create a common basis of knowledge. Apart from this, it is obvious that the same physiological pathways and rules apply to both standard drugs and nanotechnological drug formulas, nanospheres, nanocontainers, nanoparticles, “nanobots”, etc., making it necessary for all involved researchers to understand these physiological pathways.

#### 5.2.2.1 Absorption

Absorption is the movement the drug has to perform from the administration site direct to the therapeutic site or to the systemic circulation. Absorption is determined by both physicochemical properties of the chemical substance or macromolecule and the biological construction of the administration site. Drugs are administered as solutions, tablets, capsules, aerosols or transdermal permeation systems. Usually the drug builds a complex with other ingredients (e.g. binders, surfactants, dispersants and diluents) that control the stability of the drug and its dissolution speed, and can control the release of the active ingredient. For instance, it is possible to lengthen the absorption time by creating special matrix tablets or tablets with encased granules with substance-specific release characteristics.

The drug complex can be administered by various routes such as oral, intravenous, intra-arterial, intramuscular, sublingual, inhalational, topical (eyes, skin), rectal or vaginal. Administration routes are divided into direct parenteral routes (intravenous, intra-arterial) where the drug does not have to permeate cellular barriers before reaching the circulation (the needle does the permeation) and indirect routes where the drug has to permeate through barriers in organs such as the intestine, the lung or the skin before it can reach the circulation. These barriers are mainly biologic semipermeable cell membranes (triblock hydrophilic–hydrophobic–hydrophilic with a central lipid block containing phospholipids and cholesterol) that selectively block the passage of smaller electrically charged molecules and all macromolecules. Various transmembrane proteins, receptors and transport systems are embedded into this triblock membrane, and are responsible for substance-specific uptake and cellular control. The drug or carrier of com-

plex functionality can cross this cell membrane by passive diffusion, facilitated passive diffusion, active transport or endocytosis according to its physicochemical properties.

Most drugs cross the cell membranes by simple passive diffusion according to the concentration gradient, which is directed from a site with high substance concentration to a site with low substance concentration (e.g. from the intestine to the epithelial cells or the blood vessel near the epithelial cells). Once the drug reaches the systemic circulation, it is washed away and the concentration stays low, thus ensuring a constant substance uptake. Apart from the concentration gradient and the size of the absorption surface, the transmembrane diffusion rate depends on the polarity (the unionized form has a faster permeation rate than the ionized), lipid solubility, drug size and pH of the drug molecule. Small, lipid-soluble substances have the fastest absorption rate.

For facilitated passive diffusion, the molecule (e.g. glucose) binds to substance-specific transmembrane carrier proteins on the cell surface, which speed up the diffusion by building a substance-carrier complex with a higher diffusion rate through the cell membrane without energy consumption. This method relies on a concentration gradient and is characterized by saturability because of the limited amount of carrier complexes.

On the other hand, there exist similar transmembrane proteins responsible for an active, energy-consuming transport. This method is characterized by high specificity (e.g. vitamins, amino acids), saturability and works against a concentration gradient.

Passive diffusion and active transport are limited to small molecules (the size of ions, glucose and amino acids); larger molecules, macromolecules, and micro/nanostructures such as viruses and bacteria can only reach the cell by endocytosis. To perform the endocytosis, the cell (mostly specialized cell types of the immune system such as granulocytes and macrophages) has to engulf the structure, enclose it into a cell membrane-derived vesicle and transport it into the cell interior. There the vesicle is transformed into a so-called lysosome. A major problem of this transport method is the intracellular degradation of the vesicle content by low pH (down to 2–3) and cellular enzymes such as phosphatases, lipases, esterases, proteases, etc., which the cell delivers into the endocytosis vesicle. This method is energy consuming, saturable and needs a ligand-receptor interaction.

Most drugs are administered orally and reach the circulation by crossing the diverse epithelial cell barriers found in the gastrointestinal system, mainly using passive diffusion and scarcely active transport (e.g. L-DOPA – a dopamine-derived drug for Parkinson's disease). Small and lipophilic molecules can use the short contact time inside the mouth to cross the epithelial cells of the buccal or sublingual area and enter the circulation rapidly. An example is nitroglycerin – a drug that dilates the coronary arteries in the case of a myocardial infarction.

Even though the next station in the way of the drug, the stomach, has a larger epithelial surface, almost no drugs enter the circulation here. Reasons are the thick mucous layer protecting the stomach from self-digestion and the usually fast passage time in the stomach. Apart from this, the stomach creates some important

problems to drug therapy because of the acidic (pH 1–2) environment and the digestive enzyme pepsin (a protease produced in the stomach wall). Some drugs can be degraded in such an environment (e.g. penicillin), especially when fatty foods or slow stomach emptying slow down the passage time. It is possible to overcome this problem by building gastric acid-resistant capsules and drug formulas when giving an instable drug orally.

Most orally applied drugs are absorbed in the small intestine (especially duodenum and proximal jejunum) over less than 6 h under normal circumstances. Special controlled-release formulations show a slower absorption kinetic and may reach the large intestine, where they can also be absorbed or may be subject to microbial degradation.

When giving a drug in a parenteral way, the substance is directly placed into the circulation (intravenous, intra-arterial) or injected into soft tissues such as the skin or muscles without having to cross the epithelial barriers. These methods are especially suitable for larger and complex molecules such as proteins, and for complex chemical structures such as liposomes or nanoparticles, because here they do not face any problems with degradation and inactivation compared with the intestine. Injections into the fat of the skin (subcutaneous) or into the muscle (intramuscular) are especially suitable for everyday applications of drugs such as insulin for diabetes or low-molecular-weight heparin for perioperative anticoagulation. The patient can perform these injections without facing serious complications such as blood infections and thrombosis when injecting substances into blood vessels. Due to passive diffusion into the porous small capillaries of these soft tissues, proteins up to a molecular weight of 20 kDa face fast and constant absorption, mostly depending on the quantity of capillaries and the perfusion speed. Larger molecules show unstable absorption, since their absorption occurs by the lymphatic system, where they also face contact with degrading enzymes and cells of the immune system such as macrophages that take up all macromolecules and produce an immune reaction (inflammation, allergic reaction) against this substance. On the other hand, parenteral injection of large molecules or rather insoluble drug formulas can be used for controlled release over a large-scale period (e.g. penicillin G benzathine or insulin in crystalline suspensions).

Drugs with a short circulation half-time have to be administered in a controlled-release form to guarantee a stable plasma concentration and persistent therapeutic effect. The best way to achieve this is to apply an intravenous catheter and to infuse the drug constantly. For long-term applications, it is necessary to change the strategy because of complications such as catheter infections, thrombosis and reduced convenience. For oral administration, the drug particles can be coated with wax or other water-soluble material such as biodegradable polymers, or can be embedded into a slow-release matrix. Another administration method is transdermal controlled-release systems consisting of drug-impregnated polymer materials with permeable membranes bonded to an adhesive bandage. These systems provide constant drug release into the skin for 12–24 h, but are restricted to smaller lipophilic molecules that can permeate the skin barrier (e.g. nitroglycerin, opiates).

### 5.2.2.2 Bioavailability

Bioavailability is the extent and the rate at which the active drug enters the systemic circulation, and is mostly determined by its physicochemical properties and the dosage form (as seen above). Different drug formulations result in different bioavailability and can have clinical significance in the terms of therapeutic effect and toxicity. The bioavailability is also determined by physiologic characteristics of the patient, mainly the gut perfusion rate and the metabolic liver function, or on a smaller scale by sex, genetic phenotype, stress, disease or previous gastrointestinal surgery.

When giving a drug parentally, the bioavailability is, by definition, 1 since all the active formula reaches the systemic circulation. On the other hand, the bioavailability of orally administered drugs is never 1, because the drug has to move down the gastrointestinal tract, has to cross the epithelial barriers of the intestine and has to pass through the metabolically active liver before it can reach the systemic circulation. This primary metabolic degradation and inactivation of the drug is called first-pass metabolism or the first-pass effect. A high first-pass effect results in a low or even zero oral bioavailability (e.g. most protein-based drugs such as insulin and complex molecules such as heparin or testosterone). Some drugs have a high oral bioavailability even though they undergo an extensive chemical change resulting in therapeutically active metabolites – this is called metabolic activation of therapeutically inactive prodrugs (e.g. the antihypertensive drug enalapril, the antiviral drug valaciclovir or heroin).

Physicochemical properties resulting in a low bioavailability are poor water solubility, slow or incomplete absorption during the passage through the gastrointestinal tract (total 1–2 days, but only 2–4 h in the small intestine) and molecule-specific chemical reactivity. Examples for molecule-specific chemical reactivity are (i) complex formation (e.g. the antibiotic tetracycline and polyvalent metal ions), (ii) conjugation in the intestinal epithelium (e.g. sulfoconjugation of the bronchodilative drug isoproterenol), (iii) hydrolysis by gastric acid (e.g. penicillin), (iv) adsorption to other drugs (e.g. the heart drug digoxin and the bile acid binder cholestyramine) or (v) metabolism by luminal bacterial microflora (normally only in the large intestine, under pathological circumstances even in the small intestine).

To assess the overall bioavailability, one has to take repetitive blood samples, and measure the time (called peak time) and the amount of the peak drug concentration in the plasma (here the drug absorption rate equals the elimination rate), and the so-called area under the plasma concentration–time curve (AUC). A higher absorption rate results in an earlier peak time and higher peak concentration; a slower absorption results in a later peak time. Parentally administered drugs have an early peak time, because the whole dose reaches the systemic circulation in a short time. The AUC is direct proportional to the total amount of drug that reaches the systemic circulation and usually allows the most reliable characterization of the bioavailability.

To increase the overall plasma concentration of the drug, it is possible to give multiple doses of the drug formulation before the entire previous dose is eliminated from the circulation. With fixed-dosing intervals, the drug concentration in-

creases for four to five plasma elimination half-lives (see the following sections for details) before reaching the steady state, where absorption and elimination are equal. Depending on the half-lives of the drug, the dosing interval can vary from some hours to some days.

### 5.2.2.3 Distribution

After entering the systemic circulation, a drug is delivered to all parts of the body through the bloodstream. Nonetheless the distribution is uneven because of differences in (i) blood flow (e.g. the eye or the kidney have much higher mean perfusion per volume than muscles or the connective tissue), (ii) tissue binding (e.g. lipophilic drugs bind to fatty tissue), (iii) regional pH and (iv) permeability of endothelial membranes of the blood vessels (e.g. very low permeability in the brain and high permeability in liver, spleen and kidney). All of these factors define the organ-specific distribution equilibrium, defined as the time-point when entry rates to the tissue and exit rates from the tissue are the same, and drug concentrations outside and inside the blood vessels are the same (plasma concentration = effective tissue concentration). Richly vascularized areas with high vessel permeability for a specific drug reach the equilibrium more rapidly than poorly vascularized areas with a low permeability, thus making it complex to assess the organ-specific concentrations when researching the borders for therapeutic and toxic effects.

To describe the distribution characteristics of a certain drug, one can use the idea of the apparent volume of distribution, defined as the fluid volume needed to contain the drug in the body at the same concentration as in the plasma. Clearly, a certain quantity of a drug with a high apparent volume of distribution (e.g. the anti-arrhythmic drug amiodarone) results in a much lower overall plasma concentration than a drug with a low apparent volume of distribution (e.g. heparin), since the same amount of drug molecules reach a higher fluid volume (e.g. the blood covers roughly 3–4 L and the whole extracellular fluid covers about 17 L). Apart from the fluid volume, other factors such as fat tissue binding, protein binding and pH of the drug influence the apparent volume of distribution, resulting in volumes up to 500 L for fat binding, mostly basic drugs such as digoxin or amiodarone. Acidic drugs such as salicylic acid and warfarin have smaller volumes of distribution than basic drugs such as amphetamine because of their preferential protein binding (the body has much more fat than free proteins for binding).

In the bloodstream, common drugs are transported either or both as unbound, free drug or bound to different blood components such as plasma proteins (mostly albumin for acidic drugs and different glyco/lipoproteins for basic drugs) and blood cells (mostly red blood cells). Differences in blood component concentrations and compositions result in unstable plasma concentrations of the given drugs, possibly decreasing the therapeutic effect or increasing toxicity.

To reach the desired “place of action”, the drug has to leave the systemic circulation (similar mechanisms to transcellular passage as described in Section 5.2.2.1) and for most drugs this is only possible for the unbound, free fraction. To assess the possible speed of vessel permeation, it is necessary to know the fraction unbound (defined as the ratio of unbound to total concentration) apart from

physicochemical properties of the drug (size, polarity, pH, hydration, chemical functionality) and the endothelial layer of the blood vessel (permeability, transport mechanisms). The fraction unbound usually has a better correlation to the effective pharmacological activity than the overall plasma concentration (both free and bound fraction). At low drug concentrations, not all the available plasma proteins or cells are bound to the drugs; increasing the drug concentration (higher single dose or shorter dosing interval) leaves the fraction unbound unchanged up to a certain upper limit where all the possible binding sites are saturated. By increasing the drug concentration above the saturation limit, the fraction unbound can be raised, thus increasing both possible therapeutic effect in the tissues and possible toxicity and interaction opportunity (e.g. with other drugs or physiological substances in the bloodstream, possibly creating unexpected side-effects).

An important idea when considering the drug effect is the drug reservoir. Clearly, tissues with a fast distribution equilibrium and high drug binding capacity (e.g. bone marrow, fat tissue) can accumulate high amounts of drug molecules before the desired drug target reaches a sufficient drug concentration for the therapeutic effect. Since the plasma and the tissue concentration are at equilibrium, the drug reservoir releases the drug when the plasma concentration decreases because of elimination mechanisms. Therefore, the drug reservoir is both responsible for lower peak concentration and slower concentration decrease, resulting in the same AUC than without a drug reservoir.

Some drugs such as antimalarial drugs, some antibiotics and cytotoxic drugs accumulate inside specific cell types because of substance-specific transport mechanisms, and binding to intracellular components such as proteins, phospholipids or nucleic acids. Thus, the drug concentration is much higher inside the cells (mostly white blood cells such as macrophages, granulocytes and liver cells, but also bacteria) than in the surrounding tissue and in the plasma. Similar to drug reservoirs in the tissue, the intracellular drug is in equilibrium with the plasma and leaves the cell, unless it binds to a certain target or performs a certain chemical reaction.

#### 5.2.2.4 Elimination

Elimination is the sum of processes of drug loss from the body, mainly metabolism (chemical alteration) and excretion (elimination without further chemical change).

Metabolism is mostly performed in the hepatocytes (main liver cell type) of the liver – different reaction pathways result in pharmacologically inactive or active metabolites. Drug metabolism pathways usually occur in two apparent phases: phase I and phase II. Phase I reactions involve forming a new or changed functional group or a cleavage (oxidation, reduction, hydrolysis) to ensure a higher rate of reactivity. Phase II reactions involve conjugation with an endogenous compound such as glucuronic acid, glycine or sulfate to ensure higher water solubility. The metabolites of these processes have a higher polarity and are excreted through the kidneys (urine) or the liver (bile) at a much higher rate than the original drug molecule.

The most important enzyme system of phase I metabolism is a microsomal family of isoenzymes called cytochrome P450, which can transfer electrons supplied by certain flavoproteins (NADPH-cytochrome P450 reductase) to catalyze drug oxidation. The cytochrome P450 superfamily is grouped into 14 families with gene sequence identity and 17 subfamilies. The isoenzymes are named by a root symbol CYP, followed by a number/letter combination. The most important CYP isoenzymes for drug metabolism are CYP1A2, CYP2C9, CYP2C19, CYP2D6 and CYP3A4. Every one of these isoenzymes is specific for different drugs and can be upregulated by repetitive drug application of so-called CYP-inductive drugs (e.g. glucocorticoids, rifampicin, carbamazepine, barbiturates, St John's wort, efavirenz, etc.) and downregulated by so-called CYP-inhibiting drugs (e.g. amiodarone, paroxetine, fluconazole, ketoconazole, ciprofloxacin, clarithromycin, ritonavir, grapefruit juice, etc.).

The most important phase II reaction is glucuronidation (conjugation to glucuronic acid), which occurs in the liver microsomal enzyme system (microsomes are intracellular organelles) and results in hydrophilic metabolites suitable for renal or biliary excretion (e.g. morphine, fluoroquinolone or chloramphenicol). Other important reactions are (i) amino acid conjugations with glutamine or glycine (e.g. salicylic acid), (ii) acetylation (e.g. sulfonamides, hydralazine), (iii) methylation (e.g. catecholamines, thiouracil, niacinamide), or (iv) sulfoconjugation of phenolic or alcoholic groups with inorganic sulfate gained from sulfur-containing amino acids such as cysteine (e.g. methyl dopa, thyroxine, acetaminophen, estradiol).

All metabolic pathways show different activities according to (i) the genetic background (most important are genetic variations in the CYP2C9 cytochrome P450, resulting in different metabolic activities for certain drugs), (ii) age (newborns and elderly patients show low metabolic activity), (iii) sex, (iv) history of liver diseases, (v) capacity of the enzyme (mostly upper limit of capacity) and (vi) up- or down-regulating endogenous or exogenous substances. Due to these individual variations in drug metabolism, it is difficult to predict the therapeutic effect of a given dose of a drug, especially when the patient is taking other drugs, drinking alcohol or smoking.

The excretion of the now hydrophilic drug metabolite or the original hydrophilic, unmetabolized drug mostly takes place in the kidneys; a smaller degree of the incorporated drug can be excreted through the biliary system (bile is produced in the liver and flows into the small intestine), saliva, sweat, breast milk and lungs (volatile substances such as anesthetics).

Kidney excretion is a complex process that can be separated into glomerular filtration, tubular reabsorption and tubular secretion. The central unit of the kidney is the so-called nephron consisting of a well-perfused capillary conglomerate called glomerulus and the tubular system that follows the glomerulus. In the glomerulus, plasma is filtered through pores in the glomerular endothelium according to (i) the pressure in the afferent and efferent arterioles, (ii) the perfusion speed, (iii) the filter permeability, (iv) the size and ionization of the molecule (maximum filterable size is 10–15 nm [7]; cationic molecules have higher permeability than anionic molecules because of the anionic charge of the glomerulus), and (v) the pressure

in the tubular system. Only unbound drugs up to certain size and ionization can be filtered through the glomerular endothelium, protein-bound drugs cannot be filtered. Most of the filtered ions (such as sodium, chloride, potassium, magnesium, calcium and bicarbonate), all glucose, amino acids, urea and other important substances are reabsorbed by specialized and substance-specific transport systems (active transport systems for glucose, amino acids and some ions; passive diffusion for most ions and water). Filtered drugs can also be reabsorbed if they show molecular closeness with endogenous physiologic substances (e.g. the antidepressant lithium is analogous to sodium). Unionized forms of nonpolar weak acids and weak bases are reabsorbed readily from the tubular filtrate, so acidification of urine increases the reabsorption of filtrated acidic drugs and decreases the reabsorption of basic drugs and *vice versa*.

Another excretion mechanism is the active, energy-dependent tubular secretion process in the proximal part of the tubule, typically used to remove drugs such as penicillin, salicylic acid, procainamide, dopamine, phenylbutazone and trimethoprim. It is possible to distinguish two separate transport mechanisms for anions and cations with a characteristic maximum of secretion. The anion secretory system is more important for drug elimination and transports metabolites conjugated with glycine, sulfate or glucuronic acid (conjugation done by phase II metabolism in the liver) into the tubular system. Due to the saturability of every active transport mechanism, anionic compounds compete with one another for secretion resulting in slower elimination times (e.g. penicillin elimination can be decreased by the therapeutically inactive molecule probenecid to increase therapeutic plasma concentrations of penicillin).

Some drugs can be removed by active biliary excretion (done by hepatocytes) across the biliary epithelium in the liver. This excretion mechanism is especially suitable for larger, lipophilic drugs conjugated with glucuronic acid. Once the excreted drug reaches the small intestine, it is treated in the same way as a drug coming from the stomach, resulting in an absorption by the intestinal epithelium, especially after enzymatic degradation of the “new” functional group (glucuronic acid). This is the enterohepatic cycle.

When assessing the overall rate of elimination, it is necessary to measure the concentrations of both unchanged drugs and possible metabolites in the main excretion routes (urine, bile, milk, saliva, sweat) over a certain time, and to compare these concentrations to the plasma concentrations. The parameter relating total elimination rate to plasma concentration is called total clearance (renal plus extrarenal clearance). The fraction of excreted unchanged drug helps to find out the impact of renal and extrarenal (mainly hepatic) elimination, since the unchanged drug can only be found in the urine and hepatic elimination is only possible for metabolites. A low fraction of unchanged drug shows that hepatic elimination is strongest and that hepatic disease may therefore affect drug elimination. The same applies to drugs with a high fraction of unchanged drug and renal diseases.

Another important assessment value is half-life elimination, defined as the time needed for the plasma drug concentration or the amount of drug in the body to

decrease by 50%. This time is usually independent of plasma drug concentration, characterizes both distribution and elimination of the drug, and determines the dosing intervals and time to reach steady state.

### 5.2.3

#### **Special Pharmacology**

Here, we will discuss the key factors found in nature that protect the internal environment from external “macroelements” (bacteria, viruses, proteins, DNA, nanovectors such as liposomes, nanoparticles, nanospheres and nanocontainers). It is important to understand the concept of these defense mechanisms when trying to overcome the challenges and develop a targeting system for site-specific delivery of drugs or diagnostic agents with a minimal negative impact on physiologic pathways. Successful strategies to overcome the defensive obstacles performed by both pathogenic organisms such as bacteria and viruses and therapeutic systems will be presented. For a deeper insight into the immune system and other defense mechanisms, refer to the specialized literature listed in the reference section.

##### **5.2.3.1 Skin Epithelium**

The outermost layer of our body consists of multiple layers of squamous epithelial cells, together building the stratum corneum of the epidermis [8]. The stratum corneum can be considered as a two-compartment system consisting of the epithelial cells themselves and the surrounding extracellular matrix. The cells produce and secrete various proteins (e.g. linking proteins for cell–cell adhesion), lipids (e.g. phospholipids, cholesterol, ceramides, sphingomyelin) and enzymes (e.g. lipases, proteases and antiproteases). This two-compartment system of lipid-depleted squamous cells and lipid-enriched, extracellular matrix ensures both physical and chemical protection, preferably against ultraviolet light, chemicals, physical force, temperature, bacteria and viruses, but also against the permeation of macrostructures such as nanovectors.

Nonetheless, the skin can be useful for therapeutic purposes, as transdermal permeation systems for morphine, nitroglycerin or female steroid hormones prove. Factors such as site of application, thickness and integrity of the stratum corneum, size, polarity and pH of the molecule, skin hydration, drug metabolism by bacterial skin flora, and change of blood flow in the skin by additives and body temperature influence the rate of transdermal drug absorption [9, 10].

Small, lipo- or amphiphilic molecules can permeate the complex skin barrier. Permeation is also possible for lipid-based nanostructures such as liposomes up to a diameter of 500 nm [10, 11]; permeation of polymer-based nanostructures is more difficult because of their hydrophilic surface. Once the drug has permeated across the epidermis, it reaches a well-perfused subepidermal layer where it can enter blood vessels through pores in the vessel wall. An intact skin barrier protects the organism from pathogenic microstructures such as bacteria and most viruses; the same applies to nanoparticles bigger than the mentioned 500 nm.

### 5.2.3.2 Mucosal Epithelium of the Respiratory Tract

The airways can be divided into the upper respiratory tract (nose, mouth, throat and larynx) and the lower respiratory tract (trachea, bronchi and terminal respiratory alveoli). Multilayered squamous epithelium consisting of epithelial cells and special cell types producing mucus and immunoglobulins covers the upper respiratory tract. The physicochemical characteristics of this squamous epithelium are comparable to the skin. Nonetheless, the permeability is much higher because of the absence of a stratum corneum and a strong perfusion with well-permeable blood vessels, making it possible to absorb small, mostly lipophilic drugs such as nitroglycerin, cocaine and steroids at a high rate.

The lower respiratory tract has to be subdivided into the trachea and bronchi with their respiratory epithelium, and the alveoli with their single-layered alveolar epithelium. The respiratory epithelium consists of ciliated epithelial cells and mucus-producing cells, together building a single-layered barrier connected by tight cell-cell adhesion complexes called tight junctions or zonulae occludentes [12].

Drug application to the lower respiratory tract [9] is possible by inhalation of vaporized, nebulized, powdered or aerosolized drugs (e.g.  $\beta_2$ -agonists, corticosteroids, and anticholinergics for asthma and chronic obstructive pulmonary disease therapy, or antibiotics for to treat children with cystic fibrosis). Access to distal airways depends on the particle size, because particles bigger than 4  $\mu\text{m}$  diameter deposit on the epithelium of the upper respiratory tract, and particles smaller than 500 nm diameter fail to deposit on the epithelium and are exhaled. Only particles with a diameter between 0.5 and 4  $\mu\text{m}$  can reach the distal airways and deposit on the epithelium of the bronchi. Once the drug molecule or drug carrier is deposited, it can permeate across the respiratory epithelium (lipophilic drugs better than hydrophilic) and can reach the systemic circulation.

### 5.2.3.3 Mucosal Epithelium of the Gastrointestinal Tract

The gastrointestinal tract consists of the esophagus, stomach, small intestine and large intestine. Because of the short passage time and the impermeable epithelial barrier in the esophagus and especially in the stomach (low pH, dense mucus layer, and strong intercellular bonds between the epithelial cells), the upper parts of the gastrointestinal tract play no role in absorbing macromolecules and microstructures such as bacteria, viruses or nanoparticles.

The small intestine is the longest section of the gastrointestinal tract, lies between the stomach and the large intestine, and has an overall length of 6 m. The small intestine with its large mucosal surface (250  $\text{m}^2$  because of mucosal folds, mucosal extensions called villi and epithelial cell membrane extensions called microvilli) and epithelial cell (also called enterocytes) lining is responsible for the enzymatic digestion and absorption of small nutritives such as monosaccharides, oligonucleotides, amino acids, fatty acids, vitamins and lipids, and macromolecules such as epidermal growth factor. Dense tight junctions join the enterocytes [13] and build a continuous layer with other cell types that are responsible for other tasks. (i) Enteroendocrine cells sense the luminal environment and can secrete peptide hormones [14] into the blood that influence the digestive process. (ii) Gob-

**Figure 5.3.** Schematic drawing of small intestine epithelium (for details refer to main text).

let cells produce peptides needed for epithelial growth and repair, and lubricating mucus consisting of glycoproteins that covers the mucosal surface, reduces the diffusion of macromolecules, and binds proteins and microorganisms. (iii) Paneth cells secrete antimicrobial digestive enzymes such as cryptidins or defensins. (iv) Finally, the M cells are phagocytic cells that control the luminal microbial environment and can trigger an immune response in the presence of harmful pathogens (see Fig. 5.3).

The epithelium is exposed to a wide variety of potentially harmful bacteria, viruses and other microorganisms that should not be able to permeate the epithelial layer [15]. It is obvious the epithelial cells had to develop sophisticated and specific receptors, transport systems and strong defense systems [16, 17] to cover all necessary functions such as digestion and absorption of all essential nutritives, endocrine functions, and immunologic and mechanical barrier for microorganisms and potentially harmful macromolecules.

The apical surface of the enterocytes is covered by closely placed microvilli (diameter 100 nm, intervillous space is variable and can decrease down to 25 nm) with a filamentous brush border glycocalyx (500 nm thick) consisting of negatively charged mucin-like glycoproteins and enzymes, responsible for terminal digestion of polysaccharides and polypeptides. Apart from this, the glycocalyx is another diffusion barrier that prevents macromolecular particles, bacteria and viruses from direct contact with the enterocyte cell membrane. Microstructures that want to enter the enterocytes have to move into the space between the microvilli or have to produce toxins or inflammatory agents that disrupt the microvilli continuity, thus allowing direct contact with the uncovered enterocytes surface.

Enterocytes take up luminal molecules by different methods. Small nutrient molecules such as glucose, amino acids and ions reach the cell through substance-specific epithelial transporters; larger molecules reach the cell by the receptor-mediated [18, 19], energy-dependent process of pinocytosis (for details,

see Section 5.2.3.6). Once the molecules have entered the enterocytes, they can enter different pathways. The first pathway leads to enzymatic degradation in lysosomes, the second pathway leads to transcytotic transport of the intact vesicle content and active release into the subepithelial space, where the molecules can reach the systemic circulation or the lymphatic vessels.

Another pathway for epithelium crossing is the paracellular transport that is only possible under pathological conditions, because normally the intercellular tight junctions block the permeation of large molecules and micro- and nanometer sized structures. Physiologically, the tight junctions can dilate up to a pore radius of 5 nm on activation of certain cellular  $\text{Na}^+$ -coupled transport systems, enabling a transjunctional osmotic flow for nutrients. Pathological insults such as inflammatory cytokines [e.g. interferon (IFN)- $\gamma$ , tumor necrosis factor (TNF)- $\alpha$ , interleukin (IL)-1 $\beta$ , IL-4 and IL-13], mechanical damage, infection, bacterial toxins (e.g. cholera toxin) and cell death can open these pores enough to allow the passage of macromolecules or nano/microstructures [15, 20, 21].

#### 5.2.3.4 Mononuclear Phagocyte System (MPS)

Once the drug molecule or drug complex reaches the systemic circulation – be it direct by intravenous or intra-arterial injection or indirect by other application ways – it comes in contact with various metabolic pathways and defensive systems. When discussing the possibility of targeted delivery of nanometer-sized structures (lipid-based such as liposomes and micelles, protein-based such as dendrimers, and polymer-based such as nanospheres, nanoparticles and nanocontainers), the most important hurdle is the MPS [22, 23] [also known as reticuloendothelial system (RES)] – a part of the innate immune system. The MPS consists of bone marrow (pro-) monoblasts, peripheral monocytes and monocyte-derived tissue macrophages in liver (called Kupffer cells), lungs, spleen, lymph nodes, thymus, gut, bone marrow and brain (called microglia). The MPS plays a major role in host defense, and is responsible for clearing unwanted and possibly pathogenic organisms (bacteria, fungi, protozoa, parasites, viruses) and macromolecules such as lipoproteins, polysaccharides, polynucleotides and nanoparticles. Macrophages can also be attracted to an infected focus by various chemotactic substances (bacterial endotoxins, immune complexes, complements factors, collagen fragments), where they phagocytose infectious agents. Apart from this, the cells of the MPS play an important role in the development of pathological conditions such as cancer, atherosclerosis, autoimmune diseases (rheumatoid arthritis, Crohn's disease, systemic lupus erythematosus, multiple sclerosis), diseases of the central nervous system and some infectious diseases (HIV, tuberculosis, leishmaniasis, salmonellosis, schistosomiasis).

When injecting macromolecular formulas such as liposomes, immunoliposomes, polymeric micro/nanospheres and nanoparticles into the circulation, the MPS clears the substances rapidly from the bloodstream, mainly in the well-perfused, macrophage-rich organs liver and spleen. For phagocytosis, the macrophages contact the particles with receptor-equipped pseudopods, attach the particle to the cell membrane and engulf them with lamellipods. After entering the macro-

**Figure 5.4.** Schematic drawing showing the principles of receptor-mediated endocytosis: (1) shows the process of pinocytosis as described in the main text; (2)–(4) show the different pathways that lead to the receptor-mediated endocytosis of various ligands, in this case bacteria. (2) The binding of native, unchanged bacteria to “unspecific” receptors (e.g. scavenger receptors, mannose receptors, TLRs) found on phagocytic cell types (macrophages, dendritic cells). (3) The binding

of complement factor-labeled bacteria to the C3 receptor, which binds the activated complement factor 3. (4) The binding of antibody-labeled bacteria to the Fc receptor, which binds a subunit of immunoglobulins. The final steps in the case of receptor-mediated endocytosis consist of the development of the early and mature lysosome with various degrading systems as described in the main text.

phage by membrane–membrane fusion or receptor-mediated endocytosis, the microstructures are subject to aggressive enzymatic (proteases, esterases, glucuronidases, phosphatases, nucleases, lipases, etc.) and nonenzymatic (free radicals, acid) degradation inside specialized, low pH (down to pH 1–2) intracellular vesicles called lysosomes (Fig. 5.4). Most of the macrostructure material gets degraded down to its chemical constituents, but some remaining protein fragments can be used by the cells to create immunogenic antigen fragments for lymphocyte presentation on class I or II major histocompatibility complex (MHC) molecules. (The MHC is a transmembrane multiprotein construct for antigen-presentation to cells of the immune system such as T lymphocytes, which are able to create a spe-

cific, antibody-mediated immune response against the presented antigen.) The range of such an immune response reaches from a fast elimination of newly injected micro/nanostructures up to a possibly fatal anaphylactic (allergic) shock. Apart from the obvious loss of material and targeting efficiency, the possible immune response is the main reason why nanostructures for targeted delivery have to be protected from fast uptake into the MPS.

The most important condition for rapid uptake into the MPS [23] is the process of opsonization, defined as the deposition of blood opsonic factors (e.g. fibronectin, immunoglobulins and complement proteins) on the surface of bacteria, viruses, and nanostructures such as liposomes, micelles, nanoparticles, nanocontainers and dendrimers. Once the structures have been labeled by opsonization, the macrophages recognize them with their specialized surface receptors (scavenger receptors, Toll-like receptors (TLRs), Fc receptors, complement receptors, mannose receptors, fibronectin receptors, etc.) and take them up by receptor-mediated endocytosis. Size and surface characteristics of the nanostructures define the opsonization efficiency, the macrostructure–macrophage interaction and thus the clearance kinetics. For instance, smaller polymer-based nanoparticles (below 200 nm diameter) show longer circulation lifetimes than larger ones, but smaller lipid-based nanoparticles show shorter circulation lifetimes than bigger particles [24]. Particles with many available functional groups and stronger polarity also show shorter circulation lifetimes. Lipid-based nanostructures such as liposomes show much shorter circulation life-times than polymer-based nanostructures because of (i) lower physicochemical stability (higher leakage rates in bloodstream turbulences), (ii) better opsonization efficiency, (iii) opsonization-independent receptor interaction of liposome compositions containing phosphatidylserine, phosphatidylglycerol or phosphatidylcholine (all ligands for certain types of macrophage receptors) and (iv) easier uptake into the macrophages because of chemical likeness with the cellular membrane (also based on phospholipids). This allows the macrophages to take up the liposomes by direct membrane-membrane fusion instead of receptor-mediated endocytosis.

Special low-protein absorbing polymeric surfaces such as poly(ethylene glycol) (PEG), poly[*N*-(2-hydroxypropyl)methacrylamide], distearyl phosphotidyl ethanolamine (DSPE) or poly(2-methyl-oxazoline) (PMOXA) can prolong the circulation lifetime of both liposomes and polymer-based nanoparticles by decreasing the grade of opsonization, making it possible to reach the desired therapeutic target before being removed from the circulation. Nanoparticles with these specialized surfaces are referred to as “stealth” particles [24], since they “hide” themselves from the MPS [25].

#### 5.2.3.5 Endothelial Barrier

The endothelial cells cover the interior surface of all blood vessels, and build an important barrier between the blood components and the tissues. The endothelium actively controls the exchange between these two compartments and shows a high grade of impermeability in most tissues. Only a limited number of small molecules such as oxygen, carbon dioxide and water, and small lipophilic molecules

diffuse passively across or along the endothelial membrane according to the concentration gradient. For some macromolecules such as glucose and amino acids, the endothelial cells have active transport mechanisms to ensure a sufficient flow of supplies for the underlying organs. Macromolecules can only leave the circulation through so-called endothelial fenestrations, principally holes between the endothelial cells, and across endothelial clefts at the cell–cell junctions. Organs such as the liver, lymph nodes or the spleen show a well-developed endothelial fenestration with an easily permeable endothelial layer. On the other hand, organs such as the testis, the brain or the spinal cord have a dense endothelial barrier with a small permeability for most drugs and all hydrophilic substances. The specialized endothelium of the brain is called the blood–brain barrier and has no fenestrations.

An important characteristic of the endothelial layer is the increase of permeability under certain pathological conditions, known as vascular leakage [26, 27]. For instance, vascular leakage is a complication that can worsen a systemic inflammatory reaction in the case of a severe bacterial infection, and leads to excessive plasma extravasation into the lung, the skin and the abdomen when plasma proteins can leave the blood vessels through enlarged endothelial fenestrations. On the other hand, it allows the white blood cells to leave the circulation in much higher numbers than under physiological conditions, and increases the oxygen and nutrients supply for the tissue. Vascular leakage is also an early step in the development of atherosclerosis, where lipoproteins leave the circulation and gather inside the inner layers of the blood vessels. Some tumors have leaky vessels, making it easier for the tumor cells to reach the systemic circulation.

On the topic of site-specific drug delivery with nanotechnological delivery systems, it is important to consider the physicochemical properties of the endothelial barrier in different tissues and under different states according to the target, size, surface and functionalization of the carrier. For instance, it is almost impossible for “normal” nanoparticles to permeate through the intact blood–brain barrier; on the other hand, the vessels of aggressive brain tumors are leaky, making it possible to reach the tumor cells with nanoparticles. Another interesting target for delivery of nanoparticles is the so-called vulnerable plaque, defined as an inflamed atherosclerotic lesion of the blood vessel wall with a thin fibrous cap covering an amorphous mass of cell detritus, cholesterol, lipoproteins and collagen. A breakup of this instable system [28, 29] leads to the formation of blood clots and may stop the blood flow in the diseased vessel, resulting in potentially fatal diseases such as myocardial infarction, stroke, skin ulcers, etc. The endothelial layer on the vulnerable plaques is known to be leaky, making it possible for nanoparticles to reach the inflamed fibrous cap and influence the diseased state.

#### 5.2.3.6 Cell Membrane

The passage across the cell membrane is the last and possibly the most difficult hurdle for targeted delivery of macromolecules because of the complex nature of the membrane, and the variety of different receptors, channel proteins, cell surface functionalizations and transport systems [30, 31]. The membrane consists mainly of phospholipids, cholesterol and proteins building a hydrophilic–hydrophobic–

hydrophilic triblock bilayer membrane stabilized by structure proteins and intercellular connections. Integrated into the bilayer membrane are different transmembrane and nontransmembrane proteins with functions such as ion channels, glucose and amino acid transporters, receptors for ligands, cell communication receptors, cell–cell adhesion, etc.

Small, nonpolar molecules such as oxygen, carbon dioxide or nitrogen dissolve in the lipid bilayer and diffuse passively into the cell according to the concentration gradient. The same applies to small, noncharged molecules such as water or ethanol. Bigger molecules (e.g. glucose, amino acids or urea) and all charged molecules (e.g. sodium, potassium, chlorine or magnesium) have only a limited possibility of passive transmembrane diffusion, making it necessary for the cell to set up transport systems for essential molecules (as described in previous subsections).

When discussing the delivery of macromolecules such as nanoparticles into the cells, one has to be aware that most cells are not intended to take up macromolecules and the nanoparticles have to use transport systems with a different purpose than “nanovehicle transport”.

The first step in the transmembrane transport of macromolecules is the binding of a ligand to a specific cell surface receptor. Some receptors answer the ligand binding with a complex process called endocytosis that can be divided into phagocytosis and pinocytosis (Fig. 5.4). Phagocytosis means the uptake of micrometer-sized structures such as bacteria and fungi, which can only be done by specialized phagocytic cell types of the innate immune system such as macrophages, granulocytes, and dendritic cells. These cell types have special cell surface receptors such as (i) Fc receptors (for immunoglobulins bound to bacteria), (ii) complement receptors (for proteins of the complement system, which plays a major role in inflammation, immune defense and tumor cell killing), (iii) scavenger receptors [32–36] (for polyanionic molecules such as lipoproteins, polysaccharides and polynucleotides) and (iv) mannose receptors [37] (for mannosylated/*N*-acetylglucosamine-terminal and fucosylated glycoproteins) that stimulate phagocytosis of the mentioned macromolecules. Pinocytosis is possible for all other cell types and is restricted to nanometer-sized structures such as viruses, proteins, lipoproteins, transferrin, cholesterol, etc.

On a molecular level, pinocytosis occurs on different, energy-consuming pathways, e.g. clathrin-mediated, caveolin-mediated, or clathrin- and caveolin-independent. Clathrin-mediated endocytosis is the most important entry pathway for macromolecules in cell types other than phagocytes and is triggered by ligand–receptor binding. It starts with the binding of the protein clathrin to the intracellular part of the transmembrane receptor, followed by the creation of small cell membrane pits. Then the cell membrane pits with the ligand–receptor complexes are dragged into the cell by the cytoskeleton and form enclosed, clathrin-coated vesicles that finally lose the contact with the cell membrane. Once the vesicle is created, it starts to “uncoat” the clathrin coating, allowing the fusion with other intracellular compartments such as lysosomes for degradation and receptor recycling (Fig. 5.5).

**Figure 5.5.** Schematic drawing of clathrin-mediated endocytosis (for details refer to main text).

During the process of phagocytosis, the phagocytic cell launches a signaling cascade that results in the formation of cell membrane protrusions that surround the pathogen and engulf it into so-called phagosomes, comparable to giant intracellular vesicles. The content of the phagosomes (bacteria, viruses, nanoparticles) is then attacked by lysosomal enzymes, free acids, and radicals, resulting in a degradation and inactivation of the macrostructure.

For targeted delivery of nanostructures, one has to overcome the inactivating lysosomal pathway when trying to cause a therapeutic impact on intracellular targets in the cytoplasm or nucleus.

### 5.3 Strategies for Targeted Delivery – Observed in Nature

#### 5.3.1 Outline

When discussing the use of nanotechnologies for targeted delivery, it is essential not to forget the enormous range of “natural micro/nanostructures”. Bacteria, viruses, fungi, parasites, prions, etc., have evolved over a long period and have spe-

cialized in targeted delivery to targets inside macroorganisms against strong defense mechanisms. To avoid the various defense systems, the microstructures had to develop specialized strategies for adherence, barrier invasion, immune system evasion, targeting and growth.

Obviously, understanding these microorganism strategies is important when trying to develop “artificial micro/nanostructures” for targeted delivery, because it is easier copying an existing targeting strategy than developing a new one. Further, there is no reason why well-tested strategies evolved during the long evolutionary fight between macro- and microorganisms should not work in a similar context like nanostructure delivery. It is also important to show that targeted nano/microstructure delivery is possible through other pathways than parenteral injection. To realize the different possibilities to reach a target inside the body by oral or transbronchial application might perhaps help to break the paradigm that says that nanoparticles can only be delivered by parenteral injection. Apart from this, it allows understanding the defense strategies of the human body from a different perspective and displays the need for a deeper understanding of the complex molecular pathways.

Here, we will discuss major strategies for barrier permeation, immune system evasion, and targeted delivery of bacteria, viruses, and prions. It is not the idea create an outline over all existing pathogenic strategies, but to highlight some of these strategies. Refer to the references section for a deeper insight into certain topics of interest.

### 5.3.2

#### **Bacteria**

To set up an infection of a macroorganism, bacteria have devised a vast range of strategies, also called virulence factors [38, 39]. Here, we will concentrate on two features of bacterial strategies that might become helpful for the design of artificial complex nanostructures for targeted delivery: host invasion and immune system evasion.

##### 5.3.2.1 **Host Invasion**

The first defense mechanism pathogenic bacteria meet when they try to invade a macroorganism is the native bacterial flora of the skin or the gastrointestinal tract, which consists of normally harmless bacteria that prevent the newly gained pathogenic bacterium from growth and invasion. By successfully erasing or suppressing this protective flora, the bacterium sets up its own nutritive environment on the skin or inside the gut. Iatrogenic (physician-made) elimination of the native flora of the gut by antibiotics also allows the spread of pathogenic bacteria such as *Clostridium difficile*.

The next step of the bacterial attack is bacterial adherence on outer body surfaces such as skin and mucosal epithelium of the respiratory and gastrointestinal tract. As we have discussed above, the outer layer of the body is build of impermeable epithelial barriers that protect the body from the entry of potentially harmful

macromolecules and structures of complex functionality. Most bacteria cannot cross the intact epithelial barrier, and can only reach the interior of the body and blood vessels through small mechanical lesions in the epithelial barrier. In particular, the skin is a reliable barrier for bacteria invasion because of the two-compartment, multilayered organization. Permeation across the single-layered epithelium of the mucosa of both the respiratory and gastrointestinal tract is much easier, and can be achieved by specialized bacteria even under physiologic conditions (no mechanical damage to the epithelium). These bacteria have special surface structures for adherence to the epithelial layers, called pili (also called fimbriae) and nonfimbrial adhesins [40]. Pili are rod-shaped protein structures on the cell walls of the bacteria consisting of long cylindrical protein subunits in a helical array. The continuously produced subunits are added from the pili interior and extend the pilus outward. The tip of the pilus adheres and binds to host cell molecules on the surface of the epithelial cells such as glycoproteins and glycolipids. Nonfimbrial adhesins are similar cell-contact structures like pili. The cell adherence structures are specific for certain host cell surface molecules and are one explanation for the tissue tropism of most bacteria (e.g. *Streptococcus mutans* colonizes teeth, but not the epithelium of the tongue). Once the bacteria has fixed the contact with the epithelial cell, it can perform a tighter binding to the cell by other bacterial proteins that can bind to surface structures such as different host cell receptors for cell–cell contact or signal transduction.

The next step is the passage across the intact epithelial layer or the invasion into the epithelial cells. Possible pathways for transepithelial passage without invasion or destruction of the epithelial cells involve paracellular entry, translocation through the M cells and luminal capture by dendritic cells [41].

The easiest method is to profit from temporary disruptions of the dense and normally impermeable cell–cell bonds caused by the paracellular transmigration of polymorphonuclear leucocytes (white blood cells) from the subepithelial tissue into the gut following an inflammatory signal. Leucocytes have the ability to weaken the intercellular connections by enzymatic degradation and cross the epithelial layer actively. Some bacteria such as *Shigella* can use these temporarily created intercellular holes to permeate across the epithelial layer without harming the cells.

The M cells, specialized phagocytic cells, are part of the mucosa-associated immune system and are placed inside the epithelial layer where they constantly take samples of the luminal flora for immunologic controlling. Some bacteria families such as *Shigella*, *Salmonella*, *Yersinia* and *Listeria* have different methods to evade the lysosomal destruction inside the M cells and can leave the M cells without loss of function. While *Listeria* have the ability to escape into the cytoplasm with their pore-forming protein listeriolysin O [42] and *Salmonella* can remodel their phagosomes for intracellular growth with the protein Spi2, *Yersinia* have an antiphagocytic strategy that inactivates the actin cytoskeleton by intracellular injection of the proteins YopE, YopH and YopT. Finally, *Shigella* can synthesize intracellular factors that cause the apoptosis (controlled cell death) of M cells, macrophages and monocytes, leading to the release of the unharmed *Shigella* bacterium after phagocytosis. *Shigella* is even able to synthesize cytokines (substances for cell–cell communica-

tion) such as IL-1 $\beta$  and IL-18 that disrupt epithelial impermeability and simplify further bacterial invasion on a paracellular pathway. All of these mechanisms allow the bacteria to cross the epithelial layer without having to kill the epithelial cells [41].

The last pathway for transepithelial passage without epithelial cell invasion is the luminal capture by dendritic cells. Dendritic cells are phagocytic cells of the innate immune system comparable to macrophages. They are not a constant part of the mucosa like the M cells, but have the ability to crawl between two epithelial cells or to send cell extensions called pseudopods through the intercellular compartment into the gut lumen. The pseudopods capture luminal bacteria and phagocyte them for degradation and detection. The bacteria mentioned above have strategies for phagocytosis evasion and can reach the systemic circulation once they leave the dendritic cells. Some bacteria such as the *Salmonella* family can even travel inside the dendritic cells as “blind passengers”.

Another method for transepithelial migration is the direct and active (not by phagocytosis [43]) invasion into the epithelial cells; these cell-invasion strategies [41] are more complicated than the methods we have met until now and require sophisticated molecular mechanisms. Bacteria such as *Yersinia pseudotuberculosis* or *Listeria monocytogenes* [44] express proteins such as invasins, internalins or InlB that can bind to surface receptors (mostly receptors for cell-matrix or cell–cell adhesion such as integrin, E-cadherin or Met) of the host cell, leading to a clustering of the bound receptors and a forming of vacuoles that engulf the bacterium through a so-called “zipper” mechanism. The ligand–receptor binding starts a cascade of signals (e.g. protein phosphorylation, recruitment of adaptors and effectors), resulting in an activation of actin cytoskeleton units and finally bacterial internalization through developing membrane extensions that enclose the bacterium.

Other bacteria such as *Shigella* or *Salmonella* can bypass the step of adherence to the host cell and interact directly with the intracellular actin cytoskeleton by injecting effectors through a secretory system that triggers the formation of macropinocytotic pits for bacterial entry. A key constituent of this “trigger mechanism” is the type III secretory system [45–48] – a complex multiprotein structure comparable to an injection needle of a syringe. The tip of the secretory system recognizes the surface of the host cell and triggers the insertion of an IpaB/C or SipB/C [49, 50] translocation pore into the cell membrane. This translocation pore allows permeation of the proteins IpaC and SipC that force the cell to form the mentioned macropinocytotic pockets by actin cytoskeleton nucleations, and of a protein called VirA that stimulates local destabilization and depolymerization of microtubules, another part of the cytoskeleton. In a next step, more proteins such as SopB/SigD, SopE or IpgD are injected through the type III secretory system and stimulate actin rearrangements and bacterial entry. In the last step, the macropinocytotic pocket closes, triggered by the injected proteins SptP and IpaA.

One major effect of these complex mechanisms is the direct invasion into intracellular vesicles or even into the cytoplasm without having to survive the direct contact with the lysosomal compartment. The bacteria can now persist inside the

epithelial cell and usually start intracytoplasmic reproduction, finally resulting in host cell killing. The newly created bacteria now can reach the well-perfused subepithelial tissue, where they can enter the blood vessels through the endothelial fenestrations.

Once the bacterium reaches the interior of the body, it has to evade the host defense if it wants to survive. In the tissue or inside the blood vessels, the bacterium meets the cellular and noncellular parts of both unspecific (innate) and specific (adaptive) immune system.

### 5.3.2.2 Immune System Evasion

One essential requirement for “targeted delivery” of complex structures such as bacteria is the ability to survive in the tissue and in the bloodstream by evading, suppressing or tricking the immune system of the host organism. The immune system [51, 52] consists mainly of the unspecific, innate immune system and the specific, adaptive immune system. The unspecific immune system organizes a first defensive barrier against microorganisms such as bacteria, fungi and parasites. It consists of noncellular (humoral) elements such as the complement system, the acute-phase proteins, the interferons and bactericidal substances such as lysozyme. Then cellular elements such as the epithelial layers, the native microbial flora and the white blood cell granulocytes (neutrophilic, basophilic and eosinophilic), mast cells, monocytes, macrophages, natural killer (NK) cells and dendritic cells. The specific immune system consists of the humoral element antibodies, and the cellular elements B lymphocytes, T lymphocytes and plasma cells. It is responsible for targeted defense against bacteria, viruses, allogeneous cells and tumor cells with molecule-specific antibodies and target-specific killer cells.

Bacteria have mainly specialized in manipulating the innate, unspecific immune system with several different strategies [53, 54]. We will discuss some of them to show successful strategies for innate immune system evasion that might be helpful for targeted delivery of artificial micro/nanostructures.

Recognizing microbial molecules by germline-encoded receptors such as the transmembrane TLRs [55, 56] of macrophages and dendritic cells, an important receptor family for the innate recognition of various microorganism, activates the innate immune system. One of the best-characterized of the TLRs is TLR4, which can bind lipopolysaccharides, an essential part of the cell wall of Gram-negative bacteria (e.g. *Escherichia coli*, *Salmonella*). Binding of a bacterium is a condition for uptake into the phagocyte and for the inflammatory cytokine response. On the other hand, many bacteria have manipulative systems that alter the function of the TLR4 system and enable an infection of the host organism. The *Shigella* bacterium, for instance, synthesizes a surplus of free lipopolysaccharides (also called endotoxins) that bind and block TLR4 of macrophages and stimulate an inflammatory response. As we have seen above, this inflammation can lead to a higher permeability of the intestinal epithelium and to a higher grade of bacterial invasion [57].

Bacteria such as *Yersinia pestis*, *Helicobacter pylori* and *Chlamydia trachomatis*, on the other hand, synthesize a slightly changed version of the free lipopolysaccharide that also blocks all TLR4, but that does suppress the inflammatory response in-

stead of stimulating it. Thus, the bacterium decreases the efficiency of the immune response and increases its own chance of surviving.

Some pathogenic members of the *Yersinia* family such as *Yersinia enterocolitica* and *Y. pseudotuberculosis* can be considered as specialists for immune system suppression. Not only do they block the TLR4 system with modified free lipopolysaccharides, they can also suppress phagocytosis (see above) and inflammatory response by injecting proteins such as YopM, and by the synthesis and secretion of the immune-suppressive V antigen [47]. The V antigen binds to another TLR, the TLR2, and activates IL-10- and CD14-dependent pathways that lead to immunity downregulation.

The bacterium *L. monocytogenes* produces a membrane-perforating protein to escape the lysosomes as we have seen in the last subsection. Once it reaches the cytoplasm of the macrophages, it can persist there and multiply by forcing the macrophage to produce the cytokine IFN- $\beta$  that suppresses the ability of the macrophage to fight the infection of its own cytoplasm [42, 58, 59].

Another specialist for innate immune system evasion is the bacterium *Mycobacterium tuberculosis*, responsible for the tuberculosis infection. Similar to *L. monocytogenes*, *M. tuberculosis* has various potent strategies [60] that allow the bacterium to survive and multiply inside macrophages [61]. For instance, it can suppress the response of the innate immune system by (i) downregulating the expression of the cytokine IL-12 [62], (ii) by blocking the response of the macrophage to the cytokine IFN- $\gamma$  that normally increases the ability and efficiency of the phagocytosis process [63], and (iii) by surrounding its own cell wall with stable and impermeable complex lipids, peptidoglycans and waxes [60] that protect the bacterium from the lysosomal enzymes.

Instead of surviving inside the macrophages or dendritic cells, some bacteria such as Enteropathogenic *E. coli*, *Pseudomonas aeruginosa* and *Yersinia* have strategies that prevent them from being subject to phagocytosis. As we have learned above, these bacteria can inject “antiphagocytic” substances (e.g. ExoS, ExoT, YopH, YopE and YopT) [64–68] into the phagocytic cells with their type III secretion system before the macrophage can bind the bacterium.

Other intracellular bacteria, *Legionella pneumophila* [69] and *Brucella* [70], use a type IV secretion system [71–73] to degrade the function of host lysosomes by intercepting intracellular vesicles from the endoplasmic reticulum that contain the lysosomal enzymes and to stop the presentation of bacterial antigens on class II MHC molecules [74, 75]. *C. trachomatis* [76] and *Chlamydia pneumoniae* [77], also obligate intracellular bacteria, have sophisticated strategies that can block the transition from innate to the adaptive immune system, thus making it hard for the immune system to remove the infected phagocytes. The *Chlamydia* bacteria secrete a proteolytic enzyme called chlamydial protease-like activity factor (CPAF) that degrades the host cell molecules RFX5 and USF-1 – transcription factors essential for activation of class I and class II MHC molecules that would present some *Chlamydia* antigens to lymphocytes for adaptive immune system activation.

The last bacterium we want to discuss here is *Streptococcus pyogenes*, which has evolved complex strategies to evade the inactivation by cells of the innate immune

system, in this case by the granulocytes (also called polymorphonuclear leukocytes) [78]. Normally granulocytes can kill invading bacteria and fungi by both phagocytosis and different microbicidal systems such as superoxide, reactive oxygen species, hydrogen peroxide and hypochlorous acid. *S. pyogenes* has the ability to inhibit the recruitment of new granulocytes to the site of infection by producing a serine endoprotease (C5a peptidase) that degrades and inactivates a potent host-derived chemotactic factor of the complement system, C5a [79].

Perhaps the most important defense strategy for our purpose is the ability of *S. pyogenes* to evade the opsonization by plasma proteins that would result in an efficient and fast clearance by phagocytes. To achieve this antiopsonic strategy, the bacterium has a dimeric coiled-coil surface protein called M protein that binds certain nonopsonic factors of the complement system such as C4b-binding protein, factor H, factor H-like protein and the plasma protein fibrinogen. In that way, it impedes the binding of the potent opsonic factor C3b to the bacterial surface [80]. Further, the bacterium produces a protein (Streptococcal inhibitor of complement, Sic) that inhibits the formation of the so-called membrane attack complex (MAC) [81, 82], the final cytotoxic formation of the complement factors C5b–C7 that would eventually perforate the bacterial wall (see below). Streptococcal pyrogenic exotoxin B (SpeB), another secretion product of the bacterium, inhibits opsonization and phagocytosis by cleaving opsonic factors such as fibronectin and vitronectin. Further, it blocks the granulocyte function by activating a metalloprotease and the pro-inflammatory and granulocyte-toxic cytokine IL-1 $\beta$  [83]. Finally, *S. pyogenes* produces the enzyme endoglycosidase (EndoS) that inactivates humoral antibodies directed against the bacterial surface for opsonization purposes, thus decreasing the possibilities for antibody-mediated phagocytosis [84].

*S. pyogenes* has also some interesting physical barriers that protect the bacterium against phagocytosis. A hyaluronic acid capsule composed of *N*-acetylglucosamine and glucuronic acid repeats offering a certain grade of phagocytosis protection covers the cell wall and inhibits the direct interaction of opsonins on the bacterial surface with granulocytes [85]. To increase the physical protection, *S. pyogenes* can cover itself with a matrix of fibronectin and collagen [86], and can even build aggregates with other bacteria, which as a result are difficult to remove for the immune system.

### 5.3.3

#### Viruses

When discussing the impact of nanotechnology for targeted delivery in biological systems, viruses are the best example found in nature and can be readily compared to artificial nanometer-sized structures such as nanocontainers. Viruses are nanometer-sized (15–300 nm diameter) complexes with a simple composition of a facultative lipid bilayer envelope with glycoproteins (viruses can be distinguished into viruses with an envelope and viruses without an envelope), a few enzymes such as reverse transcriptase, RNA polymerase or kinases, and a central nucleo-

protein complex called a capsid containing the viral DNA or RNA. Viruses themselves have no means of independent locomotion or growth and depend on host cell metabolism. Once they enter the host organism, they have to penetrate the different defense barriers such as mucus layer, epithelial layer, immune system, endothelial layer and finally the cell membrane of their target cell. Here, we will discuss some important virulence factors of different viral species and we will show their enormous ability for target-specific delivery of their content in biological systems. We will also briefly discuss the current state of viral gene therapy and the impact of nanotechnology in gene therapy.

#### 5.3.3.1 Immune System Evasion

Due to the much smaller size compared with bacteria and because of the intracellular reproduction, fighting viral infections is much more difficult for the immune system [87, 88]. To be able to recognize and inactivate the free virus, the immune system has to label the viral surface with opsonins such as unspecific complement factors or specific antibodies. As complement system activation is an important condition for an effective innate and adaptive immune response, most viruses have strategies to evade or manipulate the complement system [89, 90].

The complement system is a defensive method of the humoral innate immune system and consists of an interacting set of plasma enzymes (called C1–C9) synthesized in the liver, and in different cell lines such as monocytes, fibroblasts, endothelial cells and neurons (nerve cell). The complement system can be activated to perform a cascade of reactions leading (i) to the recruitment of antibodies, more complement factors and phagocytic leucocytes to the site of infection by producing potent anaphylatoxins (C3a–C5a), (ii) to the opsonization of viruses and virus-infected cells, and (iii) to the destruction of microorganisms and cells by the final ring-shaped, membrane-perforating MAC (consisting of activated C5–C9) [51]. The complement system activation can be achieved by three different pathways. (i) Classically by binding of the factor C1q to antibody–antigen complexes or certain viruses or virus-infected cells [91–94]. (ii) Lectin-mediated by binding of the mannan-binding lectin protein to oligosaccharides with unprotected repetitive carbohydrates such as mannose on certain viruses or virus-infected cells [95–97]. (iii) Alternatively by spontaneous and indiscriminate breakdown of the factor C3 in the serum or on surfaces of cells or particles when lacking sufficient levels of endogenous complement-regulating proteins such as C1 inhibitor factor 1 (C1-Inh), complement receptor 1 (CR1), decay-accelerating factor (DAF), protectin and Factor H [98–100]. Normally these factors inhibit the complement activation. All three pathways result in the terminal activation of a C3 convertase enzyme that activates C3 by cleavage. Active C3 activates C5, which launches the creation of the MAC. Viruses have a wide variety of complement-evading strategies; we will discuss some of them.

By forcing the virus-infected cell to shed or internalize antibody–antigen complexes on their surface, viruses from the families Herpes and Corona can obstruct the classical complement activation [101]. Further, Herpes and Pox viruses can produce and express proteins such as vaccinia virus complement control protein

(VCP) [102], glycoprotein C1 (gC1) [103, 104], glycoprotein C2 (gC2) [105] and complement control protein homolog (CCPH) [106], with functional likenesses [89] to the complement-regulating proteins that suppress the complement activation (see above). Some viruses of the families Pox [107], Herpes [108], Retro [109–112] and Toga [113] that cannot produce these proteins themselves are able to incorporate some of the complement-regulating proteins produced by the host organism into their envelope or to force the virus-infected cell to synthesize and secrete these proteins.

Another interesting strategy found in some Herpes [114, 115] and Corona [116] viruses enables these viruses to express Fc receptors (receptors for antibody binding) on the viral envelope or on the infected host cell. The Fc receptor binds non-immune immunoglobulin G (IgG) and protects the virus or the virus-infected cell by sterically blocking the binding of virus-specific IgG [117], and by decreasing the efficiency of an antibody-mediated immune response [118].

### 5.3.3.2 Host Cell Invasion

If a virus wants to multiply, it has to invade a potential host cell [119, 120], has to deliver its capsid and the content of the capsid into the cell, and has to force the infected cell to create new viruses by adding its own genetic information of DNA or RNA to the synthetic machinery of the host cell. One important point is the attachment to the host cell membrane and the invasion into the cell without damaging the cell and without creating an immune response that would finally kill the infected cell.

The first step of cell invasion is the attachment to cell surface proteins, carbohydrates, or lipids that can serve as pure anchors for the virus or can mediate its uptake. The most important cellular receptors for viral attachment are intercellular adhesion molecule (ICAM)-1, integrins, CD4,  $\alpha$ -dystroglycan, MHC-I, CXCR4, CCR5, CD46, DAF, CAR, LDLR, PVR, aminopeptidase-N, heparan sulfate glycosaminoglycan, and sialic acids [120].

One well-studied virus, HIV, even binds to multiple attachment factors such as C-type lectin receptors, the ICAM-3-grabbing nonintegrin (DC-SIGN) found on dendritic cells, and the ICAM-3-grabbing nonintegrin (L-SIGN) [121, 122] found in liver and lymph node tissue. Once HIV attaches to its target cell (macrophage, T lymphocyte, dendritic cell), its envelope-bound glycoprotein 120 binds to a surface receptor of the host cell, CD4, and changes its conformation – a condition for the final binding of glycoprotein 120 to the host cell co-receptors CXCR4 or CCR5 [123]. Only by cobinding to both CD4 and CXCR4 or CCR5 can the virus switch its envelope to the fusion-competent conformation [124, 125].

Attachment and binding factors used by other viruses are (i) heparan sulfate proteoglycans (binding site for glycoprotein C of alphaherpes viruses, for Dengue virus, for papilloma virus), (ii) sialic acid groups (for hemagglutinin of influenza virus, for myxo- and paramyxoviruses) [126], (iii) Herpes entry mediator A HVEA (for glycoprotein D of herpes simplex virus 1) [127], (iv) gangliosides GM<sub>1</sub>, GD<sub>1a</sub> and GT<sub>1b</sub> (for VP1 of polyoma virus) [128, 129], and (v) human lymphocyte antigen (HLA)-DR (for gp43 of Epstein–Barr virus) [130].

For viruses without an envelope, the next step is the endocytosis (clathrin-mediated, caveolin-mediated or clathrin- and caveolin-independent [131]) of the bound capsid that allows the virus to cross the barrier of the cortical cytoskeleton, and to reach deep intracellular structures such as the lysosomes, the endoplasmic reticulum and the Golgi complex [132, 133]. For some viruses the decrease in pH in the endo-lysosome acts as a molecular trigger for membrane penetration mechanisms [134–136]. For most viruses the activation starts at pH 6–6.5, matching early endosomes [137, 138]. Endosome escape is possible by different mechanisms. Adenoviruses become membrane-lytic at low pH and leave the ruptures endosomes intact [139, 140]. Reoviruses can expose a hydrophobic capsid peptide that makes the capsid membrane lytic [141]. Picorna viruses have the ability to sink into the bilayer and to form a protein-lined channel for the viral RNA in the endosomal membrane by exposing a myristic acid end group of the protein VP1 [142].

These methods allow the virus or its genetic information to leave the lysosomal pathway before the enzymatic environment reaches its full degrading power that would inactivate the virus. Further, the lysosomal escape prevents the virus from being subject to an adaptive, MHC-mediated immune response, because the cell does not have any viral antigens to present to lymphocytes on the MHC complex. After leaving the lysosomal compartment, the viral capsid can use the cytoskeleton or intracellular transport motor proteins [143, 144] to reach the cell nucleus or specific cytoplasmic membranes.

Viruses with a protective envelope around the capsid cannot only reach the cell interior by endocytosis as the nonprotected viruses, they can also perform a “simple” membrane fusion to reach the cell. As the protective envelope is a lipid bilayer, membrane fusion is theoretically easy and comparable to the fusion of liposomes and target cells. More complicated is the mechanism that protects the enveloped viruses from fusion with every available cell and allows the membrane fusion only with the desired target cell, thus ensuring a targeted delivery. Membrane fusion is triggered by events such as binding to specific cell surface receptor or a decrease in pH [142, 145], on which the viral envelope changes its conformation and allows the fusion with both host cell membrane and lysosomal membrane.

Viruses have two different fusion factors that can induce the mentioned conformation changes of the lipid bilayer. Type I factors found in the influenza virus consist of homotrimeric spike glycoproteins with coiled-coil subunits and can insert exposed hydrophobic fusion sequences of a lower energy conformation into the target membrane on activation. The released free energy forces both viral and target membranes closer together, resulting in a membrane fusion [124, 126, 146]. Type II factors found in flaviviruses and alpha viruses [147] build a heterodimer with another viral membrane protein and can change their quaternary protein structure after a pH decrease. The fusion subunits of these two proteins dissociate and build a new active homotrimer [148, 149] that forces the membrane fusion. One major advantage of the membrane fusion strategy is the possibility to reach the cytoplasm direct without the complicated way through the receptor-mediated endo-lysosomal system.

To be able to reach the cellular reproduction machinery, the virus capsid has to cross the membrane of the cell nucleus [150–152], mainly through nuclear pore complexes [153–155] that allow the passage of particles up to a diameter of 39 nm [156]. To activate this transport system, the virus has to bind to cytoplasmic import receptors. For example, HIV and adenovirus bind to importin  $\beta$ , and papilloma viruses, hepatitis B virus and influenza virus bind to importin  $\alpha$  and  $\beta$  [157–161].

Larger viruses and capsids have to deform or disassemble to allow the DNA or RNA to reach the nucleus. Adenovirus disassembles its capsid after binding to a subunit of the nuclear pore and releases its DNA for transmembrane passage [162]. The large capsid (diameter 120 nm) of herpes simplex virus 1 also binds to the nuclear pore and releases its DNA direct into the pore without disassembly of the capsid [163, 164], leaving the empty capsid bound to the nuclear pore.

### 5.3.3.3 Viral Vectors for Therapeutic Applications

Genetically modified viruses have been used in a wide range of experiments in gene therapy [165, 166] of both hereditary diseases and acquired illnesses such as cancer. The promising idea is to use the sophisticated viral targeting strategies without having to create new lipid-, protein- or polymer-based nanoparticulate carriers for targeted delivery of missing or defective genes to the diseased cells. After replacing the viral DNA with the necessary human sequence vector, the modified virus is applied to the patient and consequently targets its natural host cell according to its surface properties. The genetically modified virus enters the host cell and delivers its genetic content to the cell nucleus, where it can be integrated into the host cell genome.

After first successful results with retrovirus-based gene therapy of patients with different forms of severe combined immune deficiency [167–169] (mostly fatal disorders of the immune system in young children), the field of virus-mediated gene therapy suffered some setbacks such as a lethal complication in a trial of adenovirus-based gene therapy of a metabolic disease and the induction of leukemia in a retrovirus-based gene therapy trial [170–172]. It also became obvious that successful and efficient gene therapy is much more difficult than originally thought because of (i) low *in vivo* targeting efficiency of the used viral vectors, (ii) inadequate targeting specificity resulting in an unwanted gene expression in healthy tissues, (iii) inappropriate integration of the gene vector into the host genome resulting in a long-term decrease in targeted gene expression and (iv) safety problems with insufficiently replication-deficient viral vectors [165]. We will present some widely used targeting systems based on viruses in areas other than cancer therapy.

One well-established virus for gene therapy is the adeno-associated virus [173, 174], popular because of its efficient gene delivery and long-term expression. Disadvantages are its low target specificity with more or less randomized gene delivery, its low gene packing capacity (less than 4000 bases), problems with activation of endogenous genes and problems with pre-existing antibodies in many patients, which lead to inactivation of the viral vector before it can reach the

target cell. Adeno-associated virus-based gene therapy has been tried for patients with type IX hemophilia [175] (bleeding disorder), cystic fibrosis [176],  $\alpha_1$ -antitrypsin-deficiency [177], peripheral arterial occlusive disease [166] and spinal cord injury [178].

Another popular gene therapy vector is the adenovirus [179–181], known to produce high-titer virus stocks and efficient long-term gene expression. Disadvantages are the strong immunogenicity (especially insufficiently inactivated viral vectors [182]), pre-existing antibodies in most patients (adenovirus is a common virus and makes airway infections) and limited packing capacity of less than 7500 bases. Adenoviral gene vectors have been used for the treatment of brain cancers [183], pulmonary diseases [177] and neurological diseases [184].

The next interesting virus is the herpes simplex virus, popular because of its high packing capacity (above 30 000 bases), good long-term expression, high target specificity for neuronal cell lines, and low toxicity when using gene-deleted non-toxic vectors [185, 186]. Application fields for the use of herpes simplex virus-based gene therapy are various neurological disorders [187] and muscular dystrophy [188].

The last group is the family retrovirus [189], commonly characterized by the enzyme reverse transcriptase that allows the virus to integrate its genetic information precisely into the host genome without the aid of host cells enzymes. Members of the retrovirus family used for gene therapy are HIV [190] and the murine leukemia virus [169] – the pioneer virus for gene therapy. Advantages of the retroviruses are the efficient long-term gene expression, the precise genome integration and the good packing capacity of about 8000 bases. The major disadvantage is the risk of oncogenesis because of an activation of oncogenes after integrating the therapeutic gene into the host genome [166]. Retroviruses are usually restricted to dividing cells; only by modifying the viral envelope (e.g. fusion with other viruses [191]) can the vector also transfect nondividing cells. Retroviruses have been used for gene therapy of hematopoietic disorders [192], immune system deficiencies [167], central nervous system diseases [193] and chronic granulomatous disease [194].

In past years, nanotechnology has enriched the field of virus-based gene delivery with new materials and new ideas, which might help to overcome some of the short- and long-term problems of potentially infectious viruses. In a new approach with adenoviruses, the viral envelope was covered with poly[N-(2-hydroxypropyl) methacrylamide] to protect the virus from inactivating antibodies [195]. Further, fibroblast growth factor (FGF) and vascular endothelial growth factor (VEGF) were incorporated into the polymer to enable a higher grade of target specificity to FGF or VEGF receptor-positive cell lines such as endothelial cells [195].

Other research groups went further and built a chimerical gene carrier consisting of a plasmid DNA encapsulated in liposomes, which themselves were covered with a viral envelope with viral targeting proteins [196] (Fig. 5.6). The construct is called a virosome, and was used for gene delivery to vascular smooth muscle cells [197] and hepatocytes [198]. Disadvantages of the virosome-based delivery system

**Figure 5.6.** Schematic drawing of virosome synthesis. In a first step, a viral-derived and usually genetically modified plasmid DNA in a viral capsid is covered with a liposomal bilayer membrane. In the next step, viral proteins are

added to the liposome for targeted delivery or the whole liposomal complex is again covered with a viral envelope, resulting in the formation of the artificial “virosome”.

are the antigenicity of the viral proteins [196] and the high uptake into the MPS because of the liposomal constituents.

#### 5.3.4

##### Prions

Prion is the abbreviation for proteinaceous infectious particle [199–201] and describes the main characteristics of this fascinating infectious agent simply consisting of a badly conformed peptide of 27–30 kDa called prion protein (PrP). It is most surprising that a small peptide with almost no virulence factors, no genetic information, and no protecting envelope, membrane or hull can persist for years or even decades in the host organism and can cause fatal neurodegenerative (spongiform vacuolation and loss of neuronal cells) diseases such as the transmissible spongiform encephalopathies (e.g. bovine spongiform encephalopathy in cows and scrapie in sheep) and Creutzfeldt–Jakob disease in humans [202–204]. Here, we will discuss some important strategies that enable the prion to invade the host organism, to evade the immune system defense, to persist in cells of the innate and adaptive immune system, and to reach its target cells in the central nervous system [205]. It is important to bear in mind that these principles might become helpful for the targeted delivery of artificial protein-based nanoparticles. On the other hand, the prion pathogenesis is a warning example that illustrates the various paths

nanoparticles can take in a complex organism, and the huge damage even small particles can cause even after years and decades.

Prions reach the host orally and enter the organism mainly in the small intestine [206, 207] by both M cell-mediated [208] and dendritic cell-mediated luminal capture (as described above for bacteria). After binding or taking up the prions, the infected dendritic cells localized in specialized lymphatic tissue in the gut wall called Peyer's patches can infect other dendritic cells or lymphocytes [209–211]. On the surface or inside the dendritic cells and the lymphocytes, the prions can persist with the help of yet unknown mechanisms and can even “multiply” by passing on their pathological conformation onto normal cellular host-encoded prion protein (PrP<sup>c</sup>) [212–214]. Further, B-type lymphocytes [215] and complex cytokine functions [203] have been discovered as the main mechanisms responsible for prion spread and for neuroinvasion. One of the few facts is that the prions can spread to various lymphoid organs with a high concentration in the spleen [216].

The next step in the prion pathogenesis is the path from the widely infected lymphoid tissue to the nervous system. It is believed that dendritic cells of spleen and especially Peyer's patches [217, 218] play a major role by setting up a close contact with nervous endings of peripheral nerves. The prions cross the space between the dendritic cell and the nervous ending by passive diffusion or with the help of “mobile elements” such as exosomes (free micellar membrane components with prions) [219], endogenous viruses, B lymphocytes [215, 220] or even special dendritic cells [221, 222]. Once inside the peripheral nerves, the prions enter the neuroretrograde transport system of the nerve that leads to the transport of the prion to structures of the central nervous system, where the destruction of the nervous cells takes place.

One important characteristic of prion pathogenesis important for us is the ability to evade the innate immune system and even use the complement system for simplification of target cell infection. The central role is occupied by the dendritic cells that settle the first contact with the prion in the Peyer's patches and that can store the prions on the surface for lymphocyte presentation. Further, the dendritic cells (and other phagocytes such as macrophages) can also bind complement- or antibody-labeled prions with their Fc and complement receptors [223, 224], usually followed by receptor-mediated endocytosis. Unfortunately, an unknown conformational characteristic allows the prion to “survive” the enzymatic degradation by proteases, making it impossible for the immune system to create an efficient antibody-mediated adaptive immune response by MHC-mediated antigen presentation.

Obviously, an inadequate degradation of the prions in cells of the MPS only leads to widespread spread of the infectious agent when it binds complement factors, because the uptake of complement-labeled prions is much more efficient than the uptake of unlabeled prions to dendritic cells, macrophages and lymphocytes.

Applied to our topic, i.e. targeted delivery of nanostructures, it can be said that unselective uptake of artificial nanometer-sized structures – be it protein-based or polymer-based – can create grave side-effects if the cells of the MPS are not capable of degrading the structure efficiently.

## 5.4

### Strategies for Targeted Delivery – Designed by Man

#### 5.4.1

##### Outline

In this section, we will discuss strategies for targeted delivery of chemically complex, nanometer-sized structures to a well-defined target site developed by researchers in recent years [225, 226]. We will concentrate on the desired targets and on the targeting strategies and moieties, independent of the nature of the carrier and its content. The section will be divided into the most important targeting pathways and sites other than cancer therapy, i.e. noninvasive and invasive delivery systems, and targeting to the brain, to atherosclerotic plaques and other targets.

#### 5.4.2

##### Noninvasive Delivery Systems

When discussing the possibilities for targeted drug delivery for pathological conditions other than cancer, we have to be aware that we are dealing with chronic illnesses such as atherosclerosis, arterial hypertension, dyslipidemia, brain disorders (e.g. Parkinson's disease, Alzheimer's disease, psychiatric disorders), chronic inflammatory diseases, diabetes, etc. These diseases normally need a long-term medication. To ensure a good adherence to the therapeutic plan and to limit the possible side-effects, drugs for these chronic disorders have to be ideal from the pharmacological side. Important issues are easy application (oral, inhalatory, transdermal), once-a-day dosage, stable plasma concentrations and no serious adverse side-effects. In particular, the application method is important for the patient's comfort and adherence to the therapeutic procedure.

For diabetes, we have to administer the protein insulin to the systemic circulation, which is right now only possible with parenteral injections (subcutaneous or intravenously). Further, the patient has to inject the insulin up to 5–6 times a day to uphold an acceptable glucose concentration and risks a potentially fatal hypoglycemia when injecting an overdose of insulin. Obviously, such a therapeutic rule decreases the patient's quality of life and is only acceptable if the therapeutic benefit outweighs the negative side-effects to a high degree.

The design of noninvasive (in contrast to invasive methods such as injectable or implantable systems) drug delivery systems for oral, transdermal and transepithelial application and controlled passage of smaller and bigger molecules is therefore an important research area, and has been enriched by nanotechnological tools in recent years [225]. All noninvasive systems we will discuss in this section are a result of a so-called “top-down” manufacturing process, where the final tool is built from larger parts (in contrast to the “bottom-up” process, where atoms and/or molecules come together to build a superstructure). For the details about pharmacology and biology of the barriers, refer to the previous sections of this chapter.

#### 5.4.2.1 Oral Delivery Systems

The most attractive delivery route is oral application – it is convenient, noninvasive and effective because of the large intestinal epithelial surface in the small intestine. In recent years, manufacturers have developed new complex drug formulas for controlled release based on nanotechnology, to ensure a continuous drug release into the systemic circulation over a longer period without toxic initial peak levels [227]. The most important controlled release drug formulation method for tablets is the osmotic oral delivery system (also called osmotic pump technology). It is based on an inner drug reservoir or drug core, a semipermeable membrane with nanometer-sized pores around the drug reservoir and a polymeric push compartment, which triggers the diffusion of the drug through the membrane on activation (e.g. hydration). This method is now commonly used for drugs such as nifedipine (Procardia XL<sup>®</sup>, Pfizer), oxybutynin chloride (Ditropan XL<sup>®</sup>, Ortho-McNeil) and methylphenidate (Concerta<sup>®</sup>, ALZA).

Another important modern drug formulation method is the multilayer matrix tablet, based on a core drug reservoir and one or more surrounding barrier layers such as hydroxypropylmethylcellulose (HPMC) [228, 229]. Various additional ingredients trigger the controlled diffusion process by swelling, gelling or erosion of the barrier layers. This method is being used for drugs such as diltiazem (Dilacor XR<sup>®</sup>, Watson Labs), paroxetine (Paxil CR<sup>®</sup>, GlaxoSmithKline) and diclofenac (Voltaren XR<sup>®</sup>, Novartis).

The last controlled release technology is called spheroidal oral drug absorption system (SODAS), and is based on spherical beads (diameter 1–2 mm) containing drugs and excipients that are coated by controlled-release polymers [225, 230, 231]. In fluids, the polymers start to dissolve at a time-dependent rate and allows the fluid to dissolve the drug core, resulting in an immediate release, a sustained release or a pulsatile delivery. This method is being used for drugs such as diltiazem (Cardizem LA<sup>®</sup>, Bioavail), methylphenidate (Ritalin LA<sup>®</sup>, Novartis) and morphine sulfate (Avinza<sup>®</sup>, Ligand).

#### 5.4.2.2 Transdermal Delivery Systems

Transdermal application of drugs is another elegant method to ensure stable plasma drug concentrations, low maximum–minimum peak concentration differences, low first-pass effect and controlled release of potent, lipophilic drugs.

The most important technology for transdermal drug application is the transdermal delivery patch for drugs such as fentanyl, morphine, nicotine, nitroglycerin and steroid hormones we have already discussed above. Recently, new technologies have been introduced to expand the possibilities for transdermal drug delivery.

First, it is possible to use the so-called iontophoretic delivery by applying an electrical current to the skin, after which the drug molecules move actively through the epidermis according to the polarity of the electrical field (similar to electrophoresis) [232].

Second, new microtechnological devices called Macroflux<sup>®</sup> (ALZA) and Microstructured Transdermal System<sup>®</sup> (3M Drug Delivery) based on microprojection technology [233] allow the skin permeation of macromolecules such as proteins

and peptides. The device consists of an array (1–2 cm<sup>2</sup>) of drug-coated titanium microprojections (200 μm each) fixed to an adhesive patch backing. The device has to be applied to the skin by using a special applicator, on which the small microprojections pierce the protective stratum corneum of the epidermis mechanically, allowing the coated drug to dissolve and to permeate into the blood vessels of the subepidermal tissue [234].

#### 5.4.2.3 Transmucosal Delivery Systems

Drug application to sites such as the buccal, nasal, rectal, intrauterine, vaginal and ocular mucosa is another interesting alternative to intravenous injection and oral application, especially for special patient groups such as children, elderly or sick people, where the conventional application pathways may be problematic. Further, the absorption is fast in the well-perfused mucosa if the drug molecule is able to cross the epithelial barrier.

Special transmucosal drug delivery systems consist of bioadhesive polymers or hydrogels that increase the contact time and contact intensity to the epithelial layer [235]. For instance, polymers such as polyanhydrides stick physically to the intestinal epithelium and lectins stimulate a ligand–receptor interaction with receptors on the small intestine villi [236], making it possible to couple drug molecules or drug carriers to the lectin molecule [237] for better adhesion and permeation. A similar strategy with drug–polymer conjugates was tested for an oral administration formula for insulin [238].

The drugs in the polymer matrix or hydrogel can be free or attached to special controlled release devices such as microspheres and rings [239, 240], reservoirs [241], or nanoparticles [242].

Further, it is possible to improve the absorption rate across the endothelial layers by disturbing the epithelial barrier with special absorption enhancers [235] such as chitosan, cyclodextrin, poly-L-arginine and various lipids [243]. Formulas enriched with chitosan [244] powder have already been used for nasal administration of insulin and morphine [245].

#### 5.4.3

#### Invasive Delivery Systems

In this section, we will discuss controlled, “top-down” micro/nanotechnological devices for drug delivery that have to be injected or implanted [246]. The variety of uncontrolled, “bottom-up” liposomes, nanoparticles and other nanometer-sized superstructures will be discussed in the next sections.

One important example of invasive delivery systems are controllable microfabricated devices (based on silicon chips, “off-wafer” techniques or microfluidic devices) with a drug reservoir that can be triggered or programmed to release a certain volume of drugs to the tissue or to the circulation [247]. Older concepts relied on the surgical implantation of the microfabricated device under the skin or into other tissues. Currently, new micro/nanofabrication techniques are being developed that allow the top-down construction of devices down to a size of 10–100 μm. These

techniques make it possible to inject the devices into the target tissue with only slight damage or to inhale the macrostructure into the bronchi, where the drug could be released permanently over a certain time. By integrating microfluidic networks with multiple reservoirs, valves and pumps [248], it is possible to program the microfabricated to perform chemical reactions and release several reaction products [249].

One essential requirement for microfabricated device is the possibility for real-time control of the drug release according to changes in chemical and physiological parameters. One approach is the activation of molecular interactions using light radiation, radiofrequency or ultrasound energy. Ferromagnetic seeds [250], rods [251], microparticles [252] or superparamagnetic nanoparticles [253] can be injected or transported to a desired target, where they can be heated using localized radiofrequency or ultrasound for thermal treatment or release activation. Further, it had been shown that high-frequency radiofrequency changes the conformation of nucleic acid conjugates or proteins coupled to nanoparticles.

Another strategy for controlled drug release in microfabricated devices is based on hydrogels, three-dimensional, hydrophilic polymer (e.g. collagen, gelatin, dextrans, chitosans, poly-*N*-vinylpyrrolidone, polyphosphazenes, PLA/polyethylene oxide/PLA copolymers, PEGT–PBT copolymers [254]) networks that swell and change their diffusion properties reversibly when exposed to water. Thus, it is possible to control the drug diffusion out of a drug reservoir or a matrix with a hydrogel covering according to the swelling properties of the hydrogel. Special hydrogels are even sensitive to specific antigens [255], to an enzyme [256], to pH changes (methacrylates) or to an applied charge and change their swelling properties [257].

Finally, special polymer-based surfaces sensitive to light [258, 259], pH, charge [260] and heat offer further possibilities for triggered controlled release of the content.

Similar to the microfabricated devices are noncontrollable diffusion chambers [261] or diffusion tubes with a central chamber filled with one or more drugs and semipermeable membrane that controls the release rate. Diffusion chambers or tubes have to be implanted into a certain tissue, and have been tested for diseases such as diabetes [262, 263], epilepsy [264] and spinal cord damage [265], and for birth control implants [266]. Diffusion chambers can also be filled with living cells [267] to enable the production of proteins, hormones and other molecules (e.g. erythropoietin [268], insulin [269, 270] or IFN- $\alpha$  [271]), but we are not going to discuss this vast area further in this chapter.

#### 5.4.4

#### **Targeted Delivery to the Brain**

The brain is well protected against the diffusion of hydrophilic molecules and macromolecules by the blood–brain barrier, consisting of the dense, unfenestrated endothelial cell layer, the subendothelial space and specialized protecting cells of the brain – the astrocytes. The blood–brain barrier makes it difficult for micro-

organisms, toxic substances and macromolecules to reach the neurons of the brain, but also complicates therapeutic applications targeting cerebral pathologies such as Parkinson's disease, Alzheimer's disease, multiple sclerosis, meningitis or encephalitis. Only small lipophilic substances are able to cross the blood–brain barrier passively by diffusion; larger or hydrophilic substances need active transport system or a functional disruption of the blood–brain barrier to reach the neurons. Due to these limits, targeted delivery to the brain is one of the most active research areas using nanotechnological devices and researchers have developed a wide range of macromolecular targeting carriers. In recent years, new nanotechnological drug formulas have been tested for transport of bigger molecules such as peptides, proteins, and genes across the blood–brain barrier, both liposomal formulations [272] and polymer-based formulations [273].

Currently used liposomes are typically sterically stabilized for prolonged circulation lifetimes by a protective coating of PEG or other “antiopsonization agents” [24]; some liposomes are further functionalized with targeting moieties such as antibodies (immunoliposomes) [274], proteins, peptides or others [275, 276] for preferred target deposition. For details on the synthesis of nanotechnological carriers, refer to the specialized sections and references.

Well-studied targeting agents for trans-blood–brain barrier delivery are monoclonal antibodies such as OX26 [277] or 8D3 [278] directed against the ubiquitous (especially liver, muscles and brain) transferrin (iron-binding protein in plasma) receptors. The murine antibodies are typically conjugated to PEGylated liposomes that have to be injected intravenously and have shown a certain affectivity to the endothelial cells of the blood–brain barrier [279]. After binding to the transferrin receptor, the antibody with the liposome is transported across the blood–brain barrier by receptor-mediated endocytosis and transcellular transport [280, 281]. The antibody–liposome complex can now diffuse freely and spread into the brain tissue, which shows a clear liposome accumulation compared with native PEGylated liposomes [282].

Other targeting moieties for targeted brain delivery of liposomes are monoclonal antibodies directed against the human insulin receptor such as 83-14 [283], which can be found on endothelial cells and neurons in a high concentration. The functionalized liposomes bind to the cell surface receptor and can be internalized by receptor-mediated endocytosis. To increase the rate of *trans*-blood–brain barrier passage, it is also possible to functionalize the liposomes further with anti-transferrin receptor antibodies [284]. In this case, the antitransferrin receptor antibody ensures the passage across the blood–brain barrier, while the anti-insulin receptor ensures the uptake into the neurons.

Due to the well-known limits when using liposomes such as low physicochemical stability, leakage, difficult preparation procedures, low possibility for controlled release, low loading efficiency and short *in vitro* lifetimes, many researchers have turned to polymer-based formulas [273, 285] to overcome these problems.

The first nanoparticles for targeted brain delivery were made using poly(alkylcyanoacrylates) such as polybutylcyanoacrylate (PBCA) [286] coated with the nonionic surfactant polysorbate 80 [287–289], and later using nanoparticles consisting

of polylactide homopolymers (PLA) and poly(lactide-co-glycolide) heteropolymers (PLGA) coated with PEG [290] to protect the nanoparticles from opsonization and to ensure longer circulation lifetimes [291, 292].

The targeting moiety of PBCA nanoparticles is the polysorbate coating, which ensures a certain nanoparticle accumulation in the brain tissue, probably by a polysorbate-mediated disruption and permeabilization of the blood–brain barrier [293, 294] or by endocytosis by the brain capillary endothelial cells [285]. It has been hypothesized that the endogenous plasma protein apolipoprotein E (ApoE) absorbs to the polysorbate coating and triggers the receptor-mediated endocytosis [285]. On the other hand, a protein-binding nanoparticle surface obviously enables opsonization and leads to a fast uptake into the MPS [288, 295, 296], making it impossible to use these nanoparticles for target-specific delivery. Further, blood–brain barrier permeabilization is a serious adverse drug event [273] that might lead to neuronal damage by exogenous or endogenous toxic substances or microorganisms.

Nanoparticles made of polymers based on glycolic acid and D,L-lactic acid enantiomers have a proven record of good biocompatibility and resorbability [297, 298], and have been used for some years in building biodegradable devices and microspheres [299]. Further, PLA and PLGA are easily degraded by spontaneous hydrolysis of the ester bonds [300] into oligomers and monomers, which are further metabolized and degraded into CO<sub>2</sub> and H<sub>2</sub>O [273]. For nanoparticle targeting applications, the PLA/PLGA polymers have to be covered with PEG moieties to ensure a prolonged circulation lifetime [301] of some hours compared with some minutes for native PLA/PLGA nanoparticles [302–306].

Possible targeting moieties for brain-specific delivery of nanoparticles based on PLA/PLGA are the monoclonal antibodies (OX26 and 8D3) against the transferrin or insulin receptors we have already met. The targeting antibodies are bound to the tips of specially functionalized PEG strands (biotinylated [307], amine reactive [308] or thiol reactive [309, 310]) and enable the endocytosis of nanoparticles with a diameter of around 100 nm to the endothelial cells of the brain capillaries and the passage across the blood–brain barrier.

#### 5.4.5

#### Macrophage Targeting

Macrophages, the main cell type of the innate immune system, play a major role in a wide range of disease states, including infections (e.g. *Leishmania*, *M. tuberculosis*, *L. monocytogenes*), autoimmune diseases (e.g. rheumatoid arthritis, sarcoidosis, type I diabetes), cancer and atherosclerosis [311–318]. Therefore, the macrophage is an interesting pharmaceutical target, despite the fact there exist only a few therapeutic choices until now.

Targeting to macrophages is theoretically easy, because the macrophages of the MPS are the primary target for all nonstealth lipid- or polymer-based nanometer-sized vehicles. Nonetheless, the macrophages of the MPS in liver and spleen are only rarely the desired target when trying to achieve a therapeutic effect; the “de-

sired” macrophages are those found in vulnerable plaques of the blood vessels, in the peritoneum, the lung and other sites of disease. In contrast to the macrophages in liver (called Kupffer cells) and spleen, the macrophages in these tissues are normally protected from the nanovehicles by a dense endothelial layer (endothelium in liver and spleen has wide fenestrations). To be able to target the “desired” macrophages, a nanovehicle has to (i) evade the phagocytic cells of liver and spleen, (ii) uphold long circulation lifetimes, (iii) find a way to leave the circulation intact at a desired therapeutic target, (iv) reach the target cells specifically (v) and enter the macrophages (vi) avoiding the destruction in the endo-lysosomal compartment. All this makes targeting to the “desired” macrophages a serious task and calls for innovative solutions based on nanotechnological tools.

Early examples of macrophage-directed drugs are nonstealth liposomes containing the antimicrobial drug amphotericin B (AmBisome®, Gilead Sciences) for the therapy of the intracellular parasite *Leishmania* (which stays in macrophages) and various fungal infections [319–321]. Similar approaches with liposomes and nanoparticles were also used for improved targeting of antimicrobial agents such as  $\beta$ -lactam antibiotics, aminoglycosids and fluoroquinolones to intracellularly infected macrophages (e.g. *Salmonella*, *L. monocytogenes*, *M. tuberculosis*, *Mycobacterium avium*, *Mycobacterium intracellulare*, *Brucella abortus* and *L. pneumophila*) [322]. The liposomal formulas allow reducing the quantity of applied drug molecules and decrease the severity of adverse side-effects [323], because most of the encapsulated drug is rapidly transported to the phagocytic macrophages or the fungi and not to other healthy tissues. Targeting can be further improved using targeting moieties such as tuftsin, a natural macrophage activator tetrapeptide (threonine–lysine–proline–arginine) based on a part of the IgG heavy chain [324].

One interesting application area for nanoparticulate formulations targeting macrophages is the development of new nanotechnological vaccines. The required protein or peptide antigen is coupled physically or covalently to a polymer- or lipid-based nanocarrier adjuvant, which promotes the preferred uptake of the coupled antigen to macrophages of the innate immune system. The antigen is then processed by the endo-lysosomal compartment and presented to T lymphocytes using the MHC class I and especially class II molecules on the surface of antigen-presenting cells (APC), increasing the immunogenic potency of the used vaccination antigen [325–327]. Similar approaches have been tried for new DNA vaccines [328, 329]. Targeting can be further improved using targeting moieties such as various mannose receptor ligands [330].

Much progress has been achieved in the use of nanotechnology-based contrast agents for diagnostic applications. Detection of activated macrophages might help the doctors to find and define a diseased tissue, especially an inflamed tissue such as the vulnerable plaque or autoaggressive immunologic process. In recent years, paramagnetic iron oxide nanoparticles (4–5 nm diameter, usually coated with PEG or dextran) have been used for detecting macrophages using the readily available technique of MRI. Macrophages or other target cells take up the nanoparticles that can be detected by MRI (negative signal in T2), because the iron oxide shortens the spin relaxation compared with surrounding tissues. Paramagnetic

iron oxide nanoparticles have been used for detecting lymph nodes metastases [331, 332], arthritis [333], fibrin molecules [334], angiogenesis in atherosclerotic plaques [335] and other constituents of atherosclerotic plaques [253, 336, 337].

The detection of actively inflamed atherosclerotic plaques that are in danger of rupture (leading to heart infarction, stroke and other organ ischemia), called vulnerable plaques [28, 318], is an active and promising research area that has been enriched by nanometer-sized vehicles for targeted delivery [3]. Several characteristics of vulnerable plaques simplify the targeted delivery, i.e. the functional and morphological disruption of the endothelial layer that covers the atherosclerotic plaque and enables the extravasation of larger molecules and superstructures such as lipoproteins, polynucleotides, polypeptides, complex lipids and advanced glycation end-products (AGE). These macromolecules initiate and support the pathological process of atherosclerosis. In the vulnerable plaque, active macrophages take up the plasma proteins and lipids and transform into so-called foam cells, instable macrophages filled with lipids that produce various cytokines and other pro-inflammatory and proliferation-stimulating chemical substances. These substances attract more white blood cells to the plaque, trigger the growth of the plaque and finally cause the breakup of the fibrous cap [338].

Intelligently designed nanovehicles such as polymer nanocontainers [32] have several properties that might enable them to reach the vulnerable plaque and block the central cell type of the pathological process – the macrophage. Covered with the inert antiopsonization polymer PMOXA, the nanocontainers (diameter 100–200 nm) have long circulation lifetimes, allowing them to leave the circulation in sites with a disrupted endothelial layer such as the vulnerable plaque. Functionalized with the polynucleotide tracking ligand polyguanylic acid [339] by multi-functional biotin–avidin–biotin bonds [32], the nanocontainers bind specifically to a highly upregulated receptor subtype of active macrophages called scavenger receptor A1 [340]. It was shown that these innovative, functionalized nanocontainers reach specifically active macrophages that express the scavenger receptor A1 and do not reach macrophage precursor cells and tissue macrophages with a low grade of upregulation [32] (Figs. 5.7–5.9).

#### 5.4.6

##### **Other Targets**

PEGylated liposomes coated with plasminogen were designed for fibrin clot targeting. The plasminogen serves as a targeting moiety, because it binds to the fibrin in clots that block the blood flow in a case of heart infarction, lung embolism or stroke. The liposomes were filled with the fibrinolytic substance plasminogen activator, which triggers the degradation of fibrin in the clot and allows the reperfusion of the infarcted area [341].

PEGylated liposomes labeled with the targeting moiety RGD peptide (containing the arginine–glycine–aspartic acid sequence) were designed for targeted delivery to  $\alpha_v$  integrin receptors on endothelial cells [342, 343]. The liposomes can be filled with different drugs such as angiogenesis inhibitors, which block this important

**Figure 5.7.** Scavenger receptor A1-mediated uptake of polyguanylic acid-functionalized polymer nanocontainers into intracellular vesicles (for details refer to Ref. [32]). PMOXA–PDMS–PMOXA triblock copolymer nanocontainers (diameter 100–200 nm) were functionalized with the oligonucleotide tracking ligand polyguanylic acid for macrophage scavenger receptor A1 targeting via biotin–avidin–biotin bonds. In cell cultures expressing the enhanced green fluorescent protein

(EGFP)-labeled scavenger receptor A1, rapid binding to the target receptor was detected by fluorescent microscopy. The nanocontainers were filled with the hydrophilic red fluorescent dye sulforhodamine B and can be detected both on the cell surface and in intracellular vesicles, most probably lysosomes. The colocalization of receptor (green, left) and nanocontainer (red, right) proves the receptor-specific targeting.

**Figure 5.8.** Functionalized polymer nanocontainers bound to macrophages (for details refer to Ref. [32]). The same functionalized nanocontainers as in Fig. 5.7 were targeted to endocytosis-inhibited macrophages in culture. Precise analysis of the experimental macrophages by scanning

electron microscopy discovered the presence of vesicular formations (diameter 100–200 nm) on the macrophage cell membrane, most probably the intact nanocontainers. Unfunctionalized nanocontainers lacking the tracking ligand polyguanylic acid did not bind to the activated macrophages.

**Figure 5.9.** Functionalized polymer nanocontainers bound to macrophages – detail (for details refer to Ref. [32]). Same set-up as in Fig. 5.8; the scanning electron micro-

scopy image offers a unique insight into the morphology of polymer nanocontainers bound to the macrophage surface.

step in the development of disease conditions such as atherosclerosis and especially cancer.

Asialoglycoprotein receptor (ASGP-R) ligands such as asialofetuin and galactosylated cholesterol, glycolipids or polymers coupled to PEGylated liposomes or other carriers were used for hepatocyte targeting of both drugs and gene sequences for gene therapy [344–347]. Other strategies for hepatocyte targeting of lipid emulsions involve the use of the lipoprotein protein ApoE as a tracking ligand [348].

The last topic we want to discuss is the field of cell-penetrating peptides, which enable the invasion of nanovehicles into the cytoplasm of the target cell [31]. Cell-penetrating peptides are naturally occurring in viruses such as HIV, herpes virus and hepatitis B virus, and in macroorganisms such as *Drosophila*. They can be divided into two classes: the lysine-rich amphipathic helical peptides (e.g. transportan [349] and model amphipathic peptide [350]) and the arginine-rich peptides (e.g. TAT [351, 352], Antp [353], VP22 [354] and penetratin) [355–359]. We will discuss the principles and applications of the most important cell-penetrating peptide, the TAT (transactivating transcriptional activator) peptide, which is a central protein of HIV [31].

After binding to cell surface receptors such as  $\alpha_v\beta_5$  integrin [360], TAT is internalized rapidly and is transported to the nucleus, where it transactivates the HIV promoter [352]. The uptake of TAT peptide and TAT-coupled small molecules is thought to be triggered by strong electrostatic binding of the peptide to the cell membrane, upon which the peptide enters an energy-independent nonlysosomal endocytic pathway [361–363]. On the other hand, TAT-functionalized nanovehicles are taken up by the cell by an energy-dependent macropinocytosis, followed by a facilitated endosome escape into the cytoplasm [356, 364].

TAT-coupling was tested for intracellular and intranuclear delivery of various proteins and peptides [365–368], genes [369–371], oligonucleotides [372], antibodies [373, 374], imaging contrast agents for scintigraphy and MRI [375–377], and finally of various macrostructures. It was shown that TAT-coupling improved the fast and nondegrading internalization of dextran-coated superparamagnetic iron oxide nanoparticles (mean diameter 41 nm) into white blood cells [378, 379], of gold nanoparticles into cell cultures [380] and of various PEGylated liposomes [381–383].

## 5.5

### Conclusion and Outlook

In this chapter, we have defined the major obstacles and barriers that have to be overcome for a targeted delivery of diagnostic or therapeutic agents to a desired cellular or subcellular target. We have discussed microbial targeting and immune system evasion strategies, and tried to give an insight into the vast field of nanotechnology-based delivery tools. We are aware that we rather had to concentrate on general principles than on a precise summary of all available targeted delivery nanovehicles. We apologize to all groups that were not mentioned and we encourage them to send us material about their research activities for future publications from our side. Please refer to other chapters of this book and to the mentioned references for details on some special topics that were not fully covered in this chapter.

As we have seen, the field of targeted delivery using nanotechnological tools is an active and promising research area, and creates new ideas at a very fast pace. Clearly, nanotechnological targeted delivery will split into specialized subtopics in the future according to the desired target. Many medical disciplines such as neurology, cardiology, gastroenterology and surgery will profit from the toolbox of nanoscience that will revolutionize current diagnostic and therapeutic applications, and that will offer possibilities for new concepts.

The final goal of nanomedicine will be to create nanometer-sized, nontoxic and easily built carriers of complex functionality such as (i) undamaging epithelial barrier passage, (ii) long circulation lifetime, (iii) immune system evasion, (iv) controlled bloodstream extravasation, (v) target-specific deposition, (vi) undisruptive target cell invasion, and (vii) precise and (viii) automated diagnostic or therapeutic intervention (Fig. 5.10). Some these criteria have already been developed for certain nanovehicles, others will be developed in future years. Combining all of them will create an exciting and complex nanostructure – some will call it nanorobot or nanobot, others will call it an artificial virus, which is perhaps the best definition.

Obviously, such a nanorobot will create fear and concerns in the public, comparable to the concern we face nowadays with scientific topics such as biotechnology, stem cell research and bioterrorism. Miniaturized defense mechanisms penetrating and probably self-replicating artificial nanorobots that invade our body and have the ability to reach every organ and tissue are much more powerful than cur-

**Figure 5.10.** Theoretical construction of a long-circulating, receptor-specific nanocarrier with a highly complex functionality (such as cell invasion, intracellular transport, diagnostic and therapeutic agents).

rent scientific tools when it comes to creating worst-case scenarios. Therefore, it is fundamental that nanotechnology researchers understand this problem, and engage themselves actively and without legislative or media pressure in discussions about “nanotoxicity” [384–386] and “nanoethics” [387, 388], which were not covered in this chapter.

Only with careful considerations on the advantages and disadvantages of new technologies will it be possible to create nanoscaled tools that will help us to overcome severe and until now incurable diseases.

## 6 Nanoporous and Nanosize Materials for Drug Delivery Systems

*Yoshinobu Fukumori, Kanji Takada and Hirofumi Takeuchi*

### 6.1 Introduction

Nanomaterials have attracted much attention recently in the pharmaceutical field as structural components of pharmaceutical dosage forms. Such an application for nanomaterials has been found in coating materials in aqueous latex systems. Their use for granules and tablets has led to the successful development of many types of controlled release dosage forms. These have provided many excellent examples of nanostructure construction in micro- and macro-devices in the field of nanotechnology. In Section 6.2, nanomaterials for particle coating that are still useful and are expected to achieve further developments in pharmaceutical manufacturing, including commercially available polymeric nanoparticles, novel terpolymer nanoparticles, core-shell nanoparticles and biodegradable chitosan nanoparticles, are described.

Further, the recent development of biotechnology and its application to therapy and diagnosis requires nanoparticulate delivery of a variety of agents. The nanomaterials prepared for various purposes are simply analyzed according to their structural characteristics in Section 6.3.

In addition, the development of nanotechnology has produced many compounds that are specially structured to be nanoporous, and the obtained compounds are applied to many fields such electronics, microfabrication technology and biotechnology, including drug delivery systems. Section 6.4 deals with this hot and attractive topic. The purpose of drug delivery systems is to deliver drug molecules to their target sites for a desired period with a desired concentration. To accomplish this, several functions including sensing, targeting and controlled release are required. Nanoporous compounds are generally used to facilitate the controlled release function to drug delivery systems. Many nanoporous materials, mostly organic and some inorganic, have been studied for drug delivery system usage. Among them, calcium compounds like calcium carbonate ( $\text{CaCO}_3$ ), calcium phosphate [ $\text{Ca}(\text{H}_2\text{PO}_4)_2$ ], tricalcium phosphate [ $\text{Ca}_3(\text{PO}_4)_2$ ] hydroxyapatite [ $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ ] and silastic compounds are well-known drug delivery system carriers. In addition, nanofabrication technology has recently prepared new nano-

porous materials like carbon nanotubes (CNTs), fullerene and single-wall carbon nanohorns (SWNHs). These novel nanomaterials have also been used to clarify the possible biocompatibility, potential utilities and applications in biological settings, i.e. a drug delivery system carrier.

Section 6.5 will focus on the pharmaceutical application of porous silica, which includes both conventional and newly developed uses. One of the topics involves a solid dispersion system to improve the dissolution property of poorly water-soluble drugs. It is demonstrated that the well-ordered porous structure of silica particles can control the crystalline form of drugs in the solid dispersion system, which leads to a much improved dissolution rate. Mesoporous silica, having a highly controlled pore size and structure, is an attractive material. Some experimental data shown encourage us to use this novel material as a carrier of peptide drugs as well as poorly water-soluble drugs.

Thus, this chapter is the first challenge to describe the role of nanomaterials in pharmaceuticals in an integrated manner.

## 6.2 Nanomaterials for Coating

The pharmaceutical application of nanomaterials can be found in latex systems that have been used as coating materials for the last 40 years. Several types of latex are commercially used worldwide. Their application in granules and tablets has led to many controlled release dosage forms on the market. Therein, spray-coating processes such as fluidized bed, spouted bed and tumbling fluidized bed processes can easily provide multilayered particle structures with each layer being monolithic, a random multiphase nanostructure or ordered multiphase nanostructure, etc., as shown in Fig. 6.1. In general, the combination of different monolithic

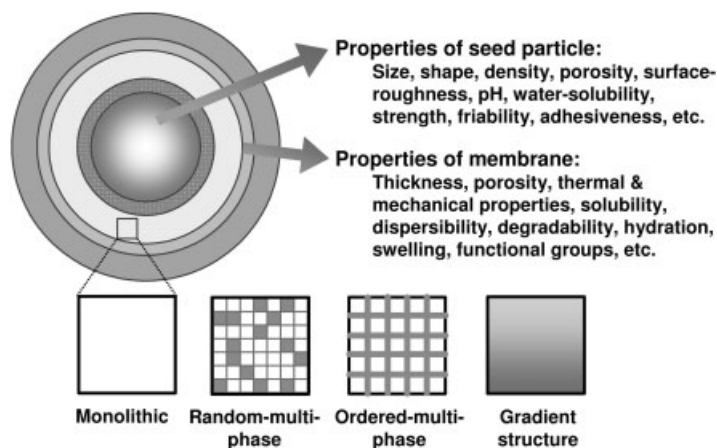

Figure 6.1. Construction of microparticles with nanomaterials.

nanomaterials and, especially, nanostructured nanomaterials can produce an almost infinite array of functional microparticulate products. However, commercially available latexes are formed as monolithic structures from random co- or terpolymerers that are designed to be used chiefly for coating such coarse particles as granules and tablets. For further and broader application of this technique, Fukumori and coworkers [1, 2] have been proposing the novel terpolymer and core-shell latexes through their development of fine particle-coating technology and highly functional microcapsules, such as thermosensitive drug-releasing microcapsules using sophisticated latexes with temperature-dependent swelling properties.

### 6.2.1

#### Commercially Available Aqueous Polymeric Nanomaterials

Table 6.1 lists commercially available nanomaterials for particle coating [1, 3, 4–16]. They are classified into two types based on the preparation methods [17]: (i) latexes synthesized by emulsion polymerization, and (ii) pseudolatexes prepared by emulsion processes such as emulsion-solvent evaporation, phase inversion and solvent change. Cellulose derivatives cannot be synthesized directly in latexes;

**Tab. 6.1.** Typical nanomaterials for coating

Brand	Supplier	Solubility	Main component	References
Aquacoat ECD	FMC	insoluble	ethylcellulose pseudolatex	4, 11, 13
Aquacoat CPD	FMC	enteric	cellulose acetate phthalate pseudolatex	
Surelease	Colorcon	insoluble	ethylcellulose pseudolatex	9
Eudragit RS30D	Röhm	insoluble	1:2:0.1 poly(EA–MMA–TAMC1) pseudolatex	7, 10–13, 16
Eudragit RL30D	Röhm	insoluble	1:2:0.2 poly(EA–MMA–TAMC1) pseudolatex	7, 16
Eudragit NE30D	Röhm	insoluble	2:1 poly(EA–MMA) latex	5, 6, 8, 11
Eudragit L30D	Röhm	enteric	1:1 poly(EA–MAA) latex	8, 12, 14
Eudragit FS30D	Röhm	enteric	7:3:1 poly(MA–MMA–MAA) latex	14–16
Kollocoat MAE30D/DP	BASF	enteric	1:1 poly(EA–MAA) latex	4
Kollocoat EMM30D	BASF	insoluble	2:1 poly(EA–MMA) latex	4
Kollocoat SR30D	BASF	insoluble	polyvinyl acetate latex	4

therefore, they are prepared as pseudolatexes (Aquacoat ECD [18], Aquacoat CPD and Surelease [19] in Tab. 6.1).

Eudragit™ L30D and NE30D are acrylic copolymer latexes synthesized by emulsion polymerization [20]. The particle sizes of these latexes are in the submicron order. L30D is a copolymer of ethyl acrylate (EA) as an ester component with methacrylic acid (MAA) (MAA:EA 1:1). It is used for enteric coating because of the presence of carboxyl groups in the copolymer. NE30D is a copolymer of ester components only, EA and MMA (2:1). The films formed from NE30D have a very low softening temperature ( $T_s$ ), and hence are flexible and expandable even under normal room conditions.

Eudragit RS and RL are terpolymers of EA and MMA as ester components with trimethylaminoethyl methacrylate chloride (TAMC1) as hydrophilic quaternary ammonium groups; RS and RL are 1:2:0.1 and 1:2:0.2 terpoly(EA–MMA–TAMC1), respectively. As Eudragit RS and RL contain MMA-rich ester components (EA:MMA 1:2), they have  $T_s$ s higher than those of NE30D (EA:MMA 2:1) and form hard films under room conditions. Eudragit RS and RL powders are easily transformed into pseudolatexes by emulsifying their powders in hot water without additives [20].

The film formation process from aqueous dispersion is shown schematically in Fig. 6.2. The mechanisms of film formation from aqueous polymeric dispersions have been discussed for a long time and many theories have been proposed. The

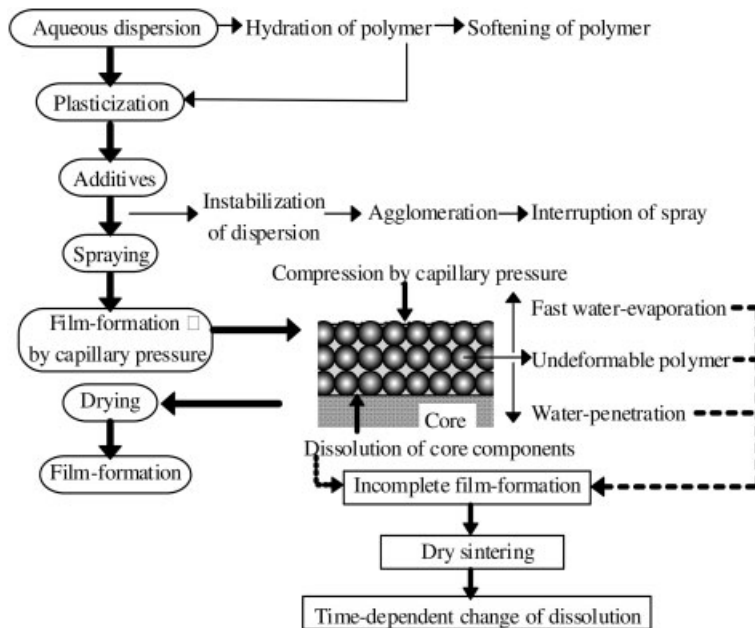

Figure 6.2. Film formation from aqueous dispersions of polymeric nanoparticles.

mechanisms were reviewed by Muroi [21]. Film formation in pharmaceutical applications was discussed by Steuernagel [18], Lehmann [20] and Fukumori [17]. Fusion and film formation of polymeric particles during the coating process can be explained by the wet sintering theory for particles suspended in water, the capillary pressure theory for particle layers containing water in various degrees of saturation and the dry sintering theory for dry particle layers. In all cases, as the particle size becomes smaller, film formation is further enhanced. This is the reason why nanomaterials have been used for aqueous suspension coating.

### 6.2.2

#### Novel Terpolymer Nanoparticles for Coating

The most serious problem encountered in fine particle coating using a wet-spraying process is agglomeration. Agglomeration takes place when coating materials supplied among seed particles possess a binding strength stronger than the separation force exerted on core particles. In water- or organic solvent-based solution systems, 10% of 53- to 63- $\mu\text{m}$  lactose particles was unavoidably agglomerated, although various additives to hydroxypropylcellulose (HPC) or ethylcellulose (EC) were sought to reduce the binding strength of sprayed materials [22–25]. In contrast, when aqueous lattices were sprayed, there were some cases where only a minor degree of agglomeration was observed, even for 32- to 44- $\mu\text{m}$  lactose particles [26].

In order to investigate latex as a candidate for spray liquid in fine particle coating, aqueous latexes of terpoly[EA–MMA–2-hydroxyethyl methacrylate (HEMA)] were newly synthesized [27, 28] (Fig. 6.3). When the molar ratio of the monomers used in polymerization was changed, the increase in MMA content raised the  $T_g$  of the cast film; HEMA affected  $T_g$  far less than MMA, but remarkably enhanced film formation and the release of a water-soluble substance (lactose) in aqueous medium. Further, when  $T_g$  was higher than the inlet air temperature, the terpolymer latexes exhibited a very low degree of agglomeration in the coating, due to their poor film-formability and, consequently, their low binding strength. This means

Figure 6.3. Chemical structure of poly(EA–MMA–HEMA).

that the drying/layering of latex particles has to be separated from the film-forming process to avoid agglomeration in fine particle coating; when both occur simultaneously, as in the solution systems; agglomeration of particles smaller than  $50\ \mu\text{m}$  cannot be avoided. This consequently led to a poor fixing efficiency of cosuspended solid particles, but the coating efficiency of the polymer dispersed as nanoparticles remained high [26]. This low tendency towards agglomeration was confirmed even in the coating of particles as fine as  $32\text{--}44\ \mu\text{m}$ .

### 6.2.3

#### Core-shell Nanoparticles for Fine Particle Coating

An aqueous latex exhibiting a low degree of agglomeration, low membrane permeation and high coating efficiency was developed using poly(EA-MMA-HEMA), whose monomer molar ratio was 6:12:8 or 12:6:4 [29]. Differing from blend latexes, the composite latexes (Fig. 6.4) composed of the low-permeable 12:6:4 polymer core and the nonadhesive 6:12:8 polymer shell with a 6:4 core-shell weight ratio formed a low-permeable membrane by curing. Thus, the 40% coated microcapsules of 53- to  $63\text{-}\mu\text{m}$  lactose released only 10% of the lactose at 3 h. Moreover, the composite latexes exhibited a very low degree of agglomeration, with the polymer yield remaining very high, and they did not induce any adhesive behavior during the coating operation. These properties were still effective even in the coating of cornstarch as fine as  $12\ \mu\text{m}$ : at a 50% level of coating, the mass median diameter of the product was  $16\ \mu\text{m}$  and it contained only 3% agglomerates. These results showed that by using the composite latex, particles of the order of  $10\ \mu\text{m}$  could be discretely coated as single-core microcapsules in the spouted bed process assisted with a draft tube.

However, there still remained five serious problems with the coating process of  $12\text{-}\mu\text{m}$  particles; (i) particle circulation and fluidization was too unsteady, (ii) the process was too time consuming, (ii) drug loading by spraying was not accom-

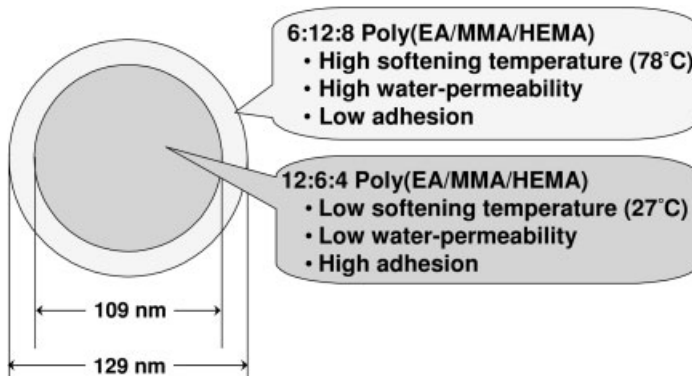

Figure 6.4. Composite nanoparticle with a core-shell structure for fine particle coating.

**Figure 6.5.** Microcapsules coated with composite nanoparticles with a poly(EA–MMA–HEMA) core and a poly(NIPAAm) shell.

plished because the corn starch particles were too small to avoid agglomeration, (iv) surfaces of the coated corn starch were too rough and porous to be cured by heating, and (v) to avoid agglomeration of core particles, spray liquid flow had to be adjusted to a low rate, leading to particle adhesion to the chamber wall due to electrostatic charge. Thus, in order to overcome the last two problems, aqueous composite latex that suppressed the particle adhesion in the coating process and had a self-film-formability in water was developed as a coating material [30]. This composite latex consisted of a poly(EA–MMA–HEMA) core and a thermosensitive poly(*N*-isopropylacrylamide) (NIPAAm) shell (Fig. 6.5). When compared to homogeneous latexes with no poly(NIPAAm) shell, the composite latexes reduced the production of poorly coated particles and the particle size dependence of polymer yield when the coating operation was done at a temperature where poly(NIPAAm) shells were able to swell, i.e. below the lower critical solution temperature (LCST: 32 °C) of poly(NIPAAm). Further, the microcapsules coated with the composite latexes also exhibited a self-film-formability in water at 37 °C, resulting from shrinkage of the poly(NIPAAm) shells in the membrane at temperatures above the LCST.

#### 6.2.4

#### Core–Shell Nanoparticles for Thermosensitively Drug-releasing Microcapsules

Recently, much attention has been focused on thermosensitive controlled-release systems developed from polymer networks with specific temperature-dependent swelling behaviors [31, 32]. In these systems, temperature variation triggers alteration of polymer configurations, leading to a thermally responsive change in the release rate of therapeutic agents to the systems.

One of the important issues in current thermosensitive release systems is how to facilitate the swelling/shrinking rate of hydrogels involving thermosensitivity. Improving swelling kinetics is an important subject for controlled drug release,

Figure 6.6. Microcapsules exhibiting positive thermosensitive drug release.

particularly pulsatile release with a thermal “on-off” switching response. The gel swelling/shrinking rate can be increased by an appropriate molecular and structural design of the polymer network. These include hydrogels with macroporous [33] and comb-type structures [34]. Incorporating thermosensitive hydrogels into fine particulate systems may be an alternative approach to make systems respond more rapidly to an external temperature change. Additionally, their small dimensions simultaneously offer considerable advantages over disk- or film-shaped macrogels hitherto developed in terms of a wide variety of biomedical applications.

The composite latexes composed of a hydrophobic poly(EA–MMA) core and a thermosensitive poly(NIPAAm) shell (Fig. 6.6) [35] were synthesized by a semicontinuous two-stage emulsion polymerization technique. The poly(NIPAAm) shell was crosslinked with methylene bisacrylamide. The microcapsules with thermosensitive coats were prepared using a Grow Max (140) spouted bed coater assisted with a draft tube and bottom spray (Fuji Paudal, Japan), known as the Wurster process. The microcapsules were cured by heating at 80 °C for 12 h and their dissolution properties were tested by a column method.

The key structure of the microcapsule designed here is its composite coat, consisting of nanosized thermosensitive hydrogels dispersed in a thermo-insensitive polymeric matrix. Ethyl cellulose pseudo latex, Aquacoat ECD (Tab. 6.1), was chosen as the polymeric matrix. As the nanosized thermosensitive hydrogels, a newly synthesized composite latex with a poly(NIPAAm)-rich shell was used. It is well known that poly(NIPAAm) has a phase transition temperature (LCST) of around 32 °C in water. The crosslinked network (hydrogel) constituted from this polymer shows an inverse temperature dependence of swelling: the hydrogel swells by imbibing water below a lower gel collapse temperature (LGCT; temperature for complete deswelling), while it shrinks at temperatures above the LGCT. At high temperatures, therefore, the poly(NIPAAm)-gel domains in the microcapsule membranes shrink, probably leading to the creation of many voids in the mem-

branes. Consequently, the water permeability increases as if a molecular valve has been opened. Due to the voids thus formed, the drug release rate at high temperatures is expected to become higher than that at low temperatures.

In order to confirm the reversibility of thermosensitive changes causing swelling, hydrodynamic size changes of the composite lattices in response to a stepwise shift in temperature were measured by photon correlation. As the temperature was elevated, particle size gradually decreased up to approximately 35 °C, near the volume transition temperature of crosslinked poly(NIPAAm) in water. Above 35 °C, particle size did not remarkably decrease any further. On the other hand, particle size became large again upon cooling. There was no significant difference between the traces of the particle size changes upon heating and cooling, indicating thermally reversible changes in the swelling/shrinking of the poly(NIPAAm) shells on the latex particles. Such a reversible change is a prerequisite to facilitate an “on-off” pulsatile drug release from the microcapsules.

No significant thermosensitivity was found in the release rate of the microcapsules with only Aquacoat film. In contrast, the microcapsules with the composite latex-dispersing coat in an 85:15 blending ratio of Aquacoat and the composite latex exhibited pulsatile thermosensitive release rate changes. Additionally, these microcapsules demonstrated a positive thermosensitivity of drug release, i.e. high release rates at high temperature (50 °C) and low release rates at low temperature (30 °C), except for a less pronounced burst effect in the initial period at 30 °C. It is noteworthy that the sharp release rate changes from the “on” state to the “off” state, and *vice versa*, occurred within a few minutes. Fabrication of composite latex having nanosized thickness poly(NIPAAm) shells and thin microcapsule coats in the order of 10 μm would be responsible for the resulting fast response.

### 6.2.5

#### **Chitosan Nanoparticles for Microparticle Coating**

As is well-known, chitosan (poly[ $\beta$ -(1-4)-2-amino-2-deoxy-D-glucopyranose]) is a hydrophilic and cationic polysaccharide derived from chitin deacetylation, which is the second most abundant polysaccharide in the world after cellulose and a promising resource originating from crustaceans shells and insects [36]. Chitosan has some interesting properties such as acting as a bioadhesive (cationic), with biocompatible (nontoxic) and biodegradable (bioerodible) capabilities. Therefore, it has been investigated in depth, and used in various industrial and medical applications. Furthermore, these interesting properties make it one of the most promising biopolymers for drug delivery [37–46]. Indeed, chitosan has been studied as a drug carrier in various forms, such as tablets, beads, granules, microparticles and nanoparticles. In particular, micro/nanoparticles are the most widely studied as drug carriers for protein, peptide, vaccine and DNA delivery.

A wide variety of preparation methods of chitosan particles such as solvent evaporation techniques, multiple emulsion methods, spray-drying methods, electrostatic complex formation with anionic materials (ionotropic gelation) and block copolymerization have been investigated. These methods often require a crosslinking

agent, such as glutaraldehyde. While the use of the crosslinking agent produces hardened particles as well as a drug-release rate possibly controllable in response to the degree of crosslinking, the toxicity of the crosslinking agent would become a major concern. In addition, it leads to a low loading of anionic drugs because amino groups in chitosan responsible for electrostatic interactions with anionic drugs become unavailable due to the crosslinking reaction between the amino groups in chitosan and aldehyde groups in crosslinking agents.

Masui and coworkers [47] reported a study aimed at preparing noncovalently crosslinked chitosan nanoparticles (CNSs) without the use of any organic solvents and additives. For this purpose, an aqueous neutralization–precipitation technique was newly developed. They prepared chitosan nanoparticles in the range of 150–300 nm. Furthermore, spouted-bed spray-coating of protein-layered particles with the noncovalently crosslinked chitosan nanoparticles was carried out and their excellent performance as a biodegradable coating agent was then demonstrated.

### 6.3

#### Materials for Nanoparticulate Therapy and Diagnosis

In general, nanoparticles for drug delivery, such as in cancer therapy and diagnosis, are simply constructed, and have a core, shell and surface (Fig. 6.7) [48]. The core determines the particle size and generally consists of an inactive matrix, the active agent itself or an active agent-containing matrix. The shell chemically or physically bound to the core acts as a base to which surface molecules, that sometimes include active agents, are anchored or bound with or without intermediate spacers; in some cases, it acts as an active agent-dispersed matrix. The surface

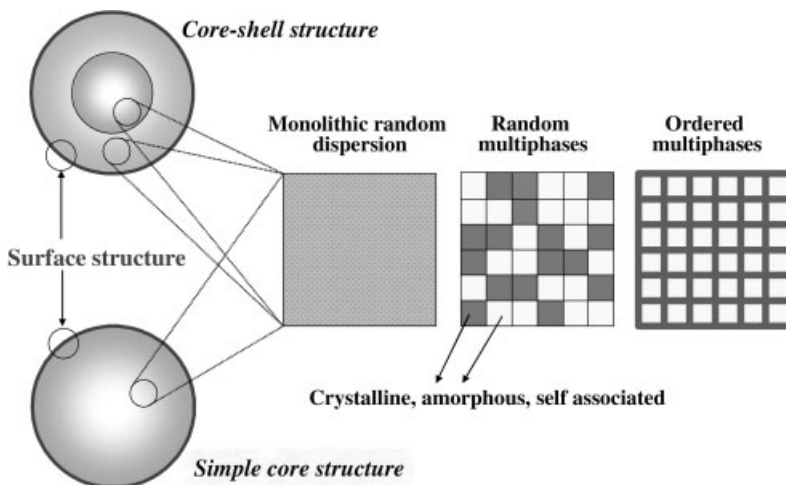

Figure 6.7. Typical structures of composite nanoparticles.

molecules strongly affect the biodistribution of the nanoparticles that usually consist of site-, tissue-, cell- and/or receptor-specific molecules (targeting agents). The poly(ethylene glycol) (PEG) molecules that possibly induce a bound water layer on the particle surface are attached to the shell or surface molecules by physical adsorption or covalent bonding with or without intermediate spacers. The mode of bonding used in particle construction is important from the viewpoint that the rate and timing of release or degradation of the components from the particles have to be controlled in order to achieve their biodistribution and active agent delivery in cancer treatment and diagnosis. The nanoparticles have to be degraded in the body and finally eliminated by globular filtration as molecules with a molecular weight of less than 30 000 or as particles with a size smaller than a few nanometers.

The structures of nanoparticles for cancer therapy and diagnosis are simple, as described above. Tables 6.2 and 6.3 show typical examples of the structures and components of nanoparticles.

### 6.3.1

#### **Inorganic Nanoparticles**

Recently, inorganic nanoparticles that interact with biological systems have attracted widespread interest in biology and medicine (Tab. 6.2). Such nanoparticles are thought to have potential as novel intravascular probes for both diagnostic (e.g. imaging) and therapeutic purposes (e.g. drug delivery). Critical issues for successful nanoparticle delivery include the ability to target specific tissues and cell types, and escape from the biological particulate filter – the reticuloendothelial system (RES).

Among inorganic materials, magnetite has been investigated most widely for cancer therapy and diagnosis [49–56]. Magnetite nanoparticles are used directly or dispersed in the polymeric matrix as cores. They have been used chiefly in hyperthermia treatment of cancer [49, 55] and, in some cases, for magnetic field-assisted targeting of nanoparticles [55]. For diagnostic purposes, they are used in magnetic resonance imaging (MRI) as contrast-enhancing agents for cancer diagnosis [49], hyperfusion region visualization [50], cell labeling in T cell-based therapy [51–53], and for detection of angiogenesis [50], apoptosis [54] and gene expression [56]. PEG [55] or oxidized starch [50] as a hydrophilic surface modifier, antibodies [49], fluorescein isothiocyanate (FITC)-labeled TAT peptide [51–53] or the Annexin V protein [54] as a specific targeting agent, and folic acid [55] or transferrin [56] as a ligand of the receptors overexpressed in tumor cells have been used as surface molecules.

Akerman and coworkers [57] (Tab. 6.2) explored the feasibility of *in vivo* targeting using semiconductor quantum dots. Quantum dots are small (less than 10 nm) inorganic nanocrystals that possess unique luminescent properties; their fluorescence emission is stable and is tuned by varying the particle size or composition. Akerman and coworkers showed that ZnS-capped CdSe quantum dots coated with a lung-targeting peptide accumulated in the lungs of mice after intravenous

injection, whereas two other peptides specifically directed quantum dots to blood vessels or lymphatic vessels in tumors. They also showed that adding PEG to the quantum dot coating prevented quantum dots from nonselective accumulation in reticuloendothelial tissues.

Tkachenko and coworkers [58] (Tab. 6.2) explored the ability of peptide-modified gold nanoparticles to target the nucleus of HepG2 cells. Five peptide/nanoparticle complexes were investigated to modify particles. They used gold nanoparticles because they are easy to identify using video-enhanced color differential interference contrast microscopy. Their studies highlight the challenges associated with nuclear targeting and the potential advantages of designing multifunctional nanostructured materials as tools for intracellular diagnostics and therapeutic delivery.

### 6.3.2

#### **Polymeric Nanoparticles**

The active agents are mostly incorporated in the cores to control or suppress their release. Polymers have been widely used as matrix materials. Table 6.3 shows examples of polymeric nanoparticles [59–78] that have recently been investigated for delivery; as an anticancer drug, doxorubicin, whose liposomes are on the market as Doxil™ (Alza) has often been used [62]. In these nanoparticles, biodegradable polymers, such as poly(lactic acid) (PLA) [59, 62], poly(lactic-co-glycolic acid), poly( $\epsilon$ -caprolactone) (PCL) [60, 61], chitosan [64, 69–72], poly(acrylcianoacrylate) (PACA), poly(lysine) [62] and poly(aspartic acid) [62], are used as the core matrix. Lipid [65, 78] and wax matrixes [63, 73–77] have also been used in nanoparticles, as shown in Tab. 6.2. The particles used in gene therapy are often cationic to enhance association with anionic cell surfaces and/or DNAs [63–66].

Kataoka and coworkers [62] developed block copolymer micelles for drug and gene delivery. They reported the utility of polymeric micelles formed through the multimolecular assembly of block copolymers as novel core–shell-type nanoparticles for drug and gene targeting. The segregated core embedded in the hydrophilic palisade was shown to function as a reservoir for genes, enzymes and a variety of drugs with diverse characteristics. Functionalization of the outer surface of the polymeric micelle to modify its physicochemical and biological properties was carried out for long circulation and receptor-mediated drug delivery.

### 6.3.3

#### **Other Case Studies**

A variety of methodologies of treatment and strategies of delivery have been applied to cancer therapy and diagnosis. In order to achieve an efficient outcome, nanoparticles have been designed using materials that are thought to be optimal for their respective applications. The following typical applications of nanoparticles have been reported: targeting lectin present on the intestinal epithelial cell surface by wheat germ agglutinin on a PCL matrix [67], antileishmania treatment by PCL matrix nanoparticles [68], gadolinium neutron capture therapy (GdNCT) by intra-

tumorally injectable chitosan nanoparticles [69–72] (Tab. 6.2) and wax matrix nanoparticles surface-modified with folic acid or thiamine whose uptake is enhanced in tumor cells [73–77] (Tab. 6.2), photodynamic therapy by solid lipid nanoparticles (SLNs) [78] (Tab. 6.2) or silicate matrix nanoparticles [79], application of dendrimer [80], antiangiogenesis radiotherapy by  $^{90}\text{Y}$  chelated on the liposome surfaces using an integrin antagonist [81], drug delivery to the brain by PACA matrix nanoparticles [82] and detection of antigen by immunolabeled europium-holding poly(styrene)nanoparticles [83].

## 6.4

### Nanoporous Materials as Drug Delivery System Carriers

#### 6.4.1

##### Inorganic Calcium Compounds

Nanoporous materials have been used as a drug delivery system carrier [84–86]. Among them, Higuchi and coworkers used hydroxyapatite as a carrier for delivering drugs to skeletal tissue at high enough local concentrations for desirable therapeutic effects [87]. Using a self-setting hydroxyapatite cement with cephalexin, norfloxacin and indomethacin (IMC), the cement was transformed into hydroxyapatite with affinity for hard bone tissue. Continuous *in vitro* drug release profiles from loaded cement pellets in phosphate buffer, pH 7.4, were obtained. As the cements have good biocompatibility in both periodontal and periapical environments, self-setting cement skeletal drug delivery systems are thought to provide temporary replacement therapy for bone [88].

Porous  $\text{CaCO}_3$  particles were reported to be useful as an intranasal carrier of insulin and hydrophilic compounds, because of their easy production and slow biodegradability [89–91]. However, the binding of adsorbed drugs to  $\text{CaCO}_3$  was weak, i.e. drugs and proteins were adsorbed on the surface of solid particles or porous  $\text{CaCO}_3$  material. Therefore, sufficient sustained release was not obtained. Mizushima and coworkers devised a simple method to incorporate hydrophilic drugs and proteins into nano- $\text{CaCO}_3$  and regulate the size of the particles. The mean particle size of the  $\text{CaCO}_3$  was 44.8–140.7 nm depending on the mixing speed of both particles and the drug. Sustained-release of erythropoietin (EPO), granulocyte colony-stimulating factor (G-CSF) and bethamethasone phosphate (BP) was observed for 1 week both in *in vitro* and *in vivo* experiments [92].

On the other hand, Ogawa and coworkers used porous hydroxyapatite particles, of which the mean inside diameter was 100 nm, as a drug delivery system carrier for long-term sustained release peptide/protein preparation for injection [93]. After protein drug is entrapped into the hydroxyapatite particles, the obtained particles are coated with a biodegradable polymer which has a hydrophilic part, as shown in Fig. 6.8.

Human growth hormone (hGH) was at first entrapped into nanoporous hydroxyapatite particles where an inorganic metal compound was added to prevent the initial release of hGH, i.e. burst phenomenon. The obtained particles were coated

**Figure 6.8.** Basic concept of a hydroxyapatite drug delivery system for sustained-release protein [10].

**Figure 6.9.** SEM images of a hydroxyapatite drug delivery system containing hGH [10].

with a hydrophilic biodegradable polymer like PEG–PLA. The mean particle size of the system is 5–8  $\mu\text{m}$ , as shown in Fig. 6.9. The hGH content of this system is around 15 wt%. About 80 mg of the preparation was injected to patients with dwarfism every 2 weeks with 27 G syringe needle. To evaluate the system, they injected the preparation into rats who received immunosuppressive therapy and it was confirmed that serum hGH levels were maintained over 2 weeks. In addition, the injected particles were not detected at the end of the experiment. They also performed a pharmacodynamic study using hypophysectomized rats. In the sustained-release hGH preparation group, the rat body weights gradually increased over 3 weeks. However, body weights did not increase in the control group rats [94].

#### Silastic Compounds

##### 6.4.2.1 Nanoporous Silastic Materials for Solidifying Oily Drugs

Porous calcium silicate, Florite™ RE (FLR; Eisai, Japan) has the structure of assembled petal-like flakes, presenting a lot of pores in its surface. Pores show a par-

**Figure 6.10.** SEM image of FLR ([www.eisai-fc.co.jp/](http://www.eisai-fc.co.jp/)).

ticular size distribution with two peaks at 12 and 0.15  $\mu\text{m}$ , which are attributed to interparticle and intraparticle pores, respectively. The mean inside diameter is 150 nm. FLR has a porous structure, as shown in Fig. 6.10, and has an excellent liquid-holding ability, about 5.0  $\text{mL g}^{-1}$ , through its numerous pores. Both FLR and colloidal silica (Aerosil™ 200, AER; Nippon Aerosil, Japan) have greater adsorption efficiency than other adsorbents, i.e. microcrystalline cellulose, cornstarch and lactose dibasic calcium phosphate. Although AER does not have interparticle pores, FLR has both interparticle and intraparticle pores. AER absorbs liquid into interparticle pores by forming liquid bridges among the particles. On the other hand, FLR adsorbs liquid into the interparticle pores by a capillary phenomenon.

As oily drugs do not dissolve in water, they are usually developed as a soft capsule preparation. As the size of the oily capsule preparation is large, pediatric and elder patients often have trouble swallowing them. In particular, when the oily capsule is taken with a small amount of water, the possibility of capsule adhesion onto the esophageal mucosa increases. In the worst case, esophageal ulcer occurs. To solve these problems, Takeuchi and coworkers formulated vitamin E acetate into a drug emulsion system with colloidal silica [95].

On the other hand, Hanawa and coworkers reported the solidification of ethenzamide (EZA) by a “melt-adsorption” method [96]. When EZA crystals were heated with FLR in a sealed glass ampoule without any solvent, EZA melted and adsorbed on FLR in an amorphous state. The dissolution rate of EZA from the preparation was greatly enhanced as compared with crystal EZA. To enable large-scale manu-

facturing, Kinoshita and coworkers used a twin-screw extruder, in which both temperature and kneading force can be controlled simultaneously [97]. The extruder allows EZA to melt and adsorb onto FLR. Therefore, the process is also called the “melt-adsorption” method. They prepared melt-adsorbed products of TAS-301 [3-bis(4-methoxyphenyl)methylene-2-indolinone] which were adsorbed on FLR using a twin-screw extruder. TAS-301 is an antirestenosis drug for use after percutaneous transluminal coronary angioplasty (PTCA). The crystallinity, solubility and oral bio-availability (BA) of TAS-301 in the melt-adsorbed products were examined. The particle size distributions of FLR, physical mixture [TAS-301:FLR (1:2)] and the melt-adsorbed product [TAS-301: FLR(1:2)] made by both methods were approximately consistent. The specific surface area decreased in the following order: FLR > physical mixture > melt-adsorbed product > TAS-301 crystal. The specific surface area decreased by mixing due to partial adsorption of TAS-301 on FLR and further decreased by heating due to its penetration into FLR pores. TAS-301 was amorphized by heating with an adsorbent above its melting point. In addition, the decreased crystallinity of TAS-301 was suggested by the endothermic X-ray diffraction (XRD) peaks. Therefore, both the amorphization and decreased crystallinity of TAS-301 might be associated with hydrogen bonding between the C=O group of TAS-301 and the syanol group of FLR. Although the solubility of the TAS-301 crystal and physical mixture was similar, the melt-adsorbed products prepared by both methods showed temporary super-saturation in water and their initial solubility was approximately 20-fold greater than that of the TAS-301 crystal. The dissolution rates of TAS-301 from the melt-adsorbed products prepared by the two methods were markedly faster than those from the physical mixture and the drug crystal. Figure 6.11 shows the results on the absorption of TAS-30 from the system

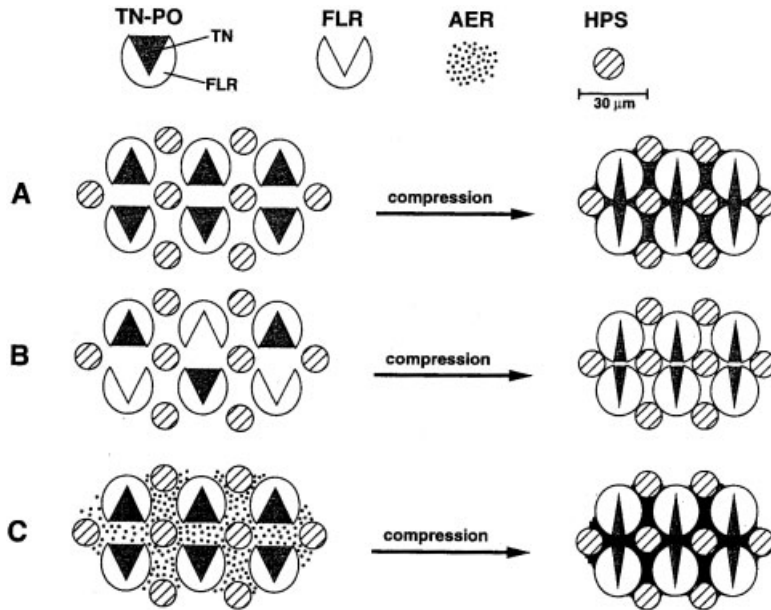

**Figure 6.11.** Plasma concentration of TAS-301 versus time profiles after oral administration of test preparations at a dose of 300 mg per dog.  $\blacktriangle$  = Melt-adsorbed product (capsule).  $\bullet$  = TAS-301 crystal (aqueous suspension).  $\circ$  = TAS-301 crystal (capsule). Each point represents the mean  $\pm$  SD ( $n = 3-6$ ).

after oral administration of three preparations to dogs being fed a standard diet. The AUC (area under the plasma drug concentration–time curve) values of the three test preparations were  $1.12 \pm 0.03$  (crystal suspension),  $1.18 \pm 0.43$  (crystal) and  $2.75 \pm 0.53 \mu\text{g h mL}^{-1}$  (melt-adsorbed products), respectively. Thus, melt-adsorption on a porous calcium silicate, FLR, is useful for improving the solubility and BA of hydrophobic drugs like TAS-301.

Yuasa and coworkers applied FLR to granulate a representative oily drug, *D,L*-tocopheryl nicotinate (TN), by adsorbing TN [98]. They also showed the possibility of tableting TN with FLR as an adsorbent and studied the possibility of the reduction of tablet coloration by TN exudation at compression, because TN was expected to be excluded from TN powder to the surface of the tablet by compression. With mixing, ethanol solution containing TN, 10–60 wt%, was added to FLR. After the adsorbents were dried, TN powder was obtained. In addition, TN powder was used to form granules. When the TN powder in which TN is adsorbed to FLR is compressed, the degree of tablet coloration caused by TN exudation from TN powder becomes larger with a higher TN content and compression pressure. It was clarified that the reduction of tablet coloration at tableting of TN is possible by compressing TN powder added with FLR or AER, both of which have a high liquid holding ability. In particular, when FLR is added at compression, a shorter disintegration time and a higher release property of TN were obtained when AER was added due to the difference of the liquid adsorbing and holding mechanism of FLR and AER. They proposed the models of the existent state of TN in the tablet at compression, which are shown in Fig. 6.12. When TN powder with hydroxypropylstarch (HPS) as a disintegrator is compressed, as shown in Fig. 6.12(A), TN is extruded by compression and reabsorbed by forming liquid bridges to the particles of TN powder and HPS. It was considered that the interparticle space decreased as these liquid bridges were formed, with the result that the penetration rate of water into the TN tablet decreased, and therefore the disintegration time was longer and the release rate of TN was slower. When TN powder with FLR and HPS is compressed, as shown in Fig. 6.12(B), TN is extruded by compression and reabsorbed to the pores in newly added FLR, with the result that a lot of interparticle spaces without TN are formed. In addition, they confirmed, by determining the pore size distributions in the tablets produced from FLR or AER alone, that the mean interparticle pore diameters among FLR or AER particles in the tablets were about 250 and 150+, respectively. It was considered that, since the interparticle space in the TNF tablet, i.e. the mean pore diameter, was larger than that in the TNA tablet, water easily penetrated into the TNF tablet. As a result, the disintegration time was shorter and the release property of TN was improved in comparison with TN and TN tablets with AER. When TN powder with AER and HPS is compressed, as shown in Fig. 6.12(C), TN is extruded by compression and reabsorbed by forming liquid bridges to the particles of TN powder, AER and HPS. When the formulated amount of AER increased, the disintegration time became shorter because the interparticle space without TN bridges increased. Furthermore, because the mean pore diameter of the TN tablet with AER is smaller and the amount of TN forming bridges to the particles in the TN tablet with AER is larger, it may be difficult to

**Figure 6.12.** Model of the existent state of TN at compression of (A) TN powder, (B) TN tablets with FLR and (C) TN tablets with AER where HPS was used as a disintegrator of tablets.

penetrate into the TN tablet with AER. As a result, the rate of TN from the TN tablet with AER was slower than that from the TN tablet with FLR.

Hwang and coworkers prepared silica particles containing retinal with a fabrication method using an oil/water/oil (o/w/o) emulsion and the sol-gel method [99]. By controlling the formulated amount of surfactants, Span 80 and Tween 20, sustained-release characteristics of retinal were obtained for 100 h.

#### 6.4.2.2 Nanoporous Silastic Materials for Poorly Absorbable Drugs

The BA of hydrophobic drugs after oral administration is very low due to their poor solubility in the gastrointestinal tract. Solid dispersion and microemulsion have been applied to improve the solubility of poorly soluble drugs [100]. These drug delivery system technologies are often used to improve the oral BA of insoluble drugs, e.g. cyclosporin A (microemulsion, Neoral<sup>TM</sup>) and tacrolimus (solid dispersion) [101, 102]. However, solid dispersion technology has limited applicability in improving the oral BA of drugs having both low solubility and low membrane permeability. The principles of the intestinal absorption mechanism of drugs are classified into the following categories: (i) passive diffusion, (ii) facilitated diffusion (endocytosis) and (iii) carrier-mediated active transport [103]. Active transport takes part in the absorption process of a limited number of drugs like vitamin B<sub>12</sub>, 5-fluorouracil, etc. [104]. Most of the clinically applied drugs are absorbed from the

gastrointestinal tract by a passive diffusion mechanism. In this case, the concentration gradient of drug molecules between the intestinal luminal side and the enterocytes is the rate-limiting process for the overall absorption process. In addition, absorption-enhancing technologies have been developed for poorly absorbable drugs, i.e. macromolecular drugs such as protein/peptide drugs, e.g. insulin, low-molecular-weight heparin (LMWH), etc. [105–107]. Emisphere developed nonacylated non- $\alpha$ -amino acid, sodium *N*-[8-(2-hydroxybenzoyl) amino] caprylate (SNAC) as an absorption enhancer for LMWH [108]. After oral administration of LMWH, 30 mg kg<sup>-1</sup> (4971 IU mL<sup>-1</sup>), in accordance with SNAC, 150 mg kg<sup>-1</sup>, the peak plasma LMWH level measured as an anti-Xa activity level of 1.2 IU mL<sup>-1</sup> was obtained. SNAC thus effectively enhanced the oral absorption of LMWH. However, after the oral administration of LMWH with SNAC, both LMWH and SNAC are diluted in the small intestine. Therefore, the absorption enhancing effect of SNAC is insufficient. Takada and coworkers used nanoporous silastic materials as oral drug carriers [109]. In their system, both the drug and absorption enhancer are held in the carrier at high concentrations. As the result of the high concentration gradients of the drug and absorption enhancer between inside the system and the enterocytes, the formulated drug can be efficiently absorbed. This drug delivery system technology is termed a “liquid formulation holding microparticulate system (LFMPS)”, as shown in Fig. 6.13. In the LFMPS system, a hydrophobic drug is solubilized in either an oil or water phase with the help of surfactant(s). Thus, the obtained particles can be formulated either as a capsule or tablet. After the

**Figure 6.13.** Concept of LFMPS. After oral administration of microparticles and adsorbent, holding both absorption enhancer and macromolecular drug-like protein drug in enteric capsules, the microparticles are

delivered to the enterocytes where high concentration gradients of enhancer and drug are formed. Consequently, high absorption efficiency of drug is obtained.

oral administration of LFMPs in an enteric capsule, the microparticles are exposed to the enterocytes, and form a high drug concentration gradient between the system and the enterocytes. In addition, when an absorption enhancer is formulated with the drug, good BA can be obtained. LFMPs can be also applied to highly soluble and poorly absorbable drugs that have a high molecular weight (e.g. gentamicin) [110] or high surface charge (e.g. LMWH) [111], resulting in poor membrane permeability. These drugs require the use of an absorption enhancer (e.g. surfactant) to improve their oral BA. The drug and absorption enhancer can be dissolved in water and, thus, the obtained mixture is introduced into the nanoporous material. Takada and coworkers first studied the effect of nanoporous materials on the BA of lansoprazole (LPZ) [109]. LPZ is a representative proton pump inhibitor, and has been clinically used in gastric and duodenal ulcerative disease therapy. LPZ is sparingly soluble in water and is unstable in the stomach, i.e. in gastric acid. According to the classification of drugs with low BA proposed by Amidon and coworkers [112], LPZ is a class II compound (low solubility and high membrane permeability) in the biopharmaceutical classification system (BCS). Clinically, gelatin capsules containing enteric-coated LPZ granules are supplied. Even if LPZ is protected from hydrolysis in the stomach, there is a possibility that LPZ does not dissolve well in the small intestine because of there being less water. Therefore, the oral BA of LPZ is low and shows wide intersubject variation. To solve these problems, nonionic surfactants were used to accelerate dissolution and improve the BA of LPZ. However, a liquid formulation is not as preferable as an oral formulation because no capsule can retain a liquid formulation without dissolution or degradation. LFMPs is composed of a surfactant, nanoporous adsorbent and LPZ. Its function is to improve the dissolution and absorption of LPZ. The BA of LPZ was measured in rats. As surfactants, Tween 80, polyoxyethylated, 60 mol, castor oil derivative (HCO-60<sup>TM</sup>) and PEG-8 caprylic/capric glycerides (Labrasol<sup>TM</sup>) were used. As adsorbents, porous silicon dioxide (Sylysia<sup>TM</sup> 550, 320), magnesium aluminosilicate (Neusilin<sup>TM</sup> S<sub>2</sub>, NS<sub>2</sub>N, US<sub>2</sub>) and porous calcium silicate (FLR) were used. Among the used surfactants, HCO-60 showed the highest absorption enhancing effect after the intra-small intestinal administration of LPZ solution. To solidify the LPZ solution with HCO-60, adsorbents were used and the obtained solid preparations were first used in an *in vitro* release experiment. Sylysia 320, Neusilin S<sub>2</sub> and Neusilin NS<sub>2</sub> showed a  $T_{50\%}$ , the time when half of the formulated amount of drug is released from the test preparation, of about 1 h. To evaluate the BA of LPZ from these solid preparations, an absorption study was performed in rats. The Sylysia 550 system showed a higher AUC than other systems, showing a BA of 28.1%. The Sylysia 550 system was placed in an enteric capsule and orally administered to dogs, and the BA was compared with an enteric tablet. The Sylysia 550 system had a BA of 71.7%, which was significantly greater than the enteric tablet. Thus, the solid system composed of LPZ, surfactant and nanoporous adsorbent, Sylysia 550, was shown to be a good system to improve the BA of LPZ.

Takada and coworkers also applied this system to gentamicin (GM), of which an oral preparation is not available because of a poor BA from the gastrointestinal tract [110]. As GM is a polar water-soluble compound, it is commonly recognized

that the intestinal membrane permeability of GM is poor. GM is a class III compound (high solubility and low membrane permeability) of BCS. They previously showed that the BA of GM was greatly increased by formulating GM in a self-microemulsifying drug delivery system (SMEDDS) using PEG-8 caprylic/capric glycerides (Labrasol™) as an absorption enhancer. Labrasol contains saturated polyglycolysed C<sub>6</sub>–C<sub>14</sub> glycerides, where C<sub>8</sub> is 58.1% and C<sub>10</sub> is 39.8%. Labrasol is a safe pharmaceutical additive, showing a high tolerance and low toxicity in animals; the LD<sub>50</sub> is 22.0 g kg<sup>-1</sup> for rats and is a surfactant listed in the European Pharmacopoeia. A SMEDDS is expected to self-emulsify rapidly in the aqueous environment of the small intestine, thereby presenting the drug in solution in small droplets of oil. The gentle agitation required for emulsification is provided by the digestive motility of the small intestine. By formulating GM in a Labrasol SMEDDS, a high BA value of GM, approximately 55%, was obtained after administration to the rat small intestine [113]. The dosage form that results from a SMEDDS is usually either a liquid or liquid-filled soft gelatin capsules. However, from the standpoint of pharmaceuticals, the solid dosage form is preferable to the liquid preparation in terms of cost-performance and the convenience of the manufacturing process. After GM was dissolved with Labrasol, the mixture was solidified with several kinds of adsorbents. The adsorbents were microporous calcium silicate (FLR), magnesium aluminometasilicate (Neusilin US<sub>2</sub>) and silicon dioxide (Sylsilia 320). An *in vitro* release study showed no significant difference between the three adsorbents. The *in vivo* rat absorption study showed that the preparation containing 10 mg of FLR had the highest C<sub>max</sub>, 2.14 ± 0.67 μg mL<sup>-1</sup> of GM. Other preparations had a C<sub>max</sub> of 0.69 ± 0.10 μg mL<sup>-1</sup> for FLR 20 mg, 1.07 ± 0.31 μg mL<sup>-1</sup> for Neusilin US<sub>2</sub> and 0.99 ± 0.21 μg mL<sup>-1</sup> for Sylsilia 320, respectively. The BA of GM from the FLR 10 mg system was 14.1%. The system was also evaluated in dogs after oral administration in an enteric capsule made of Eudragit S100. High plasma GM levels with a C<sub>max</sub> of 1.26 ± 0.20 μg mL<sup>-1</sup> were obtained. These results suggest that the FLR system is useful as an oral solid delivery system of poorly absorbable drugs such as GM [110]. LFMPs can also be applied to highly soluble and poorly absorbable drugs that have a high surface charge (e.g. LMWH) resulting in poor membrane permeability. Thus, LFMPs is a useful system for solving the low BA problem of both hydrophilic and hydrophobic drugs.

#### 6.4.2.3 Nanoporous Silica Materials for Controlled Release of Drugs

Calcium silicate was used as a porous carrier for repaglinide, an oral hypoglycemic agent, to prepare microspheres, and a gastroretentive floating drug delivery systems was challenged, as shown in Fig. 6.14 [114]. An *in vitro* release study showed the sustained-release characteristics of repaglinide for 8 h.

On the other hand, porous particle technology was applied to obtain an immediately dissolving intravenous preparation. Straub and coworkers prepared drug powder particles of paclitaxel, a water-insoluble hydrophobic anticancer drug. Ethanol solution containing paclitaxel, Tween 80 and polyvinylpyrrolidone (PVP) C15 was mixed with an aqueous solution containing the pore-forming agent, ammonium bicarbonate and mannitol. The mixture was spray-dried and porous dry

**Figure 6.14.** Gastroretentive floating drug delivery system made of calcium silicate-based microspheres.

powder particles (shown in Fig. 6.15) were obtained. The mean particle size was about 1  $\mu\text{m}$  and nanosize pores were formed. An *in vitro* dissolution experiment showed that more than 90% of paclitaxel was dissolved from the dry powder within 10 min, although about 80% of the authentic paclitaxel bulk was dissolved at 2 h after the start of the dissolution experiment [115].

Foraker and coworkers applied porous silicon (pSi) as a platform technology for a new generation of drug delivery systems. Macropores (above 50 nm), mesopores (2–50 nm) and nanopores (below 2 nm), occupying 1–95% of the Si volume, were used as a scaffold suitable for loading of drugs. As a model hydrophilic macromolecular drug, insulin was loaded into pSi particles by freeze drying, where sodium laurate was used as an absorption enhancer. Using an *in vitro* permeation system using Caco-2 monolayer, a 10- to 50-fold increase in insulin transport efficiency was obtained by the pSi particle system [116].

**Figure 6.15.** TEM image of a cross-section of paclitaxel porous particles.

## 6.4.3

**Carbon Nanotubes (CNTs)****6.4.3.1 CNTs for Oral Delivery of Protein Drug**

CNTs are produced by deposition of carbon atoms vaporized from graphite by an electric arc or by a laser onto metal particles. Recently, CNTs have been produced by the chemical vapor deposition (CVD) method. The obtained CNTs often aggregate into bundles or ropes. An individual CNT molecule is about 1 nm in diameter and several microns long [117]. The specific gravity of CNTs is very light because of their large outer and inner surface areas. The adsorption efficiency of CNTs is larger than the conventional adsorbents like silastic compounds. Takada and co-workers used CNTs as an adsorbent of both the absorption enhancer and drug, and the resulting system was evaluated as an oral drug delivery system for poorly-absorbable drugs like peptide/protein drugs [118]. Surfactants such as a saturated polyglycolysed C<sub>8</sub>-C<sub>18</sub> glyceride (Gelucire™ 44/14), Labrasol and HCO-60 were used as absorption enhancers at 50 mg kg<sup>-1</sup> and EPO was used as a model protein drug. As adsorbents, solid particles such as Sylysia 550, CNTs, carbon nanohorns (CNHs), fullerene, charcoal and bamboo charcoal were used. After either surfactant was loaded into the adsorbent by mixing well, disintegrator (Explotab™) was added and mixed thoroughly. Finally, EPO solution was added to this mixture and mixed well. The test preparations were directly administered into the rat small intestine at the EPO dose level of 100 IU kg<sup>-1</sup> and EPO absorption was studied by measuring serum EPO levels by ELISA. Labrasol showed the highest absorption

**Figure 6.16.** CNTs as carriers for oral delivery of macromolecular drug. After the oral administration of CNTs holding both absorption enhancer (Labrasol) and EPO in

enteric capsules, CNTs are delivered to the enterocytes where high concentration gradients of Labrasol and EPO are formed. Consequently, high absorption efficiency of EPO is obtained.

**Figure 6.17.** Serum EPO concentration versus time curve after small intestinal administration of CNTs holding both absorption enhancer (Labrasol) and EPO ( $100 \text{ IU kg}^{-1}$ ).

enhancing effect after intra-jejunum administration than Gelucire 44/14 and HCO-60. Therefore, Labrasol was used as an absorption enhancer for EPO and the systems were evaluated by an *in vivo* absorption model using rats. As in the case of LFMPS, CNTs can deliver both absorption enhancer and EPO by holding onto the enterocytes, and a high concentration gradient between the intestinal mucosal site and enterocytes is formed (Fig. 6.16). Scanning electron microscopy (SEM) image of CNTs used in this system is shown in Fig. 6.18. As a result, a high peak serum EPO level ( $C_{\max}$ ),  $62.7 \pm 11.6 \text{ mIU mL}^{-1}$ , was obtained. Other adsorbents showed lower  $C_{\max}$ s,  $25.9 \pm 3.7 \text{ mIU mL}^{-1}$  for Sylsya 550,  $18.7 \pm 5.3 \text{ mIU mL}^{-1}$  for CNH,  $50.0 \pm 11.4 \text{ mIU mL}^{-1}$  for fullerene,  $40.4 \pm 13.1 \text{ mIU mL}^{-1}$  for charcoal and  $34.1 \pm 7.5 \text{ mIU mL}^{-1}$  for bamboo charcoal, respectively. The other BA parameter, AUC, also showed the same absorption enhancing order. Among the used adsorbents, the BA values were in the order of CNT > fullerene > Sylsya 550 > CNH > bamboo charcoal > charcoal, where the BA of EPO from the CNT system was 6.7%. By formulating an enzyme inhibitor, casein, into the adsorbent system, the BA of EPO was increased, as shown in Fig. 6.17, where

**Figure 6.18.** TEM image of CNTs used for the oral delivery of EPO.

$C_{\max}$  was  $143.1 \pm 15.2$  mIU mL<sup>-1</sup>, resulting in the highest BA of EPO, i.e. 11.5%. Labrasol also showed good absorption enhancing effects on other poorly absorbable drugs like insulin, vancomycin and gentamicin [119, 120]. CNT is a good adsorbent of Labrasol for the oral delivery of these poorly absorbable drugs.

#### 6.4.3.2 CNTs for Intracellular Delivery of Protein

CNTs were applied to the intracellular delivery of drugs, genes and proteins. Kam and coworkers suggested the ability of single-walled CNTs (SWNTs) to penetrate mammalian cells and deliver various drugs i.e. peptides, the protein streptavidin (SA) and nucleic acids inside living cells, as shown in Fig. 6.19 [121]. The investi-

**Figure 6.19.** Confocal microscopy of cells after incubation in protein–SWNT (proteins labeled to be green fluorescent) solutions for 2 h.

(a) HL60 cells after incubation in SA–SWNTs. (b) HL60 cells after incubation in BSA–SWNTs. (c) HeLa cells after incubation in SA–SWNTs in the presence of the FM 4-64, a red membrane

and endocytotoxic vesicle marker. Yellow color in the image is due to colocalization of fluorescently labeled green proteins and red FM 4-64. (d) HeLa cells after incubation in cytochrome *c*–SWNTs in the presence of FM 4-64.

gated proteins were SA, protein A (SpA), bovine serum albumin (BSA) and cytochrome *c*. Intracellular protein transport and uptake by SWNT were also generic for various adherent and nonadherent mammalian cell lines, including HeLa, NIH-3T3 fibroblasts, HL60 and Jurkat cells. Energy-dependent endocytosis was confirmed to be the internalization mechanism. Furthermore, with cytochrome *c* as the cargo protein, they explored the fate of internalized protein–SWNT conjugates, attempted to release the conjugates from the endosome vesicles into the cell cytoplasm using chloroquine and investigated the biological functions of the released proteins. Once released into the cytoplasm of cells, the proteins can perform biological functions, i.e. apoptosis, or programmed cell death, induced by cytochrome *c* transported inside cells by SWNTs after their release from the endosomes. On the other hand, Pantarotto and coworkers and Bianco and coworkers showed that SWNTs were generic intracellular transporters for various types of proteins (below 80 kDa) noncovalently and nonspecifically [122, 123]. The SWNT uptake mechanism was suggested to be via insertion and diffusion through the lipid bilayer of the cell membrane. Therefore, a precise study must be performed to clarify the uptake mechanism of SWNTs. Thus, SWNTs may constitute a new class of molecular transporters for various *in vitro* and *in vivo* delivery applications.

Electroporation has been used to transfer molecules, like DNA or drugs, into living cells, where pulsed electric fields of several  $\text{kV cm}^{-1}$  in amplitude and submicrosecond duration are required. Thereby, membrane pores are formed temporarily and DNA or drugs penetrate. However, existing electroporation technology has limitations, i.e. a low efficiency. In addition, high electric field pulses lead to cell lysis. Chapana and coworkers applied CNTs to increase the efficiency of electroporation [124]. Their technology reduces to the nanoscale the large-scale process of electroporation by the use of CNTs as physical “electroporation vectors”. Their technique differs fundamentally from other methods used today, because electrodes are not needed. Water dispersible CNTs have an anionic surface charge attached to the surface of Gram-negative bacteria. This arises mainly due to an electrostatic interaction between the CNTs and the likewise charged bacterial surface. On the other hand, the effect of a microwave electromagnetic field pulse on the interaction of CNTs with the cells leads to electropermeabilization through individual CNTs. At first, they prepared water dispersible CNTs by treating them with acid solution for 1 h in a nitric:sulfuric (1:3) acid solution, which generates carboxylic groups at the ends as well as in the defects on the sidewalls of the CNTs. After purification, they obtained a stable CNT suspension with no precipitation after several months. Transmission electron microscopy (TEM) examination of the sample shows the presence of individual CNTs approximately 40 nm in diameter and less than 0.6  $\mu\text{m}$  in length. Plasmid DNA pUC19 was successfully introduced into *Escherichia coli* cells. TEM examination showed that the electroporation process proceeded through the intact cell wall of the suspended cells without inducing changes in their morphology. They could isolate pUC19 DNA from cultures made from blue colonies, because  $\beta$ -galactosidase activity was visualized by feeding the transformed cells a lactose analog called X-Gal that turns blue when hydrolyzed by  $\beta$ -galactosidase. Therefore, the transformation of *E. coli* was successfully facili-

tated by CNTs. CNTs having hollow structures were used to fulfill both requirements, i.e. electroporation and injection (nanopipette). If CNTs recognizing cell surfaces can be designed, it will be possible to deliver DNA molecules and colloidal particles confined in their interstitial channels to a particular cell type through the cell envelope and into compartments. These applications are new challenges in cell biology and biomedicine.

#### 6.4.3.3 Toxicity of CNTs

In the study of Takada and coworkers, CNTs were used as carriers of oral drug delivery systems. However, no toxicity information about CNTs after oral or systemic administration is available. On the other hand, when fine particles of CNTs are aspirated by humans, a health risk occurs. The Occupational Safety and Health Administration (OSHA) set the permissible inhalation exposure limit (PEL) for synthetic graphite at  $15 \text{ mg m}^{-3}$  of total dust and  $5 \text{ mg m}^{-3}$  for the respirable fraction [125]. Lam and coworkers performed a pulmonary toxicity study on SWNTs in mice 7 and 90 days after intratracheal instillation [126]. Three CNT products made by different methods and containing different types or amounts of residual metals, i.e. raw CNTs (RNTs) and purified CNTs (PNTs), iron-containing HiPco products of Rice and CarboLex's nickel-containing electric-arc product (CNT), were used for the toxicity study. For their study, mice were intratracheally administered 0, 0.1 or 0.5 mg of CNTs, a carbon black negative control or a quartz positive control and euthanized 7 days or 90 days after treatment for histopathological study of the lungs. All CNT products induced dose-dependent epithelioid granulomas and, in some cases, interstitial inflammation in the animals of the 7-day groups. The lesions persisted and were more pronounced in the 90-day groups; the lungs of some animals were also revealed to have peribronchial inflammation and necrosis that had extended into the alveolar septa. The lungs of mice treated with carbon black were normal, whereas those treated with high-dose quartz had mild to moderate inflammation. Their results showed that if CNTs reach the lungs, they are more toxic than carbon black and can be more toxic than quartz, which was considered a serious occupational health hazard in chronic exposures. Lung toxicity of intratracheally instilled SWNT was also studied in rats [127]. The lungs of rats were instilled either with 1 or  $5 \text{ mg kg}^{-1}$  of the following control or particle types: (i) SWNT, (ii) quartz particles (positive control), (iii) carbonyl iron particles (negative control), (iv) phosphate buffered saline (PBS) + 1% Tween 80 or (v) graphite particles. Exposures to high-dose ( $5 \text{ mg kg}^{-1}$ ) SWNT resulted in about 15% mortality in the SWNT-instilled rats within 24 h postinstillation. This mortality resulted from mechanical blockage of the upper airways by the instillation and was not due to inherent pulmonary toxicity of the instilled SWNT particulate. Exposures to quartz particles produced significant increases versus controls in pulmonary inflammation, cytotoxicity and lung cell parenchymal cell proliferation indices. Exposures to SWNT produced transient inflammatory and cell injury effects. Histopathological study indicated that pulmonary exposures to SWNT in rats produced a non-dose-dependent series of multifocal granulomas, which were evidence of a foreign tis-

Figure 6.20. Structure of *f*-CNTs.

sue body reaction and were nonuniform in distribution and not progressive beyond 1-month postexposure.

#### 6.4.3.4 Functionalized CNTs (*f*-CNTs) for Drug Delivery

As shown in Fig. 6.20, Bianco and coworkers synthesized several hydrophilic CNT derivatives called *f*-CNTs), *f*-CNT 1–8 [128]. The aqueous solubility and cationic surface character of *f*-CNTs 1 render them potentially novel delivery vehicles. They initially showed the efficiency of *f*-CNTs to transport across the plasma membrane and penetrate into the cytoplasm of cells. To obtain the proof of the concept experiment, they prepared two different FITC-labeled *f*-CNTs, by introducing either FITC directly to the amino functions of the soluble CNTs or a fluorescent peptide. Their molecular structures are shown as conjugate 4 and 8 in Fig. 6.20. This peptide mimics the effect of  $G_s$ -protein by increasing the agonist affinity for the P-adrenergic receptor. The free peptide did not penetrate the cell membrane. To evaluate the ability of the *f*-CNTs to penetrate HeLa cells, both conjugates were incubated with the cells and analyzed. The intracellular distribution of the fluorescence was studied by fluorescence microscopy. While *f*-CNT conjugate 4 with the FITC alone mainly distributed into the cytoplasm, slowly moving towards the nucleus, peptide–CNTs 8 rapidly translocated into the cell nucleus. The same results

were obtained using other types of cells including human and murine fibroblasts and keratinocytes.

#### 6.4.3.5 *f*-CNTs for Gene Delivery

*f*-CNTs were also used for gene delivery. Gene therapy is one of the possible methods for cancer and genetic disorder therapy. For gene targeting, viral and nonviral vector systems must be developed. However, these vectors have several pitfalls, i.e. induction of undesirable immune responses, inflammations and oncogenic side-effects. Therefore, nonviral vectors have been studied because of their higher level of safety. However, they have several limitations: (i) poor membrane permeability of the administered oligonucleotide and plasmid DNA conjugates, and (ii) low levels of gene expression. As a vector system, Bianco and coworkers also examined the potential of *f*-CNTs [128]. The observation of the ensuing supramolecular assemblies using TEM indicated that nanotube–DNA complexes were formed. In addition, they obtained a clear effect using the DNA complexes with *f*-CNTs 1 to carry the P-gal gene inside the cells, by monitoring the expression of P-galactosidase. Improved levels of gene expression were also obtained for the *f*-CNT 1–DNA complex in the range of positive:negative charge ratios between 2:1 to 6:1. Gene expression offered by the complexes between plasmid DNA with *f*-CNTs was 5–10 times higher than that of DNA alone. These promising results suggest the possibility of exploiting *f*-CNTs in gene therapy and genetic vaccination.

#### 6.4.4

#### CNHs for Drug Delivery

Single-wall CNHs (SWNHs) are aggregates of graphitic tubes that have closed ends with cone-shaped caps (horns). Each tube has a diameter of 2–3 nm, which is larger than the 1.4 nm of typical SWNTs, while the aggregates are 80–100 nm in diameter and have “dahlia-like” or “bud-like” spherical structures [129]. SWNHs have extensive surface areas and multitudes of horn interstices, which enable large amounts of guest molecules to be adsorbed on SWNHs [130]. Moreover, the surface area can be further enlarged by oxidization, which causes the formation of nanowindows in the SWNH walls [131]. Through these nanowindows, a variety of small molecules [e.g. N<sub>2</sub>, Ar and fullerene (C<sub>60</sub>)] infiltrate into their inner space and quadruple the adsorptive surface areas. In addition, the sizes of the pores can be controlled by changing the oxidization conditions. Murakami and coworkers prepared a series of oxidized SWNHs (oxSWNHs) having distinct molecular sieving effects and their utility as a drug delivery system carrier was studied using dexamethasone (DEX), an anti-inflammatory drug, as a model drug [132]. DEX was adsorbed on oxSWNHs. oxSWNHs (100 μg mL<sup>-1</sup>) were dispersed by sonication in 0.1–20 mL of a 1:1 mixture of ethanol and water and was filtrated with a 0.22-μm filter, after which DEX (1000 μg mL<sup>-1</sup>) in ethanol:H<sub>2</sub>O (1:1) solution was added at a volume ratio of 1:1. The resultant mixture was incubated at room temperature overnight and then centrifuged at 18 000 g for 5 min to collect DEX–oxSWNH

complexes, which were then dried in the vacuum overnight for experiments. At first, they studied the release characteristics of DEX from the DEX–oxSWNHs complex. In the case of *in vitro* release experiments in PBS (pH 7.4) at 37 °C, the amount of DEX released was nearly proportional to the incubation time, i.e. 7–10% per day during the first few days. The release rate then gradually declined and about 50% of the total bound DEX was released from the complex within a period of 2 weeks. When cell culture medium was used instead of PBS, distinctly different release profiles were obtained. Almost half of the DEX was released within the first 8 h, after which the release rates sharply declined, so that by 24 h about 50% of the total bound DEX had been released into the RPMI 1640 medium. As mentioned above, only about 10% was released into PBS during the same time period. One possible explanation for this difference in the release profiles is that hydrophobic organic compounds present in the culture medium are competitively absorbed onto the surface of oxSWNHs or they may increase the apparent solubility of DEX in medium. They also performed the biological assay of the DEX–oxSWNH complex and showed that the DEX released from DEX–oxSWNHs had biological activity.

Murakami and coworkers also applied oxSWNHs for the delivery of the anti-cancer drug, doxorubicin (DXR) [133]. At first, they prepared the complex, PEG–DXR, of PEG and DXR by introducing PEG into the amino groups of DXR. With PEG–DXR, oxSWNHs were well dispersed in water and the mean diameter was about 200 nm. The obtained PEG–DXR–oxSWNH had a strong antitumor activity in the *in vitro* assay system.

### Physicochemical Aspects of Porous Silastic Materials for Drug Delivery

In the pharmaceutical field, several porous materials, such as silica, calcium silicate [97, 98], controlled pore glass [134, 135] and porous cellulose [136], are used to formulate solid dosage forms. Among them, silica particles are characteristic in having many silanol groups on their surfaces, which may be able to form hydrogen bonds with drug molecules [137]. There are several grades of silica particles with different properties, such as particle size, degree of hydrophilicity and pore structure. Recently, a new grade of porous silica, mesoporous silica, has also been developed. It has been pointed out that the porous structure itself confers special characteristics, such as a decrease of melting point and a decrease in the crystallinity of drugs entrapped in the pores [134–136, 138]. Using these characteristics of porous silica particles, several applications have been reported in the field of pharmaceutical preparations.

In this section, two different types of applications with porous silastic materials, i.e. improvement in the drug dissolution properties and entrapment of peptide drugs for their sustained release, will be introduced.

## 6.5.1

**Solid Dispersion Particles with Porous Silica**

Improvement of the dissolution property of pharmaceuticals is extremely important, especially since the percentage of drugs with poor water solubility has increased in recent years. According to the Noyes–Whitney equation [139], the dissolution rate of a drug depends on its surface area and solubility. It is easier to increase the surface area by reducing the particle size of drug crystals than to increase the drug solubility. The particle size may be easily reduced by simple grinding. However, the ground crystals tend to agglomerate, thereby creating a surface with higher energy than that of the original crystals and reducing the effective surface area for dissolution.

To improve the dissolution properties of drugs, several methods have been studied as pharmaceutical engineering techniques such as grinding with additive [140], formation of salt [141] and preparation of an inclusion compound with cyclodextrin [142], as well as simple grinding [143]. Solid dispersion is a useful method to disperse drugs in the molecular state in a carrier matrix [144, 145]. The interaction between the drug molecule and carrier is responsible for drug dispersion, and may depress the crystallization of the drug in the prepared system. The most popular carrier materials are water-soluble polymers such as PEG [146] or PVP [147]. However, it is often reported that drugs prepared by solid dispersion with a water-soluble polymer carrier tend to be sticky or tacky. This property leads to a decrease in the recovery of solid dispersion in the preparation and also a difficulty in handling in the subsequent processes. Milling or mixing with other excipients is required before preparing the final dosage forms by plugging into capsules or tableting. These processes sometimes facilitate crystallization of the drug in an amorphous state in the solid dispersion. The change in the crystalline forms of the drug in the dosage form affects its BA after administration.

Takeuchi and coworkers [148] demonstrated that solid dispersion particles of a poorly water soluble drug, tolbutamide (TBM), could be prepared by spray-drying the diluted ammonium solution of the drug with nonporous silica, AER 200. The spray-drying technique is a useful method to obtain spherical particles with a small size and narrow distribution. This method also has the advantage that granulation and drying are completed in one step. It was also confirmed that the drug was molecularly dispersed in the matrix formed with silica particles. The resultant solid dispersion particles were free-flowing and remarkably improved the dissolution property of the drug.

In preparing the solid dispersion particles of TBM using porous silica (Sylysia 350; Fuji Silisia, Japan) as a carrier from ethanol solution, the metastable crystalline form (type II) was observed in the resultant particles [149]. It is well known that the drug crystalline form can be controlled by controlling the crystallization conditions, such as the type of solvent and crystallization rate. In the case of TBM, four types of crystalline forms including the stable form of type I and three types of metastable crystalline forms (types II, III and IV) were characterized based

on their physicochemical properties, and the dissolution, BA and stability of these polymorphs have been investigated [150–152].

To confirm the factors controlling the crystalline forms of drug in the silica solid dispersion particles, solid dispersion particles of TBM were prepared by formulating various types of silica such as nonporous [AER 200 (hydrophilic), AER R972 (hydrophobic)] or porous [Sylysia 350 (hydrophilic), Sylophobic 200 (hydrophobic)] silica as carriers and applying the spray-drying or evaporation method. In the solid dispersion particles prepared by the spray-drying method, TBM existed in a metastable form (form II) irrespective of the type of silica. On the other hand, when the evaporation method was used, various crystalline forms of TBM were observed in the solid dispersion particles depending on the type of silica. Polymorphs of forms III and IV were prepared with AER 200 and AER R972, respectively, while crystalline form II was obtained when either of the forms of porous silica, Sylysia 350 or Sylophobic 200, was formulated [149].

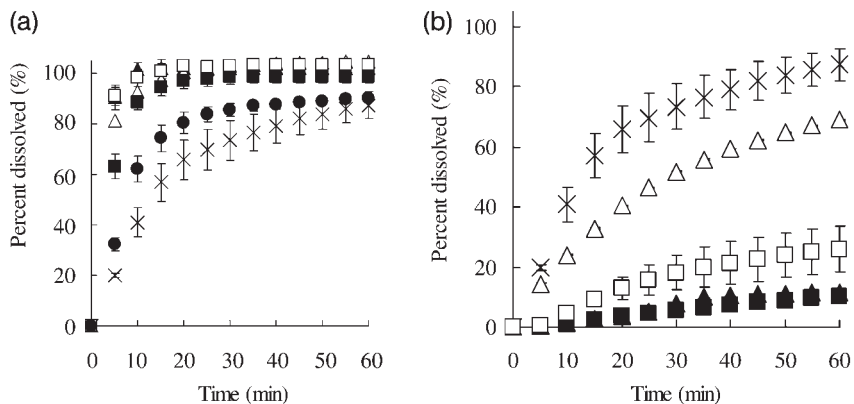

There may be two main factors affecting the final crystalline form of the drug in this process – the removal rate of solvent from the drug solution and the type of carrier formulated with the solid dispersion. The rapid solvent evaporation from the drug solution in the spray-drying method facilitated formation of the metastable form II of TBM in the resultant particles irrespective of the type of silica. Formation of this crystalline form was also observed for evaporation solid dispersion with porous silica (Sylysia 350 or Sylophobic 200), although the solvent evaporation speed was not rapid. In this case, formation of the metastable crystalline form (form II) may have been due to restriction of the crystallization of drug molecules in the pores of carrier particles during evaporation.

To examine the pore size effect on the resultant crystalline form of TBM in evaporation solid dispersion particles, several types of porous silica with different average pore sizes (Tab. 6.4) were used. The solid dispersion with Sylysia 740, having an extremely small pore size, showed metastable form III, while form II was detected in other types of silica solid dispersion. This result suggested that pores of this type of silica were not effectively utilized in this solid dispersion formulation. In the case of other porous materials, a similar tendency was observed. Porous cel-

Tab. 6.4. Properties of porous silica and other materials

Commercial name	Average particle size ( $\mu\text{m}$ )	Specific surface area ( $\text{m}^2 \text{g}^{-1}$ )	Pore size (nm)	Pore volume ( $\text{mL g}^{-1}$ )

from solid dispersion particles with AER R972 or Sylophobic 200 prepared by the spray-drying or evaporation method. × = Original TBM crystals; ▲ = spray-drying solid dispersion with AER R972; ■ = spray-drying solid dispersion with Sylophobic 200; □ = evaporation solid dispersion with AER R972; ○ = evaporation solid dispersion with Sylophobic 200.

lulose, having a small pore size of 4.0 nm, formed a mixture of forms II and IV in the resultant solid dispersion. The larger pore volume of porous cellulose than Sylysia 740 may be responsible for the formation of form II, although the average pore size of Sylysia 740 is as small as 2.5 nm. Another type of silastic particle, FLR, which has extremely larger pore volume, showed form II in the resultant solid dispersion. We should pay attention to the critical pore size and pore volume in using the porous silica as the drug carrier of solid dispersion [153].

The dissolution property of TBM was dramatically improved in the spray-drying solid dispersion system with hydrophilic silica (Sylysia 350 and AER 200), as shown in Fig. 6.21(a) [149]. Both the metastable crystalline form of the drug and the increased hydrophilicity of the solid dispersion particle may have contributed to this improvement. The latter effect was confirmed by measuring the drug dissolution of solid dispersions with the hydrophobic silica, Sylophobic 200 or AER R972. The spray-drying solid dispersion with the hydrophobic silica containing crystalline form II showed an extremely decreased dissolution rate (Fig. 6.21b). TBM of evaporation solid dispersion with Sylysia 350 and AER 200 showed a similar improved dissolution pattern to that of the corresponding spray-drying solid dispersion, as shown in Fig. 6.21.

The drug:carrier ratio is an important factor in designing an optimum solid dispersion system. In powder XRD analysis, the solid dispersion particles loading excess amount of drug, which was prepared in the formulation of TBM:silica =

5:1, showed much larger peaks than that prepared with the formulation of TBM:silica = 1:1. The resultant drug dissolution rate was decreased. When the spray-drying method was used, the results were almost the same [153].

From the practical point of view, the stability of metastable crystalline forms of drugs in the solid dispersion particles is an important factor in designing the final dosage forms. The metastable form of TBM in the solid dispersion particles was stable for at least 4 weeks when stored at 60 °C and 0% relative humidity (RH), while the spray-dried TBM without silica (form II) gradually changed to the stable form (form I) under the same storage conditions. Under humid storage conditions (60 °C, 75% RH), the spray-dried TBM without silica (form II) immediately converted into the stable form (form I) within 1 day, while TBM (form II) in the solid dispersions in a matrix of silica was stable for at least 1 week. In comparing their stability with respect to the type of carrier particles formulated in the solid dispersion, porous Sylysia 350 was more effective than nonporous AER 200. The same tendency was observed for the evaporation solid dispersion. As shown in Tab. 6.5, metastable form II in evaporation solid dispersion with Sylysia 350 was unchanged for up to 14 days, while metastable form III in AER 200 was converted to stable form I within the same storage period [149].

The effectiveness of porous silica as a solid dispersion carrier was confirmed using another model drug, IMC [154, 155]. IMC, whose solubility in water is 5  $\mu\text{g mL}^{-1}$  [156], has a tendency to form an amorphous state. This amorphous state property of IMC was examined extensively by many workers [157, 158]. Zografi

and coworkers [159, 160] reported the interaction of IMC and PVP at the molecular level and the effect of PVP on the inhibition of crystallization of amorphous IMC in the solid dispersion system. Yoshioka and coworkers also reported the crystallization of IMC from the amorphous state above and below its glass transition temperature [161].

The solid dispersion particles of IMC were prepared with nonporous (AER 200) or porous silica (Sylysia 350) in a similar way as for TBM solid dispersion [155]. The powder XRD charts shown in Fig. 6.22 show the decreased crystallinity of IMC for spray-dried IMC and the solid dispersion particles. IMC in solid dispersion particles is almost amorphous irrespective of the type of silica formulated. In characterizing them based on the trace size of the peaks in the powder XRD charts, the crystalline form of the spray-dried IMC was a mixture of the metastable form ( $\alpha$ -form) and stable form ( $\gamma$ -form), while the original IMC crystals were the stable form ( $\gamma$ -form). Differential scanning calorimetry (DSC) patterns of various types of IMC and IMC in solid dispersion particles are shown in Fig. 6.23. The profile of spray-dried IMC showed transformation of the amorphous part of IMC into the metastable crystalline form by heating. On the other hand, the solid dispersion particles containing amorphous IMC showed a trace endothermic peak at the lower temperature compared to the melting endothermic peak for the stable or metastable IMC crystals, which confirmed that the carrier prevented the crystallization of amorphous IMC. Comparing the small endothermic peak for the two types of solid dispersion particles with different types of silica, the area of melting peak of IMC in solid dispersion with Sylysia 350 is smaller and the position of the peak is at a lower temperature than that with AER 200. In general, the melting point of drug molecules in the pore is lower than that in the bulk state [162, 163]. Nakai and

**Figure 6.23.** DSC patterns of various types of IMC and solid dispersion particles with AER 200 or Sylysia 350. (A) Original IMC crystals ( $\gamma$ -form). coworkers reported this phenomenon with porous silica or porous cellulose as the carrier in the mixing system of drug crystals and the porous materials [97, 136, 138].

Figure 6.24 shows the dissolution profile of IMC from the solid dispersion particles with AER 200 or Sylysia 350 [155]. The dissolution rate of spray-dried IMC

**Figure 6.24.** Dissolution profiles of IMC from solid dispersion particles with AER 200 or Sylysia 350. + = Original IMC crystals ( $\gamma$ -form).  $\times$  = Spray-dried IMC.  $\circ$  = Solid dispersion particles with AER 200.  $\bullet$  = Solid dispersion particles with Sylysia 350.

particles was faster than that of original IMC crystals because of the decrease in particle size, crystallinity and change in the crystalline form. However, 100% of spray-dried IMC could not dissolve within 60 min. On the other hand, the dissolution profile of IMC in the solid dispersions particles was remarkably improved irrespective of the type of silica formulated. This might be due to the improvement in wettability and dispersibility in the medium as well as the decrease in crystallinity of IMC in the particles, as mentioned above for the TBM solid dispersion with silica. Comparing the dissolution profiles of solid dispersion particles with AER 200 and Sylysia 350, the dissolution rate of IMC from solid dispersion particles with Sylysia 350 was faster than that with AER 200. As the drug crystallinity of the solid dispersion particles is almost the same, the difference in wettability may be responsible for the difference in the drug dissolution rate of the two different types of solid dispersion particles.

The effect of wettability on the dissolution property was clearly demonstrated with the solid dispersion particle with Sylysia 740, whose average pore size is 2.5 nm (Tab. 6.4). The dissolution rate of IMC solid dispersion with Sylysia 740 was much decreased compared with that of Sylysia 350, although Sylysia 740 was also hydrophilic silica and the drug to silica formulating ratio was the same at 1:1 [154]. The measured specific surface areas of the solid dispersion particle with Sylysia 740 and Sylysia 350 were 7.4 and 99.5 m<sup>2</sup> g<sup>-1</sup>, while those of Sylysia 740 and Sylysia 350 were 700 and 300 m<sup>2</sup> g<sup>-1</sup>, respectively. The greatly decreased specific surface area of Sylysia 740 solid dispersion implied the stuffing of pores with silica, which may lead to the reduced dispersion of the drug molecule in the pore of the carrier and covering of the silica particles with the hydrophobic drug molecule, as illustrated in Fig. 6.25. Thus, the resultant drug dissolution was decreased due to the hydrophobic property of the solid dispersion. These results may show that the pore size of silica is an important factor in obtaining the improved dissolution profile of the solid dispersion system.

The stabilizing effect of porous silica on the amorphous state of drugs was the same as observed in the case of the metastable form of TBM. In a stability test,

**Figure 6.25.** Schematic drawing of the state of IMC molecules in the pore of solid dispersions with Sylysia 350 or Sylysia 740.

amorphous IMC in the solid dispersion particles with each of the silica particles did not crystallize under storing at severe storage conditions (40 °C, 75% RH) for 2 months, while amorphous IMC without silica easily crystallized under the same conditions.

Through these two examples mentioned above, we can conclude that the porous silica particle effectively forms solid dispersion particles of poorly water-soluble drugs. Although nonporous colloidal silica has a similar carrier property to form an amorphous state of the drug in the particles, porous silica is sometimes superior to nonporous silica from the point of the resultant drug dissolution property or stability of the amorphous or metastable state of the drug.

Watanabe and coworkers [137] have reported that controlled release of IMC with nonporous silica leads to an improvement in its BA in an *in vivo* experiment. For this experiment, IMC was compounded with silica (AER 200) by cogrinding or melt-quenching. The initial dissolution rate of the coground compound was lower than the melt-quenched one, although both of them showed higher dissolution rates than a simple physical mixture of crystalline IMC and silica. The lower dissolution rate of coground IMC was explained by a stronger chemical interaction between IMC and the mechanically induced siloxane dangling bonds on the surface of silica. The resultant AUC values of coground and melt-quenched compounds were 1711 and 1519  $\mu\text{g h mL}^{-1}$ , respectively, while that of the physical mixture was 751  $\mu\text{g h mL}^{-1}$ . These results suggested that the initial controlled release of the drug leads to a higher BA.

### 6.5.2

#### Mesoporous Silica

Mesoporous silica is a porous silica with tightly size-controlled pores of 2–50 nm. Two types of mesoporous silica, i.e. FSM16 [164] and MCM-41 [165], have been developed by two different groups separately [166]. Both of them have the same hexagonal pore structure, although the proposed structure formation mechanism is different. FSM16 can be synthesized from a layered silicate, kanemaitite, and a folding sheet mechanism was proposed. The process including the resultant structure of FSM16 is illustrated in Fig. 6.26 [166]. The pore size and specific surface area of FSM16 are 3.0 nm and around 1000  $\text{m}^2 \text{g}^{-1}$ , respectively. Although there are several reports on mesoporous silica dealing with the preparation process and application in catalysis, few papers are available in the field of pharmaceutical engineering [166].

We have examined the usefulness of this porous particle as a carrier of the macromolecular drug insulin, because its pore size is comparable to that of the macromolecules. The simple adsorption profile of insulin on FSM16 is shown in Fig. 6.27 [167]. By assuming Langmuir-type adsorption, the maximum adsorption amount was estimated as 137  $\mu\text{g mg}^{-1}$  of FSM16. The adsorption amount of insulin to Sylysia 350 or Sylysia 740 was low, although their surface area is comparable to that of FSM16 and the pore size of Sylysia 740 (2.5 nm) is similar to that of FSM16.

Figure 6.26. Formation and pore structure of FSM.

To increase the entrapment efficiency of insulin into the porous material, we devised a freeze–thawing method. Although the freeze–thawing method has been reported as a drug encapsulation method into liposomes, the concept of this freeze–thawing method for mesoporous silica is completely different. In this method, we used nonfrozen water formed in the pores of particles. In general, porous material has special properties such as a decreased melting point and forms nonfrozen water in the pores [162, 163]. It has also been reported that silica gel forms nonfrozen water on its surface and that nonfrozen water can be formed in the porous materials [168–170]. Morishige and coworkers [170] have observed that free water in the pores of MCM with a pore diameter of 4.2 nm was frozen abruptly around 232 K to give rise to cubic ice, while the water confined in the pores with a pore diameter of

Figure 6.27. Adsorption amount of insulin on FSM16, Sylysia 350 and Sylysia 740 at various concentration of insulin solution. Adsorption conditions: temperature = 5 °C; shaking time = 24 h.

Figure 6.28. DSC profiles of FSM16 containing water.

2.4 nm was frozen very gradually at lower temperature. To confirm the formation of nonfrozen water in FSM16, we measured DSC patterns of FSM16 containing water. As shown in the DSC chart (Fig. 6.28), two clear exothermic peaks in the freezing process and two endothermic peaks in the melting process were observed [167]. The peaks observed at the lower temperature may be attributed to the freezing and melting of water in the pores. In the case of Sylysia 350, such peaks were not observed, because the pore size was much larger than FSM16. In the case of Sylysia 740, similar peaks were detected because its average pore size is as small as FSM16. However, the peaks were very small compared with that of FSM16. This may be attributed to its large pore size distribution, as observed for normal silica.

In freezing the FSM16 suspension in drug solution, the drug solution may be concentrated in the pores when the bulk water is frozen and then the freezing is stopped just before freezing of the pore water. Based on the DSC analysis which showed the pore water was frozen at around  $-40^{\circ}\text{C}$ , the freezing temperature in the freeze–thawing method was set at  $-30^{\circ}\text{C}$ . Figure 6.29 shows the increased entrapment of insulin into FSM16 using this freeze–thawing method. The entrapment amount increased by increasing the number of freezing–thawing cycles. When the freezing temperature was set at  $-100$  instead of  $-30^{\circ}\text{C}$ , the efficiency was much reduced. This result confirmed our assumption stated above for the mechanism of drug entrapment in the freeze–thawing method. In both cases of Sylysia 350 and Sylysia 740, the entrapment amount of insulin was in the range of  $50\text{--}100\ \mu\text{g mg}^{-1}$ , even by applying this freeze–thawing method (10 times) [167].

The drug release from the insulin-loaded FSM16 was measured *in vitro*. The result showed that half of the entrapped insulin was released within 1 h (burst re-

**Figure 6.29.** Entrapment of insulin into FSM16 with the freeze–thawing method. Initial adsorption conditions: temperature = 5 °C; shaking time = 24 h. \*Maximum adsorption amount of insulin on FSM16 calculated with the Langmuir adsorption isotherm (137.0  $\mu\text{g mg}^{-1}$ ).

lease) followed by a very slow and sustained release (1.3  $\mu\text{g mg}^{-1}$  of FSM16  $\text{day}^{-1}$ ). To utilize mesoporous silica as a drug carrier, it may be important to control the burst release. This might be achieved by modifying the entrance of the pores of FSM with some hydrophobic molecules.

To check the effectiveness of the freeze–thawing method in the encapsulation of macromolecules, three types of FITC–dextran with different molecular weights (4400, 9500 and 21 200) were selected as a model drugs [171]. When the adsorption amount of these FITC–dextran was compared under the same conditions, where 10 mg of FSM16 was dispersed in 1  $\text{mg mL}^{-1}$  of drug solution at 5 °C, the adsorption amount of FITC–dextran depended on their molecular weight, in the order of FITC–dex4400 > FITC–dex9500 > FITC–dex21200. In applying the freeze–thawing method to the entrapment of these FITC–dextrans, the entrapment amount was increased, as shown in Fig. 6.30. As the adsorbed amount of FITC–dex9500 and FITC–dex21200 was very small in the simple adsorption process, their adsorption amounts to FSM16 with the freeze–thawing method were 6.1 and 20.7 times higher compared with a simple adsorption procedure, respectively.

FSM16 is also an excellent carrier for poorly water-soluble drugs with low molecular weight as well as usual porous silica (as discussed in the previous section). We prepared a solid dispersion of beclomethasone propionate using FSM16 as a carrier in the same manner as for the Sylysia solid dispersion [172]. The simple adsorption amount of drug to FSM16 in the dichloromethane solution was large and the maximum adsorption amount was estimated as 333.3  $\mu\text{g mg}^{-1}$  of FSM16. In the case of Sylysia 350, the estimated maximum adsorption amount was 156.3  $\mu\text{g mg}^{-1}$  FSM16. In the dissolution test, FSM16 solid dispersion showed a supersaturated concentration of the drug, which was 3 times higher than the saturated concentration, while Sylysia 350 solid dispersion showed almost the same drug concentration as the crystalline drug. The different drug dissolution phenomenon

**Figure 6.30.** Entrapment of FITC–dextran with different molecular weights (4400, 9500 and 21 200) into FSM16 with the freeze–thawing method. Conditions of entrapment test: FITC–dex.sol., 1 mg mL<sup>-1</sup>, 1 mL solvent (Mcllvaine buffer, pH4.0); silica; FSM16 (10 mg); freezing temperature = –30 °C. \*Maximum adsorption amount of FITC–dex4400 on FSM16 calculated with the Langmuir adsorption isotherm (22.57 µg mg<sup>-1</sup>).

for FSM16 and Slysia 350 solid dispersions suggested different adsorption modes or forces between the surface of the silica and the drug molecule.

Tozuka and coworkers [173] recently investigated the adsorption and entrapment of salicylamide molecules into FSM16. They confirmed crystalline salicylamide converted into an amorphous state on heating at 120 °C for 3 h. By measuring a shift in the fluorescence emission peak of salicylamide in the carrier, they suggested dispersion of the drug molecule into the hexagonal channels during the heating process. It was also demonstrated that the dissolution rate of the solid dispersion was higher than the crystalline one.

As mesoporous silica such as FSM16 is quite a new product, for which large-scale production processes are still being developed, the number of reports in the pharmaceutical field is small. However, data shown in this section may indicate its unique characteristics due to its extremely high surface area and tightly controlled pore size. A lot of interesting data should follow in the near future.

**NANOEGG<sup>®</sup> Technology for Drug Delivery**

*Yoko Yamaguchi and Rie Igarashi*

## 7.1

**Introduction**

Retinoids, the natural and synthetic metabolites and analogs of vitamin A (retinol), are important regulators of epidermal proliferation and differentiation [1–6]. All-*trans* retinoic acid (ATRA, vitamin A acid) is the major naturally occurring biologically active form among retinoids. In various epithelia that normally keratinize, ATRA inhibits keratinization and induces mucous metaplasia [7, 8]. Nevertheless, ATRA has been a focus of research into topical treatments for aged skin for more than 15 years. In 1986, Klingman and coworkers [9, 10] reported that ATRA could produce smoother, less wrinkled and less pigmented skin after a few months of treatment. Melanin loss and less-wrinkled skin are, however, frequently accompanied by excess skin irritation after ATRA treatment [11]. Clinical responses predominantly comprised severe irritant dermatitis in the early stages of application (around 3 or 4 days). Such damage with a high magnitude of inflammatory events after ATRA treatment can induce chronic skin pigmentation on the area being treated, potentially resulting in imperfect repair of skin displaying a pigmented appearance. Inflammation can occur through at least two mechanisms: the acidic function (-COOH) of the terminal domain is in principle an inducer, and the presence and long-term adhesion of ATRA molecules on the stratum corneum epidermidis would presumably act as a strong irritant. Preventing undesirable adverse effects would be expected to allow ATRA therapy to overcome the limitations of classical ATRA therapy.

In this chapter, we describe the development of a novel drug delivery system using nanotechnology with a core-shell structure using a boundary-organized nanoscale reaction. This reaction is based on the biological control of mineralization which refers to the general biochemical activity of the cells [12]. In the enclosed environments, the cells have several important functions, including spatial delineation, ion accumulation, mineral nucleation and transportation. Phospholipid and polypeptide vesicles, cellular assemblies, and macromolecular frameworks can be assembled into enclosed permeable structures that provide diffusion-limited spaces for biomineralization processes. The study of biomineralization offered valuable

insights into the scope of materials chemistry at the organic–inorganic interface. Mann [13] began some examples that involved biomineral-inspired approaches for the synthesis of inorganic nanoparticles using boundary-organized nanoscale reaction droplets. Reverse micelles, microemulsions, vesicles and lipid bilayer films are templates for the nucleation of minerals. The synthesis of nanoparticles with a core–shell (minerals) structure requires the supramolecular assembly of structures that contain chemical reactions or phase transformations.

The conceptual framework in this study is that the preparation of ATRA nanoparticles with a core–shell structure (NANOEGG) plays a crucial role in solving the low permeation of ATRA into spaces in the stratum corneum epidermidis and the strong symptoms of irritation. Preparation of NANOEGG particles was achieved using boundary-organized nanoscale reaction droplets [13]. The strategy in which micelles are utilized as a drug carrier is already well known in the drug delivery system field. Although the normal micelles are thermodynamically stable, for human application there remains the problem of stability of micelles in blood after the injection. As a result, drugs included in micelles would be immediately released. Thus, a micelle system is occasionally not enough to control the long-term drug-release kinetics. The novel NANOEGG system is not in the equilibrium state because ATRA molecules cannot migrate from the micelle self-assembly to the continuous aqueous phase due to an inorganic coating on the surface of the micelle. It can be expected that NANOEGG will improve the potential of micelles in the drug delivery system field. This chapter provides a novel drug delivery system technology such that NANOEGG may not only prevent adverse effects, but also markedly enhance its main effect. Indeed, this technology would become an evolution of classical ATRA therapy and may enhance the potential utility in the topical drug delivery field.

In Section 7.2, the discussion focuses on the equilibrium and kinetic parameters that govern the behavior of ATRA within aqueous phase, and how the core–shell structure of NANOEGG is prepared, and the shelf stability of ATRA molecule, which is one of the improved points of NANOEGG structure, is explained. The possible implications of NANOEGG for the pharmacological mechanisms underlying the dermatological aspects of ATRA biology are then considered. In final section, as well as other aspects and drugs of NANOEGG, attention is placed on the role of NANOEGG in regeneration medicine, especially diabetes therapy medicine.

## 7.2

### New Nanoparticles with a Core–Shell Structure: The NANOEGG System

#### 7.2.1

##### Physicochemical Properties and Action of ATRA

Retinoids, the natural and synthetic metabolites and analogs of vitamin A (retinol), are important regulators of epidermal proliferation and differentiation. In recent years, discovery of the *in vitro* and *in vivo* differentiation of acute promyelocytic

Figure 7.1. Structure of ATRA (molecular weight: 300.44).

leukemia (APL) blasts by ATRA has modified the therapeutic approach of APL, but has also led to important advances in the biology of APL and opened up new perspectives for differentiation therapy in cancer.

As a consequence of the presence of a large hydrophobic moiety in ATRA (Fig. 7.1), this compound is poorly soluble in water. This compound is comprised of three distinct structural domains: a  $\beta$ -ionone ring, a polyunsaturated chain and a polar end-group. The polar end-group of ATRA exists in a higher oxidation state than retinol and/or retinal. Quantitative data on the aqueous solubility of ATRA is scarce. One study used a spectrophotometric method relying on the differential absorption spectra of ATRA in water versus ethanol to measure the aqueous solubility of ATRA and found that the solubility limit of ATRA in water is 210 nM [14]. It should be noted, however, that interpretation of the data concerning ATRA may be complicated because whilst the absorption spectrum of ATRA is indeed sensitive to the polarity of the solvent, the spectrum also changes dramatically in response to variations in pH and in the ionization state of ATRA.

Self-aggregation of ATRA can have significant implications for the biological functions of this compound. For example, a reasonable explanation for the observation that the solubility of ATRA in water is higher than predicted [15] is that the observed solubility reflects self-association into micelles rather than the monomeric ATRA solubility. Thus, micelle formation may allow higher than expected aqueous concentrations of ATRA to be maintained and this concentration may be high enough to support diffusional fluxes of free ATRA sufficient for short-distance transport in cells or to allow metabolism of free ATRA. Another action of ATRA that may be affected by its self-association properties relates to the often-raised notion that at least some of the toxic effects of vitamin A are due to surface-active, “membranolytic”, properties. Consideration of the chemical structure of ATRA suggests that its amphipathic nature results in “detergent-like” characteristics, and several studies have shown that the presence of ATRA affects various aspects of membrane structure and function [16, 17]. As with other detergents, ATRA may disrupt membranes both by intercalating into the lipids, thereby changing the characteristics of the bilayer, and by drawing lipids out of the bilayers into ATRA–lipid mixed micelles, leading to dissolution of the membranes. Few studies have addressed the self-association properties of ATRA. The ATRA molecules may carry an actual net charge. This feature may result in a stronger detergent-like characteristic of the ATRA and perhaps provide an explanation for the reported differences

between the effects of ATRA versus other retinoids on membranes [17]. This consideration raises the question of whether the carboxyl group of ATRA is protonated or negatively charged at physiological pH and whether the self-association characteristics of ATRA affect the compound's ionization state.

The physicochemical properties of ATRA and the characteristics of its interactions with the various environments in which it is distributed *in vivo* affect its biological functions. As a consequence of the presence of a large hydrophobic moiety in ATRA, it is poorly soluble in water. However, self-aggregation of ATRA can have significant implications for the biological function of this compound. It has been reported that while the  $pK$  of monomeric ATRA in an aqueous medium is lower than 6.1, the transition from a monomeric to a micellar state results in an increase in  $pK$  to 8.5, i.e. micelle formation stabilizes the protonated form of ATRA [18]. Thus, at physiological pH and at concentrations of ATRA that are higher than the critical micellar concentration (CMC), a large fraction of ATRA is protonated; at concentrations of ATRA that are lower than the CMC, a predominant fraction of ATRA is ionized. As the aqueous solubility of the anionic ATRA is significantly higher than the solubility of the protonated form, these observations suggest that the concentrations of free ATRA molecules in aqueous spaces *in vivo* are indeed of the order of 20–50  $\mu\text{M}$ .

In the presence of alkaline or physiological pH, ATRA molecules self-associate and formed micelles in aqueous solution [19]. In an alkaline environment, hydrophobic ATRA molecules abruptly change to amphiphilic molecules and when a specific concentration of ATRA is exceeded, micelles spontaneously form in water as an oriented colloidal aggregate. The CMC of ATRA was detected by the specific electron conductivity method (Fig. 7.2). Phillips defined CMC as the concentration corresponding to the maximum change in the gradient in the solution property versus concentration ( $\phi-C_t$ ) curve [20]:

$$\left(\frac{d^3\phi}{dC_t^3}\right)_{C_t=\text{CMC}} = 0, \quad (1)$$

where:

$$\phi = \alpha[S] + \beta[M], \quad (2)$$

where  $\alpha$  and  $\beta$  are proportionality constants,  $C_t$  is the concentration of surfactant, and  $[S]$  and  $[M]$  are the concentrations of monomeric surfactant and micelle, respectively. Figure 7.2 shows the determination of CMC with surfactant in the case that the solution property  $\phi$  is the electrical conductivity change. In an ionic surfactant system, higher concentrations are necessary to overcome the electrostatic repulsion between ionic head-groups of ionic surfactants during aggregation. As a result, the repulsive interaction between the head-groups in an ionic micelle is moderated by the strong counterion binding to the surface in the process of micelle formation. This idea is easy to understand from the fact that the slope before formation of a micelle is larger than that above the CMC in the conductivity measurements.

**Figure 7.2.** CMC of ATRA molecules in the presence of NaOH aqueous medium using the specific electric conductivity measurement. The measurement was carried out 25 °C under stirring. The dashed line corresponds to the CMC.

The CMC of ATRA is lower than 1 mM [19], but more than three orders of magnitude lower than reported CMC values for bile acids [21] and 10-fold lower than the CMC of the long-chain fatty acid palmitate [22]. This observation indicates that ATRA self-associate into micelles at substantially lower concentrations than other small amphiphatic compounds.

### 7.2.2

#### NANOEGG Preparation and Characterization

Above the CMC, we synthesized inorganic-coated nanoparticles using boundary-organized nanoscale reaction droplets. In turn, the interfacial properties of organic architectures, in ATRA micelles, were used to template the nucleation and growth of inorganic minerals ( $\text{CaCO}_3$ ). Since the surface of ATRA micelles displays numerous negative charges, oppositely charged ions (such as  $\text{Ca}^{2+}$  divalent ions) can easily thermodynamically adsorb on the surface. The interfacial properties of the ATRA micelle can thus be used to template the formation of a  $\text{CaCO}_3$  shell. This procedure is shown in Scheme 7.1. The surfaces of ATRA micelles containing nonionic surfactant were coated by inorganic  $\text{CaCO}_3$  with an amorphous structure. First, the mixed micelle of ATRA molecules and nonionic surfactant with polyoxyethylene function was prepared to prevent micelle sedimentation after the adsorption of divalent ions. The adsorption of divalent  $\text{Ca}^{2+}$  ions and the dissociation of surface charge of the micelle should be strongly suppressed. Finally, the micelle

**Scheme 7.1.** Schematic preparation process of NANOEGG particles with a core–shell ( $\text{CaCO}_3$ ) structure. The aqueous solution containing ATRA molecules is seen to be transparent in each step without any sedimentation.

would sediment. The presence of polyoxyethylene function on the micelle surface can maintain the hydrophilic character even if divalent ions are bound on ATRA micelle.

The solution properties of a binary surfactant mixture fall either between or outside the solution properties of the two single-surfactant solutions. Most CMCs of binary surfactant mixtures fall between the CMCs of the two components. Many of the theories concerning the CMC of binary surfactant mixtures have assumed the ideal of each component in the micellar phase [23]. An approach using a non-homologous surfactant mixture can elucidate binary mixtures quite well by using the single adjustable parameter developed by Rubingh [24]. At the CMC ( $C$ ) of the binary system, the following relationships are satisfied from the mass balances for components 1 and 2:

$$\alpha C = C_1 \quad \text{and} \quad (1 - \alpha)C = C_2, \quad (3)$$

where  $\alpha$  is the net mole fraction of component 1,  $C_1$  is the concentration of component 1 and  $C_2$  is the concentration of component 2. Then:

$$\begin{aligned} \alpha C &= \gamma_1 x C_1^0 \\ (1 - \alpha)C &= \gamma_2 (1 - x) C_2^0, \end{aligned} \quad (4)$$

where  $x$  is the mole fraction of component 1 in the binary surfactant phase,  $C_1^0$  and  $C_2^0$  are the CMCs of each single component, and  $\gamma$  is the activity coefficient due to nonideal mixing. If the values of  $C_1^0$ ,  $C_2^0$ ,  $\gamma_1$  and  $\gamma_2$  are available,  $x$ ,  $C_1$  and  $C_2$  may be determined by calculation. The values of  $C_1^0$  and  $C_2^0$  are obtained from the CMC values of the single-surfactant solutions, but the activity coefficients are given by the regular solution theory as:

$$\begin{aligned}\gamma_1 &= \exp[\beta(1-x)^2] \\ \gamma_2 &= \exp[\beta x^2].\end{aligned}\quad (5)$$

At the same time,  $\beta$  can be evaluated by substituting Eq. (4) into (5):

$$\beta = \ln(\alpha C/xC_1^0)/(1-x)^2. \quad (6)$$

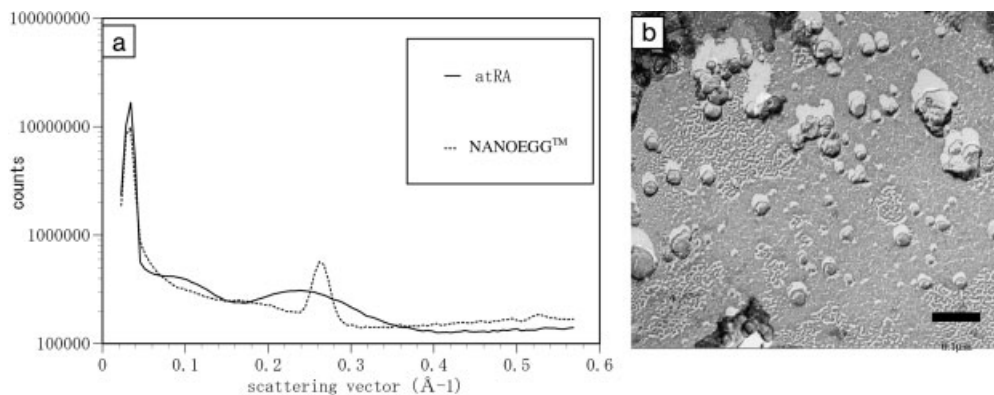

In general, a single parameter value of  $\beta$  is determined by averaging the  $\beta$  values against each  $\alpha$  value over the entire composition range. The  $\beta$  value is an index of interaction between two surfactants. The sign of  $\beta$  corresponds to positive or negative deviation from ideal, and moderate interaction between anionic and nonionic surfactants was shown for many binary surfactant systems. Thus, our micellar system between ATRA as anionic surfactant and nonionic surfactant maybe forms homogenous mixed micelles, and could not form ATRA and nonionic surfactant micelles, respectively. In the dynamic light scattering (DLS) measurement, two different diffusion coefficients of each micelle are usually detected when the different micelles are present in the system. At this case the correlation function will decay double exponentially as a function of delay time. DLS measurement was carried out on the binary ATRA and nonionic surfactant system (Fig. 7.3). The correlation function almost decayed mono-exponentially (solid line in Fig. 7.3). This is evidence for the presence of only mixed micelles being formed under our conditions.

As  $\text{CaCO}_3$  is formed on the high curvature  $1/R$ , where  $R$  is the radius of the micelle, its structure is rather difficult in crystal state. Wide-angle X-ray scattering shows the broad scattering curve between  $5^\circ$  and  $10^\circ$  angles (data is not shown).

**Figure 7.3.** DLS measurements of ATRA sodium salt and nonionic surfactant in aqueous solution. The correlation function of ATRA sodium salt and nonionic surfactant mixed solution ( $45 \text{ mg L}^{-1}$  of ATRA and  $330$

$\text{mg L}^{-1}$  of nonionic surfactant) was measured at  $25^\circ \text{C}$  as a function of decay time. The curve fittings were carried out by two methods, i.e. single- and double-exponential decays.

**Figure 7.4.** Physicochemical properties of NANOEGG in aqueous media. (a) SAXS patterns as a function of scattering vector. Solid line: ATRA micelle (1.0 wt%); dotted line: NANOEGG particles (1.0 wt% as ATRA). (b) Freeze-fracture TEM of NANOEGG aqueous solution. Bar = 0.1  $\mu\text{m}$ .

High biocompatibility of the  $\text{CaCO}_3$  structure is thus expected due to the amorphous coating on micelle. Thus, calcium storage in the epidermal and/or dermal region cannot take place after the external treatment.

Analysis by small-angle X-ray scattering (SAXS) reveals the presence of spherical micelles of ATRA molecules with a diameter of around 10 nm (Fig. 7.4a). This size corresponds well with the normal ionic surfactant system [13]. The SAXS profile reveals an eggshell-like structure with different electron densities in the inner structure. Discontinuous electron distribution in the inner structure is detected as a peak with a specific scattering-angle region (Fig. 7.4a). The presence of this sharp peak corresponds to a discrete thin layer of  $\text{CaCO}_3$  on the surface of the ATRA micelle. This micelle displaying a core–shell (ATRA– $\text{CaCO}_3$ ) structure represents the NANOEGG particles. In addition, since the diameter of NANOEGG is estimated to be 13–16 nm using the scattering curve in Fig. 7.4(a), the thickness of the  $\text{CaCO}_3$  layer is probably 1.5–3 nm. The presence of an egg-like core–shell structure was also confirmed using freeze-fracture transmission electron microscopy (Fig. 7.4b).

The schematic structure of the NANOEGG system is shown in Fig. 7.5. In fact, the shell-like structure of 1–2 nm width was observed outside of the spherical ATRA particles.

### 7.2.3

#### Improved Lability of ATRA in the NANOEGG System

The conjugated double bonds of the isoprenoid chain render ATRA susceptible to photodegradation, isomerization and oxidation. Consequently, naturally occurring ATRA is extremely labile. Actually, the structural integrity of ATRA must be maintained *in vivo*. The answer lies in part with the observation that most retinoids *in vivo* are associated with retinoid-binding proteins. Many of these proteins bind

**Figure 7.5.** Schematic representation of a NANOEGG particle. The worm-like ribbon in the representation corresponds to the PEG function. The inside domain corresponds to ATRA molecules.

their ligands in hydrophobic pockets, thereby effectively shielding them from the aqueous environment. Binding to proteins is thus expected to protect ATRA from nonspecific oxidation and may also stabilize its isomerization state. In the same way, micelle formation of ATRA molecules can be expected to protect ATRA from the aqueous environment. The life-times of free ATRA in cytosol and in extracellular spaces, and the mechanisms by which the integrity of ATRA in these pools is maintained, are unknown. However, it has been reported that both degradation and isomerization of ATRA in water can be prevented by addition of biological antioxidants such as tocopherol [25, 26], suggesting the possibility that under at least some physiological conditions free ATRA can remain stable in cytosol. Even with the use of an antioxidant, the stability of ATRA micelles cannot be maintained over 95% of its activity for 3 years at room temperature and/or 6 months at 50 °C. Unfortunately, such a stability level of ATRA cannot be employed by pharmaceutical companies.

Figure 7.6 shows the high potential of NANOEGG for improved stability. As ATRA has a specific maximum absorbance at 340–345 nm, born of the decrease

**Figure 7.6.** Stability of ATRA (circles) and NANOEGG (squares) at 40 °C. The ATRA was solubilized in ethanol as a negative control. Each sample was packed in the sunscreen tube.

of peak height and isomeric another peak detection in HPLC measurement are available concerning to the loss of activity. It can be seen that the peak height of NANOEGG scarcely changed for approximately 70 days in the accelerated environment at 40 °C, even without any antioxidant. It can be seen, thus, that the lability of the ATRA molecule was rather improved against temperature, as can be expected. As a result, long-term storage of ATRA ointment became possible.

### 7.3

#### NANOEGG for Dermatological Aspects

Within the epidermis, the processes of proliferation and differentiation are tightly controlled, resulting in a tissue at steady-state in which the cells that are desquamated and lost are equal to those that are produced in the germinative basal layer. Cells within the basal layer are highly proliferative and display an undifferentiated phenotype characterized by the coexpression of cytokeratin 5/14 (K5/K14) [27]. Mitosis is restricted to the basal layer and, as keratinocytes migrate into the suprabasal layers, they undergo a well-defined program of thermal differentiation, characterized by the coordinated induction of specific proteins. The initial change is the loss of K5/K14 expression and the synthesis of the K1/K10 keratins [28]. With subsequent movement into more suprabasal layers, cornified envelope substrate proteins are synthesized, including lorocrin [29], filaggrin and involucrin, together with type 1 transglutaminase – the calcium-dependent enzyme responsible for the crosslinking of the proteins. During the final stages of the differentiation process, the substrate protein crosslinking forms the resistant cornified envelopes, resulting in the cutaneous permeability barrier.

The dramatic effects of ATRA upon the skin have been known for many years. Hyperkeratinization is the result of ATRA deficiency in animals, with many epithelial sites becoming satisfied and keratinized. The historical data has been supported somewhat by more recent *in vitro* data. When keratinocytes are treated *in vitro*, ATRA inhibits terminal differentiation, suppressing the expression of K1/K10, profilaggrin, lorocrin, involucrin, transglutaminase and cornified envelope formation. The topical application of ATRA promotes keratinocyte proliferation, resulting in epidermal hyperplasia. Specifically, the thickness of the granular layer is increased and the stratum corneum is compacted, indicating effects upon differentiation in addition to proliferation. ATRA treatment not only leads to a decrease in stratum corneum thickness, but also to cell loosening and fragility, changes in lipid levels, and a subsequent decrease in the permeability barrier. As outlined, *in vivo* ATRA treatment upregulates differentiation markers.

Hyperpigmentation on the face is a anxiety-producing symptom. Photoaging refers to premature skin aging caused by repeated exposure to ultraviolet (UV) radiation from the sun for many years. Fine and coarse wrinkles, hyperpigmented macules, sallow color, dry texture, and loss of tone in habitually sun-exposed skin characterize the photoaged phenotype. Our understanding of photoaging has been greatly aided by the discovery that ATRA can repair photoaged skin, coupled with

tremendous advances in the field of molecular biology, especially in the areas of how retinoic acid receptors function and how intracellular signaling is initiated by UV irradiation. For several years, ATRA and other synthetic retinoids have been widely used in the treatment of a variety of skin diseases associated with hyperproliferative processes. Retinoids induce a characteristic series of biochemical and histological modifications when applied to skin. Their effects on keratinocytes are still incompletely understood in spite of the recent discovery of nuclear ATRA receptors, which are highly expressed in human adult skin [30].

In 1986, Klingman and coworkers [9, 10] reported in the first suspicion that ATRA molecules could produce smoother, less-wrinkled and less-pigmented skin after a few months of treatment, and this has been one focus of research into topical treatments for a potent inhibitor of new melanin production [31, 7, 8]. Since the 1990s, many dermatologists have recommended the use of ATRA for a variety of nonsurgical treatments of photodamaged skin, because of a certain physiological regulation and high induction of epithelial differentiation [2–6]. The substance has been approved by the Food and Drug Administration in the US, and has been marketed as RENOVA™ and Retin-A™. Clinical responses predominantly comprised severe irritant dermatitis in the early stages of application of RENOVA and Retin-A (around 3 or 4 days) [11, 7, 8]. Such damage with a high magnitude of inflammatory events after ATRA treatment can induce chronic skin pigmentation on the area being treated, potentially resulting in imperfect repair of skin displaying a pigmented appearance.

### 7.3.1

#### Improved Irritation of ATRA in the NANOEGG System

In addition to keratinocytes and melanocytes, the epidermis also contains Langerhans cells, dendritic cells and innervating peripheral neuron cells. This means that the skin is an organ capable of responding to signals from both outside and from within the body. A predominant feature during the pathogenesis of many skin disorders is chronic inflammation, characterized by the infiltration of activated T lymphocytes. Among the factors that are critical for controlling those processes, transcription factors (such as AP-1, NF- $\kappa$ B, etc.) appear to be essential. Interestingly, the members of the nuclear hormone receptor superfamily are known to interact with many of these transcription factors, suggesting that ligands for these nuclear receptors may be an effective means of modulating inflammation as well as the immune response in general.

As already mentioned, ATRA causes a variable amount of irritation, more properly a heightening of cutaneous reactivity termed ATRA dermatitis, early in therapy. In the first few weeks approximately 80% of patients experience stinging, hyperesthesia or pruritus, fine scaling, dryness and mild erythema (Fig. 7.7a).

The conceptual framework in this section is that NANOEGG plays a crucial role in solving of the symptoms of irritation. After daily treatment with NANOEGG at different ATRA concentrations on the dorsal area of Wistar rats (5 weeks old, male), the induction of inflammation was visually observed. Inflammation tests are his-

**Figure 7.7.** Facial features at 1 week following one time daily applications of (a) RENOVA ATRA 0.05% and (b) NANOEGG 0.05%. Note mild erythema and scaling along the jaw line and around the eye area in RENOVA treatment, while side-effects were rare in NANOEGG treatment.

torically carried out on the dorsal area of rats in cosmetic and medical companies as a standard method. It is known that this method will almost link to the degree of inflammation in the case of human skin. Hence, we also followed a rat system for the evaluation of NANOEGG. Only this experiment was carried out in a rat system. This stimulation degrees are normally numbered as three groups; 0–2: no change–fair, 2–4: stimulation, 4–6: high stimulation, which are based on visual observations. Figure 7.8 obviously shows the improvement of inflammation induced by the ATRA treatment in the case of NANOEGG.

Commercially, both Retin-A, a 0.1% ATRA cream, and RENOVA, a 0.05% ATRA cream, are marketed by Johnson & Johnson in the US. An *in vivo* experiment on the porcine dorsal area was performed for comparison with these commercial products. In the case of NANOEGG, the irritation against the porcine skin, which is known to be similar to human skin, showed the lowest level compared with other commercial products. One distinguishing feature of the human skin response to ATRA is the generation of clinical erythema. Since the erythema response of human skin to ATRA is normally dose-dependent [32], the reduced erythemogenic potential of NANOEGG should expect the reduction of irritation (Fig. 7.7b) with decreasing dose of ATRA, compared to the normal ATRA therapy.

The inflammation induced by topical ATRA treatment on skin should be caused by the elevation of AP-1 and NF- $\kappa$ B, and translated forms of inflammation cytokines, interleukin (IL)-1 $\alpha$  and tumor necrosis factor (TNF)- $\alpha$ . Thus, the inflammation cytokines IL- $\alpha$  and TNF- $\alpha$  mRNA were measured on the skin domain treated with NANOEGG ointment (Fig. 7.9).

**Figure 7.8.** Stimulation degrees for the external administration on the dorsal area of ddY mouse of ATRA and NANOEGG in Vaseline media. Different concentrations (0.01, 0.05 and 0.25% of ATRA) were carried out as

daily treatment (30 mg,  $2 \times 2 \text{ cm}^2$  on the dorsal area of Wistar rats, 5 weeks old, male) for 2 weeks. Stimulation degree was determined by visual observation.

**Figure 7.9.** Expression of inflammation cytokines IL-1 $\alpha$  and TNF- $\alpha$  mRNA on mouse skin. Each compound (NANOEGG, its base and Retin-A-Micro) was administered as 30 mg on  $2 \times 2 \text{ cm}^2$  for 15 days. The tissues were sacrificed 4 days after the topical administration.

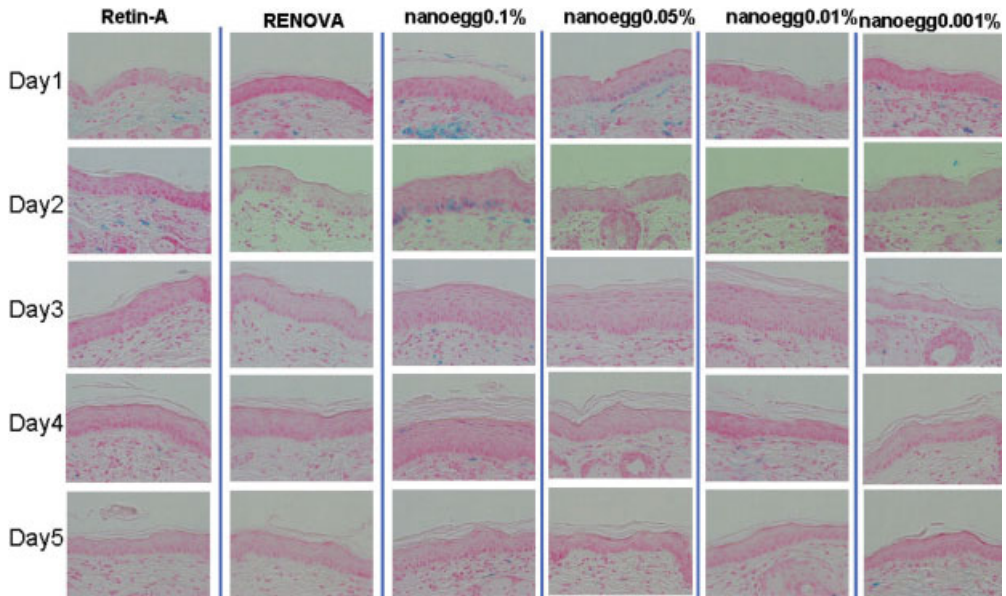

## 7.3.2

**Pharmacological Effects of the NANOEGG System**

Histological improvements in the appearance of photodamaged skin following ATRA usage are associated with thickening of the epidermis and a relative reduction in melanin content [7, 8]. A study was undertaken to specifically evaluate the efficacy of NANOEGG in treating hyperpigmented lesions. Histological evaluation of ddY mouse epidermis after daily application of NANOEGG Vaseline cream for 4 days revealed more than double the increase in epidermal thickness than when using ATRA Vaseline cream (Fig. 7.10a–d). In general, a period of at least a few months is required for clinical effectiveness in treating mottled pigmentation using ATRA. Given the major increase in thickness of the epidermis in our prelim-

**Figure 7.10.** Histological and tissue analysis of the epidermis after a 4-day treatment. (a) Vehicle (Vaseline) treatment, (b) 0.1% ATRA treatment, (c) 0.1% NANOEGG treatment and (d) estimated epidermis thickness for each specimen ( $n = 10$ ).

**Figure 7.11.** Histological evaluation of commercial products and NANOEGG 0.1, 0.05, 0.01 and 0.001% at each day after topical administration until day 5. All tissues were stained using the colloidal iron stain method to detect HA. Blue domains correspond to the presence of HA and red domains correspond

to nuclear staining. The external treatments were carried out once and the tissues were sacrificed at each day until day 5. The amount of 30 mg of compound was administered in a 1-cm<sup>2</sup> of dorsal area of hairless mice (HR-1, male, 5 weeks old).

inary trials, reduction of melanin should rapidly be produced by NANOEGG treatment in humans.

NANOEGG-treated hairless mice underwent more progressive epidermal hyperplasia than with the commercial products at the same dose (Fig. 7.11). Even at a lower dose of ATRA (0.001%), histological evaluations suggested the effective skin regeneration of mice. Significant increases in epidermal thickness for NANOEGG treatment at all doses was revealed compared with treatment using commercial product creams. The hyperplasia of epidermis in Fig. 7.11 shows the thickened epidermal layer in all tested groups, but the NANOEGG-treated groups at each concentration of ATRA were dominant to other commercial products. The thickness of the epidermis layer in NANOEGG 0.01% treatment corresponds to that in the Retin-A (ATRA 0.1%)-treated group, thus the efficacy of NANOEGG can be supposed to be approximately 10 times that of the Retin-A commercial product. Likewise, NANOEGG may show sustained release of ATRA molecules until at least 5 days because of the observed continued hyperplasia of epidermis.

## 7.3.3

**Expression of mRNA Heparin-binding Epidermal Growth Factor-like Growth Factor (HB-EGF) on Mouse Skin**

Stoll and coworkers reported that mRNA expression of HB-EGF is induced by ATRA in human keratinocytes and skin [33]. Recently, production of HB-EGF has been shown to be one of the hallmarks of the turnover of keratinocytes [33]. Figure 7.12 shows HB-EGF mRNA expression in mouse ears in ATRA- and NANOEGG-treated groups. Daily application was performed for 4 days. Excess expression of HB-EGF in the NANOEGG-treated group was apparent compared with ATRA. This correlates well with the increased epidermal thickening for NANOEGG treatment (Fig. 7.10). Even at 4 days after the external administration, it seems that NANOEGG would gradually release tretinoin molecules from its egg-like capsule. It was confirmed whether NANOEGG possesses the controlled release ability as a drug delivery system or pulsatile release. Figure 7.13 shows the result of the expression of HB-EGF mRNA each day after a single treatment of NANOEGG on the mouse dorsal area. The small figure in Fig. 7.13 shows the concentration dependence of the expression of HB-EGF mRNA on tretinoin. With increasing concentration of NANOEGG, the production of HB-EGF mRNA was enhanced from ker-

**Figure 7.12.** Expression of HB-EGF mRNA in mouse ears after continuous daily treatments for 4 days with ATRA or NANOEGG (0.1%) in Vaseline cream.

**Figure 7.13.** Expression of HB-EGF mRNA in mice dorsal areas at each day after 1-day treatment with NANOEGG. The large figure shows the continuous expression of HB-EGF mRNA by NANOEGG as tretinoin concentration 0.2%. The small figure shows the concentration dependence of

atinocytes, while this was different from the case with the single treatment of tretinoin. As is obvious in Fig. 7.13, NANOEGG treatment as 0.2% tretinoin concentration could achieve expression of HB-EGF mRNA for 1 week. It is suggested that, at least here, tretinoin would gradually release from NANOEGG and as a result long-term release for around 1 week was successfully achieved by NANOEGG technology.

Also, Fig. 7.14 shows HB-EGF mRNA expression in hairless mouse dorsal tissues in Retin-A-, RENOVA- and NANOEGG-treated groups. One-day application was performed, and tissue was sacrificed and frozen in liquid nitrogen daily until day 5. Especially on the first day, excess expression of HB-EGF mRNA in the NANOEGG-treated group was apparent compared with the commercial products, RENOVA and Retin-A. Furthermore, even at the most dilute ATRA dose, the elevated expression of HB-EGF mRNA at day 1 was observed that will be expected to accelerate proliferation and differentiation of keratinocytes. The hyperplasia of the epidermis in Fig. 7.11 almost corresponds to the expression of HB-EGF mRNA in Fig. 7.14, but it would seem that a 1- or 2-day period is needed due to the thickened epidermal layer after the production of HB-EGF.

#### 7.3.4

#### Proliferation and Differentiation of Keratinocytes

The mammalian epidermis is made up of multilayered epithelium consisting mainly of proliferating and differentiated, postmitotic keratinocytes. The differenti-

**Figure 7.14.** Expression of HB-EGF mRNA in hairless mice (HR-1, male, 5 weeks old) dorsal areas after 1-day treatment at day 5 with no treatment, NANOEGG (0.1, 0.05, 0.01 and 0.001%, respectively), RENOVA Retin-A. The tissues of dorsal areas were frozen using liquid nitrogen and extracted was RNA by the Isogen method.

ation is continuously replaced and recruited via transit-amplifying cells originating from stem cells, which represent a restricted number of basal keratinocytes. The continued renewal of cells in conjunction with mechanical strain poses a particular challenge to the cytoskeleton. It comes as no great surprise that epidermal keratinocytes have evolved a complex program of keratin expression along with mechanisms to alter the shape of the cytoskeleton during terminal differentiation.

As overexpression of HB-EGF mRNA was observed in NANOEGG treatment, we examined the expression of molecular markers in skin from the treated mice (5 weeks old, male) by immunofluorescence (Fig. 7.15). Cytokeratin 1 (K1) and larrikin (lord), markers of terminal differentiation in the normal epidermis layer, and cytokeratin 5 (K5), a maker of basal keratinocytes, were detected in the tissue after the treatment of atRA and NANOEGG 0.1% ointment. Expression of K5 (Fig. 7.15b and c) and larrikin (Fig. 7.15h and i) were rather enhanced in comparison with the control (wild-type mice, Fig. 7.15a), but the big difference between atRA and NANOEGG treatments was not observed, whereas the strongest expression of K1 was detected in the NANOEGG treatment (Fig. 7.15f). Excess expression of K1 might be associated with the enhanced thickening of the epidermis (Fig. 7.11b and Fig 11c). Thus, hyperplasia in the treatment of NANOEGG would mainly be due to the overexpression of HB-EGF, which could induce differentiation of keratinocytes. As a result, the differentiation of suprabasal and granule cells, which are related to the differentiation marker K1, seemed to be accelerated.

**Figure 7.15.** Expression of molecular markers in the epidermal layer of ddY mice. Green corresponds to antibody staining and red corresponds to nuclear staining. Dorsal skin sections from ddY mice at 4 days after the external treatment were stained with antibody against K1, K5 and loricrin (lor). The treatments were carried out by ATRA and

NANOEGG 0.1% as ATRA, respectively. The dorsal sections ( $1.0 \times 1.0 \text{ cm}^2$ ) were administrated 30 mg ointment (base is Vaseline). K1 is a marker from the suprabasal layer to the stratum corneum; K5 is a marker from the basal cell; and loricrin is a marker from the granular layer to stratum corneum.

### 7.3.5

#### Production of Hyaluronic Acid (HA) in the Epidermal Layer

Another change was noteworthy – the intercellular spaces were wider and more prominent. This probably accounts for the intensified result with colloidal iron staining. Interestingly, wrinkling and skin texture may also be influenced by other epidermal factors as well as HB-EGF expression. Another histological finding of NANOEGG efficacy was obtained in this study. The influence of ATRA on epidermal differentiation is associated with the metabolism of HA by keratinocytes [36]. Tammi and coworkers reported tentative results in 1989 that HA was produced between ATRA-exposed keratinocytes [34]. The ATRA molecule leads to an accumulation of HA in the superficial layers of the epidermis by stimulating HA synthesis in keratinocytes. Deposition of HA coincides with cell proliferation and migration in several developing tissues and organs [35, 36], whereas onset of differentiation is often accompanied by reduced HA synthesis [37]. In order to evalu-

**Figure 7.16.** Expression of HA among keratinocytes after treatment by ATRA and NANOEGG. The dorsal tissues (ddY mouse, 5 weeks old, male) were stained using the colloidal iron stain method. The treatment of ATRA and NANOEGG was carried out once and the corresponding tissues were sacrificed

3 days after the treatment. Blue spots in the pictures correspond to HA, and they disappeared completely following the treatment with hyaluronidase (data not shown). ATRA (a) 0.1%, (b) 0.2% and (c) 0.4%; NANOEGG (d) 0.1%, (e) 0.2% and (f) 0.4%.

ate the efficacy of NANOEGG on HA production, empirical histology of the epidermis was investigated. Skin specimens treated daily for 4 days were taken from the mouse dorsal area. Specimens were prepared using colloidal iron staining to retain HA. In ATRA- and NANOEGG-treated groups, the intercellular spaces of the epidermal basal and spinous cells displayed negative and abundant presence of HA, respectively (dark blue spots correspond to accumulation of HA; Fig. 7.16a–c for ATRA treatment and Fig. 7.16d–f for NANOEGG treatment). Within the experimental period (4 days of treatment), it seems to be difficult to produce HA by ATRA treatment, at even with increasing the ATRA concentration to 0.4% (Fig. 7.16c).

Furthermore, intercellular spaces between both basal and suprabasal cells were extended wider with NANOEGG (Fig. 7.16d–f) than those with ATRA treatment (Fig. 7.16a–c). This may account for the reduced cohesion between cells compared to ATRA treatment, as HA displays a lubricating effect. Basal and suprabasal cells would therefore proliferate and migrate to the upper stratum corneum more easily. Finally, promotion of epidermal thickening accompanying melanin migration could occur with continuous application of NANOEGG on skin. In the NANOEGG system, rapid regulation of HA in the epidermis might effectively help keratinocyte growth. Production of hyaluronate in the epidermis would accelerate turnover of the epidermis, as the lubricant among cells eventually contributes to a reduction

**Figure 7.17.** HA stain by colloidal iron. Dark-blue color domains correspond to the presence of HA. Each treatment was carried out for 4 days. (a) 0.1% ATRA in Vaseline, (b) 0.1% nano-ATRA in Vaseline, (c) same specimen as (b) but at a different area, (d) specimen (c)

after treatment by hyaluronidase for 16 h and (e) change of fine wrinkles on the neck area of an aged hairless mouse (18 weeks old, male). The treatment was carried out for 4 days, with 30 mg of ATRA and NANOEGG (0.1%) in Vaseline creams.

in macular hyperpigmentation and less apparent fine wrinkles [19]. Since hyaluronidase treatment on NANOEGG-treated specimens resulted in a complete disappearance of the stained domain, this histological evaluation identified production of HA (Fig. 7.17c and d).

### 7.3.6

#### **Hyperpigmentation and Fine Wrinkle Improvements by NANOEGG Treatment on Animal Skin**

Photoaging involves the adverse effects of chronic UV radiation (UVR) on the skin, superimposed on the intrinsic aging process. The later sections review evidence gathered from animal and human studies regarding the ability of topical NANOEGG application to reverse many aspects of the photoaging process.

By definition, photoaging involves UVR exposure – mainly from the sun, but also from therapeutic sources of UVR. UVC (200–290 nm) is the most biologically damaging portion of the UVR spectrum, but is almost entirely absorbed by the ozone layer of the Earth's atmosphere. The strongest UV light to reach the Earth's surface is UVB (290–320 nm). UVA (320–400 nm) has the greater penetration into the skin, but is much weaker than UVB. Clinical features of photoaging include fine and coarse wrinkles, skin roughness, sallowness, mottled hyper/hypopigmentation, lentigines, telangiectasias, and skin laxity.

**Figure 7.18.** Change of fine wrinkles on the neck area of an aged hairless mouse (18-week, male). The treatment was carried out for 4 days, with 30 mg of ATRA and NANOEGG (0.1%, respectively) in Vaseline creams.

A systematic study of the photoaging process is difficult or impossible using human subjects. Animal models in which the process is accelerated are therefore desirable models. There is no naturally occurring animal model of photodamage, as diurnal animals are covered with fur, feathers or scales that protect them from UVR. The normally laboratory generated hairless mouse (HR-1) and guinea pig have been widely utilized because the animals wrinkle and produce brown spots in response to UVR within their relatively short life expectancies. To establishment fine wrinkles, first, the aged hairless mouse (HR-1, 18 weeks old) was utilized for the topical treatment of NANOEGG (Fig. 7.18). Guinea pigs (Weiser maple, 5 weeks old ) were irradiated with UVA and UVB using an established protocol for 10 days to induce photodamage, and topical NANOEGG was applied at a concentration 0.05% for an additional 5 days (Fig. 7.19).

### 7.3.7

#### Clinical Trials of Fine Wrinkles and Brown Spots on the Human Face

In general, a period of at least a few months is required for clinical effectiveness in treating mottled pigmentation using ATRA cream. Given the major increase in thickness of the epidermis in our animal trials (Figs. 7.11 and 7.12), a reduction of melanin pigments should be rapidly produced by NANOEGG 0.05% treatment in humans. As a preliminary clinical trial for *in vivo* treatment of wrinkles and pigmental spots, NANOEGG therapy was performed for 1 month on human faces. The Institutional Review Board of St Marianna University permitted the clinical trial of NANOEGG ointment in human faces over 40 years old. The trial was carried out for 1 month in 30 wrinkles and 30 brown spots induced by aging and/or

**Figure 7.19.** Improvement in hyperpigmentation of guinea pig dorsal skin with the topical application of NANOEGG. The establishment of brown spots was carried out by 10 days of total UVA and UVB irradiation.

(a) Before treatment, (b) after the treatment of NANOEGG 0.05%, and (c) and (d) histological research corresponding to (a) and (b). The tissue was stained by melanin staining. Black granules correspond to melanin.

UV irradiation. The brown spots were also fairly decreased (Fig. 7.20). Otherwise, coarse wrinkling at the side of the eyes was consistently diminished after NANOEGG 0.05% treatment without strong irritation and inflammation (Fig. 7.20). This would certainly be due to the abundant HA accumulation in the epidermal layer at an early stage. Commercial ointment treatment could not usually achieved the decrease of hyperpigmentation after only 1 month, while the NANOEGG system could reduce the hyperpigmentation without serious irritation, as is obvious in Fig. 7.20. Actually, after treatment of NANOEGG for several days weak inflammation took place for several people. Compared with commercial products, these levels were rather weak. Accordingly, we believe that the risks due to the continuous treatment of ATRA such as erythema and irritation can prevent exactly by NANOEGG technology. Because the pharmacological effect would be gotten by the short-term treatment with the NANOEGG system. Simultaneously, the amount of water in stratum corneum also showed a statistically increase for 1 month treatment of NANOEGG (Fig. 7.21).

Figure 7.20. Pictures of wrinkles and photoaged hyperpigmentation on human faces (female, 48 years old). Before treatment with NANOEGG 0.05%, and after treatment for 1 month. The external daily administration was carried out one time at night, continuously.

Figure 7.21. Change of amount of water in the stratum corneum of human skin. The measurements were carried out on people over 40 years old before and after treatments with NANOEGG and ATRA.

#### 7.4

### Why does NANOEGG Show the High Performance on the Improvement of Brown Spot and Wrinkles?

The superb results *in vivo* and histological evaluations obtained for NANOEGG are attributable to effective permeation into the skin. The stratum corneum is covered with lipids, natural moisturizing factors and ceramides as a barrier. In the presence of water, ceramide and other natural compounds spontaneously promote the formation of lyotropic lamella liquid crystals. When materials diffuse in such a lyotropic phase, the hydrophile–lipophile balance (HLB) of a molecule plays a significant role in the effective permeation into skin. In practice, hydrophobic ATRA would theoretically show minimal permeation through the stratum corneum epidermis. As a result, almost all of the ATRA would remain on the surface of the stratum corneum, eventually inducing irritation and inflammation. The surface of NANOEGG displays an amphiphilic character due to the coexistence of a hydrophobic domain ( $\text{CaCO}_3$ ) and a hydrophilic PEG domain. As our NANOEGG is therefore easily dispersed in both aqueous and nonpolar media (Fig. 7.22), its permeability through the stratum corneum was substantially enhanced. Fortunately, permeability of NANOEGG can be indirectly evaluated in terms of histological staining of  $\text{Ca}^{2+}$  ions (Fig. 7.23). After treatment, red-smear domains of biopsy specimens extended over time to the entire epidermis (Fig. 7.23b and c), while  $\text{CaCO}_3$ -treated subjects displayed no permeation to the inner dorsal skin (Fig. 7.23a).

Surprisingly, it is obvious that even in a quite short time (10 min, Fig. 7.23b) NANOEGG can already permeate into the skin. Not only the high permeation of NANOEGG, but also the stability of the capsule showed drastic performance in the epidermis. Since after 24 h the epidermal layer was more stained than the dermis, it indicates that NANOEGG capsules may be trapped in epidermis.

The skin is the outermost organ of the body. It is a complex membrane comprising of three major layers – epidermis, dermis and hypodermis. The epidermis is an avascular stratifying layer of epithelial cells that overlies the connective tissue layer – the dermis. The outermost layer of epidermis, i.e. the stratum corneum, is pri-

**Figure 7.22.** Solubility of NANOEGG 0.1% in polar (water) and nonpolar (corn oil) solvents. Both solutions showed a quite transparent appearance because of the amphiphilic property on the surface of NANOEGG.

**Figure 7.23.** Dahl's calcium staining, which selectively traps the presence of Ca. Red smeared domains correspond to Ca distribution, particularly  $\text{CaCO}_3$  [indicated by arrow as positive control (a)]. Permeation potential of NANOEGG through mouse skin as a function of time after external administration. The tissues of ddY mice were utilized for staining. Calcium was regarded as a permeation maker from the stratum corneum epidermis to the dermis region. As the NANOEGG particle is at the nanoscale, the stain in the specimen would be detected as smeared domains. Treatment with 0.1% NANOEGG Vaseline cream after (b) 10 min and (c) 24 h.

marily responsible for the barrier properties of the skin. The underlying viable epidermis is different from the stratum corneum in being physiologically more akin to other living cellular tissues, but also plays the role as second barrier, especially for ions. Following passive application, the unionized form of any compound is better absorbed than its ionized counterpart [38]. However, the penetration rates of drug molecules across skin or other epithelial surfaces are usually low due to their excellent barrier properties.

For the reasons discussed above, it can be suggested here that NANOEGG capsules could successfully permeate into skin due to passive diffusion.

## 7.5 NANOEGG for Other Indications

In multicellular organisms, a balance between differentiation, proliferation and cell death maintains tissue homeostasis in adult tissues and directs normal development during embryonic morphogenesis. Retinoic acid is one of the critical factors regulating the molecular events involved in these processes. The requirement for ATRA for normal development and tissue homeostasis has been known since Wolbach and Howe first reported the defects that occurred in vitamin A-deficient animals in 1926. A large literature base has since appeared describing the role of retinoids in promoting proliferation, differentiation or apoptosis *in vivo*, in a variety of cell culture systems and more recently through studies using retinoid receptor knockout strategies. In addition, these investigations have provided the mechanisms by which retinoids induce teratogenic effects and inhibit neoplastic development, particularly in cancer. Significant progress has been made in understanding the molecular mechanism by which retinoids modulate the action of negative and positive growth factors including EGF, the transforming growth factor (TGF) family, insulin, IL-1 $\alpha$ , IL-6, IFN- $\gamma$ , estrogen and vitamin D $_3$ . Regulation by

retinoids can occur at the level of expression of growth factors and cytokines, and their respective receptors/binding proteins in the signaling pathway.

Many of the biological effects and changes in gene expression induced by ATRA are mediated by six known retinoic acid receptors (RAR $\alpha$ , RAR $\beta$  and RAR $\gamma$ ) and/or retinoid X receptors (RXR $\alpha$ , RXR $\beta$  and RXR $\gamma$ ) [39–41]. It is known that each of the RAR subtypes has a specific tissue distribution pattern [42]. For example, RAR $\gamma$  is the most abundant retinoid receptor in the skin [43, 44], whereas RAR $\beta$  is found primarily in the heart, lung and spleen. RAR $\alpha$  is expressed at low levels in many tissue types. It follows that retinoids that activate a particular receptor subtype may elicit biological responses in specific tissues. Thus, it can be expected that retinoids would greatly improve therapeutic indices in the treatment of retinoid-responsive diseases because of receptor expression on many tissues. The full therapeutic potential of ATRA may only be realized if new technologies with vastly improved therapeutic indices can be developed.

We have been investigated the radical therapy of diabetes mellitus induced by NANOEGG. Since the ATRA molecule is soluble in water, it is impossible to inject, whereas NANOEGG is easily soluble in aqueous media. Injection of NANOEGG may systematically induce the proliferation of pancreatic  $\beta$  cells and differentiation of anaplastic cells in Langerhans islands and/or pancreatic ducts, resulting in the regeneration of  $\beta$  cells. Recent studies showed that differentiation of in different cells on pancreatic ducts could be induced by HB-EGF and, as a result, glucose tolerance was improved [45]. As already shown, the topical treatment of NANOEGG could produce abundant HB-EGF. The pancreas must also express retinoic acid receptors. HB-EGF induced by NANOEGG, thus, will be expected to regenerate pancreatic  $\beta$  cells in diabetic animal models. Figure 7.24 shows the change of body weight of type I diabetic rats induced by streptozotocin in the case of subcutaneous administration of NANOEGG. Obviously the loss of weight was stopped

Figure 7.24. Change of body weight of Wistar rats (male) in subcutaneously administered NANOEGG (6 mg as ATRA, once a week). Model animals were induced with type I diabetes by STZ administration.

**Figure 7.25.** Change of insulin level in plasma after the administration of NANOEGG (6 mg as ATRA, once a week). Model animals were induced with type I diabetes by STZ administration.

in the NANOEGG-injected group around 60 days. In this case, the concentration of insulin in plasma also increased compared to the nontreated group (Fig. 7.25). Expression of transcription factor of pancreas PDX-1 in Langerhans islands relates to the differentiation of somatic stem cells to  $\beta$  cells [46, 47]. Figure 7.26

The newly developed DDS technology described

**Figure 7.26.** Immunostaining of insulin and transcription factor PDX-1, and  $\beta$  cells in Langerhans islands of rat pancreas. Model animals were prepared by the administration of STZ. Over 99% of  $\beta$  cells could not be observed in Langerhans islands in the case of STZ groups.

shows slight expression of PDX-1 in Langerhans islands in the group administered NANOEGG.

The administration of NANOEGG cannot only be used for the regeneration of skin, but also can be expected to be used for the regeneration therapy of  $\beta$  cells. New nanoshell technology NANOEGG may also be useful for other retinoid response diseases. Major advances with ATRA and/or its nanocapsule NANOEGG would be continuously in progress in clinical applications.

## 7.6

### NANOEGG for Other Drugs

The self-assembly property in aqueous media is absolutely necessary to prepare NANOEGG. The physicochemical amphiphilic balance of the molecular structure leads to molecular association in water. ATRA can spontaneously form micelles in water with a small amount of alkaline. If drugs can form self-assemblies like micelles and their surfaces have ionic charges, the NANOEGG structure should be prepared. Even if drugs have a high molecular weight, it is possible to form the core-shell structure of the NANOEGG system. Prostaglandin and its derivatives may be able to form micelle-like structures. It would expect that NANOEGG technology will be also indicated in other drugs.

## 7.7

### Conclusion

Up to now, clinical responses predominantly comprised severe irritant dermatitis in the early stages of application (around 3 or 4 days) of ATRA. This problem is generally managed by modifications to the dosage and schedule. Such damage with a high magnitude of inflammatory events after ATRA treatment can induce chronic skin pigmentation in the area being treated, potentially resulting in imperfect repair of skin displaying a pigmented appearance. Preventing undesirable adverse effects would be expected to allow ATRA therapy to overcome the limitations of classical ATRA therapy. Herein, we describe the development of a novel drug delivery system using nanotechnology. The conceptual framework in this study is that NANOEGG plays a crucial role in solving the low permeation of ATRA into spaces in the stratum corneum epidermis and the also the symptoms of irritation.

The newly developed drug delivery system technology described herein could help with nonsurgical treatment of photodamaged skin for which use of ATRA has been recommended. Detailed studies concerning the efficacy of NANOEGG have already been reported [19, 48, 49], suggesting not only improved permeability to the stratum corneum, but also simultaneous enhanced keratinization due to  $\text{CaCO}_3$ . Drastically increased epidermal thickness could be expected to result in a relative decrease in melanin content and excess expression of HA aids induction of hyperplasia, resulting in less-wrinkled skin. Moreover, the high permeability and

controlled release of ATRA induces accelerated epidermal turnover. Promotion of keratinocyte proliferation and acceleration of keratinocyte differentiation are most likely the result of ATRA in regimentering treatments. Melanin granules may be washed out of the epidermis by a rapid and stronger stream of keratinocytes in the epidermis compared to topical ATRA treatment. This study clearly shows that our newly developed novel drug delivery system technology for NANOEGG offers great potential for new ATRA therapy. Histological and ultrastructural findings for empirical evaluation of NANOEGG indicate that ATRA therapy causes more than esthetic improvement, inducing histological changes in the epidermis, in all likelihood without regard to changes induced by time or sunlight.

The new nanoshell technology NANOEGG can be useful for other clinical approaches and other drugs. It would expect that drastic advances in the treatment of intractable diseases will be achieved by the NANOEGG drug delivery system.

# Polymeric Nanomaterials – Synthesis, Functionalization and Applications in Diagnosis and Therapy

*Jutta Rieger, Christine Jérôme, Robert Jérôme, and Rachel Auzély-Velty*

### 8.1 Introduction

In the last decade, polymeric nanoparticles have received increasing interest both for drug delivery purposes and as diagnostic tools. The interest in nanoparticles as drug carriers relies on the difficulties met in drug delivery. In fact, after extravascular administration of a drug, its fate is determined by the combination of several processes, i.e. absorption, distribution, metabolism and elimination (ADME). In contrast, intravenous routes circumvent the absorption process as the drug is directly available in the blood circulation. Regardless of the administration route, each of these processes depends mainly on the physicochemical properties of the drug. Therefore, drug carrier systems have been developed that allow for controlling the fate of a drug within the patient. These “drug delivery systems” cannot only influence the absorption of a drug from the gastrointestinal tract, but they also permit governing of the drug distribution within the organism. In particular, nanoparticles have received increasing interest because of their ability to deliver a wide range of drugs (or diagnostic agents) to various organs or tissues for sustained periods of time. In this chapter, two applications of nanosized polymeric colloidal carrier systems are discussed together: their use as drug delivery systems and as diagnostic tools. Indeed, for both applications most of the required features and preparation techniques are similar, if not identical.

As a remark, polymer nanoparticles are considered here as submicron carriers in the nanometer range (diameter below 1  $\mu\text{m}$ ) mainly prepared from natural or synthetic polymers. This definition does not take into account the morphological and structural organization of the polymer. The term “nanosphere” is used to describe nanoparticles that are constituted by a solid “homogeneous” polymeric matrix. The delivery of the therapeutics proceeds either by the diffusion through the polymer matrix or, in the case of biodegradable particles, by the degradation of the latter, or by both processes. In contrast, “nanocapsules” are nanoparticles where a polymeric membrane surrounds a cavity filled by an oily or an aqueous content. They are therefore considered as a “reservoir” system, where the diffusion of the hydro-

philic or hydrophobic drug is controlled by the nature of the polymeric membrane. In this chapter, we focus on “frozen”, not dynamic systems, i.e. systems where an exchange between individual polymer chains and polymer chains of the nano-object cannot take place. Consequently, dynamic systems such as micelles as well as liposomes are barely considered in this review. However, in Section 8.4.3.4.1, several approaches based on so-called shell crosslinked knedel-like (SCK) nanoparticles are quoted. Such SCK nanoparticles are micelles, whose outer shell is crosslinked. They can be prepared in two steps, starting from the self-assembly of amphiphilic block copolymers to form micelles, of which the shell formed by the outer block is frozen by crosslinking in a second step [1].

Polymeric nanoparticles have now been the subject of numerous studies for more than 20 years and have progressed since then. Three generations of nanoparticles may be considered.

(i) *First-generation nanoparticles.* Nanoparticles with no specific surface properties have been called “nanoparticles of the first generation”. Indeed, whenever such kinds of nanoparticles are introduced in the human body, they are rapidly recognized as foreign bodies and, as a consequence, removed from the blood circulation. Once nanoparticles are introduced in a biological system, numerous plasma proteins adsorb at their surface, leading to the activation of the complement system. As a consequence, the colloidal drug carriers are rapidly recognized by macrophages of the mononuclear phagocyte system (MPS) and removed within seconds from the blood stream. Organs with high phagocytic activity are the liver, spleen and bone marrow. These organs possess a discontinuous, i.e. more permeable, endothelium, where the blood is directly in contact with the immune active macrophages. Therefore, nanoparticles of the first generation accumulate in and passively target the liver, spleen and bone marrow. This natural tendency to be captured by the MPS has therefore found application in the treatment of liver cancer and other liver-related diseases.

The protein adsorption on the nanoparticle surface, i.e. the key step to induce a cascade of biological processes leading to their elimination, is based on various interactions, but especially on interactions of hydrophobic domains of the proteins with hydrophobic domains present at the nanoparticle surface.

(ii) *Second-generation nanoparticles.* In order to target other organs than tissues with high phagocyte activity, further developments strove for avoiding the rapid adsorption of blood proteins, i.e. the activation of the complement system. This has been achieved by modifying the surface of the nanoparticles, especially by hydrophilic materials, in order to inhibit hydrophobic protein–particle interactions. The coating of the particle surface by hydrophilic chains leads to repulsion of proteins and consequently a prolonged residence time of the particles in the blood stream. These surface-modified nanoparticles are also called carriers of the “second generation”, or “Stealth™” nanoparticles, as they are designed to successfully avoid MPS sequestration. The hydrophilic polymers that have been used for the surface coating of nanoparticles are synthetic polymers, particularly poly(ethylene oxide) (PEO) [2, 3], but also polysaccharides, such as heparin [4, 5] and dextran [6].

**Figure 8.1.** Extravasation of long-circulating (Stealth) nanoparticles in the tumor interstitium by passive diffusion or convection across the altered and hyperpermeable neoplastic endothelium.

These long-circulating colloidal systems have received much interest in the field of cancer diagnosis and treatment. Indeed, cancerous tissues are characterized by an “enhanced permeability and retention” effect [7] (Fig. 8.1). The phenomenon, that long-circulating colloidal systems are preferentially accumulated in cancerous tissues, is called “passive targeting”, and is used in numerous studies both for drug delivery purposes and diagnosis [8].

(iii) *Third-generation nanoparticles – active targeting.* It is possible to give carriers affinity to specific tissue by decorating their surface with targeting ligands. This kind of carrier delivers a drug specifically to its pharmacological site in the organism, and thus allows us to decrease the administered quantity of drugs and to minimize side-effects. Indeed, the latter are generally the result of the presence of the drug at other tissues than at the desired one.

Targeting ligands can be monoclonal antibodies, sugars, hormones, peptides (e.g. the tripeptide, arginine–glycine–aspartic acid (RGD) [9]), vitamins (e.g. biotin [10]) or other small organic molecules (e.g. folic acid [11]). Colloidal carriers, of which the surface is decorated with targeting moieties, are also called “nanoparticles of the third generation” and today most studies tend to design such nano-objects. Quite a lot of systems have already been patented. Targeting demands optimal interaction between a targeted site and its ligand. Therefore, targeting molecules have been fixed at the end of linker molecules, such as flexible PEO chains [10].

The surface functionalization of polymeric nanoparticles is thus the key point for both targeted drug delivery and diagnosis. Indeed, this chapter focuses mainly on nanoparticles of the third generation, i.e. surface-modified nanoparticles, designed for drug delivery and diagnosis. The objective of this chapter is to discuss (i) the different ways to obtain surface-modified nanoparticles, (ii) the biological molecules used for surface modification, and (iii) the current and future applications of such polymeric nanoparticles in the field of drug delivery and diagnosis. In line

with our subjects of research, we mainly report on nanospheres, rather than nanocapsules, and restrict the cited examples to approaches interesting for biomedical applications. Because of their importance for diagnosis purposes, we also report on nanoparticle composites composed of both polymer and inorganic materials (that serve as label/marker). However, metallic nanoparticles coated by polymer chains are not the subject of this chapter.

The chapter is divided into five main sections. Section 8.2 deals with polymeric materials used for the preparation of nano-sized carrier systems. In Section 8.3, the different techniques to obtain such systems are discussed. Section 8.4 describes how the surface of nanoparticles can be modified and briefly summarizes the most common techniques to characterize nanoparticle surfaces. Section 8.5 describes their application as drug delivery systems and diagnostics.

## 8.2

### Polymer Materials Used for the Synthesis of Nanoparticles

Depending on the route of administration (oral or parenteral) and the application of polymeric nanoparticles (drug carriers or diagnostic systems), the materials used to produce the colloidal systems meet different physiological and biological requirements. Among these requirements, biocompatibility and safety are of crucial importance.

Additionally, it must be considered whether bioerosion and/or biodegradation is desired or not. Although there is no universally accepted definition for the terms bioerosion and biodegradation, bioerosion refers to solubilization of an initially water-insoluble material with or without changes in the chemical structure, while biodegradation refers to solubilization that occurs as a consequence of cleavage of main-chain bonds. The prefix “bio” is used because the erosion or degradation takes place in a biological environment, either by biocatalytic processes (fungi, enzymes, etc.) or by chemical/radical processes (hydrolysis, oxidation, UV irradiation). Degradable synthetic polymers have great potential for drug delivery purposes. They are typically degraded by chemical hydrolysis, whereas the degradation of natural polymers (i.e. polymers derived from animal or plant sources) generally requires enzymes to catalyze the hydrolysis. On the other hand, polymers used for diagnosis purposes, especially in the case of *ex vivo* (*in vitro*) tests, should not be biodegradable; therefore, nondegradable, i.e. long-term stable polymers, which are often more easy to synthesize, are used. In that way, recycling and repeated use of the device are possible. Concerning synthetic biodegradable polymers, it must be noted that not only the polymer itself used for the formulation, but also the degradation products (metabolites) must be nontoxic, biocompatible and chemically inert. The practical consequence of that is that only a limited number of nontoxic, monomeric starting materials can be really applied for the development of biodegradable nanoparticles.

In the following, the main polymers used for the preparation of nanocarriers will be described. We distinguish three groups of polymers, i.e. (i) natural poly-

mers (“biopolymers”), (ii) synthetic polymers which are “degradable” by biological or chemical processes in the human body and (iii) “nondegradable” synthetic polymers.

### 8.2.1

#### Natural Polymers

Polysaccharides represent – besides polypeptides – the most important group of natural polymers [12]. We have chosen to focus here only on polysaccharides that display very interesting physicochemical properties, in terms of gelation characteristics, chelating properties and biological activity. Many polysaccharides show biocompatibility and biodegradability, which are the basic characteristics for using polymers as biomaterials, as reviewed by Dumitriu and coworkers [13]. Moreover, their physicochemical properties as well as their interactions with living medium can be altered by chemical modifications.

Several biocompatible polysaccharides such as chitosan, dextran, heparin and hyaluronic acid have been shown to be interesting candidates for the modification of nanoparticle surfaces. This allows, for instance, reducing nanoparticle uptake by the MPS and also, in some cases, conferring specific biological functions [14].

In addition, due to its polycationic nature, chitosan could be advantageously used as a constitutive core material of nanoparticles. This biopolymer is obtained by partial *N*-deacetylation of chitin – a natural polysaccharide found in crustacean shells. Chitosan consists of a linear chain of (1–4)-linked 2-amino-2-deoxy- $\beta$ -D-glucopyranose and 2-acetamido-2-deoxy- $\beta$ -D-glucopyranose units (Fig. 8.2). It is water-soluble in acidic conditions ( $\text{pH} < 6$ ) due to the existence of amino groups making it thus possible to prepare derivatives with optimized properties under homogeneous conditions. Its hydrophilicity allows covering the domain of applications in solution and in gel (after crosslinking by chemical or physical bonds). Due to its mucoadhesive properties, chitosan has been largely investigated for coating colloidal carriers administered to the gastrointestinal tract [15], or by nasal, ocular, buccal and vaginal routes. The strong mucoadhesion of chitosan can be explained by ionic interactions between this polycationic molecule and anionic substructures such as sialic moieties of the mucus gel layer on mucosa. Apart from its muco-

Figure 8.2. Chemical structure of chitosan.

adhesive properties, chitosan displays low toxicity, degradability by enzymes such as chitinase and lysozyme [13], anticoagulant properties, and antibacterial and antifungal action. It has also been demonstrated to be a promoter of wound healing in the field of surgery.

As mentioned above, taking advantage of the polycationic nature of chitosan, Alonso and coworkers [12, 16] developed chitosan nanoparticles based on ionic gelation of chitosan with sodium tripolyphosphate. The size, surface characteristics and *in vitro* release properties of these nanoparticles can be modulated by the preparation conditions and in particular by incorporation of an additional polymer such as a diblock copolymer of ethylene oxide and propylene oxide (PEO-*b*-PPO). The authors demonstrated that these nanoparticles have a great protein-loading capacity (protein loading up to 50%, i.e. 50 mg of protein per 100 mg of nanoparticles). Such drug-loaded chitosan-based nanocarriers have been mostly administered by mucosal routes (i.e. oral, nasal, ocular). Alonso and coworkers also investigated the nasal absorption of such chitosan nanoparticles loaded with insulin (via the glucose blood concentration) and, furthermore, studied the *in vitro* release profiles of hydrophilic drugs, such as anthracycline and doxorubicin [12], as well as of hydrophobic peptides such as cyclosporine A.

Furthermore, the polycationic character of chitosan makes it an interesting material for nonviral gene delivery. It forms polyelectrolyte complexes with the negatively charged DNA, condenses the DNA, which protects it from degradation by DNase [12, 17]. Nevertheless, the transfection rate of such chitosan-DNA complexes is very low. Therefore, more sophisticated DNA-loaded chitosan-based nanoparticles have been developed and shown to be promising gene delivery systems exhibiting better transfection rates [12].

Finally, the properties of chitosan have been modified by chemical modifications such as deacetylation, *N*-sulfation or modification by organic molecules (e.g. sugars etc.), which give rise to other applications. Very recently, polyelectrolyte complex nanoparticles have been prepared from self-complexation of amphoteric *N*-sulfated chitosan [18].

In contrast to topical (locally applied) application of chitosan-based formulations, the safety/toxicity of positively charged polysaccharides for systemic applications (e.g. intravenous administration) is currently controversial. Indeed, it has been reported that chitosan induces the opening of tight junctions between epithelial cells, enhancing their permeability [19, 20].

Exhaustive reviews on recent advances on chitosan-based micro/nanoparticles are given by several authors [21, 22].

Dextran is an  $\alpha$ -D-1,6-glucose-linked glucan with side-chains 1–3 or 1–4 linked to the backbone units (Fig. 8.3). The branches are mostly one or two glucose units long. This biopolymer can be obtained from fermentation of sucrose-containing media by *Leuconostoc mesenteroides* bacteria. The clinical use of dextran over the past 50 years provides impressive proof of its safety and quality. Dextran may be ingested orally and is well tolerated. Due to its biocompatibility and hydrophilicity, it is often utilized as a coating material for nanoparticles. Indeed, it has been demonstrated to display protein-repulsive properties and to decrease the uptake by the

**Figure 8.3.** Chemical structure of dextran. R<sub>1</sub>, R<sub>2</sub> and R<sub>3</sub> are positions of branching.

MPS. Moreover, the dextran macromolecule presents a large number of reactive hydroxyl groups for chemical attachment of functional molecules. Many reactions characteristic for alcohol can be used; however, due to the presence of three hydroxyl groups per glucose residue in the backbone, such reactions are not selective.

Hyaluronic acid (HA) is a linear polysaccharide composed of a repeating disaccharide unit of *N*-acetyl-*D*-glucosamine and *D*-glucuronic acid, belonging to the glycosaminoglycan family (Fig. 8.4). It is a component of the synovial fluid, cartilage, vitreous humor and extracellular matrices [13, 23]. Protein interactions with HA play crucial roles in cell adhesion, cell mobility, inflammation, wound healing and cancer metastasis. Its carboxyl groups are mostly deprotonated at physiological pH, thus conferring a polyanionic character to the polymer. Similar to chitosan, the advantage of using HA as a surface modifier in the field of drug delivery/nanoparticles relies on its bioadhesive properties, which have been particularly ex-

**Figure 8.4.** Repeating disaccharide units of HA.

ploited for ophthalmic applications. Indeed, as for other anionic polymers [e.g. poly(acrylic acid) (PAA)], it has been found that carboxylic groups are responsible for their adhesion to the mucus gel layer. Carboxylic acid moieties are supposed to form hydrogen bonds with hydroxyl groups of the oligosaccharide side-chains of mucus glycoproteins. It should also be emphasized, that the biological activity of HA depends on the molecular weight [24].

Chemically modified natural polymers have received increasing interest, and especially hybrid materials combining synthetic and natural polymers open up new possibilities and applications, combining the unique features of the different materials. As an example, poly( $\epsilon$ -caprolactone) (PCL)-grafted dextran copolymers (glycopolymers) have demonstrated amphiphilic properties, and have been used as emulsifiers and for the preparation of nanoparticles (by an emulsion-evaporation technique) [25].

### 8.2.2

#### Degradable Synthetic Polymers

In contrast to natural polymers, of which the molecular weight and distribution depend on the fabrication and extraction procedure, synthetic polymers can be tailor-made. Their physical and chemical properties can be varied over a wide range, particularly by copolymerization with appropriate (functional) comonomers. Additionally, using controlled polymerization techniques, the macromolecular characteristics can be adjusted and narrow molecular weight distribution (PDI) can be reached, in contrast to most of the natural polymers. Furthermore, some synthetic polymers can be obtained in oil-in-water (o/w) emulsions, which makes the *in situ* synthesis of nanoparticles by emulsion-polymerization possible.

Fig. 8.5 presents the chemical structure of the main synthetic polymers used for the preparation of nanoparticles.

Domb and coworkers have given a complete review on “biodegradable polymers as drug carrier systems” [26]. The first and probably most important and frequently used groups of biodegradable polymers are linear polyesters. (Co)polyesters based on poly(lactic acid) [or poly(lactide) (PLA)], poly(glycolic acid) (PGA) and poly(lactide-*co*-glycolide) (PLGA) have been used for more than three decades for a variety of medical applications [26], and are considered as the best biomaterials with regard to design and performance. Indeed, they meet the biological requirements of safety and are biodegradable to nontoxic metabolites, and are approved by the Food and Drug Administration (FDA).

Since lactic acid contains an asymmetric  $\alpha$ -carbon atom, two different optical isomers exist, D- and L-lactic acid, that give rise to morphologically distinct polymers. The polymers derived from the optically active monomers, i.e. poly(D-lactide) [(P(D-LA))] and poly(L-lactide) [(P(L-LA))] are semicrystalline materials and exhibit identical physicochemical properties, whereas the racemic P(D,L-LA) is purely amorphous and has striking different properties. Furthermore, these racemic and semicrystalline polymers exhibit different degradation rates, as the (bio)degradation is dependent on the polymer crystallinity [27].

## (a) “Degradable” synthetic polymers

## (b) “Non degradable” synthetic polymers

**Figure 8.5.** Chemical structure of (a) the main biodegradable synthetic polymers: (4) poly(glycolic acid), (5) poly(lactic acid), (6) poly(lactide-co-glycolide), (7) poly( $\epsilon$ -caprolactone), (8) poly(malic acid), (9) poly(ethylene carbonate) ( $R = \text{H}$ )/ poly(propylene carbonate) ( $R = \text{CH}_3$ ) and (10) poly(anhydride), and (b) the main

nondegradable synthetic polymers: (11) poly(methyl methacrylate) ( $R = \text{CH}_3$ )/ poly(hydroxyethyl methacrylate) ( $R = \text{CH}_2\text{CH}_2\text{OH}$ ), (12) poly(*N*-isopropylacrylamide), (13) poly(alkylcyanoacrylate) and (14) poly(ethylene oxide) used as core material for the preparation of polymeric nanoparticles.

However, apart from the morphological state of the macromolecule, the biodegradation of polymeric devices is affected by many other important factors such as the chemical stability of the hydrolytically sensitive groups in the polymer backbone, the hydrophilic/hydrophobic character of the repeating units, the initial molecular weight and the molecular weight distribution. The fabrication process, size, geometry (specifically the surface area to volume ratio) and porosity of the device also have a tremendous impact on the degradation rate as well as the environmental conditions [27]. Since the hydrolytic degradation is caused by the reaction of water with labile bonds, typically ester bonds in the polymer chain, the reaction rate is intimately connected with the ability of the polymer to absorb water. Thus, devices made of PGA erode faster than identical devices made of the more hydrophobic PLA, although the ester bonds have almost the same chemical reactivity toward water in both polymers. Furthermore, as mentioned above, although P(L-LA)

and P(<sub>D,L</sub>-LA) have chemically identical backbone structures and an identical degree of hydrophobicity, devices made of P(L-LA) tend to degrade much more slowly than identical devices made of P(<sub>D,L</sub>-LA). The slower rate of erosion of P(L-LA) is related to its semicrystalline morphology.

Vert and coworkers [28] demonstrated the complexity of PLA, PGA and PLGA degradation, and emphasized that the hydrolytic process depends on the size and morphology of the biomedical device. Although at first sight astonishing, it has been demonstrated that PLA microparticles degrade faster than PLA nanoparticles, and that this phenomenon relies on a diffusion mechanism [29]. Indeed, due to the large nanoparticle surface in relation to the volume, the acid (produced during the degradation) can easily diffuse out of the nanoparticle. On the contrary, within microparticles, the produced acid accumulates inside the particle as the diffusion is slower. This local decrease of the pH has an autocatalytic effect on the degradation process. Indeed, after the water uptake the polymer chains degrade in the core of the nanoparticles (corresponding to a decrease of the molecular weight), and only afterwards appears weight loss of the material due to the diffusion of the degraded polymer chains out of the bulky material.

Another example of a polyester is PCL, which is widely used in the field in biomaterials. This polymer is semicrystalline, more hydrophobic than PLA and PLGA, and hence is characterized by a slower (bio)degradation.

Furthermore, other biodegradable polyesters derived from naturally occurring, multifunctional hydroxy acids and amino acids, such as malic acid and aspartic acid, have been investigated by Lenz and Guerin [30]. Poly(malic acid) is biocompatible and degradable, and water-soluble in contrast to PLA and PCL. Biocompatibility tests indicated that poly( $\beta$ -malic acid) is nontoxic and nonimmunogenic [31].

Due to the fact that most of these polyesters lack functional groups, efforts have been made to prepare biodegradable aliphatic polyesters bearing functional groups available for further modification. Such copolymers can be reached by copolymerization of novel functional monomers with conventional ones [32–36]. Their features are affected by the comonomer compositions, the polymer architecture, and the molecular weight. Copolymers have thus been synthesized in order to adjust degradation rates as well as mechanical properties. For instance, PEO-*b*-PLA block copolymers have been synthesized and used to prepare nanoparticles showing a faster degradation with respect to plain PLA nanoparticles. Indeed, the introduction of a hydrophilic polymer (PEO) favors hydration of the polyester nanoparticles, which is the key requirement for the hydrolytic degradation to take place as explained above. For the same reason, the ester functions next to the PEO segment degrade first and the PEO chains are lost rapidly.

In addition, polycarbonates, such as poly(ethylene carbonate) and poly(propylene carbonate) have been explored in the design of new polyester-related structures for the preparation of nanoparticles for drug delivery. For instance, they have been tested as biodegradable carriers for the delivery of 5-fluorouracil [37] and were found to be degraded enzymatically [38].

In addition to natural proteins, synthetic (co)poly(amides), such as poly(lysine) and poly(glutamic acids), have also been studied as drug carriers [39].

As well as the described groups of biodegradable polymers, there are a lot of other classes of biodegradable polymers used for biomaterials, such as poly(anhydrides), poly(phosphate esters), poly(phosphazenes) and poly(orthoesters). An exhaustive overview on their properties, synthesis, degradation characteristics, biocompatibility and toxicity is beyond the scope of this work, and may be found in the literature [26].

### 8.2.3

#### Nondegradable Synthetic Polymers

Polymers made of acrylic or vinylic monomers constitute an important group of nondegradable materials used for the preparation of “biostable” polymeric nanoparticles. The interest of these materials relies mainly on the ease of preparation and the availability of functional groups.

Poly(alkylcyanoacrylate) (PACA) represents an intermediate class between the synthetic biodegradable and nonbiodegradable polymers [40]; indeed, it has been shown that PACA particles are degraded by a surface erosion process [41], through enzymatic hydrolysis of the ester side-chains of the polymer. The polymer chains are therefore degraded to hydrophilic compounds and the rate of elimination is dependent of the length of the nondegradable alkyl chain [42]. It was demonstrated that materials based on PACA are well tolerated *in vivo*.

Finally, we would like to emphasize, that stimuli responsive polymers, such as poly(*N*-isopropylacrylamide) (PNIPAAm), are promising materials for the preparation of stimuli responsive colloidal carrier systems. Despite the importance of this group of materials, we are not able to discuss the materials used for nanoparticles in this chapter. There are a lot of reviews on this subject [43, 44] (see also Sections 8.5.1.3 and 8.5.2.3).

### 8.2.4

#### PEO

This section is dedicated to PEO because of its importance and frequency of use for biomaterials and, especially, nanoparticles. PEO is a hydrophilic, neutral, very flexible polymer, which is widely used for the surface modification of nanoparticles. It is FDA approved and quite an important number of PEO–drug conjugates are on the market for intravenous administration. PEO is nonbiodegradable but, due to its hydrophilicity, bioeliminable whenever its molecular weight is less than 20 000 g mol<sup>-1</sup> [45].

The mechanisms of PEO–protein interactions are reported in the review by Vermette and coworkers [46]. Briefly, the protein repellence of PEO coatings has been associated to “steric repulsion” and/or “hydration”/“water structuring” of the chains. The flexibility of these PEO chains, which is particularly high in comparison to other hydrophilic polymers, is one explanation for its protein-repulsive, antifouling properties. Indeed, the reason for its flexibility must be found in the

easy rotation of the ether bonds and in the absence of any bulky substituent on the PEO skeleton. The rapid and transitory change of the conformation of PEO chains is probably responsible for the poor interaction of the PEO chain with proteins. In addition, whenever a protein or another surface approaches with sufficient kinetic energy, PEO chains forming a dense brush at a surface will be compressed by the collision. This will increase the local concentration of polymer segments (corresponding to a loss of entropy of the PEO chains), enhancing the free energy and inducing the repulsion of the protein from the surface [46]. The interaction energy is thus repulsive.

A lot of works tried to understand the influence of the density and length of PEO chains at surfaces on its protein-repulsive properties. The conformation of the PEO chains changes when the distance  $D$  that separates two neighboring PEO chains tethered at the surface becomes close to or smaller than the radius of gyration of the polymer ( $R_g$ ) (Fig. 8.6). In good solvents for PEO such as water, the polymer chains form “mushroom”-like structures at long distances ( $D \gg R_g$ ), as illustrated in Fig. 8.6(A) and (B), in poor solvents flat “pancake”-like structures are expected. With decreasing distance ( $D \sim R_g$ ), the chains start to interact with each other and approach the mushroom to brush transition (Fig. 8.6(C) and (D)). For  $D < R_g$ , the polymer chains strongly interact and in order to minimize the contact between them they stretch away from the surface, forming the so-called “brush” conformation [46]. It is thus clear that one of the most important parameters in determining the protein adsorption onto PEO layers is the grafting density of the PEO chains. It

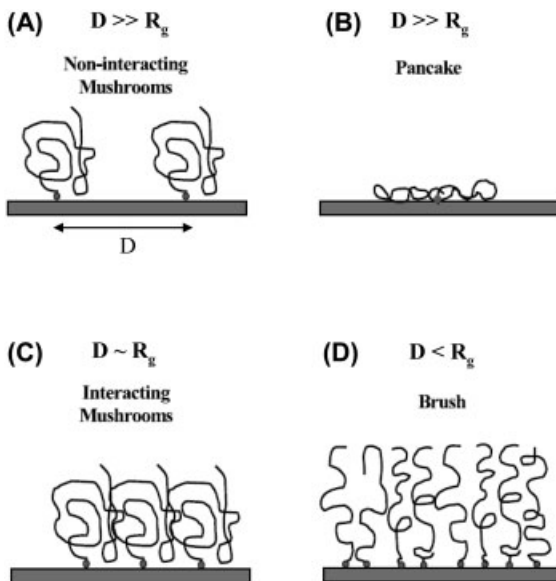

Figure 8.6. Schematic representation of polymer (PEO) structures at the interface.

has been reported that a distance  $d$  of 1.5 nm between two terminally attached PEO chains at the nanoparticle surface was found ideal for reducing protein adsorption. In addition, it has been demonstrated that rather long PEO chains (a molecular weight of 2000–5000 g mol<sup>-1</sup> has been proposed as ideal molecular weight earlier [47–49]) are not necessarily a prerequisite for low protein adsorption [46].

These are the reasons why PEO is the polymer of choice for the design of nanoparticles of the second generation and third generation.

### 8.3

#### Preparation of Polymeric Nanoparticles

In the last decades, several techniques have been developed to prepare colloidal carrier systems from polymeric materials. These can be obtained either (i) by association of preformed polymers (natural, modified natural or synthetic polymers, see Section 8.2) using techniques, such as emulsion-evaporation, emulsion-diffusion and salting-out, or (ii) by (mini)emulsion or micellar polymerization of polymerizable monomers dispersed in an aqueous phase. The preparation technique must be suitable for the material with regard to solubility and stability of the polymer. In the case of emulsion polymerization, the availability of monomers polymerizable in o/w emulsion is the limiting factor.

#### 8.3.1

##### Preparation of Nanospheres from Preformed Polymers

The use of preformed polymers for the preparation of nanospheres has several advantages, such as the availability of a large variety of materials with controlled and optimized macromolecular characteristics (molecular weight and polydispersity), as well as suitable physicochemical and biological properties. Indeed, in order to favor reproducibility, colloidal carriers must be synthesized from well-defined macromolecular materials. A large number of reviews are available describing in detail the different techniques to obtain colloidal carriers (e.g. Ref. [50]). In the following, we briefly discuss the most popular methods to obtain nanospheres from preformed polymers, i.e. emulsion-evaporation, emulsion-diffusion, salting-out and nanoprecipitation.

Polymers that are insoluble in water are generally used for the formation of dispersed colloidal systems in aqueous media. Thus, organic solvents are often required to dissolve the polymers – the first step to nanoparticle formation. Depending on the preparation procedure described in the following sections, the organic solvents used are either miscible or immiscible with water.

##### 8.3.1.1 Emulsion-evaporation

Organic volatile solvents, such as chloroform and dichloromethane that are poorly miscible or immiscible with water, are suitable for the emulsion-evaporation tech-

nique, patented by Vanderhoff and coworkers [51]. First, the polymer is dissolved in the organic solvent and tiny solvent droplets are formed by emulsification in an aqueous phase containing an emulsifier [e.g. poly(vinyl alcohol) (PVA) or albumin]. Then, the crude o/w emulsion is exposed to a high-energy source, such as ultrasonic devices or homogenizers, etc. [50], and, finally, stable solid nanoparticles are formed from the emulsion droplets by slight evaporation of the organic solvent (under reduced pressure). During the evaporation process, the organic solvent diffuses from the inner core of the droplets to the external phase, maintaining a saturation of the water phase by the organic solvent. The progressive elimination of the solvents induces the precipitation of the polymer and the nanoparticles formation. The size of the droplets and also the nanoparticles can be adjusted by the nature and quantity of emulsifier, the viscosity of the dispersing phase, and stirring rate. Unfortunately, this method requires the use of large quantities of surfactants (e.g. ranging from 0.5 to 8 wt% for PVA [50]) and high energy to form stable homogeneous emulsions. When ultrasonication is used instead of high-speed homogenizers, only very polydisperse nanosuspensions could be obtained. Only hydrophobic drugs can be efficiently encapsulated, by this o/w process. As far as hydrophilic drugs are concerned, a double-emulsion (w/o/w) technique has been developed in order to obtain nanospheres of hydrophobic polymer (such as PLGA) loaded by hydrophilic biomolecules, such as proteins [52]. Therefore, an inverse w/o emulsion is first prepared from an aqueous phase, containing the hydrophilic drug, and the organic phase, containing the matrix building polymer. Then this emulsion is emulsified in a second surfactant-containing aqueous phase to form the w/o/w emulsion. Finally, the organic solvent is removed by evaporation at reduced pressure.

#### 8.3.1.2 Salting-out

Solvent immiscibility and polymer precipitation can be induced through changes in temperature, pH or the addition of alcohol, but also by the addition of large quantities of salt ("salting-out"). The principle of the salting-out method [53] is to saturate the aqueous phase by electrolytes in order to reduce drastically the miscibility of the organic solvent (normally water miscible) with the aqueous phase. First, an o/w emulsion is formed between the organic phase and the surfactant [e.g. PVA, hydroxyethylcellulose or poly(vinyl pyrrolidone) (PVP)]-containing aqueous phase, which was previously saturated by the salt. Then, distilled water is added in such an amount that the total quantity of the organic solvent becomes miscible with the aqueous phase. As a result, the organic solvent diffuses into the aqueous phase, leading to the precipitation of the polymer as nanospheres. Several factors, such as stirring rate and polymer concentration, have been reported to influence the mean size of the nanoparticles. The salt is generally removed by cross-flow ultrafiltration/dialysis. This methodology allows using organic solvents of low toxicity (generally acetone) and which can be easily removed at the end of the preparation process by ultrafiltration or evaporation. However, the use of large amount of surfactants and electrolytes is necessary.

### 8.3.1.3 Emulsification-diffusion

The emulsification-diffusion method can be considered as a modification of the salting-out procedure, avoiding the use of salts and hence intensive purification steps [54]. Before dissolution of the polymer, the partially water-miscible organic solvent (ethyl acetate, propylene carbonate, benzyl alcohol) is saturated in water to ensure the thermodynamic equilibrium of both liquids. Then, the polymer solution is emulsified (o/w emulsion) under vigorous stirring in an aqueous solution containing a stabilizer (e.g. PVA or poloxamers, i.e. a series of copolymers composed of two PEO blocks separated by a PPO block). The subsequent addition of water to the system causes the diffusion of the organic solvent to the external aqueous phase, resulting in the formation of nanoparticles. Finally, the organic solvent is removed, depending on its boiling point, either by evaporation or crossflow ultrafiltration. The size of the nanoparticles depends on numerous factors, such as the concentration of the stabilizer (emulsifier), as well as the nature of the polymer and the stirring rate [55].

This method is only efficient for the encapsulation of lipophilic drugs. In addition, it requires the removal of large volumes of water due to the dilution-induced diffusion process. However, the advantages of this approach rely on its good reproducibility and high loading efficiencies.

### 8.3.1.4 Nanoprecipitation

Fessi and coworkers [56] described and patented a simple technique to obtain polymeric nanoparticles which does not require the preliminary formation of an emulsion. It relies on the use of organic solvents that are perfectly miscible with water, such as acetone, ethanol or dimethyl sulfoxide (DMSO). Furthermore, the polymer must be insoluble in the aqueous phase, but also in the mixture of both phases. This method is called the “nanoprecipitation” or “solvent displacement” technique.

Thus, the organic polymer solution is added drop-by-drop into a large volume of an aqueous phase, typically containing a surfactant (e.g. PVA, Poloxamer®). Under these conditions, the nanoparticles are formed instantaneously by the precipitation of the polymer induced by the diffusion of the organic solvent in the aqueous phase. Depending on its boiling point, the organic solvent is then eliminated by evaporation or dialysis. This technique has been modified and adjusted by various research groups [57, 58]. Polymer precipitation has also been induced by gentle progressive diffusion of water to an organic polymer solution placed in a tube of dialysis membranes [59]. The size of the nanoparticles obtained by nanoprecipitation processes is typically about 200 nm depending on the nature, miscibility and viscosity of the solvent, the polymer and its concentration in the organic solvent, and the preparation conditions.

This technique is especially interesting because of its low energy consumption and very simple handling.

As described above, most of these techniques require the use of surfactant in the aqueous phase, i.e. amphiphilic polymers such as PVA or triblock copolymers of

PEO and PPO (PEO-*b*-PPO-*b*-PEO, known as poloxamers) that exhibit interfacial activity, to guarantee the stability of the colloidal dispersions.

### 8.3.2

#### Synthesis of Nanospheres by *In Situ* Polymerization

In contrast to the techniques described above, where preformed polymers are used, nanoparticles can also be synthesized by polymerization of suitable monomers in (mini)emulsion [60, 61] or dispersion. Emulsion polymerizations employ water-insoluble monomers that are emulsified as micron-sized oil droplets (1–10  $\mu\text{m}$ ) in an aqueous phase stabilized by a surfactant. The initiators used in emulsion polymerizations are generally water-soluble and dissolved in the aqueous phase. Most emulsion polymerizations use a radical polymerization method. The drawback of such (macro)emulsion polymerizations is that the size of the latex particle does not correspond to the primary emulsion droplets, but rather depends on polymerization kinetic parameters. Miniemulsion polymerizations (Fig. 8.7) are a special class of emulsion polymerizations. They have many similarities, but the particle nucleation and reagent transport phenomena are different. In fact, miniemulsions consist of two immiscible liquids, a surfactant and a special cosurfactant (additive) that is only soluble in the dispersed phase. They are prepared by high-shear treatment of these mixtures, either by ultrasound or by a high-pressure microfluidizer and contain stable nanodroplets with a diameter of 30–300 nm.

Figure 8.7. The principle of miniemulsion polymerization.

The combination of the two surfactants makes the droplets extremely stable, inhibiting the diffusion of monomers out of the miniemulsion droplets and preventing their coalescence [60]. The size of the polymer nanoparticles corresponds thus to that of the initially formed nanodroplets, which is controlled by the shear and the stabilizer system, and not [as for the (macro)emulsion] by the polymerization parameters. The active compound (drug) is generally incorporated in the dispersed phase, and therefore encapsulated in the nanoparticles during the polymerization process. More seldom, it is adsorbed onto the surface of preformed nanoparticles (after the polymerization).

Nanoparticles made of PNIPAAm, poly(*N*-vinylacetamide) (PNVA), poly(vinylamine) (PVAm) and poly(methacrylic acid) (PMAA) have been prepared according to this methodology. The corresponding vinylic and (meth)acrylic monomers are generally polymerized under free radical conditions using, for instance 2,2'-azobisisobutyronitrile (AIBN) as an initiator [62].

New processes based on the miniemulsion concept use amphiphilic polymers both as emulsifiers and surface modifiers of the final nanoparticles. For instance, the radical polymerization of styrene has been carried out in miniemulsions stabilized by amphiphilic derivatives of dextran [63]. The size of the polysaccharide-coated polystyrene particles was directly correlated to that of the initial nanodroplet and depended on the monomer concentration. The use of functional emulsifiers as surface modifiers is discussed in detail in Section 8.4.3.3.

Furthermore, other polymerization systems have also been used to prepare polymeric particles, such as dispersion or suspension polymerization. In the suspension polymerization process, the initiator is soluble in the monomer and larger particles (above 1  $\mu\text{m}$ ) are obtained.

In addition, dispersion polymerizations have been rediscovered in recent years for the preparation of (sub)micron-size polymer particles with narrow size distributions. This process differs notably from emulsion and suspension polymerization as it starts with a homogeneous solution of monomer(s), stabilizer(s) and initiator in a mostly organic solvent. The polymer precipitates as a colloidal dispersion during the polymerization process. As an interesting example, polystyrene core glycopolymer corona nanospheres have been obtained by free radical copolymerization of hydrophilic macromonomers and styrene (as hydrophobic comonomer) in dispersion in a polar solvent (e.g. ethanol/water mixture) [64–66] (details see Section 8.4.3.3).

One of the advantages of emulsion polymerization for the preparation of polymeric nanoparticles is its reproducibility regarding size and drug-loading rate, even at a semi-industrial level. On the other hand, the disadvantages of this approach are the possibility of residual emulsifiers, monomers, but also oligomers, and the risk of drug interaction (with the reactives) during polymerization and thus inactivation.

### 8.3.3

#### Preparation of Nanocapsules

As mentioned in the Introduction (Section 8.1), nanocapsules are built of an oily or sometimes aqueous core, surrounded by a thin polymeric wall. Similar to nano-

spheres, nanocapsules can be obtained from either preformed polymers or by (interfacial) polymerization of monomers at the oil–water interface. The main techniques for the synthesis of nanocapsules rely on the use of a water-miscible organic solvent, solubilizing the polymer or monomer, and the insolubility of them in both the oil and the aqueous phase. The miscibility of the organic solvent is thus the driving force for the diffusion of the polymer (or monomer) to the water–oil interface [67, 68].

In general, the polymer or monomer is first dissolved in the organic phase (consisting of the oil and a water-miscible organic solvent). Then, upon addition of the organic phase to the aqueous phase (containing a hydrosoluble surfactant), the polymer/monomer diffuses with the water-miscible organic solvent and is stranded at the interface between oil and water. As an example for interfacial polymerization, the polymerization of alkylcyanoacrylate has been initiated at the oil–water interface by hydroxyl ions present in the aqueous phase, leading to the formation of nanocapsules [69].

It should be mentioned that colloidal capsules can also be prepared by the layer-by-layer approach. This technique is based on the self-assembly of two oppositely charged species by electrostatic interactions [70, 71]. In general, the capsule wall is formed by alternating deposition of a two oppositely charged polyelectrolytes on a template core, which can be removed at the end of the process e.g. by dissolution. However, the size of the as-prepared capsules is generally in the micrometer-scale (1–5  $\mu\text{m}$ ) rather than in the nanoscale [72, 73].

One of the advantages of nanocapsules over nanospheres is their low polymer content and a high loading capacity for lipophilic drugs. The percentage of encapsulation is generally related to the solubility of the drug in the core phase [74].

## 8.4

### Surface Functionalization

The surface characteristics of nanoparticles are of fundamental importance for their interaction with the environment, i.e. with living medium. In the last decade, numerous surface-modified carrier systems have thus been developed allowing the targeting of specific tissues. Polymeric materials functionalized with targeting moieties, such as sugars [75], peptides [76], folic acid [77] and antibodies [78], have received considerable interest as means to generate intelligent delivery vehicles capable of (polyvalent) specific binding interactions.

#### 8.4.1

##### Functionalization with Biological (Macro)molecules

The first group of bioactive molecules considered here interacts nonspecifically with tissues. Among them, polysaccharides are of great interest, especially to confer to nanoparticles bioadhesive or mucoadhesive properties (*cf.* Section 8.2). Therefore, nanoparticles have been surface-coated by polysaccharides, such as chi-

tosan [19] and HA [14]. It could be demonstrated that nanoparticles coated by such bioadhesive polymers, especially HA, significantly increased the ocular drug availability [79].

To overcome the fast capture of nanoparticles by the MPS, nanoparticles have been coated with dextran and heparin. Such nanoparticles circulate for an enhanced period of time in the blood stream. The polysaccharide shell probably avoided complement activation and opsonization of the nanoparticles by preventing protein adsorption [80, 81]. Aside from being long circulating, heparin-coated nanoparticles showed antithrombic activity [81].

In the 1980s, a tripeptide, RGD, was identified to promote cell attachment [9]. Consequently, RGD peptides have been attached on the surface of polystyrene nanoparticles. These nanoparticles have been shown to induce a 50-fold increase in transport across the human intestine epithelial cells compared to blank polystyrene nanoparticles [82, 83]. It has also been demonstrated that a number of RGD peptides and peptidomimetics bind preferentially to a particular integrin  $\alpha_v\beta_3$ , which is often overexpressed on endothelial cells in tumor neovasculature [84]. A cyclic peptide with the RGD sequence has thus been covalently attached to the surface of doxorubicin-loaded nanoparticles and it was shown that they were preferentially internalized in tumoral tissues compared to other organs, such as the liver or the spleen [85].

#### 8.4.2

#### **Functionalization with Specific Ligands: Specific Interaction through Biological Recognition**

One of the greatest challenges is to find the optimal vector molecules or ligand to transport nanoparticles specifically to the targeted tissue. The strategy relies on the ability of the targeting agents or ligands to bind specifically to cell surface receptors triggering receptor endocytosis. The following will describe some examples of these ligands identified and used up to now for the functionalization of nanoparticles.

##### 8.4.2.1 Mono- or Oligosaccharides (Carbohydrates)

As well documented in the literature [86–88], cell surface carbohydrates from glycoproteins and glycolipids play an essential role as recognition sites between cells or cells and microorganisms. These recognition mechanisms are essentially based on specific interactions between the oligosaccharide chains and soluble or membrane proteins called lectins. The communication network based on carbohydrate–protein interactions is crucial in a large variety of important biological phenomena such as cell growth, inflammation, cancer, viral and bacterial infections.

Taking advantage of these specific carbohydrate–lectin interactions, numerous glycomimetics have been developed for analytical, diagnostic and therapeutic purposes. In particular, sugar-mediated drug delivery allows targeting cells that possess glycoreceptors on their plasma membrane. Such a mode of drug delivery is considered as one of the most promising routes in cell-specific targeting. Indeed,

membrane lectins of some cell types are able to internalize their ligands and hence the glycoconjugates that are specifically recognized by these lectins can be used as efficient carriers of drugs [89]. In particular dendritic cells of the human blood express cell surface mannose-specific lectins, i.e. specific receptors for mannose (mannose receptors) [90, 91]. In fact, these cells capture, process and present antigens to native T cells, inducing the cellular immune response [92, 93]. The possibility to target specifically dendritic cells thus makes mannose-coated nanoparticles attractive delivery systems for vaccines (see Section 8.5.1.2). Apart from this potential application, mannose-coated nanoparticles have been designed to target specifically Gram-negative bacteria, exposing mannose receptors at their surface. They could be used as carriers for antibacterial drugs [94].

In contrast to mannose, galactose interacts with hepatic cells via a Gal/GalNAc-binding mammalian lectin. Galactose conjugates have thus been synthesized, which have been used to carry antiparasitic [95] and antiviral drugs [96] specifically to liver cells. For the same purpose, polymeric nanoparticles decorated with galactose [97, 98], have been synthesized for hepatocyte-specific targeting.

It should be noted that the binding of a particular sugar to its glycoreceptor occurs in a regioselective manner [87] and thus the introduction of saccharidic ligands on polymers is generally performed by 1-*O* substitution of the sugar. Furthermore, it has been emphasized that sugar–lectin interactions depend on the “density” of the partners at a surface. Indeed, their affinity can be enhanced by multiple interactions between the binding proteins and the carbohydrate ligands, which is known as the glycoside cluster effect [99].

#### 8.4.2.2 Folate Receptor

All cells require folic acid as a vitamin for essential functions. They are thus equipped with several pathways for folate internalization. Folate conjugates were shown to enter cells only via the “alternative route”, i.e. via the folate receptor. This cell surface receptor is only expressed in measurable quantities on activated macrophages and at the apical surface of some polarized epithelia. In addition, the folate receptor is significantly overexpressed on the surface of many cancer cells because they require more extensive folic acid to enable their rapid proliferation. The folate receptor is thus a possible target for a number of types of cancer. Their localization on activated macrophages, but not on their quiescent or resting counterparts, makes folate conjugates promising in targeting inflammatory and autoimmune diseases because those specific macrophages cause or contribute to these diseases.

It has been shown that folate-targeted delivery cannot only enhance the drug uptake in the targeted pathologic cells, but can also reduce the drug deposition into nonpathologic cells, thereby diminishing collateral toxicity to normal tissues. This is due to the high specificity of folate for its receptors combined with the high stability of the folate-receptor complex ( $K_d \sim 10^{-10}$ ). Consequently, such conjugates can be administered at very low (nontoxic) concentrations and still achieve a clinical response [100].

Similar to the uptake of the free vitamin, folate conjugates are taken up into cells

via folate receptor-mediated endocytosis and released into the cytosol. Since folic acid is taken into cells to favor their proliferation, they are thus not delivered to lysosomes for destruction. In contrast to that, other ligands are destroyed in the latter in order to prevent continuous signalization of the cells. This feature is important when macromolecular or hydrolytically sensitive drugs have to be delivered, since most of them are inactivated by the lytic enzymes that are concentrated in lysosomes. A lot of studies on targeted drug delivery are thus based on the functionalization of nanoparticles by folic acid [11, 101–103].

#### 8.4.2.3 Antibodies

Apart from ligand–receptor interactions, antigen–antibody interactions are highly specific molecular recognition processes and thus promising tools for specific targeted delivery. In fact, with the advent of monoclonal antibody technology, the utilization of antibodies increased dramatically. Monoclonal immunoglobulin G antibodies represent today a promising groups of vector molecules to transport a colloidal carrier system very specifically to the target tissue. In particular, in the field of cancer, monoclonal antibodies have been shown to be able to bind to specific tumor antigens. The ideal antigen should be expressed on all tumor cells, but not expressed on critical host cells. To date, a remarkable number of antibodies that are specific to a certain cancer type have been identified and approved by the FDA.

Unlike folic acid, which is chemically very stable (e.g. to organic solvents, acids and bases), antibodies are sensitive biomolecules and thus their introduction on the surface of nanoparticles requires the use of mild chemical ligation reactions. Apart from the interest for targeted drug delivery, antibody-decorated nanoparticles are useful tools for clinical analysis by immunoassays and medical diagnostics [104].

#### 8.4.2.4 Biotin

Finally, biotin (vitamin H), a small organic biomolecule, is widely used as a versatile linker molecule to which a large variety of functional moieties can be bound via a biotin–avidin complex. Actually, biotin is known to form very stable complexes with its tetravalent ligand, avidin. The avidin–biotin complex is known as one of the strongest noncovalent biological interactions (association constant  $K_a = 10^{15} \text{ M}^{-1}$ ). In addition, a large variety of biotinylated targeting ligands are commercially available and they can be attached to the surface of biotin-coated nanoparticles via biotin–avidin–biotin complexes (Fig. 8.8) [10].

Figure 8.8. Surface functionalization via biotin–avidin–biotin complex formation.

**Figure 8.9.** Surface functionalization of avidin-bearing nanoparticles with biotinylated molecules.

Indeed, after complex formation with one of the sites of avidin, the residual three binding sites of avidin are still available for the binding of biotin conjugates. A very versatile tool for surface modification was thus made available. It is, however, questionable whether the stability of colloidal dispersions of such nanoparticles may be maintained after the addition of avidin, as interparticular cross-linking via free avidin binding sites might take place.

To avoid this problem, it might be advantageously to attach avidin (NeutrAvidin) directly in a covalent manner to the surface of nanoparticles (Fig. 8.9). This has been developed in the work of Balthasar and coworkers (see Section 8.4.3.4.2) who prepared antibody-decorated crosslinked gelatin nanoparticles as drug carriers for the specific targeting of T lymphocytes (using biotinylated anti-CD3 antibodies).

### 8.4.3

#### Strategies for Surface Modification

Surface functionalization of nanoparticles can be achieved by various approaches. In general, the posterior attachment of bioactive molecules on the surface of preformed nanoparticles may be achieved by (i) noncovalent interaction, (ii) specific complex formation and (iii) covalent linking of the targeting moieties to the nanoparticles by chemical reactions (Fig. 8.10).

These different strategies are closely connected with each other and often combined. As mentioned above, complexing molecules such as avidin have first been covalently coupled to the nanoparticle surface before the desired biotinylated targeting moiety could be attached to the surface by avidin–biotin complex formation [102]. Figure 8.10 makes it clear that the crucial condition for successful attaching targeting moieties at the nanoparticle surface is the presence of “reactive sites”, such as (i) charges, (ii) biomolecules and (iii) reactive groups, at surface of the nanoparticles. They can be introduced by different ways: by adsorption of reactive molecules on the surface of preformed nanoparticles, by preparing nanospheres from preformed polymers in the presence of “functional surfactants”, or by *in situ* emulsion polymerization using functional surfactants/emulsifiers or functional monomers or functional initiators. It should be noted that these techniques can also be used to directly modify the surface by bioactive targeting probes. Therefore, the synthesis of hybrid materials, i.e. materials containing both the biologically

**(i) Unspecific non-covalent interactions (IA)****(ii) Complex formation****(iii) Chemical reactions**

**Figure 8.10.** Different strategies for the conjugation of targeting moieties to nanoparticles. (i) Unspecific noncovalent interactions, adsorption of functional molecules by (a) electrostatic and (b) hydrophobic interactions. (ii) Complex formation. (iii) Covalent linking by chemical reactions.

active molecules and synthetic (polymeric) components, is often required. In this context, a major problem is maintaining the biomolecule–nanoparticle conjugates bioactive and to ensure the bioavailability of the bioactive entity. For this purpose, hydrophilic spacer molecules, such as PEO chains [10], have often been introduced between the surface and the biological ligand, thereby allowing the accessibility of the biomolecule and its interaction. Furthermore, the conjugation reactions must be carried out under mild, nondegrading reaction conditions.

The different strategies to achieve surface modifications of nanoparticles as well as the chemistry used to reach biomolecule–nanoparticle conjugates are detailed in the following sections. Finally, “molecular imprinting” of the surface of nanoparticles using template molecules is also discussed as a promising approach to modify the surface of nanoparticles.

#### 8.4.3.1 Adsorption on Preformed Nanoparticles

Polymer adsorption on solid–liquid interfaces is a widely studied phenomenon connected with many important processes such as colloidal stabilization, flocculation, adhesion and coating [105]. Based on this concept, several works report on the adsorption of functional molecules on preformed nanoparticles [106]. The driving force for physisorption to happen is the affinity of at least part of the molecule to the nanoparticle surface.

Two kinds of adsorption should be distinguished: (i) the adsorption of polyelectrolytes or charged molecules onto oppositely charged nanoparticles and (ii) the adsorption of hydrophobic or hydrophobically modified (macro)molecules onto preformed hydrophobic polymeric nanoparticles [107].

Quite a lot of studies used electrostatic interactions to coat nanoparticles. For instance, positively charged chitosan nanoparticles loaded with proteins have been coated with sodium alginate in order to avoid a burst release, and to enhance their mechanical and thermal stability [14]. Furthermore, chitosan has been adsorbed on negatively charged PLA nanoparticles to prepare fully bioresorbable mucoadhesive nanoparticles [108].

Very recently, potential targeting probes have been adsorbed onto polymer nanoparticles by electrostatic interactions: cationized antigens [Tat(1–72)] were adsorbed on negatively charged nanoparticles [109].

On the other hand, hydrophobic nanoparticles has been surface-functionalized by using amphiphilic or hydrophobically modified macromolecules, the hydrophobic part of the macromolecule ensuring their durable adsorption and physical anchorage. Based on this approach, numerous studies have used amphiphilic block copolymers, such as Pluronic® (block copolymers based on PEO and PPO, e.g. PEO-*b*-PPO-*b*-PEO triblock copolymer also called poloxamers) as surface modifiers of hydrophobic nanoparticles [110]. The hydrophobic PPO block is the driving element for the adsorption onto the surface of nanoparticle, while the hydrophilic PEO chains expand in the aqueous environment forming a steric barrier that stabilizes the nanoparticles, prevents their aggregation and makes them stealthy to the MPS. Similarly, polystyrene nanoparticles have been surface-modified by Pluronic F-108 (PEO<sub>129</sub>-*b*-PPO<sub>56</sub>-*b*-PEO<sub>129</sub>) end-capped by polypeptides containing the RGD sequence. Exposing cell adhesive peptides at their surface, these nanoparticles are promising devices for diagnostic purposes [83].

Apart from amphiphilic block copolymers, randomly hydrophobically modified polymers have also been used. Polystyrene-divinylbenzene (PS-DVB) particles have been coated with dextran partially substituted by phenoxy groups. Adsorption was achieved by simple incubation of the particles in the polymer solution (20 h) and the adsorbed polymer layer was then chemically crosslinked in order to avoid polymer desorption (using epichlorhydrin or butanediol diglycidyl ether). The dextran layer was shown to greatly reduce the nonspecific adsorption of bovine serum albumin (BSA) [105].

Furthermore, dextran-bearing hydrophobic phenoxy groups and comb-like copolymers of dextran-bearing pendant phenoxy groups and PEO chains (DexP-*g*-PEO) were synthesized [111]. They were adsorbed on polystyrene nanoparticles and the effects of the polymer composition and architecture on the protein adsorption were studied (Fig. 8.11).

It was found that the most important parameter in preventing the adsorption of BSA was the extent of the contact points between dextran and the surface, rather than the grafting density of PEO chains, in the case of DexP-*g*-PEO [111].

On the other hand, the naturally occurring adsorption of proteins, which is generally not desired, has also been exploited, e.g. in the case of protein delivery [109].

**Figure 8.11.** Adsorption of amphiphilic dextran (DexP) with (a) high and (b) low amounts of grafted phenoxy groups and (c) of graft DexP-g-PEO copolymer at the hydrophobic surface [111].

The advantage of surface modification via adsorption relies on the complete localization of the adsorbed molecules at the surface. However, it must be considered that the post-modification of the surface of preformed nanoparticles can alter their stability and induce their aggregation. In fact, the stability of colloidal systems relies on steric or electrostatic repulsion of the particles, so that the adsorption of material on the nanoparticle surface might diminish the interparticular repulsion and would thus induce their aggregation. Finally, the risk of desorption upon dilution and introduction into complex biological media must be considered. Therefore, most of the recent approaches rely on the covalent linking of the functional (macro)molecules to the nanoparticle's constitutive polymer (Section 8.4.3.2) or directly to the nanoparticle surface (Section 8.4.3.4).

#### 8.4.3.2 Functional Surfactants as Stabilizers and Surface Modifiers

As explained in Section 8.3, methods for the preparation of polymeric nanoparticles generally use surfactants, which play the role of emulsifier and stabilizer. It was demonstrated that in the case of hydrophobic nanoparticles, the amphiphilic surfactant is located at the surface of the particle, i.e. at the water–hydrophobic solid interface [14, 49]. Amphiphilic copolymers conjugated with bioactive molecules may thus serve as both emulsifiers and surface modifiers. Such copolymers may be synthesized with various architectures, e.g. block [diblock (Scheme 8.1A

**Scheme 8.1.** Amphiphilic copolymers: red = hydrophobic, blue = hydrophilic, star = functional (bio)molecule.

and B) or triblock] or comb-like structures (Scheme 8.1C–E), employing controlled polymerization techniques. The functional biomolecule is rather attached on the hydrophilic part of the copolymers, in order to optimize its availability for interaction in aqueous environment. PEO has preferentially been used because of its hydrophilicity and flexibility properties (see Section 8.2.4).

**8.4.3.2.1 Functional Amphiphilic Block Copolymers** A first group of copolymers used for surface functionalization typically consists of amphiphilic block copolymers as schematically presented in Scheme 8.1A. In general, such copolymers can be obtained through four different strategies: (i) by post-polymerization functionalization, where the functional moiety is grafted to the hydrophilic end of the amphiphilic block copolymer bearing a reactive group [112], (ii) by linking the bioactive group at one end of an  $\alpha,\omega$ -bifunctional hydrophilic homopolymer, followed by the initiation of the polymerization of the second block from the other chain end, (iii) by using biologically active molecules as initiators for the sequential polymerization of the diblock copolymer (hydrophilic block being polymerized first) or (iv) by using polymerizable hydrophilic biomolecules.

The first approach (i) has mainly been applied for the functionalization of diblock copolymers by sugars and peptides. For instance, the hydrophilic end of amphiphilic PEO-*b*-P(D,L-LA) diblock copolymers has been end-capped by mannose [112], lactose [113] or peptides [114] using a reductive amination reaction. For this purpose, aldehyde (CHO)-capped copolymers and amino or aminophenyl derivatives of the biomolecule were synthesized. Then, the conjugation of both compounds was carried out in the presence of reducing agents [NaBH(OAc)<sub>3</sub> or NaBH<sub>3</sub>CN] [112–114].

On the other hand, biotin [115] or protected monosaccharides [86] have been used to initiate the polymerization of the hydrophilic block (approach iii). For instance, Qi and coworkers [115] prepared nanoparticles coated by biotin from biotin-terminated PAA-*b*-poly(methyl acrylate) diblock copolymers (biotin–PAA-*b*-PMA). These functional copolymers were prepared using a biotinylated initiator for the sequential atom transfer radical polymerization (ATRP) of acrylic acid and methyl acrylate (Fig. 8.12).

Not only radical polymerizations, but also ring-opening polymerizations (ROPs) have been successfully initiated by suitably protected molecules. Yasugi and co-

**Figure 8.12.** Synthesis of biotin end-capped PAA-*b*-PMA by ATRP.

**Figure 8.13.** Sequential polymerization of 2-lactobionamidoethyl methacrylate (LAMA) with methacrylic monomers (R-MA) by ATRP at 20 °C.

workers [86] synthesized amphiphilic biodegradable PEO-*b*-PLA diblock copolymers that were end-functionalized by galactose. Therefore, they initiated the anionic polymerization of ethylene oxide by a metal alkoxide of a regioselectively protected galactose, followed by ROP of lactic acid.

Finally, amphiphilic functional copolymers were prepared using polymerizable carbohydrates as monomers. Armes and coworkers synthesized new sugar-modified methacrylic monomers (2-gluconamidoethyl methacrylate and 2-lactobionamidoethyl methacrylate) suitable for the preparation of sugar-modified methacrylate-based diblock (see Fig. 8.13) and triblock copolymers by ATRP starting from different (macro)initiators [116].

**8.4.3.2.2 Functional Random (Comb-like) Copolymers** The most popular pathway to amphiphilic random (comb-like) copolymers (Scheme 8.1C–E) functionalized by biomolecules relies on the synthesis of copolymers bearing groups that are prone to further chemical modification. Then, in a second step, reactive biomolecule derivatives can be grafted onto the (hydrophobic or hydrophilic) polymer backbone (called “grafting onto” approach).

For example, the pendant carboxylic acid groups of poly(methyl methacrylate-*co*-methacrylic acid) copolymers have been successfully used as reactive sites for the covalent linking of biotin molecules [117]. These random amphiphilic copolymers were efficient stabilizers and surface modifiers of PLA nanoparticles [117].

With the purpose to obtain fully biodegradable nanoparticles, biodegradable amphiphilic copolymers bearing reactive sites have been synthesized. For instance,  $\epsilon$ -caprolactone has been randomly copolymerized with  $\gamma$ -substituted functional  $\epsilon$ -caprolactone (comonomers) (bromo-, hydroxyl-, carboxylic acid-substituted), allowing the posterior reaction with biologically active compounds. Fully biodegradable surface-modified nanoparticles could be obtained by coprecipitation of PLA with these functional amphiphilic copolymers and the presence of the latter at the nanoparticle’s surface was demonstrated [118].

Maruyama and coworkers also prepared biodegradable nanoparticles based on poly(D,L-LA) and poly(L-lysine)-*g*-polysaccharide (dextran, maltose or amylose) co-

**Figure 8.14.** Structure of amphiphilic galactosylated copolymers Gal<sub>x</sub>-Dody<sub>y</sub>.

polymers either by a solvent evaporation process or a diafiltration method. These copolymers were easily prepared by a reductive amination reaction between the pendant amine function of the polypeptide and the reductive extremity of the polysaccharide. Aggregation assays using specific lectins revealed the presence of carbohydrate moieties at the nanoparticle surface. Furthermore, due to the polycationic nature of poly(lysine), the nanoparticles are positively charged. Consequently, they appear as promising candidates for the transfection of DNA (gene delivery) [119].

The efficient synthesis of amphiphilic maleic anhydride copolymers grafted by galactose units and dodecyl chains has been recently reported. (Fig. 8.14) In fact, reactive anhydride functions were introduced through copolymerization of maleic anhydride and *N*-vinylpyrrolidone in a copolymer backbone. They have then been used as reactive sites for further functionalization with *N*-(4-aminobutyl)-*O*- $\beta$ -D-galactopyranosyl-(1-4)-D-gluconamide (an amine-functionalized galactose derivative) and dodecylamine. As illustrated in Scheme 8.1(E), amphiphilic maleic anhydride copolymers bearing pendant hydrophilic galactose moieties, as biological targeting units, and hydrophobic alkyl chains (for the interfacial activity) could be obtained [120]. These copolymers were successfully used as stabilizers and surface modifiers to produce stable nanoparticles coated with galactoses as targetable moieties on their surface, using the emulsification-diffusion technique. The presence and bioavailability of the galactose moieties at the nanoparticle surface were clearly demonstrated by lectin-sugar interactions [98].

#### 8.4.3.3 Emulsion, Miniemulsion or Dispersion Polymerization

As mentioned in Section 8.3.2, polymeric nanoparticles can be prepared using emulsion, miniemulsion or dispersion polymerization. In order to modify the surface of nanoparticles, several approaches have been proposed. One relies on the miniemulsion polymerization of monomers in the presence of amphiphilic biopolymers as emulsifiers. A second approach is based on the dispersion copolymerization of a hydrophilic functional macromonomer with a hydrophobic comonomer.

According to the first strategy, the polycation chitosan [121] has been used as stabilizer to prepare chitosan-coated latexes by (mini)emulsion polymerization. While the use of chitosan alone resulted in rather large droplets and a major amount of coagulate, addition of a low-molecular-weight surfactant or a flexible polymeric costabilizer significantly improved the stabilization of the nanodroplets during the polymerization. This efficient stabilization allowed the production of well-defined chitosan-coated nanoparticles in the range of 100–300 nm.

Later, Dellacherie and coworkers coated polystyrene nanoparticles by dextran in a miniemulsion process which did not require the addition of any costabilizers and led to monodisperse nanoparticles. For this purpose, they hydrophobically modified dextran chains by randomly grafted phenoxy groups. This amphiphilic dextran showed strong interfacial activity, and could be successfully used as an emulsion stabilizer and surface modifier in miniemulsion processes to prepare polystyrene particles carrying dextran at the surface [63].

In contrast to this approach, the macromonomer method allows covalently linking biomolecules, such as monosaccharide moieties, to the surface of nanoparticles. A direct pathway to carbohydrate-functionalized nanoparticles has thus been proposed [66]. For this purpose, a hydrophilic macromonomer bearing glucose moieties has been synthesized by radical polymerization of 2-(glucosyloxy)ethyl methacrylate (GEMA) in the presence of 2-mercaptoethylamine as a chain transfer agent, followed by a peptide-like coupling reaction with 4-vinylbenzoic acid (VBA) (Fig. 8.15). Nanospheres with a polystyrene core and a GEMA oligomer corona were then obtained by free radical copolymerization of the GEMA macromonomer with styrene in an ethanol/water mixture. As mentioned in Section 8.4.2.1, such glucose-decorated nanoparticles were expected to increase the interaction with a glucose specific lectin [concanavalin A (Con A)] due to the cluster effect. Hence, investigation of the glucose-lectin interaction by the enzyme-linked lectin assay (ELLA) demonstrated that the binding activity of the carbohydrate decorated nanoparticles was less than that of the free GEMA macromonomer. It decreased even with increasing amount of glucose at the nanospheres. Steric hindrance was proposed as a possible explanation for the low bioavailability [66] (Fig. 8.16).

The choice of technique for the surface modification by biomolecules is thus crucial. Biological recognition assays are necessary to test the bioavailability of the biomolecules.

#### 8.4.3.4 Covalent Linking of Functional Molecules to Preformed Nanoparticles

The surface functionalization of nanoparticles by covalent grafting of functional molecules on preformed polymeric nanoparticles is challenging (see Fig. 8.10, iii).

Such reactions require (i) the availability of functional reactive groups at the nanoparticle surface, (ii) the synthesis of biomolecules bearing reactive groups, and (iii) the use of coupling reactions that are selective and efficient. Above all, they must be smooth, not causing neither denaturation of the biomolecules nor degradation of the polymer material. These challenges led to the development of “chemical ligation”, i.e. the selective covalent coupling of mutually and uniquely functional groups under mild and aqueous conditions [122]. Hitherto, only a few

Figure 8.15. Synthesis and copolymerization of a glucose-capped macromonomer (GEMA macromonomer).

of these methods have been applied to the chemical coupling of biomolecules onto preformed nanoparticles.

In the following, we report on the universally applied amine–acid coupling and on another very selective and smooth coupling reaction, relying on the reaction of thiol groups with maleimides.

Figure 8.16. Schematic representation of a GEMA nanosphere and its interaction with Con A [66].

**8.4.3.4.1 Amine–Acid Coupling** The amine–acid coupling is one of the most universally applied and efficient coupling reactions. As an example, biomolecules bearing carboxylic acid groups have been conjugated onto  $\text{NH}_2$ -coated nanoparticles. Such nanoparticles have been prepared using amine-functionalized comonomers, either in an *in situ* copolymerization process (Section 8.3.2) [101], or by using amphiphilic copolymers that serve as surfactants and surface modifiers, e.g. in a nanoprecipitation technique (Section 8.3.1) [102]. Folic acid was then successfully conjugated to the surface using 1,3-dicyclohexylcarbodiimide (DCC).

Based on the same conjugation reaction, biomolecules bearing an amine function have been conjugated to nanoparticles exposing carboxylic acid groups. Woolley and coworkers prepared SCKs from micelles formed by poly( $\epsilon$ -caprolactone-*b*-acrylic acid) diblock copolymers (PCL-*b*-PAA) [123] followed by crosslinking of the PAA shell (consumption of approximately 50% of the acrylic acid groups) (Fig. 8.17, step 1). The remaining acrylic acid groups were then used for the conjugation to the amino group of a fluorescent dye [fluorescein-5-thiosemicarbazide (FTSC)] (Fig. 8.17, step 2) and a biologically active peptide sequence, respectively. The latter was prepared by standard solid-phase peptide synthesis (SPPS) and extended with a flexible linker. (Fig. 8.17, step 3). The following conjugation of the peptide to the SCK nanoparticle was performed on a solid support. This technique allows attaching the peptide selectively to the surface of the SCKs, as the reaction can only take place at the interface of the SCK and the peptide-bearing resin. Moreover, by performing the SCK–peptide coupling on a solid support, any nonconjugated nanoparticles were removed by washing of the resin support. Finally, by degradation of the PCL core, fluorescent peptide-exposing nanocapsules (nanocages) could be obtained, which demonstrated good binding interactions with cells and transduction into cells [124] (Fig. 8.17, step 4).

**8.4.3.4.2 Thiol–Maleimide Coupling** The introduction of thiol groups at the surface of nanoparticles opens up a lot of new possibilities in ligand conjugation (ligation). In particular, conjugation reactions between thiols and maleimides have received increasing interest due to their specificity and reactivity. Such reactions have been found to be quantitative under physiological conditions [125]. Antibody or protein conjugation is commonly performed using bifunctional crosslinkers such as *m*-maleimidobenzoyl-*N*-hydroxysuccinimide ester (MBS) that offers two binding sites – one for primary amino groups (present in antibodies, drugs, specific peptides) and one for thiol functions (Fig. 8.18) [126].

Thus, thiolated polymer nanoparticles have been synthesized. For instance, Langer and coworkers introduced free sulfhydryl groups onto the surface of gelatin (protein) nanoparticles by the reaction of primary amino groups with 2-iminothiolane [127]. Furthermore, Nobs and coworkers developed a suitable method for the introduction of thiol functions on the surface of PLA nanoparticles. The modification of the surface involved the activation of the carboxylic acid end-groups of PLA followed by the nucleophilic attack by cysteine or cystamine in a carbodiimide reaction (providing thiol functions via an amide bond) [128].

**Figure 8.17.** Solid-phase synthesis strategy involved coupling of the protein transduction domain (PTD) with fluorescein-labeled SCK nanoparticles, followed by cleavage from the support and excavation of the nanoparticle core domain to yield FTSC-labeled PTD nanocage bioconjugates.

**Figure 8.18.** Coupling agent: bifunctional MBS.

**Figure 8.19.** Schematic representation of antibody-loaded NeutrAvidin-modified gelatin nanoparticles. Sulfhydryl groups were introduced onto the particle surface by 2-iminothiolane followed by a conjugation

reaction with NeutrAvidin using the heterobifunctional crosslinker MBS. A biotinylated anti-CD3 antibody was then attached to the particle surface by avidin–biotin complex formation.

In both cases (gelatin and PLA nanoparticles), thiol-functionalized nanoparticles were thus made available. Then, avidin (NeutrAvidin), as a model protein and linker molecule (see Section 8.4.2.4), could be successfully conjugated to the nanoparticles via MBS, as illustrated in Fig. 8.19 [129]. Balthasar and coworkers have further attached biotinylated antibodies at the surface via avidin–biotin complex formation and their bioavailability could be shown using indirect methods, such as immunoblotting or fluorimetry [130].

**8.4.3.4.3 Molecular Imprinting** In the last decade, so called molecular-imprinted polymeric materials (MIP) have gained increasing interest for biomimetic molecular recognition elements [131]. The three-dimensional arrangement of the binding functional groups on the MIP is obtained by linking the functional monomers covalently or noncovalently to the template during polymerization (Fig. 8.20).

Removal of the template from the formed polymer then generates a structure that is complementary to the template structure. Very recently, based on this prin-

**Figure 8.20.** Strategies used to place binding or catalytic functional groups at defined positions in imprinted sites of network polymers.

Multiple interfacial imprinting techniques have been developed to reach surface-imprinted (colloidal systems). This approach has been used for the synthesis of surface-imprinted polymeric nanoparticles. Therefore, using emulsion or precipitation polymerization techniques monomers bearing bonds to a “template molecule” have been polymerized in the presence of bioactive molecules as templates [132]. Removal of the latter leaves a polymer nanoparticle containing a memory of its shape and functionality on its surface. They are therefore synthetic analogs of biological recognition systems.

First attempts have been undertaken, and Carter and coworkers synthesized nanoparticles bearing imprints of caffeine or theophylline at their surface that show a high affinity to the template molecule (caffeine or theophylline). Such particles possessed a core-shell structure [133]. The core was prepared first by emulsion polymerization of styrene and divinyl benzene monomers (1:1). The resulting particles were then coated, in a second polymerization stage, with the imprinting monomer mixture consisting of ethylene glycol dimethacrylate and oleyl phenyl hydrogen phosphate, and caffeine (or theophylline) as noncovalent template.

#### 8.4.4

#### Analytical Techniques for Surface Modification

The efficiency of the surface functionalization of nanoparticles with biomolecules, but also their bioavailability for recognition interactions, depends on many factors.

These include the architecture and composition of the polymers, the conformation of the polymer chains, and also the conditions employed for the nanoparticle formation. Therefore, numerous (indirect and direct) techniques have been developed and used to characterize the surface of nanoparticles [134]. Some of the most frequently used physicochemical techniques (Section 8.4.4.1) and biological assays (Section 8.4.4.2) are highlighted next.

#### 8.4.4.1 Physicochemical Techniques

Physicochemical techniques can supply information both on the chemical composition of the surface and also on its physical properties, such as hydrophilicity or surface charge. In addition, the biological properties of a surface can be investigated. Thus, specific interaction reactions between biomolecules fixed on the nanoparticles and their ligands fixed on the analytical device can be revealed by physicochemical means.

**8.4.4.1.1 The  $\zeta$  Potential** The  $\zeta$  potential measurement of aqueous suspensions of nanoparticles is one of the most common techniques to determine surface charges and therefore surface modification. The  $\zeta$  potential reflects the electrical surface potential of particles, which is influenced by the different materials located at the interface with the dispersing medium. Thus, the mobility of charged particles is monitored by applying an electrical potential. High  $\zeta$  potential values, above 30 mV (positive or negative value), lead generally to stable colloidal suspensions, because electrostatic repulsion between particles prevents their aggregation.

**8.4.4.1.2 X-ray Photoelectron Spectroscopy (XPS)** Another commonly used technique is XPS, also known as electron spectroscopy for chemical analysis (ESCA), which provides information about the chemical (atomic) composition of the top layer of nanoparticles. Here, under ultra-high vacuum, the dried sample is bombarded with X-rays. When the photon is of suitable energy, it is absorbed by an atom causing ionization and the emission of a core electron (inner shell electron). Since binding energies of core electrons are characteristic for elements in a certain chemical environment, the spectrum gives information on the elemental composition of the shallow surface region. From small shifts in the binding energies, additional chemical information can be derived (e.g. the oxidation state of the element). Since photons possess a limited penetration energy, only those electrons pertaining to atoms at or near the surface (up to 10 nm) escape and can be counted. This quantitative technique gives the average composition over about 10 nm depth inside the nanoparticles. XPS at various angles allows for the determination of the composition on different depth of the sample.

**8.4.4.1.3 Time-of-Flight Secondary Ion Mass Spectroscopy (TOF-SIMS)** SIMS is a physicochemical technique of the outmost surface (10 Å). TOF-SIMS uses a pulsed primary ion beam to desorb and ionize species from a sample surface. The resulting secondary ions are accelerated into a mass spectrometer, where they are mass

analyzed by measuring their TOF from the sample surface to the detector. The mass spectrum and the secondary ion images are then used to determine the composition and distribution of the sample's surface constituents. TOF-SIMS provides spectroscopy for the characterization of the surface's chemical composition, imaging for determining the distribution of the chemical species, and depth profiling for thin-film characterization. This technique thus allows to prove the chemical linkage of biomolecules to a surface via the analysis of the fragments.

**8.4.4.1.4 Electron Paramagnetic Resonance (EPR)** EPR, or electron spin resonance (ESR), is a spectroscopic technique that detects species that possess unpaired electrons. The basic physical concepts of the technique are analogous to those of nuclear magnetic resonance (NMR); however, instead of the spins of the atom's nuclei, electron spins are excited. Due to the difference in mass between nuclei and electrons, weaker magnetic fields and higher frequencies are used compared to NMR. For electrons in a magnetic field of 0.3 T, spin resonance occurs at around 10 GHz. EPR is helpful for nanoparticle characterization by using nanoparticles tagged with biological spin probes. EPR of free radicals conjugated to polymer chains has been used to discriminate between highly mobile (liquid-like) and slowly mobile (solid-like) spin labels on the basis of their magnetic relaxation times. EPR can thus provide useful information at the molecular level on the structure, mobility and organization of polymers at interfaces [135, 136].

**8.4.4.1.5 Surface Plasmon Resonance (SPR) [137]** SPR is a biophysical technique allowing us to measure biomolecular interactions in a quantitative, real-time manner. A ligand ("target") is immobilized on a special chip (SPR crystal) and a solution of the analyte ("binding partner") flows across the chip. The progress of binding is then measured by optical instruments.

This technique was applied to measure the interaction of nanoparticle–biomolecule conjugates with surfaces that had been modified by the corresponding ligand (generally a protein). As an example, for the measurement of interactions of folic acid-coated nanoparticles with the folate-binding protein, the latter was immobilized on the sensor surface [102]. It could be demonstrated that the folate nanoparticle conjugates were able to bind specifically to immobilized protein, whereas nanoparticles without folic acid-targeting moieties showed a much lower interaction (Fig. 8.21).

#### 8.4.4.2 Biological Assays/Methods

**8.4.4.2.1 Nonspecific Interactions with Proteins** The adsorption of proteins has often been used to indirectly demonstrate the presence of a protein-repulsive coating. For this purpose, the amount of adsorbed model proteins, such as bovine- or human serum albumin (BSA or HSA), has been determined by quantification of the nonadsorbed proteins in the supernatant after centrifugation and precipitation of the nanoparticles. In a recent study the repellent properties of dextran and PEO could be demonstrated. Indeed, PCL–dextran nanoparticles adsorbed

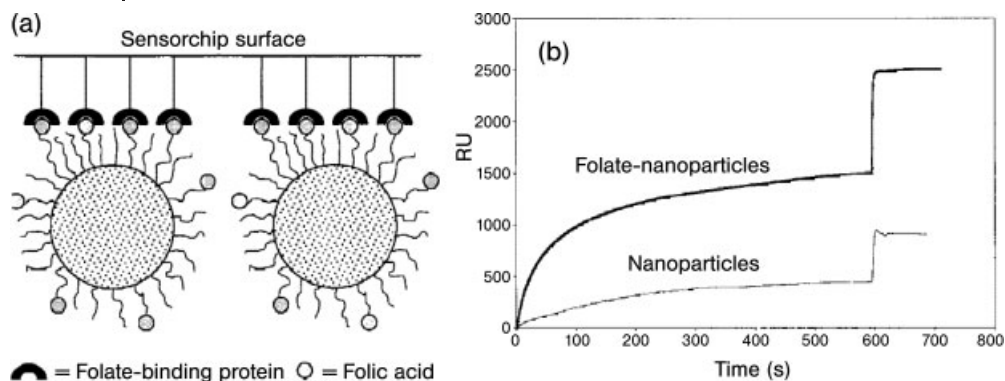

Figure 8.21. SPR on folate-coated nanoparticles.

only  $0.2 \text{ mg m}^{-2}$  BSA, which is comparable with the amount detected on the corresponding PEGylated nanoparticles taken as control [138, 139].

Other approaches tend to identify the proteins that are adsorbed most when incubating the nanoparticles with mixtures of proteins. Two-dimensional poly-(acrylamide) gel electrophoresis, (2-D PAGE) has thus been used to reveal adsorption and to identify proteins and fragments.

Finally, Passirani and coworkers [5] and Chauvierre and coworkers [81] evaluated the activation of the complement system by nanoparticles, which leads to their rapid elimination from the blood circulation through the uptake by macrophages of the MPS. In fact, the key step of complement activation to take place is the adsorption of serum proteins on the surface of the nanoparticles. Thus, nanoparticles coated by different polysaccharides were incubated in normal human serum (NHS) and the activation of the complement systems determined by quantification of a key protein – complement component C3.

**8.4.4.2.2 Specific Interactions (Carbohydrates–Lectins, etc.)** Apart from physico-chemical techniques, numerous biological methods have been used for the investigation of specific interactions between surface-functionalized nanoparticles and their targets, such as protein–ligand interactions.

Based on such lectin–carbohydrate interactions, the surface modification of nanoparticles by galactose could be demonstrated. Therefore, pyrene-labeled galactose-coated micelles (galactose–PEO-*b*-PLA) have been passed on a column packed with *Ricinus communis* lectin (RCA-1 lectin) immobilized beads. By fluorescence spectroscopy, they were shown to be specifically retained at the column, in comparison to non- and glucose-functionalized micelles [86].

Furthermore, numerous biological assays (based on specific biomolecular interactions) such as enzyme-linked immunosorbent assay (ELISA), ELLA and aggregation assays have been used to demonstrate the presence of biomolecules at the surface of nanoparticles.

ELISA is a biochemical test that quantifies by colorimetry a biological substance (e.g. proteins, sugars) in a biological liquid using the reaction of an antibody to its antigen. This method is based on the fixation of a first antibody to a solid device. Once the antibody is fixed and nonfixed residual free molecules are eliminated, the sample (to be quantified) is incubated, using conditions that favor antibody–protein interaction. Then, after a washing step, the complex formed is revealed by reaction with a second, detecting antibody, which is specific to another site of the protein. This antibody is typically linked to an enzyme, which serves for the quantification of the initial protein–antibody complex by reaction with a substrate and coloration of the medium by the formed product.

ELLA is a descendant of ELISA employing the lectin–carbohydrate interaction. It allows to quantify the capacity of a ligand X (e.g. sugar moieties at the surface of a nanoparticles) to inhibit the adhesion of a lectin on a reference ligand Y deposited on a solid device. Using this method, the surface functionalization of polymer nanoparticles with monosaccharides could be demonstrated via biotin–avidin sandwiching using streptavidin–horseradish peroxidase (HRP) as a detection system [98] (Fig. 8.22).

Finally, aggregation assays, based on the aggregation of carbohydrate-decorated nanoparticles by multivalent lectins, have been used to indirectly show the presence of poly- or monosaccharides at the surface of nanoparticles [119, 140] (see also Section 8.5.2.1.2). Similarly, hemagglutination inhibition assays have been developed, which are based on the inhibition of the agglutination of erythrocytes by lectins. In fact, erythrocytes are naturally decorated by saccharidic moieties. Carbohydrate-bearing polymeric particles can therefore act as inhibiting agents, as they compete with erythrocytes for the interaction with lectins [94].

**Figure 8.22.** Scheme for the multistep titration of particle-fixed mannose by biotin-labeled biotin.

## 8.5 Applications

### 8.5.1 Drug Delivery Systems [141]

As already mentioned, colloidal drug delivery systems are designed to modify the pharmacokinetics and biodistribution of their associated drugs, and/or to serve as drug reservoirs (i.e. as sustained release systems). Indeed, one of the main problems of drug delivery is the poor solubility of hydrophobic drugs in aqueous media. Drug delivery systems that provide hydrophobic domains can be advantageously used to help “solubilization” of the drug. By the careful choice of the drug delivery system and the polymer material, the release profile of the drugs from the device and thus their blood concentration with time (pharmacokinetics) can be substantially controlled. Additionally, sensitive drugs can be protected from premature (enzymatic/metabolic) degradation by encapsulating them in a protecting polymer matrix.

Furthermore, colloidal drug carrier systems change the biodistribution of drugs. Due to their “large” size, colloidal drug delivery systems accumulate in diseased tissues such as tumors, which are characterized by an enhanced permeability and retention (“passive targeting”). On the other hand, the surface functionalization of particulate carriers by specific ligands should allow the specific targeting of tissues. The gain in selectivity thus leads to the concentration of the drugs at the targeted tissues, which permits to reduce the amounts of administered drug and consequently avoids side-effects resulting from the presence of the drug at undesired sites (“active targeting”).

#### 8.5.1.1 Routes of Administration

Nanoparticles can be administered via multiple routes, such as intravenous, oral, pulmonary, nasal and ocular routes, as a solid or suspension. It should be noted that most of the current systems are designed for intravenous and oral administration.

Oral administration is the most convenient route for drug delivery, improving the compliance and quality of life of the patients compared to therapy by injection or infusion. However, the oral absorption of many therapeutic agents, such as peptides [142] (e.g. insulin), proteins, oligodesoxynucleotides (ODN) and also cancer drugs, is one of the greatest challenges in the pharmaceutical field. Indeed, their bioavailability is low because of instability in the gastrointestinal tract and low permeability through the intestinal epithelium. Nanoparticles are promising carriers for such bioactive molecules, because they may protect them against enzymatic/hydrolytic degradation (e.g. by gastric or intestinal juices, which are rich in proteases such as trypsin and chymotrypsin) and they may enhance their bioavailability. Polymeric particles have been shown to cross the intestine barrier. The size of the particles as well as the nature of the polymer are critical parameters for the particle uptake by the gastrointestinal tract. Bioadhesion of nanoparticles to the

mucous membrane in the gastrointestinal tract can be a tool to prolong the residence time of the drug carriers at the absorption sites and thus enhance the drug absorption. In fact, the coating of nanoparticle surfaces with hydrophilic mucoadhesive polymeric chains, such as PMAA [143] and chitosan [15, 19, 22], was shown to increase the absorption of the nanoparticles from the gastrointestinal tract.

Whenever drugs or drug delivery systems are degraded or not sufficiently absorbed after oral administration, parenteral administration, i.e. administration other than via the digestive system, is the route of choice.

Nowadays, alternative routes of administration via mucosal membranes, such as pulmonary and nasal mucosae, that circumvent the passage by the gastrointestinal tract and the liver presystemic metabolism (known as the “first-pass effect” – the first metabolic process with cytochrome P450 in the liver) are receiving a great deal of attention. Pulmonary delivery for both local and systemic treatments via aerosol inhalation has many advantages over other delivery pathways. Indeed, the lungs are characterized by a large surface area (43–102 m<sup>2</sup>), slow mucociliary clearance and low enzymatic activity. Compared to other nasal administration, they possess a thinner, more permeable absorption barrier. Recently, various high-molecular-weight drugs have been successfully absorbed through alveolar region of the lungs, e.g. heparin, growth factors (e.g. granulocyte colony stimulating factor), peptides and proteins such as insulin [144, 145]. Micro/nanoparticles are interesting drug delivery systems for pulmonary administration as they [146] increase the systemic availability of substances by offering protection as well as exhibiting controlled release properties. The pulmonary route of application is challenging, requiring the optimal size of the drug formulation, in order to ensure the “atomization” of the drug formulation for inhalation and deposition of the aerosol particles in the alveolar region, where the drugs are absorbed best. It was found that microdrug particles (below 5 µm) were rapidly eliminated from the lung by ciliary movement and phagocytosis with macrophages [147]. Recently, polymeric nanoparticles for administration in the respiratory tract have been coated by mucoadhesive copolymers. Similar to the results of earlier studies on the intestine mucosa, chitosan-coated nanoparticles were proposed to open the tight junctions of the lung epithelium [20], enhance mucoadhesion and enable pulmonary systemic delivery [19]. Apart from the pulmonary route, nasal administration of drugs and especially of vaccines has found increasing interest. Similar to the lungs, the nasal mucosa is thin, highly permeable and incorporates a dense vascular network, and possesses a surface of “only” 50 cm<sup>2</sup>. As an example, chitosan-coated PLGA nanoparticles have been found to enhanced the nasal transport of encapsulated tetanus toxoid [148, 149].

Numerous colloidal carrier systems have also been designed for the intravenous route of administration, especially in the case of the delivery of proteins and oligonucleotides. However, severe requirements concerning the size, size distribution and surface properties of nanoparticles are imposed. In fact, the smallest capillaries in the body are only 5–6 µm in diameter. Consequently, particles being distributed in the blood stream must be significantly smaller than 5 µm in diameter

and ought not show aggregate formation in order to avoid clog formation and embolism. As mentioned in Section 8.1, the surface properties of the colloidal systems must be adapted in order to tune their biodistribution, pharmacokinetics and residence time in the vascular system before elimination by the MPS.

Compared to the intravenous route, subcutaneous/intramuscular administration imposes fewer requirements concerning particle size and size distribution. The subcutaneous route has proved to be promising in different therapeutic applications; subcutaneous injection of PLGA nanoparticles containing antitubercular drugs in mice resulted in sustained therapeutic drug levels in the plasma for 32 days and in lung/spleen for 36 days. In the field of tumor therapy, it has been demonstrated very recently that subcutaneous injection near the tumor site is the preferential route for facilitating high tumor uptake and retention, compared to intravenous or intraperitoneal injection [150]. Additionally, it should be emphasized that subcutaneous injection of nanoparticles proved to be very promising for vaccine delivery. Indeed, colloidal formulations of vaccines administered subcutaneously have been found to have strong “adjuvant activity” (defined in Section 8.5.1.2), which is usually required to cause a sufficient immune response [151, 152].

Polymeric nanoparticles have also demonstrated great potential for ophthalmic formulations. Probably the most severe disadvantage of eye-drop formulations is their rapid elimination of the instilled drug solution from the precorneal site [153]. In fact, only 1–2% of the applied dose reaches intraocular tissues. Consequently, colloidal suspensions were designed to combine ophthalmic sustained action with the ease of application of eye-drop solutions. Upon topical instillation, these particles are expected to be retained in the “cul-de-sac” and the drug to be slowly released from the particles through diffusion, chemical reaction or polymer degradation, or by an ion-exchange mechanism. Concerning the size of particles for ophthalmic purposes, Sieg and Triplett demonstrated that an upper size limit (below 10  $\mu\text{m}$ ) should be considered to avoid discomfort of the patients and that the retention time before washout diminishes with decreasing particle diameter. Apart from the size, the surface properties of nanoparticles have been changed in order to prevent their premature elimination. HA was found to be the polysaccharide of choice to coat polymeric nanoparticles and has been proved to enhance the ocular bioavailability of drugs, probably due to its mucoadhesive properties [79].

Finally, nanoparticles are also used for topical applications. In particular, polysaccharide-coated nanoparticles, such as chitosan-coated particles, are promising drug delivery systems for their enhanced wound-healing properties [154].

#### 8.5.1.2 Therapeutic Applications of Nanoparticles

Nanoparticles cannot only change the distribution of drugs at the organ or tissue level, but also at the cellular level, by increasing uptake or modifying the intracellular localization of the drug. This opens up the route for a large variety of therapeutic applications. In this section we report examples of three important groups of therapeutics that can be delivered by colloidal systems, i.e. chemotherapeutics (anticancer drugs), ODNs or genes, and proteins for cancer treatment, gene therapy and vaccination.

Anticancer drugs are often poorly bioavailable and barely compatible with oral delivery, due to their poor solubility, stability and permeability across biological membranes. After intravenous administration, they are distributed throughout the body as a function of the physicochemical properties of the molecule and do not necessarily accumulate in the targeted tissues. Due to the strong toxicity of cytostatic drugs, the specific targeting of the tumor cells is extremely interesting, allowing for effective therapy by reducing side-effects. Another major problem in cancer chemotherapy is the ability of tumor cells to develop simultaneous resistance to multiple lipophilic therapeutics. This resistance has been attributed to an active drug efflux from resistant cells linked to the presence of transmembrane P-glycoprotein (P-gp), which forms transmembrane channels and pumps the drugs out of the cell. The use of nanoparticulate carriers seems a promising solution to address these problems.

In fact, as already reported in Section 8.1, cancerous tissues possess a defective vascular architecture (due to the rapid vascularization, which is necessary to serve fast-growing cancers) coupled with poor lymphatic drainage. This phenomenon is known as an “enhanced permeation and retention” effect and allows long-circulating nanoparticles (due to their large size in comparison to free drugs) to passively target cancerous tissues [7]. The coating of nanoparticles by hydrophilic polymers avoids their rapid uptake in the liver and spleen, and favors their prolonged circulation time in the blood stream allowing the nanoparticles to accumulate in tumor tissues. It has actually been shown that anticancer drugs encapsulated in such surface-modified nanoparticles accumulate preferentially in cancer cells [8, 11]. To further enhance the targeting specificity, probes that are specific to tumor cells have been conjugated to the surface of nanoparticles. One of the greatest challenges is thus defining the optimal targeting agent to selectively and successfully transport nanoparticles systems (nanoparticles) to cancerous tissue. These strategies also rely on the ability of the targeting agents or ligands to bind to the tumor cells’ surface in an appropriate manner then triggering receptor endocytosis (receptor-mediated cell internalization). The therapeutic agent will hereby be delivered to the interior of the cancer cell. The folate receptor, which is over-expressed on malignant human cells, has been found to be a promising target. The folate-conjugated nanoparticles not only selectively target cancer cells, but they also improve the internalization of the encapsulated drugs within the targeted cancer cells [8]. On the other hand, monoclonal antibodies that specifically bind to the tumor antigens of a specific cancer type have been identified, and are currently used and approved by the FDA for targeted cancer treatment [11]. Thus, antibodies specific to breast cancer, etc. seem promising ligands for the covalent conjugation to nanoparticles [155].

Another challenging application of nanoparticles is their use as carriers for (anti-sense) nucleotides and plasmid DNA in the field of gene therapy. The ultimate goal of gene therapy is to cure both inherited and acquired disorders in a straightforward manner by removing their cause, i.e. by adding, correcting or replacing genes [156]. However, the administration of genes poses a challenge to pharmaceutical technology because of their susceptibility to enzymatic degradation (by nucleases) and their poor penetration across biological membranes (poor bioavailabil-

ity). The first potential gene delivery vectors were viruses. In the last decade, however, nanoparticles, similar to liposomes, have received growing interest as condensing nonviral gene carrier systems. These synthetic colloidal carrier systems are expected to be safer, but must be optimized in terms of keeping a comparable transfection rate. Such ODN-carrying nanoparticles are generally prepared on the basis of the electrostatic interactions (ion pairing); indeed, due to the phosphodiester group, ODN are negatively charged and can therefore be adsorbed at the surface of positively charged nanoparticles (such as chitosan nanoparticles [12]) or encapsulated in the core of nanoparticles.

Nanoparticles have also been designed as delivery vehicles for proteins. Similar to oligonucleotides and genes, proteins and peptides are very sensitive compounds that need to be protected from degradation in the biological environment. Moreover, their efficiency is highly limited by their inability to cross biological barriers and to reach the target site. As such, appropriate colloidal carriers for the successful delivery of proteins in the body have been designed, either incorporating the protein into the nanocarrier [157] or else adsorbing it on the surface of the nanocarrier [109].

Nowadays, both proteins and genes are the agents of choice for vaccination. Nanoparticles are very promising carriers for subcutaneous or mucosal vaccination [149, 151]. In fact, it has been reported that due to their size, nanoparticles have general “adjuvant” properties, i.e. act in a nonspecific manner to increase the specific immunity to an antigen (as compared to that introduced by the vaccine or the antigen alone) [158].

Concerning mucosal vaccination, the use of nanoparticles coated by mucoadhesive polymers is particularly interesting, because they exhibit prolonged residence time at the mucosae and avoid a premature clearance (see Section 8.5.1.1). As an example, chitosan nanoparticles have been found successful as a nasal vaccine in some animal studies, producing significant IgG serum responses when using influenza, pertussis and diphtheria vaccines [149].

Another approach to enhance the immune response after subcutaneous injection relies on the specific targeting of dendritic cells that are involved in the immune response and have been identified as target cells for the particle-mediated immune response [93]. It has been reported that dendritic cells expose specific receptors to mannose (mannose receptor) [91]. Therefore, the functionalization of vaccine-loaded particles by mannose seems a promising approach to specifically target dendritic cells [91, 93].

In contrast to other drug delivery systems, such as drug–polymer conjugates and liposome-based formulations, nanoparticles are in clinical trials, but have not yet reached the market [159].

### 8.5.1.3 Triggered Release

Recently, stimuli-responsive nanoparticles have been proposed as exciting delivery systems. Such delivery systems enable the release in response to an appropriate stimulus at the target site and/or at the right moment [160]. This stimulus can be environmental, chemical or physical, such as a change in pH [161, 162], tempera-

ture [101, 163, 164], ionic strength, application of laser light [165, 166] or magnetic field [167], and/or physiological, such as a change in enzyme concentration [168]. Up to date, only few works have been dedicated to the design of stimuli-responsive nanoparticles. Due to the importance of this application, some recent promising approaches to particulate-responsive systems are highlighted here.

It is known that in some tissues/physiological fluids of the human body, the pH may be different from most of the other physiological fluids. The pH is therefore an interesting stimulus. Apart from the drop in pH in the stomach, two other sites of low pH have been reported. So, the pH in endosomes is lower than that of the cytosol by 1–2 pH units [169]. It is known that endosomes are one of the principle transporters for drugs or drug delivery systems to enter a cell (by endocytosis). Once introduced in the cytosol, the release of the drug from the drug delivery systems may thus be induced by the drop in endosomal pH as triggering mechanism [169].

Furthermore, most solid tumors can be distinguished from normal surrounding tissues by a decrease in extracellular pH due to the higher aerobic and anaerobic glycolysis in cancer cells. Drug delivery systems have thus been designed that release anticancer drugs in response to a drop in pH [170].

For instance, Soppimath and coworkers prepared pH-triggered thermally responsive polymer core-shell nanoparticles for the delivery of chemotherapeutics (doxorubicin) to tumor cells [161]. They synthesized core-shell nanoparticles self-assembled from the amphiphilic tercopolymer poly(*N*-isopropylacrylamide-*co*-*N,N*-dimethylacrylamide-*co*-10-undecenoic acid), P(NIPAAm-*co*-DMAAm-*co*-UA) (Fig. 8.23). The UA was used as the core building hydrophobic and pH-sensitive segment, whereas the PNIPAAm segment exhibits a low critical solution temperature (LCST) in aqueous solution (about 32 °C) and is thus thermosensitive. DMAAm was employed to adjust the LCST of the polymer. The stability of nanoparticles prepared from the tercopolymer with optimized ratios of the different monomers at 37 °C depended on the environmental pH. Indeed, at physiological pH (pH 7.4) the LCST was 38.6 °C, meaning that the nanoparticles remained in their initial shape. However, in slightly acidic environments (pH < 6.6), the LCST of the terpolymer was decreased to 35.5 °C, i.e. a temperature lower than the normal body temperature. At this pH, the release of a model anticancer drug (doxorubicin) from

Figure 8.23. Molecular structure of P(NIPAAm-*co*-DMAAm-*co*-UA).

such nanoparticles was found to be significantly enhanced compared to the release at pH 7.4, probably due to the deformation and precipitation of the nanoparticles in acidic environment triggering the release of the entrapped anticancer drug (doxorubicin).

Recent efforts have focused on the development of optically addressable delivery systems, since irradiation with light promises to be an effective mean of releasing bioactive materials. The method relies on making the wall of polymer capsules sensitive to light by doping them with metal nanoparticles or organic dyes [171, 172]. Then, upon pulsed (below 10 ns) laser illumination, they absorb laser energy and disrupt the local environment due to a temperature increase, thus increasing the permeability of the capsule wall [166]. Such polyelectrolyte microcapsules were obtained using a layer-by-layer technique (see Section 8.3.3). This permitted for the tailoring of the composition of the wall, and the incorporation of metal nanoparticles (Fig. 8.24). In biological systems, it is desirable to trigger drug release in the near-infrared (NIR), around 800–1200 nm, as most tissues show negligible absorption in this region. Indeed, the absorption of gold nanoparticles incorporated in a polymeric capsule wall is red-shifted to the NIR (700–1500 nm) compared to the absorption of individual gold nanoparticles (around 500 nm). Such gold nanoparticles should thus absorb under *in vivo* conditions [171]. It has further been shown that fluorescein isocyanate (FITC)-labeled dextran [165] and rhodamine-labeled polystyrenesulfate (PSS-Rh) [166], convenient models for high-molecular-weight biomolecules, can be loaded into the capsules by exploiting the pH dependence of the shell permeability and then released on demand from the capsules by irradiation with 10-ns pulses of laser light at 1064 nm. These systems are thus promising vehicles for triggered topical or endoscopic drug delivery. Recently, the surface of such light-responsive polyelectrolyte/gold nanocapsules has been functionalized

**Figure 8.24.** Schematic representation of a polyelectrolyte multilayer capsule incorporating PSS-Rh. The polyelectrolyte multilayer walls consist of PSS and PAH polymers and metal nanoparticles.

**Figure 8.25.** Scheme of the assembly and permeability test for microcapsules embedded with Co@Au nanoparticles under an oscillating magnetic field.

by model ligands (monoclonal immunoglobulin G antibodies), which opens new possibilities to targeted light-responsive drug delivery [165].

Similar to this work, magnetic fields has been used to trigger release from polyelectrolyte microcapsules. These capsules were designed to be more or less permeable to macromolecules depending on the application of a magnetic field. Indeed, ferromagnetic gold-coated cobalt nanoparticles (3 nm) (“Co@Au”) were embedded inside the capsule wall made of bilayers of poly(sodium styrene sulfonate)/poly(allylamine hydrochloride) (PSS/PAH). It could be shown that upon application of an external alternating magnetic field, the permeability of the capsules for hydrophilic macromolecules increased significantly due to the rapid movement of the embedded Co@Au nanoparticles. Figure 8.25 illustrates the synthesis of such particles by a layer-by-layer technique and shows how dextran can be encapsulated in such particles upon application of an oscillating magnetic field inducing an enhanced permeability of the capsule wall. This process was found to be reversible and the triggered release of dextran could be demonstrated [167].

Finally, magnetites of a suitable size and magnetic properties have also been used for magnetic heating [173]. The phenomenon of magnetic hyperthermia may be exploited for colloidal drug carrier systems that are composed of magnetites embedded in a thermoresponsive polymer matrix (exhibiting LCST). In fact, the application of a magnetic field leads to the heating of the colloidal system and may induce the phase transition of the thermosensitive polymers. Consequently, the release or entrapment of a drug may be triggered. Indeed biocompatible polymer drug carriers, which released drugs in response to the application of a high-frequency magnetic field, have been reported [174].

## 8.5.2

**Diagnosis**

Polymeric nanoparticles have found great interest not only as drug delivery systems, but they have also been used as carrier systems of molecules/labels that allow for their detection *in vivo* and *in vitro*. Labeling nanoparticles allows for their (optical) imaging, and thus provides a valuable tool to follow the delivery vehicle on its journey through the body, to elucidate the real-time cellular localization of nanoparticles and to determine their *in vivo* distribution after administration. It is a powerful means to ascertain whether successful delivery to the desired organ or tissue structure can take place.

As an example, the monitoring of optically labeled drug delivery devices in the field of tumor targeting is one of the many applications in which the imaging process has been implanted successfully. Indeed, many of the same techniques used to reach delivery of drugs to cancerous tissues may also be used to target imaging agents. In fact, as targeted delivery systems approach the stage where they can be used clinically, primary assessment of the utility of a particular colloidal formulation in a particular patient may be made with imaging agents to verify that the delivery system goes rapidly to the cancerous tissues before any drug regimen is begun.

Apart from that labeled polymeric nanocarrier have found rising interest as diagnostics, i.e. in the field of medical imaging [magnetic resonance imaging (MRI), etc.] to detect morbid tissues and diseases. The interest of using polymeric nanoparticles as diagnostic tools (by encapsulating the diagnostic label) relies in (i) its size, (ii) the possibility of using biocompatible materials and (iii) the possibility of modifying the surface of the colloidal vehicle to achieve targeting devices. As explained in Section 8.1, the nanoparticles' size allows for the passive targeting of organs such as the liver or spleen, whereas the use of coating materials (e.g. PEO) permits the passive targeting of cancerous tissues (due to the enhanced permeability of blood vessels), together with an enhanced residence time (half-life time) in the blood. In addition, the surface functionalization of nanoparticles by specific probes/molecules allows the active targeting of specific cellular districts.

The following gives a nonexhaustive overview on the different types of diagnostic systems based on polymeric nanoparticles. It is structured with regard to the different labels (fluorescent dyes, contrast agents for MRI, quantum dots, gold nanoparticles, radiolabeled nanoparticles, nanoparticles for ultrasound imaging). Furthermore, their utility for *in vitro* (immunoassays, biosensors, etc.) and *in vivo* tests (MRI, etc.) is mentioned.

**8.5.2.1 Fluorescence Labeling of Polymeric Nanoparticles**

**8.5.2.1.1 Organic Fluorescent Dyes** Fluorescent labeling is a widely used and convenient tool in biology and biological imaging. In the field of drug delivery, it has been used to (i) simulate drug release (establishment of release profiles) or (ii) to

localize nanoparticles and understand their fate after administration. The fluorescent label has to be chosen depending on the purpose and the physicochemical properties of the nanoparticles. In the first case (i), the fluorescent dye is used as a model drug and should therefore have similar physicochemical properties as the drug. For instance, commercially available FITC-labeled dextran (“FD-4”) and tetramethylrhodamine-labeled dextran have often been used as a model for hydrophilic macromolecular “drugs” (such as proteins) to study their release profile from nanospheres [143] and nanocapsules [165].

For diagnostic applications (case ii), however, a durable encapsulation of the dye is desired, requiring good affinity of the dye for the nanoparticles material. For instance, small organic hydrophobic fluorescent molecules (rhodamine [175], fluorescein [176], etc.) are suitable for nanoparticles made of hydrophobic polymers or nanocapsules with an oily core [146]. In the case of PLGA nanoparticles labeled by lipophilic 3-(2-benzothiazolyl)-7-(diethylamino)coumarin (“coumarin 6”) [177], it has been demonstrated that the nanoparticles’ physical properties, such as particle size and  $\zeta$  potential, were not significantly different from those of unloaded nanoparticles. As to the preparation, the small organic fluorescent molecule is generally dissolved together with the core-forming polymer during the nanoparticle preparation. These fluorescent nanoparticles thus allow the calculation of the amount of fluorescent carriers taken up by cells (*in vivo* or *in vitro*) by fluorimetry.

However, particles labeled by “free” fluorescein rapidly released this fluorescent probe in the medium used for the biological investigation [176], as a consequence of diffusion. Thus, recent developments tend to focus on covalently conjugate/link fluorescent dyes to (co)polymers in order to avoid diffusion of the dyes from the polymer matrix of nanoparticles to the surrounding medium, e.g. fluorescein has been conjugated to PLGA end-capped by a carboxylic group using carbodiimide chemistry in order to diminish the diffusion from the fluorescent dye from PLGA nanoparticles [178].

**8.5.2.1.2 Quantum Dots** Semiconductor nanocrystals (also known as quantum dots) are emerging as a new class of fluorescent probes for *in vitro* and *in vivo* biomolecular and cellular imaging [179, 180]. In comparison with organic dyes and fluorescent proteins, quantum dots, whose size ranges from 1 to 10 nm in radius, have unique optical and electronic properties, including sharp emission spectra (with full width at half maximum as narrow as 25 nm) improved signal brightness and photostability [181], resistance against photobleaching (long fluorescent lifetime), and tunable size dependent emission peaks. Due to their broad excitation profiles and narrow/symmetric emission spectra, high-quality quantum dots are also well-suited for multicolor optical coding for biological assays, by combining different color quantum dots with different intensity levels. Quantum dots are mostly synthesized in nonpolar organic solvents, such as tri-*n*-octylphosphine oxide, which coordinate on the surface of quantum dots to prevent the formation of bulk semiconductors. As a result, the nanoparticles are capped with a monolayer of organic ligands and are soluble only in nonpolar organic solvents. However, for biological imaging, quantum dots must be water-soluble. To address this, different

strategies have been devised including ligand exchange with thiol-functionalized molecules, and encapsulation by a layer of diblock or triblock copolymers or else in silica shells, phospholipid micelles or polymer beads. Further developments in biological applications of quantum dots aimed to functionalize the surface of quantum dots by bioaffinity ligands, such as monoclonal antibodies, peptides, oligonucleotides or carbohydrates. Thus, hydrophilic  $\alpha$ -mannopyranosyl moieties have been linked to a phosphine oxide, which could then be used as ligand in the surface-functionalized hydrophilic quantum dots [182]. Furthermore attachment of PEG could lead to improved biocompatibility and reduced nonspecific interactions [183]. Such bioconjugated quantum dots thus have raised new possibilities for ultrasensitive and multiplexed imaging of molecular targets in living cells, animal models and, possibly, in humans.

Recent works have focused on the encapsulation of the nanocrystals in natural or synthetic polymeric materials to form “bigger” quantum dot–polymer composites in the range of some hundreds of nanometers. Such systems were expected to reduce the toxicity of quantum dots and to be suitable for further conjugation with biomolecules, while maintaining the high emission quantum yield of the quantum dots. It should be emphasized that the use of a polymeric matrix also opens up the possibility of incorporating several probes (quantum dots of different size), allowing in particular multiplexed optical coding. In the following, we will focus on quantum dot–polymer composites.

Several strategies to embed quantum dots in polymer matrices have been envisaged. Quantum dots have been incorporated either by noncovalent interactions, such as electrostatic and hydrophobic interactions, or by copolymerization of monomers with quantum dots surrounded by polymerizable ligands.

In 2003, Chen and coworkers developed an interesting method to assemble negatively charged CdSe–ZnS quantum dots into glyconanospheres through electrostatic interactions with carboxymethyl dextran and poly(lysine). To enhance the long-term stability of these glyconanosphere composites built by the layer-by-layer procedure, quantum dots were cross-linked with the polysaccharide matrix by covalent amide bonds. Spherical luminescent glyconanospheres of an average diameter of 190 nm were thus obtained. The presence of glucose residues at the surface of the nanoparticles was evidenced by fluorescent imaging microscopy; indeed, upon addition of a carbohydrate-binding protein, Con A, the glyconanoparticles aggregated (Fig. 8.26(A)). As shown in Fig. 8.26(B), this aggregation was, however, prevented when free  $\alpha$ -D-glucose was added, since glucose effectively competes with the glyconanospheres on the binding sites of Con A. These quantum dot–polysaccharide composites are thus promising tools for real-time monitoring of carbohydrate–protein (lectin) interactions that are critical steps in bacterial and viral infection [140].

On the basis of hydrophobic interactions, polymeric microbeads loaded with quantum dots could be prepared, allowing multiplexed/multicolor optical probing for biological assays. Several groups have successfully incorporated quantum dots into polymeric nanoparticles via polymerization in dispersed media [184–187]. Hydrophobic quantum dots (ZnS-capped CdSe nanocrystals) with different sizes were

**Figure 8.26.** Lectin (Con A) initiated aggregation of CdSe–ZnS quantum dot luminescent glyconanospheres. (A) Luminescence image of aggregated glyconanospheres in the presence of Con A.

(B) Luminescence image of the glyconanospheres in the presence of Con A and free  $\alpha$ -D-glucose molecules. The latter compete with the glyconanospheres for the Con A binding sites and prevent nanoparticle aggregation.

thus embedded at precisely controlled ratios in the outer layer of swollen polystyrene polymer beads, previously prepared by miniemulsion polymerization of styrene, divinylstyrene and acrylic acid (98:1:1). The quantum dot-loaded particles were sealed by a silica layer, then, streptavidin molecules were covalently coupled to the surface via the carboxylic acid groups of acrylic acid [184]. Biomolecular probes, such as oligonucleotides or antibodies, were then conjugated to the silica surface via streptavidin–biotin complex formation. The fluorescence spectra of the quantum dot-tagged beads (1.2  $\mu\text{m}$ ) were narrow (even narrower than those of free quantum dots) and the emission maxima remained unchanged, which indicates that the beads were highly uniform and reproducible, and that the beads were spatially separated by the beads structure. Thanks to the identification code embedded in the interior of the beads, bead identification accuracies as high as 99.9% could be reached. This approach allows combining molecular recognition and optical “barcoding” by polymeric beads, which is expected to open new opportunities in gene expression studies, high-throughput screening and medical diagnostics [184]. In comparison with bigger (150  $\mu\text{m} \times 150 \mu\text{m} \times 150 \mu\text{m}$ ) planar DNA chips, encoded-bead technology is expected to be more flexible regarding target selection (e.g. adding new genes or single-nucleotide mutations), to show faster binding kinetics (similar to that in homogenous solution) and to be less expensive to produce.

In contrast to these approaches based on the noncovalent immobilization of quantum dots in polymeric materials, O’Brien and coworkers adapted an approach previously reported by Emrick and coworkers [188] and covalently incorporated

quantum dots into a polymer matrix using suspension polymerization. Thus, they prepared quantum dots surrounded by polymerizable ligands and copolymerized them with styrene using DVB as crosslinking agent. This facile procedure seems very promising for the commercialization of many bead-types with diameters ranging from 100 nm to 500  $\mu\text{m}$ , where the CdS quantum dots are evenly distributed throughout the polystyrene spheres. These quantum dot–polymer composites may be used for optical biological probing/assays or combinatorial chemistry applications (in solid phase organic chemistry), benefiting from quantum dots encoding [189, 190]. Employing miniemulsion polymerization, Elaissairi and coworkers synthesized quite monodisperse (100–350 nm) quantum dot-tagged colloids by copolymerization of styrene with vinyl-functionalized quantum dots [191]. Very recently, another promising approach to covalently incorporate quantum dots in latexes was proposed by Esteves and coworkers [192]. Indeed, they applied radical polymerization to miniemulsion using ATRP and initiated the miniemulsion polymerization of butyl acrylate by quantum dots functionalized by an ATRP initiator.

In conclusion, the use of fluorescent nanocrystal–polymer composites opens up new possibilities for designing luminescent surface-modified nanoparticles to deliver quantum dots specifically to the targeted tissue or cells. These luminescent quantum dots are ideal fluorophores for biological labeling because their fluorescence emission wavelength can be continuously tuned by changing the particle size and a single wavelength can be used for simultaneous excitation of different sized quantum dots. The unique properties of luminescent quantum dots thus allow multicolor experiments in cellular imaging and diagnosis, offering substantial advantages over organic dyes in multiplexed target detection.

#### 8.5.2.2 Contrast Agents for MRI

MRI is based on the NMR signal of hydrogen present in body tissues (water, membrane lipids, proteins, etc.). It is currently the most important available diagnostic method and as a noninvasive technique routinely clinically used for diagnostic imaging. However, the intrinsic sensitivity and selectivity of conventional MRI techniques is very low. It has been clearly shown that the use of contrast agents, which alter the relaxivity of water, can greatly improve the sensitivity and thus the diagnostic value of MRI.

The first generation of contrast agents consists of high-spin paramagnetic ions ( $\text{Gd}^{3+}$  chelates) that are at present routinely used as MRI contrast agents. More recently, magnetic nanoparticles, with a size generally between 3 and 10 nm, have been used as contrast agents for MRI. Due to their size, these superparamagnetic nanoparticles accumulate in MPS organs (passive targeting). Third-generation magnetic nanoparticles are surface-modified by specific ligands, such as antibodies, allowing the specific targeting of cells/tissues.

Recent works tend to incorporate magnetic nanoparticles in larger polymeric nanoparticles. Such relatively “big” polymer nanoparticles are expected to passively target tumors. In addition, targeting moieties may be attached at the surface of the latter (active targeting). For this purpose, polymeric nanoparticles decorated

**Figure 8.27.** (a) Schematic diagram for preparing the  $\gamma\text{-Fe}_2\text{O}_3$ -PLGA-Arg-FITC nanoparticles. (b) Sequence of arginine peptide.

by targeting molecules and labeled by contrast agents have been designed. One interesting work published recently reports on the synthesis of a novel intracellular polymeric carrier as a MR molecular image diagnostic agent. Here, superparamagnetic iron oxide nanoparticles were encapsulated with peptide-conjugated PLGA using an emulsification-diffusion method. In addition, these polymer nanoparticles were labeled twice: first, by encapsulation of metallic nanoparticles for MRI and, second, by a fluorescent dye for detection by fluorescence microscopy; actually, a FITC-conjugated arginine peptide, a “cell penetration peptide”, was conjugated via its thiol group to maleimide-derivatized PLGA. Thus, nanoparticles of 110 nm diameter have been synthesized allowing for combined targeting and multiple/versatile detection [193] (Fig. 8.27).

Aside from their use in MRI, there are multiple other applications of magnetic particles encapsulated in polymer beads which are illustrated in the following.

### 8.5.2.3 Magnetic Nanoparticles for *In Vitro* Assays

Increasing interest has been focused on the preparation of surface-modified latexes, and their use as solid supports of biomolecules in biomedical diagnostics

**Figure 8.28.** Schematic representation of the specific capture and detection of the targeted antigen (ELISA).

and purification of biological materials. The particular interest in using such colloidal systems for biomedical diagnostic systems relies on their high specific surface. Due to their size, surface-modified latex beads have been used for the capture of biological materials, their purification and concentration, and more specifically in immunoassays. In fact, the size of the nanoparticles allows their separation from the biological medium by centrifugation. Recent studies tend towards the use of magnetic latex particles. Magnetism is used here as an easy tool to separate the nanoparticles, replacing the centrifugation step applied in the case of classical non-magnetic particles. Similar to the latter, magnetic latex nanoparticles are principally used as a solid support for biomolecules involved in the specific capture of targeted biomolecules, such as antigens for immunoassays [i.e. ELISA, Fig. 8.28, and nucleic acid detection in “enzyme-linked oligosorbent assay” (ELOS), Fig. 8.29]. For that purpose, magnetic latex particles bearing either immobilized antibodies or ODNs, complementary to the single stranded DNA of interest, are used.

Furthermore, such nanoparticles can be used for the nonspecific capture of biomolecules or viruses [194] in order to concentrate or to purify samples. In fact, this process is based on the well-controlled adsorption of biomolecules on the colloidal particles, followed by the concentration of the nanoparticles and, finally, the desorption of the adsorbed biomolecules. Thus, for the capture of nucleic acids, cationic magnetic colloids are used in order to favor attractive electrostatic interactions. Adsorption and desorption are controlled by monitoring the pH and the salinity of

**Figure 8.29.** Schematic representation of the specific capture and detection of targeted DNA or RNA (ELOS).

the medium [195]. Similarly, magnetic latex particles with a hydrophobic surface have been successfully used for the extraction, purification and concentration of proteins. Indeed, as mentioned in Section 8.1, unspecific adsorption of proteins on surfaces is mainly governed by hydrophobic attractive forces, such as van der Waals forces [196].

The synthesis of “smart” magnetic colloids has also been reported. Thus, thermosensitive magnetic latex particles have been synthesized, allowing the controlled adsorption, concentration and desorption of proteins [197]. At temperatures above the LCST, thermosensitive polymers undergo a phase transition from a hydrophilic to a hydrophobic state. Thus, nanoparticles with a thermosensitive PNIPAAm shell showed a volume phase transition temperature ( $T_{VPT}$ ), below which protein adsorption was low (due to the hydrophilic character of the particle surface) and above which the adsorption was considerably high [198].

Recently, an interesting approach for the synthesis of fluorescent magnetic nanoparticles that possess reactive carboxylic acid groups at their surface was reported. First, fluorescent polystyrene nanodots (25 nm) were adsorbed onto magnetic emulsions (250 nm) via electrostatic interactions. The surface of these “hybrid” particles was then sealed by adsorbing film-forming polymer nanobeads (40 nm) on their surface and heating above the glass transition temperature ( $T_g$ ) [199].

A representative review about magnetic colloids, their preparation and their use in biomedical diagnostics was given by Elaissari [200]. The incorporation of magnetic nanoparticles in polymer beads is thus a promising tool in the field of diagnosis and triggered drug delivery, but they can also serve as therapeutic systems. In

fact, magnetic nanoparticles have potential therapeutic applications as they can locally induce hyperthermia by application of an alternating magnetic field. This magnetically induced hyperthermia remains promising for cancer therapy aside from conventional methods, such as surgery, chemotherapy and radiotherapy [173]. Depending on the temperature, hyperthermia can be used either for immune stimulation (41–46 °C) or tumor destruction (46–56 °C).

As illustrated in Section 8.1, encapsulating magnetic nanoparticles in a sub-micron polymeric vehicle allows for the size-controlled “passive targeting” to tumoral tissue. Besides, they are suitable for surface functionalization by targeting biomolecules. In fact, the combination of magnetic particles in a drug-containing polymeric matrix that is sensitive to temperature is a very comprising approach. As developed in Section 8.5.1.3, the release of drugs embedded in a stimuli-responsive polymer can be induced by various stimuli, such as pH or temperature. Intracellular drug release from polymeric nanoparticles could thus be triggered by the temperature increase during the hyperthermia sequence under MRI monitoring. Instead of using thermosensitive polymers (e.g. PNIPAAm), such a mechanism could also use thermolabile bonds [174].

#### 8.5.2.4 Electron Dense Agents for Transmission Electron Microscopy (TEM)

Organic fluorescent labels allow studying intracellular nanoparticle uptake and distribution using confocal fluorescence microscopy. More precise TEM observation requires the labeling of the nanoparticles by an electron-dense agent. For that purpose, e.g. PLGA nanoparticles have been successfully loaded with osmium tetroxide – a widely used staining agent for TEM observation [177].

Another approach relies on the labeling by gold nanoparticles. For this purpose, the surface of gold nanoparticles must be modified in order to enhance/optimize their affinity to the nanoparticles’ core-forming polymer. Indeed, Qiu and co-workers successfully encapsulated gold nanoparticles surface-modified by PLA chains in PLA nanospheres [58].

#### 8.5.2.5 Radiolabeled Nanoparticles

For a long time, radiolabeled (e.g.  $^3\text{H}$ ,  $^{14}\text{C}$ ) polymers have been synthesized for nanoparticles, and then the radioactivity could be quantified in order to elucidate their uptake and distribution [10, 201]. However, this method necessitates not only the synthesis of radiolabeled polymers, which require special laboratories, but also expensive equipment for the quantification.

## 8.6

### Conclusion and Perspectives

Polymeric nanoparticles are of particular interest due to their size, the wide range of polymeric materials available, and the possibility to tailor-make both the constituting elements and the nanoparticles. Furthermore, recent developments in (polymer) chemistry, biology, biotechnology and physics have drastically enlarged

the use and importance of polymeric nanoparticles. For drug delivery purposes, polymeric nanoparticles no longer possess only a protecting role, while releasing drugs in a controlled way. They are rather “Trojan” horses that allow drug delivery to a selected target, such as cancerous cells, organs or even viruses. Further trends go towards smart colloidal drug delivery systems that release drugs in response to an external trigger, such as light or a magnetic field, or even in response to an physiological internal trigger, such as pH, glucose concentration, etc.

Nanoparticles possessing targeting moieties on their surface have also found applications in diagnosis. In fact, the surface functionalization of fluorescent and magnetic colloids allows the selective detection of, for example, a tumor expressing specific antibodies at its surface. The latest developments in quantum dots technology allowing multiplexed sensing have been a revolution in the field of diagnostics.

Nowadays, the developments in polymeric nanoparticles tend towards multifunctional nanoparticles, which allow simultaneous targeting, imaging and treatment by one single system. Monitoring of the localization of the drug in a living system and the release of the drug as response to an external trigger is no longer a dream. First attempts of such combined drug delivery systems have been already proposed as “nanoclinics” [202], i.e. complex surface-functionalized polymeric nanoparticles that contain various probes for diagnostics and drugs for targeted delivery in one single unit.

# Polymeric Nanoparticles for Drug Delivery

*Paraskevi Kallinteri and Martin C. Garnett*

### 9.1

#### Introduction: Application of Nanoparticles for Noncancer Applications

The scientific literature contains many reviews on the therapeutic uses of nanoparticles, from formulation through to *in vitro* and *in vivo* assessment of activity, and for various routes of delivery, including oral, lung, mucosal and parenteral. Therapeutic development of nanoparticulate delivery systems has been dominated by applications for cancer because of the potential advantages in localization in cancer tissues and hence in targeting advantages to drugs which lack specificity. However, there are a variety of more subtle reasons why nanoparticle therapeutics should be useful for other delivery routes and diseases. These include protection of the drug, enhancing circulation half-life, acting as a slow release system and compartmentalization of the delivery system either by preventing the drug reaching certain tissues or by enhancing uptake into particular cells/tissues. These potential advantages have led to work on nanoparticles in a number of other areas including delivery to local sites such as the eye and lung, the delivery of peptides and proteins via a number of alternative routes, including oral, nasal and pulmonary routes, and for treatments where cells of the immune system can be readily targeted by nanoparticles e.g. vaccine delivery, AIDS, antifungal treatment and tuberculosis. However, we have been unable to find any recent reviews covering the noncancer applications as a group, the distinctive reasons why these should be useful targets for polymeric nanoparticles or why nanoparticles may produce more effective delivery systems.

In this chapter, we have attempted to bring together a number of different areas. First, to understand the physiology and anatomy underlying the diseases which may be treatable using nanoparticulates and the way that nanoparticles are handled by the body. The effect of the route of application has also been considered here. Second, to review the main work that has been carried out with polymeric nanoparticle formulations for this range of applications and assess their future potential. This second area of work has been arranged into individual diseases or groups of diseases which would benefit from similar formulations or similar

principles of delivery for the nanoparticles. Finally, we draw some brief overall conclusions.

One of the first areas to consider in assessing the potential of nanoparticles as delivery systems are the potential physiological barriers to transport of nanoparticles and how physiological factors can be best exploited to maximize the advantages of nanoparticulates.

### 9.1.1

#### **Physiological and Uptake of Particles**

In general, nanoparticles cannot simply partition across membranes, or cells, so uptake is limited to specific transport pathways through cells and the paracellular route passing between cells. The paracellular route poses a problem for the passage of nanoparticles through epithelia and endothelia because of the presence of tight junctions in most of these tissues. The tight junctions typically restrict the gap between cells to about 4–6 nm in endothelia and 2 nm in epithelia, and would therefore be expected to prevent the passage of macromolecules and nanoparticles past these barriers [1]. In addition the presence of a basement membrane underlying these tissues, with a fibrous mesh thought to be around 15 nm between strands, would also be expected to restrict passage of nanoparticles [2].

##### **9.1.1.1 Routes of Tissue and Cellular Uptake of Particles**

Although unable to partition through membranes and gain direct access into cells, there are a variety of endocytic mechanisms for the uptake of macromolecules and small particles into cells. These include phagocytosis of large particles by specialized cells such as macrophages and neutrophils [3], and uptake of macromolecules and smaller particles by a variety of mechanisms, which probably include a non-specific pinocytosis as well as receptor-mediated uptake involving clathrin [4] or uptake via caveolae [5]. Endocytosis may offer two major drug delivery advantages: (i) a preferential uptake to macrophages and other cells associated with the immune system, and (ii) access to the endosomal/lysosomal compartments of cells where the acidic and degradative environment offers a useful drug release mechanism.

More recently, evidence is beginning to accumulate that the endothelium may be less of a barrier to nanoparticle delivery systems than once believed. It was proposed some years ago that the extravasation of macromolecules into lymphatic tissues was mediated by a process of transcytosis in which macromolecules were endocytosed on one side of the cell and exocytosed on the other through a vesicular system [6]. Recent evidence suggests that this process may be mediated by caveolae and involves some specific transport [7]. Some nanoparticles have been reported able to exploit this transcytosis process to pass across endothelia for the brain [8], lymph nodes [9] and bone marrow [10], although it is not yet clear how many tissues can be accessed by this route nor how selective it is for particular tissues. Too little work has been done in this area for this to be reflected in the development of drug delivery systems for specific applications, except as directed towards therapy

of brain tumors [8]. However, it offers prospects to widen the range of diseases, which may be accessible to nanotherapeutics.

#### 9.1.1.2 Uptake by Macrophages and Lymphoid Tissues

Delivery to macrophages and other cells of the immune system could allow access to a range of conditions. A number of parasites and diseases are known to inhabit the endosomal compartment of macrophages, e.g. malaria and tuberculosis [11]. In addition, both macrophages and other cells of the immune system are involved in antigen processing, so serve as a port of entry for vaccine antigens.

The macrophages are the main component of the mononuclear phagocytic system (MPS). Due to the preferential uptake of particulates by macrophages, particles tend to accumulate in the main tissues of the MPS such as liver, spleen and lymph nodes. For nanoparticles less than 250 nm, the spleen tends to be less important as a site for uptake [12]. This uptake is potentiated by opsonization [13] – the coating of particulates by blood proteins occurring either specifically through antigen recognition or nonspecifically mainly through hydrophobic interactions. The surface properties of nanoparticles are therefore very important and hydrophilic coatings by polymers such as polysaccharides or poly(ethylene glycol) (PEG) reduce both opsonization and uptake by the MPS. These coatings are usually achieved either by coating with PEG containing surfactants which adsorb to the surface of particles or by the use of PEG copolymers incorporated into the nanoparticles. The hydrophilic coatings also stabilize the particles against aggregation [14]. A further property of the coatings in reducing protein adsorption is that certain blood components can adsorb preferentially to the coated surfaces and this can result in adsorption of a protein, mediating transcytosis to specific organs such as the brain [8].

A further consequence of the MPS uptake of particulates is that, eventually, most particulate preparations do end up in the liver for detoxification and this has the potential to cause liver toxicity. This is particularly important because there is no opportunity for elimination of drug through the kidney until drug has been released from the particle, either by slow release from the particle or by metabolism at its target site or the liver. However, once more this offers a possible drug delivery opportunity by providing a generalized slow release system for drugs mediated by liver metabolism.

#### 9.1.1.3 Mucosal-associated Lymphoid Tissues (MALT)

The mucosae have an important role as an interface between the outside world and the body. They are thus a key element of the defense of the body, both from the point of view of acting as a barrier to the outside world, while at the same time being uniquely placed to sample the environment. Lymphatic tissue is found at a variety of mucosal sites including the bronchi (BALT), nose (NALT) and gut (GALT) [15]. These lymphoid tissues constitute an efficient way of inducing protective immune responses, both humoral and cellular. Moreover, the stimulation of one mucosal site can result in dissemination of response to other mucosal sites. MALT constitutes 80% of immunocytes and functions independently from the systemic

system. The lymphoid tissues contain a number of specialized cells, which include fixed macrophages, and also cells like dendritic cells, which act as mobile scouts sampling the environment. These lymphoid tissues, as will be seen below, also seem to act as conduits by which particles may pass through to other tissues.

### 9.1.2

#### **Routes of Delivery**

##### 9.1.2.1 **Oral**

The gut at first sight appears an unpromising route for nanoparticle delivery systems. The presence of a very acid environment in the stomach, high concentrations of degradative enzymes and a thick layer of mucus above an epithelial layer are all significant physiological barriers. Also, it is well known that macromolecules are poorly absorbed in the gut. However, reports of orally administered particles being present in the lymphatics and circulation have been documented for many years. There have been a number of recent and comprehensive reviews collating the evidence supporting this route of particle uptake. These include specific consideration of the physical barriers and their relevance to oral absorption [16], how particles are taken up across the epithelium and into the lymphatics [17], specific mechanisms and routes of transcytosis [18], and the role of polymers comprising the nanoparticles in influencing uptake [19]. Consequently, only a brief summary of these aspects of oral particulate delivery will be presented here.

Mucus does appear to operate as a barrier to uptake, particularly for larger particles (above 300 nm). Penetration of mucus by nanoparticles is also affected by surface characteristics, with hydrophilic particles penetrating more easily. There are several potential routes of nanoparticle uptake in the gut. Paracellular transport is not expected to be significant as there are tight junctions in the gut as in most other epithelial tissues. However, there have been reports of particles up to 50–100 nm penetrating by this route in the presence of modifiers such as chitosan or calcium ions. Polyacrylate and starch have also been reported to enhance paracellular transport. The process of persorption has also been described in the gut, where the tips of villi become denuded of epithelial cells allowing larger particles access to the underlying mucosa. However, it is not thought that this route of uptake is particularly prominent.

There has been intensive study of the lymphoid tissue within gut as a possible portal of entry for particles. Peyer's patches consisting of multiple lymphoid follicles are the most widely discussed, but are not the sole lymphoid tissue within the gut. A significant number of isolated lymphoid follicles and lymphocyte-filled villi also exist. However, the degree to which these various lymphoid tissues contribute to particle uptake is widely debated. Similarly, it is unclear the extent to which nonlymphoid epithelium is involved in nanoparticle uptake. The principal route of uptake is often assumed to be the M cells in Peyer's patches, but it may be that only a small proportion of M cells are involved.

Uptake of particles involves both transcytosis across the epithelial layer and translocation to other tissues. Peyer's patches, as well as containing M cells also have a

more porous basement membrane and are closely associated with efferent lymphatics. These characteristics would account for the reported route of translocation of nanoparticles via the mesenteric lymph ducts. It is also possible that particles may be shuttled to distant mucosal sites following uptake by immune cells.

The uptake of particles by Peyer's patches has, like passage through mucus, been found to be dependent on size. Uptake and translocation to mesenteries and liver seems to be greatest for particle of 50 nm. However, immune responses are most effectively stimulated by particles of 4  $\mu\text{m}$ , which correlates with the observation that larger particles tend to be found in dendritic cells. The surface characteristics of particles have also been reported to be important for both uptake and translocation.

Overall, studies show that there are clearly routes of nanoparticle uptake, but the extent of uptake is under debate due to the wide range of uptake rates reported. It is thought that in general uptake rates are lower than for typical small drug molecule administration. Consequently it is likely that nanoparticle delivery systems will be most appropriate for immune delivery, delivery to intestinal lymph and drugs which are poor for oral delivery because of poor solubility or permeability characteristics, e.g. potent and labile biological macromolecules.

#### 9.1.2.2 Nasal

The nasal epithelium has been investigated as a delivery route for conventional drugs, peptides and proteins, and vaccines. A useful description of the anatomy of the nose relevant to drug delivery can be found in reviews by Illum [20] and Jones [21]. The nasal epithelium has a relatively large surface area because of the presence of microvilli and has the advantage that it avoids first-pass metabolism to the liver. However, the nasal mucosa has a significant level of degradative enzymes. Like the gut, nasal mucosa is covered by a layer of mucus, which poses a barrier to delivery mainly because of the rate of clearance into the nasopharynx and gut. The epithelium is well vascularized.

In humans, there is a limited amount of macroscopically visible nasal lymphoid tissue, which is confined to the nasopharynx and tonsils. However, antigen-presenting cells (APCs), and B and T lymphocytes are present within the mucosa.

#### 9.1.2.3 Pulmonary

Delivery to the lung is an attractive route because of the easy access and administration of formulations, and the large surface area of the lung provided by the alveoli, estimated to be about 140  $\text{m}^2$  of internal surface area.

The lung structure is that of a multibranching tree with the airways dividing further at each branch. The airways divide repeatedly into primary bronchi, lobar, segmental bronchi and bronchioles until reaching the terminal bronchiole leading to 15–20 alveoli. The walls of the entire respiratory tract are covered by a mucus blanket about 5  $\mu\text{m}$  thick. The mucus is a mucopolysaccharide which can trap particles for subsequent removal by the ciliated cells of the bronchi. This happens by a continual upwards movement of mucus known as the mucociliary escalator.

The alveoli mainly consist of thin squamous cells about 5  $\mu\text{m}$  thick (type I cells). There are also a few thicker type II cells responsible for secreting the surfactant coating the surface of the lungs. The capillaries are closely associated with the alveolar cells and partly form the wall of the alveoli. The alveolar wall therefore consists of alveolar cells, basement membrane and capillary endothelial cells held together by connective tissue. The alveolar membrane is covered by a thin (15 nm) layer of surfactant. Due to the tight junctions joining the alveolar epithelia and the capillary endothelium, penetration of macromolecules from the alveolar space into the capillary circulation is limited, so it would be expected that penetration of nanoparticles would be even more limited. However, it is clear that there is transport of materials across lung endothelium and epithelium by caveolae [22], so this may also be a route for transport of small nanoparticles as well.

Alveolar macrophages may be found either fixed within the connective tissue of the alveoli or free within the mucus layer. They can leave the lung either via the mucus through the mucociliary escalator and out through the sputum or, alternatively, leave via the lymphatics within the lung. This may therefore be another route of transfer of materials from within the airways of the lung into the tissues.

Delivery of particles to the lung is dependent on a number of physical processes, which are diameter dependent. Particles larger than 5  $\mu\text{m}$  are deposited by inertial impaction on the trachea walls following a change in direction of air flow. Settling is proportional to the square of the particle diameter and is less important for small particles. Particles less than about 500 nm in diameter are deposited largely by Brownian diffusion. So, overall, particles in the size range 5  $\mu\text{m}$  down to 500 nm largely avoid impaction on the airways and are large enough to deposit by sedimentation, while those below 500 nm can only deposit by Brownian motion. In general, optimum pulmonary penetration is found with monodisperse aerosols of 2–3  $\mu\text{m}$  diameter. Extremely small aerosols (below 100 nm diameter) also appear to deposit very efficiently through Brownian diffusion, but such fine aerosols are very difficult to produce. Only particles that contact the mucus layer can be deposited and thus be available for either drug release into the mucus or uptake into the macrophages, or possibly the epithelial cells. There may therefore be some possibility of exploiting these various transport mechanisms for drug delivery systems.

A more complete description of pulmonary structure and its effects on drug delivery can be found in Washington and coworkers [23].

#### 9.1.2.4 Transdermal/Subcutaneous

One of the main functions of the skin is to act as a barrier to the entry of macromolecules and particles. The stratum corneum, consisting of eight to 16 layers of flattened, stratified and keratinized dead cells is largely responsible for the barrier function of the cell. Due to the barrier function of the skin, there is also a complex relationship with the immune system. Langerhans or dendritic cells are specialized APCs, which constantly monitor the environment by taking up antigens and processing them. They are an integral part of the immune system, and are involved in migration from the epidermis to the regional lymph nodes, resulting in the induction and maintenance of cutaneous immunity sensitization or stimulation of the

immune system [24]. These cells could therefore take up and transport particles to the lymph nodes and lymphatics.

In addition to topical application of particulates, the intradermal or subcutaneous route of injection delivers particles to the extracellular space, where they can be taken up by the lymphatics. This route therefore gives a potential route for delivery to the lymphatics, and in particular to the lymph nodes [25].

In summary, therefore, there are a number of routes with potential for delivery of nanoparticles for a variety of therapeutic applications. Work carried out on these applications is detailed below.

## 9.2 Drug Delivery

### 9.2.1

#### Ocular Delivery

##### 9.2.1.1 Anatomy of the Eye

Current ocular drug delivery is by administration of eye-drops, suspensions, ointments, gels, subconjunctival and intraocular injections, and, more recently, implants. There are, however, physiological and anatomical features of the eye that prevent effective therapy. Looking in detail at the eye (Fig. 9.1), there are anterior and posterior sections.

**Figure 9.1.** Anatomy of the eye. The general anatomy of the eye is shown on the right, with an inset on the left showing the detailed structure of the cornea.

The anterior section includes the lens and the cornea. The posterior segment consists of three layers, i.e. the sclera, choroid and retina, surrounding the vitreous cavity, which is filled by the vitreous humor [26].

The first barrier to drug uptake is the cornea comprising three parts. The outer part is the epithelium, consisting of five to six layers of tightly packed cells restricting the passage of hydrophilic and ionized compounds, with little penetration via the paracellular route. The middle part is the hydrophilic stroma restricting passage of lipophilic compounds. Due to a relatively open structure, drugs with a molecular size up to 50 000 can diffuse in normal stroma. The third part is a monolayer of endothelial cells. Effective drugs therefore need to combine both hydrophilic and hydrophobic properties to be able to pass through the cornea. Formulation pH adjustment can improve the trans-corneal drug accumulation.

It has been reported that less than 5% of the applied eye-drop reaches the intraocular tissues [26–28]. The percentage dose of the drug absorbed through the cornea depends very much upon the time that the instilled drop remains on the corneal surface, which is mainly dependent on the lachrymal system of the eye. The lachrymal glands secrete tears, which are distributed over the eyes by the blinking reflex of the eyelids and collected in the lower conjunctival sac. From there, the tears are drained into the lachrymal sac through the puncta and the lachrymal duct. Eventually, the fluid reaches the nasopharynx and, finally, the gastrointestinal tract. Consequently, blinking and tear secretion stimulated after the eye-drop instillation are responsible for the fast washout of the drug from the precorneal area, while nasolacrimal drainage can lead to serious side-effects through uptake into the blood circulation. A good example is the  $\beta$ -blocker, timolol, which is used for the treatment of the wide-angle glaucoma and can cause side-effects to the heart if transported to the systemic circulation via nasolacrimal drainage.

The conjunctiva, a thin vascularized mucus membrane, which lines the inner surface of the eyelids and covers the anterior part of the sclera up to the cornea is also responsible for a large amount drug uptake. This uptake route adds to the systemic side-effects [28].

In the posterior section, the sclera maintains the shape of the eyeball and the choroid is a vascular layer that provides the blood supply that supports the retinal cells. The retina is separated from the choroid by Bruch's membrane.

#### 9.2.1.2 Pathology

Ocular formulations aim to treat either inflammatory external eye infections (i.e. conjunctivitis, blepharitis, keratitis sicca) or intraocular diseases like glaucoma, uveitis, etc. The latter can be classified to anterior (iritis, iridocyclitis), intermediate (behind the iris and lens in the region of ciliary body and pars plana), posterior (retinitis, choroiditis, optic neuritis) and diffuse (all parts of the eye).

#### 9.2.1.3 Drug Delivery

Ocular delivery has a low efficiency due to the cornea's low permeability to drugs, rapid tear turnover and nasolacrimal drainage. Diseases of the posterior segment

are treated by intravitreal or subconjunctival injections, which are quite invasive and are able to cause inflammatory reactions.

There is a need for production of new formulations able to ensure increased stability of the drug and longer elimination half-life through sustained release. Nanoparticles and nanospheres are attractive as alternative delivery systems for the treatment of eye disorders because they are characterized by increased stability and longer elimination half-life in the tear fluid (20 min) in comparison to conventional drugs applied topically to the eye (1–3 min).

Ideally, particles need to be biodegradable, biocompatible, nontoxic, sterile, have a sustained release at a desirable rate, easy manufacturing procedure and be smaller than 10  $\mu\text{m}$  so as to avoid any scratching or discomfort to the patient. Other important factors influencing the efficiency of such carriers are the charge, the drug lipophilicity and/or the carrier.

A number of polymers can be used to prepare particles (nanoparticles or nanospheres), which can be classified mainly into two categories: acrylate derivatives like poly(butyl cyanoacrylate) (PBCA) [29], PEG–polyethyl-2-cyanoacrylate (PECA) [30], poly[methoxy poly(ethylene glycol)cyanoacrylate-co-hexadecyl cyanoacrylate] (PEG–PHDCA) [31], copolymers of poly(ethylacrylate, methyl methacrylate and chlorotrimethyl-ammonioethyl methacrylate) [Eudragit®] [32–34] and the positively charged chitosan [35–37]. Poly(lactic acid) (PLA) [38], poly(D,L-lactic-co-glycolic) acid (PLGA) [39] and poly( $\epsilon$ -caprolactone) (PCL) [40] have been tested, too. Particles have been made using the mucoadhesive poly(acrylic acid) (PAA) and poly(itaconic acid) (PIA) [41], while hyaluronic acid (HA) [40] has been treated as a coating material for nanospheres made out of PCL (Fig. 9.2). Enhanced polymer–cornea affinity is the main aim to increase the particle residence time in the eye.

The mechanism of action is different for each of these polymers. PBCA, PAA, PIA and HA are characterized as mucoadhesive because they attach to the precor-

**Figure 9.2.** Scanning electron microscopy photographs of PCL nanospheres positively charged by stearylamine (SA) (a) or BKC (b) and coated with HA 0.025% (PCL/SA/HA ads

and PCL/BKC/HA ads) Bar = 1  $\mu\text{m}$ ; original magnification  $\times 10\,000$ . (Reprinted from Ref. [40], © 2002, with permission from Elsevier.)

neal mucin layer via noncovalent bonds [40]. PEG molecules interact via hydrogen bonds with the mucin macromolecules present on the ophthalmic surface and may induce reversible opening of the tight junctions of the conjunctival tissue (allowing paracellular transport of drug molecules across ophthalmic tissues) [30]. Positively charged Eudragit™ and chitosan interact strongly with the negatively charged sialic acid residues in mucus. PLA and PLGA are generic materials for particle preparation, with FDA approval.

The physicochemical and surface characteristics are important in efficient drug accumulation into the eye. Other important factors are the preparation method and the presence of surfactants. Most of the particles produced using the materials mentioned above have a size range between 35 [Eudragit RL100, poly(acrylic acid) (PAA)] and 280 nm [PBCA, chitosan, PCL–benzalkonium chloride (BKC)] with an average size around 100 nm. The particle size mainly depends on the preparation method. According to de Campos and coworkers [35], the production of chitosan nanoparticles is dependent upon the chitosan concentration (decreased concentration leads to decreased size) and the acetonitrile/water volume (increasing the ratio leads to size decrease). Ibuprofen-loaded Eudragit RL100 and RS100 nanoparticles are prepared by the quasi-emulsion solvent diffusion method. Thus, the particle size is reduced as the polymer concentration or the volume of ethanol decreases [32]. Giannavola and coworkers [38] studied the incorporation of acyclovir into PLA nanoparticles using the nanoprecipitation method using various nonionic surfactants (Triton X-100, Tween 80, Brij 96, Pluronic F68). The particle size decreased as the polymer molecular weight increased while Tween 80 was the most efficient in decreasing the size and maintaining particle stability. Fresta and coworkers [30] produced similar PECA nanospheres by micellar polymerization using Pluronic F68.

Nanoparticles are preferred to microparticles because Giordano and coworkers [42] reported that the latter can cause a localized reaction confined to the inferior retina involving macrophages and multinucleated giant cells. Also, there was a nonuniform drug distribution within the vitreous cavity due to the accumulation of the particulate systems at the inferior retina [43]. Calvo and coworkers [44] reported that the *in vivo* corneal uptake of indomethacin-loaded PCL colloidal particles was higher than microparticles after topical instillation into the albino rabbit eye. Qaddumi and coworkers [39] drew the same conclusion studying the uptake of PLGA nanoparticles of 100 nm, 800 nm and 10  $\mu\text{m}$  on primary cultured rabbit conjunctival epithelial cells (RCECs) The smaller (100 nm) particles exhibited the highest uptake.

The surface charge of the particles is important for particle adhesion to cornea. Positively charged colloids are able to deliver drugs to the eye due to their interaction with the negatively charged cornea. Positively charged chitosan nanoparticles or microspheres are much more effective than negatively charged particles due to the strong electrostatic interaction of the former with the negatively charged sialic acid residues in mucus [45]. The particulate nature is also important in increasing the intraocular penetration of drugs and decreasing the systemic absorption [46]. The importance of the cationic surface was shown by studying indomethacin con-

taining nanocapsules coated with either poly(L-lysine) (PLL) or chitosan, resulting in completely different drug kinetics profiles [47]. Chitosan-coated nanocapsules significantly increased the indomethacin concentration in the cornea and aqueous humor 30 min and 1 h after the instillation to the eye in comparison to the uncoated and PLL-coated nanocapsules. The bioavailability [area under the concentration–time curve (AUC)] of indomethacin from chitosan-coated nanocapsules was 7- to 8-fold higher in the cornea and aqueous humor respectively, while the values for PLL-coated capsules were almost 4-fold higher than the Idocollyre® in both cornea and aqueous humor.

Drug incorporation and drug release are the main limiting factors for these systems. The drug–polymer affinity, the drug hydrophilic/lipophilic balance and solubility are some of the main obstacles and challenges to efficient ocular nanoparticle formulations. A great example is cyclosporin A (CyA) – an endcapeptide used in a variety of immune-mediated ocular surface phenomena like vernal conjunctivitis, dry eye syndrome, prevention of corneal allograft rejection [36]. Its high lipophilicity reduces corneal uptake and many formulations (e.g. oil solutions, complexation with cyclodextrins, micelles, etc.) were unsuitable for a variety of reasons. However, Calvo and coworkers [48] achieved a 50% incorporation of CyA in the oily phase of Mygliol nanocapsules surrounded by PCL where the final drug concentration was 10 mg mL<sup>-1</sup>. These nanocapsules were taken up by corneal epithelial cells, so the drug level at the cornea was increased 5 times more than that obtained using the conventional 10 mg mL<sup>-1</sup> CyA oily solution. Even here, drug retention at the ocular mucosa was poor, so it was considered useful only for the treatment of extra-ocular diseases. Chitosan particles were more promising carriers since the drug loading was approximately 9%, but they were characterized by rapid drug release (62% in 15 min in sink conditions). Even so 2- to 6-fold increase of CyA was found in cornea and conjunctiva after topical instillation of these carriers. It was also noteworthy that the CyA amount found in cornea was higher than that in conjunctiva because drug-loaded carriers are cleared faster from the conjunctiva either due to the uptake by macrophages or to the passage to the blood circulation [35].

The antivirals, aciclovir and ganciclovir, have been in the focus of research since they are used for the treatment of herpes simplex infections and their ocular administration faces some problems. Aciclovir is used for Herpes simplex keratitis with the spread of the virus, at the most severe cases, in to the stromal cells, thus damaging them. However, the topical administration of the drug is difficult due to the low corneal penetration, and its poor water and lipid bilayer solubility [38].

The incorporation of aciclovir into PLA and PEG–PLA nanospheres was attempted in the presence of Tween 80 (0.5% w/v). The loading capacity was 2–5.9% in the former and 7.7% in the latter. The drug loading increased as the polymer molecular weight decreased for the PLA spheres, while it exhibited a further increase after the PEG insertion. This probably happened because the drug interacted with the PEG moiety, which retained the drug close to the particle surface. The drug release showed a burst effect and biphasic kinetics. Drug release reduced as the polymer molecular weight increased, while the presence of PEG did not offer any advantage in the release rate. In fact, the drug release was faster than the

uncoated particles, which indicated a different drug distribution in the polymeric matrix.

Fresta and coworkers [30] studied the drug loading in PECA or PEG–PECA nanospheres in the presence of Pluronic F68, and showed that the drug entrapment was not affected by the presence of either PEG or cyclodextrins, or the concentration of surfactant used. PEG-coated spheres released aciclovir slower than uncoated PECA nanospheres, while the presence of cyclodextrin did not improve the release rate. The aciclovir release showed the same profile as that observed using the PLA nanospheres.

Ocular bioavailability tests showed that using PLA nanospheres, the effective levels of aciclovir in the aqueous humor at 6 h were ( $1 \mu\text{g}$  of aciclovir  $\text{mL}^{-1}$  aqueous humor) in comparison to the free drug formulations (no drug was detected 6 h later). PEG-coated PLA nanospheres were more effective than the uncoated PLA nanospheres and the free drug formulation, with 1.8- and 12.6-fold increase, respectively [38]. Similar results were reported after the instillation of aciclovir-loaded PEG–PECA nanospheres to the eye, which showed a 25-fold increase in comparison to free drug suspensions. Both research groups attributed the higher degree of success to mucoadhesive properties because of the polyoxyethylene presence on the nanosphere surface.

Ganciclovir is used for the treatment of more acute viral infections like the human cytomegalovirus (HCMV) retinitis, which is the major cause of visual loss in AIDS patients. Intravitreal administration of the drug is quite effective with a half-life of about 13 h, so frequent injections are needed to maintain the therapeutic efficacy. On top of that, the administration route imposes a high risk of cataract development, retinal detachment and endophthalmitis [49–50].

Another Food and Drug Administration (FDA)-approved antiviral drug is fomivirsen, which exhibits a 55-h half-life after intravitreal administration [51]. Despite its resistance to the nucleases, the administration of this drug is problematic due to its poor penetration through cell membranes because it is a polyanion. Albumin nanoparticles have been investigated for the entrapment of those drugs and the study of the intraocular disposition after their intravitreal injection to rats. Ganciclovir-loaded albumin nanoparticles were prepared by either adding drug after the particle preparation or during the preparation procedure. Drug loading and release was  $15 \mu\text{g}$  ganciclovir  $\text{mg}^{-1}$  nanoparticles and 60% in 24 h for the first preparation, while it was  $27 \mu\text{g}$  ganciclovir  $\text{mg}^{-1}$  nanoparticles and 40% in 24 h for the latter. The first formulation was more active and inhibited the expression of the HCMV early antigens at a lower concentration than the conventional drug solution after their incubation on a cell line.

Formivirsen was entrapped into albumin nanoparticles made in the same way as the ganciclovir, and resulted in  $3.35$  and  $5.24 \mu\text{g}$   $\text{mg}^{-1}$  nanoparticles, respectively. The oligonucleotide release was 100% after 8 h, while the latter formulation exhibited sustained release for up to 5 days. The release of both drugs show the same biphasic release profile with burst release as described earlier. According to the literature [51, 52], the albumin molecules have fusogenic properties enabling the transfer of the oligonucleotides to the nucleus of the cells. The intraocular disposi-

tion of biotin-labeled albumin nanoparticles was studied by intravitreal injection of 900  $\mu\text{g}$  of particles per 5  $\mu\text{l}$ . Two weeks later it was shown that the carriers diffused through the vitreous space, with most of them located in a thin layer overlying the retina as well as in adjacent sites to the blood aqueous barrier and the ciliary body. There was no evidence of nanoparticles in the inner retinal layers like the visual cells and the neuronal interplay area.

Tamoxifen (nonsteroidal estrogen receptor modulator) for the treatment of uveoretinitis [31] has been formulated into PEG-coated PHDCA nanoparticles. The drug loading and release were not reported but it was found that the intraocular injection of 0.25  $\mu\text{g}$  of tamoxifen/10  $\mu\text{l}$  incorporated in PEG–PHDCA particles was efficient in reducing the uveoretinitis induced to rats while the free tamoxifen had no effect on the inflammation. According to the reported results in the rats carrying uveoretinitis, the nanoparticles were dispersed through the anterior and posterior segments of the eye 8 h after intravitreal injection. After 24 h, the particles passed through the edematous retina, and accumulated in the subretinal space and within the retinal pigment epithelium. Particles were not found in the choroid, but a high amount was detected in the anterior chamber of the eye. The particles were still detected in the retinal pigment epithelium 3–9 days after the injection.

The nonsteroidal anti-inflammatory drugs, ibuprofen and flurbiprofen, were formulated into RS100 and RL100 acrylate nanosuspensions to treat miosis induced by surgical manipulation, e.g. cataract extraction [32, 34]. Approximately 92% of flurbiprofen incorporation into both types of nanoparticles was achieved. Drug release from RS100 particles was slower than that from RL100 particles because the latter contain a higher amount of quaternary ammonium group which makes the nanoparticle matrix more permeable. Drug release studies showed no burst release. The flurbiprofen-loaded RS100 formulation was found in the aqueous humor and antagonized successfully the miosis caused because of a surgical trauma.

Ibuprofen incorporation was as high as flurbiprofen in RS100 particles (approximately 90%). Most of the drug was released after 24 h, but even though the drug concentration in the aqueous humor was higher than that of the free drug solution, the reduction of miosis was not significant [33].

Brimonidine ( $\alpha_2$ -adrenoreceptor antagonist) has been incorporated into PAA and polyitaconic acid (PIA) [41] nanoparticles with a loading capacity of 3.6 and 2.7 mg per 10 mg of nanoparticles respectively at pH 6.5. This corresponds to 80–85 and 70–75% loading efficiency in these systems, and 98% of the drug was retained for a period of 5 weeks at room temperature.

An alternative way to increase the residence time of the drug in the eye is the loading of nanocapsules into disposable soft contact lenses [53]. Nanocapsules were made with octadecyltrimethoxysilane (OTMS) in presence of Brij 97 (final size 13 nm) and loaded with lidocaine. OTMS creates a silica shell around the particles. The capsules were added to the polymerization medium, for lens formation of 1 mm thickness from poly(2-hydroxyethyl methacrylate) (pHEMA). The final particle content in the gel was 25%. When the gels were soaked in water, the drug was released almost completely after 7–8 days with burst release.

The mechanism of action is described herein. The drug diffuses from the particles through the lens matrix. A tear film is trapped between the cornea and lens; therefore, drug molecules will remain longer (30 min) in the post-lens tear film than in the case of eye-drops (2–5 min). This will enhance the influx of the drug through the cornea and reduce the systemic escape of the drug. Even so, there is still a fraction of the drug that will be lost due to tear drainage and absorption through the conjunctiva. According to these researchers, loading the lens with 0.024 mg of timolol will be enough to release therapeutic levels of the drug for 4 days.

The mechanism of interaction of various particles was studied either using primary cell lines or *in vivo*. Qaddoumi and coworkers [39] investigated the uptake mechanism of PLGA nanoparticles (100 nm) by primary cultured RCECs. After using a series of inhibitors for different specific uptake mechanisms located on the cell membrane, the group concluded that particle endocytosis takes place independently of both clathrin heavy chain and caveolin-1, although PLGA uptake may in part occur via clathrin-mediated processes. However, some endocytic process must be occurring because the conjunctival epithelium is a very strict barrier [54] and the paracellular pore radius is only 5 nm [55].

Chitosan nanoparticles are taken up by conjunctival epithelial cells more effectively than corneal epithelial cells because the conjunctival epithelium covers a larger surface area, and the concentration of mucin is higher there [56]. Chitosan nanoparticles can be transported by both paracellular and transcellular pathways because they are able to open the tight junctions between the epithelial cells due to the interactions between the positively charged groups of the polymer and the negative sites of the cell membrane and tight junctions. However, in conjunctiva, chitosan nanoparticles are located mostly in the cells rather than in the intercellular spaces. This happens because the conjunctival epithelium is more heterogeneous than that of cornea and contains goblet cells and APCs as well as epithelial cells. Thus, the particles could be transported to the APCs (Langerhans cells and macrophages) or even a specific cell receptor might be involved in the transport to some epithelial cells [45].

#### 9.2.1.4 Tolerability

As potential candidates for ocular drug delivery, most of the systems described above were well tolerated without any sign of irritation or inflammation to the animal model tested, apart from the PIA nanoparticles, which were proved highly cytotoxic. Approximately 90% loss of corneal epithelial cells viability was observed 30 min after the incubation of the PIA nanoparticles with the cells.

#### 9.2.1.5 Future Prospects for Nanoparticles in Ocular Delivery

Polymeric nanoparticles seem promising carriers for drug delivery to the eye. Some particles have shown adequate drug loading, prolonged site residence and good tolerability, but there are many more challenges to be faced yet. Drug loading, sustained release, storage stability and shelf-life are the main problems for many formulations. From a manufacturing point of view, the difficulty of producing sterile

dispersions is also problematic. No nanoparticulate systems have yet solved all these problems and reached the market.

## 9.2.2

### Macrophage-related Diseases

#### 9.2.2.1 Leishmaniasis

Leishmaniasis is a disease occurring mostly in tropical and subtropical countries. Leishmanial promastigotes invade macrophages and survive in the phagolysosomal compartments of the host cells [57]. Primaquine, an antimalarial drug, has demonstrated some activity against visceral leishmaniasis, but it is highly toxic against red blood cells. PACA nanoparticles without drug showed some activity against *Leishmania donovani* infection in rats [58]. Primaquine-loaded poly(isohexyl cyanoacrylate) (PIHCA) nanoparticles were tested for their anti-infection activity *in vitro* using the macrophage-like J774G8 cell line. PIHCA nanoparticles can be phagocytosed by Kupffer cells and spleen macrophages; hence, they can be potentially used against visceral leishmaniasis [59]. The nanoparticles were not toxic to the J774G8 cells at concentrations up to  $48 \mu\text{g mL}^{-1}$  for 48 h of incubation. Primaquine-loaded PIHCA nanoparticles showed a 21-fold increase of antileishmanial activity, while the two components, i.e. primaquine and nanoparticles, acted synergistically compared to the mixture of free drug and nanoparticles at equivalent concentrations.

Primaquine was also incorporated in poly(D,L-lactide) nanoparticles and was administered intravenously to healthy and infected BALB/c mice with the aim to evaluate tolerance [60]. The particles were formed in presence of phospholipids and Poloxamer (1%) and the final drug-loaded carriers were 150–200 nm, while the  $\zeta$  potential was  $-14.6 \text{ mV}$ . The efficiency of primaquine was 85–94% using an initial drug concentration  $0.5 \text{ mg mL}^{-1}$ .

The acute lethal toxicity of primaquine after intravenous administration to healthy mice was reduced after incorporation of the drug in the particles. For example,  $\text{LD}_{50}$  of free primaquine was  $17.5 \text{ mg kg}^{-1}$ , while for drug-loaded particles it was  $26.9 \text{ mg kg}^{-1}$ , corresponding to  $536 \text{ mg PLA kg}^{-1}$ . The lower toxicity is attributed to the rapid clearance of the particles to the MPS system so that the drug showed activity in the infected macrophages.

Neither free drug nor primaquine-loaded particles showed any lethal toxicity after injection of  $10 \text{ mg kg}^{-1}$  3 times in a 5-day period to infected BALB/c mice. As reported previously, the primaquine-loaded nanoparticles were 3.3 times more effective than the free drug in the suppression of the amastigotes of *L. donovani* in the liver of BALB/c mice [61].

Another drug used for the treatment against *Leishmania* is pentamidine, which is not fully effective and it has toxic side-effects [62]. Pentamidine has been incorporated onto the surface of methacrylate nanoparticles based on the ionic interactions with the free carboxyl groups of the polymer. Complete binding of pentamidine was obtained after mixing the drug ( $7 \mu\text{g mL}^{-1}$  nanoparticle suspension). The particle size was approximately 330 nm. Methylglucamine antimoniate was used as

the reference antileishmanial drug. The drug-loaded carriers suppressed the parasite burden by 77%, which was close to that achieved administering the reference drug (86%). The mean suppression by free drug was 35% while unloaded particles had no effect.

The pentamidine-loaded methacrylate particles were found to be effective against *Leishmania infantum* infection of BALB/c mice [63]. Parasite suppression of 50% was obtained after 1.06 mg of free drug  $\text{kg}^{-1}$  and 0.17 mg of pentamidine-loaded particles  $\text{kg}^{-1}$ . The latter  $\text{ED}_{50}$  was comparable to that achieved using liposomal amphotericin B (0.256 mg  $\text{kg}^{-1}$ ).

Paul and coworkers [64] studied the physicochemical properties of pentamidine-loaded methacrylate nanoparticles and shown that the optimum stabilization of the drug on the particle surface was pH 7.5, where both drug and polymer are highly ionized. They found out that at the lysosomal pH of 5, 50% of the drug is released. Following the fate of the drug-loaded vesicles in the liver Kupffer cells of infected BALB/c mice, the authors found that phagocytotic vacuoles containing nanoparticles were fused with primary lysosomes to form secondary lysosomes. Half of the pentamidine was released in the lysosome due to its acidic pH. However, the drug is still ionized, so it cannot pass through the lysosomal membrane. The parasitophorous vacuole (pH 4.7–5.2) is fused with the secondary lysosome and the drug is still retained in the vacuole. Despite the fact that nanoparticles cannot be internalized by the parasites, the released pentamidine resulted in parasite growth suppression.

Another group incorporated amphotericin B in PLGA nanoparticles (size 166 nm), and evaluated the leishmanicidal potency of those particles on macrophages *in vitro* as well as the effect of trehalose on the multiplication of promastigotes and the macrophage activation [65]. Amphotericin B is sometimes used for the treatment of visceral leishmaniasis when the usual antimonial drugs are noneffective [66]. Liposomal amphotericin is used to reduce the toxicity and increase the drug efficacy. However, the amphotericin-loaded nanoparticles did not exhibit any advantage over the free amphotericin B in treating the infected macrophages, probably because the majority of the particles were washed away so there was only a limited amount endocytosed by the macrophages. Moreover, trehalose reduced promastigote multiplication. It has been shown previously that *L. donovani* promastigotes interact with the mannose/fucose receptors on human monocyte-derived macrophages in order to invade the host cells [67]. The presence of trehalose was shown to be toxic to the macrophages in a concentration higher than 50%. The sugar was tolerated in a concentration of 1 mg  $\text{mL}^{-1}$  by both infected and noninfected macrophages, but infected macrophages showed higher tolerance than the noninfected ones. This happened because lower amounts of specific receptors were available on the infected macrophages rather than the noninfected ones. Also, both infected and noninfected macrophages were activated by the presence of trehalose, while a greater effect was obtained for the infected ones. Thus, the sugar can alter the fate of *L. donovani* in the cells.

There is still a need for the development of new molecules with antileishmanial activity due to the toxic effects of the current drugs or due to their lack of

efficiency [68]. Based on a previous report that the chalcones are quite effective against *L. donovani* [69], a group of researchers incorporated 2',6'-dihydroxy-4'-methoxychalcone (DMC) extracted from *Piper aduncum* in PLA nanoparticles [70]. Pluronic F68 (1%) was used as surfactant to facilitate the particle formulation. The size of empty and loaded-nanoparticles was 130 and 168 nm, respectively, and the encapsulation efficiency was approximately 92%. BALB/c mice infected with *L. amazonensis* promastigotes were injected intraperitoneally with either empty particles (1 mg), DMC-PLA particles (200 µg DMC mg<sup>-1</sup> PLA), glucantime (200 µg) or phosphate-buffered saline alone on days 42 and 48 after infection. It was shown that DMC-PLA particles were as effective as glucantime (first choice drug for the treatment of leishmaniasis) in reducing the number of parasites into the cells, making the drug-loaded particles promising agents for antileishmanial treatment.

Many other attempts to develop new antileishmanial agents have been reported [71–73]. One of these is quercetin, which belongs to the flavonoid family and is metabolized in the colon – it exhibits mostly antioxidant, anti-inflammatory, anti-hepatotoxic and antiulcer properties [71]. It has been formulated in different carriers, like liposomes, niosomes, microspheres and nanocapsules (PLA). It has been shown that quercetin inhibits the growth of *L. donovani* promastigotes and intracellular amastigotes both *in vitro* and *in vivo*, while it leads *L. donovani* promastigotes to apoptosis through inhibition of DNA topoisomerase II inhibition [74]. Quercetin EC<sub>50</sub> was 3 mg kg<sup>-1</sup> body weight; therefore, the different formulations were administered subcutaneously to hamsters after 30 days of their infection at a dose of 300 µg per 0.5 ml of vesicles suspension every 3 days for a total of 6 doses in 15 days. The final administered dose was equivalent to the EC<sub>50</sub> of quercetin. The highest efficiency was obtained after the quercetin-loaded nanocapsules, which demonstrated 87% reduction of spleen parasite burden compared to the 25% achieved with the free drug. As for the rest of the formulations tested, the efficacy was 68, 51 and 44% for drug loaded-niosomes, liposomes and microspheres, respectively.

The same set of experiments was carried out with the carriers mentioned above using another potential antileishmanial agent named harmine (7-methoxy 1-methyl β-carboline), previously shown to be effective at Parkinson's disease and related neurological/psychiatric diseases [72]. Harmine has also exhibited activity against *Trypanosome cruzi*, while it can be effective against AIDS and tumors. It is believed that harmine condenses chromatin [75] and inhibits DNA topoisomerase I [76]. The effective dose of harmine was found to be 25 µg kg<sup>-1</sup> body weight in 24 h after incubation of *L. donovani* *in vitro*. After the subcutaneous injection of the harmine-loaded particles, the reduction of the spleen parasite load was by 44% for the free drug, and 61, 67 and 79% for liposomes, niosomes and nanocapsules, respectively. One reason for the highest efficacy of the nanocapsules was the fact that they were the smallest formulation and their composition enabled them to circulate in the blood stream longer in comparison to the other type of vesicles, probably due to the presence of Tween 80 as a capsule component.

The same group carried out a similar piece of work on arjunglucoside, a pentacyclic triterpene glycoside of the saponin group, in nanogels of 90 nm or PLA

nanoparticles (250 nm) for similar reasons [73]. The nanogel consisted of *N*-isopropyl-acrylamide (NIPAAm) and *N*-vinyl-pyrrolidone (VP). The drug incorporation efficiency was 80 and 60% for nanogel and PLA nanoparticle, respectively. After the subcutaneous injection of the two formulations in infected hamsters, they both exhibited a similar reduction in the spleen parasite load, which was recorded to be 75 and 79% for the nanogel and the nanoparticles, respectively. The effective dose of the drug was 4 mg kg<sup>-1</sup> body weight. *In vitro* release of drug from nanogels was accompanied with an initial burst release of 50% and a total release of 75% after 25 h, while the drug release from PLA nanoparticles was 40% initially and it remained mostly constant up to 25 h.

Particles with neoglycoproteins having either glucose, mannose or fucose moieties grafted on the vesicle surface would enable more effective macrophage targeting according to comparative studies between liposomes, niosomes, microspheres and nanoparticles as presented by Basu and coworkers [77].

#### 9.2.2.2 Other Parasitic Infections

Unloaded poly(isobutyl cyanoacrylate) (PIBCA) nanoparticles demonstrated anti-trypanosomal activity after their *in vitro* and *in vivo* tests on *Trypanosoma brucei* [78]. More specifically, after *in vitro* treatment of *T. brucei* with different concentrations of PIBCA, the parasitic mobility disappeared in the presence of 1.2 μg mL<sup>-1</sup>. Mice pretreated with 1.2 μg mL<sup>-1</sup> and infected with trypanosomes survived until 30 days later, but they were not completely cured. The above nanoparticles were not effective against *Trypanosoma vaginalis* or *Entamoeba histolytica*.

Schistosomiasis is another serious public health problem in tropical countries. Praziquantel is the drug of choice, but the poor water solubility and the fast metabolism make long-lasting therapy hard to achieve. PLGA polymer was used to prepare nanoparticles with the emulsion-solvent evaporation method and a variety of factors were considered in order to prepare a formulation with optimum physicochemical properties [79] (Fig. 9.3). Those factors were PLGA and surfactant content in the formulation, time of sonication, ratio of the volume of aqueous to organic phase, and praziquantel content. Sonication (20 min) led to a particle size of 255 nm with polydispersity index of 0.22 and a monomodal distribution.

**Figure 9.3.** PLGA nanoparticles prepared with 20% of praziquantel. (Reprinted from Ref. [79], © 2005, with permission from Elsevier.)

Using 12.5 mg of PLGA polymer, the particles were of spherical shape without agglomeration.

As the polymer concentration (12.5, 25 and 50 mg) increased, the particle size increased and the particle shape deviated from the spherical pattern. As the surfactant content increased, the particle size reduced and the best formulation was obtained using 0.7% of surfactant. Also, the rate of evaporation of the organic solvent should be as slow as possible, so as the volume of the organic phase is reduced and the viscosity increases, the droplet size equilibrium will not change instantaneously and the particles will have the time to be formed in a good spherical shape of small size without agglomeration.

Praziquantel encapsulation efficiency was constant (approximately 75%) over the range of initial amount of the drug used from 10 to 30%. As the drug content increased, the size of the particles increased due to the increase of the dispersion viscosity. *In vitro* release of praziquantel was studied using particles prepared in the presence of 10 and 30% theoretical loadings; 100% of the drug was found in the dispersion medium in 2 h. As for the drug-loaded particles, 6 and 20% of drug was released from nanoparticles after 24 h from 10 and 30% drug-loaded particles. It is concluded that highest drug release is obtained with the highest drug loading.

An Antimalarial nanoparticle formulation has been reported by Legrand and coworkers [80]. Nanocapsules were prepared using PLA-PEG copolymers (PLA:PEG molecular weight ratios of 45:5 and 45:20) and Miglyol 810 to encapsulate halofantrine – a very hydrophobic antimalarial drug. Drug incorporation was better than 99.5% with 25% drug by weight of nanocapsules. Their particles were stable for more than 10 months at 4 °C and had a size of 175–220 nm.

Drug release was slow in the presence of Tween 80 (used to allow solubility of drug in water), but rapid in the present of serum proteins. The nanocapsules were long circulating and when administered to mice infected with *Plasmodium berghei* showed a reduction in parasite infection within a short period, which was maintained for several days. The nanocapsule treatment was much more rapid in onset than with the free drug. The toxicity of the encapsulated drug was also much reduced in comparison to free drug.

### 9.2.3

#### Antifungal

##### 9.2.3.1 Treatment

Drugs used in fungal infections are polyene antifungals (amphotericin, nystatin), imidazole antifungals (ketoconazole, miconazole), triazole antifungals (fluconazole, itraconazole), and others like griseofulvin, caspofungin, flucytosine and terbinafine [66]. Some of those drugs exhibit limitations either of absorption via the oral route or high toxicity. For example, polyene antifungals are not absorbed when given orally. They are used for oral, oropharyngeal and perioral infections by local application in the mouth. Amphotericin is highly toxic and mostly nephrotoxic, but lipid formulations (Abelcet<sup>®</sup>, AmBisome<sup>®</sup> and Amphocil<sup>®</sup>) have been produced reducing its toxicity.

Also, ketoconazole is characterized as highly hepatotoxic, but it is absorbed well when it is given orally. Itraconazole is another drug associated with liver damage.

### 9.2.3.2 Drug Delivery Systems

Only a few attempts have been reported using nanoparticles to improve the therapeutic prospects of the above mentioned drug molecules by reducing their limitations. Amphotericin B (used against infections by *Candida albicans*) was launched in the market as lipid formulations that are expensive. Thus, Tiyaboonchai and coworkers [81] have incorporated the antifungal drug in polyethylenimine (PEI)–dextran sulfate (DS) nanoparticles produced with the complex coacervation method (Fig. 9.4).

This method has the advantage of being simple and low cost without the need for organic solvents. It is based on the electrostatic interaction of the two oppositely charged molecules. Due to the poor water solubility of amphotericin B and low absorption from the gastrointestinal tract, the drug is administered parenterally. Particle size and size distribution are crucial parameters for parenteral formulations. The pH of PEI solutions, the charge and mass ratio of the two polymers as well as the zinc concentration influenced the particle size. The optimal conditions for am-

**Figure 9.4.** Scanning electron microscopy micrographs of unloaded nanoparticles formed with pH 7 PEI solution and a PEI:DS mass ratio of 1:1, and washed in (A) water and (B) 5% w/v mannitol. (C) Scanning electron

microscopy micrograph of amphotericin B particles formed with pH 8 PEI solution and a PEI:DS mass ratio of 2:1, and washed in 5% mannitol. (Reprinted from Ref. [81], © 2001, with permission from Wiley.)

photericin B nanoparticle formation was the use of a PEI solution of pH 8, PEI:DS polymer ratio 2:1 and 25  $\mu\text{m}$  zinc sulfate. Entrapment efficiency was about 85%. The particles produced had an average size of approximately 260 nm with a range of 100–600 nm. Mannitol was used as a cryoprotectant during the lyophilization procedure making the particles easily redispersable, which was not the case when mannitol was not present.

*In vitro* dissolution studies showed a rapid release of the drug, which, according to the authors, would be clinically useful due to the poor drug solubility and thus, the sustained release effect.

After incubating the drug-loaded nanoparticles with human cells, amphotericin B-loaded vesicles exhibited 100-fold lower toxicity compared to a reduction in the antifungal activity of the molecule of only 2-fold.

A different approach was to prevent the adhesion of *C. albicans* so to prevent the start of the infection [82]. This was based on using poly(propyl cyanoacrylate) nanoparticles in the presence of anionic, cationic or nonionic surfactants to promote adsorption onto the blastospore surface and, hence, reduce blastospore adherence to buccal epithelial cells. The adherence of blastospores that had been treated with nanoparticles produced in presence of docusate sodium was 73% lower than that of untreated blastospores. This phenomenon was reported to be due to the steric hindrance that the particles cause after their adherence on the spore's surface.

Molina and coworkers [83] improved the therapeutic efficacy of a sterol biosynthesis inhibitor, DO870, by incorporating it into PEG–PLA nanoparticles. This inhibitor was used successfully against the Y and CL strains of *Trypanosoma cruzi* in Chagas' disease, but its development has been discontinued [84]. Also, ketoconazole- and itraconazole-loaded particles were used for comparison. Particle sizes in the range 100–200 nm were achieved and entrapment efficiencies were 90, 87 and 92% for DO870, itraconazole and ketoconazole, respectively. The drug-loaded nanoparticles were administered to infected mice either orally or intravenously and were well tolerated by the mice for the treatment period of 93 days. In contrast, for the group of mice treated with free DO870, 100% death was observed at the day 93, postinfection period.

After administration of DO870-loaded particles via the intravenous route (1.5–3.0  $\text{mg kg}^{-1} \text{day}^{-1}$ ) or the oral route (5  $\text{mg kg}^{-1} \text{day}^{-1}$ ) no reappearance of parasites in the blood was observed. The cure rate for those formulations was approximately 80% in mice infected with the CL strain of *T. cruzi*. For the Y strain, infected mice received an intravenous administration of 3  $\text{mg kg}^{-1} \text{day}^{-1}$ . The cure rate of DO870-loaded particles was 60%, while there was no positive influence of the ketoconazole or itraconazole-loaded spheres.

Nisin is a bacteriosin produced by *Lactococcus lactis* and is used as a food preservative, but it is unstable and so it was incorporated into nanoparticles [85]. Those particles were made using PLA with the method of supercritical fluids. Using supercritical or compressed gas techniques to make nanoparticles is very attractive due to the omission of surfactants or stabilizers that may cause protein denaturation or toxic effects, the process flexibility, the high product yield and, possibly,

**Figure 9.5.** Atomic force micrographs of chitosan nanoparticles at pH 5.0: chitosan nanoparticles (A) and copper-loaded nanoparticles (B). (Reprinted from Ref. [86], © 2004, with permission from Elsevier.)

efficient protein encapsulation. The optimal ratios for particle preparation were: dimethylsulfoxide:dichloromethane 50:50 where the nisin solubility was  $60 \text{ mg mL}^{-1}$ , and a PLA solution of  $10 \text{ mg mL}^{-1}$  containing  $0.5$  or  $2 \text{ mg mL}^{-1}$  nisin. The optimal preparation conditions were:  $1 \text{ mL min}^{-1}$  organic solution injection into the precipitation vessel,  $288 \text{ K}$  and  $15 \text{ MPa}$ ,  $1500 \text{ NL (normal liters) h}^{-1}$   $\text{CO}_2$  flow rate and  $1 \text{ h}$   $\text{CO}_2$  washing after the particle preparation. The process yield was approximately 80% and the remaining DMSO and DCM were less than 300 and 15 p.p.m., respectively. Biological studies showed that nisin was entrapped in the particles in its active form so the efficacy of the preparation procedure was demonstrated. However, the nisin-loaded particles had a weaker antibacterial activity attributed to the delay of protein release from the spheres.

Finally, we should mention the recently reported antibacterial activity of chitosan nanoparticles and copper-loaded chitosan nanoparticles [86] (Fig. 9.5). The particle preparation took place in presence of tripolyphosphate (TPP) with anionic gelation at room temperature. Absorption of copper ions on the particle surface affected the physicochemical properties of the particles. The particle sizes were 4 and 275 nm and the  $\zeta$  potentials were 51 and 96 mV for the chitosan and copper-loaded chitosan nanoparticles, respectively.

Bacteria can adhere on the chitosan surface either in the particle or the molecular form in 30 min. According to the literature, chitosan possess antimicrobial activity against a number of Gram-negative and Gram-positive bacteria [87–88]. Chitosan nanoparticles and copper-loaded chitosan nanoparticles showed stronger antibacterial activity than chitosan alone or doxycycline. Chitosan nanoparticles surround the bacteria after 30 min. This leads to the cell degradation in 60 min and finally the cells begin to fragment after 3 h. A possible mechanism of action is that either it chelates with nutrients and so inhibits the bacteria growth or chito-

san interacts with the anionic groups of the cell surface and forms polyelectrolyte complexes with bacterial surface compounds. Hence, they form an impermeable layer around the cell, which prevents the transport of essential solutes in the bacterial cell. Also, it was shown that the nanoparticle nature of chitosan was responsible for the higher antimicrobial activity.

In the case of copper-loaded nanoparticles, copper was adsorbed on the chitosan particles and passes through the pores of the vesicles towards the inner surface of the particles, where it is chelated. The antimicrobial mechanism of action of copper is that copper is reduced from  $\text{Cu}^{2+}$  to  $\text{Cu}^{1+}$  in the bacteria. The  $\text{O}_2^-$  and  $\text{H}_2\text{O}_2$  produced by such redox reactions cause cytotoxicity by inhibition of DNA synthesis and thus reduction of cell viability.

## 9.2.4

### Tuberculosis

#### 9.2.4.1 Physiology and Pathology

*Mycobacterium tuberculosis* is the causative organism of tuberculosis, which occurs mainly in the lungs, although it can be disseminated to other organs. Bacteria reach the deep lung and are phagocytosed by alveolar macrophages. There, the bacteria will be either destroyed, replicate within the macrophages or remain latent indefinitely. If replication is not prevented the bacilli will multiply and eventually cause the macrophage to rupture.

Tuberculosis is transmissible between people and is most prevalent in places where poor hygienic conditions are found, e.g. during war, famine, homelessness, people lacking adequate medical care, etc. It continues to be found worldwide and causes about 2 million deaths per year. Treatment is long and inadequate or incomplete treatment promotes the development of resistant strains of tuberculosis.

#### 9.2.4.2 Treatment

Tuberculosis is treated in two phases. (i) An initial phase of 2 months, which comprises daily administration of a combination of at least three of the drugs rifampicin (RIF), isoniazid (INH), pyrazinamide (PZA) or ethambutol according to the patient tolerance or bacterial strain resistance. (ii) A continuation phase of 4 months using two drugs, mainly INH and RIF. The treatment is usually oral, but sometimes treatment is parenteral. INH, RIF and PZA are associated with liver toxicity, so hepatic function and renal function should be checked before the treatment commences. Visual acuity should be tested before induction of ethambutol to the therapeutic scheme. Patient noncompliance due to daily multidrug dosing is a significant drawback in tuberculosis therapy.

The main aim of microparticles or nanoparticles for antituberculosis therapy is to reduce the drug systemic toxicity and dosage whether by oral or pulmonary delivery. According to Pandey and coworkers [89], using nanoparticles is preferable to microspheres because of “the high drug loading minimizing the consumption of polymers, their ability to pass through various barriers due to their small size eliciting better therapeutic response”.

**9.2.4.2.1 Oral** Polymeric nanoparticles for oral delivery have been prepared using PLGA polymer [90–92]. The three drugs, RIF, INH and PZA were coencapsulated and exhibited a high drug encapsulation efficiency of 56.9, 66.3 and 68%, respectively with a particle size range of 186–290 nm. After a single oral administration (therapeutic dose of RIF: 12 mg kg<sup>-1</sup> + INH 10 mg kg<sup>-1</sup> + PZA 25 mg kg<sup>-1</sup>) of these particles to mice with experimental tuberculosis, therapeutic levels in plasma were maintained for 4 days in the case of RIF, and for up to 9 days for INH and PZA. Therapeutic concentrations in the tissues higher than the mean inhibitory concentration (MIC) were found for up to 11 days for INH. The free drugs or mixture of free drugs with empty PLGA nanoparticles, administered as a one single oral dose, were cleared rapidly since no drug was detected in the plasma after 12–24 h. According to Pandey and coworkers [90], PLGA polymers are adhesive to the intestinal mucosa so the nanoparticles can be adsorbed directly by intracellular or paracellular routes. More specifically, the nanoparticles can be taken up either by transcytosis via M cells, or intracellular uptake and transport via the epithelial cells lining the intestinal mucosa or uptake via Peyer's patches [93]. Increased lung accumulation was not observed with multiple dosing (five doses at 10 day intervals), but no tubercle bacilli could be detected in the tissues. It was also shown that reducing the oral administration of the previously mentioned formulation by one-third, RIF remained in the circulation for 5 days while INH and PZA remained for 12 days. The drug tissue levels were higher than the MIC up to 14 days in guinea pigs [91]. Even with two-thirds of the therapeutic dose of PLGA-NP, bacilli could not be detected after five doses of treatment.

In order to increase the therapeutic efficacy of the PLGA nanoparticles, the lectin, wheat germ agglutinin (WGA), was incorporated onto the particle surface [92] to interact with specific receptors on intestinal and alveolar epithelium. This lectin has very low immunogenicity, thus making these particles potential candidates for oral and aerosol drug delivery. After a single oral administration of drug-loaded WGA–PLG nanoparticles to guinea pigs with tuberculosis, RIF was still found in the blood circulation 7 days later, and INH and PZA after 13 days. The therapeutic levels in the tissues were maintained higher than the MIC for 15 days and nanoparticle formulations did not show any hepatotoxicity.

**9.2.4.2.2 Pulmonary** During oral administration, only a fraction of the total dose of drugs reaches the lungs and even this fraction is cleared quickly so that frequent doses of antitubercular drugs are necessary [89]. Bearing in mind those problems as well as the fact that the pulmonary route leads the drug directly to the most affected organ, the lungs, nanoparticle administration has also been attempted via nebulization or aerosolization. Pulmonary administration is particularly attractive because of the direct targeting of alveolar macrophages, which are used by mycobacteria as a site for their prolonged survival. Lung delivery will also reduce drug systemic toxicity, therefore improving patient compliance. The lungs offer an enormous surface area for absorption, a favorable environment for proteins, avoidance of first-pass metabolism and better patient acceptability than an injection [94].

PLGA nanoparticles loaded with RIF, INH and PZA with a mass median aerodynamic diameter (MMAD) of  $1.88 \pm 0.01 \mu\text{m}$  were used for inhalation as a single dose every 10 days in guinea pigs [95, 96]. The drug plasma concentration was detected from 6 h onwards until 6 days for RIF, and until 8 days for INH and PZA. The tissue drug concentration at levels higher than MIC was seen for up to 11 days. When the WGA lectin was incorporated on the surface of those nanoparticles [4] (MMDA  $2.8 \pm 1.4 \mu\text{m}$ ), the formulation showed improved potency. After one dose to guinea pigs the INH and PZA plasma levels were retained up to 13 and 14 days, respectively, whereas the RIF levels were detected for up to 6 days. The tissue drug levels higher than MIC were estimated up to 15 days and no hepatotoxicity was observed.

PLGA polymer has limitations as a carrier for lung delivery because of the degradation products of the polymer which can be accumulated in the lung tissue. The polymer induced a mild inflammation lasting for 2–3 weeks [97], but with no obvious consequence on lung function. Bulk PLGA degradation creates an acidic environment, which can damage pH-sensitive drugs such as peptides and proteins [94].

New biomaterials have also been used for drug delivery via aerosolization. Fu and coworkers [94] synthesized the polyether anhydride, sebacic acid (SA)–PEG copolymer, consisting of FDA-approved materials. The PEG content of this polymer leads to the decrease of aerodynamic diameter as well as to increased degradation times. These characteristics give the flexibility of producing particles of different properties for different parts of the lung.

Dailey and coworkers [98] prepared nanoparticles with the branched polyester, diethylaminopropylamine–poly(vinyl alcohol)-*g*-poly(lactide-*co*-glycolide) (DEAPA–PVAL-*g*-PLGA). The nanoparticles included some polyions [carboxymethylcellulose (CMC), dextran sulfate, DNA] in order to modify the physicochemical properties and to study the formulation with the best stability. The greatest advantage of these polymers was that they could be assembled into particles in the absence of surfactant, to reduce possible effects on lung function. It was shown that the positively charged particles interacted efficiently with lung cells, unfortunately only the anionic particles, which did not show any interaction with cells, could be nebulized efficiently.

Alginate, a biodegradable FDA-approved natural polymer, has also been investigated. Nanoparticles made after cation-induced controlled gelification of alginate were of approximately 235.5 nm diameter and the drug encapsulation efficiency was 80–90% for RIF, and 70–90% for INH and PZA. After aerosolization the MMAD was  $1.1 \pm 0.4 \mu\text{m}$  [99]. A single dose of particles loaded with RIF, INH and PZA was administered to guinea pigs. The drugs were detected in the plasma from 3 h onwards. RIF was found in the plasma up to 10 days, and INH and PZA for 14 days. The drug tissue levels were higher than MIC up to 15 days. Thus, overall, alginate particles appeared earlier in the plasma, and RIF was present in the serum for longer than WGA–PLGA nanoparticles with similar retention of tissue drug levels. Again, hepatotoxicity was not observed using the alginate nanopar-

ticles. All these formulations were capable of eliminating the mycobacteria after administration of five doses once every 10 days.

**9.2.4.2.3 Subcutaneous Administration** PLGA nanoparticles loaded with RIF, INH and PZA, and administered via subcutaneous injection to mice, showed sustained release maintaining therapeutic drug levels for up to 36 days in the lungs and the spleen and up to 32 days in the plasma [100]. This resulted in undetectable colony-forming units, while the subcutaneous injection of the free drugs did not reduce the bacterial presence in the organs of infected mice.

#### 9.2.4.3 Future Prospects

From the results reported so far, it seems that the formulation of the three main antitubercular drugs into nanoparticles is very promising for the effective treatment of the disease using either the oral or the pulmonary pathway. The drug loading was high and inhalable formulations were produced from polymer nanoparticles. The use of ligand-bearing particles or particles made with natural polymers promoting cell binding and uptake showed prolonged therapeutic efficacy. A significant reduction in dosage from 45 administrations to five was achieved without compromising performance. The reduction of the dosing scheme is very encouraging because it contributes to patient convenience. The problems that still have to be tackled are mainly the improvement of inhalable formulations, and the cost for the large-scale production of those particles and final products, which will have to exhibit long shelf-life.

### 9.2.5

#### AIDS

##### 9.2.5.1 Pathology

HIV is a retrovirus with two primary types: HIV-1 and HIV-2. There are many strains of both types and all mutate rapidly, which has made it particularly difficult for researchers to find an effective vaccine or treatment for the virus. HIV infection is often mostly or entirely asymptomatic (without symptoms) and the most common signs, which include fever, fatigue, rash and lymphadenopathy (swollen lymph nodes), are often mistaken for mononucleosis, flu or similar, comparatively harmless diseases. Eventually, full-blown AIDS develops in the vast majority of cases.

##### 9.2.5.2 Treatment

The infection caused by the HIV cannot be cured, but drugs are used to slow down the progression of the disease [66]. Drugs for HIV are toxic and expensive, but they increase life expectancy considerably. The aim of the treatment is to reduce the plasma viral load as much as possible and as long as possible before the immune system is irreversibly damaged. The treatment scheme should be chosen taking into account the drug toxicity, patient convenience and tolerance. Using a combina-

tion of drugs can halt the drug resistance. This drug combination should have a synergistic therapeutic effect, but not an additive toxic effect. The suggested treatment is the combination of two nucleoside reverse transcriptase inhibitors with either a non-nucleoside reverse transcriptase inhibitor or one or two protease inhibitors.

Nucleoside analogs or nucleoside reverse transcriptase inhibitors were the first substances used for the HIV treatment. They are DNA chain terminators or competitive inhibitors of the virus-associated reverse transcriptase. Such nucleoside analogues are zidovudine [azidothymidine (AZT)], abacavir, didanosine, lamivudine, stavudine, tenofovir and zalcitabine.

The second group of molecules used for HIV treatment are protease inhibitors, and include amprenavir, indinavir, lopinavir, nelfinavir, ritonavir and saquinavir. They can block the replication of HIV in chronically infected cells. They are metabolized by P450 enzyme systems, and are associated with lipodystrophy and metabolic effects.

The third category of anti-HIV drugs is made up of the non-nucleoside reverse transcriptase inhibitors efavirenz and nevirapine.

### 9.2.5.3 Nanoparticle Delivery Systems

Due to the high dosage scheme in order to achieve antiviral activity and the high toxicity of anti-HIV drugs, there have been attempts to entrap some of these drugs into polymeric nanoparticles to make the treatment more tolerable for the patient and to effectively reduce the drug dosage.

At first, the potential of the antiviral activity of zalcitabine or saquinavir loaded into nanoparticles was studied by incubating HIV-infected primary human macrophages *in vitro* and comparison with the free drug activity on the same cells [101]. The problem with zalcitabine is the rapid viral resistance, while saquinavir is a poorly soluble drug with low bioavailability. Poly(hexyl cyanoacrylate) (PHCA) was used as the polymer of choice to make nanoparticles, which entrapped 15–20% of zalcitabine and 50–60% of saquinavir, respectively. The particle size was approximately 200 and 475 nm, respectively. After the incubation of the drug-loaded nanoparticles with the macrophages, the antiviral activity of zalcitabine did not show any advantage by incorporating the drug into the polymeric carriers, while the activity of saquinavir showed 10-fold improvement. This can be explained on the basis that the zalcitabine molecule itself enters the cell through diffusion and through some transport mechanisms. The activity of this drug is depended on its intracellular conversion to the corresponding 5' mono-, di- and triphosphate derivatives [102].

Later, AZT bound to hexylcyanoacrylate nanoparticles was administered intravenously to rats to estimate the targeting feasibility of these nanoparticles to macrophages [103]. Polysorbate 80 (1%)-coated nanoparticles loaded with AZT were used as well to study the influence of the surfactant on the uptake by the brain with the aim of treating the dissemination of the virus to the brain (microglia). Indeed, 8 h postinjection, 60% of AZT was found in the reticuloendothelial system (RES) or-

**Figure 9.6.** Liver concentrations of AZT (mg of AZT  $\text{g}^{-1}$  liver) after intravenous injection of Polysorbate-80-coated AZT nanoparticles, AZT nanoparticles, an AZT control solution (with emulsifier) and a saline AZT solution (without emulsifier). (Reprinted from Ref. [103], © 1998, with permission from Elsevier.)

gans, while only 12% of the drug injected in its free form was found in the same organs (Fig. 9.6). No trend was obtained in the other organs mainly due to the large fluctuations observed.

Polysorbate-80-coated nanoparticles showed a significant decrease in the liver accumulation, prolonged half-life and significant increase in the brain 1 h after intravenous injection. The increase of the surfactant coated nanoparticles was 35% higher compared to the uncoated particles and 45% compared to the unbound AZT, so there is the possibility of reducing the AZT dose to reduce the AZT side effects.

The same drug was formulated in nanospheres made by PIHCA aiming to concentrate AZT in the intestinal epithelium and associated immunocompetent cells which are known to be one of the major reservoirs of HIV [104]. PIHCA was used due to the controlled release properties in the gastrointestinal tract and its tendency to interact with the intestinal mucosa. The nanospheres were administered by intragastric intubation to rats. The carrier size was approximately 250 nm and the  $\zeta$  potential  $-23$  mV. The release of AZT was estimated in different media; a burst release of 35% of AZT was observed in water or USP XIII-simulated gastric medium containing pepsin. In the presence of pancreatin, 80% of AZT was released 8 h later, probably due to the presence of esterases.

AZT accumulation was 4.4 and 5.9 times higher in intestinal mucosa 30 and 90 min later, respectively, in comparison to the control systems. Similarly, 67% and 64% of the initial dose of AZT was found in the gastrointestinal tract, while only

15 and 11% of the drug was found, respectively, after the administration of drug solution.

The drug accumulation from the particles was 4- and 28-fold higher in stomach 30 and 90 min postadministration, respectively and around 5.5-fold higher in intestine. AZT concentration was maintained constant in the intestine, while it was very low in cecum and colon. Additionally, nanoparticles resulted in higher AZT concentrations in the mucus when compared to the solution (59 and 60.5 nmol AZT g<sup>-1</sup> organ for the nanoparticles at 30 and 90 min, respectively, compared to 8.1 and 10.6 nmol g<sup>-1</sup> organ for the solution). Moreover, 4-fold AZT increase was achieved in Peyer's patches while a very low concentration was found in the lymphatics.

HIV protease inhibitors are characterized by poor pharmacokinetic characteristics and bioavailability problems, which were addressed by the use of nanoparticles. Thus, the HIV protease inhibitor, CGP-57813, was incorporated into pH-sensitive nanoparticles made by Eudragit S100 or L100-55 (approximately 14% drug loading, 250 nm size) [105]. The difference between the two types of polymers lay in the part of the gastrointestinal tract where they were soluble. Also, the influence of the presence of food in the gastrointestinal tract in the effective delivery of the HIV protease inhibitor was studied after the oral administration (25 mg CGP 57813 mL<sup>-1</sup>) of the particles to dogs. According to these studies, Eudragit L100-55 particles did not show any improvement in bioavailability in fasted dogs and only a small increase was obtained in fed dogs, probably because of the rapid dissolution of the polymer in the intestinal pH, which led to the precipitation of the compound.

The presence of food had a more pronounced effect on CGP 57813 bioavailability, while no detectable plasma levels were reported in fasted dogs. The same series of experiments were carried out in mice with opposite results. Eudragit L100-55-loaded particles were more favorable in increasing the bioavailability of the protease inhibitor, indicating that the optimal formulation depends strongly on the animal species [106].

Eudragit L100-55 was studied for improvement of the solubility and bioavailability of HIV-1 protease inhibitor CGP 70726 after oral administration to dogs in the presence or absence of food [107]. Not only nanoparticles, but microspheres were studied here to investigate the influence of the size. The latter did not seem to make any significant difference in the performance of those pH-sensitive systems, but the presence of food reduced the bioavailability especially in the case of nanoparticles. This is probably due to the pH alterations in the gastrointestinal tract in presence of food, which resulted in fast release and precipitation of the drug in the stomach.

Saquinavir is a HIV-1 and HIV-2 protease inhibitor, which is well tolerated, but suffers from low oral bioavailability [108]. This is because it undergoes hepatic metabolism, it exhibits poor water solubility and thus a very low absorption, and it is unable to cross the intestinal barrier due to the multidrug resistance transporter, P-glycoprotein. Therefore, saquinavir was complexed with hydroxypropyl- $\beta$ -cyclodextrin (HP $\beta$ CD) and incorporated in nanoparticles made by either PIBCA or PIHCA polymers. Only 2.4 and 2.9  $\mu$ g of saquinavir mg<sup>-1</sup> of polymer, respectively,

were incorporated in to the nanoparticles mentioned earlier. However, in the presence of 10% HP $\beta$ CD, the entrapped saquinavir was 45 and 50  $\mu\text{g mg}^{-1}$  of particles for PIBCA and PIHCA, respectively. The drug loading reached a plateau when the HP $\beta$ CD-saquinavir complex attained 5 and 7.5  $\text{mg mL}^{-1}$  for PIBCA and PIHCA, respectively, which corresponds to a 20-fold increase. The  $\zeta$  potentials of unloaded nanoparticles were  $-36.9$  and  $-37.1$  mV for PIBCA and PIHCA, respectively. These values became more positive as the cyclodextrin concentration increased. Apparently, PIHCA exhibited higher drug loading because it was more hydrophobic. This study showed that these nanoparticles could potentially reduce the dose of saquinavir for the treatment of HIV patients.

Berton and coworkers [109] tried to protect a cytotoxic phosphorothioate oligonucleotide, GEM91 in polymeric nanoparticles consisting of PLA. Antisense oligonucleotides (AS-ODNs) are used to block different replication phases of the virus life cycle and phosphorothioate analogs are less sensitive to nucleases than phosphodiesteres. Another serious obstacle for the successful antiviral activity of these oligonucleotides is their uptake into appropriate cellular compartments. The results indicated that the PLA formulation facilitated the delivery of the incorporated oligonucleotides to both HeLa P $_{4-2}$ CD $_4^+$  and CEM (human lymphoid T cells) cell lines at nanomolar concentrations. [The P $_{4-2}$  indicators cells are HIV-1-susceptible HeLa CD $_4^+$  cells carrying the bacterial *lacZ* gene driven by the HIV-1 long terminal repeat (LTR).  $\beta$ -Galactosidase expression is induced by the LTR transactivation by the viral Tat protein produced during infection.]

Models used to test the antiviral activity were: (i) cells containing the Tat activation region (TAR) of the HIV-1-LTR, which controls the transcription of the  $\beta$ -galactosidase reporter gene. Incubation of cells with the oligonucleotide-loaded nanoparticles at the time of virus infection resulted in a reduction in  $\beta$ -galactosidase production 48 h later. This indicates that these antisense carrier systems have the ability to inhibit the early events of the viral cycle life. (ii) Acutely infected CEM cells were treated with the oligonucleotide carriers and it was showed that the HIV-1 reverse transcriptase activity was reduced significantly and kept at low levels for the duration of the experiment. GEM91 alone (100 nm) did not have any impact on the HIV-infected cells, while it caused 90% inhibition after incorporation into the particles.

Another way to enable the delivery of AS-ODNs into cells is by complex formation with protamine, which was studied using primary human macrophages and CD $_4^+$  T cells [110]. Protamine complexation shields the negative charge of the ODN and protects it from degradation. The mean particle size was 150–180 nm and the  $\zeta$  potential was positive for protamine:AS-ODN ratios above 1.5 and negative for protamine:AS-ODN ratios below 0.5. Complete complexation occurred when protamine:AS-ODN ratio was above 1.25. High internalization rates were obtained after the treatment of primary human macrophages and T cells with protamine/AS-ODN nanoparticles with no any sign of cytotoxicity up to 5  $\mu\text{M}$  concentration.

By tracking both components of the complex by fluorescent labeling and incubating them with primary human macrophages, it was shown that the AS-ODN

was released in the cell 24 h after cellular uptake. Complexes comprised of phosphorothioate (PTO) and protamine treated in the same way as the protamine/AS-ODN mentioned earlier, showed that the particles were stable even after 48 or 72 h following their cellular uptake. The specific inhibitory effect of protamine/anti-Tat AS-ODN nanoparticles was about 30% at a concentration of 2  $\mu\text{M}$ , in contrast to protamine/PTO complexes, which did not show any significant inhibition. The latter happened due to the very slow release of the PTO from its carriers indicating that the dissociation of the antisense compound from the complex was an essential process for antisense activity.

#### 9.2.5.4 Vaccines and AIDS

Apart from the improvement in delivery of anti-AIDS drugs incorporated into nanoparticles, research has been focused on development of anti-HIV vaccines. AIDS is characterized by immunosuppression due to the overproduction of immunosuppressive cytokine interferon (IFN)- $\alpha$  and the regulating HIV-1 Tat protein released in the extracellular compartment of acutely infected lymphoid tissue [111]. Tat reduces the immune reactivity of still uninfected T cells and further induces overproduction of IFN- $\alpha$  by APCs. Tat toxoid is the version of Tat that is detoxified, but still immunogenic. This is the antigen used to produce anti-Tat antibodies. Anti-Tat vaccination is aimed at mucosal immunity since the virus entry to the body is through the mucosal membranes, which constitutes the 70% of lymphoid tissues of an organism. Therefore, the induction of mucosal immunity was attempted towards Tat protein in mice by either intranasal or oral route using either an oily adjuvant, chitosan nanoparticles or PLGA microparticles. None of these formulations was found to be more advantageous over the other and it seems that all of them were effective enough to cause the production of anti-Tat IgA antibodies. It was shown that cell-mediated immunity was caused as the stimulation indices obtained after the treatment of splenocytes of anti-Tat-immunized mice with Tat protein or Tat toxoid were higher than those of nonimmunized mice.

Using Tat toxoid may not be the optimum antigen because some important epitopes could have been damaged due to the preparation procedure [112]. In more detail, Tat protein is a small protein consisting of 86–101 amino acids and encoded by two exons. There are five domains, but the three most important are the amino-terminal domain (1–21 amino acids), the cysteine rich domain (22–37 amino acids), which is the trans-activation domain, and the basic domain (49–72 amino acids), which contains the nuclear localization signals. That basic domain is responsible for the transactivation of HIV to the other cells and of cellular processes altering the intracellular signaling of various cell types [113, 114]. The biologically active Tat (1–72) protein, which was confirmed to be immunogenic and non-immunosuppressive, was adsorbed on the surface of anionic nanoparticles. The latter were made by the emulsification of wax (oil phase) and sodium dodecyl sulfate (SDS, anionic surfactant) dissolved in water. Tat was adsorbed on the particles (100 nm) produced by its basic domain and the final formulation was administered subcutaneously to mice on days 0 and 14. Immune responses recorded from mice immunized with the particle formulation were compared to those obtained from

mice immunized either with alum Tat ( $T_H2$  control) with alum adjuvant and Tat ( $T_H1$  control) with lipid A as adjuvant. There were strong antibody responses (IgG and IgM) and the IgG titer from the Tat-immunized mice was approximately 3-fold higher than that in “naive” mice, even after 10 000 dilution of the particle formulation. The Tat-coated nanoparticles caused the production of IFN- $\gamma$  to the same level as the Tat with lipid A as adjuvant, which indicates that the specific formulation induces an enhancement of  $T_H1$  immune response and, thus, is considered as a promising vaccine product.

Another novel nontoxic polyelectrolyte formulation is composed of polylysine modified with imidazole side-chains condensing HIV-2 *env* DNA into nanoparticles [115]. The size of the resulting nanoparticles was approximately 150 nm and it was considered ideal for targeting clathrin-coated pit uptake into the cell. The complexation with cationic polymer prevents DNA degradation in the lysosomal compartment and the imidazole side-chains optimize the escape to the cytoplasm of the target cell. The polyelectrolyte complexes induced higher levels of IgA, IgM and IgG antibodies by the intradermal route to BALB/c mice (Fig. 9.7).

Kawamura and coworkers [116] used concanavalin A-polystyrene nanospheres (Con A-NS) to capture HIV-1 envelope antigen gp120 due to the high affinity that the lectin exhibits for the HIV-1 antigen. In this study, dendritic cells were the targets for the immune response since they are unique major APCs capable of stimulating “naive” T cells in the primary immune response and more potent APCs

**Figure 9.7.** Comparison of HIV-2 gp120-specific antibodies in mice immunized with a polylysine nanoparticle formulation. Serum from mice was evaluated using samples taken 28 days after the third DNA immunization by the intradermal route. IgG subclasses (A) and antibody isotypes (B) were evaluated in mouse serum samples. ELISA results are shown using

serum from mice immunized with polylysine nanoparticles containing DNA encoding HIV-2 gp140 (solid bars), naked DNA encoding gp140 (diagonal lines) and plasmid vector DNA formulated with polylysine nanoparticles (stippled bars). (Reprinted from Ref. [115], © 2003, with permission from Elsevier.)

than monocytes/macrophages or B cells. This is due to the high level of expression of major histocompatibility complex (MHC) and costimulatory molecules such as CD40, CD80 and CD86. They cause the secretion of  $T_H1$  cytokines (interleukin-12, IFN- $\alpha$ ). BALB/c mice were immunized intranasally with either gp120, or p24 or HIV-NS suspension on days 0, 7, 14 and 42. After that, a low level of gp120-specific IgA was detected in the vaginal samples of the HIV-NS immunized mice. Con A-NS were taken by pulmonary dendritic cells 24 h after intranasal administration. Phagocytosis was partially responsible for the uptake of Con A-NS and gp120-NS. Thus, approximately a 100-fold increase of the gp120-NS uptake was observed in comparison to gp120 alone. T cells from mice immunized with gp120-NS produced much more IFN- $\gamma$  than those immunized with gp120, which indicates that the gp120-NS are more advantageous in inducing  $T_H1$  responses.

However, according to Miyake and coworkers [117], the mouse is not a representative model for developing a HIV-1 vaccine. That group tested inactivated simian/human immunodeficiency virus KU-2-capturing nanospheres (SHIV-NS) in macaques, while Con A-NS were used as control. Two groups of three macaques in each group were given a series of six immunizations in a week with either Con A-NS or SHIV-NS intranasally. Vaginal anti-HIV-gp120 IgA and IgG antibodies were detected in all SHIV-NS-immunized macaques, but not in the Con A-NS-immunized macaques. After intravaginal challenge with the virus SHIV-KU2, one of the three macaques of each group was infected. The population of  $CD4^+$  T cells was less in the Con A-NS and “naive” macaques, while it remained constant in the SHIV-NS-immunized mammals. The two uninfected macaques were rechallenged with the intravenous injection of SHIV-KU2, which led to infection of all macaques. A significant decrease of RNA viral loads was observed in SHIV-NS-immunized macaques 3 and 8 weeks after their rechallenge with the virus. The peripheral  $CD4^+$  T cell population decreased at the beginning of the infection and recovered to about 30–50% of the preinfected levels. Also, the intravenously infected SHIV-NS macaques showed a rapid antibody response and the highest levels of anti-gp120 antibodies, which means that gp120 specific memory cells were acquired.

### 9.2.6

#### Vaccines

Vaccines are a form of active immunity because they cause the production of antibodies and cellular responses in the patient [66]. Vaccines can be:

- Live attenuated form of a virus or bacteria.
- Inactivated preparations of the virus or bacteria.
- Extracts of or detoxified exotoxins produced by a microorganism.

The immunization after administration of live attenuated vaccines is generally achieved with a single dose and lasts for long time, but not as long as if it was produced from the natural infection. Inactivated vaccines need more than one dose for

adequate immunity to be achieved. The duration of immunity varies from months to years. Extracts of or detoxified exotoxins are more immunogenic if adsorbed onto an adjuvant (i.e. aluminum hydroxide). They require a series of injections followed by booster doses.

#### 9.2.6.1 Delivery Route

The most common way of administering vaccines is by injecting them intramuscularly or subcutaneously. Of course this is not a pleasant way, especially for children. Therefore, the formulation of vaccines to exploit other available routes (i.e. oral, intranasal) is under investigation. Also, many vaccines in the form of peptides are difficult to administer due to low immunogenic response or the toxicity of the adjuvants used. Nanoparticles have been tested as potential carriers to increase the immune response or for alternative routes of administration.

**9.2.6.1.1 Systemic** Again as reported in previous sections, chitosan and PLGA are the main polymers of choice for nanoparticle formulation. A number of parameters like polymer hydrophobicity, particle size and the use of adjuvants were evaluated for the best immunization responses. Raghuvanshi and coworkers [118] used a mixture of nanoparticles and microparticles prepared with either PLA or PLGA using the water/oil/water (w/o/w) emulsification technique to entrap tetanus toxoid (TT) in the particles. The mean size of nanoparticles and microparticles were 630 nm and 4  $\mu\text{m}$ , respectively. TT was released from the particles with a burst release (20%).

The immunization responses were recorded after intramuscular injection of a mixture of either, PLA (45 kDa) nanoparticles and microparticles (1/1) or PLGA (50:50) nanoparticles and microparticles (1:1) to rats. Immune responses from polymer-entrapped TT particles were higher than those obtained with saline TT and lasted for 5 months. However, a single injection of the particles, either one type or the physical mixture of particles, resulted in immune responses lower than those achieved after two doses of alum-adsorbed TT.

Low-molecular-weight PLGA particles elicited higher and faster immune responses in comparison to high-molecular-weight PLGA due to the lower  $T_g$  of the polymer. Thus, the polymeric matrix was softening and released the entrapped TT near the periphery of the particle matrix more rapidly, so the antigens were presented quickly to the APCs. Immunization with PLA particles elicited significantly higher anti-TT antibody titers than PLGA particles (antibody titers were 2-fold higher from PLA than PLGA particles). This is believed to be because the PLA polymer is more hydrophobic than the PLGA and so the APCs are attracted more to the PLA particles.

Coadministration of alum (adjuvant) at the same time as the particles improved serum immune responses still further. High antibody titers were detected 15 days postimmunization using PLGA and alum, which was faster than that obtained with the particles alone. PLA microparticles administered with alum proved almost as effective as a two-dose immunization with alum-adsorbed TT only. The antibody titers were not only high, but were also maintained for almost 150 days. This in-

creased effect is probably due to the adsorption of the TT by the alum, enabling the antigen to be presented to the APCs, resulting in high antibody response. Also, it was shown that  $Al^{3+}$  cations neutralize the negatively charged protein and make it more hydrophobic facilitating the attraction to APCs [119].

The desirable physicochemical properties that particles should possess to develop an optimum vaccine delivery system able to permeate the skin were investigated by other groups. Kohli's group [120] used latex nanoparticles of various sizes (50, 100, 200 and 500 nm) and surface charge (positively charged, neutral and negatively charged particles). Only negatively charged particles of size 50 and 500 nm permeated through the skin. The authors assumed that the contradictory phenomenon of the permeability of negative particles through the skin is due to repulsive forces between negatively charged lipids within the skin and particles at the surface. These forces might result in a temporary initiation of channels in the skin, allowing for particle permeation. On this basis, it was suggested that there might be a threshold charge, which must be reached to allow adequate repulsion of lipids to permit permeation of species through the skin, although this mechanism has not been confirmed yet.

According to Newman and coworkers [121], PLGA nanoparticles are taken up preferably by dendritic cells after intradermal administration of the particles in mice. Based on this finding, the same group studied the *in vitro* optimization of PLGA particle delivery for activation of T cells using murine bone marrow-derived dendritic cells [122]. Also, the influence of the coadministration of an immunomodulator [monophosphoryl-lipid A (MPLA)] was evaluated. The PLGA nanoparticles contained a human MUC1 lipopeptide, BLP25 prepared with the double-emulsion technique (mean size: 287 nm, peptide loading: 1% w/w). Particle uptake was found to depend on the incubation time and particle concentration. The optimum incubation conditions used were 2 mg of nanoparticles with  $1 \times 10^7$  dendritic cells (day 7 culture) in 20 ml medium for 24 h in a Petri dish. Finally, it was shown that after incubation of dendritic cells with PLGA particles, dendritic cells exhibited an increase in the expression of MHC class II and CD86 compared to untreated cells. This phenomenon was increased further after the coincubation of PLGA particles and the immunomodulator, MPLA. Particle size is an important parameter for the maturation of dendritic cells according to results reported after the incubation of PLGA microparticles (approximately 10  $\mu$ m) with dendritic cells, which did not increase the expression of MHC class II and CD86 [123].

PLGA nanoparticles were then used to incorporate either the hepatitis B core antigen (HBcAg) only or HBcAg plus the immunomodulator, MPLA, in order to examine their influence on the  $T_H1$  immune responses [124]. PLGA particles were prepared with the emulsification method, and the loading efficiency of HBcAg was 50.8 and 51.0% in the absence and presence of MPLA, respectively. When MPLA was incorporated in the particles, the loading efficiency was approximately 45%. The average size of all formulations was approximately 265–270 nm. Particles (10 mg) containing 1  $\mu$ g of HBcAg and 20  $\mu$ g of MPLA were injected subcutaneously to mice. It was shown that the mice immunized with HBcAg + MPLA nanoparticles exhibited the strongest HbcAg-specific T cell proliferation. The incorporation

of MPLA in the HBcAg nanoparticles increased the stimulation index almost 4 times compared to the unencapsulated HBcAg. Also, the high level of IFN- $\gamma$  production from the primed T cells due to the immunization with HBcAg + MPLA nanoparticles indicated a predominant T<sub>h</sub>1 immune induction.

Again, the particle size importance was emphasized by those authors because particles of size smaller than 500 nm induced higher immune responses than particles of mean size greater than 2  $\mu$ m [125].

Due to the fact that dendritic cells are the most important APCs involved in antigen uptake and presentation to antigen-specific T cells, the state of maturity of dendritic cells was evaluated as to the nanosphere uptake and the dendritic cell responses [126]. However, both immature and mature dendritic cells exhibited the same ability to take up polystyrene nanospheres or antigen-loaded nanospheres in a dose- and time-dependent manner. Phagocytosis was the suggested mechanism of nanosphere uptake. The particulate nature of the antigen-loaded nanoparticles was responsible for the enhanced immune responses by dendritic cells in comparison to soluble antigens. Thus, when low amounts of ovalbumin (OVA) were adsorbed on the nanosphere surface, strong antigen-primed T cell proliferation and production of IFN- $\gamma$  were induced *in vitro*. The antigen adsorption/loading on the particle surface means that lower amounts of antigens will be needed to induce immunity in the future.

Nanoparticles have also been used for DNA vaccine formulations. Cui and co-workers [127] have tried to develop chitosan-based nanoparticles containing plasmid DNA (pDNA) as a potential approach to genetic immunization by topical application. The pDNA was either added during the preparation procedure or added on preformed cationic chitosan/CMC nanoparticles. Different ratios of chitosan:CMC and chitosan oligomers (lower molecular weight than that of chitosan: 102 kDa) were used. The particle size range was between 90 and 270 nm for almost all of the ratios tested. A chitosan:CMC ratio of 1:1 (w/w) was chosen for pDNA coating studies because of the relatively small size (179 nm) and positive  $\zeta$  potential (+44 mV) of the particles produced. Chitosan oligomer:CMC ratios of 3:1 and 4:1 were chosen for pDNA coating studies due to the particle small size (121 and 93 nm, respectively) and positive  $\zeta$  potential (+24 and +25 mV respectively). The incorporation efficiency of pDNA on the chitosan oligomer/CMC complexes was almost 100%, which was expected using positively charged nanoparticles.

The final pDNA-coated chitosan/CMC or chitosan oligomers/CMC complexes selected for the genetic immunization by topical application were negatively charged. The latter is based on previous results reported by the same group [128], suggesting that the positively charged particles or complexes produce lower immune responses and gene expression in comparison to negatively charged ones. A number of particle specifications were tested. Also, "naked" DNA was administered topically as control. Only pDNA (300  $\mu$ g mL<sup>-1</sup>) coated on chitosan oligomer/CMC nanoparticles (300/100 w/w,  $\mu$ g mL<sup>-1</sup>) caused a 32-fold increase of the IgG titer in mice as compared to that obtained after immunization using "naked" pDNA alone applied topically. None of the other formulations tested demonstrate any influence in comparison to the administration of the "naked" pDNA alone.

The same group carried out further work using pDNA-coated nanoparticles to induce immune responses after topical application to the skin [129]. The difference in this study was the type of the nanoparticles. They were not made with chitosan but with a mixture of emulsifying wax/Polysorbate 60 in a ratio 20/1 with hexadecyltrimethyl-ammonium bromide (CTAB) as a surfactant (cationic) (mean size 100 nm,  $\zeta$  potential about 25 mV). No allergic, inflammatory or toxic effects have been observed with these systems in mice after their delivery via the intramuscular, subcutaneous and topical route. Also, dioleoyl phosphatidylethanolamine (DOPE) and cholesterol were part of the nanoparticle composition as endosomolytic agents. DOPE causes disruption of the endosomal membrane because it changes to the hexagonal conformation in the acidic environment of the endosome. *In vitro* studies showed a 7-fold increase of the transfection efficiency compared to nanoparticles without DOPE, but the effect of the cholesterol incorporation was not statistically significant. Also, pDNA remained functional after coating onto the preformed engineered cationic nanoparticles. Mannan cholesterol was also incorporated into the nanoparticles because human and mice dendritic cells have mannose receptors, which stimulated robust  $T_h1$  and cytotoxic T lymphocyte responses [130–132]. Negatively charged nanoparticles were also used for these formulations (Fig. 9.8).

It was shown that pDNA-coated nanoparticles and pDNA-coated particles with DOPE and the mannan ligand caused 6- and 16-fold enhancement of IgG titer, respectively, compared to that of “naked” DNA. *In vitro* and *in vivo* studies proved that the incorporation of DOPE in the nanoparticles improved both the transfec-

**Figure 9.8.** Transmission electron micrographs. (A) Mannan-coated cationic nanoparticles and (B) pDNA-coated nanoparticles. Spherical and homogeneous cationic nanoparticles were engineered directly from the oil droplets of a clear microemulsion composed of emulsifying wax (2 mg), DOPE (100  $\mu$ g) and CTAB (15 mM) in 1 mL water at 55 °C, cooling to room temperature during

gentle stirring. Chol-mannan was added. Mannan-coated nanoparticles were purified by gel permeation chromatography, prior to the addition of pDNA. pDNA (CMV- $\beta$ -galactosidase) was coated on the surface of the cationic nanoparticles (1 mL) to obtain a final pDNA concentration of 50  $\mu$ g mL<sup>-1</sup>. (Reprinted from Ref. [133], © 2003, with permission from Elsevier.)

tion efficiency and the overall immune response. Surprisingly, the mannan-coated nanoparticles showed only a modest effect on enhancing the immune response. This was subsequently shown to be due to the reduced binding of mannan caused by the presence of pDNA on the particle surface. Thus, maybe the topical route is not the most efficient to target the dendritic cells using the mannan ligand. In these studies, pDNA doses as low as 4–5  $\mu\text{g}$  applied topically to chemically untreated skin resulted in significant and measurable humoral and proliferative immune responses.

The route of injection has also been investigated. The same type of nanoparticles was administered either (i) via topical immunization with application of the formulation over the skin without applying pressure, (ii) via subcutaneous injection or (iii) via jet injection [133]. It was shown that the intradermal jet injection of pDNA-coated nanoparticles led to the highest antibody titer of all groups. The titer obtained with pDNA-coated nanoparticles delivered by jet injection was over 20 and 65 times higher than that obtained after subcutaneous or the topical route, respectively. After the administration of the “naked” DNA via the routes mentioned above, the IgG titers after jet injection and subcutaneous injection were almost the same, and both titers were significantly greater than after topical application of the “naked” DNA only. Also after the subcutaneous injection of pDNA-coated nanoparticles, the IgG titer in sera was 10-fold higher in comparison to DNA only. Intradermal injection of the same particles increased the IgG titer in sera 200-fold compared to DNA alone.

Various adjuvants have been investigated for promotion of DNA vaccine effectiveness. When the pDNA was coadministered with cholera toxin (CT) (10 or 100  $\mu\text{g}$ ) via the topical route, the IgG titer increased 4- and 20-fold, respectively, compared to pDNA alone. The IgG titer demonstrated a more than 300-fold increase after the topical administration of pDNA-coated nanoparticles with 100  $\mu\text{g}$  of CT compared to “naked” DNA alone. Another known adjuvant, lipid A, was coadministered subcutaneously in mice with either pDNA or pDNA-coated nanoparticles [134]. A 16-fold increase of the IgG titer was achieved after immunization with “naked” pDNA in presence of lipid A (50  $\mu\text{g}$ ) compared to pDNA alone. In the case of delivery of pDNA-coated nanoparticles with lipid A (50  $\mu\text{g}$ ), the IgG titer showed a 16- and 250-fold increase compared to pDNA nanoparticles without lipid A or pDNA alone in absence of lipid A, respectively. Therefore, lipid A (subcutaneous) and CT (topical route) are potential adjuvants to further improve immune responses using the novel cationic nanoparticle-based DNA vaccine delivery system described.

**9.2.6.1.2 Oral** The main reason to develop oral vaccines is that the mucosal surfaces are the entry point for many pathogens to the body [135]. However, purified antigens given orally are not effective due to their degradation in the gut and because the antigens give only short-lived low-titer immune responses. A major obstacle to mucosal vaccination is the absence of nontoxic but potent adjuvants, which are able to enhance the poor immunogenicity of antigens delivered via mucosal routes. In order to protect the antigens and change their immune potency,

nanoparticles have been formulated loaded with the mucosal antigens and help them to reach the desirable sites of action – the M cells in the Peyer's patches.

PLGA nanoparticles were made with the double-emulsification method incorporating *Helicobacter pylori* lysates with a loading efficiency of 67% and a mean particle size of 320 nm [135]. Oral immunization of mice took place in three doses at weeks 0, 1 and 2, and another booster dose was given at week 8. The adjuvant, CT, was given in a mixture with either the *H. pylori* lysates or the *H. pylori* lysate-loaded PLGA nanoparticles. *H. pylori* lysate-loaded PLGA nanoparticles induced high immune responses at week 9, after the booster dose at week 8. A mixture of *H. pylori* with 10 µg of CT induced high immune responses at week 4 and was enhanced significantly after the booster at week 8. A mixture of *H. pylori* with CT enhanced the immune response significantly higher than the *H. pylori*-loaded PLGA particles. Apart from IgA, the major IgG subclasses produced were IgG1, IgG2b and lower levels of IgG2a. The synthesis of those antibodies was supported by T<sub>H</sub>2 cell-secreted cytokines induced by CT. This means that the *H. pylori* loaded nanoparticles resembled the action of CT since both a mixture of *H. pylori* with CT and the *H. pylori*-loaded PLGA particles induced the production of the same antibodies after oral immunization.

The low entrapment efficiency of peptides/proteins in PLGA nanoparticles, the unavoidable use of organic solvents and the emulsification preparative technique are obstacles that demand alternative solutions. Therefore, Jung and coworkers [136] evaluated the adsorption of TT on particles made with the branched polymer poly(sulfobutyl-polyvinyl alcohol)-*g*-(lactide-*co*-glycolide) (SB-PVAL-*g*-PLGA) using a solvent displacement technique. The particle size was in the range from 100 to 200 nm and different degrees of sulfobutylation produced particles with different  $\zeta$  potentials ranging from -3.2 to -22 mV (for a degree of substitution of 43%). The amount of TT adsorbed on the particle surface started from 6.5 µg mg<sup>-1</sup> polymer in the case of PVAL-*g*-PLGA up to 56.8 µg mg<sup>-1</sup> for the 43% substituted polymer. Increasing surface hydrophilicity and/or surface charge density resulted in a higher TT adsorption onto the particle surface. The adsorption is a result of the electrostatic interactions between the negatively charged particle surface and positively charged protein residues. According to adsorption isotherm data, a monolayer adsorption model describes the interaction of TT with the particle surface. The antigenicity of the TT was influenced only slightly making the delivery system a potent one for mucosal immunization.

In another attempt to improve the formulation characteristics and preparation procedure, mucoadhesive cationic and anionic materials like alginate, carrageenans and pectin [137] were used. Also a different method was tried in order to omit the harmful organic solvent during the preparation procedure and to create a friendlier environment in the interior/core of the nanoparticles. According to this, the anionic solution (core) was introduced in the form of a mist into the cationic solution (corona), which resulted in instantaneous particle formation [138]. The antigen is part of the core and the shell according to the nature of the protein/peptide entrapped and the particle composition. The  $\zeta$  potential was positive and the entrapment efficiency varied (it could reach even almost 50%). By using

polydextran aldehyde, crosslinking could occur and, thus, the particles were stabilized even more. The 100% crosslinked particles released only about 20% OVA after 24 h incubation in presence of 3% NaCl as dissolution medium, while approximately 40% was released after 5 days incubation from the same particles in a medium of pH 1.83. Also, the crosslinked nanoparticles provoked high immune responses while the noncrosslinked ones did not cause any response after oral immunization. This was the case for particles having either OVA or TT incorporated. The OVA-loaded nanoparticles show a dramatic difference in the immune response compared to that obtained with OVA in solution and OVA in a mixture with empty nanoparticles. Concluding, this system seems to offer a higher versatility in developing protein-loaded carriers for oral vaccination.

The hydrophilic polymer chitosan, due to its mucoadhesive properties, is very popular in the field of vaccine development. The cationic nature of the polymer ensures electrostatic interactions with negatively charged proteins (i.e. BSA, TT, CT) according to the pH of the preparation solutions during the nanoparticle formation and the *pI* of each protein [139]. The loading efficiency was estimated as almost 90, 50 and 50% for BSA, TT and CT, respectively, when the proteins were dissolved in the TPP solution (pH 8.3) and the particle formation took place with a chitosan solution of pH 5.0. Poly(ethylene oxide-co-propylene oxide) (PEO-PPO) polymer was introduced to the nanoparticles during the preparation procedure in order to modify the particle size and  $\zeta$  potential. Thus, lower entrapment efficiency of BSA was obtained due to the lower amount of chitosan available when PEO-PPO was present. BSA release from 25% CS nanoparticles or 20% CS/PEO-PPO nanoparticles was slow and prolonged without a burst release. A burst release was exhibited by 40% BSA-loaded particles, probably due to adsorbed BSA molecules on the carrier surface. TT release from 14% TT-loaded CS particles at pH 5 was approximately 20% after 18 days and the toxoid was still antigenically active.

From a formulation point of view, coating of OVA-adsorbed chitosan nanoparticles with sodium alginate increased both the stability of protein adsorbed on the particle surface and the particle stability in simulated intestinal fluid at 37 °C [140] (Fig. 9.9).

The loading capacity with OVA on the chitosan nanoparticles ranged from 30 to 50%, but significant desorption of OVA occurred during the coating procedure, especially if the latter took place at pH 5.5. Thus, the coating procedure was carried out at pH 7.4 due to compromised results between loading capacity and coating efficiency. Another drawback of the preparation procedure was the high polydispersity of the particle population produced, with a mean average size of approximately 650 nm. Despite those disadvantages, the alginate coating offered protection against the degradation of chitosan and OVA in the simulated intestinal fluid as it showed a 60% release of OVA after 7 h of particle incubation at 37 °C.

The introduction of lectins on the particle surface was also shown to enhance the uptake of antigen-loaded nanoparticles by M cells or other epithelial cells of the intestinal wall [141, 142].

DNA vaccines have also been incorporated into nanoparticle formulations for oral delivery. *Toxoplasma gondii* GRA1-pDNA was incorporated into chitosan nano-

**Figure 9.9.** Scanning electron micrographs of chitosan nanoparticles. (A) After freeze-drying and resuspending in water. (B) After the coating procedure with sodium alginate. (Reprinted from Ref. [140], © 2005, with permission from Elsevier.)

particles of mean size of 400 nm and  $\zeta$  potential of 27 mV [143]. The incorporation into the polymeric carriers (more than 98%) protected the plasmid from the degradation of DNase I. The interaction of pDNA with the chitosan molecules in the formulation was strong enough so DNA did not escape into the dissolution medium 8 days after the carrier incubation in pH 7.3 at 25 °C. However, the plasmid-loaded nanoparticles did not induce any significant response 1 month postintra-gastric administration of the formulation in mice. Therefore, mice were boosted with intra-gastric administration of chitosan nanoparticles and, indeed, a higher response was obtained from mice immunized with either GRA1 microparticles or GRA1-pDNA-loaded nanoparticles. The latter response was enhanced more after a second round of immunization with intramuscular administration of pDNA, although, GRA1-loaded microparticles demonstrated the highest immune responses compared to GRA1-pDNA-loaded nanoparticles. The difference between the two types of formulations is that the GRA1-microparticles raised/caused a mixed  $T_H1/T_H2$  response, while the GRA1-pDNA-loaded nanoparticles induced the secretion of IgG1, which is associated with  $T_H2$ -type responses. The latter is unusual as  $T_H1$  immune responses were expected to be obtained as reported previously by the same and other research groups.

In another study it was shown that the pDNA of a house dust mite allergen, Der p1, was incorporated in chitosan nanoparticles efficiently enough to be able to cause immune responses (IgG2a production) to Der p1 and the Der p1-derived peptides after oral administration in mice [144]. The intramuscular administration of those particles could not raise such responses. However, the orally induced immune responses could be boosted about 13 weeks postfeeding by intramuscular injection of “naked” DNA.

**9.2.6.1.3 Intranasal** The advantages of drug delivery through the nasal cavity have already been highlighted, but the most important feature is that the drug

delivery system bypasses the liver. The required qualities for a drug delivery system appropriate for intranasal delivery, such as particle hydrophobicity, size and  $\zeta$  potential, were investigated more thoroughly by Tobio and coworkers [145]. TT-loaded PLA and PLA-PEG nanoparticles were prepared with the double-emulsification method and the final size was less than 200 nm. The  $\zeta$  potential of PLA and PLA-PEG particles was  $-50$  and  $-30$  mV, respectively. The encapsulation efficiency was about 35% regardless of the particle composition. PLA-PEG particles showed a prolonged TT release in comparison to the more hydrophobic PLA particles. At 24 and 48 h postintrasal administration of the toxoid-loaded PLA-PEG nanoparticles in rats, TT was found in a 10-fold higher concentration in blood and lymph nodes compared to TT levels obtained after PLA intranasal particle administration. The accumulation of TT in the lymph nodes after administration of PLA-PEG vesicles was almost 2-fold higher than that recorded in blood 24 and 48 h after intranasal administration. Also, the TT accumulation in the lymph nodes was significantly higher than that in organs like the liver, spleen, lungs and small bowel 24 and 48 h postadministration. Therefore, the suggested hypothesis was that a part of PLA-PEG nanoparticles was taken up by the M cells of the NALT and another part passed to the submucosal layer and then to the lymphatics and the blood. Also, some of the particles could have been taken up by the BALT and GALT. This hypothesis can be supported by the fact that the free toxoid was cleared from the blood rapidly and absorption by the organs was very much lower compared to the particles.

Another study demonstrated the potential of using PLGA as a carrier for the entrapment of bovine parainfluenza type 3 virus (BPI-3) for vaccination of young calves [146]. However, preliminary experiments were carried out by intranasal inoculation in mice using two particle types: PLGA, where BPI-3 was incorporated in the particle matrix, and poly(methyl methacrylate) (PMMA), where the antigen was adsorbed on the particle surface. The latter formulation was not successful in inducing any immune response in contrast to BPI-3-loaded PLGA particles.

The use of particles made from high-molecular-weight chitosan have already been described. Vila and coworkers [147] investigated the feasibility of using lower molecular weight chitosan (23 and 38 kDa molecular weight) to formulate nanoparticulate vaccine carriers incorporating TT. The nanoparticles had a size of approximately 350 nm and  $\zeta$  potential of  $+40$  mV, while the TT loading efficiency was 50–60%. Burst release occurred, but the release profile was prolonged and the TT was antigenically active. Indeed, it was shown that the TT-loaded nanoparticles significantly enhanced either the humoral (IgG) or mucosal (IgA) immune responses compared to those achieved by the soluble vaccine. Also, the immune responses were not affected significantly by the dose of the antigen-loaded low-molecular-weight chitosan nanoparticles for the range used between 70 and 200  $\mu$ g.

An alternative to the previous chitosan formulations was the development of chitosan-coated emulsions where OVA and CT were adsorbed on the emulsion surface [148]. Chitosan nanoparticles were prepared for comparison, and the two types of formulations were administered intranasally and intraperitoneally in rats. The particle sizes achieved for the nanoparticles and the chitosan-coated emulsions

were in the range of 0.4–3 and 0.4–0.7  $\mu\text{m}$ , respectively. The  $\zeta$  potential was positive due to the chitosan presence, and it was approximately 35 and 15 mV, respectively. The adsorbed OVA was very high in both formulations (85 and 100%, respectively) and there was no release of OVA detected after 3 h of incubation in phosphate-buffered saline (pH 7.2) at 37 °C. Nanoparticles induced significantly higher IgG response in comparison to control (OVA only, or nanoparticles only) administered either intraperitoneally or intranasally regardless of the particle size. Nanoparticles of 0.4 and 1  $\mu\text{m}$  exhibited significantly higher IgA response than those of 3  $\mu\text{m}$ .

Chitosan-coated emulsions did not elicit IgG production of any significance compared to control after intraperitoneal administration irrespective of the particle size, while the IgA levels were similar to those obtained with the nanoparticles after intraperitoneal administration. However, chitosan-coated emulsions showed a significant increase of both IgG and IgA levels compared to control after intranasal administration regardless of the particle size. Thus, the chitosan-coated emulsions are considered as another approach for vaccine formulation for intranasal delivery.

Some work has also been carried out on DNA vaccines for intranasal delivery. Cui and coworkers [149] worked on cationic emulsions made of the emulsifying wax CTAB and/or Brij 78 where pDNA was adsorbed on the surface of the final products. The positive  $\zeta$  potential of the particles is attributed to CTAB presence. Due to its potential toxicity, the amount used is being reduced and partly replaced by Brij 78. IgG responses caused by pDNA on the Brij 78 and CTAB nanoparticles were 18- and 28-fold higher than those recorded with pDNA alone. Also, the IgA levels increased 25- and 30-fold more than pDNA alone. It is worth noting that the amount used for the intranasal immunization in this study was 1.25  $\mu\text{g}$  compared to 50  $\mu\text{g}$  used by another group [150]. This system would probably enable immunization with significantly lower doses of pDNA.

### 9.2.7

#### Diabetes

Diabetes is classified as insulin- and noninsulin-dependent diabetes type I or II, respectively [66]. Type I diabetes is also known as diabetes mellitus (IDDM) and it is caused because of a deficiency of insulin following autoimmune destruction of pancreatic  $\beta$  cells. Patients with type I diabetes require administration of insulin. Type II diabetes (NIDDM) is due to insufficient secretion of insulin or to peripheral resistance to the action of insulin. Type II diabetes can be controlled by diet alone, but oral antidiabetic drugs or insulin can be used if needed.

##### 9.2.7.1 Treatment

Insulin is a polypeptide hormone of complex structure and is the required treatment for IDDM and ketoacidosis. Insulin used for therapeutic purposes can be extracted from pig pancreas, or, alternatively, human sequence insulin can be produced either semisynthetically by enzymatic modification of porcine insulin or biosynthetically by recombinant DNA technology from bacteria or yeast.

It is inactivated by gastrointestinal enzymes and has to be administered by subcutaneous injection. Fat hypertrophy can occur due to subcutaneous injections, but can be minimized by rotating the injection sites. Soluble insulin is administered for urgent treatment, for fine control in serious illness and in the perioperative period.

Drug administration via injections is not the most convenient or desirable route for the patient; therefore, alternative routes of insulin administration, mainly oral or intranasal, have been investigated. These have utilized complexation of insulin with polymeric materials into self-assembled nanoparticles. A brief overview of the current research towards these objectives follows.

### 9.2.7.2 Delivery Routes

**9.2.7.2.1 Oral** PIBCA and chitosan have been the polymers of choice for insulin formulation into nanoparticles. PIBCA was shown by Damgè and coworkers [151–152] to be able to deliver a sufficient amount of active insulin after oral administration of insulin-loaded PIBCA nanocapsules to fasted, streptozotocin-induced diabetic rats and they decreased the blood glucose level from 300 to the normal 125 mg dL<sup>-1</sup>. Indeed, PIBCA nanocapsules were found to protect insulin in the gastric environment both *in vitro* in reconstituted gastric and intestinal medium compared to phosphate-buffered saline as control, and *in vivo* (intragastric administration to rats; insulin dose: 57 and 2.8 IU kg<sup>-1</sup>) [153]. In the intestine, 75% of insulin was released, although most of the capsules were degraded after 30 min according to results deduced from the *in vitro* release of insulin in reconstituted intestinal medium. The remaining intact nanocapsules were localized on the intestinal mucosa and passed through the submucosal layers.

In another study, the same polymer was used to prepare nanoparticles and not nanocapsules, incorporating the insulin at the very beginning of the polymerization procedure and using a pluronic surfactant as stabilizer [154]. The desired particle size was less than 100 nm and was achieved by using an appropriate concentration of pluronic acid (2.0%) in contrast to nanocapsules of 265 nm used in the previously mentioned study. Insulin-loaded nanoparticles were administered subcutaneously or orally to streptozotocin-induced diabetic rats. A prolonged hypoglycemic effect of the hormone was observed up to 72 h postinjection. A similar pattern was observed after oral delivery of insulin-loaded nanoparticles with the hypoglycemic effect starting 2 h postadministration, while a less prominent effect was shown by the same dose of insulin-loaded nanocapsules as reported by Damgè and coworkers [151]. The enhanced effect in the case of nanoparticles could be due to the smaller particle size, leading to faster intestinal absorption.

Chitosan is used to enhance the absorption of insulin by the intestinal mucosa due to its mucoadhesive properties and transient opening of the tight junctions between the epithelial cells. Pan and coworkers [155] made insulin-loaded chitosan nanoparticles by ionotropic gelation of chitosan with tripolyphosphate anions. Insulin association was found up to be approximately 80%, and the electrostatic interactions between the acidic groups of insulin and the amino groups of chitosan

**Figure 9.10.** Hypoglycaemic effect of oral administration of: control (drinking saline without oral administrating anything, ♦); insulin-chitosan solution (Δ); insulin solution (◻); 14 IU kg<sup>-1</sup> insulin-loaded chitosan

nanoparticles suspended in pH 5.5 saline (×). Data represents the mean ± SD,  $n = 8$  per group. Statistically significant difference from control ( $*P < 0.01$ ). (Reprinted from Ref. [155], © 2002, with permission from Elsevier.)

were highly contributory to this. Insulin was rapidly released from nanoparticles in pH 7.4 and 4.0, but it was slower at pH 5.8, probably due to lower insulin solubility at this pH. After oral administration of insulin-loaded chitosan nanoparticles at a dosage of 14 IU kg<sup>-1</sup>, there was no significant blood glucose decrease observed for the first 6 h, but the hypoglycaemic effect was very prominent 10 h later (post-administration) in comparison to the insulin control solution and lasted for 10 h from the onset of the hypoglycemia (Fig. 9.10). Increasing the insulin-loaded nanoparticle dosage to 21 IU kg<sup>-1</sup>, the blood glucose dropped to normal levels for more than 8 h. These results show that the chitosan nanoparticles facilitated the intestinal absorption of insulin.

The presence of Poloxamer 188 in the nanoparticle formulation could have affected the *in vivo* behavior of insulin-loaded nanoparticles because it can reduce the intestinal peristalsis and so prolong the retention of nanoparticles in the intestinal tract. Also, the surfactant can reduce the opsonization and thus the particle clearance from the RES due to the hydrophilic groups on the particle surface.

The successful incorporation of insulin in the nanoparticles depends strongly on the formulation conditions and pH is a very important parameter of the procedure. Optimization of the formulation process will lead to highly efficient nanoparticles in delivering insulin after oral administration [156]. Thus, insulin was premixed with either pentasodium TPP anions or the chitosan solution prior to nanoparticle formulation and the particles produced were designated as TPP-np or CS-np, respectively [155] (Fig. 9.11). The particle preparation was carried out in a pH range of 2.3–6.3. Up to that maximum of pH 6.3, the particle size was not affected significantly by the pH changes, but beyond that value, particle agglomeration was observed.

When the initial insulin concentration was 0.88 mg mL<sup>-1</sup>, the association efficiency of insulin was pH-dependent. Maximum association efficiency was 62.99

**Figure 9.11.** Scanning electron microscopy micrographs of (A) TPP-np and (B) CS-np prepared at pH 5.3 with an insulin-loading concentration of  $4.28 \text{ U mL}^{-1}$ . Nanoparticles were prepared by ionotropic gelation of chitosan with TPP anions; TPP-np were

obtained by premixing insulin with TPP solution, and CS-np by premixing insulin with chitosan solution, prior to nanoparticle formation. (Reprinted from Ref. [156], © 2002, with permission from Wiley.)

and 57.67 at pH 6.1 for the TPP-np and CS-np nanoparticles, respectively. Small changes around pH 6 led to big variations of association efficiency in both types of formulations. This is not the case for more acidic environments. The association efficiency of insulin was improved significantly by increasing insulin-loading concentrations. Regardless of the insulin concentration, the maximum association efficiency was achieved at pH 6.1. Insulin-loading concentration did not affect the mean particle size. The loading efficiency (amount of insulin incorporated per milligram of nanoparticle) was not affected by the pH of the formulation process.

Although, insulin was released rapidly (100%) from the particles made at pH 6.1 even if the association efficiency was approximately 80%, it was very much slower (10–20%) from particles made at pH 5.3 (association efficiency approximately 50%). At pH 5.3, the association of insulin to chitosan occurs via stronger electrostatic interactions and it is pH dependent, while at higher pH seems that the association is of a hydrophobic nature.

Lim's group also evaluated the uptake of chitosan molecules and chitosan nanoparticles by Caco-2 cells, and their ability to enhance the insulin transport into these cells [157]. They show that nanoparticle uptake was dependent on time, temperature and loading concentration. It was a saturable event and more likely to be taken up by clathrin-mediated adsorptive endocytosis.

In contrast, chitosan polymer molecules were taken up by endocytosis through caveolae. The chitosan polymer was more effective at disrupting the intercellular tight junctions than chitosan nanoparticles, so the former facilitated the insulin transport via the paracellular pathway, being more effective than the particles. Their results agree with those reported by Dyer and coworkers [158], where the insulin-loaded nanoparticles given intranasally showed a lower hypoglycemic effect in comparison to chitosan solutions in sheep and rats.

After particle optimization for different pH range and insulin-loading concentrations, *in vivo* evaluation of two chosen formulations [made at pH 5.3 (f5.3) and 6.1 (f6.1)] followed in streptozotocin-induced diabetic rats [159]. Particles were administered orally at two insulin doses: 50 or 100 IU kg<sup>-1</sup>. It was shown that the 100 IU kg<sup>-1</sup> insulin of f5.3 demonstrated a higher hypoglycemic effect lasting up to 11 h. The f6.1 nanoparticles were less efficient even if the hypoglycemic action started 2 h postadministration in comparison to f5.3 particles where blood glucose dropped only after 10 h.

**9.2.7.2.2 Nasal** The intranasal administration of insulin has been attempted using chitosan nanoparticles or more recently nanocomplexes with branched polyesters. Chitosan is by far the most used polymer in research in the delivery of small or larger molecules via the oral, nasal or pulmonary route due to the previously mentioned properties of mucoadhesion and transient opening of the tight junctions of the epithelial cells. Urrusuno and coworkers [160] studied the potential of chitosan nanoparticles as a formulation to increase the availability of insulin after nasal instillation to rabbits. The particles were made with the ionotropic gelation method using two types of chitosan (0.1% CS-210Cl and 0.2% CS-110Cl) with TPP in a ratio chitosan:TPP 6:1. The particle size was 300–400 nm and the  $\zeta$  potential varied from 25 to 54 mV. Insulin association efficiency was greater than 87% and loading efficiency was approximately 55%. After nanoparticle instillation to rabbits, the blood glucose level dropped to 60% of basal levels at 1 h postadministration of insulin-loaded CS-210Cl nanoparticles. This formulation demonstrated the strongest hypoglycemic effect. The same activity was obtained using the insulin-loaded CS-110Cl nanoparticles (two types of chitosan were used in the form of HCl salt, CS-110Cl and CS-210Cl, and their differences were molecular weight, below 50 and 130 respectively, deacetylation degree, 87 and below 70% respectively, and intrinsic viscosity, 10 and 20–200, respectively) (Fig. 9.12). In contrast, the administration of 5 IU kg<sup>-1</sup> insulin control solution (pH 4.3) resulted in a decrease of blood glucose levels of less than 15% at 30 min postinstillation. This is an indication that insulin was released from the nanoparticles in its active form, which meant that the formulation preparation did not affect the peptide. Moreover, these authors showed that chitosan in nanoparticle form decreased blood glucose more significantly than the chitosan solution, a finding that is different to that reported by other groups [157].

The pH of chitosan solutions plays an important role in their ability to act as absorption enhancers. The *in vivo* effect was investigated by comparing insulin-loaded nanoparticles with insulin solutions following nasal instillation at pH 6.4 and 4.3. The hypoglycemic effect of insulin solution at pH 6.4 was negligible due to slow solubility and formation of high-molecular-weight aggregates. When insulin-loaded chitosan nanoparticles were administered intranasally at the same pH, a reduction of blood glucose levels was recorded for 1.5 h. Even if the hypoglycemic effect of insulin from the nanoparticles was lower at pH 6.4 than 4.3, the increase in the response to the hormone-loaded nanoparticles and the insulin/chitosan solutions was the same: 18.6% at pH 6.4 and 17.4% at pH 4.3.

**Figure 9.12.** Plasma glucose levels achieved in rabbits following nasal administration (at pH 4.3) of: insulin-loaded chitosan 210 Cl nanoparticles suspended in acetate buffer, 0.16 mg kg<sup>-1</sup> chitosan (●) and 0.35 mg kg<sup>-1</sup> chitosan (◻), and insulin-loaded chitosan 110 Cl nanoparticles suspended in acetate buffer (◊) ( $n = 6$ ). (Mean  $\pm$  SD  $n = 6$ .) \*Statistically

significant differences from insulin-loaded chitosan 210 Cl nanoparticles suspended in acetate buffer, 0.16 mg kg<sup>-1</sup> chitosan ( $P < 0.05$ ). (Reprinted from Ref. [160], © Plenum Publishing Corporation with permission of Springer Science and Business Media.)

Insulin/chitosan solutions and insulin-loaded chitosan nanoparticles were studied for their ability to improve the bioavailability of insulin in two animal models [157]. Again particles were made by the same gelation method used by Urusuno and coworkers [159]. In this study, insulin-loaded chitosan nanoparticles were used as well as postloaded insulin/chitosan nanoparticles. The empty (non-loaded) nanoparticles had a mean particle size around 250 nm and a  $\zeta$  potential of about 29 mV. All nanoparticles exhibited a size less than 1  $\mu$ m. The result was that in the rat model the chitosan nanoparticles were not advantageous in comparison to the chitosan solutions in the overall hypoglycemic effect.

Regarding the response in the sheep model, the insulin/chitosan solution was more effective than the insulin-loaded and postloaded insulin chitosan nanoparticles. However, the best acting formulation was the insulin/chitosan powder, which is assumed to remain longer (115 min) in the nasal cavity of the sheep than the chitosan solution (45 min).

Another promising approach to develop a carrier system for insulin delivery exploiting the intranasal or the oral route was one based on the complexation between polymer/peptide according to the hydrophobic and electrostatic interactions of the two parts [161]. Therefore, a hydrophilic charged-modified poly(vinyl alcohol) backbone was produced with covalently bound diethylamine groups.  $\alpha$ -Lactide groups were grafted onto the backbone imparting a hydrophobic character to the previously hydrophilic molecule. The nanocomplexes produced were of a range of sizes between 200 and 500 nm according to the backbone composition and number of grafted lactic acid groups. Increasing the amount of lactic acid groups, the

complexes tend to be smaller and more compact. The  $\zeta$  potential ranged from +3 mV at a low substitution to +35 mV at the highest substitution. The insulin complexation was higher with high degrees of amine substitution or by a combination of medium charge density and a higher lactic acid content. When the initial insulin concentration was  $1.25 \text{ mg mL}^{-1}$ , approximately 98% of insulin was found in the complexes.

**9.2.7.2.3 Pulmonary** Drug delivery via the pulmonary route is, of course, preferable to injections because it is noninvasive and systemic absorption is expected to be at higher rates since the lung provides a large surface area and enzymic degradation is relatively low. PBCA nanoparticles were used to compare the pharmacological potential between pulmonary and subcutaneous delivery of insulin-loaded particles [162]. The mean size of the particles was 255 nm and the insulin association efficiency was 79%. Burst release phenomena accompanied the release profile of insulin at pH 7 in saline at  $37^\circ\text{C}$ . The particles were administered intratracheally to normal rats and an increase in the reduction of blood glucose level was observed as the insulin dose increased from 5 to  $20 \text{ IU kg}^{-1}$ , while the minimum glucose level was reached in 4, 4 and 8 h for 5, 10 and  $20 \text{ IU kg}^{-1}$ , respectively. The hypoglycemic effect of insulin-loaded nanoparticles at doses 10 and  $20 \text{ IU kg}^{-1}$  was prolonged compared to that obtained with the insulin solutions (Fig. 9.13). However, the hypoglycemic effect achieved after subcutaneous administration of  $5 \text{ IU kg}^{-1}$  insulin-loaded nanoparticles was much higher than that obtained after intratracheal delivery of the same nanoparticles. According to these authors, this phenomenon is attributed to the ability of normal rats to adjust the blood glucose level.

An idea for pulmonary delivery of insulin-loaded chitosan nanoparticles was the microencapsulation of those particles into microspheres made by lactose or mannitol by spray-drying [163]. Indeed, it was shown that the microspheres produced were mostly spherical with the appropriate aerodynamic properties for good deliv-

**Figure 9.13.** Hypoglycaemic effect of a single intratracheal administration of insulin-loaded nanoparticles of  $20 \text{ IU kg}^{-1}$  (■) and insulin solution of  $20 \text{ IU kg}^{-1}$  (▲) to normal rats fasted overnight. The glucose concentration at

time zero served as the basis for comparison (%). Results are means for five or six animals. The control (◆) is phosphate buffer solution (pH 7). (Reprinted from Ref. [162], © 2001, with permission from Elsevier.)

ery, but their morphology was strongly influenced by the nanoparticle content. The microspheres with the best properties were those made with mannitol:nanoparticles 80:20 and the nanoparticles were made with chitosan:TPP: 6:1. The insulin-loaded chitosan/TPP nanoparticles were of approximately 350 nm size, and had a  $\zeta$  potential of +40 mV and a protein loading capacity 65–80%. After 15 min incubation in phosphate-buffered saline (pH 7.4) at 37 °C, 75–80% of insulin was released from either nanoparticles or nanoparticles encapsulated into microspheres. Also, the nanoparticles could be recovered from microspheres after their contact with water with no significant changes in their physicochemical properties. Therefore, the microspheres containing nanoparticles would be able to be delivered to the deep lung and thereafter the aqueous environment would release the nanoparticles and subsequently the entrapped insulin.

**9.2.7.2.4 Parenteral Delivery (Subcutaneous, Intravenous, Intraperitoneal)** In addition to the high instability and degradation of insulin in the gastrointestinal tract, it also exhibits a short half-life when administered by subcutaneous injections. Its incorporation in to nanoparticles was therefore also investigated to sustain the hypoglycemic effect. Barichello and coworkers [164] evaluated the use of Pluronic gels (20% and 30% Pluronic concentration used), PLGA nanoparticles and their combination for parenteral delivery of peptides and proteins having short half-lives, using insulin as a model molecule. The important characteristic in using Pluronic gels is the enhanced protein stability into the gel matrix with complete recovery of full insulin activity when the gel is dissolved in excess buffer. The drawback is the loss of gelation ability in the presence of inorganic salts used to control the pH in such gels. Insulin was released more slowly from gels with higher concentration of Pluronic (20 and 30% Pluronic concentrations in the gels were used) while the possible mechanism is erosion and probably some diffusion due to zero-order release kinetics.

PLGA nanoparticles were produced with an insulin content around 60% and particle size 128 nm. After subcutaneous injection of insulin-loaded PLGA nanoparticles, a constant hypoglycemic effect was observed with a slow recovery of the serum glucose levels during the 2 h postadministration period. Subcutaneous injection of insulin solution only demonstrated an acute hypoglycemic effect of insulin with a peak 1 h later; however, when insulin loaded in the Pluronic gel was injected, the impact of the hormone was more prolonged. The same profile was obtained after nanoparticle-gel injection with an effect up to 6 h later. The bioavailability of the peptide from the nanoparticle-gel formulation increased almost 3-fold to that estimated after the subcutaneous injection of insulin solution only.

A sustained hypoglycemic effect up to 4 h after subcutaneous injection to diabetic rats was achieved using nanoparticles made with the oppositely charged PEI and DS stabilized by crosslinking with zinc [165]. PEI solution of pH 9 was mixed with DS in a ratio of approximately 2:1 with 25  $\mu$ M of zinc as a stabilizer in the presence of insulin in the polymer mixture. Ninety percent of insulin was entrapped in to particles of size 250 nm and of  $\zeta$  potential +30 mV. However, 70% of particle-bound insulin was dissociated from the particles in 10 mM phosphate

buffer in 5 min, which suggests that insulin was adsorbed on the particle surface through apolar interactions. The interaction of insulin with PEI caused conformational changes to insulin at low pH, but not at pH 9. Moreover, a hypoglycemic effect was induced in diabetic rats regardless of polymer ratio, indicating preservation of insulin biological activity.

Simple mixing of cholesterol-bearing pullulan with insulin resulted in complex formation (size of 20–30 nm) that did not demonstrate any particular advantage to the blood glucose reduction in comparison to free insulin solution after intravenous injection to normal fasting rats [166]. Insulin was stabilized in those complexes, but it was replaced with BSA after nanoparticle incubation in the presence of the latter protein (50 mg mL<sup>-1</sup>) for 1 h at 37 °C.

**9.2.7.2.5 Other Formulations** A very promising technique for enhancement of insulin incorporation into nanoparticles is the use of gas antisolvent techniques or supercritical fluids [167]. This method is considered advantageous for labile pharmaceutical molecules and polymers due to mild operation conditions and a reduction in the amount of organic solvent used. The remaining organic solvents in the final preparation are much reduced and the ability of drug entrapment higher as entrapment is not dependent on the drug partitioning between the liquid phases. Supercritical carbon dioxide precipitation was applied to a mixture of PLA (molecular weight 102 000)/insulin or PLA/PEG/insulin organic solutions (DMSO:dichloromethane 50:50) resulting in polymeric nanoparticles with a mean size of 400–600 nm. The residual dichloromethane was only 8 p.p.m., less than that of 400 and 600 p.p.m. reported by the US and European Pharmacopoeia, respectively. The residual DMSO was 300 p.p.m.

Insulin loading was 90% and it was affected by the presence of PEG in the nanoparticle composition. By increasing the PEG content or the PEG molecular weight, a decrease of insulin loading was observed. High insulin loading was achieved using PEG molecules of less than 1900 molecular weight. The content and molecular weight of PEG used influenced the insulin release from those particles. Using PEGs of higher molecular weight of 1900 or a high concentration of PEG, insulin was released with a burst release phenomenon, which is not the case with PEGs smaller than 1900. Less than 3% of insulin was released from particles with PEG of molecular weight 350, 750 or 1900. Additionally, 80% of the peptide activity was retained, as an induced-hypoglycaemic effect was caused in mice by the insulin extracted from the nanoparticles.

A self-regulating insulin delivery system was developed by Zhang and coworkers based on insulin release from membranes embedded with insulin-loaded nanoparticles. A decrease in the pH of the microenvironment is caused when the system senses an increase in glucose concentration [168]. When the pH of the microenvironment decreases, the particle size in the matrix decreases and insulin is released. Glucose oxidase (GOD) embedded in the membrane was used as a glucose sensor. GOD converts glucose to gluconic acid causing the pH to decrease. Due to the low amount of oxygen available for the amount of glucose to be oxidized and because of toxic hydrogen peroxide formation as a side-product, catalase is coentrapped in/

on to the membrane breaking down the hydrogen peroxide into oxygen and water. The GOD incorporated in to the membrane retained 80% of its activity in comparison to free enzyme and the addition of catalase favored the oxidation rate of glucose.

The nanoparticles were made with the pH sensitive polymer poly(NIPAAm-co-methacrylic acid) and the insulin was released after 5–15 min from the onset of hyperglycemia. The responsiveness of the system to glucose levels was evaluated by increasing the amount of glucose in the surrounding medium. It was found that the insulin permeability increased 3-fold as the glucose concentration increased from 50 to 200 mg mL<sup>-1</sup>. In general, it was shown that the glucose concentration fluctuations stimulated the insulin release in a rapid and reversible way.

### 9.3

#### Conclusions

This chapter has presented most of the ongoing research using polymeric nanoparticles for noncancer applications. The most important diseases have been discussed in some detail, but nanoparticles have been evaluated on a few other noncancer diseases as well, such as arthritis, osteoporosis, problems with arteries, etc. Most of the applications reported in this chapter have displayed very promising therapeutic results with only a few exceptions, and the advantages and limitations of using polymeric nanoparticles have been reported in each case examined.

The most obvious advantages of incorporating drugs into nanoparticles are the reduced toxicity of highly toxic drugs, the protection against environmental conditions, the reduction of the drug dose to give the prospect of better patient compliance and versatility in delivery route. The latter advantage arises because the characteristics of the final formulation, which can favor the use of alternative delivery routes over conventional ones (e.g. pulmonary or nasal delivery instead of subcutaneous injection).

PLGA polymer and chitosan have been the most used polymers. In general, chitosan seems to be more favorable than PLGA, especially when the particles are destined to interact with mucosal surfaces (pulmonary, nasal, ocular, oral/gastrointestinal tract interaction), because it seems to enable the paracellular transport of the nanoparticles. Also, chitosan particles can be made into nanoparticles using methods that do not need the use of organic solvents (important because solvents remain in the particles at low levels and can be irritant or toxic in some cases). In addition, PLGA can be disadvantageous because its degradation products can create an acidic environment, damaging pH-sensitive proteins or peptides.

The drug release profile is one factor that requires further development. With some drugs and applications, the rapid rate of drug release can be a limiting factor (e.g. PLGA almost always shows a significant initial burst release). Thus, there is a need for polymer development to produce particles with sustained drug release and which retain the essential properties of polymer delivery systems, such as biodegradability and biocompatibility.

Finally, in order to reach the clinic and the market, these polymeric formulations will need to be produced in a large scale, have to exhibit a long shelf-life, and to be characterized by reasonable manufacturing cost and formulation stability. There is still a problem of producing sterile dispersions for ocular delivery, too. However, with the promise already shown in the formulations discussed above, it seems likely that the necessary resources will be found to resolve these remaining issues.

# Solid Lipid and Polymeric Nanoparticles for Drug Delivery

*José Luis Pedraz, Gorka Orive, Manoli Igartua, Alicia R. Gascón,  
Rosa M. Hernández, Maria Angeles Solinis,  
and Amaia Esquisabel*

### 10.1 Introduction

Over the past few years, significant effort has been devoted to design and develop nanoparticles and nanosystems for drug delivery. Scientists have understood that apart from the synthesis of the drug molecule, the efficient release of the latter from the drug delivery system is essential if a suitable therapeutic efficacy is to be achieved. Therefore, the development of effective drug delivery systems which could transport and deliver the drug at the right time, in a safe and reproducible way, and only to the target where it is needed is becoming the “holy grail” of pharmaceutical researchers [1, 2].

The idea that nanotechnology could be used as a tool for efficient drug delivery has recently emerged since nanoparticles can be designed with different structures and compositions favoring a wide range of therapeutic applications [3]. Nanoparticles do not only differ in their relative size, but also in their biopharmaceutical properties and therapeutic applications. In general, the therapeutic product [drug, peptide, protein, DNA, small interfering RNA (siRNA), etc.] is either entrapped, adsorbed, attached, dissolved or encapsulated into the particle, allowing the precise control over drug release profiles [4]. Nanoparticles are less than 1000 nm in size and they present higher intracellular uptake compared with microparticles, which makes nanoparticles excellent candidates for targeted drug delivery to specific intracellular compartments.

One focus of research is the technological design and development of the nanoparticles assuming that the latter can present very different compositions and biological properties. However, a more interesting and effective way to design these nanosystems would be to rationally fabricate them based on a full understanding of the pathobiological characteristics of the disease under study and the biological microenvironment where the nanoparticles are to suppose to work. For example, if the intracellular release of the drug is required, a deep knowledge of the mecha-

nisms that regulate the uptake of the particles, intracellular trafficking, retention and sorting pathways will be necessary [5]. Furthermore, the biopharmaceutical and technological properties of the nano drug delivery systems are also major issues to be considered. In fact, the therapeutic dose to be administered and the duration of drug delivery required at the target site are key factors in the pharmaceutical design of the nanoparticles in order to obtain an efficient treatment.

The present chapter describes two different types of nanoparticles suitable for continuous drug delivery. The selection of these nanoparticles is based on their extensive application for drug delivery purposes. The basic principles of solid lipid nanoparticles (SLNs) and polymeric nanoparticles will be presented in detail. The aim of this chapter is to describe the production processes and the main parameters related to their characterization. Furthermore, a wide range of therapeutic applications of both types of nanoparticles will be discussed in detail.

## 10.2 SLNs

### 10.2.1

#### Introduction

SLNs are colloidal carrier systems made from solid lipids with an average diameter in the nanometer range, introduced at the beginning of the 1990s as a drug delivery system alternative to existing colloidal carriers. Incorporation of a drug into a carrier system can protect it against degradation, the release can be controlled and it also offers possibilities of targeting. There is, however, a need for further, improved particulate carrier systems, which should fulfill as much as possible the following main requirements [6]:

- Easy to produce.
- Applicable to as many drugs as possible.
- Physically stable.
- Being composed of well-tolerated excipients that are accepted by the regulatory authorities.
- Feasibility of large-scale production.
- Production lines should be able to be qualified and acceptable by regulatory authorities.

The SLN is a particulate drug carrier system developed with the aim of combining the advantages of other innovative carrier systems such as lipid emulsions, liposomes and polymeric micro/nanoparticles, minimizing the associated problems. Excellent tolerability and the possibility of qualified industrial large-scale production are clear advantages of SLNs. Main disadvantages are the coexistence of alternative colloidal structures and, in general, low drug-loading capacity.

## 10.2.2

**Composition**

SLNs are particles made from solid lipids (usually lipids in solid state at room temperature and also at body temperature), water and stabilized by surfactant(s); for certain preparation methods a cosolvent, which is generally removed, is also used.

In general, physiological lipids such as triglycerides (e.g. tristearin), partial glycerides (e.g. Imwitor), fatty acids (e.g. stearic acid), steroids (e.g. cholesterol) and waxes (e.g. cetyl palmitate) are used. This physiological lipid matrix is more biocompatible, thus decreasing the danger of acute and chronic toxicity, and increasing their toxicological safety. There are a few exceptions and some authors have prepared SLNs with different types of molecules, such as amphiphilic cyclodextrins [7] and calixarenes [8, 9].

Most of the lipids used represent a mixture of several chemical compounds. The general lipid composition will have different crystallinities and capacities for accommodating foreign molecules. The composition might therefore vary from different suppliers and even for different batches. However, small differences in the lipid composition (e.g. impurities) might have a considerable impact on the quality of SLN dispersion [10] (e.g. by changing the  $\zeta$  potential, retarding crystallization processes, etc.).

In addition to the lipid composition, the influence of lipid content on particle size has been studied, showing that increasing the lipid content over 5–10% in most cases results in larger particles (including microparticles) and broader particle size distributions [11]. The other main SLN ingredient is the stabilizing agent; a large variety of ionic and nonionic emulsifiers of different molecular weight have been used to stabilize the lipid dispersions and to prevent particle agglomeration. The most frequently used compounds include different kinds of poloxamer, polysorbates, lecithin and bile salts. The choice of the emulsifier depends on the administration route and is more limited for parenteral administrations [10]. The emulsifiers selected and their concentration have a great impact on the quality and stability of the SLNs dispersion [12–14]. It has been found that the combination of emulsifiers might prevent particle agglomeration more efficiently than the use of a single surfactant. Another important point to consider is the influence of the emulsifier on drug incorporation; stabilizing agents are not localized exclusively on the lipid surface, but also in the aqueous phase in different forms, which might serve as an alternative location to accommodate the drug molecules [10].

As it has been reported [6, 10, 15, 16], the status of excipients for SLNs has to be discussed as a function of the administration routes. SLNs can be produced with regulatory accepted excipients or at least with material able to be degraded in the body to physiological compounds or to products used for parenteral nutrition. Therefore, they are not problematic at all for topical and oral administration. The full range of surfactants and lipids used in dermal products, tablets and capsules can be exploited. Even such “nasty” surfactants with regard to parenteral administration such as sodium dodecyl sulfate can be applied to stabilize the suspension. They possess excellent dispersing properties and are accepted up to a certain con-

centration in oral products. The situation is slightly different for parenteral administration – to our knowledge, no solid lipids have been administered parenterally; therefore, they would require a toxicity study before their use. However, the glycerides used for nanostructured lipid carrier (NLC) production can be selected with this purpose, since they are composed of fatty acids already present in the oils of emulsions for parenteral nutrition [6].

### 10.2.3

#### Production Processes

The four main procedures existing for the preparation of lipid nanoparticles dispersions are briefly described in this section. Later, scaling-up feasibility and secondary production steps such as drying and sterilization will be reviewed.

##### 10.2.3.1 Preparation Techniques

**10.2.3.1.1 High-shear Homogenization and Ultrasound** High-shear homogenization and ultrasound are dispersing techniques which were initially used for the production of solid lipid nanodispersions [17, 18]. Both methods are widespread and easy to handle. The disadvantages of these techniques are due to the presence of microparticles and the fact that metal contamination has to be considered when ultrasound is used.

**10.2.3.1.2 High-pressure Homogenization (HPH)** HPH has emerged as a reliable and powerful technique for the preparation of SLNs. Homogenizers of different sizes are commercially available from several manufacturers at reasonable prices. The two basic production methods for SLNs are the hot homogenization technique and the cold homogenization technique. In both cases the drug is incorporated in the lipid melt. The hot homogenization technique is carried out at temperatures above the melting point of the lipid. The drug-containing melt is dispersed under stirring in a hot aqueous surfactant solution to the same temperature. Then the obtained pre-emulsion is homogenized. The primary product is a hot oil/water (o/w) nanoemulsion that is cooled down to room temperature, leading to solid lipid nanoparticles.

Cold homogenization has been developed to overcome the following three problems of the hot homogenization technique: temperature-induced drug degradation, drug distribution into the aqueous phase during homogenization and complexity of the crystallization step of the nanoemulsion. This technique minimizes thermal exposure of the sample. The drug-containing lipid melt is rapidly cooled and the solid lipid ground to lipid microparticles which are dispersed in a cold surfactant solution yielding a presuspension. Then this presuspension is homogenized at or below room temperature leading to solid lipid nanoparticles.

**10.2.3.1.3 Microemulsion** Microemulsion-based SLNs preparation techniques have been developed by Gasco [19]. Emulsions are made by stirring the melted

lipid and a mixture of water, cosurfactant(s) and the surfactant heated to the same temperature as the lipid. A transparent, thermodynamically stable system is formed when the compounds are mixed in the correct ratio. Finally, this microemulsion is dispersed in a cold aqueous medium (2–3 °C) under stirring, thus resulting in the formation of SLNs.

**10.2.3.1.4 Solvent Emulsification/Evaporation** Sjöström and Bergenståhl described in 1992 a production method to prepare nanoparticles in o/w emulsions [20]. The lipophilic material is dissolved in a water-immiscible organic solvent that is emulsified in an aqueous phase to give an o/w emulsion. Upon evaporation of the solvent a nanoparticle dispersion is formed by precipitation of the lipid in the aqueous medium. An important advantage of this method is the avoidance of heat during the preparation, which makes it suitable for the incorporation of highly thermolabile drugs. However, problems might arise due to solvent residues in the final dispersion.

### 10.2.3.2 Scaling-up, Sterilization and Drying

**10.2.3.2.1 Scaling-up** The possibility of qualified industrial large-scale production must be provided for the introduction of a product to the market. HPH production for SLNs and scaling-up feasibilities have been widely investigated [21–24]. Moreover, production lines for HPH already exist in the pharmaceutical industry and have been even used for the production of parenteral products. The HPH lines used for parenteral nutrition can be qualified and accepted by the regulatory authorities. Based on this premise, no regulatory hurdles are expected in the use them for SLNs carriers systems [6]. A system has been developed and scale-up feasibility has been investigated for the production via microemulsions [25].

**10.2.3.2.2 Sterilization** SLN dispersions can be sterilized or prepared aseptically using already established techniques in the pharmaceutical industry. Aseptic production, filtration,  $\gamma$ -irradiation and heating are normally used in order to achieve sterility. Filtration sterilization of dispersed systems requires high pressure and is not applicable to particles larger than 0.2  $\mu\text{m}$ . SLN dispersions can be sterilized by filtration similar to emulsions for parenteral nutrition. It is very important to filter them in liquid state, since this allows particles with a size larger than the pores in the filter to be filtered [10, 15, 25].

**10.2.3.2.3 Drying** It is expected that the solid state of SLNs will present a better chemical and physical stability than aqueous lipid dispersions. Transformation into a solid form will prevent crystal growth by Ostwald ripening and avoid hydrolysis reactions.

Lyophilization is a widely used process in the pharmaceutical field to remove water from samples. This technique involves two necessary and additional transformations that may be the source of additional stability problems – freezing of the sample and evaporation of water under vacuum. The addition of cryoprotectants

to the sample will be necessary in order to decrease SLN aggregation and to obtain a better redispersion of the dry product. Typical cryoprotective agents are sorbitol, mannose, trehalose, glucose and polyvinylpyrrolidone. The lyophilization process has been optimized with regard to the operating conditions, lipid concentration, type and concentration of cryoprotectant, and redispersing conditions [26–28].

Spray-drying might be an alternative procedure to lyophilization. The influence of lipid type and concentration, carbohydrate type and concentration, redispersion medium, and spraying medium has been investigated by Freitas and coworkers [29]. An evaporative drying process with a nitrogen stream at low temperatures has been evaluated and compared to lyophilization by Marengo and coworkers [30]. The advantages of this process are the avoidance of freezing and the energy efficiency resulting from the higher vapor pressure of water.

#### 10.2.4

### Drug Incorporation, Loading, Incorporation Efficiency, Nanoparticle Recovery and Drug Release

#### 10.2.4.1 Drug Incorporation

In different studies, which were later reviewed by Müller [15], Menhert proposed that there are basically three different models for the incorporation of active ingredients into SLNs (Fig. 10.1):

- *Homogeneous matrix model*: consisting of a homogeneous matrix with molecularly dispersed drug or drug being present in amorphous clusters.
- *Drug-enriched shell model*: an outer shell enriched with active compound.
- *Drug-enriched core model*: a core enriched with active compound. This leads to a membrane controlled release governed by the Fick law of diffusion.

The structure obtained is a function of the formulation composition (lipid, active compound, surfactant) and of the production conditions (hot versus cold homogenization). A large number of drugs with a great variety of lipophilicity and different structures have been studied with regard to their incorporation into SLNs. However, few data exist on the localization site and the physical state of the drug mole-

**Figure 10.1.** Three drug incorporation models. (Adapted from Ref. [15], with permission from Elsevier.)

cule. Drug incorporation implies the localization of the drug in the solid lipid matrix. Micelle-forming surfactant molecules will be present in different forms, and may lead to colloidal species such as micelles, mixed micelles and liposomes, that are known to solubilize drugs and are, therefore, alternative drug incorporation sites [10].

#### 10.2.4.2 Drug Loading

SLNs were first developed for the administration of lipophilic drugs, although they have been also applied for the encapsulation of hydrophilic drugs. One of the main drawbacks of particulate drug carriers is drug-loading capacity, which is limited to approximately 25% with regard to the lipid matrix. The drug-loading capacity of SLNs is limited by the solubility of drug in the lipid melt, miscibility of the melted drug and lipid, chemical and physical structure of the matrix, and the polymorphic state of the lipid matrix [15]. The prerequisite to obtain a sufficient loading capacity is a sufficiently high solubility of the drug in the lipid melt. To enhance the solubility in the lipid melt one can add solubilizers, especially in the case of hydrophilic drugs.

The structure of the lipid is important because if the lipid matrix consists of especially similar molecules (i.e. tristearin or tripalmitin), a perfect crystal with few imperfections is formed and cannot accommodate large amounts of drug. Therefore, the use of more complex lipids (mono-, di- and triglycerides with different chain lengths) is more sensible for higher drug loading.

Crystalline structure – related to the chemical nature of the lipid – is a key factor to determine whether a drug will be expelled or firmly incorporated. The transition to highly ordered lipid particles is also the reason for drug expulsion. Directly after production, lipids crystallize; if the crystallinity index increases during the storage, then the drug will be expelled from the lipid matrix and it can then neither be protected from degradation nor released in a controlled way [31]. Consequently, intensive characterization of the physical state of the lipid particles is highly essential in order to get a controlled optimization of drug incorporation and loading.

#### 10.2.4.3 Determination of Nanoparticle Recovery and Drug Incorporation Efficiency

These are general characterization parameters that can be applied to any type of nanoparticle, including SLNs.

The nanoparticle (NP) recovery, which is also referred to as nanoparticle yield in the literature, can be calculated using:

$$\text{nanoparticle recovery (\%)} = \frac{\text{mass of nanoparticle recovered} \times 100}{\text{mass of drug and excipients}}. \quad (1)$$

An additional important *in vitro* characterization parameter is the determination of the drug incorporation efficiency in nanoparticle formulations. Drug incorporation efficiency is expressed both as drug content (% w/w), also referred to as drug loading in the literature, and drug entrapment efficiency (%); represented by:

$$\text{drug loading (\% w/w)} = \frac{\text{mass of drug in nanoparticle}}{\text{mass of nanoparticle recovered}} \times 100 \quad (2)$$

$$\text{drug entrapment efficiency (\%)} = \frac{\text{mass of drug in nanoparticle}}{\text{mass of drug used in formulation}} \times 100. \quad (3)$$

Two different methods have been suggested for the determination of drug loading and entrapment efficiency. The first involves the solubilization of nanoparticles by dispersing a measured amount of them in a suitable medium under agitation. The second method is based on the estimation of the differences between the total amount of the drug added to the formulation and the untrapped amount detected in the supernatant of the nanoparticle dispersion. The amount of drug is analyzed by an appropriate analytical technique.

#### 10.2.4.4 Drug Release

The effect of formulation parameters and production conditions on the release profile from SLNs was intensively investigated by Mehnert and zur Mühlen [32, 33] by the study of the model drugs tetracaine, etomidate and prednisolone. A burst drug release was obtained with tetracaine and etomidate SLNs; in contrast, prednisolone SLNs showed a prolonged release. This demonstrated the principle suitability of the SLNs system for prolonged drug release. More interestingly, they showed that it was possible to modify the release profiles as a function of lipid matrix, surfactant concentration and production parameters (e.g. temperature).

Müller and coworkers [34] reviewed in detail the release of active compounds from SLNs and summarized that the higher the solubility in the water phase during production, the more pronounced is the burst effect. The solubility increases with increasing production temperature and increasing surfactant concentration (the latter only when the surfactant solubilizes the active compound). Consequently, little or no burst will be obtained when SLNs are produced at low temperatures, low surfactant concentration or in surfactant-free medium.

#### 10.2.5

##### Related Structures and Stability

Potential problems associated with SLNs such as limited drug-loading capacity, adjustment of drug release profile and potential drug expulsion during storage are avoided or minimized by the new generation of lipid nanoparticles, the NLCs, although the term SLNs is sometimes used to describe different types of lipidic matricial structures [such as NLCs and lipid–drug conjugates (LDCs)] regardless of their composition and arrangement. Using spatially incompatible lipids leads to special structures of the lipid matrix and, thus, three types of NLCs [35] (see Fig. 10.2):

- (i) *The imperfect type.* A potential problem in SLNs is the formation of a perfect crystal. Using spatially different lipids leads to imperfections in the crystal to accommodate the drug.

**Figure 10.2.** The three types of NLCs compared to the relatively ordered matrix of SLNs (upper left); NLCs types: imperfect type (upper right), amorphous type (lower left) and multiple type (lower right). (Adapted from Ref. [34], with permission from Elsevier.)

- (ii) *The amorphous (structureless) type.* Drug expulsion is caused by an ongoing crystallization process of the solid lipid towards a perfect crystal. The particles are solid, but crystallization upon cooling is avoided by mixing special lipids.
- (iii) *The multiple type.* System comparable to w/o/w emulsions since it is an oil-in-solid lipid-in-water dispersion. The solid lipid matrix contains tiny liquid oil nanocompartments. Many drugs show a higher solubility in oils than in solid lipids so that they can be dissolved in the oil and still be protected from degradation by the surrounding solid lipids.

Recent studies concluded that neither SLNs nor NLCs lipid nanoparticles showed any advantage with respect to the incorporation rate or retarded accessibility to the drug compared with conventional nanoemulsions. It has been shown that the liquid lipid forms a half drop on the solid platelet [36–38]. SLNs are useful for the incorporation of lipophilic (soluble) drugs. Aiming to increase the drug-loading capacity of hydrophilic drugs, the structure of LDCs has been recently suggested as more adequate [16].

LDC nanoparticles present drug-loading capacities of up to 33% [39, 40]. Here, an insoluble drug–lipid conjugate bulk is prepared either by salt formation (e.g. with a fatty acid) or by covalent linking (e.g. to esters or ethers). In the salt formation process, the free drug base and fatty acid are dissolved in a suitable solvent. The solvent is then consequently evaporated under reduced pressure. For the covalent linking, the drug (salt) and a fatty alcohol react in the presence of a catalyst, and the LDC bulk is then purified by recrystallization. The obtained LDC bulk is then processed with an aqueous surfactant solution to a nanoparticle formulation using HPH.

The physical stability of SLN dispersions has been investigated intensively, e.g. by measurements of particle size [photon correlation spectroscopy (PCS), laser diffraction (LD)], charge ( $\zeta$  potential) and thermal analysis [differential scanning calorimetry (DSC)], as reviewed later in this chapter. In addition, as noted above, transformation of SLNs into a solid form by drying will have a better chemical and physical stability than aqueous lipid dispersions.

#### 10.2.6

##### **Analytical Characterization of SLNs**

An adequate characterization of SLNs is a prerequisite for the control of the quality of the product. Several parameters have to be considered in the characterization of lipid nanoparticle formulations which have direct impact on the stability and release kinetics [10, 15]:

- (i) Particle size and  $\zeta$  potential.
- (ii) Degree of crystallinity and lipid modification.
- (iii) Coexistence of additional colloidal structures (micelles, liposomes, super-cooled melts, drug nanoparticles) and dynamic phenomena.

##### **10.2.6.1 Particle Size**

Particle size is predominantly used to evaluate the colloidal size range. This parameter is crucial in the development and optimization of preparation processes as well as in the evaluation of dispersion stability.

The most widely used method to characterize the size of SLNs is PCS. This method measures the fluctuation of the intensity of the scattered light which is caused by Brownian motion. PCS is a good tool to characterize nanoparticles, but it is not available for the detection of larger microparticles. They can be visualized by means of LD measurements. This method is based on the dependency of the diffraction angle on the particle radius (Fraunhofer spectra). Smaller particles cause more intense scattering at high angles compared with the larger ones. Difficulties may arise both in PCS and LD measurements for samples which contain several populations of different size. Therefore, additional techniques might be useful. The Coulter counter method and light microscopy may be considered to detect trace amounts of microparticles in SLN dispersions. Electron microscopy, in contrast to PCS and LD, provides direct information on the particle shape and structure. However, possible artifacts may be caused by the sample preparation.

Atomic force microscopy (AFM) has also been applied to image the morphological structure of SLNs [41, 42]. Advantages of AFM are the simplicity of sample preparation as no vacuum is needed during operation and that the sample does not need to be conductive. Therefore, it has the potential for the direct analysis of the originally hydrated, solvent-containing samples. A disadvantage of this method is the required fixation of the particles (by removal of water), which changes the status of emulsifier and might also cause polymorphic transitions of the lipid.

Particle sizing by field-flow fractionation (FFF) is based on the different effect of a perpendicular applied field on particles in a laminar flow. The separation principle corresponds to the nature of the perpendicular field and may, for example, be based on different mass (sedimentation FFF), size (cross-flow FFF) or charge (electric-field FFF). Mäder and coworkers have been applied recently cross-flow FFF to investigate nanoemulsions, SLNs and nanostructure lipid carriers [38].

#### 10.2.6.2 The $\zeta$ Potential

The surface charges and the strength and extension of the electrical field around the particles play an important role in the mutual repulsion of nanoparticles, and thus in their stability against aggregation. Therefore, the measurement of the  $\zeta$  potential allows for predictions about the storage stability of colloidal dispersion. In general, particle aggregation is less likely to occur for charged particles (high  $\zeta$  potential) due to electric repulsion. However, this rule cannot strictly be applied for systems which contain steric stabilizers, because the adsorption of steric stabilizers will decrease the  $\zeta$  potential due to the shift in the shear plane of the particle [10].

#### 10.2.6.3 Crystallinity and Polymorphism and Colloidal Structures

Particle size measurements alone are not sufficient for the characterization of SLN dispersions. The degree of crystallinity and lipid modifications are strongly correlated with drug incorporation and release rates. DSC and X-ray techniques are the most widely used for the characterization of crystallinity and polymorphism of solid lipid particles. DSC uses the fact that different lipid modifications possess different melting points and melting enthalpies. By means of X-ray scattering it is possible to assess the length of the long and short spacing of the lipid lattice [15]. The coexistence of additional colloidal structures (micelles, liposomes, mixed micelles, supercooled melts, drug nanoparticles) has to be taken into account for all SLN dispersions. Nuclear magnetic resonance (NMR) and electron spin resonance (ESR) are powerful tools for investigating dynamic phenomena and the characteristics of nanocompartments in colloidal lipid dispersions. Both methods are sensitive to the simultaneous detection of different colloidal species, do not require preparatory steps and, due to the noninvasiveness, repeated measurements of the same sample are possible. Similar results to the ERS experiments can be obtained with fluorescence measurements [36]. Rheometry has been used for the characterization of the viscoelastic properties of SLN formulations [43].

#### 10.2.7

##### Applications

Since the development of lipid microparticles by Speiser and coworkers at the beginning of the 1980s [44] and the later evolution in the 1990s towards SLNs, these lipidic particulate systems have been applied to encapsulate different drugs aiming to get sustained release of the entrapped drug, to improve drug stability by protecting the drug from degradation or to improve the bioavailability of poorly soluble drugs. SLNs can be administered by different routes: parenteral, oral, ocular, pulmonary, rectal, etc., as recently reviewed by Wissing and coworkers [16]. SLNs ap-

pear to be a promising sustained release for orally administered lipophilic drugs [45, 46], showing increased bioavailability and prolonged plasma peaks. In addition, these nanoparticles could be directly administered (as an aqueous dispersion) or formulated in different dosage forms, such as tablets or capsules. Regarding topical application, SLNs are considered as a good alternative to liposomes, possessing similar film-forming properties after application onto the skin [15]. These can be presented either in creams, gels or ointments, or topically applied as highly concentrated lipid dispersions [10]. Moreover, SLNs have been found to target drugs to particular skin layers and to sustain drug release into the skin.

When thinking about SLN administration one should bear in mind the *in vivo* fate after their administration. As widely reported in the literature, nanoparticles with a hydrophobic surface administered by different routes that will reach the blood stream will be rapidly taken up by the mononuclear phagocytic system (MPS). As a result, several approaches have been developed in order to increase the circulation time of the nanoparticles, and their targeting to organs and tissues other than the liver, lung and spleen [47]. In order to increase nanoparticle circulation time it has been stated that these particles should be 100 nm or less and have a hydrophilic surface. The approaches used to avoid unwanted uptake by macrophages include adsorption of surfactants to the nanoparticle surface, formation or inclusion with block copolymers with hydrophilic and hydrophobic domains (poloxamers and poloxamines) or grafting of a hydrophilic polymer such as poly(ethylene glycol) (PEG) [48].

In a recent study, Göppert and Müller [49] have investigated the surface modification of SLNs by the use of different poloxamers and poloxamines, and the influence of such surface modification on the adsorption of different proteins to SLNs assessed by two-dimensional polyacrylamide gel electrophoresis. They were looking for the type of poloxamer/poloxamine which would render the surface more hydrophilic, thus allowing the adsorption of albumin or apolipoproteins, giving rise to stealth SLNs and a more prolonged blood circulation time. They found that SLNs stabilized with low-molecular-weight Poloxamer 184 and Poloxamer 235 showed interestingly high adsorption of apolipoprotein E (ApoE), which mediates the uptake through the blood–brain barrier and, thus, the delivery to the brain. Interestingly, they have also reported that nanoparticles surface modified with high-molecular-weight Poloxamine 908 are able to circulate longer in the blood despite the high adsorption protein patterns found in this study, concluding that in order to avoid uptake by the MPS it is important to characterize the type of proteins that are adsorbed onto SLNs surface; if dysopsonins (such as albumin and apolipoproteins) are adsorbed and the absence of immunoglobulins and complement-activating proteins on the surface is avoided, a long circulation time of the nanoparticles might be expected.

Table 10.1 summarizes some of the main applications described for SLNs.

#### 10.2.7.1 Gene Therapy

Gene therapy is a rapidly advancing field with great potential for the treatment of genetic and acquired systemic diseases. Present delivery systems can be divided

**Tab. 10.1.** Some examples of drugs and genes encapsulated into SLNs.

Application	Drug/gene	Administration route	Reference
Gene therapy	$\beta$ -galactosidase expression plasmid	–	50
	dimeric HIV-1 Tat peptide (TAT2)	lung (inhalation)	51
	green fluorescent protein (GFP) plasmid	–	52
Peptides and proteins	gonadorelin	oral–parenteral	53
	calcitonin	oral	54
	insulin	oral	55
	[D-Trp-6]LHRH	parenteral	56
	thymopentin	parenteral	57
	lysozyme	oral, nasal, parenteral (immunization)	58
	cyclosporin A	oral	46, 59
	sodium cromoglycate	–	60
Low soluble drugs	tobramycin	ocular	61
	ketoconazole	topical	62
	clobetasol propionate	–	63
	clotrimazole	topical	64
	THP-adriamycin	parenteral	65
	ibuprofen	oral	66
	all- <i>trans</i> retinoic acid (anticancer drugs)	parenteral	67
	paclitaxel	parenteral	68
	progesterone	–	60
	doxorubicin	parenteral	69
	bupivacaine	parenteral	70
	5-fluoro-2'-deoxyuridine (FUdR) derivative	parenteral	71
	AZT and derivatives	parenteral	72, 73
	etoposide	parenteral	74
	acyclovir	–	75
	camptothecin	oral	45
ascorbyl palmitate	topical	76	
piribedil	oral	77	
Topical/cosmetics	vitamin A	topical	78
	coenzyme Q10	topical	79
	vitamin E	topical	80
	sunscreens: <i>n</i> -dodecyl-ferulate	topical	81
	perfumes	topical	82
	$\alpha$ -lipoic acid	topical	83

into virus-based, plasmid-based, and composites of both virus-based and plasmid-based systems. Plasmid-based delivery systems for so-called nonviral gene therapy are being developed as an alternative to virus-based systems. The isolated plasmid by itself can be administered locally, yielding expression in the injected tissue. Formulating the plasmid with synthetic gene delivery systems can increase the transfection efficiency.

In recent years, SLNs have been developed as potential carriers for a number of drugs, but there are only a few reports of the use of SLN delivery of genes [51, 84, 85]. However, there are a large number of publications about cationic liposomes for gene therapy; in spite of that, no marketed products have been developed. SLNs and liposomes formulated from the same cationic lipids showed equipotent *in vitro* transfection efficiencies. It is not the colloidal structure in which the cationic lipids are arranged, but the cationic lipid composition that seems to govern gene transfer efficiency. As SLNs can be produced in large scale and under favorable technological parameters, they may become a valuable addition to the well-established repertoire of nonviral transfection agents led by cationic liposomes [85].

Olbrich and coworkers [50] showed that cationic SLNs were able to transfect mammalian cells (COS-1) *in vitro*.

For over a decade, cationic lipids have been used for gene transfer both in cell culture and in animals [86, 87]. A cationic lipid is a positively charged amphiphile with a hydrophilic head and a hydrophobic tail that self-associates in aqueous solution to form either micelles or bilayer liposomes. This results in particles which can interact with the negative charges on a polynucleotide, such as DNA. The goal of cationic lipid-mediated gene transfer is to deliver a plasmid of DNA to a cell such that it becomes transcribed and translated into a desired protein/peptide [88]. The sequence of events involved in cationic lipid-mediated gene transfer include, but are not exclusive to: (i) the formation of the cationic lipid into a nanoparticle or liposome, providing a multivalent surface charge that is (ii) attached via electrostatics to the negative charges on the DNA phosphate backbone. This mixture forms a small particle. If these particles have an excess of positive charge they will (iii) bind to the negative charges on the surface of cells. The complexes become (iv) internalized through a vesicular pathway, followed by (v) the release of DNA from the particle into the cell cytoplasm. The release of DNA is thought to occur concomitantly with the release from the cationic lipid. Then some fraction of the released DNA is (vi) successfully trafficked by, as yet, an unknown mechanism to the nucleus where it is transcribed and later translated to protein. These cellular barriers to gene transfer are reviewed in depth by Meyer and coworkers [89].

SLNs must incorporate cationic lipids in order to facilitate DNA binding. When SLNs are produced with cationic lipids, a matrix lipid and, in most cases, additional surfactants are required. The resulting particles consist of a lipid core that presents cationic lipids on its surface. The cationic components are likely to be organized in raft-like monolayers that allow interaction between the modified SLN surface and DNA. Recent studies revealed the relation between transfection activity and SLN composition [85]. A large number of cationic lipids with low

toxicity and exhibiting different abilities to mediate gene transfer have been synthesized and studied for gene delivery [90–96]. In addition to *N*-[1-(2,3-dioleoyloxy)propyl]-*N,N,N*-trimethyl ammonium chloride (DOTMA) and 1,2-dioleoyloxy-3-(trimethylammonio)propane (DOTAP) (two of the most used cationic lipids), which are both two-chained amphiphiles whose acyl chains are linked to the propyl ammonium group (through ether and ester bonds, respectively), numerous new lipids have become commercially available for transfection purposes. Although a direct correlation between the nature of the cationic lipids and their ability to mediate transfection and to develop toxicity has been established, the nature of this dependency has not yet been completely clarified [97].

The incorporation into nanoparticles of colipids such as DOPE and others improves the ability to transfect cells. This fact has been attributed to the ability of dioleoyl-1- $\alpha$ -phosphatidylethanolamine (DOPE) to facilitate the formation of the complexes in conjunction with cationic lipids and to its tendency to undergo a transition from a bilayer to a hexagonal configuration under acidic pH, which facilitates fusion with or destabilization to target membranes. More recently, it was suggested that DOPE can also play a role in facilitating the disassembling of the lipid-based DNA formulations after internalization and escape of DNA from endocytotic vesicles. Cholesterol has also been employed as a colipid to prepare cationic liposomes, resulting in the formation of more stable but less efficient complexes than those containing DOPE [97].

Another approach to circumvent the problem of low efficiency of transfection is to incorporate peptides that are capable of penetrating the plasma membrane. Such peptides are called protein transduction domains (PTDs) or cell-penetrating peptides (CPPs). The most well-known CPPs are penetratin, corresponding to the third helix of the Antennapedia homeodomain, Tat(48–60), derived from HIV-1 Tat protein and oligoarginines [98]. Thorén and coworkers [98] have studied the interaction of different CPPs with phospholipids vesicles in order to better understand the mechanism of cellular uptake. Nonendocytotic uptake was only observed for the arginine-rich peptides TatP59W and R7W. Studies of the leakage from dye-loaded vesicles indicate that none of the assayed peptides (penetratin, R7W, TatP59W and TatLysP59W) forms membrane pores and that vesicles fusion is not accompanied by leakage of the aqueous content of the vesicles. The authors suggest that the discovered variations in propensity to destabilize phospholipid bilayers between the peptides investigated, in some cases to induce fusion, may be related to their different cellular uptake properties. Hyndman and coworkers [99] have demonstrated that the incorporation a protein transduction domain of the HIV-1 into gene delivery lipoplexes improves gene transfer, suggesting that the endocytosis uptake pathway is involved. The mechanism for the CPP-facilitated cellular uptake is unknown [100, 101]. Zieger and coworkers [102] have shown that membrane-associated heparan sulfate is involved in the uptake of HIV-1 protein.

The attachment of ligands to target the particles for cell-specific uptake via highly internalizing receptor can be a very useful strategy for the treatment of some diseases. Pedersen and coworkers [103] prepared SLNs with Compritol ATO 888 with a size of approximately 100 nm and a  $\zeta$  potential of +15 mV which

were able to condense DNA, they are very stable under physiological conditions and they display low cytotoxicity in cell culture. In addition to binding to DNA, the SLNs could simultaneously bind substantial amounts of streptavidin directly via electrostatic interactions. The SLN:DNA:streptavidin complexes are stable and are capable of binding biotinylated ligands, which can interact with surface receptors.

#### 10.2.7.2 Peptide and Protein Delivery

Over the last few years, and thanks to the development of the biotech industry, a great number of bioactive molecules and vaccines based on peptides, proteins and oligonucleotides have been discovered, showing great promise as therapeutic agents. However, the administration of these molecules is often limited because of their poor stability, low oral bioavailability, short *in vivo* half-lives and limited ability to cross cell membranes. In order to overcome such disadvantages, a suitable design of sustained release carrier systems is needed to enter the therapeutic market [104]. Peptide and protein nanoparticles can be administered by different routes, depending on the application intended. If they are to be administered by the oral route, formulation of peptides and proteins into a suitable drug carrier is a relevant task, especially due to epithelial barriers of the gastrointestinal tract, and gastrointestinal degradation by the acidic pH of the stomach and digestive enzymes [105].

The most commonly used particulate drug carriers for the administration of peptide and protein drugs have traditionally been poly(lactic acid) (PLA), poly(glycolic acid) (PGA) and their copolymers, poly(lactide-*co*-glycolide) (PLGA). However, there are only a few of products on the market based on PLGA microparticles and, to the best of our knowledge, no nanoparticulate product based on this kind of polymers has reached the market, probably because of the cytotoxicity of polymers and the difficulties for the scaling-up of the nanoencapsulation processes [15].

Among the different particulate drug carriers proposed as alternative materials, lipids appear to be suitable matrix materials for sustained release formulations of peptide and proteins, presenting good biocompatibility properties and being able to form different colloidal drug carriers, as microemulsions, SLNs, lipospheres, NLCs or microparticles.

In fact, one of the advantages of SLNs compared to PLGA nanoparticles is their better tolerability. Müller and coworkers [106] compared the *in vitro* toxicity of PLA, PLGA and SLN nanoparticles in order to determine the toxicological acceptance as an intravenous formulation. They found that the effective dose to reduce viability of the cells to 50% was around 0.30% for PLA polymers, 0.15% for PLGA and above 10% for SLNs, proving that SLNs are the least cytotoxic preparation.

Schöler and coworkers [107] have recently studied the cytotoxic properties of SLNs intended for parenteral administration, analyzing the viability and activation of macrophages [production of interleukin (IL)-6, IL-12 and tumor necrosis factor (TNF)- $\alpha$  as a function of the lipid type used and SLN particle size]. No activation of peritoneal was observed when triglycerides, cetylpalmitate or paraffin were used for the lipid matrices, although a concentration-dependent cytotoxicity was found for

SLNs. This is the reason why it is essential to select properly the lipid matrices of SLNs to be used for parenteral administration. As previously summarized in Tab. 10.1, SLNs have been applied to the encapsulation of different peptide and proteins aiming a controlled release of the entrapped protein, to overcome the gastrointestinal barriers for the oral administration of the peptide or even an adjuvant capacity of the particulate carrier system.

Olbrich and coworkers [108] have described the adjuvant capacity of antigens adsorbed or entrapped in SLNs, inducing an immune response comparable to that of Freund's incomplete adjuvant. However, this adjuvant capacity was found to be strongly dependent on the SLN size: SLNs bigger than 100 nm exhibited a strong adjuvant capacity, whereas for SLNs smaller than 100 nm this adjuvant capacity was quite low or even negligible. In addition, SLNs may offer a sustained release of the antigen, which can be continuously presented to the immune system contributing to an optimized immune response and making these systems appropriate for the administration of vaccines.

Morel and coworkers [56] first adapted the techniques they were using for the preparation of microemulsions for the encapsulation of the peptidic drug [D-Trp-6]LHRH. They obtained lipospheres by a warm multiple water/oil/water (w/o/w) microemulsion using stearic acid as lipid matrix. The encapsulation efficiency was about 90% and the drug was sustained release following a pseudo-zero-order kinetic. Later, the same research group [57] applied the same encapsulation method (w/o/w microemulsion) and the o/w microemulsion for the formulation of thymopentin. In order to increase the incorporation of hydrophilic drugs into lipospheres, lipophilic ion-pairs of the drug with hexadecylphosphate were prepared in this warm o/w microemulsion technique. As expected, this later technique allowed the incorporation of a much higher amount of the drug than the w/o/w multiple microemulsion technique (5.2 versus 1.7%). Moreover, the percentage of the drug released from lipospheres prepared by both methods was practically identical (10% in 6 h).

One of the most interesting studies on the feasibility of the encapsulation of peptide drugs into SLNs was published in 1997, when Almeida and coworkers [58] studied the influence of production parameters of peptide SLNs using lysozyme as model protein. These researchers applied the cold HPH technique for the encapsulation of this model peptide, studying different parameters that could affect the formation of these SLNs: the type of lipid used, the time of exposure to different temperatures, pressure and number of homogenization cycles. They showed that lysozyme was able to withstand the formulation conditions needed to prepare SLNs, without losing its activity and integrity. The entrapment efficiency of hydrophilic drugs of these SLNs is usually low (they obtained encapsulation efficiencies between 43.2 and 59.2%), and depends on the lipid mixture employed and the homogenization conditions. However, every protein may behave differently, and its encapsulation must be studied in depth and optimized accordingly.

As commented above, some of the peptidic drugs that have been successfully introduced to the market in particulate drug carrier form are luteinizing hormone-releasing hormone (LHRH) analogs. In order to improve the formulation by

means of improving drug stability during polymer degradation, Hu and coworkers [53] prepared SLNs to encapsulate gonadorelin. In this case, SLNs were obtained by a novel solvent diffusion method in an aqueous system. Using this technique, encapsulation efficiency increased up to 69.4%. In addition, gonadorelin showed a slow release profile after a burst release period of 6 h in which 24% of the drug was released, after that burst release almost 4% of gonadorelin was sustained-released every day during the 14 days of the study.

Another procedure that has been applied for the preparation of SLNs containing peptides is the w/o/w multiple emulsion technique. The group of Alonso [54, 55, 109] have modified this technique to develop surface-modified lipid nanoparticles for the encapsulation of different peptidic model drugs. As previously reviewed in this chapter, different polymers can be used to modify the surface properties of lipid nanoparticles. In the first study, poloxamer and PEG–stearate were used to form a coating on the surface, and thus protect orally administered nanoparticles from the effect of gastrointestinal fluids. They established that coating lipid nanoparticles with PEG–stearate prevents them from aggregation and reduced pancreatin-induced degradation, making them suitable for oral administration. In a later study, Prego and coworkers [109] coated lipid nanoparticles with chitosan, reporting that this type of coating can switch their  $\zeta$  potential from negative to positive, and confers on them the capacity of enhancing the *in vitro* intestinal absorption of calcitonin, assayed in Caco-2 cells – results that were corroborated after the oral administration of calcitonin in rats. Next, this group [54] studied the release profiles of these PEG–stearate- and chitosan-coated nanoparticles. Both types of nanoparticles exhibited an initial burst release (lower for chitosan-coated nanoparticles) followed by a more prolonged slow release in which 40% of calcitonin was released during the 6 h of the study, for both PEG–stearate- and chitosan-coated nanoparticles. Moreover, and as was the case for PEG–stearate nanoparticles, coating with chitosan also protected lipid nanoparticles from the acidic and intestinal environment. Recently, they have determined the interaction of these surface-modified nanoparticles (PEG–stearate and chitosan) with Caco-2 cells, concluding that PEG–stearate did not affect the permeability of Caco-2 cells monolayers unlike chitosan nanoparticles.

Cyclosporin is another of the peptidic drugs that has been successfully incorporated into SLNs [59, 46]. It is an undecapeptidic hydrophobic drug, insoluble in water and widely used for the prevention of xenograft rejection following organ transplantation. Cyclosporin was encapsulated into SLNs aiming to improve oral bioavailability and thus reducing toxic side-effects, maintaining at the same time good, sustained plasma levels.

### 10.2.7.3 Low-soluble Drugs

Despite having good therapeutic effects, many drugs fail in clinical situations due to their poor water solubility. Although many techniques have been employed to improve the oral absorption of poorly soluble drugs, little information is available in the literature on the improvement in the oral bioavailability of poorly soluble drugs by incorporation into SLNs. Like other formulations, such as microemul-

sions or submicron emulsions, reduction in the particle size is a key factor for improving the peroral performance of poorly soluble drugs. Due to their small particle size, SLNs may exhibit bioadhesion to the gastrointestinal tract wall or enter the intervillar spaces, thus increasing their residence time in the gastrointestinal tract. Another advantage of SLN formulations is the lipid protection of the drug from chemical and degradation, thereby delaying the *in vivo* metabolism. Good physical stability also plays an important key in the oral absorption of the incorporated drugs [110].

Incorporation of drugs into SLNs opens the perspective of enhanced and/or less-variable bioavailability and prolonged plasma levels [77, 111], which is postulated due to a controlled, optimized release in combination with general adhesive properties of small particles [112]. Zimmermann and Müller [113] evaluated the influence of artificial gastrointestinal media on the physical stability of SLN formulations consisting of different lipids and various surfactants/stabilizers with respect to ionic strength and pH. They showed that it is possible to produce SLNs stable in the gastrointestinal tract by optimizing the surfactant/mixture for each lipid *in vitro*. The stabilizing properties obviously depend on the specific interaction of the lipid matrix with the emulsifier, e.g. anchoring of the stabilizer on the lipid surface and density on the surface.

On the other hand, knowledge about enzymatic degradation velocity of SLNs is essential. Olbrich and Müller [114] studied the effects of different surfactants on the degradation velocity. These authors showed that the degradation velocity is substantially affected by the stabilizer used for the preparation of the SLNs. Some stabilizers such as cholic acid sodium salt have degradation accelerating effects, other such as Poloxamer 407 distinctly slow down the degradation velocity. Degradation velocity can be thus modulated by changing the surfactant ratio. Müller and coworkers [115] had previously showed that the degradation velocity of SLNs in solutions of pancreatic lipase/colipase depends on the composition on the lipid matrix. In general, degradation velocity increased with decreasing length of the fatty acid chain length when using glycerides as lipid matrix [116]. In addition, the degradation of SLNs based on waxes (e.g. cetylpalmitate) was found to be slower compared to glyceride matrices.

El-Gibaly and coworkers [117] encapsulated allopurinol into sustained-release solid lipospheres elaborated by melting wax components and hexaconasol, a new hydrophobic wax modifier. The drug was dispersed in the respective molten wax under continuous stirring using a magnetic stirrer. In this study, SLNs were intended for use in a suspension formulation and other oral dosage forms. A significant decrease of plasma uric acid levels and hepatic impairment in male rats was observed after oral administration of SLS suspension of one of their formulations, compared to suspensions of pure allopurinol.

All-*trans* retinoic acid (ATRA) has been limited in clinical use due to its poor aqueous solubility. ATRA has been formulated into SLNs [110] elaborated by HPH with Compritol 888 ATO and soy lecithin/Pluronic F 68 or soy lecithin/Tween 80 as emulsifiers in order to increase its oral bioavailability. After oral administration to male rats, SLNs produced a significant improvement in the bio-

availability of ATRA compared with ATRA solution. Compared with the ATRA emulsion, which also produced an improvement in oral absorption, SLNs exhibit a high physical stability.

#### 10.2.7.4 Topical and Transdermal Administration

SLNs are being investigated as drug carrier system for topical application. These carriers are composed of physiological and biodegradable lipids of low systemic toxicity and also low cytotoxicity [118]. SLNs for topical application to the skin are made up from lipids such as glyceryl behenate (Compritol 888 ATO), glyceryl monostearate (Inwitor 900), glyceryl palmitostearate (Precirol ATO 5), triglycerides (trimyristin, tripalmitin, tristearin) or the wax cetyl palmitate [119].

The generally low lipid content and the poor viscosity of lipid nanodispersions render these preparations, as they are, less suitable for dermal drug application. The handling of the preparation by the patient is improved by SLN incorporation into ointments, creams and gels. Alternatively, ready-to-use preparations may be obtained by one-step production, increasing the lipid phase to at least 30%. However, increasing the lipid frequently results in an unwanted increase in particle size. Surprisingly, it has been found that very concentrated (30–40%) semisolid cetyl palmitate formulations preserve the colloidal particle size [34]. If SLNs are incorporated into vehicles, interactions with the vehicle constituents may induce physical instabilities such as dissolution or aggregation of lipid particles. It is important to follow the particle size and the solid character of the particles during storage.

Particle size of the SLNs influences drug penetration, as has been shown for nanoemulsions, in such a manner that when decreasing particle size, drug penetration and systemic activity of drug increase [120]. Similar effects for particle size reduction on penetration into the skin were found for polymeric particles [121].

Occlusion properties which can enhance the penetration of drugs through the stratum corneum by increased hydration have been reported [120, 122]. Occlusion properties are due to the formation of a film on the skin which enhances the penetration of drugs through the stratum corneum.

SLNs can provide a sustained drug release due to the solid matrix of the particles [78]. Sustained drug release becomes important in dermal application concerning drugs that are irritating at high concentrations. Furthermore, it provides the possibility to supply an active agent over a prolonged period of time and can reduce systemic absorption. Controlled triggered release of drugs is feasible due to polymorphic transitions of the lipids induced by water evaporation from the dosage form after application to the skin. Furthermore, electrolytes present in the upper skin surface can initiate polymorphic transitions accompanied by drug expulsion due to the formation of a stable polymorph [123].

Common disadvantages of SLNs are their particle growth, their unpredictable gelatin tendency, their unexpected dynamic of polymorphic transitions and their inherent low incorporation rate because of the crystalline structure of the solid lipid [10, 124, 125]. It has been claimed that this last drawback can be overcome by oil-loaded solid nanolipids (also described as NLCs) [34, 35, 123]. Liquid lipids

solubilize the drug to a much higher extent than solid lipids. In a preferred scenario, the liquid lipids form inner droplets in the solid nanoparticles. In this model, the NLC nanoparticles would provide a high incorporation rate (because of the liquid lipid) and a controlled release (because of the outer solid lipid).

Souto and coworkers [62, 64] have prepared SLNs and NLCs for topical delivery of clotrimazole and ketoconazole. The authors show that these lipid nanoparticles are useful as modified release formulations for lipophilic drugs over a prolonged period of time.

#### 10.2.7.5 Cosmetic Applications for SLNs

SLNs are also considered a promising carrier system for cosmetic active ingredients due to their numerous advantages. These kind of delivery systems (i) provide protection to labile compounds against chemical degradation, as is the case of retinol and tocopherol, (ii) can provide sustained release of the active ingredients, (iii) act as occlusives, e.g. they can be used in order to increase the water content of the skin and (iv) show a ultraviolet (UV)-blocking potential, i.e. they act as physical sunscreens on their own and can be combined with molecular sunscreens in order to achieve improved photoprotection [126].

SLNs have been shown that they act as active carriers for sunscreens [127]. Song and Liu [128] prepared SLNs as carriers for 3,4,5-trimethoxybenzoylchitin, a new UV-absorbing macromolecule and vitamin E; the nanoparticles act both as physical sunscreens themselves and as carriers in order to enhance the effect of UVB protection. The incorporation of vitamin E appears to have a better effect on UVB absorption.

### 10.3

#### Polymeric Nanoparticles

##### 10.3.1

##### Introduction

Polymeric nanoparticles are small colloidal particles ranging in size from 10 to 1000 nm, which are made of nonbiodegradable or biodegradable polymers. Depending on the method used for their preparation, two different types of nanoparticles can be obtained: nanospheres and nanocapsules. Nanospheres have a matrix-type structure, where active compounds can be absorbed at their surface, entrapped or dissolved in the matrix. Nanocapsules, which are reservoir systems, have a polymeric shell and an inner core. In this case, the active substances are usually dissolved in the core, but may also be adsorbed at their surface. Among the polymeric nanoparticles currently under investigation for controlled drug delivery and drug-targeting applications, those receiving most attention are probably the nanoparticles based on synthetic polymers such as PLA, PGA and PLGA. These polymers are known for both their biocompatibility and resorbability through natural pathways. Additionally, the degradation rate and accordingly the drug release

rate can be manipulated by varying the ratio of PLA (increased hydrophobicity) to PGA (increased hydrophilicity).

### 10.3.2

#### Nanoparticle Preparation Methods

Nanoparticles can be prepared by a number of methods, which are classified into two main categories depending on whether the polymer is formed by *in situ* polymerization of monomers or by dispersion of the preformed polymers.

##### 10.3.2.1 Nanoparticles Prepared by *In Situ* Polymerization of Monomers

The polymerization methods can be classified into two groups based on whether nanospheres or nanocapsules are formed. Nanospheres are mostly prepared by emulsion polymerization, whereas nanocapsules are obtained by interfacial polymerization performed in emulsions or microemulsions.

**10.3.2.1.1 Emulsion Polymerization** The polymerization is usually initiated by the reaction of an initiator with the monomer molecules that are dissolved in the continuous phase of an o/w or w/o emulsion. Couvreur and coworkers [129, 130] reported the production of biodegradable poly(alkyl cyanoacrylate) (PACA) nanospheres (40–250 nm diameter) by a simple emulsification polymerization procedure. The nanospheres were obtained by mechanically emulsifying alkylcyanoacrylate monomers in an aqueous acidic medium in the presence of a non ionic surfactant (e.g. Polysorbate 20, Poloxamer 188) and stabilizers like Dextran 70. The polymerization is spontaneously initiated by the hydroxide ions present in water, under vigorous mechanical stirring at ambient temperature. The NP suspension is then purified by ultracentrifugation or by resuspending the particles in an isotonic surfactant-free medium. The drug is dissolved in the polymerization medium either before the addition of the monomer or at the end of the polymerization reaction, so that it can be either incorporated into the matrix or adsorbed at the surface of the nanospheres. A wide variety of drugs have been efficiently incorporated into PACA nanospheres including cytostatic agents, a peptide growth hormone and several antibiotics [131–133].

Methylidene malonates are other monomers that give biodegradable polymers and polymerize according to a mechanism similar to that of alkylcyanoacrylates [134]. Other polymers proposed for the production of nanospheres by emulsion polymerization include polyglutaraldehyde, poly(vinyl pyridine) and polystyrene; however, their lack of biodegradability compromises their clinical use [135, 136].

**10.3.2.1.2 Interfacial Polymerization** In this procedure an ethanolic phase containing an oil or a nonmiscible organic solvent, the monomers and the drug to be encapsulated is dispersed in an aqueous external phase containing a surfactant. The ethanol rapidly diffuses out of the organic phase giving tiny oil droplets. Due to their interfacial properties, the monomer molecules spontaneously locate at the surface of the oil nanodroplets at the water/oil interface, leading to the formation

of nanocapsules [137]. This method has been used for the encapsulation of oily soluble products into PACA nanocapsules. In order to entrap water-soluble molecules, the process was adapted by addition of the monomer to the oily phase of a previously prepared microemulsion [138, 139].

### 10.3.2.2 Nanoparticles Prepared from Preformed Polymers

The nanoparticles prepared by *in situ* polymerization suffer from two main drawbacks: (i) the presence of toxic residues (unreacted monomers, initiators and surfactant molecules) whose elimination is time-consuming and not always efficient, and (ii) the possible interaction of monomer molecules with the active substance during the polymerization process, leading to the denaturation and inactivation of the drug. Therefore, new encapsulation techniques involving the dispersion of already polymerized materials have been developed to avoid these problems. A major advantage of these methods over the previously described techniques is that the polymers are well characterized and the nanoparticle preparation conditions will not determine their physicochemical characteristics.

**10.3.2.2.1 Emulsification/Solvent Evaporation–Extraction Method** In this method, the polymer is dissolved in a volatile organic solvent like dichloromethane, chloroform or ethyl acetate. The drug is dissolved or dispersed into the polymer solution, and this mixture is further emulsified by high-speed homogenization or sonication into an aqueous solution containing a suitable emulsifier like poly(vinyl alcohol) (PVA), polysorbate, poloxamer, etc. After the formation of a stable o/w emulsion, the organic solvent is either extracted by the continuous phase (solvent extraction), diffuses into the same and evaporates by increasing the temperature/under pressure or by continuous stirring (solvent evaporation) or is removed by a combination of both, leading to the formation of nanoparticles. At the end of the procedure, the solidified particles are usually collected by centrifugation, washed and dried.

The emulsification/solvent evaporation–extraction method has been used for the production of nanospheres with a wide range of polymers including PLGA, poly( $\epsilon$ -caprolactone) (PCL) and poly(hydroxybutyrate) (PHB). Although this method was proposed for the encapsulation of lipophilic compounds [140, 141], a modification of this technique has been used for encapsulating a model protein, bovine serum albumin (BSA), achieving encapsulation efficiencies up to 70% [142]. An aqueous solution of BSA was emulsified in a PLGA solution in dichloromethane by sonication. This w/o emulsion was then added to an aqueous PVA solution resulting in a w/o/w emulsion which is sonicated again. Polymer hardening and nanoparticle formation is induced by solvent evaporation–extraction upon addition of an aqueous isopropanolic solution.

More recently, Freitas and coworkers [143] have developed a novel ultrasonic flow-through cell for the production of PLA or PLGA nanoparticles with a mean diameter of 500 nm. The equipment consisted of a glass tube for the conduction of the sonicated fluid, which was installed in a steel jacket excited by a transducer and filled with pressurized water for the transmission of sound waves. This novel

technology can avoid the contamination of the fluid from the environment and is well suited for aseptic continuous nanoparticle production.

**10.3.2.2.2 Emulsification/Solvent Diffusion Method** This method uses partially water-soluble solvents like benzyl alcohol or propylene carbonate instead of chlorinated solvents that could degrade certain drugs and proteins. The polymer and active compound are dissolved in the solvent and emulsified in the aqueous phase containing the stabilizer. Water is added to the emulsion to allow the diffusion of the solvent into the water and leading to the formation of the nanoparticles. Once the nanoparticles are formed, they can be collected by centrifugation or the solvent can be removed by dialysis [144].

**10.3.2.2.3 Salting-out Method** The salting-out method was first reported by Bindschadler and coworkers in 1988 [145]. In this case, an o/w emulsion is formed by addition of an aqueous phase saturated with electrolytes, and containing PVA as stabilizing agent to an acetone solution of polymer and the active compound. The miscibility of both phases is prevented by the saturation of the aqueous phase with electrolytes according to a salting-out phenomenon. Subsequently, water is added until the volume is sufficient to disrupt the equilibrium between the two phases and to allow diffusion of the acetone into the water, which results in polymer precipitation and the formation of nanoparticles. Finally, this suspension is purified by cross-flow filtration and lyophilization. One disadvantage of this procedure is the use of salts that are incompatible with many bioactive compounds.

**10.3.2.2.4 Direct Precipitation-based Method** The nanoprecipitation method developed by Fessi and coworkers [146] represents an easy and reproducible technique that allows us to obtain nanoparticles without a previous emulsification step. The process is based on the drop-wise addition of the polymer dissolved in water-miscible solvents such as acetone, ethanol or methanol to an aqueous medium under stirring. The polymer precipitation gives rise to nanoparticle formation. The solvent is then removed by evaporation under reduced pressure. This technique is mostly suitable for the encapsulation of hydrophobic compounds due to the rapid migration and therefore loss of water-soluble drugs into the aqueous phase. Molpeceres and coworkers [147] encapsulated cyclosporin A into PCL nanoparticles based on this method. The polymer and drug were dissolved in acetone and this organic phase was injected through a needle into an aqueous medium containing Poloxamer 188. Nanoparticle formation could be visualized by the Tyndall effect.

### 10.3.3

#### **Characterization of Polymeric Nanoparticles**

Nanoparticles are usually characterized in terms of size, morphology, charge, constituent properties, drug content and *in vitro* drug release. The techniques used are similar to those described for SLNs in Sections 10.2.4 and 10.2.6.

## 10.3.4

**Pharmaceutical Applications of Nanoparticles**

Polymeric nanoparticles are promising candidates for the delivery of a broad number of peptide and protein drugs for diagnostic and therapeutic applications, since they are advantageous in a number of ways. On the one hand, the solid matrix of particulate carriers protects the incorporated drugs against enzymatic and hydrolytic degradation. On the other hand, they present tissue-targeting capacities, thereby increasing the bioavailability of drugs at the site of action and simultaneously reducing both the total dose and the side effects associated with the drug. Furthermore, they can be used to modulate the immune responses against encapsulated antigens due to their ability to efficiently target professional antigen-presenting cells (APCs), and to facilitate appropriate processing and presenting antigens to T cells. One additional advantage of particulate carriers is that their surface properties can be modified in order to evade the macrophages of the reticuloendothelial system (RES) or in such a way as to improve the uptake and transport across mucosal barriers.

**10.3.4.1 Protein Delivery**

Advances in biotechnology and biochemistry had led to the discovery of numerous bioactive molecules, some of which are peptides and proteins. These macromolecules are characterized by poor solubility, limited chemical stability *in vitro* and *in vivo* after administration, and poor bioavailability. Indeed, they are usually administered by the parenteral route and frequent, high-dose injections are required to circumvent their extremely rapid clearance in the body. One approach for improving the therapeutic index of these macromolecules could be the development of nanoparticulate carriers able to maintain appropriate drug blood levels for long periods of time. Csaba and coworkers [148] have developed a new nanoparticulate system consisting on a blend nanomatrix of PLGA and a poly(ethylene oxide) (PEO) derivative for the encapsulation of insulin providing a more stable environment to the encapsulated macromolecules. These new nanoparticles release the insulin in a constant rate over a time period of 2 weeks with a negligible burst effect typically observed for proteins encapsulated in PLGA micro/nanoparticles. In another study reported by Barrichelo and coworkers [149], different bioactive agents and insulin were encapsulated into PLGA nanoparticles using the nanoprecipitation method. Insulin was preferentially bound to the surface of PLGA nanoparticles. Nevertheless, a strong hypoglycemic effect of the insulin was observed after administration of the nanoparticles suspension to the ileum loop of male Wistar rats, indicating that insulin was absorbed.

More recently nanoparticles are being investigated as drug carriers for proangiogenic growth factors proposed as a novel approach for the therapy of various ischemia-related pathophysiological conditions. Proangiogenic growth factors have shown promising results in preclinical studies using protein- and gene-based therapies. However, their success in clinical trials is hindered by the lack of an optimal delivery strategy that would provide sustained and localized levels of the

growth factors in the diseased tissue [150]. Davda and coworkers [151] evaluated the efficacy of sustained release biodegradable nanoparticles, formulated with PLGA, for the delivery of vascular endothelial growth factor protein (VEGF), a potent proangiogenic agent. Nanoparticles encapsulating VEGF, which were formulated using a double-emulsion solvent evaporation technique, demonstrated sustained release of the growth factor in bioactive form. Furthermore, the growth factor encapsulated in nanoparticles demonstrated greater and more sustained effect compared with a solution on endothelial cell proliferation, migration and morphogenesis, which are key elements of blood vessel outgrowth. The greater efficacy of encapsulated VEGF was due to the ability of nanoparticles to maintain the growth factor level in culture for a sustained period of time. The data thus suggest that nanoparticles can be used as an effective delivery system for growth factors to induce therapeutic angiogenesis.

A new method to prepare heparin-functionalized PLGA nanoparticles for the controlled release of growth factors has been recently reported by Chung and coworkers [152]. The system is composed of PLGA as a hydrophobic core, Pluronic F-127 as a hydrophilic surface layer and heparin as the functionalized moiety. The incorporation of heparin is based on its high specific binding for various growth factors, which enables them to crosslink their receptors and to be protected from proteolytic degradation. The release of VEGF from the nanoparticles (below 200 nm) showed a linear profile without initial burst over 1 month. The authors proposed that these nanoparticles can be used as a growth factor delivery system in tissue engineering scaffolds as well as sustained release systems of various heparin-binding growth factors.

Interferon (IFN)- $\alpha$  is another macromolecule that has been encapsulated in order to simplify its administration and improve its therapeutic effects. The currently approved therapies require the injection of repeated high nonphysiological doses due to the short half-life of the free macromolecule [153]. Nevertheless, the potential of IFN formulated in these controlled release systems has been limited by the reduction of its biological activity during the encapsulation and/or release process [154]. Sanchez and coworkers [155] have used Poloxamer 188 as a stabilizing agent for the encapsulation of IFN- $\alpha$  into biodegradable micro/nanoparticles. PLGA/poloxamer blend microspheres were able to provide significant amounts of active IFN- $\alpha$  for up to 96 days. These new delivery systems might improve the effectiveness of IFN- $\alpha$  and the quality of life of patients.

#### 10.3.4.2 Protein Delivery by Mucosal Routes

In recent years, considerable research has been done using nanoparticles for the delivery of protein and peptide drugs by mucosal routes. After oral administration the drug carriers are expected to remain in the gastrointestinal tract while protecting the entrapped peptide drugs from enzymatic degradation until they are absorbed. Carino and coworkers [156] developed an oral nanosphere formulation to protect insulin from degradation and facilitate systemic uptake by the oral route. This formulation was shown to have 11.4% of the efficacy of intraperitoneally de-

livered zinc insulin and was able to control plasma glucose levels when faced with a simultaneous administered glucose challenge.

The same concept could be also applied to the pulmonary route, which has been considered as a promising way to improve delivery of insulin with particulate systems. The nebulized PLGA nanospheres significantly reduced the blood glucose levels of fasted guinea pigs and the hypoglycemia was prolonged over 48 h compared to the nebulized aqueous insulin solution as a reference (6 h). This result could be attributed to the sustained release of insulin from the nanospheres deposited widely on to the whole lung [157]. When developing polymeric nanoparticles, controversy still exists on physicochemical factors governing nanoparticle uptake and transport across mucosal barriers, including size, size distribution, hydrophobicity and surface properties. Many studies on size effects have demonstrate that size is an important parameter controlling the internalization of nanoparticles into the epithelia of the gastrointestinal tract and, as a rule of thumb, sizes smaller than 500 nm are required [105]. Apart from particle size, surface properties seem to influence the uptake by intestinal epithelia. Summarizing numerous absorption studies of polymeric nanoparticles in intestinal tissues, it can be concluded that a combination of both nanoparticles surface charges and increased hydrophobicity of the matrix material seem to affect gastrointestinal uptake in a positive sense [158–160]. In addition, different research groups have demonstrated that increased nanoparticle internalization can be achieved by conferring mucoadhesive properties to them by coating their surface with mucoadhesive polymers such as chitosan and carbopol. Takeuchi and coworkers [161] reported the preparation of elcatonin-loaded PLGA nanospheres coated with chitosan. They found that, following the oral or pulmonary administration in rats and guinea pig, the reduction in calcium concentration obtained with mucoadhesive nanoparticles was more effective and prolonged in comparison with that obtained with noncoated systems. These results indicate that chitosan nanospheres adhere to the mucus layer in the gastrointestinal tract and lung tissues, due to the mucoadhesive properties of chitosan, and release the drug over a longer period of time. In another study by Vila and coworkers [162], it was demonstrated that the coating of tetanus toxoid-containing PLA nanoparticles with PEG or chitosan improved their stability in physiological fluids, and enhanced the transport across the intestinal and nasal mucosae, thereby confirming the usefulness of mucoadhesive nanoparticulate systems for the delivery of peptide drugs.

Nanoparticles have also been used in the induction of oral tolerance, since successive and extended exposure of the immune system to the antigen in the intestine is indispensable for inducing peripheral immune tolerance. Kim and coworkers reported that a single administration of PLGA nanoparticles entrapping type II collagen could induce oral tolerance more efficiently than repeated administration of intact protein [163]. In a subsequent study, they prepared PLGA nanoparticles entrapping PEG-conjugated immunodominant peptides of type II collagen for oral tolerance induction in collagen-induced arthritis. The single intragastric administration of these nanoparticles induced the production of IL-4 and

IL-10 in CD4<sup>+</sup> T cells of Peyer's patches, which was comparable to that in mice fed 6 times with peptide solution. Taking into account that IL-4 and IL-10 play a critical role in arthritis suppression, they conclude that oral administration of nanoparticles might block arthritis progression through this mechanism [164].

#### 10.3.4.3 Vaccine Adjuvants

Nanoparticles containing entrapped or adsorbed antigens have been intensively investigated as vaccine adjuvants alternatives to the currently used aluminum salts [165, 166]. A major drawback with current vaccination regimes lies in the method of administration, which generally employs the parenteral route, which might lead to noncompliance. Thus, alternative routes of vaccine administration have been tested: nasal, oral, intradermal and vaginal. Carcaboso and coworkers [167] have demonstrated the adjuvant properties of PLGA nanoparticles containing encapsulated Spf66 antigen. The systemic immune response obtained following nasal administration with nanoparticles was superior to that induced by the same dose of peptide solution; however, in this study, the best responses were obtained with 1- $\mu$ m particles. This latter formulation greatly improves and maintains higher antibody levels compared to conventional alum adjuvant and to the administration of the particles by others routes (subcutaneous, oral).

In recent studies, Coolí and coworkers [168] have investigated the effect of size and charge on the permeation of nanoparticles through the skin as the first step in designing a transdermal vaccine delivery system. The results showed that only 50- and 500-nm fluorescent particles that were negatively charged were able to permeate the pig skin. This provides evidence of the potential of nanoparticles as delivery vectors for antigens and DNA for the purpose of transdermal vaccination protocols.

In general, vaccination against major diseases requires a humoral immune response; however, in the case of intracellular viral, bacterial and parasitic infections a cellular response is needed [169]. It is known that aluminum hydroxide can preferentially induce T<sub>h</sub>2 immune responses [170, 171] and deposits the antigen only for 2–3 weeks [172]. Although aluminum hydroxide can induce the production of antibodies, it has little effect on eliciting CD4<sup>+</sup> T<sub>h</sub>1 cells (defined by their production of IL-2 and IFN- $\gamma$  cytokines, that induce cell-mediated immune responses) or CD8<sup>+</sup> T cell response. Polymeric nanoparticle delivery systems play an interesting role in the design of new vaccines since it have been demonstrated that they can elicit a T<sub>h</sub>1/T<sub>h</sub>2 combined response. According to the results reported by Schöll and coworkers [173], the subcutaneous administration of the major allergen of birch pollen loaded into PLGA nanoparticles modulated an ongoing T<sub>h</sub>2 response in the BALB/c mouse model. This response was demonstrated by downregulation of IgG1, and production of IFN- $\gamma$  and IL-10, suggesting that PLGA nanoparticles can be used for formulations of allergen extracts or derivatives for the “few-shot” treatment of type 1 allergy.

Furthermore, it has been suggested that PLGA nanoparticles are suitable for simultaneous targeting of immunoadjuvants and antigens to APCs, and can reduce the effective adjuvant dose significantly [174]. Chong and coworkers [175] investigated the immune-enhancing effects of codelivery hepatitis B core antigen

(HBcAg) and monophospholipid A (MPLA) in a murine model. In this study, a single subcutaneous immunization with a vaccine formulation containing MPLA and HBcAg coencapsulated in PLGA nanoparticles promoted a stronger T<sub>H</sub>1 cellular immune response with IFN- $\gamma$  production than those induced by the antigen alone, mixed with MPLA or HBcAg-loaded nanoparticles. Such response is critical for the control of viral replication and the elimination of chronic hepatitis B, indicating that the simultaneous delivery of antigens and immune modulators in a single particulate formulation may be an interesting strategy for the development of effective hepatitis B virus therapeutic vaccines.

## 11 Intelligent Hydrogels in Nanoscale Sensing and Drug Delivery Applications

*J. Zach Hilt*

### 11.1

#### Introduction

This chapter highlights recent activities in the field of intelligent hydrogels, specifically in sensing and drug delivery micro/nanotechnologies. This is a relatively undeveloped field, but there is high promise and interest in the area, which has led to rapid growth. Here, some selected examples of the cutting-edge research being conducted are presented and, where appropriate, the reader is directed to key reviews within the field. In the past, numerous research groups have utilized hydrogels as functional components in biomedical applications, such as in biomaterials and biosensors, but only recently have hydrogels begun to be applied at the micro/nanoscale.

Example applications of hydrogels at the small scale include work by Ito and collaborators [1–3] patterning pH-sensitive and thermosensitive hydrogels for potential use in various microdevices. In other studies by Matsuda and coworkers [4–8], hydrogels have been micropatterned using a surface polymerization technique to create regions with different physicochemical properties to control the direction of cell adhesion and cellular behavior. In addition, Peppas and coworkers micropatterned poly(ethylene glycol) (PEG)-based hydrogels for application in biomedical devices [9]. Several other groups have focused on developing microdevices utilizing the mechanical response of environmentally sensitive hydrogels for microactuation. Beebe and coworkers [10, 11] have micropatterned pH-responsive hydrogels inside microfluidic channels to create flow controls that could respond to the ambient environmental conditions.

The application of intelligent hydrogels in micro/nanoscale sensing and drug delivery applications are highlighted within this chapter. First, in Section 11.2, the field of intelligent hydrogels is introduced and several example systems are highlighted, including ionic, temperature responsive, biohybrid and imprinted hydrogels. Section 11.3 focuses on sensor applications of intelligent hydrogels. Section 11.4 introduces drug delivery applications of intelligent hydrogels, such as in microfabricated devices and nanoscale structures.

## 11.2

### Intelligent Hydrogels

The molecular structure of polymer networks can be designed to result in preprogrammed and intelligent interactions with their environment. Of particular interest, environmentally responsive hydrogels have been synthesized that are capable of sensing and responding to changes to external stimuli such as changes to the pH, specific analytes and temperature, and recent reviews have highlighted the extensive research focused on developing new and applying current environmentally sensitive hydrogels [12–15]. The response mechanism of these hydrogel systems results from the chemical structure of the polymer network, such as the functionality of side-chain groups, branches and crosslinks.

#### 11.2.1

##### Ionic Hydrogels

In ionic hydrogels containing weakly acidic or basic pendent groups, differentials in water sorption can result from ionization of these pendent groups depending on the solution pH and ionic composition. In the ionized state, these hydrogels act as semipermeable membranes to the counterions influencing the osmotic balance between the hydrogel and the external solution through ion exchange, depending on ion–ion interactions. For ionic gels containing weakly acidic pendent groups, the equilibrium degree of swelling increases as the pH of the external solution increases, while the degree of swelling increases as the pH decreases for gels containing weakly basic pendent groups.

#### 11.2.2

##### Temperature-responsive Hydrogels

Temperature-responsive hydrogels are some of the most widely studied responsive hydrogel systems, with most systems based on poly(*N*-isopropyl acrylamide) (PNIPAAm) and its derivatives. The response to changes in temperature is due to a reversible volume-phase transition with a change in the temperature and these systems have been studied for a variety of applications, including in drug delivery and tissue engineering [13, 16]. This type of behavior is related to polymer phase separation as the temperature is raised above a critical value known as the lower critical solution temperature (LCST), e.g. PNIPAAm exhibits a LCST around 33 °C. Networks showing lower critical miscibility temperature are in a collapsed state above the LCST and the networks swell upon lowering the temperature below the LCST.

#### 11.2.3

##### Biohybrid Hydrogels

Biohybrid hydrogels can be created by integrating biological entities with synthetic hydrogels, and these systems have the potential to synergistically combine the well-

evolved biological mechanisms (e.g. high affinity and specificity of binding) and the tailorable hydrogel properties (e.g. mechanical stability and environmentally responsive nature). For example, research groups have immobilized enzymes within the network structure of hydrogels. Activated glucose oxidase has been incorporated into pH-sensitive cationic hydrogels. The glucose oxidase converts glucose into gluconic acid, lowering the pH of the local environment and causing the hydrogel network to swell in the case of a cationic gel [17]. In other work, Miyata and coworkers [18] prepared biohybrid hydrogels containing grafted antigen and corresponding antibody within the hydrogel network and demonstrated these systems to be responsive to a specific antigen. Furthermore, Wang and coworkers [19] have prepared hybrid hydrogels containing hydrophilic monomers and coiled-coil protein domains, which were demonstrated to exhibit a temperature-dependent swelling response based on the change in protein structure.

#### 11.2.4

#### **Imprinted Hydrogels**

Another class of intelligent hydrogels is based on molecularly imprinted polymers (MIPs), which are prepared using template-mediated polymerization techniques that create recognition domains able to specifically bind template molecules with high affinity. Although MIPs have been studied for more than three decades, imprinted hydrogel systems have only recently gained attention [20–23]. These systems are designed and synthesized to create chemical functionality and structure that is organized in a precise three-dimensional configuration, and these have potential application where controlled recognition properties to various biological analytes and physiological processes are required.

### 11.3

#### **Sensor Applications**

By tailoring the response properties of hydrogel systems, they can be optimized for application in sensor devices. In particular, environmentally responsive hydrogels have been applied as sensing elements for development of novel sensor platforms. For example, hydrogels have been utilized as actuation elements where the mechanical response of the network was applied to actuate various transduction elements. In other examples, hydrogel matrices have been used for optical sensing platforms and electrical sensing platforms. In the following, selected examples are highlighted.

#### 11.3.1

#### **Actuation Detection**

The mechanical response of hydrogels resulting from network swelling with changes in ambient environmental conditions can be used to actuate a transduc-

ing element to create a sensor platform. For example, Grimes and coworkers [24, 25] demonstrated wireless pH sensors utilizing the actuation response of pH-responsive hydrogels integrated with magnetoelastic thick films. The sensor device functioned by monitoring the change in resonance frequency due to applied mass load of the magnetoelastic sensor device. In other research, Han and coworkers [26] demonstrated a constant-volume hydrogel osmometer as a novel sensor platform. The concept was illustrated with a device where a pH-responsive hydrogel was confined between a rigid semipermeable membrane and the diaphragm of a miniature pressure sensor, where changes in the osmotic swelling pressure of the hydrogel resulting from changes pH were accurately measured via the pressure sensor. Although the device was of macroscale in dimensions, the design can be easily miniaturized for microscale or even nanoscale sensor development.

Recently, microelectromechanical system (MEMS) sensor platforms have been applied in a wide variety of applications. Gerlach and coworkers [27] developed piezoresistive sensors which measured the swelling of hydrogel systems by monitoring the deflection of the silicon membrane within the sensor chip (Fig. 11.1). Specifically, two systems, i.e. a network based on a poly(vinyl alcohol) (PVA) and poly(acrylic acid) (PAA) blend and a network based on PNIPAAm, were applied in

**Figure 11.1.** Operational principle of hydrogel-based sensors: (a) with PVA/PAA hydrogel layer, deposited onto the bending plate and (b) with PNIPAAm foil piece in a cavity. (1) Bending plate; (2) mechano-electrical transducer (piezoresistive bridge); (3) swellable hydrogel; (4) Si chip; (5) socket; (6) tube; (7) interconnect; (8) solution; (9) grate [27].

this sensor platform to develop pH and organic solvent concentration sensors, respectively. In other work, a MEMS sensor based on a capacitive pressure sensing technique and an uncrosslinked poly(2-hydroxyethyl methacrylate) (PHEMA) hydrophilic polymer was demonstrated [28]. An inductor–capacitor (LC) LC circuit was utilized to enable wireless detection of the sensor response.

MEMS sensor platforms based on micro/nanocantilevers have also been of high interest, as a result of their ultrahigh sensitivity. For example, environmentally responsive hydrogels have been integrated with silicon microcantilevers to develop an ultrasensitive bioMEMS sensor platform (Fig. 11.2). Specifically, a pH microsensor was demonstrated based on a methacrylic acid based pH-responsive hydrogel [29, 30] and this was the first demonstration of a microscale MEMS sensor device where actuation is controlled by an intelligent polymer network. In similar work, Thundat and coworkers [31] have demonstrated a variation on this sensor platform by integrating hydrogels responsive to  $\text{CrO}_4^{2-}$  with commercial silicon microcantilevers to create  $\text{CrO}_4^{2-}$  sensors. More recently, another variation has been demonstrated where hydrogels containing benzo-18-crown-6 coated on microcantilevers to create  $\text{Pb}^{2+}$  sensors [32].

In other research, Richter and collaborators [33] investigated the suitability of a quartz crystal microbalance as a transducer element for hydrogel-based liquid sensors. A blend of PAA and PVA was polymerized onto the sensor surface, and the system was demonstrated to have response time of 500 ms for a pH change from 1.8 to 3.1. Ionic hydrogels, microparticles [34] and thin films [35, 36] have also been applied for the detection of  $\text{CO}_2$  gas by measuring the pH decrease that occurs when  $\text{CO}_2$  diffuses through a gas-permeable membrane and into an electrolyte solution. A commercially available pressure sensor was used for the transduction of the swelling event and a schematic of the device is included in Fig. 11.3.

### 11.3.2

#### Optical Detection

There have been various optical-based detection schemes applied to hydrogel-based systems, and a few of these are highlighted in the following. For example, researchers have demonstrated a multianalyte hydrogel biosensor array platform which consists of analyte specific features that are indexed by shape [37]. The platform was based on lithographically patterned PEG diacrylates that contained biomolecules for oligonucleotide and cell-based sensing applications.

In other research, McShane and coworkers have developed a novel hydrogel microsphere sensor platform based on polyelectrolyte-coated calcium alginate microspheres (Fig. 11.4) [38, 39]. In particular, glucose oxidase was encapsulated with an oxygen-quenched ruthenium compound, allowing for the detection of glucose concentrations. The polyelectrolyte multilayer films were nanoscale in thickness (around 10–100 nm), and were used to stabilize enzyme entrapment and control of substrate diffusion.

**Figure 11.2.** Hydrogel as a sensing element in a bioMEMS sensor platform. (a) A schematic of the bioMEMS sensor platform based on a microcantilever patterned with an environ-

tally responsive hydrogel. (b) A detailed examination of the equilibrium bending response versus pH (constant ionic strength of 0.5 M) is shown [30].

**Figure 11.3.** Cross-section and exploded view of the hydrogel-based CO<sub>2</sub> sensor [35] (permission pending).

**Figure 11.4.** Illustration of nanoengineered microspheres optical glucose sensors. (a) A functional schematic of the microsphere sensor. (b) Confocal laser scanning micrograph of an actual prototype glucose sensor (red fluorescence = O<sub>2</sub> indicator in alginate microsphere, green fluorescence = reference fluorescence in polyelectrolyte film) [39].

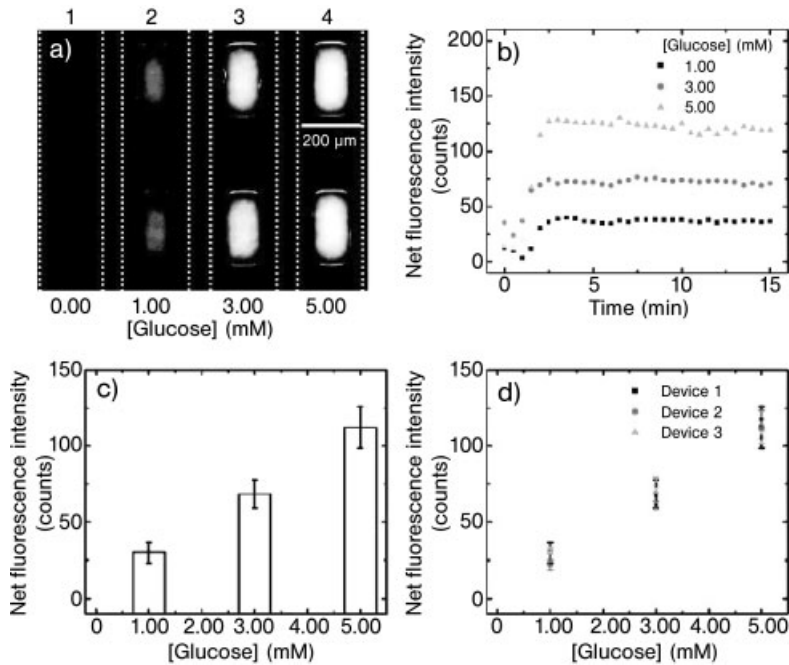

**Figure 11.5.** A multiphenotypic microdevice containing (left to right) hepatocytes, macrophages and endothelial cells stained with calcein AM [41].

Other researchers have applied hydrogel microstructures as three-dimensional scaffolds for the encapsulation of living cells [40–42], and these structures have potential advantages in the development of cell-based sensors for detecting chemical and biological toxins, and for assaying cellular responses to target compounds (e.g. drug screening). For example, a multiphenotypic whole-cell microsensor platform (Fig. 11.5) was demonstrated that could monitor cell viability via optical methods [41]. This platform enabled the comparison of the toxic effect of concanavalin A on macrophages and hepatocytes relative to the relatively unaffected endothelial cells.

By incorporating enzymes within hydrogel networks, biosensing elements can be fabricated. These biohybrid structures can be advantageous by allowing the precise control over the micro/nanoenvironment of the enzymes. In addition, these biohybrid structures can be patterned at the micro/nanoscale, allowing for their integration into sensor devices [43–45]. Pishko and coworkers [43, 44] have applied photolithography techniques to pattern hydrogel arrays containing immobilized enzymes, such as alkaline phosphatase, acetylcholinesterase and urease. The enzymes were conjugated to pH-sensitive fluorophores, allowing for optical detection of the changes in microenvironment pH due to the enzyme-catalyzed reactions. In addition, Crooks and coworkers [45] have demonstrated a microfluidic biosensor based on arrays of hydrogel-entrapped enzymes (micropatches). This platform was applied to simultaneously detect different concentrations of the same analyte (e.g. glucose) and multiple analytes in real time (Fig. 11.6).

Nanoscale probes encapsulated by biologically localized embedding (PEBBLEs) have been developed by Kopelmann and collaborators [46], and these sensing and imaging probes range from 20 to 600 nm in diameter, and are often constructed of hydrogel networks (e.g. polyacrylamide). For information on recent activities in this area, the reader is referred to a recent review of the topic [46].

**Figure 11.6.** Biosensor based on hydrogel-containing microchannels. (a) Fluorescence micrograph obtained 15 min after solutions containing 0.10 mM Amplex Red plus different concentrations of glucose (shown at the bottom of each channel) were introduced into each of the four channels. The flow rate was  $1.0 \mu\text{L min}^{-1}$ . Each micropatch contained both glucose oxidase and hydrogen peroxidase. The fluorescence emission was integrated for 0.7 s. The dashed white lines indicate the positions of channel walls. (b) Time-dependent net fluorescence intensity profiles collected from the hydrogel micropatches shown in the top row of (a). The net fluorescence intensity was obtained by subtracting the intensity of the

micropatch in channel 1 (no glucose present) from the fluorescence intensities arising from the micropatches in channels 2–4. (c) Graph showing the average net fluorescence intensity as a function of the glucose concentration for the three micropatches present in each channel of the device shown in (a). The error bars represent  $1\sigma$  for the three micropatches. (d) Plot of net fluorescence intensity as a function of glucose concentration for three independently prepared microfluidic devices. The error bars represent  $1\sigma$  for the three micropatches in each channel of each device. Fluorescence micrographs were obtained with a Photometrics 16-bit gray scale CCD camera [45].

### 11.3.3

#### Electrical Detection

Several research groups have patterned biohybrid hydrogels containing immobilized oxidoreductase enzymes, such as glucose oxidase, lactate oxidase and alcohol oxidase, onto electrodes to create biosensors for monitoring various analyte levels [47–50]. For example, Jimenez and coworkers [50] fabricated enzymatic microsensors that employed polyacrylamide as a entrapment matrix for immobilization of enzyme recognition elements, including glucose oxidase and urease, that was pat-

terned onto a pH-sensitive ion selective field-effect transistor (FET). In other work, Sheppard and coworkers developed miniature conductimetric pH sensors based on the measurement of the conductivity of pH-responsive hydrogels that were photolithographically patterned onto planar interdigitated electrode arrays [51–53]. The sensor monitored the changes in the electrical conductivity of the hydrogel membrane that resulted with its swelling/collapsing. In related work, Guiseppe-Elie and coworkers [54] demonstrated chemical and biological sensors that applied conducting electroactive hydrogel composites as recognition elements and utilized electrochemical detection.

In the above sensor applications, the majority of patterning applications of hydrogels have relied on UV photolithography and, thus, have been limited to microscale applications. For the application of hydrogels in nanoscale sensing applications, it is critical that nanopatterning techniques are developed, and this is a new area receiving much research attention. For example, Libera and coworkers [55] have applied electron-beam crosslinking methods to pattern amine-terminated PEG thin films on silicon substrates with lateral dimensions of order of 200 nm (Fig. 11.7). It was demonstrated that the amine groups remained functional after electron-beam exposure, enabling the covalent attachment of proteins of interest.

**Figure 11.7.** AFM images of a  $5\ \mu\text{m} \times 5\ \mu\text{m}$  array of amine-terminated PEG hydrogels with an inter-gel spacing of 715 nm. (A) Dry, (B) hydrated and (C) height profiles of a row of nanogels which swell by a factor exceeding 5 times [55].

## 11.4 Drug Delivery Applications

For the application of hydrogels as intelligent carriers in controlled drug delivery, researchers have optimized their properties by engineering their physical and chemical properties at the molecular level, such as permeability for sustained release applications, environmentally responsive nature for pulsatile release applications, surface functionality for targeted or stealth release (PEG coatings) and biodegradability for bioresorbable applications [12, 15, 56, 57]. In particular, environmentally responsive hydrogels have been applied in a wide variety of controlled drug delivery applications, since they allow for release that is controlled by the conditions of the environment. For example, temperature-responsive hydrogels have been widely used to create drug delivery systems exhibiting a pulsatile release profile in response to temperature changes [13, 16]. In addition, pH-responsive hydrogels have been applied in numerous controlled release applications, such as

**Figure 11.8.** Two valves formed at a T-junction in a microfluidics device, one made of a gold–colloid nanocomposite hydrogel and the other a gold–nanoshell nanocomposite hydrogel. The channels are 100  $\mu\text{m}$  wide. (a) When the entire device was illuminated with green light (532 nm, 1.6  $\text{W cm}^{-2}$ ), the gold colloid valves

opened while the nanoshell valve remained closed. (b) However, when the device was illuminated with near infrared light (832 nm, 2.7  $\text{W cm}^{-2}$ ), the opposite response was observed. In both cases, the valves opened within 5 s [65].

PEG-containing ionic networks that have been applied for the oral delivery of proteins, including insulin [58, 59] and calcitonin [60, 61].

In therapeutic applications, polymeric micro/nanotechnologies have found widespread application in the form of implantable devices, functional particles and tissue engineering constructs. The reader is directed to Ref. [62] for detailed information on the application of hydrogel nanoparticles. In the following, the application of hydrogels as functional components of devices is highlighted, and there is also a brief mention of nanoshell hydrogel structures.

#### 11.4.1

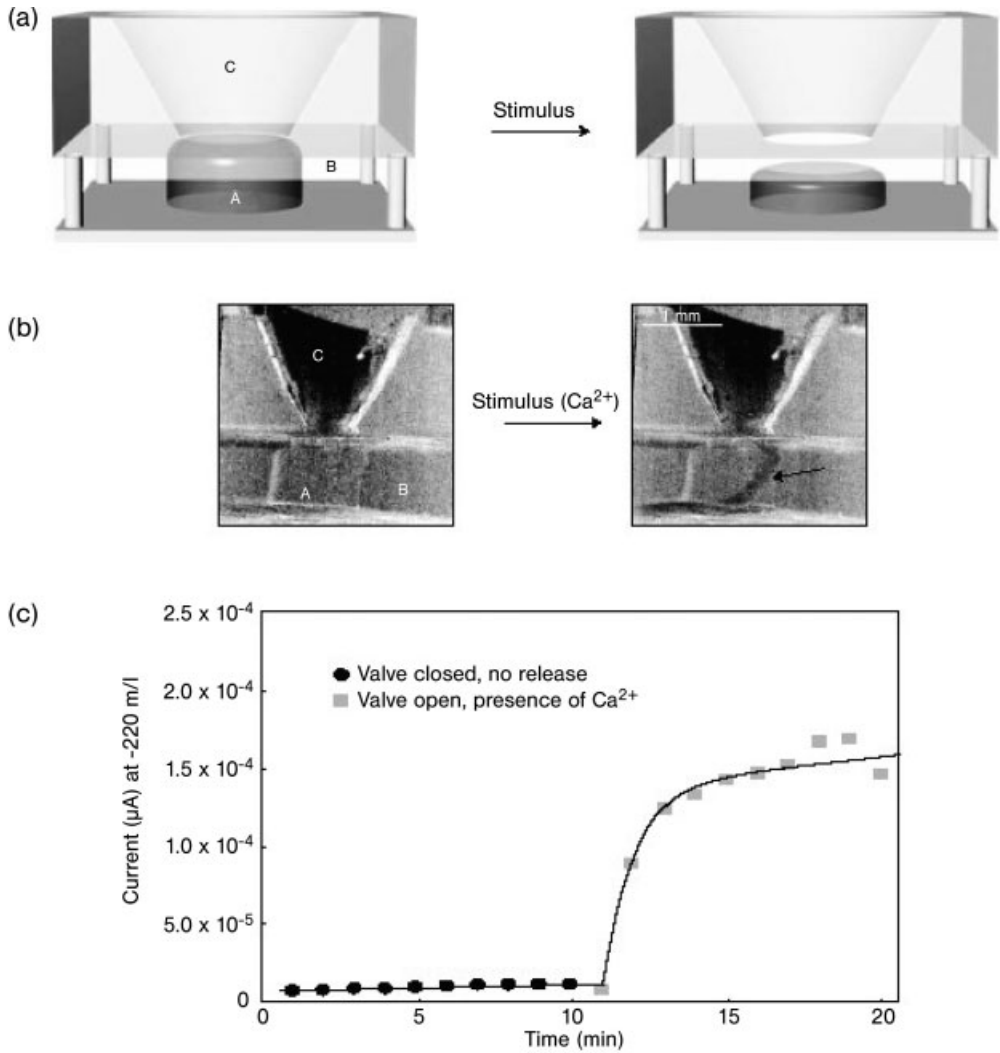

##### **Micro/nanoscale Devices**

In a recent review, polymeric systems for implantable drug delivery systems have been highlighted [63]. In recent years, several controlled drug delivery devices where a target release is controlled by hydrogel valves have been proposed [64–67]. Optomechanically responsive nanocomposite hydrogels have been developed based on poly(*N*-isopropylacrylamide-*co*-acrylamide) and particles with distinct and strong optical-absorption profiles (gold colloids and nanoshells) [64, 65]. These nanocomposite hydrogels were photopatterned as valves in a microfluidics device and their wavelength dependent actuation was demonstrated (Fig. 11.8). Recently, Daunert and collaborators [66] developed novel biohybrid hydrogel systems that exhibited stimuli responsive swelling due to  $\text{Ca}^{2+}$  and applied these as valves in a microdevice (Fig. 11.9). Madou and coworkers [67] developed electro-active polymers for application as microvalves potentially for controlled drug delivery.

#### 11.4.2

##### **Nanoscale Macromolecular Structures**

In recent years, there has been increased interest in the practical application of organic chemistry, and its molecular-level control, for the preparation of nanostructured macromolecular structures with tailored properties and functions [68]. A prime example has been the work of Wooley and coworkers [69–72], where well-defined nanostructured materials have been created by organizing polymers into micellar assemblies followed by stabilization through intramolecular crosslinking of the chain segments that compose the polymer micelle shell [shell crosslinked knedel-like (SCK)]. In Fig. 11.10, a schematic of the synthetic approach for preparing SCK polymer assemblies is provided. These SCK nanostructures have great potential as nanoscale intelligent drug delivery carriers, such as their ability to be tailored to be entirely hydrophilic and responsive to environmental conditions [70], be functionalized for targeted drug delivery applications (e.g. cancer cell targeting) [71], and be mineralized on their surface to further control dissolution and permeability properties for controlled drug delivery applications [72].

**Figure 11.9.** Incorporation of hydrogels in microfluidic systems. (a) Schematic of microactuator ‘plunger’ configuration. The stimuli-responsive hydrogel (A) shrinks in the presence of a stimulus in the bulk solution (B) allowing release from a reservoir (C). (b) The

release of a solution containing blue dextran and an electrochemical probe [hexamine ruthenium chloride(III)] in the presence of a stimulus ( $\text{Ca}^{2+}$ ). Arrow denotes release plume. (c) Electrochemical response of probe during the release event [66].

**Figure 11.10.** The general synthetic approach for the preparation of SCK polymer assemblies involves a combination of self-assembly and covalent stabilization, providing robust nanostructured materials from supramolecular, dynamic precursors [69].

## 11.5

### Conclusions

This chapter has highlighted the recent activities in the field of intelligent hydrogels, with a focus on the applications in sensing and drug delivery micro/nanotechnologies. The field of intelligent hydrogels was introduced and several example systems (e.g. ionic, temperature-responsive, biohybrid and imprinted hydrogels) were highlighted. Selected sensor and drug delivery applications of intelligent hydrogels were introduced and briefly discussed. Although this is a new field, the potential is clear with many expected applications where intelligent hydrogel systems will positively impact the fields of sensing and drug delivery.

### Nanoshells for Drug Delivery

Melgardt M. De Villiers and Yuri M. Lvov

#### 12.1

##### Introduction

Nanomedicine, especially the field of nanopharmaceuticals (drugs and drug delivery systems), describes the preparation of nanoscale assemblies, which can be relatively simple nanoemulsions, nanoparticles or polymer conjugates (of proteins or drugs), or complex multicomponent systems containing drugs, proteins or genes, arrays of targeting ligands and/or signal systems to enable *in vitro* or *in vivo* detection. Therefore, nanopharmaceuticals is defined as the science and technology of nanometer-sized complex drug delivery systems, consisting of at least two components, one of which is the active ingredient. In this field the concept of “nanoscale” is seen to range from 1 to 1000 nm. Currently just one nanoparticle product – Abraxane® (an albumin nanoparticle containing paclitaxel) – has been approved, but many more are being developed and are in phase I, II or III of the drug development process. This means that this class of drug delivery systems is rapidly growing, and is moving from the development of individual building blocks to multifunctional, often biomimetic and bioresponsive systems [1, 2].

These more complex nanosized drug delivery systems are either self-assembling or involve covalent conjugation of multicomponent systems, e.g. drug, protein and polymer. The bioresponsive and/or biomimetic materials used to create such drug delivery systems typically include synthetic or semisynthetic polymers, and/or natural materials such as lipids, polymers and proteins. One nanosystem that is being proposed as a drug carrier is nanoshells or nanocapsules because these novel “nanoparticles” can address the three principal goals of drug delivery research today, i.e. more specific drug delivery and targeting, greater safety and biocompatibility, and faster development of new, safe medicines. Current research in nanoshell drug delivery could lead to, amongst others, vectors that will overcome the biological barriers for effective gene delivery, cancer targeting, brain delivery and the combination of the potential of antibody targeting with nanoparticle technology. This would improve drug targeting to the whole body or cellular and subcellular localization of drugs, proteins and genes [2].

The nanoshells most studied as potential nanopharmaceuticals are metallic nanoparticles composed of a dielectric (e.g. silica) core coated with an ultrathin metallic (e.g. gold) layer and nanoshells formed by electrostatic layer-by-layer molecular self-assembling (E-LbL). Here, the two types of nanoshells are compared and their application in drug delivery illuminated. Although several reviews and chapters have appeared describing the properties of these nanoshells separately, this chapter focuses on the differences between the two types of nanoshells as it applies to drug delivery. As, to date, metallic nanoshells have found limited application in drug delivery the bulk of the chapter describes the assembly, characterization and properties of E-LbL self-assembled polymeric or polymeric/nanoparticulate nanoshell drug delivery systems.

## 12.2

### Metallic Nanoshells

In the past few years, silica–gold nanoshells have emerged as powerful building blocks for devices in which electromagnetic waves can be controlled at the nanometer length scale [1]. Due to this unique property, Halas and West demonstrated in a series of clever experiments how silica–gold nanoshells are uniquely suitable for use in whole-blood immunoassays, optically triggered drug delivery and targeted photothermal destruction of cancer cells [2]. The use of metallic nanoparticles dates back to the Renaissance when artists handcrafted vibrantly colored church windows and glass vases by dissolving minute amounts of noble metal impurities in a glass melt to induce precipitation of nanometer-size metallic clusters [3]. Gustav Mie provided the theory explaining this phenomenon [4]. This theory predicts that metallic nanoclusters strongly absorb visible light at a well-defined plasmon resonance frequency that depends on the particle size and shape, the presence of other particles, and the dielectric environment [5]. Due to this phenomenon the silica–gold nanoshells offer enormous flexibility to tune the resonance frequency by varying the relative dimensions of the silica core and gold shell [6, 7]. In contrast to solid-core metallic nanoparticles, the resonance of a silica–gold nanoshell particle can easily be positioned in the near-infrared (NIR) region between 800 and 1300 nm, where absorption by biomatter is low. Together with the high degree of biocompatibility of these nanoshells, low bioabsorption opens the door to a wide variety of biological applications.

#### 12.2.1

##### Synthesis of the Nanoshells

Numerous methods have been reported for preparing metallic nanoshells. For example gold nanoshells with a gold sulfide core and a gold shell are formed by combining specific volumes of 2 mM  $\text{HAuCl}_4$  and 1 mM  $\text{Na}_2\text{S}$ . The progress of the reaction is monitored using an ultraviolet (UV)/visible spectrophotometer to observe the extinction spectrum of the solution from 400 to 1050 nm [8, 9]. As

**Figure 12.1.** Schematic representation of the production of gold nanoshells by templating against silver nanoparticles [adapted from Ref. 10].

the nanoshells formed, the extinction spectra exhibit a peak that red-shifts into the IR, then halts and begin to blue-shift into the visible spectrum. The peak narrows and increase in magnitude as this occurs. Mercaptopropionic acid is added to halt this shift by halting the growth of the gold shell when the extinction peak is centered around 1050 nm. The solution then is adjusted to pH 10.5 with 1 M NaOH, centrifuged at 3000 r.p.m. for  $4 \times 20$  min and stored at 4 °C. The size and polydispersity of the resulting nanoshells are determined by evaporating a drop of the nanoshell solution onto a carbon film on a copper grid and viewing the nanoshells via transmission electron microscopy (TEM).

Sun and coworkers demonstrated a procedure based on replacement reactions for generating highly crystalline nanoshells from various metals [10]. The major steps involved are shown in Fig. 12.1 with gold/silver combination as an example. Since the standard reduction potential of the  $\text{AuCl}_4^-/\text{Au}$  redox pair is higher than that of the  $\text{Ag}^+/\text{Ag}$  redox pair silver nanoparticles are immediately oxidized to silver ions when mixed with an aqueous  $\text{HAuCl}_4$  solution. Elemental gold is thus confined in the vicinity of the template surface where it will nucleate and grow into small clusters and eventually will evolve into a shell around the silver template. The reaction initiates at facets with the highest surface free energy. As a result the thin shell formed initially is incomplete, and therefore both the  $\text{HAuCl}_4$  and  $\text{AgCl}$  will diffuse across the layer until the silver template is completely dissolved. The wall of each gold nanoshell can then be reconstructed into a highly crystalline structure via processes such as Ostwald ripening. Since stoichiometrically one gold atom is generated when three silver atoms are oxidized the thickness of the gold nanoshell is only one-ninth of the lateral dimension of the silver template.

In an alternative preparation method, Caruso and coworkers employed the LbL adsorption of polyelectrolytes and charged gold colloids to build shell-like structures around colloidal template particles whose surfaces have been derivatized with appropriately charged groups [11]. However, the gold nanoparticles prepared by all these methods are characterized by relatively low yields, problems with sur-

face roughness, polycrystallinity, nonuniformity in shell thickness, poorly defined composition and difficulty in removing colloidal templates without breaking the shells [12].

### 12.2.2

#### **Application in Nanomedicine**

In one study, Halas and West showed how NIR resonant nanoshells could be used to enable fast whole-blood immunoassays [13]. For conventional blood immunoassays, optical tests are performed at visible wavelengths. As a purification step needs to be performed to separate out a variety of unwanted biomaterials that absorb visible light, the whole procedure can take several hours or days. In the proposed immunoassay procedure nanoshells are conjugated with antibodies that act as recognition sites for a specific analyte. The analyte causes the formation of dimmers, which modify the plasmon-related absorption feature in a known way. The presence of analyte can then be determined by a fast absorption measurement in the water window, circumventing the time-intensive purification step.

Gold nanoshells can also be incorporated into temperature-sensitive hydrogels to synthesize a new type of composite material that collapses on laser irradiation [2]. Upon irradiation plasmon excitations are quickly damped and the electron kinetic energy is converted into heat through electron–phonon interactions. This fast damping is usually undesirable, but here the efficient light-to-heat conversion in metallic nanoshells is used to shrink the volume of the hydrogel from a remote location. The absorption cross-section of a nanoshell is about a million times larger than that of a typical molecular chromophore and hydrogel collapse thus occurs at relatively low pump-power densities. By incorporating nanoshells with different resonance frequencies, one can selectively collapse specific hydrogel volumes. Such remotely addressable hydrogels may find application in drug delivery and microfluidic valves or pumps.

For example, composites of thermally sensitive hydrogels and optically active nanoparticles have been developed for the purpose of photothermally modulated drug delivery [2]. Copolymers of *N*-isopropylacrylamide (NIPAAm) and acrylamide (AAm) exhibit a lower critical solution temperature (LCST) that is slightly above body temperature. When the temperature of the copolymer exceeds the LCST, the hydrogel collapses, causing a burst release of any soluble material held within the hydrogel matrix. When gold–gold sulfide nanoshells, a new class of nanoparticles designed to strongly absorb NIR light, were incorporated into poly(NIPAAm-*co*-AAm) hydrogels temperature changes in the hydrogel could be induced with light. Light at wavelengths between 800 and 1200 nm, which is transmitted through tissue with relatively little attenuation, was absorbed by the nanoparticles and converted to heat. Using this system, significantly enhanced drug release from composite hydrogels was achieved in response to irradiation by light at 1064 nm as shown in Fig. 12.2. This system controlled the release of methylene blue and proteins of varying molecular weight.

**Figure 12.2.** Release of BSA from nonirradiated and irradiated hydrogel with and without nanoshells. Irradiation was at 1064 nm at  $164 \text{ mJ pulse}^{-1}$ , 7 ns pulse length and 10 Hz repetition rate. (Adapted from Ref. [2].)

The nanoshell composite hydrogels can also release multiple bursts of protein in response to repeated NIR irradiation [2]. If the entire drug load is not released during the initial irradiation sequence, additional bursts of release of the drug can be elicited by subsequent irradiation. Once the laser irradiation is stopped, the driving force for the convective transport of material out of the hydrogel matrix is removed. During this time, the drug release is driven by diffusion and the amount released is much less than that generated by irradiation. The hydrogel will begin to swell as soon as the laser is turned off, returning to its equilibrium state. A second irradiation sequence delivered at this time will cause the hydrogel to collapse again, resulting in another burst of release of the “drug” molecule. Such a release pattern for bovine serum albumin is shown in Fig. 12.2. This type of release profile may be useful in insulin therapy as well as in other applications where controlled pulsatile release of a drug is necessary.

Additionally, it has been speculated that metallic nanoshells could play a role in future cancer treatments. These particles are small enough to find their way through the human circulatory system on injection. Bioactive molecules can be attached to the nanoshell surface to cause selective binding or accumulation of these particles within a tumor. Using a NIR laser, carcinoma tissue can then be destroyed by local thermal heating around the nanoshells. For example by tuning the nanoshells to strongly absorb light in the NIR, where optical transmission through tissue is optimal, a distribution of nanoshells at depth in tissue can be used to deliver a therapeutic dose of heat by using moderately low exposures of extracorporeally applied NIR light [14]. In this study, human breast carcinoma cells

incubated with nanoshells *in vitro* were found to have undergone photothermally induced morbidity on exposure to NIR light (820 nm,  $35 \text{ W cm}^{-2}$ ), as determined by using a fluorescent viability stain. Cells without nanoshells displayed no loss in viability after the same periods and conditions of NIR illumination. Likewise, *in vivo* studies under magnetic resonance guidance revealed that exposure to low doses of NIR light (820 nm,  $4 \text{ W cm}^{-2}$ ) in solid tumors treated with metal nanoshells reached average maximum temperatures capable of inducing irreversible tissue damage ( $\Delta T \sim 38 \text{ }^\circ\text{C}$ ) within 5 min. Controls treated without nanoshells demonstrated significantly lower average temperatures on exposure to NIR light ( $\Delta T < 10 \text{ }^\circ\text{C}$ ). These findings demonstrated good correlation with histological findings. Tissues heated above the thermal damage threshold displayed coagulation, cell shrinkage, and loss of nuclear staining, which are indicators of irreversible thermal damage. Control tissues appeared undamaged.

Due to all these positive developments, the design and fabrication of new types of plasmonic metallic nanostructures have seen a flurry of activity. In particular, the unique properties of nanoshells seem to promise a golden future for metallic nanostructures in drug delivery and it will be fascinating to see what other applications arise in the near future [12–14].

### 12.3

#### Nanoshells Formed by Polyion E-LbL Self-assembly

This nanoencapsulation method involves the formation of an outer nanothick shell around a core that is stable, permeable, compatible and allows the release of the core material through the shell. In the last decade, E-LbL self-assembly has been developed as a practical and versatile nanoencapsulation method to form nanoshells. The core templates may be “passive” (such as 50–300 nm latex or silica), which later will be dissolved, or “active” and functional (such as drug micro/nanocrystals). Tailoring of the different components of individual particles becomes important in order to develop these functionalized colloids, i.e. to combine several properties in one core–shell structure. Due to these advantages E-LbL assembly has the capacity to employ a great variety of substances as shell constituents as well as core material. Only general aspects of the method had been elaborated to demonstrate its potential, and it still has to be further developed and better understood [15–20].

#### 12.3.1

##### Preparation of E-LbL Nanoshells

The sequential adsorption of oppositely charged colloids was reported in a seminal paper in 1966 by Iler [21]. The technique of E-LbL self-assembly of thin films by means of alternate adsorption of oppositely charged linear polyions was then further developed in earnest starting in the early 1990s [22–25]. The basis of the

**Figure 12.3.** The procedure of E-LbL self-assembly on two-dimensional substrates and three-dimensional micro/nanotemplates. Particles with negative surface charge is coated with a layer of polycation (step 1). This

reverses the surface charge, which is then coated with an anionic polyelectrolyte (step 2). The original surface charge change is restored and the surface is ready for further assembly (step 3). (Adapted from Refs. [20, 22].)

method involves resaturation of polyion adsorption, resulting in the reversal of the terminal surface charge of the film after deposition of each layer (Fig. 12.3) [20, 22].

As a standard approach for film preparation on a solid support, the following steps are employed [22, 24, 26]:

- (i) Take aqueous solutions of polyion, nanoparticles or protein at a concentration of  $0.1\text{--}1\text{ mg mL}^{-1}$  and adjust the pH in such a way that the components are oppositely charged.
- (ii) Take a substrate carrying a surface charge [e.g. plates or polymer films covered by a layer of cationic poly(ethylenimine) (PEI) which may be readily attached to many surfaces].
- (iii) Carry out alternate immersion of the substrate in the component's solutions for 10 min with 1 min of intermediate water rinsing. To rinse a sample use a solution with pH that keeps the polyions ionized.
- (iv) Dry the sample using a stream of nitrogen (note that drying may hinder the assembly process and it is not necessary for the procedure).

The method provides the possibility of designing ultrathin multilayer films with a precision better than 1 nm of defined molecular composition. To date, this method has been used with more than 50 different charged macromolecules. The polyions predominately used in the assembly are:

- Polycations: PEI, poly(dimethyldiallylammonium chloride) (PDDA), poly(allylamine) (PAH), polylysine, chitosan.
- Polyanions: poly(styrene sulfonate) (PSS), poly(vinylsulfate), poly(acrylic acid) (PAA), dextran sulfate, sodium alginate, gelatin, chondroitin, heparin, DNA.

These charged materials can be combined with enzymes, antibodies, viruses and inorganic nanoparticles to produce multifunctional shells in both two- and three-dimensional nanoassembly processes. The architecture of these shells can be designed with nanometer precision (in cross-section) to meet different requirements such as thickness, biocompatibility, controlled permeability, targeting and optical or magnetic properties.

The only crucial factor for successful deposition is the surface charge reversal upon deposition of layers, which can be achieved by choice of proper deposition conditions. Since then various polyelectrolyte species could be adsorbed onto the surface of solid or liquid materials by means of electrostatic adsorption, forming layered structures with unique properties. It has been established that films can contain more than 1000 polyelectrolyte multilayers [27]. The universal character of the method does not impose any restriction on the type of polyelectrolyte. The multilayers can also produce diverse shapes when various materials beside polyelectrolytes, such as organic, inorganic nanoparticles and crystals, biomolecules, lipids and viruses, are used in the coating process. Such a coating produces complicated laminated structures. The use of polymers as the coating component is often advantageous in comparison with employment of their low-molecular-weight analogs. Mechanical strength, elasticity, electrical, optical and other properties make them unique building blocks for the creation of composite materials. In addition, the incorporation of proteins and nucleic acids in multilayer films may lead to the application as biosensors and in biotechnology [28–30].

The latter may even provide the base for development of ultrathin multistep chemical catalysts or photosynthesis systems mimicking plants. Applications can also be found in the fabrication of optical devices [31] and gas separation membranes [32]. The efficient use of this unique multilayer coating is interlinked with investigations of their properties. Although the methods for studying multilayer properties are straightforward, they are very often not applicable or are time consuming because of the low amount of material studied and the possible influence of the surface used as a support for layer growth. To eliminate the first factor, one should drastically increase the total surface of the multilayers, which can be done by using colloidal particles as templates [33]. Dissolution of the colloidal core could avoid the second objection. The derived hollow capsules allow the study of polyelectrolyte multilayers at the liquid–liquid interface, which seems to be very difficult while working on the solid support [23, 34].

These developments show that after the first publications on nanoshell formation in 1992–1999 [15–17], the structure of nanoshells has been characterized and the procedures to increase the functionality of the nanoshells have been elaborated through the efforts of several research groups [18, 22, 30]. For example, pore openings in these polyion multilayers were first discovered by Mendelsohn and co-

workers [35], and then later applied for enzyme loading into nanoshells by Lvov and Caruso [18]. This growth in our knowledge regarding E-LbL nanoshell fabrication, structure and properties has led to noteworthy achievements that have many advantages. However, many practical clinical applications in nanomedicine remain to be developed.

#### 12.3.1.1 Proving the Nanoshells

For the time-dependent monitoring of the assembly *in situ*, a quartz crystal microbalance (QCM) is most often used because of its proven suitability [22, 36, 37]. First of all, the kinetics of the adsorption process can be delineated by the QCM technique, which is indispensable for establishing proper assembly conditions (e.g. saturation adsorption time). Multilayer assembly is generally characterized by means of the QCM technique in two ways: (i) after drying a sample in a nitrogen stream we measure the resonance frequency shift and calculated an adsorbed mass by the Sauerbrey equation or (ii) by monitoring of the resonator frequency during the adsorption process onto one side of the resonator which is in permanent contact with the polyion solutions. Frequency shifts of about 800 Hz are seen for every adsorption cycle in solution QCM, which is more than that detected, for example, for a dried film of PSS/PAH. This difference is ascribed to the strong hydration of the layer that had just been adsorbed. The bound water is included in the film and is removed after drying. This means that most polyion films swell by 40–60% before drying and that only 5–10% of the water remains in polyion films after drying.

It is assumed that polyion adsorption occurs in two stages: quick anchoring to a surface and slow relaxation. To reach a surface charge reversion during linear polyion adsorption one needs a concentration greater than  $10^{-5}$  M [36]. However, the dependence of polyion layer thickness on concentration is not great because in the concentration range of 0.1–5 mg mL<sup>-1</sup> the PSS/PAH pair yielded a similar bilayer thickness. A further decrease in polyion concentration (using 0.01 mg mL<sup>-1</sup>) decreased the layer thickness of the adsorbed polyion. Other the other hand, an increase in the component concentrations to 20–30 mg mL<sup>-1</sup> may result in the nonlinear (exponential) enlargement of the growth rate with adsorption steps, especially if an intermediate sample rinsing is not long enough [38].

In addition, at the beginning of the alternate assembly process one often sees nonlinear film growth [36, 39]. As shown in Fig. 12.4, in the first two to three layers, smaller amounts of polyion are adsorbed as compared with further assembly, when the film mass and thickness increase linearly with the number of adsorption cycles. Tsukruk and coworkers [40] explained this as an island-type adsorption of the first polyion layer on a weakly charged solid support. In the following two to three adsorption cycles these islands spread and cover the entire surface, and further multilayer growth occurs linearly. If a substrate is well charged then a linear growth with repeatable steps begins earlier.

In addition to measuring weight changes with a QCM, following changes in the UV spectra is another simple method to control LbL assembly on glass or quartz slides. After every other layer one can measure the sample UV spectra and use Beer's law (absorbance is proportional to the material mass) to judge the amount

**Figure 12.4.** Frequency shift and film thickness of each assembly layer for PDDA + (PSS/PDDA)<sub>2</sub> + (PSS/gelatin)<sub>4</sub> adsorption on QCM electrodes. The first four-layer precursor is about 4 nm thick. The averaged frequency shift of every gelatin layer is 483 Hz, corresponding to a thickness of 8 nm.

of adsorbed polymer and whether the assembly process linear with number of adsorbed layers. Figure 12.5 shows the UV spectra for three, five, seven and nine bilayers of PSS/PAH deposited on quartz slide. There is a linear increase of absorbency with an increase in the number of layers; therefore, the mass of the film was increasing linearly too. The absorbance maximum at 225 nm corresponds to the absorbency of benzyl rings of PSS.

**Figure 12.5.** The increase in absorbance with an increase in the number of PSS/PAH layers deposited on a glass slide. The insert show the linear increase in layer mass.

**Figure 12.6.** Changes in the  $\zeta$  potential of the coated dexamethasone particles as a function of the number of adsorption steps for capsule composition of dexamethasone core/(PDDA/gelatin A)<sub>4</sub>/PDDA (broken line and open squares) and dexamethasone core/PDDA/(PSS/gelatin A)<sub>4</sub>/(PSS/PDDA)<sub>1</sub> (solid line and open triangles). dexamethasone core/(PDDA/PSS)<sub>4</sub>/PDDA (solid line and solid squares),

Another method to monitor the assembly process is to ensure the reversal of charge after each polyion coating as shown in Fig. 12.6 [41]. For this the  $\zeta$  potential of the suspended nanoshells is measured after each layer has been applied. If the solid support (e.g. drug crystal) with negative surface charge is, for example, incubated in a solution containing a cationic polyelectrolyte, a layer of polycation is adsorbed. As the adsorption is carried out at a relatively high concentration of polyelectrolytes, a number of ionic groups remain exposed at the interface with the solution and thus the surface charge is effectively reversed. The reversed surface charge prevents further polyion adsorption. Solid supports or microtemplates are then rinsed with pure water or washed by centrifugation, respectively, to remove excess free polyions. The surface is then immersed in a solution of anionic polyelectrolytes. Again, a layer is adsorbed, but now the original surface charge (negative) is restored and the surface is ready for further assembly. These two steps are repeated alternately until a layer of the desired thickness is obtained. More than two components can be used in the assembly as long as one condition, i.e. a proper alternation of positive and negative charge, is observed [20, 22, 41].

More detail structural information can be obtained from X-ray and neutron reflectivity data. X-ray or neutron reflectivity measurements of polyion films show patterns with profound intensity oscillations, the so-called Kiessig fringes, due to the interference of radiation beams reflected from solid support/film and air/film interfaces [42]. From the periodicity of these oscillations one can calculate the film thickness (with the help of the Bragg-like equation and taking into account refraction phenomena which are essential at small-angles). Growth steps for a bilayer of 1.1–2.0 nm are typical for alternate linear polyion assembly and a thickness of one

layer often equals half of this value [43]. These values correspond to a polyion cross-section and show that in one cycle of excessive adsorption we have approximately one monolayer coverage of the substrate. The nanoparticle/polyion bilayer thickness is determined by the diameter of the particle. Model fitting of X-ray data gives a surface roughness of the polyion film of order 1 nm, while atomic force microscopy (AFM) and scanning electron microscopy (SEM) data revealed a surface roughness of 1–2 nm [42]. Polyion films are insoluble in water and in many organic solvents and are stable to 250–280 °C [44].

The polycation/polyanion bilayer thickness depends on the charge density of the polyions. It was shown that more than 10% of polyion side-groups have to be ionized for a stable reproducible multilayer assembly via alternate electrostatic adsorption [45]. High ionization of polyions results in a smaller step of film growth (1–2 nm) and lower ionization gives a larger growth step (3–6 nm). It can be reached either by adding salt to a polyion solution (as discussed above for strong polyelectrolytes, such as PDDA and PSS) or by varying the pH for weak polyelectrolytes [46].

#### 12.3.1.2 Influence of the Core on Nanoshell Properties

So far it has been shown that the procedure of E-LbL nanoshell formation is a multistep process. Although the further properties of capsules depend strongly on the choice of polyelectrolytes employed and adsorption conditions, such as ionic strength, temperature, solvent composition, number of layers, etc., an extremely important step in determining the success of the experiment is the proper choice of the cores type [27]. This is especially important when fabricating intact capsules consisting only of the material used during the coating – the process of core dissolution should result in 100% elimination of the core without affecting the polyelectrolyte multilayers. In fact, the molecular weight of core components is typically 100 times more than that of the polymers forming the shell and the task of complete core removal seems to be complicated from a chemical point of view. At present, cores that have been exploited to template hollow capsules can be classified into three groups differing by dissolution properties and chemical interaction with polyelectrolyte components of the shell [27].

The first class is made up of organic cores made of water-insoluble oligomers including the widely studied melamine formaldehyde (MF) cores dissolvable at low pH and in some organic solvents, polystyrene (PS) cores soluble in tetrahydrofuran (THF) and biofriendly poly(lactic acid)/poly(lactic-co-glycolic acid) (PLA/PLGA) soluble in acetone/*N*-methyl-2-pyrrolidinone mixture. The second class is made up cores that dissolves into small molecules and ions. These can be either ionic or molecular crystals soluble in acidic or basic conditions or in an organic solvent. At present, different carbonate particles ( $\text{CaCO}_3$ ,  $\text{CdCO}_3$  and  $\text{MnCO}_3$ ) [47] and  $\text{SiO}_2$  particles [48] have been used for polyelectrolyte multilayer templating. The main advantage of exploiting such inorganic particles is the absence of osmotic stress upon dissolution and complete elimination of the core. The third class of cores is made up of those subjected to strong oxidation. A biological cell is a typical example of this kind of cores. For example, the assembly of polyelectrolyte multi-

layers can be performed using fixed erythrocyte cells as templates [49, 50]. The removal of the cell cores can be achieved by oxidation with sodium hypochlorite solution. The main effect of changing the core is that the employment of a different core material will result in different permeability properties of the shell.

### 12.3.1.3 Barrier Properties of E-LbL Assembled Nanoshells

The barrier properties of nanoshells formed by E-LbL depend on film thickness, ionic strength and charge of the permeating molecule, temperature annealing, re-sealing by additional layers, and chemical modification. If the permeability of the polyelectrolyte multilayer is provided by diffusion through the entangled polymer network, it should scale with the inverse of the layer thickness. However, most studies show that the permeability decreases with increasing layer number much faster than expected for a straightforward thickness increase. Only from approximately eight layers onwards does the permeability multiplied by the shell thickness become constant, indicating that the permeability is now controlled by the thickness increase and the diffusion-limiting region relates to the properties of the polyelectrolyte layer [51]. Normally, the deeper layers are denser, resulting in a 5-fold reduction of the estimated diffusion coefficient, while the loose structure of the interfacial layers leads to a very slow increase in the dissolution time. This means that only the presence of the internal dense layers can slow down the dissolution time. For thinner walls, the drastic dependence on shell thickness may be explained either by the existence of pores that are successively closed by further layer deposition or by a thickness-dependent diffusion coefficient. Diffusion dependent on layer depth was indeed observed when the diffusion of polar labels in planar polyelectrolyte films was studied [51].

Another parameter that can influence the multilayers structure is the ionic strength [27]. It has been shown that the multilayer structure is affected if the salt concentration is changed once the film is built up. Polyelectrolyte multilayer vesicles can be subjected to temperature treatment that significantly influences their properties. For example, at temperatures up to 95 °C the polyelectrolyte capsules keep their integrity, but undergo irreversible structural changes [52]. The resulting structure is characterized by decreasing capsule diameter with simultaneously increasing shell thickness as revealed by scanning force microscopy (SFM). From thermodynamic point of view this effect can be explained by approaching the equilibrium state of polyelectrolyte complexes. In another example hollow capsules were fabricated by LbL deposition of oppositely charged diblock copolymers each containing a PNIPAAm block and a charged negative or positive block (20 mol%) [53]. PNIPAAm is known to undergo a phase transition at a temperature of 32 °C (the so-called LCST), after which it is not soluble. This transition is rather sharp and completely reversible upon cooling. The obtained capsules exhibit changes in morphology and permeability at elevated temperatures. However, this process is only partially reversible in the multilayers. Relaxation requires more than 1 month, which limits their thermosensitivity to one heating circle.

Chemical modification can be another way to induce the excessive charge into the polyelectrolyte multilayers and change other characteristics of the film. One

method proposed is using PAA, partially modified by Fisher esterification with different alcohols, as a multilayer constituent [54]. Depending on the nature of the derivatizing alcohol, the hydrophobicity of the film could be tuned. The hydrophobicity of ester groups was shown to result in advancing water contact angles to more than  $100^\circ$ . Crosslinking of these hydrophobic films via heat-induced amidation stabilized coatings over a wide pH range, but did not significantly influence their permeability. It has been proposed that crosslinking of the reactive groups in the multilayers is sometimes the only possibility of making films composed of weak polyelectrolytes stable at a wide range of pH and ionic strength. One example is PAA/PAH multilayers, which readily decompose upon a shift of pH or ionic strength, that can be crosslinked in order to gain stability [55]. In contrast, nanoshells composed of PSS/PAH multilayers have semipermeable properties [26]. They are permeable for small molecules, such as dyes and ions, while under most conditions high-molecular-weight compounds are excluded. One of the explanations for this is the much smaller size of the pores in the multilayer film in comparison with the hydrodynamic radius of the permeating molecule.

Filled capsules can also serve as microreactors [56]. This is advantageous because for macromolecules there is an advantage in encapsulating enzymes and proteins in general because their inaccessibility for inhibitors, proteases (which are polymers and cannot permeate the capsule wall) and, of course, for bacteria. This means the activity of enzymes encapsulated is higher as compared with typical values of chemically immobilized enzymes. In addition, the native conformation of proteins such as hemoglobin does not change upon encapsulation due to contact with the nanoshell because there was no change registered in the position of a so-called Soret band, which is very sensitive to the changes in the heme conformation. All these studies showed that the possibility exists to control and reversibly change the capsule permeability for both low- and high-molecular-weight molecules as shown in Fig. 12.7. This can be desirable for many applications, including drug delivery. This means that the exploration of the permeability properties of capsules and multilayers must be further developed because it promises many possibilities as drug carriers, biosensors, micro-reactors and catalysts, construction materials, etc. [56].

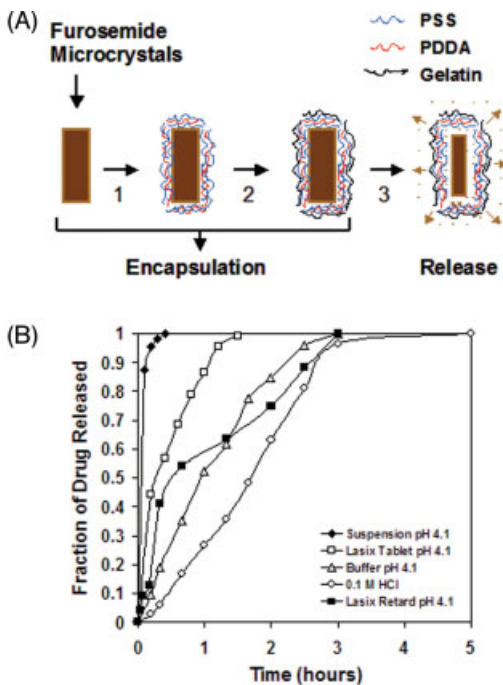

### 12.3.2

#### **Controlled Release of Active Pharmaceutical Ingredients Encapsulated by E-LBL Assembled Nanoshells**

A major challenge in the development of carrier systems of submicron dimensions lies in the field of advanced drug formulations, especially when it comprises the elaboration of delivery systems capable of providing sustained release of bioactive materials [27]. Mainly, these bioactive compounds are small molecules with different solubility and diffusion coefficients. If we consider only physical entrapment without any covalent binding in order to develop a delivery system, one has to encapsulate the active molecules within the shell proving certain release character-

**Figure 12.7.** (A) Polyelectrolyte microcapsules with (PSS/PAH)<sub>5</sub> wall composition loaded with FITC-labeled glucose oxidase (confocal image). (B) AFM tapping mode image of the same broken dry capsule on mica; release of the encapsulated material is visible. (Adapted from Ref. [56].)

**Figure 12.8.** (A) Illustration of furosemide microcrystal encapsulation and release study. In step 1, precursor layers of (PSS/PDDA)<sub>2</sub> are assembled onto positively charged furosemide microcrystals. In step 2, (PSS/gelatin)<sub>2-6</sub> layers are added. In step 3, drug release in aqueous solution was monitored at different pH values.

(B) Dissolution profiles of (PSS/PDDA)<sub>2</sub> + (PSS/gelatin)<sub>4</sub>-coated furosemide micro-particles compared to uncoated particles and a commercially available tablet in physiologically relevant media using the dissolution test described in the USP 24. (Adapted from Ref. [22].)

istics. The potential use of polyelectrolyte capsules with drug entrapped in the nanoshell for controlled drug delivery currently requires more study and is not well established. In contrast, microencapsulation of drug microparticles is a well-established technique for prolonging release. When microcapsules are coated with appropriate antigens, they can also be targeted to specific regions in the body. This can lead to lowered overall dosage requirements, increased drug concentrations in the necessary regions and reduced side-effects. Polymer- and liposome-based systems have been used for drug encapsulation, mostly as unordered drug-polymer conjugates [57–60].

The E-LbL self-assembly technique based on alternate adsorption of oppositely charged components was developed to add nanometer-thick films to surfaces [15, 17, 35, 61, 62], offering the opportunity to design controlled release systems by encapsulating micron-scale cores with a very thin outer shell. The core must be insoluble under some conditions, such as low pH, and soluble under the conditions at which controlled release is to take place. The release rate generally depends on the thickness of the encapsulating shell and the material used in the coating. Thicker shells lead longer release times.

#### 12.3.2.1 Nanoshell Permeability for Low-molecular-weight Compounds

In the first report on controlled release, fluorescent dye microcrystals were used as a model system for controlled release studies [24]. PSS and PAH were used to form a polyelectrolyte shell on the fluorescein core. Increasing the number of layers decreased the shell permeability and resulted in prolonged dye-core dissolution. Encapsulation of ibuprofen also resulted in prolonged release at different pH values [63]. The ibuprofen dissolution time from capsules with walls built from 15 bilayers of chitosan-dextran was 40 s at pH 7.4, compared to 10 s with no coating. Therefore, prolongation of the release was minimal.

To determine whether encapsulation by E-LbL assembly can substantially increase drug release time, the technique was used to assemble polypeptides and polyions on microcrystals of 5-(aminosulfonyl)-4-chloro-2-[(furanylmethyl)amino] benzoic acid, commonly known as furosemide [22]. Furosemide is a diuretic and antihypertension drug that is practically insoluble in water. Although the therapeutic effect is fast and intense after oral administration of furosemide, the oral bioavailability of the drug from an immediate release dosage form is poor and highly variable [64]. These problems can potentially be overcome by developing a modified release dosage form. Ai and coworkers encapsulated furosemide microcrystals with polyions and gelatin to control the release of the drug in aqueous solutions (Fig. 12.8) [22]. In step 1, precursor layers of (PSS/PDDA)<sub>2</sub> are assembled onto positively charged furosemide microcrystals. In step 2, (PSS/gelatin)<sub>2–6</sub> layers are added. In step 3, drug release in aqueous solution was monitored at different pH values. Charged linear polyions and gelatin were alternatively deposited on 5- $\mu\text{m}$  drug microcrystals through E-LbL self-assembly. Sequential layers of PDDA and PSS were followed by adsorption of two to six gelatin/PSS bilayers with corresponding capsule wall thicknesses ranging from 45 to 115 nm. They

then determined furosemide release from the E-LbL encapsulated crystals under two physiological pH conditions, i.e. pH 1.4 (stomach) and pH 7.4 (blood). At both pH values, the release rate of furosemide from the encapsulated particles was reduced by 50–300 times (for capsules coated with two to six bilayers) compared to uncoated furosemide. The results provide a method of achieving prolonged drug release through self-assembly of polymeric nanoshells on drug microcrystals.

In a study that further expanded the application of core–shell structures fabricated by E-LbL self-assembling for drug delivery, Pargaonkar and coworkers reported the controlled release of dexamethasone from microcrystals encapsulated with a polyelectrolyte shell [41]. The E-LbL self-assembly process was used to produce dexamethasone particles layered with  $\text{PDDA}^+$ ,  $(\text{PDDA}/\text{PSS})_4/\text{PDDA}$ ,  $(\text{PDDA}/\text{gelatin A})_4/\text{PDDA}$ , dexamethasone core/ $(\text{PDDA}/\text{gelatin B})_4/\text{PDDA}$  or dexamethasone core/ $\text{PDDA}/(\text{PSS}/\text{gelatin A})_4/(\text{PSS}/\text{PDDA})_1$ . The nanothin shells were characterized by QCM measurements, microelectrophoresis, microcalorimetry, confocal microscopy and SEM. The *in vitro* release of dexamethasone from the microcapsules suspended in water or carboxymethylcellulose (CMC) gels, measured using vertical Franz-type diffusion cells, showed that the assembly of multiple polyelectrolyte layers around these monodispersed cores produced a polyelectrolyte multilayer shell around the drug microcrystals which allowed for controlled release depending on the composition and the number of layers.

Ye and coworkers showed that indomethacin microcrystals can be directly encapsulated with polysaccharides sodium alginate and chitosan multilayers through LbL self-assembly [65]. The retention of the drug microcrystal was found to gradually decrease due to its partial dissolution in the deposition solution. It was very significant that increasing the deposition temperature from 20 to 60 °C reduced the release rate efficiently, due to the increase in multilayer thickness and formation of a more perfect multilayer film. This finding provides a new and simple method to control the permeability of the LbL assembled multilayer films.

#### 12.3.2.2 Nanoshell Permeability for High-molecular-weight Compounds

DNA and polynucleotides (polyuridylic and polyadenylic acids) can be readily assembled in alternation with polycations (PEI, PAH, polylysine) [66]. Alternate adsorption of 0.1 mg mL<sup>-1</sup> DNA at pH 5.2 with polycations gave multilayers with a DNA/PEI bilayer thickness of 4.4 nm and DNA/PAH bilayer thickness of 3.6 nm. Fourier-transform IR spectra confirmed the native double-stranded DNA conformation in DNA/PEI and DNA/PAH multilayers. Coating DNA/polyion films on medical implants may have applications in local gene therapy. In other studies, proteins including lysozyme, horseradish peroxidase, albumin, bacteriorhodopsin, immunoglobulins, glucoamylase, glucose oxidase (GOx), catalase, glucose isomerase and diaphorase were used at concentrations of 0.1–2 mg mL<sup>-1</sup> for LbL assembly [20]. As the surface structure of the solid support can affect the stability of proteins, precursor films of alternate PEI/PSS are normally used as standard surfaces.

Proteins immobilized in multilayers with strong polyions, such as PSS, PEI and PDDA, are insoluble in buffers in a pH range between 3 and 10. Protein multilayers with weak polyions are partially soluble in solutions with a pH close to the isoelectric point of one of the components, but such multilayers can be stabilized with crosslinking agents. Assembled proteins are in most cases not denatured [67, 68].

Nano-organized encapsulation of protein microcores such as insulin nanoparticles in the presence of high concentration of neutral polymers (PEG) was also elaborated with a LbL assembly. Uncoated insulin PROMAXX microparticles formed by controlled phase separation from hydrophilic compounds undergo to a fast dissolution if the PEG concentration is decreased [69]. Insulin release from PROMAXX was extended with LbL encapsulation. After the complex of insulin in the core and the first layer of oppositely charged polymer is formed, the microparticle is stabilized and adding new polyelectrolyte layers can be continued. Balancing strong interaction of the first polyelectrolyte layer with protein microcore and easing this interaction by depositing the second oppositely charge polyelectrolyte (polyanion/polycation for positive cores at pH 5.8 and polycation/polyanion for negative cores at pH 7.0) allowed us to control complexation of the encapsulated proteins and to reach a sustained insulin release. Fine tuning of the release profile was reached by using the third and fourth polyelectrolyte layer addition.

Therefore, the general idea of controllable complex formation is as follows. Adsorption of the first polyelectrolyte layer results in strong complex formation and very slow release. An addition of the second, oppositely charged polyelectrolyte layer results in relaxed complex and quicker release. The third oppositely charged layer again gives slower release, etc. Just growing thickness of the capsule walls within five to 10 bilayers (30–60 nm) did not slow insulin release from the microparticles. With this, the concept formulated in a Max Planck Institute research group [23, 24, 28] defining LbL multilayer as a tight diffusion barrier with adjustable thickness in the range of five to 12 bilayers was converted to a new approach where the main role in the controlled release from protein microaggregates is given to adjustable interpolyelectrolyte complex formation controlled by alternate polycation/polyanion coating of two to three monolayers.

E-LbL can also increase the stability of macromolecules as demonstrated for membrane-disrupting peptide that are easily degraded *in vivo* [70]. The peptides are important because when conjugated to peptide hormones they have been shown to specifically destroy primary tumors and metastases in mouse models. Consequently, the encapsulation and sustained systemic release of these peptides could further improve treatment efficacy by protecting the peptides from degradation. When silica nanoshells are coated by E-LbL with polyelectrolyte layers of gelatin B or CMC carrying the peptide drug, Phor21- $\beta$ CG(ala), the release kinetics of the embedded peptide drug, can be controlled and its potency to destroy breast cancer cells can be enhanced *in vitro*. The silica-peptide nanoshells produced by this process had a diameter of 450 nm, and the adsorption efficacy was 20% and was linear with an increasing numbers of layers. Up to 34% of the embedded Phor21- $\beta$ CG(ala) was released in a linear fashion from the CMC multilayers over

a period of 20 h. The release kinetics was dependent on the pH. *In vitro* toxicity to human breast cancer cells using gelatin B and CMC silica-peptide nanoshells showed that Phor21- $\beta$ CG(ala) was released from the multilayers, and the peptide retained its potency in destroying human breast cancer cells and did not cause aggregation of the peptide drug. This showed that E-LbL assembled silica-peptide nanoshells may be used not only for sustained release of a peptide cancer drug to treat primary tumors and metastases, but also to increase the stability of the active ingredient.

Taken together, all these studies demonstrate the successful controlled delivery of large biomolecules not only from a core encapsulated with a nanoshell, but also from the nanoshell where the active molecule was used in the construction of the nanoshell via the E-LbL process.

### 12.3.3

#### **E-LbL Assembled Nanoshells as Protective and Functional Barriers**

Nanoshells prepared by E-LbL self-assembly can be used as a new type of protective microcontainer, capable of preventing oxidation of encapsulated compounds by low-molecular-weight oxidizing agents [29, 30, 34]. These researchers developed protective polyelectrolyte microcapsules that effectively prevents the oxidation of encapsulated bovine serum albumin by a low-molecular-weight agent,  $H_2O_2$  (Fig. 12.9). Two approaches for designing protective capsule microcontainers were demonstrated. First, the “passive armor” approach is composed of a sacrificial reducing agent as a shell constituent, while the “active armor” approach includes the catalyst for  $H_2O_2$  decomposition deposited onto the shell as the outer layer. In the latter case, the protective material is not consumed during the  $H_2O_2$  treatment, thus prolonging the protection activity of the microcapsule. The designed microcontainers combine the protective function with the controlled release of the encapsulated substance and, moreover, can possess magnetic activity to perform magnetically adjusted delivery of the encapsulated material in aggressive media. Protective polyelectrolyte capsules can find applications as delivery and depot systems in medicine, drug industry and biotechnology. These results demonstrated the possibility of using developed microcontainers for preserving the bioactivity of different encapsulated enzymes such as urease, chymotrypsin, etc.

Another novel use of E-LbL nanoassembly is using biocompatible nanoparticulate  $TiO_2$  multilayers to coat photosensitive materials to increase their photostability. The added benefit of this process is that due to surface modification, an increase the dissolution rate and possibly the bioavailability of a poorly water-soluble drug can be achieved. The photostability of nifedipine microcrystals (35  $\mu$ m) coated with a nanoshell composed of multiple bilayers of positively charged PDDA and negatively charged nanosized  $TiO_2$  particles (20–25 nm) was increased because even with one  $TiO_2$  layer the shelf-life of nifedipine was increased by 30 h independent of the intensity of the light exposure, as shown in Fig. 12.10. With an increase in the number of  $TiO_2$  layers, the photostability of the drug was enhanced even more. In addition, a  $TiO_2$  monolayer decreased the contact angle by 20° for water

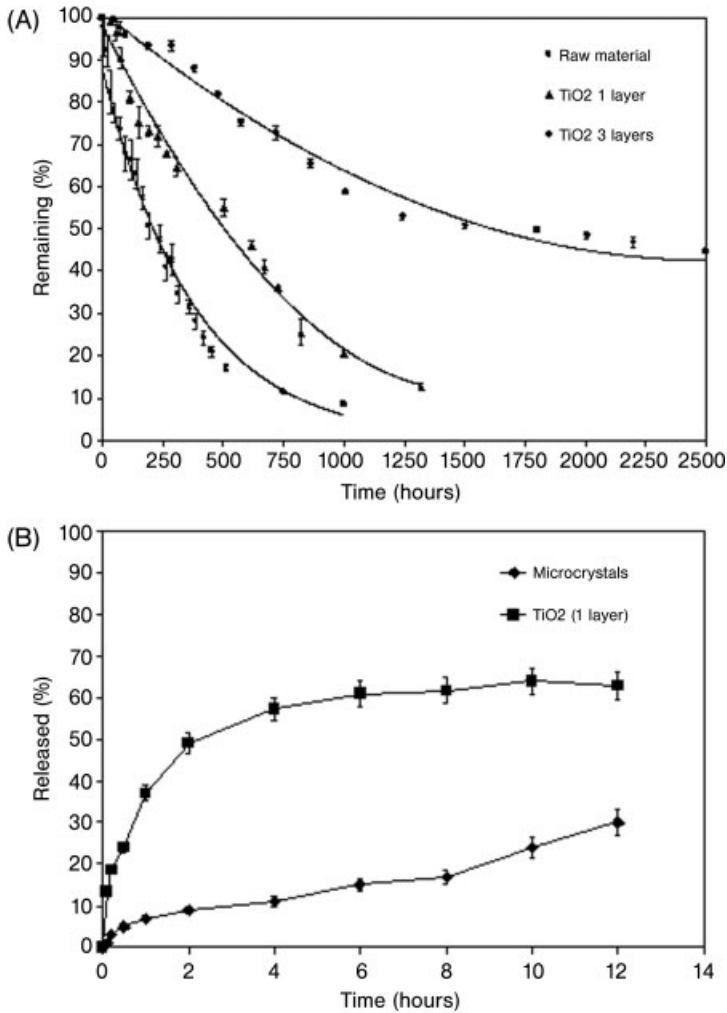

**Figure 12.9.** Schematic overview of the “passive” and “active” protection approaches for nanoengineered polyelectrolyte capsules. For “passive” shells (b and c), part of the  $H_2O_2$  is reduced by the PAH/PSS shell material. “Active” ones (d and e) combine

catalytic and redox mechanisms to provide a more efficient protection barrier. The magnetic activity of polyelectrolyte capsules doped with  $Fe_3O_4$  is also preserved after (and during)  $H_2O_2$  treatment. (Adapted from Ref. [33].)

and  $33^\circ$  for the dissolution medium as compared with uncoated nifedipine surfaces. This increase in wettability due to a decrease in contact angle increased the dissolution rate of nifedipine microcrystals coated with one PDDA/ $TiO_2$  bilayer 13-fold after 10 min, 5-fold after 1 h and 2-fold after 12 h when compared to uncoated microcrystals. It is assumed that  $TiO_2$  increased the photostability because the nanoparticulate multilayers act as a potential filter protecting the drug from damaging light rays reaching the drug crystals. The dissolution rate was increased because the hydrophilic  $TiO_2$  nanoparticles increased the aqueous wettability of the drug crystals, thereby preventing aggregation in the dissolution medium. This ensured that the maximum drug surface area was exposed to the dissolution medium.

The increased dissolution observed for  $TiO_2$ -coated drug particles showed that in addition to protecting the drug load, E-LbL nanoshells can also assist in changing the physicochemical properties of drug cores. This was also illustrated for dexamethasone where sonication during the layering process helped to reduce the particle size of the drug, thereby increasing the dissolution rate of this practically water-

**Figure 12.10.** (A) Decrease in the photostability of nifedipine microcrystals when LbL coated with nanosized  $\text{TiO}_2$  particles where exposed to an illuminance of  $12 \text{ W m}^{-2}$  corre-

sponding to a light dose of 30 klux. (B) *In vitro* release profiles for nifedipine showing the increase in the dissolution rate of the drug when coated with one layer of  $\text{TiO}_2$  nanoparticles.

insoluble drug, while also increasing the suspension stability [41]. For negatively charged micronized dexamethasone particles the effective adsorption of a first layer of PDPA during sonication as evidenced by microelectrophoresis measurement of the reversal in charge caused enhanced dispersability of the dexamethasone particles because of the colloidal stabilization produced by the positively charged PDPA coating combined with a significant reduction particles size to below  $2 \mu\text{m}$ . Stabilizing of the practically monodispersed particles also reduced the

**Figure 12.11.** Illustration of the monodispersion of micronized dexamethasone drug particles by E-LbL encapsulation followed by the subsequent controlled release of the drug through the insoluble porous shell.

Ostwald maturation of the colloidal particles of the scarcely soluble dexamethasone, thereby preserving the reduction in particles size and the integrity and the shape of the original crystals. A schematic of this process is shown in Fig. 12.11.

#### 12.3.4

#### Magnetic Nanoshells

By using the E-LbL assembly it is also possible to include magnetic nanoparticles (such as magnetite or cobalt) into the shell, thereby making the entire capsule magnetic. The example in Fig. 12.12 shows a 400-nm diameter capsule composed of a glucose oxidase core covered with a shell composed of two bilayers of 12-nm diameter magnetite alternating with cationic PEI. Deposition of magnetite nanoparticles provided a magnetic momentum that allowed the nano/bioreactors to be self-stirred and even be separated by the application of an external magnetic field [71].

In a further development based on this work, ferromagnetic cobalt nanoparticles coated with gold (Co@Au) were included in the capsule shell. With these particles, the application of a low-frequency rotating magnetic field rotated these particles, eventually providing shell distortion and release of the capsule content (Fig. 12.13) [72]. While looking at these functional capsules it is important to underline that the effect is not due to hypothermal heating because this effect works at much

**Figure 12.12.** A 400-nm diameter GOx core coated with (PSS/PEI)<sub>2</sub> + (magnetite/PEI)<sub>2</sub> shells. The 12-nm diameter magnetite nanoparticles are visible on the surface.

higher frequencies of the magnetic field. However, a magnetic field to modulate the permeability of polyelectrolyte microcapsules prepared by LbL self-assembly was also explored. For this purpose 5-nm diameter ferromagnetic Co@Au nanoparticles were embedded inside capsule walls. The final 5- $\mu\text{m}$  diameter microcapsules had wall structures consisting of four bilayers of PSS/PAH, one layer of Co@Au and five bilayers of PSS/PAH. Applying an external alternating magnetic field of 100–300 Hz and 1200 Oe rotated the embedded Co@Au nanoparticles. This rotation subsequently disturbed and distorted the capsule wall, and drastically increased its permeability for macromolecules like fluorescein isothiocyanate (FITC)-labeled dextran. The capsule permeability change was estimated by taking the capsule interior and exterior fluorescent intensity ratio using confocal laser scanning microscopy. Capsules with one layer of Co@Au nanoparticles and 10

**Figure 12.13.** SEM images of (a) hollow capsules with (PSS/PAH)<sub>11</sub> and (b) magnetic capsules with one layer of embedded Co@Au [(PSS/PAH)<sub>4</sub>(PSS/Co@Au)<sub>1</sub>(PSS/PAH)<sub>6</sub>] (both in the dry and collapsed state).

polyelectrolyte bilayers were optimal for magnetically controlling permeability. In this study the authors provided a theoretical explanation for the permeability control mechanisms. What is important to realize is that “switching on” of these microcapsules using a magnetic field makes this method a good candidate for controlled drug delivery in biomedical applications.

### 12.3.5

#### **Nano-organized Shells with Functions other than a Adjustable Diffusion Barrier**

##### **12.3.5.1 Colloidal Stabilization**

The above discussions have focused on the concept of nanoshell assembly based on the possibility to design multilayer walls with controllable diffusion which may include active defense of the capsule interior. One of the advantages of this approach is using in mild cooperative electrostatic interaction not involving covalent bonding that may disturb drug molecules structure (especially for enzymatic drugs). One of disadvantages of this technology is the necessity of a multistep deposition process which often may be reached only after 10–16 sequential adsorption steps. During development of this technique, we found that not only slow drug release is in demand, but colloidal stabilization and faster release for poorly soluble drugs are also important. In such an application, one does not need many adsorption steps that produce a thick nanoshell and we can convert submicron insoluble drug particles to stable colloids with controllable fast release only with two to three deposition steps as shown in Fig. 12.11.

##### **12.3.5.2 Interpolyelectrolyte Complex Formation**

Working with soft protein microcores (such as insulin), the crucial importance of interpolyelectrolyte complexation between the shell polyelectrolyte layers and the protein core was shown [69]. In this case, the shell grows “roots” into the core and for controlled release the optimization of this complex formation is more important than just increasing of number of polymer layers in the shell wall [69]. To illustrate this, nano-organized encapsulation of protein microcores in the presence of high concentrations of a neutral polymer (PEG) was elaborated using the E-LbL process. This is important because it was found that uncoated insulin microparticles formed by controlled phase separation from hydrophilic compounds undergo fast dissolution if the PEG concentration is decreased. For the same insulin, when E-LbL encapsulation was used, the microparticle was stabilized after complexation of the insulin core with the first layer of oppositely charged polymer. This meant that the addition of new polyelectrolyte layers was easier. However, balancing the strong interaction of the first polyelectrolyte layer with the protein microcore was crucial, and the controlled release depended on the second and subsequent layers because this interaction was decreased by depositing the second oppositely charge polyelectrolyte. This allows for the control of complexation of the encapsulated proteins with the first polyelectrolyte layer until sustained release of the insulin is achieved. The general idea of controllable complex formation can be summarized as follows. First, adsorption of the first polyelectrolyte layer results in strong com-

plex formation and very slow release. Addition of the second, oppositely charged polyelectrolyte layer results in a relaxed complex and quicker release. The third oppositely charged layer again gives slower release, etc. Therefore just increasing the thickness of the capsule walls within five to 10 bilayers (30–60 nm) did not slow insulin release from the microparticles. With this, the concept formulated earlier [69] where the LbL multilayer was considered as a tight diffusion barrier with adjustable thickness is now converted to a new approach where the main role in the controlled release from protein microaggregates is governed by adjustable interpolyelectrolyte complex formation controlled by alternate polycation/polyanion coating of as few as two to three monolayers.

### 12.3.5.3 Biomimetic Approach

The concept of using E-LbL shells to act as a nonbiological (engineered) replica allows the reproduction of the shape and maybe even some organization features of biological cells and viruses. Ai and coworkers [73] demonstrated the E-LbL nano-coating of blood platelets. This nanocoating included an antigen outermost layer for targeting these cells to antibody-coated regions in a capillary that simulated a blood vessel. Using this approach, other small biological cores may also be reproduced through shell formation. For example, the nonbiological replication of the shape and dimensions of a virus with E-LbL nanoassembly is a feasible goal to develop, for example, a viral-like drug delivery vehicle. Figure 12.14 gives preliminary results for the design of a nanoparticulate shell replica of bacteriophage Sd that has an average diameter of 78 nm. As can be seen for the transmission electron microscopy (TEM) images, the nanocapsule E-LbL assembly may be a good instrument for designing artificial virus systems to serve as intercellular drug carriers. In addition, with this nano-architecture, the E-LbL method can be used to reproduce some features of the virus structure, such as certain protein or lipid layers, in the replica shell, making this drug nanocarrier very similar to the virus. This means that treatment with such replicas will follow the same biological path as the viral infection.

**Figure 12.14.** TEM images of bacteriophage Sd used as a template for the formation of a 8-nm silica nanoparticle shell (right image with the icosahedra shape), overall diameter  $D = 78$  nm, clearly showing the small tail or “basal plate”. The DNA core diameter is 68 nm and protein shell thickness is about 5 nm.

## 12.4

### Conclusion

Nanoshells present a unique class of nano/microparticles with a wide range of potential application in nanomedicine. The most exciting include the possibility of engineering very small and/or very thin structures that through experimentation can be developed into reproducible and reliable platforms that integrate micro/nanotechnologies for the advanced delivery and targeting of drugs. In addition they can be used to immobilize and copy cells or viruses, and to trap, embed and protect small and macromolecules on surfaces. Although this field is still in its infancy, many ongoing developments (and the products produced) offer some unique opportunities for possible clinical applications that still need to be explored. Concurrently exploring of these technologies can also lead to the development of very sensitive *in vivo* testing methods and targeted *in vivo* diagnostic systems. The ultimate goal is to combine delivery, sensing and targeting into a single multifunctional nanoshell.

These novel possibilities should ensure that the future for nanoshell technologies remains bright. As we learn more about the construction and permeability properties of these nanothick shells, their applications as drug carriers, biosensing devices, microreactors, etc., are becoming clearer. This is especially true if one looks at recent research results that have uncovered the effect of and the controlled use of variables such as pH, ionic strength and temperature to modulate not only the fabrication of nanoshells, but also to control the permeability of these shells. Progress in the understanding of these principles of multilayer construction, interaction of charges within the shell and competition of various interactions within the crowded environment of polyelectrolyte layers is vital for the future progress in the area of responsive metallic and polyelectrolyte nanoshells.

In addition, answering the fundamental questions of the effect of self-assembly conditions and the strength of intermolecular adhesion within nanoshells and their effect on the rate of macromolecular rearrangements in responsive films and the permeation rate of solute molecules within or from nanoshells may enable the rational design of nanoshells with specific response characteristics. Hopefully, unraveling these fundamental properties may lead to new strategies in the construction of responsive coatings, e.g. those that respond to multiple stimuli and deliver multiple active molecules in a controlled way, thus producing novel drug delivery systems.

Last, but not least, we speculate that nanoshells could play a role in the future treatment of specific diseases such as cancers. These particles can be designed in such a way that they are small enough to find their way through the human circulatory system after injection. Bioactive molecules can be attached to the nanoshell surface, trapped within the shell or covered by the shell to cause selective binding or accumulation of these particles within a tumor. Using external sources such as magnetic fields or heating with a NIR laser, carcinoma tissue can then be destroyed by local effects such as thermal heating around the nanoshells.

To conclude, nanotechnology as represented by nanoshells can provide numerous advances for medicine. It might revolutionize methods used in medical science, enabling future medicine to become even more successful in its objective to save lives. We believe that the examples mentioned here represent a small fraction of the future advances that will come from nanoshells. We also believe that although the two methods to prepare nanoshells have the same foundation, there is no evidence that the future developments obtained using the two methods will be equivalent. The presence of some trends and research data leads us to believe that the versatility of polyelectrolyte LbL nanoencapsulation currently makes its wide application in drug delivery perhaps more promising. However, it will be fascinating to see what new applications arise in the future for both these systems.

# Bionanoparticles and their Biomedical Applications

*L. Andrew Lee, Hannah N. Barnhill, and Qian Wang*

### 13.1

#### Introduction

Bionanotechnology is a newly emerging field in which novel nanomaterials are developed from biological building blocks. Primary building materials, DNA and peptides (or peptidomimetics), have been extensively studied as starting materials for nanomaterial synthesis [1–4]. Other basic elements derived from Nature's own designs include the virus and virus-like particles, ferritins, and other self-assembled protein cages such as heat shock protein (Hsp) cages [5] and some enzyme complexes [6]. These biogenic systems self-assemble based on multiple noncovalent interactions to become highly organized scaffolds with robust physical properties. These bionanoparticles (BNPs), in particular, offer fascinating structural features and sophisticated chemistries, yet are under the control of malleable genetic information. These qualities are exploited to tailor the BNPs at the atomic and molecular scales with specific functionalities (i.e. biomedical applications, supramolecular chemistry, etc.). Moreover, Hsp cages and ferritin average 12 nm in diameter, and the different viral cages span from 15 [7] to 160 nm [8], offering an extensive array of sizes.

Distinctive features of BNPs, in comparison to synthetic nanoparticles, make these biomaterials attractive for the following reasons:

- Monodispersed particles with uniform size distributions.
- Three-dimensional structures characterized at atomic or near-atomic levels.
- Genetic control over the composition and surface properties.
- High stability and organization of self-assembled architecture in nanometer ranges.
- Economic large-scale production in gram and kilogram quantities.

The aim of this chapter is to provide an overview in BNP programming and its current research in biomedical applications. There is a growing interest in BNPs as new biomaterials for directing cellular processes, such as cell growth and differentiation. Multiple ligands and peptides can be anchored to the biomaterials with

predetermined nanometer spacing to act as homing signals for tissue-specific targeting, and these precise adornments on the nanosystems can even be transferred to more complex schemes for host immune evasion or activation. Notable nanosystems already in clinical uses as vaccines are the recombinant chimeric hepatitis B virus (HBV) particles [9] and the virus-like particles of human papillomavirus [10, 11]. The highly ordered and repetitive structures of BNPs facilitate pattern recognition by the immune systems and, consequently, are of a great benefit in protective immunity induction [12, 13]. Additionally, both genetic and chemical tools can be used to mold the scaffolds, which ultimately allows the precise control over the spatial layout of functional groups at the molecular level.

The different methods involved in manipulating the viruses and ferritins without affecting the self-assembly process is covered in section 13.2. In the following section, there is particular emphasis on controlling the orientation and density of ligands decorated on the surface of biomolecular shells via chemical and genetic methods. Then the following sections in this chapter have been divided and devoted to the various programmed functionalities of the protein-based nanoparticles: cell targeting, gene/drug delivery, bioimaging, vaccine development, immune response modulation and, lastly, the future directions of BNP research.

### 13.2 BNPs

Viruses provide a wide array of shapes such as rods and spheres, and a variety of sizes spanning from tens to hundreds of nanometers. These protein structures are evolutionary tested, multifaceted systems with highly ordered spatial arrangements, and natural cell-targeting and genetic information-storing capabilities. The years of dissecting the details of virus infection, replication and assembly pathways have imparted a wealth of information on the stabilities and functionalities of these materials. The structural information provided by X-ray crystallography, nuclear magnetic resonance and previous mutagenesis studies lay the firm, primary foundation for viral vector redesign. Intricately fashioned, multifunctional BNPs for various biomedical applications have spun off from viral vector-based gene therapy and vaccine development founded on the polyvalent antigen display on virus coat proteins. Virus-based assemblies are, and continue to be, a major point in the nexus of bionanotechnology.

Ferritin, another primary building block in bionanoscience, is a highly conserved protein complex that spans approximately 12–13 nm in diameter as a tetracosameric protein shell. The interior shell measures approximately 7–8 nm in diameter and encapsulates the mineralized iron core. This protein shell is endowed with astounding thermal and pH stabilities, along with tremendous resistance to denaturation in high ion concentrations to act as protein templates for inorganic material synthesis. The biomineralization with a variety of other metal atoms in apoferritin,

the hollow protein shell without the iron core, exemplifies this concept of using such a biological template for inorganic nanoparticle synthesis [14–16].

Although research on viruses and ferritin outweighs the other protein cages, new systems such as chaperones [5, 17] and carboxysomes [18] have sprung up as possible alternative protein cages for bionanosciences. The characterizations of these systems are in much earlier phases compared to the preceding nanosystems of viruses and ferritin, but each individual system is a potential novel nanomaterial for future chemistries and genetic reprogramming. These platforms, derived from protein-based systems like viruses and ferritin, offer a high degree of spatial organization with well-characterized self-assembly motifs – a quality that can be of major advantage in BNPs for controlling functional group density and orientation. Many of these protein shells permit biological modifications by genetic insertions of foreign peptide sequences and orthogonal chemistries to alter the native protein to incorporate multiple functionalities.

Viruses and other BNPs have been previously employed as vaccine carriers and gene therapy vectors [19–23], but the potential applications of viruses and BNPs for chemical reactions and material synthesis have not been systematically explored until recently. Current research topics in BNP chemistry can be broadly classified as host–guest chemistry (including biomineralization and phage display), controlled self-assembly and bioconjugate chemistry.

BNP-based inorganic materials development has advanced greatly over the past few years, pioneered by S. Mann, T. Douglas (together with M. Young) and A. M. Belcher. Mann and coworkers have prepared magnetic nanoparticles with apoferritin as nanoreactors by biomimetic syntheses [14]. Douglas, Young and coworkers have made important contributions in the syntheses of inorganic nanoparticles with cowpea chlorotic mottle virus (CCMV) and other protein cages as templates [15, 24–28] or catalysts [16]. Belcher and coworkers' work on using filamentous bacteriophage M13 to bind and align nanocrystals in an ordered array is another example of harnessing the logic of biological synthesis for nanomaterial development [6, 29, 30]. Genetically modified M13 have been used as templates to align inorganic, organic and biological nanosized materials into nanowires [31, 32], nanorings [33], nanofibers [34], films [35, 36] and other nanostructures [29, 37–39].

In addition to the organic reactions of ferritin and adenovirus [40–44], there have been many recent developments in the chemoselective organic modifications of BNPs. Finn and coworkers have extensively quantified the organic chemical reactions of viruses as molecular entities [45–48]. Cowpea mosaic virus (CPMV) has been demonstrated to be a robust platform for conjugation with a variety of molecules, including fluorescent dyes [45–48], poly(ethylene glycol) (PEG) chains [49], stilbene derivatives [45], biotin [47, 48], DNA, peptides [50], antibodies [45] and carbohydrates [51]. This strategy permits the covalent installation of functional groups in multiples of 60 at well-defined locations. Following CPMV, the chemical reactivities of many other viruses have been studied, including CCMV [52], *Nu-daurelia capensis*  $\omega$  virus (N $\omega$ V) [53], tobacco mosaic virus (TMV) [54], small Hsp

[5], turnip yellow mosaic virus (TYMV) [55, 56] and bacteriophage MS2 [57]. In short, BNPs provide chemists and material scientists with conveniently accessible scaffolds whose structure and functionality can be genetically programmed and manipulated.

These protein shells are treated as complex chemical compounds that can be utilized as vehicles for drug/gene delivery [58–60], two-dimensional ordered arrays [35], nanowire synthesis [31], depositions on films or polymers or even biocomposite material synthesis [29, 32, 34, 37–39]. The precise manipulation of these platforms relies heavily on the multidisciplinary integration of organic synthesis, molecular, structural and cell biology, and bio-organic chemistry to devise, functionalize and analyze these complex macromolecular structures. These disciplines are unified under a unique theme of re-engineering the self-organizing biological systems in the nanometer range with molecular specificity for a strategic purpose – gene or drug delivery, eliciting an immune response or *in vivo* bioimaging.

### 13.3

#### Genetic and Chemical Alterations of BNPs

##### 13.3.1

##### Chemical Modifications

Although a few organic reactions of ferritin and adenovirus have been reported [40–44], it was not until recently that the chemoselective organic modification of BNPs has been studied systematically. In all the cases, the accessibility is the key to the reactivity of a functional residue on BNPs. In other words, if a functional side-chain is exposed on the surface (either interior or exterior) or is accessible to the reactant, it generally can be modified.

##### 13.3.1.1 Conventional Bioconjugation Methods for Selective Modifications

The conventional way to modify the BNP relies on the protein chemistry, particularly the reactivity of the functional groups of the side-chains. The amino group of lysine residues (Lys), the thiol group of cysteine residues (Cys), the carboxylic groups of glutamic acid (Glu) and aspartic acid (Asp), and the phenol groups of tyrosines (Tyr) are among the best for chemical modification (Fig. 13.1) [61]. If accessible Lys, Cys, Glu/Asp and Tyr can be found or created, they should be able to be derivatized. In addition, orthogonal reaction conditions are generally required to modify a group of residues selectively without interference with the other functional groups.

CPMV, as a prototype of icosahedral viruses for organic reactions, is now well understood from the studies of Finn and Johnson groups over the past 5 years [45–48, 51, 62, 63]. The particle has been found to be highly rigid in the X-ray crystal structure, such that residues are shown to be hindered and remain inaccessible to chemical reagents in solution.

**Figure 13.2.** Structure of the pentameric units of CPMV coat protein with lysines marked in blue. (A) Top view of the space-filling model showing the exterior surface-exposed lysines. (B) Side view of the ribbon diagram of the pentamer with all lysines highlighted. Most of the lysines locate at the interior surface of the protein cell to bind to the RNA inside.

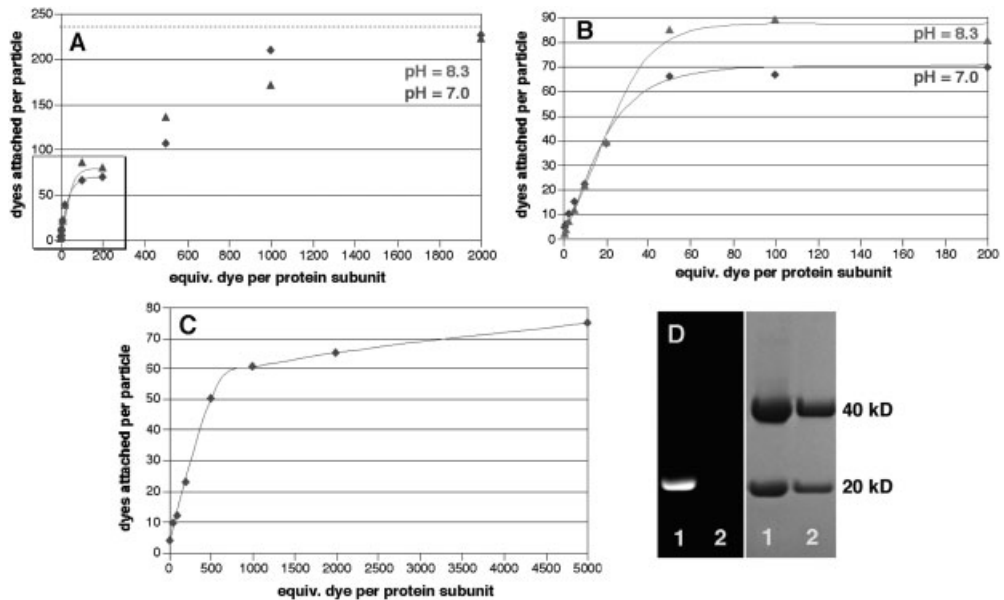

**13.3.1.1.1 Lysine Reactivity** Figure 13.2 shows the space-filling and ribbon diagrams of the outside surface of the CPMV pentameric unit. Only five lysine residues appear to be exposed to the solvent on the exterior, whereas at least 10 are found on the interior surface, presumably involved in electrostatic interactions with the packaged RNA genome and therefore unreactive with external reagents. In initial studies, fluorescent dyes were employed as probes to monitor the reactivities of CPMV. The exposed lysines of wild-type CPMV were reacted with fluorescein *N*-hydroxysuccinimide (NHS) ester **1** and isothiocyanate **2**, which are reagents selective for reactions with available lysine residues (Scheme 13.1) [48].

**Scheme 13.1.** Chemical modification of CPMV at reactive lysines and cysteines (virus shown in a schematic manner).

The particles were very stable, which can withstand the organic reagents and the conditions. The integrity of the modified viral particles was confirmed by sucrose gradient sedimentation, transmission electron microscopy (TEM) and fast protein liquid chromatography (FPLC) analysis. Covalently modified virions were separated from excess dye reagents by multiple passages through size-exclusion columns until dye was undetectable in the wash solution and the relevant absorbance ratios for the virus samples were constant. Nonspecific dye adsorption to the virus had not been observed. The stoichiometries were determined by absorption measurements on solutions of labeled particles by comparison of the intensities of dyes (495 nm for fluorescein) to viruses (260 nm), each having nonoverlapping bands with well-established molar absorptions.

At neutral pH, wild-type CPMV was found to be readily labeled by NHS esters at room temperature, up to a ratio of between 60 and 70 dye molecules per virion, in a dose-dependent fashion through a reagent ratio (dye:viral protein) of 200:1 (Fig. 13.3B). Pushing the reaction with greater amounts of 1 (up to

**Figure 13.3.** Relationship of the ratio of reactants (Scheme 13.1) to the number of attached dyes per CPMV particle. (A) Results of reactions using fluorescein NHS ester 1, showing the full range of ratios of the reactants used. (B) Expansion of the boxed area in (A). (C) Results of reactions using fluorescein isothiocyanate (FITC) 2. (D) Sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE): lanes 1, CPMV-

*N*-fluorescein prepared using reagent 2, containing approximately 50 dyes per particle; lanes 2, underivatized wild-type CPMV. (Reprinted from Ref. [48], © 2002, with permission from Elsevier.)

dye:protein = 4000:1) gave a maximum loading at both pH 7.0 and 8.3 of about 240 dyes per virion, indicating that four lysine residues per asymmetric unit are accessible under forcing conditions (Fig. 13.3A). The isothiocyanate reagent proved to be less reactive and thus more selective, requiring approximately 1000 equivalents to get a loading of 60 dyes per virus particle (Fig. 13.3C). Further increasing the amount of isothiocyanate dye by a factor of 5 resulted in only a modest increase in the number of dye molecules attached per virion. Electrophoresis of the resulting particles under denaturing conditions showed predominant lysine reactivity at lower loading (50 dyes per particle using isothiocyanate 2) to be associated with the small subunit (Fig. 13.3D).

NHS esters and isothiocyanates are very efficient reagents to modify accessible lysines on BNP. For example, fluorescent dye 1 has also been applied to derivatize the lysines of CCMV [52] and the small Hsp (MjHsp) cage from *Methanococcus jannaschii* [5]. The latter has been used in selective attachment and release of chemotherapeutic agents [64]. A similar strategy has been applied to study the differentiated reactivities of lysine residues of  $N\omega$ V virus-like particles (VLPs) during a pH-induced conformational change [53].  $N\omega$ V is a single-stranded RNA icosahedral insect virus, whose capsid is composed of 240 copies of the 70-kDa subunit protein. The VLPs of  $N\omega$ V are readily produced using a recombinant baculovirus system. At pH 7.6 the coat protein assembled into a stable (“procapsid”) particle, which is 480 Å in diameter and quite porous. Upon lowering the pH to 5.0, a concerted reorganization into a 410-Å diameter mature capsid structure occurs. The

**Figure 13.4.** (A) Cryo-electron microscopy analysis results of Nanogold-modified CPMV with the density of gold labeled with a golden color. The electron densities of gold clusters were generated by subtracting density computed with the native CPMV X-ray structure from the density of Nanogold-

derivatized CPMV cysteine mutants. (B) A pentameric section of the gold densities superimposed on the atomic model of CPMV showing that the gold is attached at the site of designed cysteine mutation. (Reprinted from Ref. [46], © 2002, with permission from Wiley-VCH.)

pH-induced contraction of N $\omega$ V is one of the largest relative changes known to occur in virus particles. Since both the procapsid and capsid forms of N $\omega$ V VLPs are stable at pH 7.6, this system offers a rare opportunity to study the chemical reactivities of such large assemblies in two dramatically different states. With fluorescein derivatives **1** and **2**, approximately 240 dye units can be attached per VLP in the mature capsid form. As expected, procapsid VLPs were significantly more reactive than their capsid counterparts under identical conditions [53]. This result clearly demonstrated the importance of accessibility of a functional group to its reactivity.

**13.3.1.1.2 Cysteine Reactivity** The reactivity of cysteines of CPMV has also been carefully studied. The crystal structure of CPMV displays no free cysteine residue exposed on the exterior surface of the capsid. When wild-type CPMV was treated with thiol-selective reagents such as *N*-bromoacetamide **3** and maleimide **4** (Scheme 13.1), the reactions were very slow and give alkylation of thiol residues located exclusively on the *interior* surface of the protein capsid. There were no obvious reactions after 6 h of incubation with **3** and **4** [46, 51]. Additional amino acids can be inserted into a few solvent-exposed sites without interfering the ability of the resulting mutant virus to propagate in the host plant [20, 65–67]. Taking advantage of the biological nature of the virus, addressable cysteine residues were genetically introduced on the exterior surface of CPMV, using standard cloning techniques. These sites, the  $\beta$ B– $\beta$ C and  $\beta$ C'– $\beta$ C'' loops of the small subunit and the  $\beta$ E– $\beta$ F loop of the large subunit, are color-marked in Fig. 13.5. Each of the virus mutants contain a cysteine residue inserted as part of an added small loop or as a point mutation, and thus each particle contains 60 such insertions arrayed in icosahedral symmetry on the 30-nm diameter capsid. The altered sequences are genetically stable through multiple rounds of infection, harvesting, and reinoculation. The average purification yield of the mutant viruses is comparable to wild-type, but the presence of  $\beta$ -mercaptoethanol (BME) or tris(2-carboxyethyl)phosphine (TCEP) was necessary throughout the isolation procedure to avoid crosslinking of particles when they were pelleted by ultracentrifugation or stored after purification.

The thiol groups of the introduced cysteine residues of the mutant viruses are more exposed to the surface than the native cysteines of CPMV. Compared with the wild-type virus, the new inserted cysteines demonstrated much higher reactivity. All the thiol groups could be derivatized with very low concentration of the maleimide or bromoacetamide electrophiles at neutral pH within 6 h at 4 °C (Scheme 13.1). More importantly, the different sites of attachment could be programmed by genetic mutagenesis based on the structure information. For example, when mutant virus was reacted with monomaleimido-Nanogold<sup>®</sup>, derivatized particles were flash frozen and examined by cryo-electron microscopy and a three-dimensional image reconstruction was computed. In Fig. 13.4, the electron densities of the gold clusters are clearly visible at the positions of the inserted cysteine residues [46]. This provided an example of the engineering of chemically reactive functional groups at designated positions on the icosahedral protein template by genetic methods.

**Figure 13.5.** CPMV structure. (A) A diagrammatic representation of CPMV showing the distribution of the two subunits that comprise the “asymmetric unit”, 60 copies of which form the icosahedral particle. The trapezoids in red and green represent the two domains of the large subunit clustered around the 3-fold symmetry axes and the blue trapezoid

represents the small subunit clustered about the 5-fold symmetry axes. (B) Ribbon diagram of the two subunits of the CPMV coat protein, with the sites of mutational insertion highlighted in red ( $\beta$ B– $\beta$ C loop) and purple ( $\beta$ E– $\beta$ F loop). (Reprinted from Ref. [48], © 2002, with permission from Elsevier).

It is an interesting observation that in general there is no cysteine exposed to the exterior environment for any native virus or other BNPs. While that may be a result of evolution to avoid nonspecific aggregation, it offers a unique opportunity to selectively modify the BNPs. Genetic introduction of accessible cysteine very often brings in a unique reactive site, which can be derivatized chemoselectively and regioselectively. In addition to CPMV, such a technique has also been applied to CCMV [52, 68] and MjHsp [5].

**13.3.1.1.3 Reactivity on Carboxylic Groups (Glutamate And Aspartate)** At neutral pH and mild conditions, amines can be used to derivatize surface-exposed carboxylic groups upon activation. A cocatalyzed system, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) and NHS, is commonly used in the modification of the carboxylic groups of BNPs. For example, horse spleen ferritin (HSF) has been modified with long-chain aliphatic amine activated by EDC/NHS. The resulted particles can be dissolved in nonaqueous solutions [41, 69]. Similarly, CCMV [52], TMV [54] and TYMV [55] can also be addressed on the exterior surface.

**13.3.1.1.4 Orthogonal Modification of BNPs** Based on conventional bioconjugation methods, it is possible to attach multiple, distinct functionalities on BNPs

with orthogonal reactions. For example, the cysteine-inserted CPMV particles maintain the native reactive lysines. Therefore, one can selectively modify the lysines with NHS ester (or isothiocyanate) and the cysteines with maleimides. With this method, blue fluorescent antibody and PEG have been attached to CPMV cysteine mutants [45]. Scheme 13.2 shows two other examples of dual modification of BNPs [70, 71].

**Scheme 13.2.** Dual modification of CPMV and HSF with orthogonal reactive lysines and cysteines.

### 13.3.1.2 “Click Chemistry” for Bioconjugation of BNPs

The copper-catalyzed azide–alkyne cycloaddition (CuAAC) reaction, discovered in 2002 [72, 73], has emerged as an excellent method for connecting diverse building blocks in organic synthesis. It is a classic example of “click chemistry” coined by Sharpless and his coworkers [73, 74]. As the azide and alkyne groups are each almost entirely unreactive with proteins, nucleic acids, acids, bases and water, the reaction is well suited to the formation of covalent bonds to biological molecules with no side-reactions. In particular, shortly after the discovery of the CuAAC reaction, many other new catalytic systems were reported [72, 75–77], which further promoted the application of this reaction in bioconjugation process. Finn and coworkers pioneered in using this reaction for the bioconjugation of plant virus [78]. CPMV was successfully labeled at all 60 identical protein asymmetric units of the capsid (Scheme 13.3A). Tris(carboxylethyl)phosphine (TCEP), a water-soluble reducing agent, was used to reduce Cu(II) to Cu(I) at 4 °C. Addition of ligand 5 drastically enhanced the reaction rate and an almost quantitative amount of modified proteins could be recovered after the reaction. The azide moiety could be attached to lysine, cysteine or tyrosine residues [62, 78]. Different fluorescent compounds

**Scheme 13.3.** Bioconjugation by azide–alkyne cycloaddition to derivatized CPMV particles through the Cu(I)-catalyzed azide–alkyne coupling reaction under different catalytic conditions [77, 78].

contained acetylene groups were anchored on viral surfaces with this reaction, while only millimolar concentrations of dye reactants were required [78, 79]. Using a new catalyst **6** [77], the reactivity of the reaction has been improved significantly so that micromolar protein can be connected to mid-micromolar concentrations of small molecules, polymers and proteins, all in high yield and with excellent purity (Fig. 13.3B) [80].

The ligation strategy developed by Finn and coworkers was confirmed to be remarkably reliable and suitable for most of bio-platforms and has been followed by other groups for different purposes. For example, Tirrell and coworkers incorporated non-natural azido-amino acids into the *Escherichia coli* cell membrane protein OmpC, which were successfully modified with biotin-alkyne via a Cu(I)-mediated 1,3-dipolar cycloaddition [75, 81]. Schultz and coworkers introduced azido-amino acids or alkyne-amino acids into proteins in yeast [82, 83] and the pIII protein of M13 filamentous phage [84]. These were sequentially reacted with fluorescent dyes or polyethylene glycols via the CuAAC reaction. Recently, two useful fluorogenic click reactions have been reported independently by the groups of Fahrni and Wang (Scheme 13.4) [85, 86]. Wang and coworkers synthesized 3-azidocoumarins (**7**), which show no or very weak fluorescence due to the quenching effect from the 3-azido groups. Upon coupling with arylalkynes, most of the triazole products strongly fluoresce [86]. The mild reaction conditions allowed the combinatorial screening of the best azidocoumarin–alkyne pairs on the basis of fluorescent emis-

**Scheme 13.4.** Schematic illustration of the fluorogenic "click" reactions.

sion. Similarly, the fluorescence of **8**, synthesized by the Fahrni group, can be greatly enhanced by the triazole formation [85].

As this reaction tolerates most of functional groups and the azidocoumarin will only attack the acetylenes [62, 78], the location of the acetylene groups can be predetermined by detailed proteomic study. Then, the CuAAC reaction with azidocoumarins can anchor different kinds of functionalities on predefined positions of BNPs and the fluorescent signals from the product can be used to monitor the reaction efficiency.

### 13.3.1.3 New Developments in Tyrosine Modification

The electron donating effect of the hydroxyl group makes the phenol group of tyrosine a good nucleophile towards electrophilic attack at the *ortho* position of the OH group. Using diazonium salts ( $Ar-N\equiv N^+$ ), tyrosine can be selectively derivatized under mild conditions [61]. This reaction has been applied to modified TMV on surface tyrosines [54]. However, the reactivity of the reaction is reduced when the diazonium reagents without electron-withdrawing group on the aromatic rings are used. To solve this shortcoming, Francis and coworkers further improved the reaction with sequential derivations to render the tyrosine residue more susceptible to sophisticated modifications [57]. As shown in Scheme 13.5, the nitro-substituted diazonium salts afforded excellent tyrosine modification with MS2 bacteriophage. The resulting particles were reduced with sodium dithionite and reoxidized to *o*-iminoquinone. A further Diels–Alder reaction with acrylamides was completed in 2 h at room temperature with conversion levels exceeding 90% [57]. This modified protocol affords a versatile orthogonal pathway for bionanoparticle modification at tyrosines.

The unique structural feature of tyrosine can support multifaceted reactions other than simple nucleophilic or electrophilic substitution reactions with amino, thiol or carboxylic groups. Many new bioconjugation pathways have been revealed or re-elaborated recently, which opened new venues toward the selective modifica-

**Scheme 13.5.** Sequential functionalization of bacteriophage MS2.

tion of BNPs. For example, selective alkylation of protein tyrosines can be achieved by  $\pi$ -allylpalladium complexes (Scheme 13.6A) [87] and the *ortho* position of the hydroxyl group of tyrosine can be addressed with Mannich-type coupling reactions (Scheme 13.6B) [88].

**Scheme 13.6.** New reactions in the selective modification of protein tyrosine residues.

### 13.3.2

#### Genetic Alterations

Many of the viruses in isolated forms are complex macromolecular assemblies of metabolically inert molecules, which can be chemically modified. Alternatively, the virus can be genetically reprogrammed in its hosts with foreign peptides to express an antigen [89, 90] or to alter the affinity of the recombinant viral particle for different cell surface receptor [59, 91]. Furthermore, single-amino-acid substitution mutagenesis allows the site-specific incorporation of reactive amino acids, such as lysines or cysteines, or non-natural amino acids (NAAs) [92] on the virus coat protein for regioselective chemical modifications. Using such methods, Schultz and his group have incorporated PEG [83], alkyne-modified amino acids [93] and pho-

toisomerizable amino acids into the proteins [94]. *In vivo* and *in vitro* protein expression systems derived from cell lysates have also been used to drive viral protein synthesis with the NAAs [93, 95]. To that end, molecular cloning techniques are well integrated into the generation of hybrid BNPs with novel biological, chemical and physical properties.

#### 13.3.2.1 Heterologous Peptide Insertions

The structural information provided by X-ray crystallography and NMR studies can be hallmarks for discovering strategic locations when designing a recombinant virus particle. Many of the BNPs have their structures resolved at near-atomic resolution, facilitating the generation of the recombinant nanoparticles. Often the outer surface exposed loops between major secondary structures ( $\beta$ -sheets and  $\alpha$ -helices) or amino/carboxy-termini of the coat protein can be prime candidate sites for insertional mutagenesis. These alterations have ranged from single-amino-acid substitutions [47] to entire protein domain incorporations [96, 97].

The biological, physical, and structural properties of CPMV have been well characterized [98, 99]. The virus resists temperatures of up to 60 °C and is stable at extremely low pH levels for extended periods [65], providing the system with an extended shelf-life. The structure of the nonenveloped plant virus has been determined at 2.8-Å resolution [100], indicating that the virus displays a picorna-like  $T = 1$  ( $P = 3$ ) protein shell (termed a “capsid”). Each capsid is composed of 60 copies of the asymmetric units and each unit contains three jelly-roll  $\beta$ -sandwich folds formed by two polypeptides (identified as “small” subunit, A domain and “large” subunit, B + C domains in Fig. 13.5).

The asymmetric units are assembled in an icosahedral surface lattice around the single-stranded viral genomic RNA to form the virus particle of approximately 30 nm in diameter. The two different RNA molecules are required for infection, which are packaged by identical capsid structures, giving virions of differing densities and molecular weights ( $5.16 \times 10^6$  and  $5.98 \times 10^6$  Da, correspondingly). The viral genes have been cloned to a robust vector driven by CMV 35S promoter [101], which eases the transfection process by allowing direct infection with the cDNA clone rather than with RNA transcripts. Thus, the virus can be easily and inexpensively isolated from in yields of 1–2 g of virus per kilogram of infected leaves by using a simple and convenient procedure [102].

A series of peptide insertions on different positions of the virus revealed that the coat protein accommodates inserts of up to 30 amino acids with little effect on virus host range [103]. Moreover, among all the recombinant vectors synthesized, increases in viral coat protein isoelectric point had an adverse effect on the ability of the virus to spread systemically [103]. In vaccine development studies, short peptide inserts on the virus with a variety of foreign antigenic sequences have been successfully engineered on the surface of the virus with gp41 of HIV type 1 [67, 104] and VP2 protein of mink enteritis virus (MEV) [105]. These chimeric viral particles properly displayed the epitopes to elicit neutralizing antibodies against the viruses and confer protective immunity in mink against a lethal challenge of MEV. In particular, the large subunit contains a highly exposed  $\beta$ B– $\beta$ C loop on

**Figure 13.6.** TYMV particle and its asymmetric unit highlighted in yellow.

the surface (Fig. 13.5), which appears to be uninvolved in intersubunit assembly and exhibits high variability in viruses within the comoviridae family [106]. A chimeric CPMV particle incorporating a 12-mer insert from the CD46 receptor on the exposed  $\beta$ B– $\beta$ C loop was shown to inhibit measles virus entry into neurons in the brains of treated mice and prevented a brain infection when the mice were pre-treated with the chimeric particles [107].

Similar protein structures within a family of viruses can be compared to reveal permissible mutational sites and identify critical residues for gene encapsidation or supramolecular assembly. TYMV (Fig. 13.6) is an RNA plant virus within the family of tymoviridae, which contains at least 20 different known species, among which three have been determined at near-atomic resolution. Selective replacements on TYMV with the homologous regions of another tymovirus, belladonna mottle virus (BeMV), had not affected the infectivity in Chinese cabbages [108]. Six of 10 such recombinants were fully viable and gave symptoms in the plants. According to this study, the amino-terminus region was particularly amendable to short peptide substitutions. The first 9 amino acids were successfully replaced with 9 amino acids from E-71 major merozoite surface antigen of *Plasmodium falciparum* to generate chimeric TYMV particles [108]. However, the study indicated that these residues reacted poorly to the antibodies raised against the E-71 epitope and the antigenic inserts were weakly immunogenic [108], suggesting that these inserts were less accessible to the surface.

In the structural comparison of the three related viruses, TYMV, physalis mottle virus (PhyMV) and desmodium yellow mottle virus (DYMov) (Fig. 13.7), the residues His68 and His/Ser180 have been identified in the crystal structures to adopt similar configurations [109]. Bink and coworkers suggest that these two residues are involved in the RNA encapsidation or decapsidation by the virus, as mutations of the two histidines to alanines showed an absence of systemic symptoms in plants, but had not affected capsid assembly when virus coat proteins were over-expressed in *E. coli* cells [109]. The comparative analysis also revealed conserved

**Figure 13.7.** Asymmetric unit (a) TYMV with H68, I180 in yellow (b) DYMoV with H68 and S180 in red, and (c) PhyMV with H69 and S181 in green.

regions throughout the coat protein gene and highly variable loops on the viral coat protein. A systematic peptide insert study on TYMV, similar to studies in CPMV, may provide valuable information on potential permutation sites.

An exceptional behavior of TYMV is its ability to release its genomic contents without completely losing its entire capsid structure. The empty vesicles can be generated via high pressures [110] or deep-freeze/thaw methods [111] and these unique structures have been visualized by cryo-electron microscopy as intact particles in solution after decapsidation. The particles offer the unique opportunity to decorate the interior cavity of about 18 nm in diameter.

TMV is a rod shaped plant virus measuring 300 nm in length and 18 nm in diameter, and assembles in a highly ordered fashion with both amino- and carboxy-termini exposed to the surface of the particle (Fig. 13.8).

The virus is highly immunogenic in mammalian hosts, which is ideal for adapting TMV-based vectors for antigen display. An initial study by Haynes and co-workers demonstrated the feasibility of incorporating immunogenic peptides as fusion proteins on the plant virus capsids [112]. Short peptide fragments of up to 21 residues had been repeatedly fused to the carboxyl-terminus of TMV using

**Figure 13.8.** Ribbon diagram of TMV CP. Amino- and carboxy-terminal residues are marked in blue and red, respectively. Residues Ser154 and Gly155 marked as green spheres.

a leaky “UAG” stop codon without losing viral replication or assembly [113, 114]. By exploiting the suppressible amber stop codon, a mixed pool of fused coat proteins and native coat proteins are synthesized, which can then assemble together to form the rod-like structures [113, 114]. In other studies, a variety of short inserts were made between Ser154 and Gly155 (see Fig. 13.3) using polymerase chain reaction (PCR)-based site-directed mutagenesis [115, 116]. Similar to CPMV chimeras, the isoelectric points of the TMV chimeric particles influenced the virus infectivity and systemic spreading of the recombinant virus through the plants [115]. Longer peptide sequences of up to 25 amino acids had also been fused to the carboxy-terminus by deleting 4–6 amino acids at the carboxyl end [117].

*In lieu* of crystallography data, other studies can provide the necessary structural information for designing a fusion peptide on the virus. Potato virus X (PVX), which has no crystallographic data, has structural [118] and serological [119] evidence suggesting that the amino-terminal domain is displayed on the surface of the virus. Based on this evidence, one team utilized PVX as foreign peptide display vector by fusing a 27-kDa green fluorescent protein (GFP) to the viral coat protein [96]. The strategy involved incorporating a 16-residue peptide derived from foot and mouth disease virus peptide 2A (FDMV 2A) at the GFP carboxy-terminus, followed by the amino-terminus of the viral coat protein gene. The linker peptide sequence, FDMV 2A, mediates a processing event that signals the cleavage of the peptides at the carboxy-terminal glycine residue [120]. This strategy allowed the generation of a heterogeneous pool of fused and free forms of viral coat proteins, which had been necessary to form virus-like rod structures in PVX, as well as in TMV [113]. Subsequently, a similar study showed the plant vector assembled as rod-like structures with a single-chain antibody fused to the viral coat protein using a mixture of native coat proteins with modified coat proteins [121]. Apparently, the fusion of larger peptides on the viral coat protein is limited by the steric constraints and the chimeric particles fails to assemble to rod-like structures without the presence of the native viral coat proteins [121]. PVX vector also facilitated the expres-

sion of an unstable peptide derived from the sequence of microbicidal yeast killer toxin (KT) by direct attachment to the viral coat protein [122]. The purified recombinant virus fused with the 10 amino acids from the yeast KT had shown enhanced antimicrobial activity against a variety of plant and human pathogens [122]. The authors suggest that the higher efficacy observed in virus-fused peptides may be due to the increased stability of the fused KP in solution when compared to the chemically synthesized KP [122].

Ferritins serve as an iron storage particle, ubiquitously found as highly ordered protein cages in higher eukaryotes [123]. The bioparticles have been demonstrated to accommodate polypeptides and proteins fused to the amino- and carboxy-termini to display the polypeptides in the interior and exterior of the protein shell, respectively [124]. A silver nucleating polypeptide fused to the carboxy-terminus had been used to sequester silver metals within the confines of the protein cage, demonstrating the potential of the ferritin cages to template inorganic materials [124].

Both site-directed and random mutagenesis are practical means of generating chimeric BNPs. However, the rate at which chimeric particles are generated in site-directed mutagenesis cannot rival the rate of chimeric particles generated by random mutagenesis. One common system, the phage display library, utilizes the natural ability of the biological system to express random polypeptides fused to the viral protein. The polypeptide is then isolated through a series of selections based on functionality or binding affinity [125]. The directed evolution of the phage system has been investigated thoroughly over the years [126] and utilized as a display platform for a variety of polypeptides (antibodies [127] and peptide ligands [125] with altered functionalities). Belcher's group exploited this feature of M13 phage to synthesize ordered nanostructures, directing the growth and assembly of the nanoparticles into one-dimensional arrays [31, 32, 36, 128]. A series of polypeptides were screened on the phage template to yield nucleating peptides for semiconductors and ferromagnetic alloys [31]. The study demonstrates that in biological systems, substrate-specific peptides can be achieved through the modification of templates.

Similar to phage display systems, a BNP can be subjected to random mutagenesis to generate variants, which can then be selected based on functionality. This combinatorial approach would be an untapped, powerful advantage in BNPs, which would require overcoming two major issues. First, the mutations of polypeptide inserts must be in the context of the BNPs as a supramolecular unit. The screening of the mutants is based on functionality and its capacity to self-assemble, which is problematic in the frame of phage display. An example is the peptide screening system designed directly on adeno-associated virus (AAV) that resulted in altered vector tropism, redirecting the selected AAV vector to primary human coronary artery endothelial cells [129]. Multiple mutation sites on the exterior of the virus coat protein had been identified and with the use of a helper virus, a series of mutant AAVs were produced. In addition, many BNPs are incompatible with bacterial expressions for rapid protein synthesis and screening. Advances in

inducible protein expression and cell-free protein synthesis systems have been integrated in this field to generate many of the plant viruses.

#### 13.3.2.2 NAA Substitutions

The advantage of generating proteins with novel functional groups encoded by the genetic template is the production of a homogenous protein unit with novel physical, chemical, and biological functionalities. Exogenous chemical agents can attach to nonspecific residues of the protein, leading to a heterogenous particle, whereas the NAA incorporation takes advantage of the natural biosynthetic translation machinery to yield a modified protein. Currently, two major methodologies exist in the production of proteins with NAAs. One method incorporates NAAs directly into the proteins *in vivo* by introducing a new tRNA–tRNA synthetase pair [82, 84, 92, 93]. The tRNA synthetase specifically aminoacylates the tRNA with the NAA, after which the charged tRNA is used in the translation process to precisely decode the RNA template. The method was used in conjunction with phage display to generate proteins with an alkyne functional group attached to the surface which was then conjugated to a variety of chemical compounds via “click chemistry” [84]. The other method involves an *in vitro* biosynthetic pathway with bacterial cell lysates and mammalian cell lysates. Over the years, Sisido and coworkers have optimized the system with a versatile tRNA aminoacylation technique [95, 130–133] to incorporate a blue-laser-excitable fluorescent amino acid [134] and multiple NAAs on a single protein using a four codon/anticodon tRNA [133].

#### 13.3.2.3 Protein Expression Systems

Ultimately, the display of polypeptides on viruses for epitope presentation has its limitations. In some cases, foreign sequence insertions in the viral coat protein can result in loss of infectivity, replication or protein folding. Two major themes have evolved to address this limitation in virus systems. The heterologous peptide sequence can be chemically conjugated to the virus scaffold by using a bifunctional linker [80] or an alternative expression system can be explored.

Since the loss of infectivity or replication in a virus is not always correlated with the assembly pathway, recombinant virions can be produced from a variety of other protein expression systems, such as the *E. coli* expression system, *Arabidopsis thaliana* protoplast, baculovirus expression and wheat germ embryo cell extract. The generation of these reactive mutants utilizes many of the protein expression technologies developed over the years to greatly expand the repertoire of programming a protein with novel functionalities. The primary route of expression still relies on the original host cell for virus expression. However, the mutations leading to the loss of infectivity eliminates the possibility of propagation and production of the virus. The bacterial expression system is another possible option or better-suited production of some viral protein shells. Recently, the bacterial expression system has been modified to incorporate NAAs with high sequence specificity. These unnatural amino acids, such as propargylglycine, consist of an alkyne group that reacts with azide with a Cu(I) catalyst to form a triazole ring complex [78, 84, 93].

However, in other viruses, the proteins synthesized from the prokaryotes fail to assemble correctly without the proper post-translational modifications made in eukaryotic systems, ultimately requiring an economic eukaryotic protein strategy.

Plant protoplasts can also be used to directly transfect with viral RNA for the production of many types of plant viruses without the necessity of retaining the natural infection pathway. The cell-free wheat germ embryo extracts have become another possible peptide synthesis factory with several advantages over the previous protein expression systems, particularly in terms of the production of cytotoxic peptides and maintaining correct eukaryotic post-translation modifications. However, until the cost and production efficiency of the cell-free system can rival or even closely match the preceding systems, it is likely to remain as the last resort to synthesize viral coat proteins.

### 13.4

#### BNPs in Therapeutics

As described in previous sections, BNPs have several advantages over synthetic platforms, such as their ease of isolation, uniform size and defined structures. The large surface area and well-defined reactivities allow regioselective expression of polyvalent targeting units, which is extremely important for cell binding or recognition. In particular, the polyvalent display of cell-binding ligands can enhance the binding affinity and specificity dramatically. For example, Manchester and coworkers have used mutant CPMV in antiviral applications [107]. A well-characterized interaction between measles virus (MV) and its cellular receptor, CD46, were chosen for the anti-MV study. Since a specific region of CD46 has been previously identified to mediate the interaction with MV and the infection could be blocked by competition with short peptides from CD46 corresponding to the MV-interacting domains [135, 136], CPMV chimeras displaying the inhibitory peptide had been generated, which efficiently inhibited MV infection of HeLa cells *in vitro*, while wild-type CPMV did not. Furthermore, CPMV CD46 protected mice from mortality induced by an intracranial challenge with MV. The CD46 peptide presented in the context of CPMV was also up to 100-fold more effective than the solution CD46 peptide at inhibiting MV infection *in vitro* [107]. These results highlighted the polyvalent effect with BNPs as display scaffolds. In addition, the benefits of BNPs include:

- (i) They represent very stable self-assembled architectures at the nanometer level with many size ranges, which are otherwise difficult to produce by standard synthetic methods in the laboratory.
- (ii) They are inexpensive to isolate in large quantities. Both CPMV and TYMV can be grown in plants and purified in gram quantities with a half-day procedure.
- (iii) Their structures have been characterized at near-atomic resolution.
- (iv) The infectious cDNA clones of viruses are available as high-yield expression

vectors. Thus, their composition and surface properties can be precisely controlled using molecular biology techniques.

- (v) In-capsid cavity can be used to encapsulate fluorescent dyes or drugs to avoid the nonspecific binding being observed with other systems.
- (vi) The large surface area and well-defined reactivity allow regioselective expression of polyvalent targeting units, which is extremely important for the requirement of weak-binding ligands (e.g. boronic acid and carbohydrates) or the demand of special geometrical arrangement.
- (vii) Orthogonal cell-targeting mechanisms can be engineered simultaneously on one BNP platform. Similarly, multiple detection functionalities (e.g. optical, magnetic resonance imaging, etc.) can be programmed.

#### 13.4.1

##### Cell Targeting

Targeting the specific diseased cell types would localize the therapeutic agent, reducing potential side-effects and increasing the therapeutic efficacy. A few strategies have evolved over the years in arming cell-targeting moieties on various systems, including BNPs. One involves taking advantage of the natural affinity of the BNPs to target the cells. In other cases, genetic modifications on the BNPs with short peptide fragments redirect the system towards different cell surface receptors. Short peptide sequences from ligands can be genetically engineered on the BNPs. Portions of antibodies can be chemically conjugated to the protein cages to confer novel cell-targeting capability. Finally, small molecules are attached to the particles to modulate the affinity of the nanosystems for different cell types [137].

One strategy is to use the pre-existent cell-targeting motifs on the noninfectious replicas for therapeutic purposes, such as gene delivery or bioimaging. Many viruses of Polyomaviridae family generate intact VLPs, solely constructed of the major coat protein, VP1, without the two minor coat proteins (VP2 and VP3) [138]. VP1, when expressed in insect cells [139–142], yeast [143] and *E. coli* [144, 145], self-assembles as protein cages, and naturally targets a cell surface glycoprotein with a terminal  $\alpha$ 2,3-linked *N*-acetyl neuraminic acid [138, 146], and is internalized by the cells via  $\alpha_4\beta_1$  integrin receptors [147, 148]. Human JC polyomavirus, which in its native form infects human oligodendrocytes in the brain [149], was engineered as VLPs to deliver therapeutic genes to human fetal glial cells [150]. HBV, a human liver-specific virus, contains three overlapping envelope genes in a single open reading frame, encoding for small, medium and large proteins in its 3.2-kb genome [91]. The large protein subunit of HBV can be isolated as an aggregate form of a phospholipoprotein vesicle with an average size of 80 nm, with a targeting motif for human hepatocytes specified by the sequence located in the amino-terminus of the large subunit [151]. These hybrid vesicles have been demonstrated as safe vehicles for delivery of genes with high *ex vivo* and *in vivo* transfection efficiencies, and high targeting specificity to human hepatocyte-derived cells [91, 151].

A cell-targeting system based primarily on natural binding motifs would severely limit its potential therapeutic applications. Redirecting the protein shells to other cell types by inserting peptide ligands or portions of ligands have been shown to be effective in programming altered affinities. In one study, urokinase plasminogen activator (uPA) sequences had been genetically inserted into VP1 proteins of polyomaviruses to direct the recombinant particles to uPA receptor (uPAR) expressing cells [139]. In HBV nanoparticles, its native biorecognition motif was replaced with the epidermal growth factor (EGF) moiety to direct the particles to EGF receptor overexpressing cells [152]. Similarly, when an integrin receptor-targeting sequence had been fused to a small Hsp, the protein cage exhibited cell-binding capability *in vitro* [153].

Another docking concept involves attaching an antibody on the surface of BNP to change its tropism. The murine polyomavirus-like particles were engineered with eight glutamic acid residues and one cysteine residue in one of the exterior loops to attach a portion of the anti-tumor antibody B3 [154]. The antibody fragment was modified at the carboxy-terminus with peptide sequences (Arg<sub>8</sub>CysPro), which associates with the mutant VLP via electrostatic interactions, and the complex is further stabilized by the formation of a disulfide linkage. This coupling reaction yielded polyoma VLPs with 30–40 antibody fragments bound to the surface, allowing the modified VLPs to bind to the breast carcinoma cells with high efficiencies [154]. Alternatively a bifunctional crosslinker had been used to conjugate the antibodies, which can effectively target specific cells within a mixed population [153].

The conjugation of antibodies on the BNPs can be difficult and costly to manufacture. Facile chemical modifications with small molecules can be designed to modify the surface of BNPs for cell-specific targeting. CPMV, TYMV, TMV and many other viral platforms have demonstrated robust chemical modifications directed via conventional bioconjugation techniques and alternative methods (see Section 13.3.1).

#### 13.4.2

##### **Gene Delivery**

Gene therapy is still a promising frontier in medicine with unparalleled potential to combat genetic diseases, cancer or viral infections. Many of the retroviruses efficiently package, deliver and integrate into the host chromosomal DNA, but the wide range of cell infectivity provides little cell specificity. In addition, the labor-intensive design and high production costs in obtaining tropism-modified recombinant retroviral vectors have diverted attention to safer and more economic gene delivery systems with VLPs, which are innocuous counterparts of the original virus. The noninfectious particles in many ways mimic the functions of the original virus, but lack the essential components of the viral genome to self-propagate in the host, reducing its potential safety hazards. HBV nanoparticles and polyoma VLPs are capable of packaging a therapeutic gene and efficiently delivering it to the

target cells and organs *in vitro* and *in vivo* [152, 155–157]. These particles consist of proteins produced in bacterial or yeast expression systems, which are also easily programmable by genetic and chemical methods to adapt various cell-targeting ligands, receptors or carbohydrates.

Since the initial proposal in 1970 to develop polyomavirus as a potential gene delivery vector by Osterman and coworkers [158], various methods have been established to introduce genes into a variety murine, monkey and human tissues [159–161]. Circular DNA sequences of up to 17.7 kb can be encapsulated *in vitro* by polyomavirus VP1 [159], and have been used to deliver exogenous DNA to human brain cells and fetal kidney epithelial cells [155]. Atomic force microscopy images indicated that polyoma VLPs aggregated around the heterologous DNA to form loosely associated structures and DNA transfer was mediated by cell surface sialic acid residues [60]. The polyoma VLPs were also adapted to deliver plasmids expressing short hairpin RNAs and synthetic small interfering RNAs to human lymphoblastoid cells and HeLa cells to downregulate gene expression [162].

Regardless of the vehicle, all effective gene delivery agents deal with complicated issues of targeting appropriate cells or tissue, efficient packaging, transferring, precisely integrating the therapeutic gene in the host genome, and properly expressing the therapeutic gene in the host genome with economic production and safety considerations [152].

#### 13.4.3

#### Bioimaging

For *in vivo* or *in vitro* imaging (such as diffusion fluorescent tomography), it is important to have high local concentrations with no quenching of fluorescence to enhance the imaging contrast. Since BNPs can be genetically or chemically modified in a chemoselective manner, high-loading fluorescent dyes can be loaded with a precisely designed geometrical distribution on the surface of BNPs and inside the cage of BNPs. The rigid and highly ordered structures of the protein structures of BNPs “fix” the attached imaging agents at designed positions on the surface. Therefore, the attached dye molecules have no mobility to interact or aggregate to each other, which often quench the fluorescence. The observation that no fluorescence quenching of the virus–dye conjugates occurred even at a high local concentration of the dyes has been evidently demonstrated [55, 56].

Fluorescent probes are the most common imaging reagent used in BNP labeling. For example, using fluorescent dye-modified CPMV, Manchester and her coworkers have studied the systemic trafficking of CPMV in mice via the oral route [163]. The pattern of localization of CPMV particles to mouse tissues following oral or intravenous dosing was then determined by confocal fluorescent microscopy and viral RNA detection. For several days following oral or intravenous inoculation, CPMV was found in a wide variety of tissues throughout the body, including the spleen, kidney, liver, lung, stomach, small intestine, lymph nodes, brain and bone marrow. CPMV particles were detected after cardiac perfusion, suggesting that the particles entered the tissues [163]. Fluorescent dye-labeled CPMV has also been

employed for intravital vascular imaging [164]. The CPMV can be labeled with high densities of Alexa Fluor or fluorescein dyes, showing no measurable quenching. The resulting exceptionally bright particles were used to visualize the vasculature and blood flow in living mouse and chick embryos to a depth of up to 500  $\mu\text{m}$ . Therefore, the intravital visualization of human fibrosarcoma-mediated tumor angiogenesis using fluorescent CPMV provides a means to identify arterial and venous vessels, and to monitor the neovascularization of the tumor microenvironment [164]. In another study, the lateral mobility of fluorescent labeled murine polyoma virus-like particles bound to living cells and artificial lipid bilayers was studied by single fluorescent particle tracking using total internal reflection fluorescence microscopy [165].

To minimize the background and enhance the deep-tissue penetration ability, near-infrared (NIR) fluorescent dyes are often used for *in vivo* imaging. Significant efforts have been placed on the development of efficient bioconjugation methods for the attachment of NIR fluorescent agents to BNPs. As shown in Fig. 13.9, cyanine NIR-782 dye was attached to CPMV with over 40 dye molecules per viral particle, making a local concentration of around 1.8 mM. The purified viral–dye hybrid has been employed as a probe for NIR fluorescence imaging. Using tissue-like phantoms, fluorescent tomographic data have been obtained through a multi-channel frequency domain system. The spatial maps of fluorescence quantum yield were detected with a finite element-based reconstruction algorithm [166]. In addition, a new class of carbocyanine dyes has been synthesized and conjugated to CPMV by the “click” reaction of azides and alkynes [79].

Magnetic imaging complexes or other probes can also be used to decorate BNPs. For example, luminescent semiconductor nanocrystals (quantum dots) were employed to modify CPMV [167]. Using CPMV mutants expressing available 6-histidine sequences inserted at loops on the viral coat protein [168], it was shown that CPMV particles were specifically immobilized on NeutrAvidin functionalized substrates in a controlled fashion via metal-affinity coordination. Two linking chemistries were employed to decorate CPMV with CdSe–ZnS core–shell quantum dots to target the histidine or lysine residues on the exterior virus surface and utilize biotin–avidin interactions. In the first case, quantum dots are immobilized on the surface-tethered CPMV via electrostatic attachment to avidin previously bound to the virus particle. In the second case, chemical modification of the surface lysine residues with biotin groups and the biotinylated CPMV is discretely immobilized onto the substrate via NeutrAvidin–biotin interactions. The biotin units on the upper exposed surface of the immobilized CPMV then serve as capture sites for avidin-derivatized quantum dots [167]. Similar conjugation chemistry has been used to produce virus–carbon nanotube [169] and virus–metal nanoparticle complexes [170], which have potential as biological sensors. For example, networks of gold nanoparticles and bacteriophage have recently been engineered to preserve the cell-targeting and internalization properties mediated by the specific peptide display [171]. In addition, the gold nanoparticles acted as signal reporters for fluorescence and dark-field microscopy and NIR surface-enhanced Raman scattering (SERS) spectroscopy [171]. In all these cases, BNPs

**Figure 13.9.** (A) Attachment of NIRF-782 to CPMV. (B) Reconstruction image of fluorescent quantum yield of dye-modified CPMV. The left and bottom axes illustrate the spatial scale in millimeters, which the color scale records the value of the quantum yield.

served as an excellent scaffold to modulate the organization of reporters for bio-sensing or bioimaging.

#### 13.4.4

#### Drug Encapsulation and Release

The interior cavities of BNPs are hollow spaces that can encapsulate other elements for drug delivery by genetic and chemical modifications. Covalently attached small molecules are tethered to the BNPs, preventing leakage from the interior, and circumventing drug degradation and avoiding nonspecific binding, until a signal or low endosomal pH within the cell releases the drug from the carrier. Recent studies with polyoma VLPs and Hsp demonstrated the feasibility of packaging chemical compounds within the protein cage. In the case with polyoma VLPs, Schmidt and coworkers inserted the first WW domain of mouse formin binding protein 11 (FBP 11) to the amino-terminus of VP1 to attach proline-rich ligands (bearing the consensus sequence PPLP) to the inner surface of the VLPs [172]. In a similar study with polyoma VLPs, a stretch of 49 amino acids of the inner core protein from polyomavirus VP2 protein had been fused to GFP or covalently attached to methotrexate (MTX) [173]. The amino acids specifically anchored GFP and MTX to VP1, resulting in VLPs with GFP or MTX enclosed by VP1 coat proteins [173]. The encapsulated MTX retained similar cytotoxicity in the cells, and destroyed MTX-resistant cell by circumventing MTX transport.

Flenniken and coworkers covalently modified the Hsp cage interior with anti-tumor drugs by genetically introducing cysteine residues at the inner surface and selectively attaching the chemical compound to the reactive cysteines with a pH-sensitive linker [64]. This Hsp assembles into a 24-subunit spherical structure with an octahedral symmetry, which is 12 nm in diameter and has a porous protein shell that allows free small-molecular exchange between the interior and bulk solution [5]. The (6-maleimidocaprol) hydrazone derivative of doxorubicin was linked to the interior surface of this Hsp via coupling of maleimide and cysteine (Scheme 13.7) [64]. The quantitative analysis by absorbance spectroscopy indicated

**Scheme 13.7.** Controlled release of doxorubicin from the interior of a small Hsp cage [64].

that 24 doxorubicin moieties were encapsulated and, under acidic conditions, doxorubicin was selectively released through the hydrolysis of hydrazone linkage (Scheme 13.7). This study demonstrates that a therapeutic agent could be housed within the interior of a BNP cage to realize its controlled release. Therefore, a BNP system has the potential to serve as a versatile drug delivery system.

## 13.5

### Immune Response

#### 13.5.1

##### Vaccine Development

The virus surface consists of highly organized repeating motifs that are ideally suited for eliciting an immune response. Although this is problematic for gene therapy or drug delivery, the polyvalent display on the BNPs can be extremely advantageous for vaccine development. In particular, plant viruses show great potential for production of pharmaceuticals in plants. The small size of plant viral genomes, the ease with which they can be manipulated and the simplicity of the infection process make the plant viral vectors an attractive alternative as transgenic systems for the displaying antigenic proteins. CPMV, TMV, PVX and alfalfa mosaic virus (ALMV) have all demonstrated enormous potential to incorporate recombinant peptide sequences to confer protective immunity and to combat against viral and bacterial infections [65, 174].

The immunological analysis of plant virus-based chimeras has been one of the most thoroughly documented among all of the BNP systems. An important demonstration of CPMV-based vaccines and its potential to stimulate protective immunity was reported by Dalsgaard and coworkers [105] using the chimeric plant virus inserted with a short linear epitope derived from the amino-terminal region of VP2 of MEV. A single, subcutaneous injection of 1 mg of chimeric particles protected mink against challenge with MEV. In a following study, dogs immunized with ultraviolet (UV)-irradiated chimera elicited high titers of neutralizing antibodies and conferred resistance to canine parvovirus [175].

PVX, another plant-based antigen display vector, showed similar results in mice with the highly conserved ELDKWA epitope from HIV-1 gp41 expressed on the viral coat proteins [176]. The mice inoculated with the PVX-derived chimeric particles were able to elicit high levels of HIV-1 epitope-specific antibodies without adjuvants. Furthermore, the human immune response to chimeric viral particles was studied with severe combined immunodeficient mice reconstituted with human peripheral blood lymphocytes (hu-PBL-SCID). hu-PBL-SCID mice immunized with chimeric viral particle-pulsed autologous dendritic cells were able to mount a specific human primary antibody response against the gp41-derived epitope [176]. Remarkably, anti-HIV-1-neutralizing activity was present in the sera from both normal and hu-PBL-SCID mice. Similar vaccine studies with ALMV have also demonstrated that peptides containing antigenic determinants of rabies virus

glycoprotein and nucleoprotein fused to the viral coat protein conferred immunity in mice against lethal challenge [177].

Chimeric TMV particles containing 10 or 15 amino acids from the spike protein of murine hepatitis virus (MHV) gave rise to intact chimeric viral particles with the MHV peptides displayed on the surface [116]. The study indicated that mucosal and parenteral immunization with the chimeric TMV particles protected the treated mice against lethal doses of MHV. However, displaying larger protein structures as genetic fusions to the capsid protein has not been possible on TMV. To address this issue, a reactive lysine was introduced near the amino-terminus of TMV CP, which was further modified with biotin [178]. The biotinylated end was then tagged with GFP–streptavidin or L2 protein of canine oral papillomavirus, resulting in TMV particles with GFP or L2 protein, respectively, decorated on the exterior. The L2 protein-coupled biotinylated-TMV was found to be more immunogenic in mice than uncoupled L2 protein fragments.

Chimeras expressing epitopes of a bacterial origin have also been shown to confer protective immunity. For example, a chimeric CPMV particle expressing amino acid sequences containing two epitopes from the outer membrane protein F (ompF) of *Pseudomonas aeruginosa* protected mice against challenge with *P. aeruginosa* in a model of chronic pulmonary infection [179, 180]. Likewise, a chimera plant virus expressing the D2 domain of the fibronectin-binding protein (FnBP) from *Staphylococcus aureus* has been shown to be able to protect rats against endocarditis [181]. Thus, plant virus-based chimeras carrying neutralizing epitopes can offer novel avenues for producing effective vaccines against various infectious viruses and, more generally, for the design of new vaccination strategies in humans. (See Refs. [20, 174] for more detailed reviews on plant virus-based vaccine development.)

### 13.5.2

#### Immune Modulation

In addition to the peptide displays, the BNPs can also be adapted to present multiple sugar residues on the exterior surface. The polyvalent scaffolds decorated with various carbohydrates have shown increased binding affinity and biological responses when compared with their monomeric constituents [182–184]. Similar to previous studies with polymers and other supports, the virus has been shown to accommodate multiple mannose residues via chemical coupling [80] and inhibit cell agglutination [51]. The virus–carbohydrate conjugate can further be designed to supplement immune responses or other biological processes.

The repetitive patterns on BNPs, while beneficial for antigen display in vaccine display, can become a major problem in adapting the BNPs for diagnostic and therapeutic applications. One modality has been to modify the particle surface with PEG polymers and other polymers to reduce the immunogenic response towards the particles [185]. In adenovirus, its bioavailability and pharmacokinetics have been investigated extensively with the intention of improving adenovirus-delivered gene therapeutics [44, 186]. To facilitate the use of other protein-based systems,

**Figure 13.10.** Schematic drawing of viral particle-modified polymer.

such as BNPs, Finn and his group studied the immune response towards viral particles modified with PEG and other polymers (Fig. 13.10) [49, 80]. The preliminary study was to assess the immunogenic response in mice towards PEG-modified CPMV. The levels of CPMV-specific antibodies in the mice treated with PEGylated CPMV were comparably similar to the levels in mice treated with unmodified CPMV, but the serum antibody level had drastically declined over the following 2 months in mice treated with modified CPMV compared with unmodified CPMV [49].

### 13.6

#### Future Directions

The major features of BNPs that were exploited for generating novel biotemplates in the nanometer range have been iterated throughout the chapter. In general, these protein structures naturally self-assemble to highly organized structures and many of the systems, either virus- or ferritin-based, demonstrate robust physical properties that can be exploited for variety purposes. The systems can be genetically engineered and chemically addressed to alter functionalities for future therapeutic applications. As platforms, the viruses provide a wide array of shapes such as rods and spheres, and vast ranges of sizes spanning from tens to hundreds of nanometers. Hsps and ferritin arrange as nanometer-sized materials with well-characterized hierarchical motifs as templates for mineralization. Several studies have demonstrated the feasibility of using various nanoparticles (BNPs, liposomal carriers, inorganic materials, etc.) tailored with ligands and small molecules to target different cell types for drug/gene delivery and cell imaging [56, 137, 151, 152, 164]. The nanosized probes can further be modified with chemical compounds, such as bioimaging agents (NIR fluorescent dyes, magnetic resonance imaging contrast agents) and drugs at high local concentrations to increase detection sensi-

Figure 13.11. Multifunctional BNP hybrid.

tivity and efficacy for therapeutic applications [166, 187, 188]. Furthermore, the BNPs can be modified with polymers to boost the half-life of the biological system either by shielding the protein structures from enzymatic degradation or immune response. Ultimately, the combination of these multiple derivatizations on the nanoparticles could yield versatile units with specific cell targeting for drug/gene delivery, with simultaneous *in vivo* imaging for biomedical purposes (Fig. 13.11).

## 14 Nanotechnology for Gene Therapy – HVJ-E Vector

*Hironori Nakagami, Yasuhiko Tabata, and Yasufumi Kaneda*

### 14.1 Introduction

Currently, more than 400 clinical protocols have been approved for human gene therapy. In 1995, the Orkin–Motulsky report indicated the importance of vector development in human gene therapy. Numerous vectors have been developed to date. In general, viral vectors are more effective for gene transfer; however, safety remains an issue [1]. In 1999, a young patient died following infusion of an adenoviral vector via the hepatic artery [2] and, in 2002, two patients with X-linked severe combined immunodeficiency treated with retroviral vector gene therapy developed leukemia-like symptoms, likely to have been induced by insertional mutagenesis of the retroviral DNA [3]. Hemophilia B gene therapy using the adeno-associated virus (AAV) vector looks promising [4], but several potential risks, such as germline transmission, remain. On the other hand, the safety of a nonviral vector has been evaluated, but inefficient gene transfection is a limitation of this vector system [5]. Therefore, the current consensus on vector development is that highly efficient and minimally invasive vectors are the most appropriate for human gene therapy. Before developing vector systems, we should analyze the biological barriers to gene transfer and create methods to overcome such difficulties.

All the current vector systems have their advantages and limitations [6]. Currently, there are several approaches to correct the limitations of each vector system. In adenovirus vector systems, one crucial improvement is reduced vector antigenicity and a helper-dependent or “gutless” vector in which most of the adenovirus genome is deleted has been developed [7]. However, the production of this “gutless” vector was much lower than that of the classical adenovirus vector. Another approach is to overcome the limitations of one vector system by drawing upon the strengths of another. Examples of chimeric vectors include the pseudo-type retrovirus vector in which the envelope component of the classical retrovirus vector is replaced with the vesicular stomatitis virus (VSV) G protein [8] and a new lentivirus vector containing human immunodeficiency virus (HIV) proteins with the pseudo-type retrovirus envelope-containing VSV G protein [9]. However, combinations of

viral vector systems are thought to be of limited utility, because the components necessary for viral replication and packaging cannot be eliminated, and the constituent viruses may interfere with each other during vector production.

Limitations of vector systems are inevitable, and the introduction of foreign genes into cells is abnormal and is directed to disturb cellular function. Current gene therapy strategies mimic viral infection and cells are designed to resist the gene transfer. Cells have biological barriers that protect against invasion by foreign genes and inhibit expression of foreign gene products [5]. Protocols for *in vivo* gene transfection consist of several steps. The first step entails the approach of the vector to the target cell from the outside environment. The second is the introduction of the transgene into the cytoplasm. Third, the transgene must migrate to the nucleus. Finally, the transgene must be retained and stably expressed. Each of these steps has barriers. For example, serum proteins and immune cells can attack gene transfer vectors before they reach target cells, the cell membrane can prevent transfer of foreign genes to the cytoplasm, the nuclear envelope can restrict nuclear targeting of molecules, and expression of the transgene can be inhibited by degradation of the DNA or by transcriptional silencing. In a narrow sense, “gene transfer” means the introduction of a transgene into the cytoplasm, and it encompasses the first and second steps described above. However, it is pointless to only refer to the introduction of a transgene into the cell without considering the final step of gene expression. Thus, Section 14.2 highlights biological barriers from the first step (approach to the target cell) to the fourth step (effective expression of the transgene) and discusses potential solutions for each barrier with respect to future possibilities for gene transfer systems.

We have developed a unique vector, “HVJ-E (Hemagglutinating Virus of Japan-envelope)”, that can rapidly transfer plasmid DNA, oligonucleotides and protein into cells by cell fusion. A detailed description is given in Section 14.3. However, this modality of targeting is still insufficient for rapid and specific accumulation of active vectors in target tissues. One solution is to engineer the surface proteins of viral vectors or to couple targeting ligands to viral as well as nonviral vectors, which might further improve tissue selectivity. Section 14.4 describes other candidates for nonviral vectors, such as cationized gelatin (CG) and magnetic nanoparticles. Finally, Section 14.5 discusses modification of the membrane surface of HVJ to achieve improvement as a future prospect. We modified HVJ-E conjugated with protamine sulfate (PS) and/or CG, which enhanced the transfection efficiency *in vitro* or *in vivo*. Moreover, we recently developed magnetic nanoparticle-conjugated HVJ-E. Importantly, the size and surface chemistry of magnetic particles could be tailored to meet specific demands of physical and biological characteristics. For example, coating with PS could be suitable for *in vitro*, but not *in vivo*, culture, whereas heparin sulfate was suitable for *in vivo* gene expression. Overall, CG or magnetic nanoparticles can enhance HVJ-E-based gene transfer by modification of the size or charge, which could potentially help to overcome fundamental limitations to gene therapy *in vivo*.

## 14.2

### Biological Barriers to Gene Transfer

#### 14.2.1

##### Reaching Target Cells

To achieve tissue-specific targeting, vector system development should be approached from at least three aspects: recognition by specific target tissues, avoidance of nonspecific uptake and resistance to degradation in the systemic circulation.

##### 14.2.1.1 Recognition by Specific Target Tissues

Targeting vectors to specific tissues has been considered an ideal method for gene delivery. Ligand-specific delivery systems have been developed for tissue-specific targeting. In one experiment, asialoglycoprotein was conjugated with DNA–polylysine complexes [10]. Since asialoglycoprotein binds to receptors on hepatocytes, DNA can be delivered specifically to hepatocytes by receptor-mediated endocytosis using this complex [11]. Transferrin has also been used for receptor-mediated delivery of DNA to cancer cells, because cancer cells express high levels of the transferrin receptor [12]. These complexes worked well in cultured cells, but the efficiency of *in vivo* gene delivery was so good. Some viruses do, however, target specific tissues [13]. Epstein–Barr virus (EBV) primarily infects B lymphocytes, hepatitis virus B attacks hepatocytes, and HIV targets lymphocytes and macrophages. Currently, adenovirus-based gene delivery vectors are being used for many gene therapy applications because of the broad range of hosts [14]. Cellular tropism of the adenovirus vector in tissues is regulated by fiber proteins and, based on the tissue tropism of these viruses, targeting viral vectors can be developed [15–17].

##### 14.2.1.2 Avoidance of Nonspecific Uptake

Colloidal particles with a diameter of more than 300 nm are trapped by reticulo-endothelial system (RES) cells in the liver, spleen and lung [18]. HVJ-liposomes containing both hemagglutinin/neuraminidase (HN) protein and fusion (F) proteins target the liver, spleen and lung when the vector is injected into the saphenous vein of monkeys [19], probably because the phosphatidylserine residues [20] present on the envelope are recognized by the RES and the particle size is 470 nm in diameter. Some phospholipids such as phosphatidylserine are also recognized by the RES. The liposome–PS–plasmid DNA (LPD) vector targets the lung, kidney, heart, liver and spleen, with the highest level of gene expression in the lung [21, 22]. To avoid such nonspecific uptake, stealth liposomes have also been developed [23]. By selecting lipid components, the liposomes are retained in the systemic circulation much longer than other liposomes. Such stealth liposomes are used for drug delivery to tumor tissues [24]. In particular, liposomes conjugated with poly(ethylene glycol) (PEG) are also of the “stealth” type [25, 26]. Cationic lipid–

DNA complexes accumulate mostly into the lung, while “PEGylated” lipid–DNA complexes exhibit lower lung accumulation. The folate receptor is abundant in tumor tissues. When folate is conjugated with PEGylated lipid–DNA complexes, pulmonary accumulation of DNA is reduced and tumor-targeted DNA increases [27]. PEGylation of various types of vectors may regulate tissue-targeting when tissue-specific molecules are conjugated with the complex.

#### 14.2.1.3 Resistance to Degradation in Systemic Circulation

In the human body, protective mechanisms against viral invasion exist. Anti-galactose antibodies present in human serum bind to retrovirus envelope proteins to induce complement-mediated lysis [28]. To avoid such lysis, a complement-resistant retrovirus has been developed [29]. Adenovirus is highly immunogenic and is attacked by the host immune system after repeated transfection [30]. As described above, to reduce immunogenicity, a “gutless” adenovirus vector has also been developed [7].

Another barrier to gene transfer is the penetration and distribution of vectors in tissues. To extravasate from blood vessels to the target tissues and cells, vectors must penetrate endothelial cells. To induce gene expression in a large area of tissue, vectors must be spread diffusely throughout the entire area. Many viral vectors including adenovirus vector and AAV vector cannot penetrate endothelial cells when administered systemically [31]. Among the nonviral gene delivery systems, cationic liposomes are the most frequently used for gene transfer. When injected into the mouse tail vein, gene expression is detected primarily in the lung [32]. However, cationic liposomes cannot penetrate past the endothelial cells when injected into the vasculature [33]. In contrast, anionic liposomes are able to penetrate endothelial cells [34]. Moreover, anionic liposomes can distribute to broader areas in the target tissues than cationic liposomes. The mean size of liposomes is also important, because tissues are more permeable to smaller liposomes.

#### 14.2.2

##### Crossing the Cell Membrane

After reaching the target cells, transgene DNA must cross the cell membrane, which is a very effective barrier that excludes foreign substances from cells. There are several ways to overcome this barrier. Although one is to facilitate DNA transfer by utilizing endocytosis or phagocytosis, in this process the foreign DNA must penetrate the membrane of the endosome or phagosome rapidly. Otherwise, the DNA will be degraded. Adenovirus can escape from the endosome by disrupting the endosomal membrane with penton fibers [35, 36]. This ability has been utilized to enhance the efficiency of gene transfer by transferrin/poly-L-lysine/DNA complexes [12]. Other viruses can fuse with the cell membrane to introduce their genomes into the cytoplasm. There are two different mechanisms of virus–cell fusion: pH-dependent and pH-independent. Influenza virus [37], Semliki forest virus (SFV) [38] and VSV [39] exhibit pH-dependent fusion, whereas HVJ (Sendai virus) [40] and retroviruses [41, 42] can fuse with the cell membrane at both acidic and

neutral pH. Viral fusion proteins have been identified and synthetic vectors that express these viral fusion proteins can transfer foreign genes efficiently into the cytoplasm [43].

### 14.2.3

#### **Nuclear Targeting**

Transport of the foreign gene to the nucleus is required for gene expression in gene therapy. In nondividing cells especially, DNA is not transported efficiently to the nucleus where transcription occurs. However, it should be noted that naked plasmid DNA can be transported to the nucleus without breakdown of the nuclear envelope. The efficiency is generally 1–2% of the DNA in the cytoplasm [44]. Therefore, nuclear targeting increases gene expression, especially in tissues. Some viruses such as adenovirus, SV40, HIV and herpes virus are known to induce rapid migration of their genomes to the nucleus even in nondividing cells [43]. In SV40, viral capsid proteins contain nuclear localization sequences (NLSs) that trigger translocation of the virion to the nucleus and disassembly of the virion within the nucleus [44]. Although rapid nuclear transport also occurs with adenovirus, disassembly of the viral capsid occurs in the cytoplasm and the DNA-NLS-containing proteins are then sorted in the nucleus [45, 46]. In HIV, an integrase is required for nuclear migration of the viral genome [44]. However, the DNA–integrase complex, or preintegration complex, of oncoretroviruses such as Moloney leukemia virus cannot pass through the nuclear pores and, thus, transport of the transgene to the nucleus does not occur in nondividing cells in these retroviral systems [1]. In nonviral vector systems, nuclear transport of plasmid DNA occurs, but the efficiency is very low [5]. Enhancing nuclear migration of plasmid DNA is an important issue for increasing transgene expression. Complexes of plasmid DNA and nuclear proteins have been constructed to improve nuclear migration of DNA [47, 48]. It was recently reported that conjugation of the NLS peptide derived from SV40 with a luciferase gene fragment enhanced luciferase gene expression approximately 1000-fold compared with the luciferase gene without the NLS peptide [49]. The NLS peptide at either the 5' or 3' end of the DNA enhanced luciferase gene expression, but incorporation of the NLS at both ends was not effective. It is thought that positioning of the NLS at one end of the gene stimulates nuclear migration of the luciferase gene, whereas incorporation of the NLS at both ends ensnares the DNA at the nuclear envelope. However, it remains unknown whether NLS conjugation improves the nuclear migration of larger DNA molecules and if NLS conjugation improves the efficiency of translocation *in vivo*. This raises the question, does only a small fraction of all the plasmid DNA go to the nucleus? Recently, several papers have suggested that nuclear migration of plasmid DNA may be sequence dependent [50]. The SV40 enhancer sequence appears to facilitate nuclear migration of DNA by binding transcription factors [51] which are transported to the nucleus by the Ran/importin system.

RNA-based vectors have also been developed. Alphaviruses such as SFV and Sindbis virus are converted into gene expression recombinant RNA vectors [52,

53], which do not require the transport of DNA into the nucleus. In general, RNA vectors produce large amounts of proteins and this production inhibits host protein synthesis, inducing cell death (apoptosis) [54]. Thus, tight regulation of protein synthesis will be required for the use of gene therapy using RNA vector systems.

#### 14.2.4

#### **Regulation of Gene Expression**

Effective expression of a transgene is also a major issue in gene therapy. We should view this step from at least two aspects. One is the stable retention of a transgene and the other is the regulation of transcription. The export of mRNA, translation and post-translational modification of polypeptides generally affect gene expression, but they are not specific for expression of a transgene. Therefore, this section focuses on the events occurring before mRNA production.

##### 14.2.4.1 **Stable Retention of Transgenes**

There are two distinct approaches to this issue. One is the integration of the transgene into the host genome. Retroviruses can integrate into random sites of the host chromosomes, but integration occurs only in dividing cells [1]. HIV inserts its genome into the host chromosomes even in nondividing cells. A lentivirus vector system containing the recombinant HIV genome along with a therapeutic gene and the vesicular stomatitis virus G protein (VSVG) gene was used to generate long-term gene expression in mouse neurons [9]. The mechanism of insertion of the viral genome into host chromosomes has been investigated. However, reconstitution of the viral machinery that confers the ability of genome insertion to non-viral gene delivery systems has not yet been successful. In 1997, *sleeping beauty*, a fish transposon/transposase system, was developed [55]. This system inserts the neomycin-resistance gene into the HeLa cell genome with very high efficiency. Application of this system to gene transfer is currently under investigation. However, insertion of the transgene into the host genome occurs at random. Although AAV integrates specifically into the AAVS1 site of human chromosome 19 [56], the recombinant AAV vector is unable to do so because it does not express Rep 65 protein [57].

Another approach is the stable retention of an episomal piece of DNA. EBV has been analyzed thoroughly in terms of latent infection. The *cis*-acting oriP (the latent viral DNA replication origin) sequence and the *trans*-acting EBV nuclear antigen-1 (EBNA-1) gene are required for latent EBV infection, which is characterized by autonomous replication and nuclear retention of the EBV genome in host cells [58–60]. It has been reported that stable retention of the EBV genome is mediated by binding of the oriP sequence with the nuclear matrix. The EBV vector can transfer genes primarily to B lymphocytes, with minimal transfer to other somatic cells. To improve long-term transgene expression, an EBV replicon-based plasmid that contains oriP and EBNA-1 was constructed and transferred to various animal

tissues using HVJ-liposomes. With the EBV replicon vector system, gene expression was sustained and enhanced both *in vitro* and *in vivo*, in several cell lines and mouse liver, respectively [61]. Without EBNA-1, transgene expression of an oriP-containing plasmid was diminished in mouse liver. However, by re-introducing EBNA-1 to the mouse liver, transgene expression was reactivated [62]. This indicates that EBNA-1 can restore gene expression of an episomal plasmid containing an oriP sequence within the nucleus. When the luciferase gene was introduced into a mouse melanoma cell line, with or without the EBV replicon components (oriP and EBNA-1), effective long-term gene expression was obtained in the plasmid containing the EBV replicon components. However, Southern blot analysis revealed that the copy number of the plasmid without the EBV components was much higher than that with the EBV replicon plasmid. This result suggests that effective gene expression by the EBV replicon plasmid results from transcriptional activation, and not from stable retention of the plasmid DNA. The regulation of transcription is further discussed below.

#### 14.2.4.2 Regulation of Transcription

Silencing of transgene expression occurs in host cells, despite insertion of transgenes into the host genome [63]. Similar silencing has also been reported in certain viral infections. For example, retroviral gene expression was inhibited after retrovirus infection of mouse embryos [64, 65]. Although low or silenced transgene expression after transfection has been a major problem in human gene therapy [66], the mechanism(s) by which transgene expression is regulated have not yet been elucidated. Since it will be essential to control transgene expression in human gene therapy, basic research on transgene expression in human gene therapy should be pursued further.

Although transcription factors have been investigated extensively [67, 68], previous studies have not fully clarified the mechanism(s) of regulation of transcription in higher eukaryotes. Recent studies have shown that chromatin remodeling factors such as the switch/sucrose nonfermenting (SWI/SNF) family and the imitation switch (ISWI) family [69] are involved in regulation of transcription. It is thought that histone acetylase and deacetylase also regulate transcription by modifying chromatin [70, 71]. Acetylation and deacetylation of histones and other proteins associated with DNA have been shown to be important in the epigenetics of regulating gene expression [70–72]. Recently, amplification of transgene expression in animals treated with a novel histone deacetylase inhibitor was reported [73]. This amplification was more effective for transgene expression than for endogenous gene expression. These data suggest that transgene expression can be regulated by chromatin modifications, such as histone acetylation/deacetylation. Methylated DNA-binding protein MeCP2 is a component of the complex that contains histone deacetylase [74]. This suggests that DNA methylation status may dictate the state of histone acetylation/deacetylation in chromatin. To overcome the silencing of transgene expression and to sustain transgene expression, *cis*-elements such as “insulators” [75–77] that are not affected by chromatin modification may be applied for transgene expression in gene therapy.

Many significant barriers to gene transfer have been elucidated. If omnipotent vector systems are eventually developed, however, gene transfer may harm patients – this is far from therapeutic. An all-encompassing vector system may not be feasible and each vector system must be evaluated with respect to the target disease. In some diseases such as arteriosclerosis obliterans, transient gene expression would be sufficient to cure the disease and sustained gene expression would be detrimental. In other diseases such as SCID-X1 and hemophilia B, it may be necessary to induce transformation of only a small population of cells. Cancer gene therapy comprises more than 60% of current human gene therapy approaches and no remarkable successes have been reported in this area to date. When we consider why gene therapy is necessary for cancer treatment, the answer is that it should be used to inhibit tumor metastasis and suppress the recurrence of cancers. For these purposes, investigations on basic cancer cell biology and technological developments should be promoted much more than at present. The issues described in this chapter present a road map for future technological developments in cancer gene therapy. Thus, technology for gene therapy should be developed on the basis of analysis of the target tissues, target cells, cellular components and relevant molecules.

### 14.3

#### **HVJ-E Vector**

##### 14.3.1

#### **Development of HVJ-E Vector**

HVJ is a mouse parainfluenza virus and is not a human pathogen. As molecules that enter the cell by phagocytosis or endocytosis often become degraded before reaching the cytoplasm, fusion-mediated delivery systems have been developed. A fusigenic viral liposome with a fusion proteins derived from HVJ was constructed [78]. HVJ fuses with the cell membrane at a neutral pH, and the HN protein and F protein of the virus contribute to cell fusion [79]. For fusion-mediated gene transfer, DNA-loaded liposomes were fused with ultraviolet (UV)-inactivated HVJ to form the fusigenic viral-liposome called the HVJ-liposome (Fig. 14.1).

Fusion-mediated delivery protected the molecules in the endosomes and lysosomes from degradation [80]. When fluorescein isothiocyanate (FITC)-tagged oligodeoxynucleotide (ODN) was introduced into vascular smooth muscle cells using HVJ-liposomes, fluorescence was detected in the nuclei 5 min after transfer and fluorescence was stable in the nucleus for at least 72 h. In contrast, fluorescence was observed in cellular components (most likely endosomes) and not in the nucleus when FITC-ODN was transferred directly in the absence of HVJ-liposomes and no fluorescence was detected 24 h after transfer. Using a fluorescence resonance energy transfer system, we demonstrated that more than 80% of oligonucleotides labeled with two different fluorescent dyes at the 5' and 3' ends were

**Figure 14.1.** HVJ-E vector system. For constructing HVJ-E vector, plasmid DNA is mixed with inactivated HVJ particles, and the mixture is treated with mild detergent and centrifugation to incorporate DNA inside the

particle. For constructing HVJ-liposome vector, plasmid DNA is incorporated in liposome and mixed with inactivated HVJ particles. HVJ can fuse with the cell membrane to directly transfer DNA into cells.

intact in the nucleus, while less than 30% of the oligonucleotides were intact when Lipofectin was used [81].

Another advantage of HVJ-liposomes is the ability to perform repeated injections. Gene transfer to rat liver cells was not inhibited by repeated injections. After repeated injections, the anti-HVJ antibodies generated in the rat were not sufficient to neutralize HVJ-liposomes. Cytotoxic T cells recognizing HVJ determinants were not detected in the rats transfected repeatedly with HVJ-liposomes [82].

A similar approach has been used to enhance the gene transfer efficiency of a receptor-mediated gene delivery system by combining fusion peptide derived from influenza virus hemagglutinin (HA) [83]. A tissue-specific gene delivery system has been developed by binding tissue-specific molecules to a poly-L-lysine/DNA complex [84]. Binding asialoglycoprotein and transferrin to a poly-L-lysine/DNA complex successfully targets DNA to hepatocytes and cancer cells, respectively [84, 85]. However, the limitation of this system is the degradation of the DNA in the lysosomes. To avoid such degradation, a fusion-mediated gene delivery system has been investigated using influenza fusion proteins. Influenza virus fuses with cell membranes at an acidic pH, and HA protein on the viral envelope is involved in the fusion between viral envelope and endosomal membrane. It has also been elucidated that a mutant N-terminal peptide of influenza HA subunit, HA-2, can fuse with cell membranes at neutral pH. The transferrin/poly-L-lysine/DNA complex bound with the HA-2 peptide increases gene transfer efficiency in cultured cancer cells more than 1000-fold compared with that in the absence of the peptide [83].

Reconstituted particles containing fusion proteins of HVJ have also been developed to promote fusion-mediated gene delivery [86, 87]. HVJ virion was completely lysed with detergent and the lysates were mixed with DNA solution. In some cases, several lipids were added to the mixture. By removing the detergent with dialysis or a column procedure, reconstituted HVJ particles containing DNA were constructed. Instead of the whole virion of HVJ, fusion proteins (F and HN) isolated from the virion were mixed with the lipid/DNA mixture in the presence or absence of detergent. Since F protein is recognized by the asialoglycoprotein receptor on hepatocytes, reconstituted HVJ particles containing only F protein have been constructed to specifically target hepatocytes *in vivo* [88]. However, DNA trapping efficiency of the reconstituted particles was not so high. To improve the limitation, another approach was that liposomes containing fusion proteins of HVJ and DNA-loaded liposomes were prepared separately, and then both liposomes were fused together [89]. These reconstituted fusion liposomes were as effective as conventional HVJ-liposomes, which contain the fully intact HVJ virion, in terms of the delivery of FITC-ODN and the luciferase gene to cultured cells. The *LacZ* gene was also transferred directly to mouse skeletal muscle *in vivo* using these reconstituted fusion particles.

A more direct and practical approach is the conversion of a fusigenic virion to a nonviral gene delivery particle. Numerous viruses such as influenza, VSV and HVJ induce cell fusion. HVJ is the most abundantly produced in chick eggs. Therefore, we tried to construct an HVJ-E vector system by incorporating plasmid DNA into inactivated HVJ particle [90]. Our approach has been to use inactivated viral envelope in which the viral genome has been destroyed to develop highly efficient and minimally invasive vectors.

There are some drawbacks to HVJ-liposomes, although they have been widely used for gene transfer both *in vitro* and *in vivo*. One disadvantage of HVJ-liposomes is the complicated procedure used to isolate and produce both inactivated HVJ and DNA-loaded liposomes. Additionally, the fusion activity of the HVJ-liposomes decreases to approximately 2% of that of native HVJ because of the reduced density of fusion proteins on the surface of HVJ-liposomes. To simplify the vector system and to develop a more effective gene delivery system, we attempted to incorporate plasmid DNA into inactivated HVJ particles without using liposomes.

HVJ is a mouse parainfluenza virus and is not a human pathogen [79]. HVJ can fuse with cell membranes in both neutral and acidic conditions. Two distinct glycoproteins, HN and F, are required for cell fusion [79, 91]. HN is required for the binding of HVJ to cell surface sialic acid receptors and the subsequent degradation of the receptors by its sialidase activity. Then, F associates with lipids, such as cholesterol, in the cell membrane to induce cell fusion. The F glycoprotein is first synthesized as inactive F0 in cells infected with HVJ. F0 is then cleaved by host protease into the active F1 and F2 forms. F1 contains hydrophobic peptides with approximately 25 amino acids that induce cell fusion [91, 92]. F protein produced in chick eggs is converted to the active F1 form by the protease in chorioallantoic fluid, while the virus produced from cultured cells contains inactive F0 that needs

to be cleaved by a protease to form active F1. Cells in the rodent airway contain enzymes to convert inactive F0 to active F1. Therefore, HVJ induces severe pneumonia in rodents but not in humans. Large amounts of viral proteins are produced in infected cells. Viral nucleocapsid protein induces cytotoxic T lymphocytes (CTLs) against infected cells [93]. However, nucleocapsid protein is indispensable for virus production. Therefore, to develop highly efficient and minimally invasive vectors based on HVJ, our approach has been to use inactivated viral envelope in which the viral genome has been destroyed.

For this purpose, we have converted HVJ to a nonviral vector containing therapeutic genes instead of the viral genome [90]. HVJ amplified in the chorioallantoic fluid of 10- to 14-day-old chick eggs was inactivated with  $\beta$ -propiolactone (0.0075–0.001%) [94] followed by UV irradiation ( $99 \text{ mJ cm}^{-2}$ ) [95]. Then, inactivated HVJ-E was purified by ion-exchange column chromatography and gel filtration (Nakajima and coworkers, unpublished method). With this inactivation procedure, virus replication was completely destroyed, but hemagglutinating activity was not affected. HVJ particles in the chorioallantoic fluid were very heterogeneous with a diameter ranging from 150 to 600 nm. More homogeneous HVJ-E was isolated with the improved purification method using the column procedure. The diameter of HVJ-E obtained from the column procedure was 280 nm and the  $\zeta$  potential was approximately  $-5 \text{ mV}$ .

Aliquots of the inactivated virus ( $3 \times 10^{10}$  particles per 1.5-ml tube) were centrifuged (10 000 g, 5 min) and the viral pellet was mixed with exogenous plasmid DNA. Exogenous plasmid DNA was incorporated into inactivated HVJ by treatment with mild detergent and centrifugation. First, inactivated HVJ ( $3 \times 10^{10}$ ) particles were mixed with 0.24–0.80% Triton X-100 in the presence of plasmid DNA (200  $\mu\text{g}$ ) in less than 100  $\mu\text{l}$  of Tris–EDTA buffer for 5 min on ice and the mixture was centrifuged at 10 000 g for 5 min to move the DNA into the HVJ particle. The DNA trapping efficiency of HVJ-E vector was approximately 15–20%. Without centrifugation, the DNA trapping efficiency was approximately 3%. Different detergents were available for the preparation of HVJ-E vector including NP-40, CHAPS, octylglucoside, sodium cholate and dodecyl maltoside, although the optimal concentration of detergent for preparation of HVJ-E vector is different. Without detergent treatment, DNA does not become incorporated into the viral particle. Electron microscopy confirms that DNA became incorporated into all of the particles of inactivated HVJ. The largest plasmid tested was 14 kb and its trapping efficiency was 18%.

The HVJ-E vector differs from the reconstituted HVJ particles that are prepared by reassembling lipids and fusion proteins after solubilization of the virus particle. To prepare HVJ-E vector, plasmid DNA is incorporated into inactivated HVJ particles by treatment with mild detergent. The virion is not destroyed, and not subjected to the dialysis, purification and addition of lipids or proteins that occurs during the preparation of reconstituted HVJ particles [86, 87, 89]. Protein analysis of HVJ-E vector using sodium dodecyl sulfate–polyacrylamide gel electrophoresis indicates that the composition of HVJ-E vector is very similar to that of native HVJ [90]. Most native HVJ proteins are retained in HVJ-E vector. Fusion proteins HN

and F1 are retained, and the molar ratio of these proteins in HVJ-E vector was approximately 2:2.3, which is the same as the ratio in native HVJ [79]. This ratio of F and HN is very important for fusion activity. Therefore, the fusion activity of HVJ-E vector is as robust as wild-type HVJ. Electron microscopic observation confirmed that the fusion between HVJ-E vector and cell membrane occurs only 3–5 s after the attachment of the plasmid-containing HVJ-E vector to a cell surface.

In contrast to recombinant HVJ viral vector [96], the HVJ-E is a nonviral vector system that consists of an envelope derived from wild-type HVJ virus by inactivation and purification. Since the viral genome is inactivated in HVJ-E vector, the virus does not replicate and viral genes are not expressed in the cells that are transfected with HVJ-E vector. However, cells infected with recombinant HVJ viral vector produce viral proteins. The recombinant HVJ vector produces a large amount of therapeutic products, but it may cause cellular toxicity and be highly immunogenic, which make it less desirable for repeated administration.

For *in vitro* transfection, HVJ-E vector containing luciferase expression plasmid was mixed with PS and this mixture was added to culture cells. Protamine sulfate enhanced luciferase gene expression 10- to 50-fold in several cell lines and the optimum conditions for *in vitro* gene transfer have been previously summarized [90]. Small interfering RNA (siRNA) is an attractive and effective tool for suppressing target protein by specifically digesting its mRNA [97, 98]. siRNA is superior to antisense oligonucleotides and ribozyme in terms of efficiency and specificity [99, 100], but finding a suitable delivery system for siRNA has been problematic [101]. Drugs, synthetic oligonucleotides, proteins and peptides as well as siRNA can be incorporated into HVJ-E vector, and delivered into cells. The HVJ-E-mediated delivery efficiency of siRNA in cultured cells was 100%. Other researchers have also demonstrated that HVJ-E vector efficiently delivers siRNA to islet cell lines [102] and Jurkat cells [103].

HVJ-E vector system can be used for *in vivo* gene transfer. The HVJ-E vector has mediated gene transfer to a variety of tissues (lung, liver, uterus, eye, skin, muscle, brain and heart) in animals including mice, rats, rabbits and monkeys. In mouse liver, HVJ-E vector-mediated luciferase gene expression was 2 times higher than the expression mediated by HVJ-liposomes prepared from inactivated HVJ. In mouse skeletal muscle, consecutive injection of DNA-loaded HVJ-E vector did not inhibit gene transfection. In this experiment, empty HVJ-E vector was injected into mouse muscle tissue twice with a 2-week interval in one experimental group, while another group received saline injections. Two weeks later, HVJ-E vector-containing luciferase gene was intramuscularly injected in all mice. In the two groups, similar luciferase gene expression was observed. Thus, HVJ-E vector appears to be less immunogenic than other viral vector.

We reported the successful gene transfection into uterus and brains by HVJ-E vector [104, 105]. For the transfection into uterus, HVJ-E vector containing plasmid DNA was slowly injected into the uterine cavity and the cervix was clamped for 10 min. For the transfection into brain tissue, we intrathecally injected HVJ-E vector containing the *LacZ* gene into the cerebrospinal fluid (CSF). HVJ-envelope vector containing plasmid DNA was infused at the rate of 50  $\mu\text{L min}^{-1}$  after removing

100  $\mu$ l of CSF. Then, the animals were placed head-down for 30 min. No behavioral changes, such as convulsions or abnormal movements, were observed. Cells that expressed  $\beta$ -galactosidase were present in the spiral ganglion cells (SGCs), cerebral cortex and medulla.

We also examined the transfection efficiency in the intravenous injection of HVJ-E vector. Luciferase gene-loaded HVJ-E vector ( $6 \times 10^9$  particles) was injected into the mouse tail vein and luciferase activity in several organs was measured 24 h after injection. Luciferase expression was detected in the spleen for at least 1 week. When HVJ-E vector containing FITC-ODNs was systemically injected, FITC-ODNs were observed in the marginal zone of the spleen. However, by intravenous injection of HVJ-E vector, coagulation functions in the mouse blood is transiently suppressed, but the functions are recovered at 24 h after the injection. It is probable that the hemagglutinating activity of HN protein will be necessary for systemic injection of HVJ-E vector to ensure the safety in gene therapy.

#### 14.3.2

### Approaches to Cancer Gene Therapy Utilizing HVJ-E Vector

#### 14.3.2.1 Transfection of Dendritic Cells (DCs) with Melanoma-associated Antigen (MAA) using HVJ Envelope Vector for Immunotherapy of Melanoma

Our first approach for developing cancer gene therapy was to construct cancer vaccines using the HVJ-E vector system. Polyvalent tumor antigen vaccines have been evaluated to increase the repertoire of antitumor T cells [106]. In this study, we chose MAA genes, glycoprotein 100 (gp100) and tyrosine-related protein 2 (TRP2), and transfected DCs with these two genes to evaluate *ex vivo* vaccination for prophylactic and therapeutic melanoma treatment.

DCs are the most potent antigen-presenting cells. DCs are capable of highly effective presentation of antigens to naive T cells and they can initiate immune responses [107]. Several clinical studies have now been conducted in cancer patients with tumor-associated antigen (TAA)-loaded DCs [108, 109]. In several of these clinical studies the DCs were loaded by pulsing with protein antigens or with peptides derived from TAAs. Studies have demonstrated that *ex vivo* transfected DCs and adoptive therapy can be very effective in inducing antigen-specific immune responses. This type of strategy has been demonstrated in animals and pilot clinical studies for a variety of cancers [110, 111].

Transfected DCs with vectors expressing TAA genes have shown promising results. Studies have demonstrated that xenogeneic TAAs are very strong immunogens capable of cross-priming to host syngeneic TAAs. Human TRP2 and gp100 proteins have a high amino acid sequence homology to their mouse counterparts. We used xenogeneic TAAs for several reasons: to break self-antigen tolerance in the host, to induce strong antitumor immunity and to enhance individual TAA immunogenicity. The approach provides a large expression of TAAs and activates DC presentation. Therefore, highly efficient transfection system is absolutely necessary for efficient induction of tumor immunity. In recent studies, adenoviral vector was the original vector of choice for efficiently transfecting DCs [112, 113]. However, ad-

enovirus has serious disadvantages as a vector for engineering DCs because of its high toxicity. Some studies have demonstrated that plasmid DNA in liposomes [114], vaccinia virus [115, 116] and retroviruses [117, 118] could be used to infect or transfect human DCs to present a variety of antigens. However, a highly efficient and minimally invasive vector system has not yet been achieved for transfection of DCs. To develop more efficient gene transfer to DCs that cause only minimal damage, we tested the potential of HVJ-E vector for transfection of DCs with two different TAA genes.

We used the luciferase gene to determine the optimal conditions for transfection of DCs. As previously reported, the optimum ratio of HVJ-E vector to cultured cells is  $6 \times 10^3$  to  $1.2 \times 10^4$  [90]. We identified  $1.2 \times 10^4$  as the optimal ratio and determined the most effective transfection conditions. When DCs were incubated with HVJ-E vector containing the luciferase gene, luciferase gene expression was not significant. We attempted to increase the luciferase gene expression by centrifuging the mixture of DCs and HVJ-E vector. Centrifugation at 9000 g was much more effective for gene transfection than 3000 and 13 000 g. The viability of DCs after transfection was approximately 70%. The centrifugation time required for the most effective gene expression was 90 min. The highest luciferase gene expression was obtained in DCs that were centrifuged for 90 min at 9000 g and 37 °C. Six days after DCs were isolated was the best time to transfect the DCs for optimal luciferase gene expression. Thus, the optimal conditions for the most effective transfection of DCs were at 9000 g for 90 min at 37 °C in DCs cultured for 6 days after isolation from bone marrow. Under these optimal conditions, we assessed the expression of yellow fluorescent protein (YFP) expression to determine the transfected DCs population. Almost all DCs that were recognized with phycoerythrin (PE)-conjugated CD11c antibody expressed YFP, as determined by fluorescence microscopy. Flow cytometry analysis revealed that approximately 99% of DCs expressed YFP.

Surface markers of mature DCs were studied by flow cytometry analysis to confirm that differentiation was not inhibited by gene transfection using HVJ-E vector. The lipopolysaccharide (LPS)-induced expression of CD40, CD80, CD86 and HLA-DR was equivalent on nontransfected DCs and transfected DCs. The nonspecific phagocytotic activity of DCs (evaluated by uptake of FITC-labeled dextran) was suppressed in transfected DCs as well as in nontransfected DCs. Thus, gene transfer with HVJ-E vector did not inhibit LPS-induced maturation of DCs.

Next, we used HVJ-E vector to transfect the gp100 and TRP2 genes into DCs. The expression of each transfected antigen was detected by flow cytometry analysis of cells stained with antigen-specific antibody. On day 1, gp100 and TRP2 were detected in 36 and 63% of DCs, respectively. Approximately 80% of DCs expressed both antigens on day 7.

DCs transfected with either the gp100 or TRP2 gene or both genes after one day were injected intradermally into C57BL/6 mice. The delayed-type hypersensitivity (DTH) response was assessed in mice immunized with MAA-transfected DCs at 24, 48, and 72 h after TAA protein challenge. Significant cutaneous DTH was detected in mice immunized with MAA gene-transfected DCs compared to the con-

trol mice that were injected with DCs without MAA. The DTH response to gp100 was significant in the groups immunized with gp100-transfected DCs or gp100/TRP2-transfected DCs. The level of response was equivalent in the two groups. A similar response to TRP2 was obtained in the groups immunized with TRP2-transfected DCs or gp100/TRP2-transfected DCs.

We examined CTLs against BL6 tumor cells on day 7 after DC administration. TAA-specific CTLs were generated with variable response rates. Mice immunized with DCs expressing gp100 and TRP-2 had the highest level of CTL activity against  $^{51}\text{Cr}$  – labeled BL6 target cells. Mice immunized with single TAA-transfected DCs generated significant CTL activity against BL6 cells when compared to the control groups that received HVJ-E vector containing pcDNA-3.1. However, these responses were lower than those generated by the cotransfer of gp100 and TRP2. Vaccination of DCs transfected with TAA genes induced TAA-specific cellular immunity consisting of CTL activity and DTH helper cell activity against melanoma cells.

We tested the effect of vaccination with MAA-transfected DCs on the inhibition of tumor growth in mice. No tumor growth was observed in mice immunized with gp100/TRP2 transfected DCs, although significant tumor masses were palpable in all control mice injected with DCs without TAA. Immunization with DCs transfected with single TAA gene was not effective, as small tumor masses were detected. However, the tumor growth rate was slower than that of the control group. In this prophylactic study, vaccination with DCs transfected with both gp100 and TRP2 was much more effective for inhibition of tumor growth than vaccination with DCs transfected with TRP2 alone.

To investigate the therapeutic effect of vaccination with TAA-transfected DCs, we vaccinated the mice with various DC vaccines 24 h after intravenous inoculation with  $10^4$  BL6 cells. All control mice injected with PBS-treated DCs and pcDNA3.1-transfected DCs died of lung metastasis in 45 and 62 days after inoculation, respectively. Vaccination with DCs that were transfected with a single TAA gene improved the survival. Vaccination with TRP2-transfected DCs was more effective than vaccination with gp100-transfected DCs. Vaccination with gp100/TRP2-transfected DCs significantly prolonged the survival rate. Eight of nine mice vaccinated with gp100/TRP2-transfected DCs survived more than 80 days after tumor inoculation. Vaccination with immature DCs that were not treated with LPS was not effective for improving survival and all of these mice died in 60 days (including the mice that received gp100/TRP2-transfected DCs).

#### 14.3.2.2 Fusion of DC Tumor Cells and Simultaneous Gene Transfer to the Hybrid Cells using HVJ-E for the Prevention and Treatment of Cancers

TAAAs have been identified in some cancers such as melanoma [119, 120]. However, TAAAs in many cancers have not been identified. The identification of TAAAs is required for the development of TAA-loaded DC vaccines.

To solve the problem, hybrid cell vaccines have been developed by fusing DCs with tumor cells [121, 122]. There is evidence that these DC–tumor fused cells possess the properties of both tumor cells containing known and unknown TAAAs and

DCs with high levels of MHC class I and II molecules and costimulatory molecules for priming and activating naive CD4<sup>+</sup> and CD8<sup>+</sup> T cells. Therefore, even though tumor cells lose MHC class I molecules, TAAs can be presented on the surface of the fused cells by DC-derived MHC class I molecules. PEG and electroporation have been used to induce tumor cell–DC fusion. HVJ has been identified as a powerful fusogen. We stained mouse DCs with red fluorescent reagent. Mouse melanoma cells were stained green and irradiated with  $\gamma$ -rays. Both cells were mixed with inactivated HVJ. After 30 min, the fusion of DCs and tumor cells occurred with approximately 50% efficiency.

We used HVJ-E to generate powerful tumor–DC vaccines, because HVJ-E can induce tumor cell–DC fusion and simultaneously transfer DNA or proteins to activate the immune response. To confirm simultaneous fusion and gene transfer mediated by HVJ-E, DCs and tumor cells were mixed with HVJ-E containing the green fluorescent protein (GFP) gene. Fusion between DCs and irradiated-tumor cells was observed, and YFP expression was detected in fused cells as well as in DCs.

Using this system, we attempted to generate anti-tumor immunity using HVJ-E with or without the interleukin (IL)-12 gene. Ten days after the second immunization, spleen cells were isolated to assess cytolytic activity. The cytolytic activity of the effector cells obtained from the mice immunized with fused cells was significantly higher than that obtained from other vaccination protocols such as PBS, IL-12, “Mix” (mixture of DCs and tumor cells without fusion) and “Mix” plus IL-12. Higher cytolytic activity was observed in the mice that received fused cells plus IL-12 as compared with that in the mice that received fused cells alone.

First, we examined the effect of this hybrid cell vaccine on the prevention of tumor generation. After two vaccinations, melanoma cells or renal cancer cells were intradermally injected. The mice vaccinated with fused cells plus IL-12 had significantly increased survival; all of these mice were alive 60 days after tumor challenge in the B16BL6 tumor model. The survival rate was 20% in the mice vaccinated with fused cells without IL-12. All mice in the other groups died. The effect of fused cells and IL-12 on the enhancement of tumor-specific immunity in mice was also observed against renal cancer. Therefore, these findings indicate that immunization with fused cells plus IL-12 strongly induces T<sub>h</sub>1 cytokines and activates tumor-specific CTLs, resulting in significant protection from melanoma, which has known TAAs or renal cancers which has unknown TAAs.

Next, we treated solid tumors by *in vivo* fusion and gene expression using HVJ-E vector. Mouse DCs and HVJ-E vector were injected into solid tumors. The effect of the transfer of a therapeutic gene by HVJ-E vector was also evaluated. To detect *in vivo* fusion of DCs with tumor cells, red-stained DCs were injected into melanoma masses expressing YFP with inactivated HVJ. Megakaryocytes, which indicate tumor cell–tumor cell fusion, were detected, as well as large orange-stained cells indicate DC–tumor cell fusion. However, the fusion efficiency *in vivo* was much less than that of *in vitro* cell fusion.

For therapeutic experiments, melanoma cells were intradermally injected. When the tumor diameter was greater than 5 mm, an injection of DCs and HVJ-E vector

was administered. Spleen cells were isolated and assayed for antimelanoma CTL activity. No therapeutic genes were incorporated into HVJ-E vector. The coinjection of DCs and empty HVJ-E vector resulted in significant antimelanoma CTL activity. DCs or HVJ-E vector alone did not induce CTL activity. When tumor growth was observed, the coinjection of DCs and empty HVJ-E vector inhibited tumor growth, but the tumor volume still gradually increased. When DCs were coinjected with HVJ-E vector that contained the IL-12 gene, a greater inhibitory effect was obtained. The coinjection of DCs and HVJ-E vector effectively prolonged mouse survival. The most effective therapeutic effect was obtained when HVJ-E vector that contained IL-12 gene was coinjected with DCs into the tumor mass; approximately 60% of these mice survived 35 days after treatment.

Thus, we developed a novel cancer vaccine using HVJ-E-mediated DC–tumor cell fusion. The DC–tumor cell fusion was induced by HVJ-E vector at a high efficiency. Both known and unknown TAAs were presented on fused cells by MHC class I molecules from DCs. Furthermore, IL-12 gene transfer was achieved in the fused cells. The expression of IL-12 stimulates the maturation of naive T cells and promotes a  $T_{h1}$  response [123]. It is believed that the presentation of TAAs and the promotion of a  $T_{h1}$  response together induce an efficient antitumor CTL response.

The HVJ-E vector holds great promise for human gene therapy. We are improving the HVJ-E vector system so that it can be used in clinical trials. So far, the virus has been produced in chick eggs, but egg-derived HVJ is difficult to use for clinical trials. It has been very difficult to produce large amounts of the virus in cultured cells and the production in cultured cells are less than 2% of that in chick eggs. We recently developed the system in producing HVJ in human cells. We cloned HEK-293 cells that produce a high titer of HVJ after infection and determined the growth conditions for these cells in an animal product-free medium using a bioreactor. We are able to culture these cells in 10 L of serum-free medium at a density of more than  $10^6$  cells  $\text{mL}^{-1}$  and we can obtain HVJ at the efficiency of more than  $3 \times 10^9$  particles  $\text{mL}^{-1}$ . The production in a 10-L culture is comparable to that in 500 chick eggs. A pilot plant to commercially produce clinical grade HVJ-E vector was established in a venture company named Genemidea (Japan; <http://www.anges-mg.com/news/030324.htm>). Genemidea created a working cell bank, master cell bank and master virus bank for producing clinical-grade HVJ for phase I and IIa trials. They also set up an apparatus to purify inactivated HVJ using two different column systems. The human cell-derived HVJ-E vector was more effective for gene transfection than the egg-derived HVJ-E vector. Human cell-derived HVJ-E vector is also available for drug delivery both *in vitro* and *in vivo*. This vector will be available for human gene therapy soon.

#### 14.4

##### Biocompatible Polymer with HVJ-E

Recent advances in biotechnology have made it possible to produce various clinically useful DNA and proteins. While this technology has brought about the dis-

covery and mass production of these bioactive macromolecules, several challenges need to be addressed with regard to their sustained delivery in a convenient, controlled manner and targeting formulations. It has been demonstrated that complexation with positively charged polymers enabled negatively charged DNA to have an enhanced stability and transfection efficiency to cells [124–126]. Recently, the use of biodegradable gelatin as a nonviral vector augmented adrenomedulin expression and thereby enhanced the therapeutic effects of adrenomedulin gene transfer which potentially induces angiogenesis [127]. They demonstrated that rhodamine isothiocyanate-labeled adrenomedulin DNA was incorporated into positively charged gelatin. In addition, intramuscular administration of adrenomedulin DNA–gelatin complexes strongly enhanced adrenomedulin production compared with that of naked adrenomedulin DNA. These results suggest that biodegradable gelatin may serve as a vector for gene transfer. In fact, adrenomedulin DNA–gelatin complexes induced more potent angiogenic effects in a rabbit model of hind limb ischemia than naked adrenomedulin DNA, as evidenced by significant increases in histological capillary density, calf blood pressure ratio, laser Doppler flow and muscle weight ratio, and a decrease in necrosis of lower hind limb and thigh muscles. These results suggest that the use of biodegradable gelatin as a nonviral vector augments adrenomedulin expression and enhances adrenomedulin-induced angiogenic effects. Adrenomedulin DNA–gelatin complexes were distributed mainly in connective tissues. They have recently demonstrated that gelatin–DNA complex is readily phagocytosed by macrophages, monocytes, endothelial progenitor cells, etc., resulting in gene expression within these phagocytes [128, 129]. These findings raise the possibility that adrenomedulin secreted from these cells acts on muscles in a paracrine fashion. Unlike adrenomedulin production in the naked adrenomedulin group, adrenomedulin overexpression in the adrenomedulin–gelatin group lasted for longer than 2 weeks. Thus, it is interesting to speculate that delaying gene degradation by gelatin may be responsible for the highly efficient gene transfer.

We succeeded in enhancing the transfection efficiency of HVJ-E by combining it with cationic polymers [130]. For cultured cells *in vitro*, the most efficient transfection was obtained by combining HVJ-E with both CG and PS. However, for *in vivo* transfection, CG–HVJ-E without PS resulted in the highest gene expression. These findings are consistent with our previous report indicating that the particle size of cationic liposomes may affect gene transfection efficiency [131]. By adding both PS and CG to HVJ-E, the size and charge of the resulting complex may have been the most suitable for *in vitro* transfection. PS and CG affected gene transfection efficiency in a variety of cell lines as well as in primary cells, although the efficiency was varied among cell types. The ratio of PS and CG used for these experiments was determined by gene transfection experiments with CT26 cells. Thus, gene expression in the other cell types may be enhanced when the conditions are optimized for each cell type.

We determined that cell fusion is the mechanism responsible for a PS–CG–HVJ-E-mediated gene transfer system. Although endocytosis appeared to be involved in gene transfection based on the wortmannin experiments, transfection

was completely inhibited by antibody against the fusion protein of HVJ. Since the fusion activity of HVJ is pH independent, HVJ can fuse with the cell membrane both on the cell surface and in endocytotic vesicles. Even for the HVJ-E complex with PS and CG, the F protein of HVJ appeared to associate with the cell membrane, and fusion activity appeared to be necessary for gene transfection.

HVJ-E complexed with CG targeted the liver. With PS, gene expression in the liver after intravenous injection was lower than with CG–HVJ-E. We speculate that larger particles with positive charge are less mobile when intravenously administered. Comparison with PS–HVJ-E and PS–CG–HVJ-E suggests that CG–HVJ-E may have the appropriate size and potential for targeting the liver after intravenous injection. Our results suggest that the CG–HVJ-E vector may be effective and practical for the treatment of liver diseases, such as liver cirrhosis and hepatitis, when therapeutic genes encoding secreted proteins, such as human growth factor, soluble transforming growth factor- $\beta$  receptor and decorin, are employed. An adverse effect of this treatment is that coagulation function is transiently decreased by CG–HVJ-E in mice, although it recovered in 1 day. This adverse effect is probably caused by HVJ hemagglutinating protein, which is necessary for binding with sialic acid, a virus receptor. When HVJ-E is complexed with CG, CG may perform the function of hemagglutinating protein and enhance the association with cell membranes. If HVJ-E without hemagglutinating protein is combined with CG, the complex may reduce adverse effects to a much lower level.

An additional advantage of CG is that it protects HVJ-E from degradation in fresh mouse serum. Although the *in vitro* transfection efficiency of HVJ-E was not inhibited by culture medium containing 10% FBS, the activity of HVJ-E was rapidly lost in the presence of fresh mouse serum. However, CG–HVJ-E was significantly stable in 50% fresh mouse serum. The high transfection activity of CG–HVJ-E after intravenous injection appears to be mediated by the stability of the vector in fresh serum. Liposomes composed of hydrogenated egg phosphatidylcholine and cholesterol activate the complement system in rats by interacting with IgG and IgM. Although it is unproven that HVJ is degraded by complement lysis in mouse serum, the interaction of serum proteins with HVJ-E may be involved in the loss of transfection activity of HVJ-E. Conjugation to CG appears to protect the surface molecules of HVJ-E from the detrimental effects of serum proteins.

The results of this study suggest that low-molecular-weight CG may be appropriate for complex formation with various envelope viruses, such as retrovirus, herpes virus and HIV, and that the CG-envelope virus vector may enhance transfection efficiency both *in vitro* and *in vivo*. This technology may lead to the achievement of an ideal vector system with high efficiency and minimal toxicity.

## 14.5 Magnetic Nanoparticles for Medicine

A novel transfection method, so called magnetofection, which comprises the association of vectors with superparamagnetic iron oxide nanoparticles and gene deliv-

ery under the application of a magnetic field, has been developed [132]. Using the method of magnetofection the efficiency of synthetic gene carriers has been enhanced up to several-hundred-fold. In particular, the duration of the transfection procedure has been reduced to minutes [132]. For magnetofection, gene carriers such as poly(ethylenimine) (PEI), which are associated with superparamagnetic iron oxide nanoparticles, are complexed with plasmid DNA (these complexes are called magnetofectins) and gene delivery is targeted by the application of a magnetic field. For an unrestricted use of magnetofection and its benefits it would be advantageous to gain more insights into the cellular uptake mechanism of the magnetofectins. For polyplexes an endocytic uptake mechanism, probably mediated by heparan sulfate proteoglycan receptors via endosomes, has been shown [133]. Due to its high buffering capacity, PEI is able to destabilize the endosomal membrane leading to the so-called endosomolysis. PEI apparently induces a massive proton accumulation in the endosomes followed by passive chloride influx leading to osmotic swelling of the endosomes and, finally, to its burst releasing the gene vectors into the cytoplasm as a prerequisite for the transport of DNA towards the nucleus. This effect is called the “proton sponge effect” [134–136]. In this context the question arises whether the PEI-based magnetofectins function in the same way as PEI gene vectors. In particular, we asked if the applied magnetic force result only in an increased accumulation of magnetofectins on the cell surface or if it is even able to pull them directly into the cells, circumventing endocytosis and leading to a different gene transfer mechanism as for PEI gene vectors.

Endocytosis is involved in various cellular processes like the transmission of neuronal, metabolic and proliferative signals, the uptake of many essential nutrients, and the ability of defense against invading microorganisms [137]. It is characterized by the formation of membrane vesicles at the plasma membrane. One distinguishes between clathrin-dependent and clathrin-independent endocytosis. The clathrin-dependent endocytosis is the best described so far. Here the vesicles (diameter of approximately 100 nm) are coated with clathrin [137, 138]. After internalization, the clathrin coat gets recycled and the vesicle fuses with an endosome where the sorting, mediated by microtubules, and the dissociation of potential receptors take place. This step is followed by degradation in lysosomes and further transport to the final destination [138]. Well-known examples for the clathrin-dependent uptake mechanism of receptor-bound ligands are transferrin and the low-density lipoprotein (LDL) [137]. The clathrin-independent pathways include phagocytosis, macropinocytosis, constitutive nonclathrin uptake and caveolae-mediated uptake [137]. Phagocytosis is generally restricted to macrophages, whereby macropinocytosis refers to the formation of large, irregular primary endocytic vesicles [138]. Clathrin-independent endocytosis in the absence of caveolae and caveolin is found and designated as constitutive nonclathrin uptake. The caveolae-mediated uptake is characterized by caveolae, which are omega-shaped, noncoated membrane invaginations (diameter 50–100 nm) present in many cell types, but especially abundant in endothelial cells [138]. Their structure is maintained by a family of cholesterol-binding proteins called caveolin. Besides caveolin, caveolae

are enriched in cholesterol, sphingomyelin and glycosphingolipids [138]. There is some evidence for a potential role of caveolae in the internalization and intracellular delivery of gene-based therapeutics, as used for somatic gene transfer or single-stranded oligonucleotide technology [139].

We focused on magnetic nanoparticles, such as magnetite and maghemite, with an average size of from 20 to 50 nm, which can be positionally regulated by a magnetic force. Magnetic nanoparticles basically consist of oxidized iron, which is commonly used as a supplement for the treatment of anemia. We hypothesized that the association of magnetite and HVJ-E technology could allow the rapid attachment of HVJ-E and cells by application of a magnetic force, leading to enhanced transfection efficiency. Moreover, magnetic nanoparticles can be modified with several chemical compounds to allow modification of the charge, size and affinity. In addition, there is increasing interest in using magnetic resonance imaging (MRI) to monitor the *in vivo* behavior of proteins labeled with magnetic nanoparticles [140, 141]. Indeed, magnetic nanoparticles were recently used for gene transfection, because magnetic targeting exploits paramagnetic particles as drug carriers, guiding their accumulation in target tissues with strong local magnetic fields [142, 143].

To evaluate the HVJ-E vector system mixed with maghemite, we mixed several doses of maghemite with HVJ-E vector infusing luciferase plasmid. However, unexpectedly, we did not find any improvement in transfection efficiency. From these results, we speculated that there might be a close association, such as electrostatic interaction, between HVJ-E and maghemite. Since we have previously reported that PS, a low-molecular-weight naturally polycationic peptide (around 4000 Da), enhanced the transfection efficiency based on HVJ-E vector in an *in vitro* culture system, we coated the surface of maghemite with PS. After modification with PS, the  $\zeta$  potential of maghemite was changed to  $23.8 \pm 1.8$  from  $17.5 \pm 1.6$  mV, which suggests that surface coating of maghemite enhanced its cationic charge. Interestingly, a mixture of PS-coated maghemite with HVJ-E vector significantly enhanced the transfection efficiency in a dose-dependent manner. Using the same system, high transfection efficiency into BHK cells was also achieved using the enhanced GFP (EGFP) gene or FITC-ODN. To confirm the interaction of magnetite and HVJ-E vector, we performed electron microscopy. PS-coated maghemite and HVJ-E vector co-existed even though a number of maghemite particles were aggregated around HVJ-E vector (Fig. 14.2).

To explore transfection *in vivo*, we further evaluated the maghemite-attached HVJ-E vector by direct injection into mouse liver. Unexpectedly, a mixture of maghemite surface-coated with PS did not enhance the transfection efficiency in the analysis of luciferase activity, differing from the *in vitro* system. Since cotreatment with heparin has been reported to enhance the transfection efficiency of HVJ-E vector in brain tissue, we next coated the surface of maghemite with heparin, which might antagonize the function of PS. The  $\zeta$  potential of maghemite was changed to  $-10.1 \pm 2.3$  from  $17.5 \pm 1.6$  mV, which suggests that the surface coating of maghemite was changed to a fairly negative net charge. A mixture of

**Figure 14.2.** Modified HVJ-E vector. PS enhanced the transfection efficiency based on HVJ-E vector in an *in vitro* culture system. In addition, we coated the surface of magnetic nanoparticles with PS and further enhanced the transfection efficiency based on HVJ-E vector.

heparin-coated maghemite with HVJ-E vector significantly enhanced the transfection efficiency in the liver. These data suggest that suitable modifications for gene transfection differ between *in vitro* and *in vivo*. Analysis of EGFP expression in the liver by immunostaining, also confirmed marked expression obtained with heparin-coated maghemite with HVJ-E vector containing the EGFP gene as compared to PS-coated maghemite. For safety evaluation, the serum levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were not further elevated in the heparin-coated maghemite group compared to the control group. Furthermore, we tried to enhance the transfection efficiency under the influence of a magnetic field by placing a magnet on the surface of the liver. However, no obvious improvement in luciferase activity in the liver was observed. Probably, a stronger magnetic field or more accurate control of magnetite might be necessary to enhance it.

In the system of magnetofection, the gene carrier itself represents a hybrid system characterized by an iron oxide inner core and a coat consisting of the cationic PEI which might also assist the endosomal escape of a gene after transfection into cells. In contrast, in our system, transfection was mediated by a cell fusion process of HVJ-E vector, which did not require endosomal escape, are not by endocytosis. Thus, we selected PS as the coating material of maghemite in combination with the HVJ-E system, as PS is a low-molecular-weight polycationic peptide that has Food and Drug Administration approval as an antidote to heparin anticoagulation

[144, 145]. Since both the surface of HVJ-E and the cell membrane have a negative net charge, cationic charged PS-coated maghemite can be speculated to enhance the association of HVJ-E with the cell membrane. Thus, PS-coated maghemite would actively carry HVJ-E to cultured cells under a magnetic force.

However, in an *in vivo* system, heparin, but not PS, was suitable as the coating material in combination with HVJ-E vector, consistent with a previous *in vivo* report. Of special interest regarding this result was a previous report showing that coinjection of trophic factors and heparin into the rat brain significantly enhanced the volume of distribution. Thus, we speculate that the distribution of these vectors may be a key to explaining this discrepancy between *in vitro* and *in vivo* gene transfer. In addition, no immunohistochemical data has been presented on potential toxic effects of heparin. The size and surface chemistry of magnetic particles could be tailored accordingly to meet specific demands of physical and biological characteristics.

Magnetically targeted drug delivery by particulate carriers to a localized disease site may be efficient as drugs and a very high concentrations of chemotherapeutic or radiological agent can be achieved near the target site, such as a tumor, without any toxic effects on normal surrounding tissue or the whole body. Magnetic carriers receive their magnetic responsiveness to a magnetic field from incorporated materials such as magnetite, iron, nickel, cobalt, neodymium–iron–boron or samarium–cobalt. As for biomedical applications, magnetic carriers must be water-based, biocompatible, nontoxic and nonimmunogenic. The first medical application directly applied magnetite or iron powder. The first clinical cancer therapy trial was performed in Germany for the treatment of advanced solid cancer in 14 patients using magnetic microspheres that were about 100 nm in diameter and filled with 4'-epidoxorubicin [146]. The phase I study clearly showed low toxicity of the method and accumulation of MMS in the target area. However, MRI measurements indicated that more than 50% of MMS ended up in the liver [147]. Conceptually, magnetic targeting is a very promising approach. However, there are a number of physical, magnetism-related properties which require careful attention. (i) More responsive magnetic materials with defined and homogenous material properties in a stable and defined oxidation state need to be synthesized. (ii) The size must be small enough that they do not clog the blood vessels through which they are guided to the target organ. (iii) Altering the surface of magnetite with appropriate molecules should be considered, to either increase or decrease the interaction of magnetite with tissues or organs. (iv) The magnetite size must be uniform enough to provide an equal probability of magnetic capture for each magnetite particle. (v) The fate of the particles in the body is an important consideration both for local and systemic short- and long-term toxicity. Thus, further improvements of this hybrid vector were required in future studies.

Overall, we have developed a novel hybrid vector of HVJ-E and magnetic nanoparticles with different surface modifications in an *in vitro* culture system as well as *in vivo*. Further modification of this system with MRI might provide new therapeutic potential to achieve tissue targeting.

## 14.6

## Conclusion

If omnipotent vector systems are eventually developed, gene transfer may harm patients – this is far from therapeutic. An all-encompassing vector system may not be feasible and each vector system must be evaluated with respect to the target disease. In some diseases such as arteriosclerosis obliterans, transient gene expression would be sufficient to cure the disease and sustained gene expression would be detrimental. In other diseases, such as SCID-X1 and hemophilia B, it may be necessary to induce the transformation of only a small population of cells. Cancer gene therapy occupies more than 60% of current human gene therapy approaches and no remarkable successes have been reported in this area to date. When we consider why gene therapy is necessary for cancer treatment, the answer is that gene therapy should be used to inhibit tumor metastasis and suppress the recurrence of cancers. For these purposes, investigations in basic cancer cell biology and technological developments should be promoted much more than at present. The issues in this chapter present a road map for the future technological developments for gene therapy. Thus, technologies in gene therapy should be developed on the basis of analysis of the target tissues, target cells, cellular components and molecules which are relevant to the biology.

# Nanotoxicology of Synthetic Gene Transfer Vectors: Poly(ethyleneimine)- and Polyfectin-mediated Membrane Damage and Apoptosis in Human Cell Lines

*Seyed M. Moghimi*

### 15.1

#### Introduction

Viral vectors are extremely efficient in transfecting cells; however, they can induce severe immunotoxicity and inflammatory responses, which restrain repeated administration [1]. The death of Jesse Gelsinger in September 1999 during an experimental adenoviral gene therapy trial conducted at the University of Pennsylvania is a grim reminder of these adverse effects. The autopsy findings confirmed that the adenoviral vector initiated an unusual and deadly immune system response that led to multiple organ failure and adult respiratory distress syndrome, and ultimately brain death. Another potential complication is insertional mutagenesis, which could pose additional risks in gene therapy programmes involving retroviruses, as evident from stem cell gene therapy trials for treatment of X-linked severe combined immunodeficiency disease at Necker Hospital, Paris, France [1–3]. Of 17 patients who participated in this programme, virtually all showed major improvement. However, three developed leukemia-like conditions; of these, one subsequently died. These issues, together with the limited loading capacity and difficulties in large-scale production of viral vectors, have generated a surge in design and engineering of synthetic cationic nonviral gene transfer systems. Examples include a plethora of cationic lipids (lipofectins) and polycations (polyfectins) such as poly(L-lysine) and poly(ethyleneimine) (PEI) in linear, branched and dendrimeric form, and variations thereof [poly(ethylene glycol)- and ligand-tagged] [4–6]. These materials can condense genetic materials into nanostructures readily amenable for transfection. PEIs have received considerable attention in gene transfer protocols as a result of excellent transfection efficiencies [4–6].

This chapter briefly reviews the structure and properties of PEI-based transfectants. PEI is also cytotoxic, but the molecular basis of its cytotoxicity is poorly understood and therefore not discussed in detail in previous reviews. The major part of this chapter critically examines recent breakthroughs in understanding of the molecular mechanisms of PEI-mediated cytotoxicity.

## 15.2

### PEI as a Nonviral Vector

#### 15.2.1

##### Structure and Properties of PEI and PEI–DNA Complexes

PEI exists in both linear and branched form and is available in a broad range of molecular weights (from a few hundred Daltons to 1500 kDa). Ring-opening polymerization of 2-substituted 2-oxazoline leads to formation of poly(*N*-formalethylenimine), which is then hydrolyzed to yield linear PEI. In contrast, the branched form of PEI is produced by acid-catalyzed polymerization of aziridine.

PEI is capable of condensing DNA and RNA into stable toroidal and globular nanostructures mainly via electrostatic interactions, as supported by a range of biophysical characterization studies [7–10]. The physicochemical nature and stability of the PEI–DNA complex (polyplex) is dependent on a number of factors, including PEI type, molecular weight, charge density, ionic strength of the media, the tertiary structure of nucleic acids (e.g. linear versus supercoiled DNA), polymer:DNA ratio and even the sequence of component addition, and these are reviewed recently in detail by Neu and coworkers [6]. For example, low-molecular-weight PEIs (2 kDa and smaller) form larger polyplexes (greater than 500 nm) than their high-molecular-weight counterparts (less than 200 nm). Also, linear PEI possesses lower DNA condensation capacity when compared to a branched counterpart, which is attributed to its lower content in primary amines [6].

Polyplex formation not only protects DNA and RNA from degradation by nucleases, but also is a necessary prerequisite for the efficient delivery of nucleic acids into cells via endocytosis and macropinocytosis [10]. Following internalization, PEI can rapidly destabilize endosomal membrane following protonation. Indeed, every third atom of PEI is a nitrogen capable of protonation. PEI exhibits a very high buffering capacity above pH 7, which is attributed to the secondary amines in the structure, but additionally shows buffering capacity in the range of endosomal pH (pH 4–6). Thus, following internalization, PEI-based polyfectins act as proton sponges, buffering the low endosomal pH and inducing membrane rupture [11–14]. This releases PEI and PEI–DNA complexes into the cytoplasm.

#### 15.2.2

##### Cytotoxicity

Various reports have indicated that PEI can induce cytotoxicity, often defined by assessing the *in vitro* metabolic activity of cells (e.g. MTT assay), but the mechanism(s) remain unclear [6, 15–17]. High-molecular-weight PEIs are more cytotoxic than their smaller counterparts and increasing the degree of branching induces more cytotoxic effects [15, 17]. The issue of PEI-induced cytotoxicity is particularly important in protocols that attempt to restore gene function, e.g. in metabolic disorders. PEI-induced cytotoxicity in normal and nontarget cells, particularly the type

of cells that the cationic vectors will encounter when first administered to the patient, must also be considered. One of the most striking features of PEI polyplexes is the large amount of PEI that remains in the free form, which may induce cell dysfunction and explain the observed cytotoxicity [18]. However, the presence of free PEI is essential for modification and permeabilization of the endosomal membrane structure, thus affording polyplexes a mode of access into the cytoplasm [6, 18]. Indeed, partially purified PEI complexes were recently shown to induce less cytotoxicity, but this also led to a decrease in transfection efficiency [19]. The removal of excess PEI may also affect the stability of polyplexes, since complex formation is an equilibrium process [18].

In light of these observations and with the view that the intracellular levels of endogenous polyamines (e.g. spermine and spermidine) are tightly regulated by means of several homeostatic mechanisms, whereas their excessive cytoplasmic accumulation (e.g. resulting from insults to anionic cellular structures) transduces a death signal to mitochondria by an oxygen-independent mechanism [20, 21], we sought to investigate the effect of PEI and related polyfectins on human cell dysfunction and apoptosis. For the first time, we have identified PEI as an apoptotic agent [22, 23]. Our observations and findings may provide a likely explanation for previously reported transient gene expression associated with polyfectin vectors. A brief overview of our findings as well as recent breakthroughs in polycation-induced cytotoxicity mechanisms is therefore discussed.

### 15.3 PEI-mediated Cell Dysfunction and Apoptosis

#### 15.3.1 PEI and PEI–DNA Complex Internalization

PEI and PEI–DNA complexes enter most cells presumably via binding to transmembrane heparan sulfate/chondroitin sulfate proteoglycans that belong to the syndecan family (e.g. syndecan-1 and -4) [24–27]. Cells, like fibroblasts, express glycosylphosphatidylinositol-anchored heparan sulfate proteoglycans (glypican) instead, which may also serve as a receptor for polyamine uptake [28].

Earlier, fluorescence-labeled studies have demonstrated that within 3 h of incubation with human cell lines, a significant fraction of PEI and PEI–DNA complexes appears in endosomes and endolysosomes [11]. Subsequent attempts with double fluorescence-labeled PEI–DNA complexes have shown disruption of some endosomes, beginning at 4 h postincubation, with evidence of some separation of DNA from PEI in cytosol [11]. Nuclear localization of PEI or PEI–DNA was relatively common by 3.5–4.5 h postincubation and the earliest localization of complexes within nuclei preceded the earliest observed transgene expression by 1 h [11]. The molecular basis of PEI–DNA complex localization to the nucleus still remains unclear, but such complexes may attract a lipophilic coating within cytosol,

thus promoting fusion with the nuclear membrane. However, PEIs in the range of 5–25 kDa are most efficient in transfection experiments because of their small size (less than 200 nm) and relatively faster cytosolic movements [6].

### 15.3.2

#### Plasma Membrane Damage and Apoptosis

We have shown that exposure of three different primary human cell lines (hepatocytes, endothelial cells and lymphocytes) to branched (B)-PEI (25 kDa) or linear PEI (750 kDa) in both free form (10 and 30  $\mu\text{g mL}^{-1}$ ) as well as complexed with a mammalian DNA (regardless of PEI:DNA) causes considerable release of lactate dehydrogenase (LDH) within 1 h, followed by a time-dependent gradual rise in LDH release, thus confirming plasma membrane damage (Fig. 15.1A) [22]. Parallel to rapid LDH release, we also reported rapid (30–60 min) redistribution of phosphatidylserine (PS) from the inner plasma membrane to the outer cell surface with PEI concentrations of 20  $\mu\text{g mL}^{-1}$  and above (Fig. 15.1B) [22]. PS redistribution was increased gradually with time. However, at lower PEI concentrations (e.g. 10  $\mu\text{g mL}^{-1}$ ) PS externalization was significant only after prolonged incubation periods (e.g. 24 h). PS translocation is a hallmark of apoptosis; caspase-3 in active form impairs the activity of aminophospholipid translocase, which leads to PS externalization [29, 30]. Early PS expression, however, was not inhibited in the pre-

**Figure 15.1.** The effect of B-PEI in free form and DNA-complexed on Jurkat T cell plasma membrane integrity. The release of the cytoplasmic LDH from cells is shown in (A),

whereas (B) demonstrates the extent of PS externalization from the inner to the outer cell surface. Detailed experimental procedures are outlined in reference [22].

**Figure 15.2.** The effect of B-PEI in free form and DNA-complexed on caspase activation and cytochrome *c* release in Jurkat T cells.

sence of Ac-DEVD (a broad-spectrum caspase inhibitor) and therefore occurs independent of procaspase-3 cleavage. A substantial delay between PS exposure and activation of the executioner caspase-3 was also observed [22]. The activity of this protease was profound particularly at 24 h post-B-PEI/B-PEI–DNA treatment (Fig. 15.2) and could be inhibited by Ac-DEVD. Also, caspase-3 activation was detectable at 24 h post-treatment with lower concentrations of PEI and PEI–DNA complexes; this was in accord with PS expression in tandem with propidium iodide staining. Hence, both PEI types induce apoptosis, but early exposure of PS is presumably the result of plasma membrane destabilization during internalization processes, where PEI may crosslink syndecan molecules and/or induce syndecan clustering. Subsequently, syndecan/glypican clustering may mediate actin stress fiber formation and activate associated signaling pathways such as those of Src family of kinases, contractin, tubulin, microfilament-regulated processes and phosphatidylinositol 4,5-bisphosphate-dependent processes [27, 28, 31]. In certain cells these processes may initiate apoptosis via activation of protein kinases, depending on polycation type and architecture (discussed later). Dissociation of PEI–DNA complexes is also known to occur in the presence of negatively charged macromolecules [32]. It is likely that PEI may interact with actin and alter membrane integrity.

However, through which of the two primary caspase activation pathways, mitochondrially mediated and death receptor-mediated, do PEIs and PEI–DNA complexes induce apoptosis? Here, studies were restricted to PEI–DNA complexes that expressed positive  $\zeta$  potential (PEI:DNA of 3:1), thus mimicking the established transfection protocols [6]. Stress-induced stimuli triggers mitochondrial permeabilization and causes the release of proapoptotic proteins such as cytochrome *c*, apoptosis-inducing factor (AIF), and Smac/DIABLO from mitochondrial intermembrane space [33, 35]. For example, cytochrome *c* release initiates apoptosis via the Apaf-1-containing apoptosome complex assembly. This results in subse-

quent cleavage of caspase-9, which, in turn, activates the executioner caspase-3 [33, 35]. On the other hand AIF, a 50-kDa protease, is capable of inducing DNA fragmentation and chromatin condensation directly [35]. PEI and PEI–DNA treatment in human cell lines was associated with substantial activation of both caspase-3 and -9; significant accumulation of cytochrome *c* in cytosol was also observed (Fig. 15.2) [22]. Since nuclear accumulation of PEI–DNA complexes was reported to occur within a few hours of transfection [11], PEI may also induce genotoxic stress via caspase-2 activation [36, 37]. Indeed, activated caspase-2 can directly permeabilize the outer mitochondrial membrane and stimulate the release of death-promoting proteins without the involvement of mitochondrial permeability transition [36, 37]. However, no evidence for caspase-2 activation even after prolonged periods following PEI and PEI–DNA complex treatment was reported [22, 38]. Also, the absence of caspase-8 activity further suggested that plasma membrane manipulation by PEI and PEI–DNA complexes has no effect on death receptor signaling, which could lead to activation of caspase-3 and -7 directly or indirectly via subsequent cleavage of the amino portion of cytosolic Bid. This would have generated truncated Bid, which, in turn, could activate proapoptotic Bax or Bak proteins to release cytochrome *c* from mitochondrial intermembrane space [35].

The loss of mitochondrial membrane potential (MMP) is also an early event in several types of apoptosis [39, 40]. In our hands, MMP in human cell lines was dramatically dropped in a time-dependent manner [22, 23] and was consistent with caspase activation (with peak activity at 24 h). MMP was determined by a specific cationic fluorescent probe, JC-1, which fluoresces differently in healthy and apoptotic cells (Fig. 15.3). JC-1 forms aggregates in healthy mitochondria with a high orange/red fluorescence, indicating a normal MMP, but following MMP loss these aggregates dissipate into the cytoplasm in the monomeric state, which is detectable with a concurrent gain in green fluorescence [22]. Therefore, these observations confirm that PEI and PEI–DNA complexes induce apoptosis via the mitochondrial pathway.

### 15.3.3

#### **Effect of PEI on the Function of Isolated Mitochondria**

To further understand the molecular basis of PEI-induced mitochondrially mediated apoptosis, attention was focused on studies with isolated mitochondria [22]. Here, PEI was able to release cytochrome *c* from the mitochondrial intermembrane space in a concentration-dependent manner. Indeed, cytochrome *c* release was detectable following treatment with both PEI types even at levels as low as 0.1  $\mu\text{g mL}^{-1}$ . Interestingly, cytochrome *c* release was not associated with changes in mitochondrial volume (Fig. 15.4). This observation may indicate a minor role for permeability transition in the release of apoptogenic proteins from mitochondria. However, it should be emphasized that permeability transition is reversible; permeability transition may cause an individual mitochondrion to swell, releasing apoptogenic proteins, and then reverse and regenerate membrane potential [41]. Therefore, this route may still operate in intact cells.

**Figure 15.3.** Time-dependent changes in MMP in Jurkat T cells by free ( $30 \mu\text{g mL}^{-1}$ ) and DNA-complexed (PEI:DNA, weight ratio 3:1) branched PEI, as determined by specific MMP fluorescent probe JC-1. Detailed experimental procedures are outlined in Ref. [22].

**Figure 15.4.** The effect of polycations on continuous swelling of isolated rat liver mitochondria, monitored as changes in  $A_{540}$  at room temperature. Detailed experimental procedures are outlined in Refs. [22, 50].

**Figure 15.5.** The effect of branched PEI on function of isolated rat liver mitochondria. (A) The effect of PEI on cytochrome *c* release (Western blot analysis). (B) The extent of DiOC<sub>6</sub>(3) uptake by isolated mitochondria at different treatment protocols. Following incubation with PEI and rCasp-3 (15 min),

DiOC<sub>6</sub>(3) was added and the sample was incubated for a further 10 min at 22 °C. Samples were then diluted in the buffer, filtered and incubated for a further 10 min before flow cytometric analysis content of individual mitochondria.

Changes in the membrane potential of isolated mitochondria can be followed by measuring the uptake of the cationic lipophilic fluor DiOC<sub>6</sub>(3) (Fig. 15.5). This membrane potential-sensitive dye electrophoretically accumulates in the negatively charged matrix of healthy mitochondria. When mitochondrial depolarization occurs, accumulation of DiOC<sub>6</sub>(3) is reduced and can be followed by flow cytometry as a decrease in mitochondrial-associated green fluorescence. Interestingly, dye uptake remained unaltered in the presence of PEI (i.e. after cytochrome *c* release) when compared to healthy intact mitochondria (where no cytochrome *c* release is detectable) (Fig. 15.5). As a control experiment DiOC<sub>6</sub>(3) responded to acute changes in mitochondrial membrane potential induced by the protonophore carbonyl cyanide *p*-chlorophenylhydrazone (CCCP). Thus, cytochrome *c* release is independent of mitochondrial depolarization [22], but in intact cells PEI was capable of altering MMP. This discrepancy may indicate a role for activated caspases in altering MMP. Remarkably, the addition of an active recombinant human caspase 3 (rCasp-3) exerted no effect on dye accumulation in intact mitochondria, whereas in the presence of PEI dye uptake was reduced dramatically unless Ac-DEVD was present (Fig. 15.5). These experiments strongly support that PEI is capable of forming channels in the outer membrane large enough to allow the release of cy-

tochrome *c*, presumably in a manner similar to proapoptotic peptides and oligomeric Bax [42, 43], without altering MMP. Thus, these observations are also in accord with the loss of MMP in intact cells following PEI or PEI–DNA uptake, which is believed to occur after cytochrome *c* release and presumably is mediated by activated caspases. Indeed, recently it was demonstrated that following cytochrome *c* release, activated caspases gain access to the intermembrane space of mitochondrion where they cleave the 75-kDa subunit of respiratory complex I, resulting in disruption of complex I activity, loss of MMP and production of reactive oxygen species [44].

#### 15.3.4

#### Other Plausible Apoptotic Routes

Recently, a spatial and functional connection between Bax and the mitochondrial fission process was suggested [45, 46]. In normal interphase cells the mitochondria exists as a tubular network. During apoptosis, the mitochondrial network becomes fragmented and Bax colocalized with the fission- and fusion-related proteins (Drp1,

**Figure 15.6.** Schematic representation of possible polycation effect on protein kinase and phospholipase activation, and the role of full-length Bid in initiation of mitochondrially mediated apoptosis.

Mfn2) at fission sites in the outer mitochondrial membrane. Due to their polycationic nature and molecular architecture, PEI molecules could hypothetically promote mitochondrial fission, which may lead to destabilization of the outer mitochondrial membrane.

It can also be speculated that following binding to plasma membrane proteoglycans, such as syndecan or glypican, PEI and related polycations may initiate apoptosis via signaling and activation of protein kinases (Fig. 15.6). For example, poly(L-lysine)s and poly(arginine)s are known to stimulate a number of cellular kinases and protein phosphatases, particularly phospholipases, even at suboptimal cytotoxic concentrations [47]. For instance, poly(L-lysine) is capable of inducing phospholipase D activation in bovine pulmonary artery endothelial cells through the involvement of protein kinase C [47]. Phospholipase activation may lead towards insertion of lysolipids into the outer mitochondrial membrane via the recently identified lipid transfer capacity of full-length Bid [48]. Once bound to lysolipid, full-length Bid is suggested to transfer lysolipid to intracellular membranes rich in cardiolipin and monolysocardiolipin, towards which the protein has a “static” selectivity of binding, thereby altering cardiolipin homeostasis [48]. Indeed, monolysocardiolipin is an inhibitor of mitochondrial phospholipase A2 [49] and thus tight binding of full-length Bid to monolysocardiolipin may lead to activation of this phospholipase. These modifications may induce a positive change in the outer mitochondrial membrane curvature leading to the release of apoptogenic factors, either directly or through other mediators.

#### 15.4

##### Cell Damage and Apoptosis with Related Polycations and Cationic Lipids

Poly(L-lysine) are also used widely in DNA compaction and gene transfer protocols [4]. Recent observations from this laboratory have shown that poly(L-lysine)s are also capable of inducing mitochondrially mediated apoptosis in a wide range of human cell lines [50]. However, low- and high-molecular weight poly(L-lysine)s/poly(L-lysine)–DNA complexes had different effect on mitochondrial functions and initiated mitochondrially mediated apoptosis differently. For example, high-molecular-weight poly(L-lysine)s were not only capable of inducing cytochrome *c* release from isolated mitochondria, but were also able to dramatically alter mitochondrial respiration and membrane potential without swelling [50]. Interestingly, in intact cells inhibition of Bax channel-forming activity was shown to reduce the extent of cytochrome *c* release from mitochondria by half. In the case of low-molecular weight poly(L-lysine)s neither cytochrome *c* release nor changes in the function of isolated mitochondria was noticed, whereas in intact cells such treatments resulted in significant accumulation of cytochrome *c* in cytosol within 24 h with a concurrent MMP drop, and caspase-3 and -9 activation [50]. These observations may indicate a possible role for protein kinases and phospholipases in initiation of apoptosis by low-molecular weight poly(L-lysine)s, as discussed above (Fig. 15.6).

Poly[2-(dimethylamino)ethyl methacrylate] is another example of a cationic polymer that facilitates cell transfection. This polymer is also cytotoxic, but the mechanisms of its cytotoxicity is primarily due to necrotic cell death [51]. Nanoparticles made from poly(D,L-lactide-co-glycolide) have also been suggested for transfection studies; these particles can escape the endolysosomal compartment within minutes of internalization in intact form and reach the cytoplasm [52]. The mechanism of rapid escape is by selective reversal of the surface charge of nanoparticles from the anionic to the cationic state in endolysosomes, thus resulting in a local particle-membrane interaction with subsequent cytoplasmic release. However, degradation products arising from poly(L-lactic acid) particles also show cytotoxicity, and can induce apoptotic and necrotic cell death [53].

We have also proposed an apoptotic role for cationic surfactants and related structures (micelles), thus limiting the applicability of cationic drug carriers for intracellular drug release [54]. Cationic lipids have also been employed in gene transfer/therapy protocols [4], but recent studies have indicated that cationic lipids are also capable of inducing apoptosis [55]. For example, apoptosis in macrophage-like cell line RAW264.7 following treatment with stearylamine-incorporated liposomes was mediated by mitogen-activated protein kinase p38 and c-jun N-terminal kinase, and a caspase 8-dependent Bid cleavage pathway [55].

Furthermore, cDNA microarray expression profiling studies are beginning to reveal that the cationic delivery vehicle can adversely influence the desired effects of the delivered genetic agents [56], which is in agreement with the observation that polycations such as PEI and poly(L-lysine) in both free form and complexed with DNA can localize to the nucleus. Gene expression changes in a wide range of gene ontologies were recently demonstrated with PEI in both *in vitro* and *in vivo* studies [56]. Remarkably, both PEI concentration and architecture had a dramatic effect on non-target gene expression.

## 15.5

### Conclusions and Future Outlook

Polycations such as PEI and poly(L-lysine) induce rapid perturbation of the plasma membrane (within 30–120 min of exposure) with characteristics resembling early necrotic-like changes, which is followed by activation of a “mitochondrially mediated” apoptotic programme at later stages (24 h), at least in human endothelial, lymphocyte and hepatic cell lines [22, 38, 50]. These findings are of relevance to transient gene expression following polycation-mediated DNA compaction and transfection both *in vitro* and *in vivo*. There are numerous developments with respect to the design and synthesis of “less cytotoxic” polycations [6, 57–59]. Cytotoxicity, however, is often assessed by the MTT assay, which is not indicative of apoptosis. Future cytotoxicity studies with newly designed cationic macromolecules and polyfectins should address and consider the time-dependent apoptotic processes, as apoptosis may compromise transcription and translation processes, and limit protein expression. Additionally, the process of apoptosis in intact cells is stochas-

tic, with different cells entering apoptosis at different times. Furthermore, different cationic polymers may interact differently with mitochondria or the endoplasmic reticulum (leading to perturbation of intracellular calcium) and initiate apoptosis differently. The inherent heterogeneity of mitochondria that make up any particular population of these organelles should also be taken into the account.

Attempts in polycation-mediated gene transfer, however, could benefit through recent advances in high-throughput approaches to polymer design and screening [60]. Such approaches may enhance our understanding of the molecular basis of interaction between cationic polymers and intracellular membranes. An understanding of such events may eventually help to design novel and safer materials, particularly those that can provide duration period-specific gene expression in clinical scenarios.

# Nanoparticles for the Treatment of Alzheimer's Disease: Theoretical Rationale, Present Status and Future Perspectives

*Gang Liu, Ping Men, George Perry and Mark A. Smith*

### 16.1

#### Introduction

Alzheimer's disease (AD) is the most common form of dementia among people over the age of 65 years, progressing slowly from mild forgetfulness to the need for total care [1]. This disease is a devastating neurodegenerative disorder with progressive and irreversible damage to thought, memory and language. In America alone, 360 000 new AD cases were identified in 2000, bringing the total to 4.5 million, and the affected population will continue to increase as the population ages [2, 3]. It is expected that the number of people with AD in the US and worldwide will be 14 and over 100 million, respectively, by 2050 if no effective prevention and treatment become available [4, 5]. As such, the disease poses a heavy economic and societal burden, with associated annual costs of care over US\$100 billion [1]. In addition, AD places an incalculable emotional and physical drain on families and caretakers. The ravaging effects of the disease call for efforts to prevent, forestall and reverse the disease. Unfortunately, despite much interest, an explicative etiology or a viable cure is not available. The current Food and Drug Administration (FDA)-approved drugs, targeted towards managing cognitive symptoms such as changes in memory and perception, provide only partial benefit to select patients and fall tremendously short as adequate means of therapeutic management. In addition to donepezil (Aricept®), tacrine (Cognex®), rivastigmine (Exelon®) and galantamine (Reminyl®), memantine (Namenda®) has recently won FDA approval for the treatment of AD. Unlike the acetylcholinesterase inhibitors (Aricept, Exelon and Reminyl) and the cholinesterase inhibitor (Cognex), memantine blocks excess amounts of glutamate that can damage or kill nerve cells. This new drug is becoming the first-line choice for advanced stages of AD [6, 7]. In contrast, the earlier approved drugs mentioned above work in the early stages of AD by delaying the breakdown of acetylcholine, vital for nerve cell communication [8, 9]. Although treatment with these drugs provides symptomatic improvements or delays in the progression of cognitive, behavioral and functional deficits, this treatment does not stop or reverse the progression of AD.

There are many medications used to treat AD, including anti-inflammatory drugs [10–14], antioxidants and vitamins [15–24], hormones [25–30], calcium

channel blockers [31, 32], angiotensin-converting enzyme (ACE) inhibitors [33], cholesterol-lowering statins [34–39], ethylenediaminetetraacetic acid (EDTA) and clioquinol [40–44], gabapentin, lamotrigine, prazosin and risperidone [15, 45–47], vaccines against amyloid- $\beta$  ( $A\beta$ ) [48–52], and even a drug (rosiglitazone) to treat insulin resistance [53, 54]. Antihypertensive medications or regular exercise are also suggested to reduce risk for AD and dementia among people aged 65 years and older [55–57]. Other medications and substances being investigated at the present time include cannabinoids, physostigmine, nerve growth factor,  $\beta$ -sheet breakers, valproate, huperzine and nicotine [58–65]. New studies on the regulation of  $A\beta$  protein precursor translation by Phenserine [66, 67], the regulation of  $A\beta$  by neprilysin [68], inhibition of the activity of amyloid precursor protein (APP) secretases [69–74] and CD45 [75] show promising progress toward the identification of new therapeutic agents. Other studies, such as targeting glycosaminoglycans or metalloprotein attenuating compounds, new chelation agents, tau phosphorylation inhibitors, NF- $\kappa$ B blocker, gene delivery and human embryonic stem cells are under investigation [51, 59, 76–95]. Unfortunately, none of the treatments or drugs currently available can prevent or cure AD. Indeed, it is likely that more than one type of drug will be required to control AD. A recent study shows that Aricept and Namenda work in tandem to ameliorate symptoms of AD [96]. These studies reveal the complexity of the disease, and indicate a great need for a better understanding of AD pathophysiology and for more effective therapeutic agents.

In addition to the complex mechanisms of AD development, another obstacle to a deeper understanding and better treatment of AD is the presence of the blood–brain barrier (BBB). Many drugs of interest cannot gain access to the brain by crossing the BBB. Its presence may also negatively affect drug efficacy and tolerance because a large dosage of drugs must be applied to achieve therapeutic effectiveness. Nanoparticulate drug delivery offers an opportunity to overcome this impediment. Accumulating studies provide evidence that this delivery method can improve drug targeting of the central nervous system and drug penetration of the BBB, thus reducing drug toxicity and improving therapeutic efficacy [97–105]. Although there are many promising studies regarding nanoparticle delivery of drugs across the BBB to treat central nervous system diseases, only a few address treatment of AD [106–110]. In this chapter, the rationale for nanoparticulate drug delivery in the treatment of AD is presented, the current studies of using this delivery systems for AD treatment are reviewed and brief perspectives on this new approach are outlined.

## 16.2

### Rationales: The Ability of Nanoparticles to Cross the BBB – A Useful Tool to Deliver Drugs into the Brain

#### 16.2.1

##### Physiological Functions of the BBB

The BBB, constituted by endothelial cells of the cerebral vasculature together with perivascular elements such as astrocytes, pericytes and basement membrane,

strictly limits and specifically controls the passage of substances between the blood and the cerebral extracellular space [111, 112]. Brain blood vessel endothelial cells characteristically have tight continuous circumferential junctions between them, thus abolishing any aqueous paracellular pathways between the cells [113]. Due to the presence of the tight junctions and the lack of aqueous pathways between cells, polar solutes and lipid-insoluble substances are greatly restricted in movement across the cerebral endothelium [114]; however, noncharged, small, lipophilic molecules may cross the BBB through the endothelial membrane by passive diffusion. This pathway is closely checked by efflux pump systems, which include the multiple organic anion transporter (MOAT), P-glycoprotein (P-gp) and multidrug resistance-associated protein (MDR) [114]. As a result, even molecules with a favorable lipophilicity, which should enable them to cross the endothelial cells, may be rapidly pumped back to the blood stream. These efflux pump systems can also effectively prevent anions, amphipathic organic cations or neutral compounds from entering the central nervous system [114, 115]. As the BBB contains biochemical systems consisting of enzymes, many drugs and blood-borne substances are specifically metabolized before entering the brain [116]. In order to allow essential substances to enter the brain and metabolic waste to leave, the BBB provides specific routes such as receptor and transporter systems to accomplish this transport [114, 117, 118]. Substances that can be absorbed or eliminated by the brain using these carrier-mediated transporter systems include amino acids, hexoses, monocarbonic substances, lipoproteins, insulin and purine compounds [99, 100]. Nanoparticulate drug delivery systems may utilize the low-density lipoprotein (LDL) receptor and the transferrin transcytosis systems to transport drugs into the brain [117, 118]. These transport pathways at the BBB are depicted in Fig. 16.1 [119].

### 16.2.2

#### **Strategies for Drug BBB Penetration**

Although the BBB's existence is absolutely necessary to isolate the central nervous system, with broad consequences for physiology, biology, pharmacology and pathology (most of which remain to be fully elucidated), the BBB represents an insurmountable difficulty for brain uptake of many therapeutic agents. These agents include some antibiotics, antineoplastic drugs and central nervous system-active therapeutics, especially neuropeptides [99, 100]. To overcome this obstacle, various strategies have been developed, which include osmotic opening of the brain endothelial cell tight junctions [120], prodrug preparation [121, 122], and utilization of carrier-mediated transporter systems such as antibodies [123–125], carbohydrate conjugation [126–129], viral and nonviral gene delivery vectors [130–132], peptide vectors [133, 134], liposomes [135–137], micelles [138, 139], and nanoparticles [100, 102, 103, 140–142]. While these studies have shown promise, most of these methods have been of limited use [133, 140]. For example, use of osmotic pressure to open tight junctions is a very invasive procedure and the opened junctions enable the passage of unwanted molecules. Prodrugs designed with higher lipophilicity and/or the ability to circumvent the efflux pump systems may enable them

**Figure 16.1.** Physiological functions of the BBB (with permission after Ref. [119], see original article for full details).

more effectively to penetrate the BBB and transport into the brain, but this approach is not often possible [99]. It is common to use viral vectors for transfecting the expression of specific protein, but this drug delivery method shows certain disadvantages such as safety of both vector and expressed transgene, and stability and regulation of transgene expression [130]. Drugs conjugated to a natural protein molecule as carrier, so called vector-mediated drug delivery utilizing chimerical peptide technology, have shown effectiveness in brain delivery; however, the amount of transported drugs is limited because the maximal ratio of drug to carrier protein is usually about 1:1 [142]. Carbohydrate drug delivery, using sugar-mediated transporters in the BBB, may only work for drugs with small molecular sizes. On the other hand, colloidal drug delivery systems including liposomes, micelles and polymeric nanoparticles have become an important tool to transport drugs into the brain [100, 102, 103, 105, 124, 140]. Compared with other colloidal systems, the polymeric nanoparticle delivery system in particular has the advantage of easier preparation and higher stability in biological fluids [141, 143]. Controlled and sustained drug release is an added virtue of the nanoparticulate drug delivery systems [104, 141]. However, passive targeting of nanoparticles, which refers to the natural distribution of a drug delivery system in organs containing sessile actively phagocytosing cells such as liver and spleen, has to be solved, especially with parenteral administration [143–147]. This passive uptake represents a major problem for nanoparticle targeting to other parts of the body including the

brain. Fortunately, studies have demonstrated that, by modification of the properties of nanoparticulate drug delivery systems, they can actively target specific organs or cells [141]. These modifications can be approached through various means that include (i) surfactant or macromolecule coating to alter system surface properties, (ii) conjugating specific antibodies to the system surface, (iii) changing the particle size and/or electric charge on the surface, and (iv) incorporating magnetite particles into the system and using a magnetic field for targeting. These techniques open the door for nanoparticulate drug targeting development and provide many possibilities to optimize particle-targeting delivery.

### 16.2.3

#### Preparation of Polymeric Nanoparticulate Drug Delivery Systems

Drugs delivered by polymeric nanoparticles can be dissolved, entrapped or encapsulated in the nanoparticles, forming a solid solution or dispersion. Also, the drugs can be adsorbed onto the particle surface or chemically attached (Fig. 16.2) [99, 100, 104]. Nanoparticles of 10–1000 nm, composed of either natural or synthetic macromolecules as therapeutic adjuvants and/or drug carriers, have potential for pharmaceutical and medical uses [99, 100, 141]. With respect to drug delivery to the brain, nanoparticles that are too small in size may result in reduced brain uptake due to rapid dissolution in the blood [101, 141]. Also, at smaller sizes it becomes difficult to obtain a monodispersed particle population [104]. On the other hand, larger size particles may suffer an increase in uptake by the mononuclear phagocytic system before reaching the brain, and increase the risk of blood capillary blockade and embolism, especially with intravenous administration [101, 148–150]. Nanoparticles in the region of 200 nm have, with surface modification, the ability to deliver drugs such as central nervous system-active substances and anticancer agents across the BBB, as shown by therapeutic efficacy [98, 100, 102, 141, 142, 151, 152].

Nanospheres (Fig. 16.2A), generally defined as a dense polymeric matrix in which drugs are dispersed, can be prepared via an emulsion and/or dispersion po-

**Figure 16.2.** Different types of nanoparticulate drug delivery systems such as: (A) nanosphere with drug incorporated in polymeric matrix, (B) nanocapsule with drug surrounded by a thin polymeric envelope and (C) drug adsorbed or chemically attached on the polymeric nanoparticle surface.

lymerization of monomers, depending on the nature of the polymers used [103, 110, 153] or by preformed polymers [103]. For example, poly(alkylcyanoacrylate) nanospheres, which are rapidly biodegradable and widely used for *in vivo* studies of drug delivery to the brain, are obtained by the emulsion polymerization process. In this method, droplets of water-insoluble monomers are emulsified in aqueous solution and stabilized by surfactants. The anionic polymerization reaction is initiated by the water itself and started in micelles after diffusion of monomers through the aqueous phase. Polymeric chains continue growing until prohibited by free-radical termination, then aggregate into fine particles. To incorporate them into nanospheres, drugs can be dissolved in the polymerization medium either before the monomer introduction or after its polymerization [104]. Using the solution-emulsification technique, nanosphere drug delivery systems can be obtained from preformed, well-defined macromolecules. This approach can avoid some potential problems associated with polymerization of monomers such as residual monomer and drug interaction and inactivation [104]. An example of this method is briefly described here. Polyester is dissolved in chloroform and this solution is mixed with an aqueous phase to form a uniform oil/water emulsion [154, 155]. Continuous emulsification under mixing is necessary to prevent organic droplet coalescence and to allow spontaneous solvent evaporation and particle formation [104]. To obtain particles with sizes less than 1  $\mu\text{m}$ , ultrafine emulsification must be performed and microfluidization was recently used for this purpose [156]. An improved method based on desolvation has been developed, in which macromolecules can be precipitated from solution following the introduction of a third component or a nonsolvent miscible with the solution. Many nanoparticulate drug delivery systems are prepared using this technique or its modifications, as reviewed in [104].

Nanocapsules (Fig. 16.2B) are characterized by the presence of a liquid core surrounded by a thin polymeric shell. Interfacial deposition and emulsification diffusion are the two main approaches for nanocapsule preparation. The interfacial deposition procedure involves mixing a water-miscible organic phase containing oil (with or without lipophilic surfactant) with an aqueous solution containing hydrophilic surfactants. This approach can also use either preformed polymers or monomers that polymerize at the oil/water interface [104, 157, 158]; preformed macromolecules should first be dissolved in the organic phase (or in a phase that can dissolve them). After mixing the organic and aqueous phases, the macromolecules diffuse with the organic solvent and are stranded at the oil/water interface. If monomers are used, e.g. alkylcyanoacrylates, they are dissolved in ethanol and oil, then dispersed in water containing surfactants. Polymerization in the oil phase is initiated at the interface, resulting in the formation of nanocapsules [104]. The emulsification diffusion technique provides a simple approach to produce nanocapsules. It also has several advantages including a large choice, small solvent quantities, and controlled size and shell thickness [104]. Using this method, nanocapsules with an inner aqueous core can be prepared [159]. Emulsification diffusion is based on the initial formation of an oil/water emulsion, which contains a polymer, a drug and oil in the organic solvent, in an aqueous solution of a stabiliz-

ing agent. Then, displacement of the organic solvent into the external phase is conducted by adding excess water [104, 160]. It is worth noting that nanocapsules have higher drug-loading capacity and lower polymeric content than nanospheres.

Drugs can also be adsorbed onto the surface of preformed nanoparticles (Fig. 16.2C) by mixing the particles with the drugs in solutions. The absorptive capacity is dependent on several factors such as the polymer, the drug and the medium pH [141, 161]. In some cases, chemical binding of drugs to nanoparticle surface (Fig. 16.2C) may be necessary as described later in our studies. The covalent bonds can be formed through chemical reactions between functional groups present in the drugs and the particles [141, 162]. Apart from polymeric nanoparticulate drug delivery, drug nanocrystals (nanosuspensions), lipid–drug conjugate nanoparticles and lipid nanoparticles are also widely used and take advantage of high drug-loading capacity. Their features, including preparation and medical application, are reviewed in Refs. [101, 102].

The nanoparticle sizes and their distribution can be evaluated by elastic light scattering. This can also be done using scanning or transmission electron microscopy (SEM, TEM), which may provide information about nanoparticle structure [103, 104, 141]. Measurement of the  $\zeta$  potential is often made to characterize the nanoparticle surface properties such as electrical surface potential, drug location and particle stability [103, 104, 141]. Some more commonly performed characterizations such as drug loading and releasing capacities are summarized in Refs. [103, 141].

#### 16.2.4

#### **Possible Mechanisms by which Nanoparticles Cross the BBB**

There is a little doubt that nanoparticles conjugated with antibody against transferrin receptor (TfR) or ligands such as thiamine are transported across the BBB by utilizing TfR or thiamine-mediated transport systems, respectively [123, 142, 148, 163]. However, the mechanisms by which nonantibody or non-ligand-coated nanoparticles deliver drugs into the brain are not fully understood. Surface coating of nanoparticles, e.g. using poly(ethylene glycol) (PEG) [164–166] and some poloxamers [100, 167, 168], and especially with polysorbates [151, 152, 169, 170] and apolipoprotein E and/or B (ApoE and/or B) [100, 167, 171], plays a critical role in nanoparticle-mediated drug transport across the BBB. The coating with these materials apparently alters the natural blood opsonization process of the nanoparticles, thus reducing macrophage recognition in the liver and spleen. This effect consequently increases the nanoparticle blood half-life and extravasation to non-reticuloendothelial systems including the brain [142].

To further elucidate the role of coating, patterns of human plasma protein absorption on the nanoparticle surface have been examined after incubation of nanoparticles in the plasma. Analyses were performed by separating the nanoparticles and releasing the absorbed plasma proteins followed by two-dimensional polyacrylamide gel electrophoresis (2-D PAGE). These analyses showed that polysorbate-coated nanoparticles preferentially absorb ApoE on their surface. In contrast, no

such adsorption was found after incubation of noncoated nanoparticles or nanoparticles coated with many other surfactants [100, 167, 168]. Moreover, in *in vivo* studies on central nervous diseases, only drugs delivered via polysorbate or ApoE (and/or B) coated nanoparticles have therapeutic effectiveness and ApoE-deficient animals exhibit a reduced therapeutic response compared to controls [172]. These findings strongly indicate the involvement of ApoE and B in nanoparticle-mediated drug transport across the BBB and the surfactant on the particle surface may serve as an anchor for ApoE [171]. It is well known that ApoE plays a key role in the transport of LDLs into the brain, and the LDL receptor exists on the BBB [118, 173–177]. Also, lipoprotein particles containing ApoE and ApoA-I are found in human cerebrospinal fluid [178]. After the polysorbate coated nanoparticles absorb ApoE from blood plasma, it is very possible that nanoparticles mimic LDL particles and interact with the LDL receptor. Thus, brain capillary endothelial cells take up the nanoparticles by receptor-mediated endocytic processes [99]. Endocytosis of nanoparticles coated with polysorbate has been demonstrated in both *in vitro* and *in vivo* studies [169, 171, 172, 179, 180]. Significant and rapid uptake of polysorbate-coated nanoparticles by endothelial cells is found at an incubation temperature of 37 °C, whereas only minimal uptake is observed for noncoated nanoparticles [169, 172]. Further evidence shows that uptake is inhibited at lower temperatures (4 °C) or by cytochalasin B (a potent phagocytic uptake inhibitor) pretreatment [169, 172].

After nanoparticle endocytotic uptake, the nanoparticles may be transcytosed through the brain blood vessel endothelial cells since LDL transcytosis across the BBB has been demonstrated [118]. It is also possible that the drug is released from the nanoparticle in the endothelial cells and diffuses into the brain [99]. Several other mechanisms involved in nanoparticle-mediated drug transport across the BBB have been suggested [99]. For example, opening of the tight junctions between the brain endothelial cells by nanoparticles could occur, and the drug could then penetrate through the opened junctions either with the particles and/or in free form. Studies show that inulin spaces, an indicator of the tight junction opening, are increased only by 10 and 99% after 10 and 45 min, respectively, in rats treated with polysorbate-coated nanoparticles. In contrast, the increase of these spaces is 1000–2000% by osmotic methods [180–184]. These studies indicate that the coated nanoparticles increase the volume available to the intravascular inulin; however, they do not disrupt the BBB significantly. The slight opening of the tight junctions caused by the particles may result from folding-up of the cell membrane accompanied by endocytotic events or from an increase in fluid-phase endocytosis of inulin associated with the internalization of the nanoparticles [99]. It is known that some surfactants such as polysorbate show the ability to inhibit P-gp present in the brain endothelial cells and responsible for the multidrug resistance [185–187]. This inhibition of the efflux pump by surfactant could be responsible for nanoparticle-mediated drug delivery into the brain [99]. It may be significant that nanoparticle brain penetration increases when brain pathologies such as cancer [188, 189] and allergic encephalomyelitis [164] occur. The potential toxicity of the polysorbate-coated nanoparticle to the brain endothelial cell has also been sug-

gested to facilitate particulate drug delivery across the BBB [170]. In fact, many studies show that there are no significant signs of toxicity associated with this process [99, 190, 191]. However, it should be mentioned that nanoparticle surface charges may affect BBB function and studies show that cationic nanoparticles pose a toxic effect on the BBB, while the neutral or anionic nanoparticles at low concentrations do not disrupt BBB integrity [192]. Lipid coating may prevent the toxic effect of the ionically charged particles to the endothelial cell and enable the particles to cross the endothelial cell layer via transcytosis with no or little degradation [99, 193].

The preparation of the drug–nanoparticle system is relatively easy and in general the system is very stable. It is also important that there is a large variety of ways to improve the bioavailability and specific targeting of the particulate drug delivery systems and to minimize the toxicity of the systems. Based on the nanoparticle-mediated transport technology, a novel approach was recently developed in our laboratories [109]. This approach allows the nanoparticles not only to deliver metal chelation agents into the brain for the treatment of AD and other metal-mediated neurodegenerative diseases, but also to bring the toxic metals out of the brain, thus increasing therapeutic efficacy and limiting metal-chelate toxicity. This principle may be useful for other biomedical applications in the delivery of drugs to disease targets and/or depletion of toxicants using nanoparticle transport technology.

### 16.3

#### **Status: Nanoparticle Targeting Transport of Therapeutic Agents for Potential Treatment of AD**

The technology of nanoparticulate drug delivery has been developed for many years, and has been demonstrated not only to improve drug safety and efficacy, but also to lead to new therapeutic agents. However, its application in the treatment of AD has only appeared recently in very limited studies, due perhaps to the complexity of the disease pathogenesis and to an incomplete understanding of the mechanisms by which nanoparticles deliver drugs across the BBB. A lack of collaboration between scientists in differing, but relevant, disciplines may also impede application. In order to understand how to advance nanoparticle application, a review of recent developments in nanoparticulate drug delivery for AD treatment is now presented.

#### 16.3.1

##### **Nanoparticle Targeting of A $\beta$ to Deliver Potentially Therapeutic Agents**

Senile plaques in the brain, composed mainly of insoluble deposits of A $\beta$  peptide with 39–43 amino acids, are a major hallmark of AD [69]. Studies, albeit controversial studies, show that the accumulation of A $\beta$  derived from APP by proteolytic cleavage are neurotoxic and believed to be responsible for the neurodegeneration observed in AD [194, 195]. Therefore, preventing and reversing the A $\beta$  accumulation is an important pharmacological target in AD treatment and several potential

therapeutics such as  $\beta$ -sheet breakers [196, 197], regulators of APP translation [66, 198–200], inhibitors of APP secretases [69–74], vaccines against  $A\beta$  [48] and metal chelators [42, 76–78] have been developed and tested. As many potential drugs are electrically charged hydrophilic and/or large size molecules, a lack of ability to enter the brain may hamper their treatment efficacy. Although nanoparticles serving as a vehicle can provide a valuable approach to carry many otherwise impermeable drugs across the BBB, the tissue distribution of nanoparticles and drug release are not fully elucidated. However, a recent study showed that the nanoparticles as well as delivered drugs are present predominantly in microglia and also in neurons [106], where the  $A\beta$  accumulation may occur and cause neurotoxicity [69, 194, 195, 201].

In this study, core-shell latex particles containing Thioflavin-(TfT) as a marker for fibrillar  $A\beta$  were synthesized by aqueous polymerization of butylcyanoacrylate and seeded onto polystyrene cores filled with TfT, then collected by ultrafiltration. The cores were prepared using emulsion polymerization of styrene in aqueous ethanol solution containing TfT and purified by dialysis against deionized water [202]. The formed core-shell nanoparticles are reported to be sphere-shaped with a diameter of about 90 nm, as demonstrated by SEM and TEM (Fig. 16.3A and B). The nanoparticles were injected into the hippocampus (AP = -1.7 mm, L = 1 mm and DV = 2 mm, relative to bregma) of C57B6 mice after anesthesia. Three days postinjection, the animals were transcardially perfused with 4% paraformaldehyde and 0.5% glutaraldehyde in 0.1 M phosphate buffer (pH 7.4). The brains were then fixed in 4% paraformaldehyde overnight and coronal vibratome 50- $\mu$ m sections of the dentate gyrus were cut. Using the oxygen-enriched photoconversion method [203], the TfT was photoconverted into an electron-dense material to localize the TfT-containing nanoparticles in the brain. After washing, osmication and dehydration, the brain tissue blocks were embedded in Ducurpan and semithin or ultrathin sections were prepared. Aggregated nanoparticles were detected in dentate granule cells and vacuolated cytoplasm in the vicinity of nanoparticle aggregates using light microscopy (Fig. 16.3C). Using TEM, this study also found clustered nanoparticles in microglia (Fig. 16.3D) and in neurons (Fig. 16.3E and F). Moreover, vacuolated inclusions and amorphous structures with moderated electron density were found in both cell types. The core-shell structure of the nanoparticles and the TfT delivered from the nanoparticles were further confirmed by TEM at higher power (Fig. 16.3F).

This study indicates that nanoparticles and the nanoparticle-delivered drugs may target  $A\beta$  in the brain, and provides strong evidence to further support the possibility of nanoparticle drug delivery for AD treatment with increased efficacy and lowered toxicity.

### 16.3.2

#### **Nanoparticulate Antioxidant Delivery to Increase Efficacy against $A\beta$ -mediated Oxidative Stress**

One of the neurotoxic effects of  $A\beta$  is to induce lipid peroxidation [204–207] that can lead to the formation of cytosolic free radicals and reactive oxygen species

**Figure 16.3.** (A) The Tft-containing latex nanoparticles with a diameter of about 90 nm (SEM analysis). (B) Image of the nanoparticles on a Pioloform-coated slot grid (TEM analysis). (C) Light microscopic analysis of a section from fixed and plastic-embedded mouse dentate gyrus after 3-day intrahippocampal injection of nanoparticles and following photoconversion of Tft. Arrows and arrowheads indicate representative adducts of photoconversion. (D–F) TEM analyses of cells in the dentate gyrus after 3-day Tft particle injection and photoconversion. (D) Analyses show clusters of aggregated particles

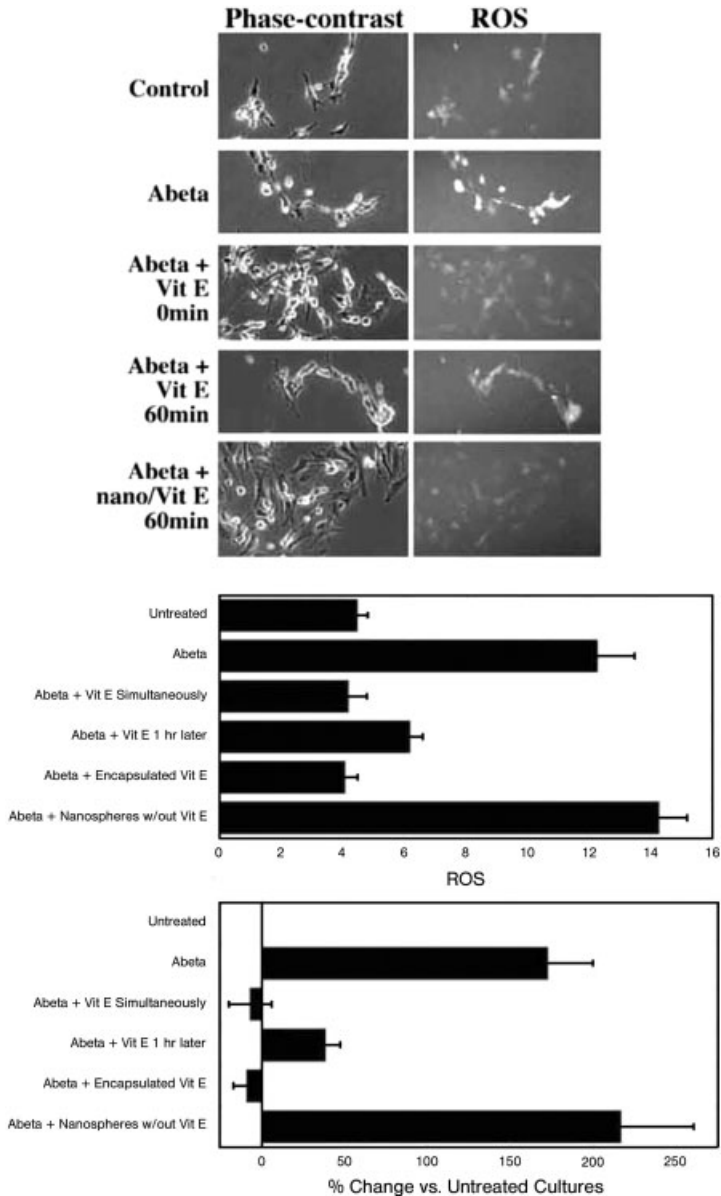

incorporated in microglia (left) and in a granular cell (right). The vacuolar inclusions and amorphous structures with moderate electron density are found in both cells. (E) Photoconverted, aggregated lattices are located in the cytoplasm of a granule cell and an arrowhead marks the same cluster in (C). (F) High magnification of intraneuronal particle clusters. Photoconverted electron-dense materials surround the most core–shell-type microspheres (arrows), indicating Tft delivered by the nanoparticles. Scale bar: 1  $\mu\text{m}$  for A, E and F; 0.1  $\mu\text{m}$  for B; 20  $\mu\text{m}$  for C; 5  $\mu\text{m}$  for D. (With permission after Ref. [106].)

(ROS) [208]. Free radicals and ROS are highly active and can cause oxidative damage to all classes of biomolecules found *in vivo*, which include cellular lipids, nucleic acids, proteins and carbohydrates [209, 210]. This is believed to be a key factor in AD development [211, 212]. With aging, the endogenous antioxidant systems may gradually lose their ability to provide adequate neuroprotection and fail to compensate for the increased ROS formation [213]. Thus, antioxidant intake may provide protective effects against oxidative neurodegeneration [214, 215]; however, as discussed before, one impediment to the success of AD antioxidant therapy is the BBB that may limit appropriate antioxidant concentrations within the brain, thus diminishing its efficacy. Reduced efficacy may also result from the inability

of antioxidants to reach specific targets. It is known that vitamin E, a lipophilic antioxidant, shows mixed results in the treatment of AD [19, 216–218]. Furthermore, although vitamin E is capable of preventing  $A\beta$ -induced ROS in cultured cells, the cells have to be treated with vitamin E before  $A\beta$  exposure, or treated simultaneously with vitamin E and  $A\beta$ . In contrast, antioxidants that can enter the cytosolic compartment of these cells give neuroprotection even if applied after  $A\beta$  exposure [219–221]. This limitation is suggested to be a consequence of the lipophilic nature of vitamin E. The lipophilicity of vitamin E reduces its access to the hydrophilic cytosolic compartment, thus minimizing its ability to quench cytosolic ROS, as well as ROS produced from antecedent membrane oxidative damage [208]. It is possible that nanoparticle-mediated drug delivery cannot only send antioxidants into the brain more effectively, but also facilitate targeting specific locations, hence increasing their antioxidative effects.

A recent study [108] showed that vitamin E encapsulated in nanoparticles possesses an improved ability to quench  $A\beta$ -induced ROS even if applied about 1 h after  $A\beta$  exposure; in contrast, nonencapsulated vitamin E does not have such a capability. This study indicates that although vitamin E can protect against  $A\beta$ -mediated ROS, it lacks the ability to access the secondary ROS, which radiates into the cytosolic compartment following prior  $A\beta$  exposure, due to the lipophilicity of vitamin E [205–208, 213, 221].

In this study, nanoparticles containing vitamin E were prepared by mixing PEG 1500 decanyl polymer and vitamin E in chloroform solution. After removal of the solution, the mixture of PEG polymer and vitamin E was redissolved into water to induce self-assembly by vortexing. Resultant vitamin E-containing nanoparticles were purified by dialysis against water to remove unencapsulated vitamin E [222]. To examine the antioxidative efficacy of vitamin E encapsulated in PEG polymer nanoparticles, SH-SY-5Y human neuroblastoma cells were used. The cells were cultured in DMEM with 10% fetal calf serum and differentiated for 7 days with 10  $\mu$ M retinoic acid. Cell cultures were exposed to  $A\beta$  (25–35) for 2 h. Vitamin E and vitamin E encapsulated in nanoparticles were added to additional cultures either simultaneously with, or 1 h following, the addition of  $A\beta$ . To monitor the intracellular peroxide concentrations as an index of ROS, 2',7'-dichlorofluorescein diacetate was added to cultures for 20 min and then cultures visualized under fluorescein UV optics. The results indicate that vitamin E prevents an increase in ROS induced in differentiated neuroblastoma cells following  $A\beta$  treatment only if applied prior to or simultaneously with  $A\beta$  (Fig. 16.4). In contrast, vitamin E encapsulated in nanoparticles can prevent ROS even 1 h after  $A\beta$  exposure. The protective effectiveness was same as application of an equivalent concentration of non-encapsulated vitamin E simultaneously with  $A\beta$  exposure (Fig. 16.4). Nanoparticles without encapsulated vitamin E do not have neuroprotective ability. This result that the nanoparticles can deliver vitamin E into cytosol, thus increasing vitamin E antioxidative capability to quench cytosolic ROS, indicates that nanoparticle-mediated delivery may serve as a valuable tool for targeted transportation of antioxidants or other therapeutic agents for the treatment of AD. However, this result needs to be confirmed using normal neuro-cells and *in vivo* studies.

**Figure 16.4.** Nanoparticle drug delivery improves the efficacy of delayed application of vitamin E against  $A\beta$ -induced ROS. Panels present phase-contrast and fluorescent images of SH-SY-5Y neuroblastoma cells examined for ROS before (control) or 1 h following addition of  $A\beta$  with or without vitamin E or nanoparticulated vitamin E at the indicated intervals. Note the increase in ROS following addition of  $A\beta$ . Note that this increase is prevented by simultaneous, but not delayed,

addition of vitamin E, yet is prevented by delayed addition of nanoparticulated vitamin E. The accompanying graphs present the mean 2',7'-dichlorofluorescein diacetate (DCF-DA) fluorescent intensity  $\pm$  standard deviation of at least 50 cells. Values are also presented in the percent change in fluorescent intensity for each condition versus untreated controls (the mean intensity for controls are defined as 1). (With permission after Ref. [108].)

## 16.3.3

**Nanoparticle Delivery of Copper Chelator for Preventing and Reversing A $\beta$  Deposition**

Copper and zinc are essential in the body, but their excess is toxic. Accumulation of these metals in the central nervous system is believed to contribute to the oxidative stress and inflammation associated with AD [223–225]. Studies reveal that A $\beta$  has the ability to bind copper and zinc with high affinity, and that these metals may, in turn, mediate the A $\beta$  deposition in AD [226–233]. The evidence showing the association of these metals with A $\beta$  deposition is that simple coinubation of A $\beta$  from postmortem AD brain tissue with copper and/or zinc chelators results in resolvable aqueous A $\beta$  [234]. This association is also demonstrated by other findings from both animal experimental studies and human clinical trials [42, 43, 77, 80, 235]. Severe changes in some metal distributions are found in the brain of AD patients compared with healthy controls [225]. Concentrations of copper and zinc are significantly elevated in amyloid plaques and neuropil regions in the brains of AD patients (about 400  $\mu$ M for copper and 1 mM for zinc) compared to the healthy brains (70  $\mu$ M for copper and 350  $\mu$ M for zinc) [226, 236]. Treatment of APP transgenic mice (an AD mouse model) with the copper and zinc chelator, clioquinol, was shown to reverse A $\beta$  deposition [237], leading to a near halving of A $\beta$  deposition in the animal brain, compared with sham-treated controls [77]. The reduction of A $\beta$  deposition was accompanied by a significant improvement in behavior and general health parameters. Clinical studies also demonstrate that AD patients treated with clioquinol show significantly slowed cognitive deterioration and lowered plasma A $\beta$  levels [42, 43]. There were no indications of toxicity associated with chelation treatment for either experimental or clinical studies. These results suggest a potential approach that can prevent and treat AD by targeting the interaction of copper and zinc with A $\beta$  using chelation agents. However, an implication of clioquinol toxicity in an epidemic of subacute myelo-optic neuropathy in Japan has forced withdrawal of the drug from the market. For neuro-chelation therapy, the BBB represents a major hurdle for most available chelation therapeutics [109, 238]. To gain a deeper understanding of the roles of metals in AD development and to make progress in AD chelation therapy, there is a great need to develop more effective and safer chelation agents. Nanoparticle-mediated drug transport as an alternative means of drug delivery to the brain may provide an opportunity for such development [109, 110].

A recent study showed that D-penicillamine, a specific copper chelator for Wilson's disease (copper overload), can be successfully conjugated to nanoparticles through covalent bonding [107]. The nanoparticles have a long circulating ability in the blood and have been shown to be taken up by the brain *in situ* and *in vivo* without significant changes in BBB integrity or permeability [107, 147, 239, 240]. The nanoparticles containing 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-N-[4-(*p*-maleimidophenyl)butyramide] (MPB-PE) or 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-N-[3-(2-pyridyldithio)propionate] (PDP-PE) were synthesized by warming microemulsion precursors composed of emulsifying wax and surfactants such as Brij 78 or Tween 80 [107, 241]. These core components of the nanopar-

ticles are considered nontoxic and nonirritant materials [107, 241]. This study shows that the stability of these nanoparticles is greatly affected by the final concentration of surfactants, and the use of 4–6 mM of Brij and 2 mg mL<sup>-1</sup> of emulsifying wax can form the most-stable particles. A further increase in Brij concentration leads to the formation of less-stable nanoparticles. This study provides a simple preparation method for stable nanoparticles that can anchor chelation agents with them. In the preparation procedure, emulsifying wax was first melted and then stirred at 50–55 °C after adding deionized and filtered water in order to form a homogenous milky slurry. The surfactant was then added with continuously stirring. After microemulsions were formed, the mixture was cooled to room temperature to produce nanoparticles. The formed particles were characterized using a Coulter N4 Plus Sub-micron Particle Sizer. To provide functional sites on the nanoparticles for covalent conjugation with the sulfhydryl group in D-penicillamine, various amounts of MPB-PE or PDP-PE were incorporated into the particles by adding different concentrations of MPB-PE or PDP-PE in chloroform. The solvent was removed by evaporation before adding the emulsifying wax. The diameter of the formed nanoparticles was less than 100 nm with a narrow size range. Size is influenced by the MPB-PE or PDP-PE concentration, although not significantly [107]; however, if the concentration of MPB-PE or PDP-PE reaches 15% w/w, the microemulsion cannot be formed and the size of the resulting particles is relatively large. This study suggests that the hydrophilic heads of MPB or PDP are exposed on the nanoparticle surface while the lipophilic dioleoyl groups in both MPB-PE and PDP-PE insert into the lipophilic core of nanoparticles [107, 241, 242]. This molecular orientation, leaving the functional groups on the nanoparticle surface, is favorable for chelator conjugation. D-Penicillamine contains a sulfhydryl group and can either react with MPB-PE or PDP-PE to form thioether or disulfide bonds, respectively, which link the chelator and nanoparticles [243–245] (Scheme 16.1). The reactions were conducted at room temperature in approximately neutral aqueous solution (pH 6.5 for MPB-PE containing particles; pH 8.0 for PDP-PE containing particles). Nitrogen gas was used to prevent atmospheric oxygen from disturbing the conjugation reaction. The chelator-conjugated nanoparticles were purified by gel permeation chromatography using a Sephadex G75 column. The short-term stability of the chelator-nanoparticles containing PDP-PE was tested by particle size measured at intervals. The stability of the particles to salt or serum was also examined: D-penicillamine-conjugated nanoparticles are stable at 37 °C for 30 min in several different biologically compatible media such as saline, 10 mM phosphate-buffered saline solution (PBS), 10% lactose and 10% fetal bovine serum in saline. The linkage of disulfide bonds between D-penicillamine and PDP-PE incorporated into particles is also quite stable in PBS at pH 6, 7 and 8. Both D-penicillamine conjugated PDP-PE nanoparticles and MPB-PE nanoparticles are stable when treated with simulated serum, thus being suitable for chelator delivery *in vivo*. D-penicillamine conjugated MPB-PE nanoparticles are more stable than D-penicillamine–PDP-PE conjugated ones because of the formation of a more stable thioether linkage of D-penicillamine–MPB compared to the less stable disulfide link between D-penicillamine and PDP [245].

**Scheme 16.1.** Conjugation reactions of D-penicillamine to (A) MPB- and (B) PDP-nanoparticles. (Minor modification from Ref. [107].)

It should be mentioned that linkages using the sulfhydryl group of D-penicillamine totally deprive its copper binding activity. This, however, may provide a targeting chelation approach by which D-penicillamine can chelate copper within the brain only if it is released from nanoparticles, thus minimizing chelator toxicity in other places. To restore the chelation activity of D-penicillamine, it was proposed that the release could take place when the D-penicillamine conjugated nanoparticles react with reducing agents such as glutathione under normal physiological conditions. In cells, glutathione is the most concentrated nonprotein thiol and its concentration is about 1–6 mM [107, 246]. In order to test this hypothesis, a reducing agent, dithiothreitol (DTT) was used to incubate with the D-penicillamine-conjugated nanoparticles. After a 1-h incubation at 37 °C in water at pH 6.7, D-penicillamine was partially released from PDP-PE-containing particles by DTT, indicating cleavage of the disulfide bond between D-penicillamine and PDP. Although this result indicates the possibility of D-penicillamine release from nanoparticles by reducing agents, further studies are warranted such as increasing the releasing efficacy in both *in vitro* and *in vivo* investigations. As A $\beta$  is known to bind metals with high affinity and its aggregates are associated with copper, the ability of D-penicillamine, D-penicillamine-nanoparticles and D-penicillamine released from nanoparticles to reverse copper-mediated A $\beta$  aggregates were evaluated in this study. The A $\beta$  deposition is obtained from incubation of A $\beta$ (1–42) with cupric chloride in Tris buffer (pH 7.4) for 1 h at 37 °C and then incubated with those chelation agents for a further 1 h at 37 °C. To determine the redissolved copper A $\beta$  aggregates in the soluble fraction, the samples were centrifuged (10 000 g for 20 min) and the supernatants were analyzed for protein concentrations using the Pierce method [107]. In order to release D-penicillamine from nanoparticles, the chelator-conjugated PDP-PE-containing particles were incubated in basic aqueous solution (0.1 M, sodium hydroxide) at 45 °C for 1 h. Under these conditions, the

**Figure 16.5.** Experiments of Cu-A $\beta$ (1-42) aggregate resolubilization. The treatments are control (no chelator), D-penicillamine, D-penicillamine conjugated to PDP-NPs (NPs) and D-penicillamine conjugated to PDP-NPs (NPs) after being treated in 0.1 N NaOH at 45

°C for 1 h (NPs treated). An asterisk indicates that the values for D-penicillamine and treated NPs are not different from each other, but are significantly higher than that of no chelator and NPs. (With permission after Ref. [107].)

disulfide bond of D-penicillamine-particle linkage is more labile [243, 247]. Results show that the D-penicillamine conjugated to nanoparticles can no longer resolubilize the insoluble A $\beta$  aggregates mediated by copper while the free D-penicillamine does. D-Penicillamine released from nanoparticles restores its ability to effectively resolubilize the copper-A $\beta$  aggregates (Fig. 16.5).

This study provides a method to prepare D-penicillamine-conjugated nanoparticles that may have the ability to cross the BBB without adverse effects on cerebral perfusion, BBB integrity and permeability [107, 239, 240]. This study also shows that the nanoparticle-delivered chelator may be released after targeting and resolubilize metal-mediated A $\beta$  deposition, thus being able to prevent and treat AD. D-Penicillamine is used to treat Wilson's disease, wherein copper is accumulated initially in the liver and eventually in other organs including the brain [248]. D-Penicillamine can conveniently be administered orally and its effect on urinary copper excretion is dramatic [249]. However, development of D-penicillamine intolerance is frequently seen among patients and the ability of D-penicillamine to cross the BBB is not clear [107, 250, 251]. Thus, nanoparticle D-penicillamine delivery may increase the brain targeting of D-penicillamine and reduce its intolerance. Although more *in vivo* studies are needed and this chelation may be imperfect due to the possible accumulation of the chelator-metal complexes in the brain, this study provides evidence to support nanoparticle drug delivery as a potential approach for AD management.

## 16.3.4

**Nanoparticle Transport of Iron Chelators and Metal Chelator Complexes Into and Out of the Brain, Respectively****16.3.4.1 Increased Levels of Various Metals in the Brain of AD Patients**

It is already known from the above that copper and zinc play an important role in the accumulation of  $A\beta$  deposits, which in the form of preamyloid lesions and neuritic plaques, are one of the key neuropathological features of AD [107, 195]. Other metal ions are also known to be toxic and may be potential risk factors for AD. For example, excess iron in the body is extremely dangerous even though it is an essential nutrient for virtually all mammalian cells. Studies demonstrate that in individuals with primary or secondary iron overload disease, extreme iron accumulation in organs is recognized as a contributor to the manifestation of other diseases, including cardiac, hepatic, endocrine and bone disorders as well as cancer [252–254]. Even moderate elevations of iron in the body, which may be associated with age, is believed to play a significant role in causing diseases such as atherosclerosis, cancer, diabetes, dementia and osteoporosis [210, 255–260]. The toxic effects of excess iron and copper result largely from their ability to catalyze free radical generation through the Fenton reaction or Haber–Weiss reaction [209]. Iron also plays a key role in the regulation of cellular functions such as respiration, oxygen transport, DNA synthesis, nitric oxide formation and other redox reactions [209]. Therefore, iron levels in particular biological compartments have a close association with various disease processes. Although the etiology of AD is not well understood, accumulating evidence supports the hypothesis that oxidative stress generated by various mechanisms may be among the major risk factors that initiate and promote neurodegeneration [16, 211, 261–263]. Compared with other tissues, the central nervous system may be particularly susceptible to oxidative damage [264, 265]. Since iron and copper catalyze oxidation reactions, the likelihood that an oxidation reaction will take place is probably increased by regional concentrations of these metals [209, 223]. Substantial studies show that the metabolism of iron is involved in AD and that the concentration of iron, like copper, in the brain of AD patients is elevated [224, 266–270]. The iron levels in neuropil of human brain are  $39 \mu\text{g g}^{-1}$  for AD patients and  $19 \mu\text{g g}^{-1}$  for controls determined by microparticle-induced X-ray emission [236, 271–273]. Studies also demonstrate that iron can induce  $A\beta$  aggregation at acidic pH [232], a pathological value found in inflammatory disorders. Another metal ion, aluminum, has also received attention in AD [274], although its role in AD development has not yet been convincingly demonstrated. Nonetheless, aluminum is found in high concentrations in both senile plaques and intra-neuronal fibrillar tangles in the brains of subjects with AD, which suggests that this metal may be involved in the etiopathology of AD [224, 269, 275, 276]. Aluminum, unlike iron and copper, is unable to participate in redox cycles of electron transfer reactions due to a fixed oxidation state of  $3+$  in biological systems, but growing evidence suggests that it can act synergistically with iron to increase free radical damage [264, 277]. A recent study shows that accumulated alu-

minimum in the central nervous system modulates  $A\beta$  formation and deposition [278]. As mentioned early, evidence already shows that copper [211, 236, 279–283] and zinc [229, 236, 269, 284, 285] are implicated in the development of AD. In the AD brain, the concentration of copper is elevated in the rim of senile plaques and the concentration of zinc is significantly elevated in senile plaques. Taken together, these studies indicate that the environmental conditions in AD, exacerbated by imbalances in several metals, have the potential of catalyzing and stimulating free radical formation [109], and of facilitating  $A\beta$  aggregation and deposition [286], thus enhancing neurodegeneration.

Simultaneously elevated levels of multiple metals promoting oxidative damage to the brain present a complex system of pathophysiology that is not yet fully understood. Despite this complexity, metal dysregulation may in fact be the Achilles' heel of AD, opening a door for chelation therapy. A chelator, regardless of synthetic or natural origin, may have high affinity for one metal ion, but it can also undesirably chelate other metals in the body leading to serious side-effects. The affinity for multiple metals such as aluminum, copper, iron and zinc may pose useful rather than detrimental effects since various metals are implicated as oxidative instigators. Perhaps this is why desferrioxamine (DFO), a specific iron chelator also with high affinities for aluminum, copper and zinc, has demonstrated some therapeutic benefits for patients with AD. Thus, simultaneous chelation of several excess metals in the AD brain may provide a novel approach for safe and effective treatment of AD.

#### 16.3.4.2 Problems with Iron Chelators for Simultaneous Removal of Multimetal Ions for Treatment of AD

Iron chelation therapy shows potential as an alternative treatment for AD by simultaneously chelating multiple excess metals. However, this promising approach is hindered by chelator toxicity and/or poor bioavailability, especially BBB impenetrability. A few clinically available iron chelators also negatively affect the development of iron chelation therapy for this disease.

DFO and deferasirox (ICL670, Exjade<sup>®</sup>) are the only iron chelation drugs approved by the FDA for iron overload disease (Fig. 16.6). Their therapy can promote iron excretion, and has led to great improvements in the quality and duration of life of patients who suffer from  $\beta$ -thalassemia and other refractory anemias [287,

**Figure 16.6.** Chemical structures of (A) DFO, (B) ICL670 and (C) L1.

288]. Although there are no reports yet on deferasirox for potential treatment of AD, DFO is found to significantly slow the progression of AD in one clinical trial [289]. In this study, only the chelation of aluminum was examined, but it is possible that the therapeutic effect may also have been due to removal of iron since DFO preferably chelates iron forming 1:1 complex (DFO, a hexadentate chelator) [290, 291]. DFO also has an appreciable affinity for copper and zinc [290, 292]. The affinity constants of DFO for Fe(III), Al(III), Cu(II), and Zn(II) are 30.6, 22.0, 14.1 and 11.1 ( $\log K$ ), respectively [293]. In this particular clinical study, copper and zinc were not monitored. Thus, it is unclear if the DFO treatment simultaneously removes these metals and/or whether such a removal plays a role in slowing the clinical progression of AD. However, 2 years after the initial publication, a verbal report at the International Conference on Alzheimer's Disease (Padua, Italy, 1992) provides evidence that iron and zinc concentrations are decreased in a post-mortem analysis for DFO-treated patients [271, 290]. This clinical study, in addition to the follow-up report, provides strong evidence that multiple metal accumulations in the brain may be key contributors to AD development and simultaneous removal of them mitigates disease progression. Aside from effective chelation of several metals, DFO also inhibits nigrostriatal degeneration induced by 6-hydroxydopamine [294]. Unfortunately, DFO has serious side-effects including neurotoxicity and neurological changes [223, 274, 295–300]. Furthermore, DFO is poorly absorbed by the gastrointestinal tract and rapidly degrades after administration [301]. Therefore, it requires long subcutaneous administration to yield significant iron excretion [287, 291, 302]. Moreover, some studies show DFO does not easily penetrate the BBB due to its hydrophilic nature [303], although this point remains open to debate [304]. Indeed, some penetration may occur due to a compromised BBB via lesion sites [303]. Nonetheless, the neurotoxicity and difficulty of administration and delivery present serious hindrances to the use of DFO for AD treatment.

Another iron chelator, L1 (deferiprone or 1,2-dimethyl-3-hydroxyl-4-pyridinone), is a bidentate chelator and approved in Europe, but not in the US, for iron or aluminum overload diseases [305–307] (Fig. 16.6). It chelates iron and aluminum with very high stability constants of  $\log \beta = 37$  and 32, respectively. Since it can also chelate copper and zinc with appreciable efficiencies ( $\log \beta = 19.6$  for copper and 13.5 for zinc), L1 is capable of simultaneously chelating these metal ions. L1 virtually lacks affinity for calcium or magnesium; therefore, unlike many other chelators, L1 has no toxic effects due to chelation of these essential metals [307]. L1 also has high oral activity and BBB penetration because of its lipophilicity and relatively small molecular size. However, its use is limited because of serious side-effects [308, 309]. Moreover, studies show that L1 lacks the ability to remove iron from the brain [304] probably due to strong hydrophilicity of the iron–L1 complex. Additionally, there is no carrier-mediated transport system available to remove the complex from the brain. Other L1 derivatives with higher lipophilicity also have the ability to cross the BBB and complex iron in the brain, but they also possess considerable neurotoxicity [295, 298, 308]. Deferasirox is a tridentate iron chelator with oral bioavailability, which is currently approved by FDA for treatment of transfu-

sional iron overload in thalassemia. However, its long-term profiles are not yet available [288]. Furthermore, its lipophilic nature like L1 may raise questions concerning potential toxicity in AD treatment.

Thus, the use of the currently available iron chelators to simultaneously remove several excess metals in the brain of AD is limited because of their toxicity and/or poor transference across the BBB. Most bi- or tridentate iron chelators with small molecular weight and high lipophilicity have the ability to penetrate the BBB, but show toxicity [310]. On the other hand, hexadentate iron chelators are considered better candidates for chelation therapy than bi- and tridentate ones because of their lower toxicity before and after chelation [310], but they have difficulty penetrating the BBB [122, 304, 310] due to their hydrophilicity and relative high molecular weight. One strategy to increase the BBB penetration is by enhancing the lipophilicity and lowering the molecular weight of the iron chelators, but this is believed to increase toxicity [311]. In addition, the increase in lipophilicity of iron chelators will decrease the solubility in aqueous solution with probable a decrease in bioavailability [309]. Also, it is possible that some lipophilic chelators which normally should cross the brain endothelial cells are rapidly pumped back into the blood stream by extremely effective efflux pumps, as mentioned before [99]. Many promising attempts have been made to develop iron chelators with oral activity (membrane penetration) and low toxicity for the treatment of iron overload disease [312–347]. This leads to the hope, that if successful, some iron chelators may also be suitable for simultaneous chelation of several excess metal ions for AD treatment.

Some existing USP drugs such as clioquinol (iodochlorohydroxyquin) that possess chelation properties and BBB penetration ability have shown therapeutic benefits in AD [42, 43]. Clioquinol is an antibiotic agent and chelator with high affinity for zinc and copper, and less for calcium and manganese [77]. As mentioned before, oral administration of clioquinol in APP transgenic mice with advanced  $A\beta$  deposition leads to a significant reduction of  $A\beta$  deposition in the mouse brain compared to nontreated animals. This reduction of  $A\beta$  deposition is reported to be associated with copper and zinc chelation by clioquinol [77]. In clinical studies with clioquinol, the clinical rate of cognitive decline is slowed in a subset of AD patients compared with controls [42, 43]. Interestingly, the zinc concentration in plasma of AD patients treated with clioquinol was significantly higher than that of controls although no parallel change in plasma copper concentration has been indicated [43]. However, further investigation with this new approach is hindered by clioquinol toxicity. It should also be mentioned that this type of chelator generally may have a low affinity for iron and would be toxic at doses needed for sufficient iron removal [293]. EDTA has also shown some clinical improvements in the patients with dementia, including AD, in a small clinical trial and a large retrospective study [40, 41].

Currently, chelators with a hydroxyquinoline backbone or with high lipophilicity show BBB permeability and neuroprotective potential in experimental studies [78–80]. However, the toxicity of these chelators related to their lipophilicity has not been studied. Other therapeutic approaches are being explored to overcome the impediment of the BBB. For example, a prochelator has been designed for the pur-

pose of easily entering the BBB. The functional groups of the prochelator are then activated by enzymatic or nonenzymatic reactions after they have entered the target organ [121]. Another example is to use simple inorganic silicate that can form very stable complexes with many metals and probably has the ability to enter the BBB [348]. A newly developed copper chelator (tetrathiomolybdate) for Wilson's disease is also suggested as a potential treatment for AD [85, 349]. Iron chelators designed with near-optimal lipophilic/hydrophilic balance of the free chelator and iron complex for the purpose of passage into and out of the cell have been synthesized and studied [309]. However, no clear-cut clinical evidence for a beneficial effect of these chelators in AD has been demonstrated and new approaches are necessary.

#### 16.3.4.3 Nanoparticle Transport Technology to Improve Chelation Therapy for AD

The use of nanoparticles to transfer chelators represents an exciting therapeutic option that may prove safer and more effective for chelation therapy. There are four advantages to this particle chelator delivery approach: (i) the chelators need not be lipophilic to cross the BBB, (ii) the lipophilic character of the chelators no longer contributes to potential toxicity and (iii) hydrophilic hexadentate iron chelators with large molecular weights may be used, as previously demonstrated with nanoparticle technology [152, 350, 351]. Finally, the most important advantage is that the chelator conjugated to nanoparticles has the potential to leave the brain after complexing metals, thus further improving chelation safety and efficacy.

For metal chelation to be effective, the chelators must be capable of leaving the brain with the corresponding complexed metal ions. Many chelators are unable to prevent iron from catalyzing free radical formation via Fenton or Haber–Weiss reaction even though the chelators can complex iron tightly [352]. Thus, the metal–chelator complexes in the brain may still catalyze free radical formation, with possible new adverse effects on the brain. In fact, there is no systematic solution for this problem and finding the solution remains a big challenge in chelation therapy for AD as well as other neurodegenerative diseases associated with metal toxicity. If the nanoparticles are not biodegradable within the brain and can mimic lipoprotein particles by preferentially absorbing ApoA-I, known to facilitate the removal of particles from the brain [99, 353], the same carrier mediated transport systems of LDL will be able to carry the metal–complex nanoparticles out of the brain. This is in contrast to lipophilic chelators that can enter the brain, but when complexed with metals, are unable to cross the BBB due to a change in their lipophilicity. For example, the distribution coefficient (DC) of free L1 determined in *n*-octanol/Tris–HCl buffer system is 0.24, but when complexed with iron is down to about 0.001 [354]. Therefore, although L1 can reportedly penetrate the BBB, it fails to remove iron from the brain [304]. Obviously, the use of nanoparticles may provide a novel approach to transport of metal–chelator complexes out of the brain. The use of nanoparticles conjugated with chelators to mimic lipoprotein particles and transfer iron chelators into and out of the brain through selected apolipoprotein absorption not only provides a useful means of improving the efficacy and minimizing the toxicity of chelation therapy, but also provides insights into the mechanisms of AD development. This novel approach can also open a new area for nanoparticle technology to clean unwanted substances from diseased sites.

#### 16.3.4.4 Experimental Descriptions

To conjugate nanoparticles covalently, iron chelators must have a functional group to react with an active moiety on the particle surface. The functional group introduced into the iron chelators should not possess adverse effects on the chelator–metal binding. Synthetic methods to produce a series of iron chelators with such functional side-chains have been developed [126, 127, 355]. The metal binding properties of these chelators and some biological properties such as the *in vitro* ability to remove iron from tissue sections of AD brains and from ferritin (an important protein for iron storage) have been examined [126, 355]. Some of these chelators can remove iron from ferritin and are capable of depleting iron from tissue sections of the AD brain more effectively than DFO. Methods for conjugation of various iron chelators to nanoparticles have also been developed. The particles can be made of biocompatible synthetic or natural macromolecules [99, 100, 356] with functional groups such as amino and carboxyl groups on their surface for covalent bonding with chelators [162, 243]. After conjugation, the amounts of chelator that conjugate to the particles and the ability of the chelator–particle systems to bind iron are determined. Interestingly, some bidentate iron chelators converted to hexadentate chelators after conjugation to particles because the particles provided backbone linkages. This phenomenon greatly improved the metal binding stability and lowered toxicity associated with metal–chelator complexes. The human plasma protein absorption patterns on iron chelator particle systems are examined using 2-D PAGE technology [99, 357]. These studies show that the protein absorption pattern on the iron chelator particle systems is totally different from that of the human plasma proteins. Through changing the system surface properties, such as chelators and surfactants, the chelator–particle systems can preferentially absorb ApoE. With the same kind of changes, it is also found that the chelator–particle systems after binding metals can preferentially absorb ApoA-I. Such preferential absorptions allow the systems to mimic the ApoE or ApoA-I nanoparticles and to cross the BBB through LDL transport mechanisms [350, 353]. Uniform coating of the systems with ApoE, B or A-I can also be achieved by overcoating of these apolipoproteins, which may enable the systems to cross the BBB with high efficiency [171]. These studies indicate that iron chelator–nanoparticle systems have the potential to enter the brain and bring excess metals out of the brain, thus effectively preventing metal-associated oxidative damage. The results also show the potential to obtain chelator–nanoparticle systems with optimal surface properties via changing chelators, linkages, coating materials and nanoparticles with different surfaces. These findings are promising and suggest that this novel method of chelation may prove useful in the treatment of AD. More studies are warranted to demonstrate the chelation efficacy of the chelator–nanoparticle systems, to evaluate the system toxicity and to optimize their capability to cross the BBB. Some experiments are briefly described as follows.

**16.3.4.4.1 Synthesis of Iron Chelators with Functional Groups for Nanoparticle Conjugation** Iron chelators containing active functional groups have been synthesized. The preparation procedures are simple and product yields are good. The synthetic chelators have been characterized using standard methods such as

$^1\text{H}$ -nuclear magnetic resonance (NMR), mass spectrometry (MS), ultraviolet (UV)-vis and elemental analysis. Their preparations are briefly given below.

**2-Methyl-*N*-(2'-aminoethyl or 3'-aminopropyl)-3-hydroxyl-4-pyridinone (MAEHP and MAPHP)** The chelators were synthesized using a modified procedure as previously described (Scheme 16.2) [358, 359]. In brief, 3-hydroxyl-2-methyl-4-pyranone and benzyl chloride were mixed in a solution of water and methanol in the presence of NaOH. The mixture was refluxed for several hours with magnetic stirring. After removing methanol under vacuum, water was added and the 3-benzyloxy-2-methyl-4-pyranone was extracted with methylene chloride. The methylene chloride solution was then washed with 5% NaOH aqueous solution followed by water and dried over  $\text{MgSO}_4$ . The product was obtained after evaporation of the solvent under vacuum and then reacted with 1,2-diaminoethane or 1,3-diaminopropane in aqueous ethanol solution at room temperature. After 1 week, solvents and residual diamines were evaporated under vacuum and the residue was dissolved in chloroform, washed with water and dried with  $\text{Na}_2\text{SO}_4$ . After removing solvent, methanol was added and the pH is adjusted to 1 with HCl. 1-(2'-Aminoethyl)-3-benzyloxy-2-methyl-4-pyridinone or 1-(3'-aminopropyl)-3-benzyloxy-2-methyl-4-pyridinone was precipitated as dihydrochloride salt and collected by filtration. The pure products were obtained by recrystallization from methanol and ether, and further reacted with  $\text{BBr}_3$  (1.0 M  $\text{CH}_2\text{Cl}_2$  solution) in  $\text{CH}_2\text{Cl}_2$ . The mixture was stirred overnight at room temperature under a nitrogen atmosphere. Water was added and stirring was continued for an additional 4 h. The aqueous phase containing the MAEHP or MAPHP was separated and evaporated under vacuum. The crude MAEHP or MAPHP was purified through recrystallization from an ethanol/ether solution.

**Scheme 16.2.** (a) Benzylchloride/NaOH. (b)  $\text{NH}_2(\text{CH}_2)_n\text{NH}_2$ ,  $n = 2, 3$ . (c)  $\text{BBr}_3$  in  $\text{CH}_2\text{Cl}_2$  at  $4^\circ\text{C}$  or hydrogenation with  $\text{H}_2/\text{Pt}$  on active carbon. (With permission after [359].)

**2-Methyl (or ethyl)-*N*-(2'-hydroxyethoxy)methyl-3-hydroxyl-4-pyridinone (MHEHP or EHEHP)** The chelators were synthesized using established methods (Scheme 16.3) [355, 360]. Briefly, 3-benzyloxy-2-alkyl-4-pyridinone was synthesized as reported in reference [358] with a minor modification. First, to protect the 3-hydroxyl group, 2-alkyl-3-hydroxyl-4-pyranone with benzyl chloride was refluxed under alka-

**Scheme 16.3.** R = Me and Et. (a) PhCH<sub>2</sub>Cl/NaOH/refluxing/6 h. (b) NH<sub>4</sub>OH/room temperature/48 h. (c) Hexamethyldisilazane, chlorotri-methylsilane. (d) Benzyloxyethoxy-methylchloride, trimethylsilyl trifluoromethanesulfonate in 1,2-dichloroethane. (e) H<sub>2</sub>, Pd/C, AcOH in 95% EtOH. (With permission after [355].)

line conditions, as described above. Then, the ring oxygen of 3-benzyloxy-2-alkyl-4-pyranone was replaced by a nitrogen atom via a substitution reaction with aqueous ammonia at room temperature for 48 h. The 3-benzyloxy-2-alkyl-4-pyridinone was silylated in hexamethyldisilazane under refluxing and nitrogen gas for 2 h. After evaporation of the solvent under vacuum, the residue was redissolved in 1,2-dichloroethane and then benzyloxyethoxymethylchloride that could be replaced by (2-acetoxyethoxy)methyl bromide [361] was added in the presence of a catalytic amount of trimethylsilyl trifluoromethanesulfonate (SnCl<sub>4</sub> could also be used as catalyst in the alkylation reaction, but might result in separation difficulties and low yields) [362]. The resulting mixture was stirred at room temperature for 4 h and then treated with an aqueous solution saturated with sodium bicarbonate. After removing the aqueous phase, the organic phase was dried with sodium sulfate and the solvent evaporated under vacuum. Both of the protection groups were removed simultaneously by hydrogenation with H<sub>2</sub>/Pt on activated carbon in acidic aqueous ethanol at room temperature for 24 h or by BBr<sub>3</sub> in CH<sub>2</sub>Cl<sub>2</sub> at 4 °C [306, 363, 364]. The chelators were obtained in pure form after recrystallization from a 1:1 solution of CH<sub>3</sub>Cl:MeOH. To evaluate whether the linked (2'-hydroxyethoxy)methyl moiety affected the geometry of the iron binding site in the chelators, molecular and crystal structures of EHEMHP were determined by X-ray crystallographic analysis. A piece of colorless crystal (0.33 mm × 0.33 mm × 0.11 mm) formed in methanol/ethyl acetate solution was used for X-ray measurement with an Enraf-Nonius CAD-4 diffractometer equipped with a graphite monochromator of MoK<sub>α</sub> (0.71073 Å) [355]. An Oak Ridge Thermal Ellipsoid Plot (ORTEP) stereoview of the EHEMHP molecular structure is depicted in Fig. 16.7.

Figure 16.7. ORTEP stereoview of chelator EHEMHP. (With permission after Ref. [355].)

**2-Methyl-3-hydroxy-1-( $\beta$ -D-ribofuranosyl or ribopyranosyl)-4-pyridinone (MHRFP or MHRPP)** The synthesis of these chelators was similar to that of MHEMHP and EHEMHP above using a modified Hilbert–Johnson reaction (Scheme 16.4) [127, 360, 365]. In brief, after silylation the silylated 3-benzyloxyl-2-methyl-4-pyridinone

was alkylated by  $\beta$ -D-ribofuranosyl or ribopyranosyl groups. The benzyl protection group on the pyridinone was first removed by hydrogenation under  $H_2/Pt$  on activated carbon in acidic aqueous methanol [306, 363, 364]. Then, the hydroxyl groups of the sugar moiety were deprotected by basic hydrolysis in an  $NH_3$ /methanol medium overnight at room temperature. The chelators were obtained in pure form after recrystallization from a 1:1 solution of  $CH_3Cl:MeOH$ . Molecular and crystal structures of MHRPP were determined using X-ray crystallographic analysis to further evaluate the effects of the linked sugar moiety on the iron binding geometry in the chelators. An ORTEP stereoview of the molecular structure of MHRPP is depicted in Fig. 16.8.

#### 16.3.4.4.2 Ability of the Chelators to Complex Iron

**Reaction of Chelators with Iron Ions in Buffer Solution** The reaction between iron and chelators was indicated by a color change of buffer solutions (Tris buffer, 25 mM, pH 7.5, 22 °C) containing chelators following ferric iron  $[Fe(NO_3)_3]$  addition to the solution. The chelators and iron formed purple complexes with the chelator:iron stoichiometry of 3:1 [126, 355]. The typical visible absorption  $\lambda_{max}$  for free chelators and chelator–iron complexes was about 280 and over 450 nm, respectively (shown in Fig. 16.9). The stoichiometry was determined spectrophotometrically by titration of chelators in Tris buffer with freshly prepared iron solution

**Figure 16.9.** A. The UV-vis absorption of free MAPHP ( $\lambda_{\max} = 281 \text{ nm}$ ,  $\epsilon = 1.43 \times 10^4 \text{ Mcm}^{-1}$ ) and B. The absorption of iron-MAPHP complexes ( $\lambda_{\max} = 455 \text{ nm}$ ,  $\epsilon = 3.02 \times 10^3 \text{ Mcm}^{-1}$ ).

at room temperature. The iron solution was added gradually and the change in absorbance of the chelator-iron complexes was monitored by UV-vis spectrophotometry after the chelation reaction reaches equilibrium. Typical titration curves using MHEMHP and EHEMHP are presented in Fig. 16.10 and the endpoints of the titration indicate the formation of chelator:iron (3:1) complexes [355].

**Iron Mobilization by Chelators from Ferritin** The removal of iron from ferritin was studied by incubation of horse spleen ferritin with chelators in Tris buffer (25 mM, pH 7.5). Each chelator was mixed with the ferritin and incubated at 37 °C. The changes in absorbance of the iron-chelator complexes were measured spectrophotometrically at different time intervals. The concentrations of iron-chelator complexes were estimated from  $\epsilon_{\max}$  values at the wavelength of  $\lambda_{\max}$  of the complexes [126, 355]. The kinetics of the iron release was investigated for periods up to 72 h. Figure 16.11 shows the iron removal from ferritin by MHEMHP and EHEMHP as a prototype compared with DFO.

**Figure 16.10.** Titration of MHEMHP (IIa) and EHEMHP (IIb) with iron. (With permission after [355].)

**Iron Mobilization by Chelators from AD Brain Sections *In Vitro*** The ability of chelators to remove iron from brain sections was examined using a histochemical method [366]. Briefly, hippocampal tissues were collected from Alzheimer's disease patients, then fixed in methacarn (methanol:chloroform:acetic acid 6:3:1) overnight at 4 °C. After fixation, the tissues were placed in 50% ethanol, dehydrated in ascending concentrations of ethanol and embedded in paraffin. Six 6- $\mu\text{m}$  sections of the tissues were cut and then mounted on silane-coated slides (Sigma). The sections were deparaffinized with two changes of xylene (10 min each) and rehydrated through graded ethanol/TBS (50 mM Tris, 150 mM NaCl, pH 7.6). Then, 40  $\mu\text{L}$  of each chelator in PBS at various concentrations were applied to each section and incubated over night at 37 °C. The sections were rinsed thoroughly with TBS. After a 2-h incubation at 37 °C in 7% potassium ferrocyanide in aqueous hydrochloric acid (3%), the sections were rinsed with Tris buffer and subsequently incubated in 0.75  $\text{mg mL}^{-1}$  3,3'-diaminobenzidine and 0.015%  $\text{H}_2\text{O}_2$  for 5–10 min. Finally, sections were dehydrated through graded ethanol and cover slip.

**16.3.4.4.3 Conjugation of MAPHF and DFO with Nanosphere or Microsphere Particles** A variety of covalent bonds such as amido, amino, ether and thioether can easily be formed for conjugation of chelators and particles, depending on the existing functional groups located on chelator side-chains and on the surface of

**Figure 16.11.** Removal of iron from ferritin by the chelators of MHEMHP (IIa), EHEMHP (IIb) and DFO. (With permission after [355].)

particles [162, 243]. Here, a simple method of particle–chelator conjugation by forming an amido bond is presented as a prototype. Monodispersed polystyrene particles with carboxyl groups on the surface were used to conjugate MAPHHP or DFO, each of which contained a free primary amino group available for the conjugation. The preparation of the chelator–particle conjugates is presented in Scheme 16.5. The carboxylic acid functional groups on the particle surface were preactivated by *N*-cyclohexyl-*N'*-(2-morpholinoethyl)carbodiimide methyl-*p*-toluenesulfonate (CMC) and conjugated with MAPHHP or DFO as described in Refs. [162, 243, 367]. The carboxylated particles were resuspended through pipetting and vortexing, and then the particles were immediately transferred into a microcentrifuge tube and the supernatant removed by centrifugation. The particles were suspended in 0.01 M NaOH solution, mixed well and the process was repeated. The particles were washed twice with 0.1 M of 2-(*N*-morpholino)ethane sulfonic acid (MES) buffer (pH 5.0) and once with cold Milli-Q water. Carboxyl groups on the particles were activated by adding cold Milli-Q water containing CMC (0.01 M) and incubating for 10 min at 4 °C with slow tilt rotation. After removal of the supernatant, CMC solution was added again along with MES buffer (0.3 M, pH 5.0). The mixture was vortexed and incubated as described above for 30 min. The particles with activated carboxyl groups were washed twice with cold 0.1 M MES as quickly as possible and resuspended in MES buffer (0.1 M, pH 5.0) containing excess MAPHHP or DFO (0.01 M). The mixture was vortexed, followed by incubation

**Scheme 16.5.** Conjugation of MAPHP and DFO to particles. (a) Reaction of CMC with carboxylic acid on particle surface in MES at room temperature for 30 min and (b) reactions of the activated carboxyl groups with excess chelators in MES for 30 min at room temperature.

for 30 min at room temperature with tilt rotation. The particles conjugated with chelators were washed with 0.1 M MES buffer twice and PBS (pH 7.4) twice and stored in PBS at 4 °C. The yield of conjugation was determined by measurements of the free chelator concentrations in the solutions before and after conjugation

using high-performance liquid chromatography (HPLC) or UV-vis spectrometry at the wavelength of maximum absorption [162]. The concentration and size distribution of the chelator–particle systems could be determined using a Beckman Coulter Multisizer II in a counting cuvette containing Isoton II diluent or using a Coulter N4 Plus Sub-micron Particle Sizer.

**16.3.4.4.4 Reaction of MAPHP– or DFO–Particle Systems with Ferric Iron** An aliquot of freshly prepared ferric iron solution [ $\text{Fe}(\text{NO}_3)_3$ , 0.002 M] in MES buffer (0.01 M, pH 5.0) was added to MES (0.01 M, pH 5.0) solution containing suspended MAPHP–particles or plain particles as a control. The mixture was rotated at room temperature for 4 h. The iron–chelator–particle systems and supernatant were separated by centrifugation. The systems were thoroughly washed with MES buffer 5 times to remove noncomplexed iron ions. After combining the supernatants, excess MAPHP in MES buffer (0.01 M) was added to complex the iron ions that did not react with the chelator–particle systems. The visible absorbance of the iron–MAPHP complex was measured using UV-vis spectrophotometry at a maximum wavelength of 455 nm ( $\epsilon = 3.02 \times 10^3$ ) after the chelating reaction reached equilibrium. A standard curve for iron concentration was obtained by measuring several solutions of iron–MAPHP complex with known iron concentrations. The identical procedure was applied in the investigation of the reaction of DFO–particle systems with ferric iron.

**16.3.4.4.5 Protein Absorption Patterns of Chelator–Particle Systems and Chelator–Particle Systems with Iron** The protein absorption patterns of chelator–particle systems and chelator–particle systems with iron, which were obtained by reaction of ferric iron with chelator–particle systems, were evaluated using 2-D PAGE analyses. In brief, the chelator–particle systems, overcoated with Polysorbate 80 at room temperature, and the chelator–particle system with iron (100  $\mu\text{L}$  of each system, 2.5% w/v in PBS buffer) were incubated separately in 1 mL of citrated human plasma (Sigma) for 5 min at 37 °C [357]. After separation by centrifugation and washing 4 times with Milli-Q water, the adsorbed proteins were eluted from the particle surface with a protein-solubilizing solution [5% sodium dodecyl sulfate (SDS), 5% dithioerythritol, 10% glycerol and 60 mM Tris, pH 6.8] [357] and analyzed by 2-D PAGE. In the first dimension, isoelectric focusing (IEF), the proteins were separated only according to their isoelectric points ( $pI$ ). The IEF was carried out in glass tubes of inner diameter 2.0 mm using 2.0% pH 3.5–10 ampholines for 9600 Vh. In the second dimension, SDS–polyacrylamide gel electrophoresis (PAGE), the separation was based on molecular weight. Each tube was equilibrated for 10 min in buffer (2.3% SDS, 50 mM dithioerythritol, 10% glycerol and 62.5 mM Tris, pH 6.8) and sealed to the top of a stacking gel that was on top of a 10% acrylamide slab gel (145 mm  $\times$  145 mm  $\times$  0.75 mm). SDS slab gel electrophoresis was performed for about 4 h at 12.5 mA per gel. After SDS–PAGE, the gels were dried between sheets of cellophane and silver-stained [357].

### 16.3.4.5 Results and Discussion

**16.3.4.5.1 Preparation of Iron Chelators with Functional Groups for Particle Conjugation** In order for chelators to conjugate with nanoparticles, the chelators must have a functional group to allow formation of a covalent bond between the two. As described above, several methods have been successfully developed to modify L1 by adding various side-chains that contain functional groups. The synthetic approaches are simple and the reaction yields in general are very high. In L1 (Fig. 16.6), the methyl group on the nitrogen atom at position 1 can be very easily replaced through various reactions, which provide many possibilities to obtain new chelators with functional groups. Also, the replacement has little effect on the geometry of metal-binding sites. Therefore, it is expected that the high binding affinity of L1 to iron as well as aluminum, copper and zinc will remain after its modification, enabling the new chelators to simultaneously complex multiple metals. The geometry of the metal-binding site in the modified chelators has been examined by X-ray crystallographic analysis. The analysis shows that the C3–O2, C2–O1 and C2–C3 bond distances of the metal binding site in MHRPP are 1.269(6), 1.361 and 1.428(7) Å, respectively (Fig. 16.8) [126]. These data compare well with the corresponding bond lengths of 1.271, 1.364 and 1.438 Å in L1 (Fig. 16.6) [368]. The unchanged geometry of the metal-binding site indicates that the affinity for iron as well as other metals is not affected [126, 355, 368, 369]. In EHEMHP, the C3–O1, C4–O2 and C3–C4 bond distances of iron binding site are 1.302(3), 1.350(3) and 1.418(4) Å, respectively (Fig. 16.7). The bond lengths of C4–O2 and C3–C4 are similar to that of L1, but the C3–O1 carbonyl bond distance is about 0.031 Å longer. These phenomena are explained by the increased electron donor effect of the ethyl group in EHEMHP compared with that of the methyl group in L1 on the 2 position of the pyridinone ring. Since the carbonyl group on the pyridinone ring is an electron draw group, the greater the electron density on the pyridinone ring donated by alkyl groups (ethyl > methyl), the longer the carbonyl bond length should be. Interestingly, the carbonyl bond distance of EHEMHP is close to that of the iron–L1 complex [370]. In the complex, the corresponding carbonyl bond length is 1.299(8) Å. The C4–O2 and C3–C4 bond lengths in EHEMHP also compare very well with the corresponding bond lengths of 1.342(7) and 1.408(7) Å in iron–L1 complex [370]. These observations indicate that the replacement of the 2-hydroxyethoxymethyl group has no negative effect on iron binding and that the iron-binding site of EHEMHP may be more favorable for iron chelation than L1 because of the preorganized effect [371].

**16.3.4.5.2 Examination of Modified Chelators Complexing to Iron** The ability of the modified chelators to complex metals was examined by titration of the chelators with iron in Tris buffer solution. The chelators react with iron forming purple complexes which have the chelator:iron stoichiometry of 3:1. The titration result also reveals that the functional groups in the side-chains are not involved in iron complexation under physiological conditions. This is important, because it ensures that

the use of the functional groups in chelator side-chains for conjugation with nanoparticles will not affect the chelator–metal binding ability.

To further examine the ability of the chelators to complex metals, the reaction of chelators with ferritin was evaluated. This protein is important for iron storage and in brain tissue most of nonheme iron is in the form of ferritin [266, 372]. Evidence shows that iron metabolism is altered in the brain of AD patients, with alterations including chelatable iron, ferritin and transferrin [267, 268, 275, 373]. The *in vitro* extraction of iron from the ferritin core by chelators is a convenient measurement of the potential efficacy of *in vivo* removal of iron from iron-overloaded organs [374]. All of the modified chelators can mobilize iron from ferritin in a slow reaction, which is monitored by the increase in absorbance of the iron–chelator complexes using a spectrophotometric method [126, 355, 374]. The formation of iron–chelator complexes in all the reactions indicated a common kinetic mobilization pattern that is characterized by initial rapid iron removal, followed by a slower iron removal rate. The end of the reaction as judged from stable absorbance. The modified chelators were more effective than DFO in mobilizing iron from ferritin at physiological pH. The initial rate of removal was faster with the modified chelators than with DFO, while the rate after 24 h was about the same, which can be seen in Fig. 16.11.

*In vitro* tests of iron removal from AD brain sections with various iron chelators were also performed and examinations of the sections using differential interference microscopy demonstrated that iron chelators have the ability to strip iron from the brain tissues. Results showed that the iron removal efficacy depends on the chelator chemical structures and concentrations used. For example, both MAEHP and MHEMHP had better ability to remove iron from AD brain sections, compared with DFO and MHRPP, at concentrations of 0.01 M (Tab. 16.1). The histochemical evaluation of iron in an AD brain section treated with MAEHP is presented in Fig. 16.12, showing remarkably less staining for iron compared with an untreated control. Importantly, this finding provides further support for the possible mechanism of metal-associated oxidative damage in AD development, by show-

**Tab. 16.1.** Iron evaluation by histochemical staining in AD brain sections after being treated with various iron chelators.

	0.1 M	0.01 M
Untreated	positive	positive
DFO	negative	very positive
MHRPP	few positive blood vessels	very positive
MHEMHP	negative	weakly positive
MAEHP	negative	weakly positive

**Figure 16.12.** Lesion-associated chelatable iron in AD brain sections was depleted with iron chelator, which was evaluated by histochemistry. (A) Control and (B) MAEHP-treated section (with permission after [375]).

ing the existence of chelatable iron in the AD brain. The chelatable iron is believed to be one of the culprits that catalyze free radical formation, causing oxidative damage to all types of biomolecules [209]. Furthermore, this result indicates the potential of chelation therapy of AD by depletion of excess metals, hence preventing metal-mediated neuro-oxidative damage. These results are consistent with early reports that chelation treatment can affect iron accumulations that are closely associated with the places of senile plaques and neurofibrillary tangles in cases of AD [366]. This iron specifically localized to the lesions of AD could participate in *in situ* oxidation and catalyze an  $H_2O_2$ -dependent oxidation [366]. Our current study also identifies a useful tool to screen potential chelators which have suitable ability to mobilize iron from the AD brain *in vitro*. This method provides important information for selecting optimal chelators to use for conjugation with nanoparticles in our studies.

As discussed previously, currently available iron chelators used in chelation therapy are problematic due to both toxicity and/or poor bioavailability. It is difficult to develop iron chelators with an optimal balance of bioavailability and low toxicity by adjusting chelator size and lipophilicity. Therefore, other strategies have been explored in order to develop therapeutic iron chelators with suitable bioavailability as well as tolerable levels of toxicity. Relevant to particulate drug delivery, attempts to improve the pharmacological properties of current clinical iron chelators include covalently conjugating DFO to dextran and hydroxyethyl-starch [376–378] or conju-

gating DFO to large agarosepolyacrolein microsphere beads [379]. Results from these studies are consistent with our studies that the conjugation does not appear to affect the normal high iron-binding affinity of DFO. Also, improved bioavailability and/or stability of DFO as well as decreased toxicity are observed. Formulations of DFO with *n*-decanesulfonate or poly(fumaric anhydride-*co*-sebacic anhydride) produced particles with increased efficiency in chelation treatment by slowing down the release of DFO from the particles [380, 381]. In addition, microencapsulated formulations of L1 with Eudragit RS, RL and L90, and cellulose acetate phthalate have been developed to further improve its bioavailability [382]. Despite all of these improvements, there still is a tremendous need to develop iron chelators with specific organ-targeting ability. Optimal organ-targeting may in itself further improve bioavailability of chelators and limit toxicity. In addition to the primary purpose of correcting primary and secondary iron overload, this particular approach may also make it possible for chelation therapy to prevent and treat other diseases especially neurodegenerative disorders associated with excess metals.

**16.3.4.5.3 Chelator–Particle Conjugation, Metal Complexation and Potential BBB Penetration** Nanoparticulate drug delivery provides an opportunity for drugs to penetrate the BBB. The nanoparticle drug system also possesses the advantage of easy preparation and high stability. To explore the possibility of nanoparticle–chelator transport for AD treatment, practical methods for chelator conjugation with nanoparticles were investigated. Here, the reaction of MAPHP or DFO, each containing one primary amino group, with polystyrene nano/microparticles with a surface carboxylic acid moiety is presented as a prototypic conjugation. As mentioned before, it also is possible to synthesize iron chelators containing different functional groups that readily react to the nanoparticle surface active sites without any adverse effects on the chelator metal binding.

Carboxylic acid functional groups on the surface of the particles used here allowed the particles to conjugate with chelators by forming covalent amido bonds. Prior to conjugation, the carboxylic acid groups were activated using carbodiimide in MES buffer at an acidic pH value to form an active intermediate ester. To remove excess carbodiimide, the particles were rapidly washed with cool Mill-Q water since the ester is unstable and undergoes hydrolysis. An alternative method, such as adding a water-soluble *N*-hydroxyl compound like sulfo-*N*-hydroxysuccinimide (NHS), could increase the coupling yield since NHS is known to form a more stable intermediate ester by replacing the oacylisourea intermediate formed by carbodiimide. The NHS-formed ester is less susceptible to hydrolysis but still highly reactive toward amino groups [383, 384]. The primary amino group in the chelators reacts with active ester intermediates derived from carboxyl groups on the particle surface, consequently forming covalent amido bond linkages in good quality yields (over 70%). Coupling yields were determined by (i) measuring the free chelator concentration in solution before and after conjugation, using HPLC or UV-vis spectrophotometry readings, and (ii) calculating the difference between the two concentrations to indicate the amounts of the chelators conjugated to particles. After the conjugation reaction, the particle size distribution was

**Figure 16.13.** Particle size distributions measured by Multizer analyzer II. There is no distribution change between particles conjugated with MAPHp and particles without conjugation.

measured and compared with the distribution prior to conjugation. A distribution change was not observed, which indicated that there was no particle clumping (Fig. 16.13). A useful protocol for particle conjugation with various molecules can be found in Ref. [162].

With rapid development of nanoparticle technology in biomedical applications, most processes for preparing various nanoparticles with different sizes and properties have become routine and standard, and many of these nanoparticles are even commercially available. The technologies to make the nanoparticles virtually monodispersed, with a narrow diameter deviation, spherical shape and constant surface area, has really advanced the development of nanoparticulate drug delivery. Also, it has become easier to obtain suitable nanoparticles with various functional groups on their surface for the purpose of covalent bond conjugation by utilizing simple chemical reactions, as demonstrated by our studies.

To test whether chelators retain their ability to complex metals after conjugation with nanoparticles, the chelator–nanoparticle systems were incubated with a  $\text{Fe}(\text{NO}_3)_3$  solution. After the reaction was complete, the  $\text{Fe}(\text{NO}_3)_3$  solution was removed and noncomplexed iron was determined by adding MAPHp and measuring the iron–MAPHP complexes using UV-vis spectroscopy. Results indicated that about two MAPHp molecules conjugated to particles complexed with every iron atom. As each MAPHp can provide only two oxygen donors to chelate iron, two more iron-binding sites are needed to form a highly stable iron complex with an octahedral coordination sphere. According to our earlier studies [385], the oxygen atoms in amido groups may be involved in chelating iron; thus, two oxygen donors

**Figure 16.14.** Four oxygen donors from two MAPHPs and two oxygen donors from amido groups constructing a hexadentate chelator through particle surface as the backbone.

from two amido groups and four oxygen donors from two MAPHPs may assemble into a hexadentate chelator, using particle surface linkages as the backbone (Fig. 16.14). This is significant, as hexadentate iron chelators possess many advantages including kinetic stability, concentration independence of iron affinity and low toxicity [310]. In addition, attempts to convert bi- or tridentate iron chelators into hexadentate chelators with various backbones suffer mainly from decreased bioavailability and the risk of potential toxicity. By contrast, the use of nano/microparticles to convert bi- or tridentate chelators to hexadentate chelators may circumvent these problems due to the particle targeting ability. In this manner, many bidentate or tridentate iron chelators, even with intolerable toxicity, can be modified by conjugation with nano/microparticles, since the toxic character of the free chelators may be diminished after particle conjugation. Our results also revealed that DFO still retains the 1:1 complex ratio with iron – an indication that conjugation with particles does not affect its iron binding ability. It is also worth mentioning that the bioavailability of some hexadentate iron chelators with high molecular weights and hydrophilicity can be improved after forming the chelator–particle delivery systems [386].

In order to demonstrate the possibility that chelator–nanoparticle systems enter the brain and that the chelator–nanoparticle systems leave the brain after chelation with metals, the protein absorption patterns of MAPHP–particle system and iron–MAPHP–particle system were evaluated; 2-D PAGE analyses were used to conduct this evaluation after incubation of the systems with human plasma. The 2-D PAGE images are presented in Fig. 16.15 and show that the protein patterns on the systems are totally different from that of the human plasma protein (Fig. 16.15a).

**Figure 16.15.** Images of plasma protein patterns examined by 2-D PAGE. (A) Plasma, (B) nanoparticle–chelator systems coated with Polysorbate 80 and (C) nanoparticle–chelator systems complexed with iron (with permission after [375]).

Through changing the surface properties of MAPH–particle system by coating surfactants such as Polysorbate 80, the system preferentially absorbed ApoE (Fig. 16.15b). On the other hand, after complexing of MAPH–particle system with iron, the iron–MAPHP–particle system possessed the absorption preference for ApoA-I (Fig. 16.15c). Such preferential protein absorptions may allow the MAPH–particle system and iron–MAPHP–particle system to mimic the ApoE and A-I nanoparticle, respectively, and therefore to enter brain without metal chelation and leave the brain with complexed metals via LDL transport mechanisms.

Simultaneous chelation of iron and other metals such as aluminum, copper and zinc may provide a useful therapeutic option for AD treatment. The use of nanoparticles to transport iron chelators into and out of the brain could lead to a safer and more effective chelation therapy for AD by means of decreasing the multiple metal load in neuro-tissue, and thereby staving off the harmful effects of oxidative damage and its sequelae. Iron chelators with functional groups can be synthesized and the functional groups can be used for conjugation with nanoparticles. The conjugation of such chelators to nanoparticles does not alter the chelator metal-binding ability and, in some cases, the conjugation even improves the chelation coordination property. The nanoparticles can be made of biocompatible synthetic or natural macromolecules with functional groups on their surface for conjugation with chelators. The macromolecules can be non- or controlled biodegradable for specific purposes. Changing nanoparticle surface properties can optimize the preferential protein absorption, thus improving the ability of the particle to cross the BBB. Many approaches to adjust particle surface properties can be used, such as coating with different surfactants or proteins, conjugating with different chelators or with various linkers and using antibodies to increase lipoprotein preferential absorption. Further studies with the chelator–nanoparticle system may provide more insights into the mechanisms of AD pathophysiology, and may show the possibility of prevention and treatment for other iron-mediated neurodegenerative diseases such as Friedrich ataxia, Huntington's disease, Parkinson's disease and Hallervorden–Spatz Syndrome. More studies are needed to demonstrate the protective efficacy of the chelator–nanoparticle systems, to evaluate their toxicity and

to optimize their capability to cross the BBB. Our studies may also open the door for the use of a nanoparticle-mediated transport to facilitate extraction of toxins from defective places in the body for disease prevention and treatment.

## 16.4

### Perspectives

Nanoparticulate drug delivery for AD prevention and treatment shows great potential; however, it is still at a very early stage of development. In order to advance this technology for AD application, knowledge is urgently needed in several basic research areas. For example, there is no study on the *in vivo* treatment of AD using nanoparticulate drug delivery technology. With the AD animal models available, the efficacy of nanoparticulate agents delivered to the brain that may offer therapeutic effects on AD based on a current understanding of AD pathogenesis should be evaluated. This will not only provide insights into the mechanisms of AD development, but also lead to more effective and safer therapeutics for the disease. It also is necessary to fully study whether the nanoparticulate drug systems possess adverse effects on the BBB and brain as well as other parts of the body, at tissue, cell and molecular levels. Additionally, the pharmacology and pharmacokinetics of the systems need to be examined, which will ensure the further development of the nanoparticulate drug systems for clinical use. Furthermore, it is suggested that the nanoparticle surface, and perhaps also the particle components, can be used to manipulate particle uptake into the brain via the LDL receptor, because nanoparticles preferentially absorb ApoE and/or B in blood, and thereby mimic these protein particles. However, the exact mechanisms are not fully understood, and thorough studies could provide valuable information that will help improve the ability of nanoparticulate drug systems to cross the BBB. Moreover, studies on improving drug-loading capacity in nanoparticulate drug systems, which should not affect the ability of these systems to enter the brain, must be carried out in order to reach sufficient drug level in the AD brain. In this regard, drug nanosuspensions have the advantage that no polymeric materials are required as carriers. Lipid nanoparticulate drug systems also show promise; both need to be investigated. Finally, because of the highly interdisciplinary nature of developing the technology of nanoparticulate drug delivery for AD treatment, it is necessary to bring together chemists, bioengineers and life scientists in order to accomplish this task.

Specifically, it would be useful to focus on nanoparticle chelation agents as a possible drug for AD treatment, because metal-mediated toxicity is believed to be an important contributor to AD development and chelation therapy shows some benefits to AD patients. In addition to nanoparticle delivery of drugs into the brain, which has been achieved in some cases, the ability of nanoparticles to bring chelator-metal complexes out of the AD brain needs to be demonstrated *in vivo*. Effects of the nanoparticulate chelator system on metal biokinetics and excretion should be studied, which will provide important information about chelation efficacy and toxicity.

Further studies should utilize the nanoparticulate drug delivery systems, one of the few valuable tools to deliver drugs into the brain, to transport available therapeutics to prevent or treat AD in clinical studies. This approach may significantly improve the efficacy of these therapeutic agents and minimize systemic side-effects or make it possible for some potential therapeutics such as nerve growth factors, non-brain-distributing ACE inhibitors and hydrophilic chelators with large molecular size to enter the brain for AD treatment. The use of this technology will also facilitate the development of other promising treatments such as antibody, gene and stem cell therapies. Simultaneous multidrug delivery can also be achieved through nanoparticle technology, which may provide better therapeutic efficacy. Biocompatible or biodegradable polymers to serve as carriers in nanoparticulate drug systems are now being developed, as are potential AD therapeutics. Coupling these studies may result in more rapid identification of more effective and safer drugs for the treatment of AD. As many nanoparticulate drug delivery systems are designed for intravenous administration, the possibility of oral administration as well as transdermal, ocular, nasal and inhalation routes should be investigated. The development of these patient-administrable nanoparticulate drug delivery systems would greatly facilitate the care of AD patients and benefit patients over extended time periods of therapy.

It is worth noting that an outstanding feature of nanoparticulate drug delivery technology is its simplicity of preparation, optimization and application. For example, the nanoparticles used for chelator transport can be made of synthetic or natural macromolecules with functional groups such as amino and carboxyl moieties on their surface for covalently bonding with chelators. Changing the chelators, linkages, surfactants and the nanoparticle surface can result in nanoparticulate chelator systems with desirable surface properties, which enable the systems to cross the BBB. Also, directly coating the chelator–nanoparticle with apolipoproteins or their antibodies may facilitate high-efficiency penetration of the BBB. In addition to nanoparticle delivery of drugs, nanoparticle conjugation with drugs or prodrugs can also offer the possibility of developing new therapeutics that not only possess specific organ targeting, but also have improved therapeutic efficacy and minimized toxicity for AD treatment. It is also possible that nanoparticles can serve as vehicles to bring toxic materials out of the brain, which will be a huge advance in nanoparticle technology for disease prevention and treatment.

The fundamentals of nanoparticulate drug delivery into the brain indicate the possibility of transporting therapeutic agents across the BBB for treatment of AD. Current investigations provide evidence to support this possibility and show promise. Further studies are needed to demonstrate therapeutic efficacy and tolerance. Enthusiasm for nanoparticle transport of drugs for AD treatment is high because this approach will not only provide more insights into the mechanisms of AD development, but also will lead to safer and more effective therapies for the disease. This approach can also be used for prevention and treatment other neurological diseases as well as for disease diagnosis.

## Acknowledgments

We are grateful for the financial support by the National Institutes of Health. We would also like to thank Drs. Mark Smith and Peggy Harris of the Case Western Reserve University for their histochemical analysis of AD brain tissues. Finally, we would want to thank all the various publishers for their kind permission to reproduce figures and schemes used in this chapter.
