**Local Administration and Long-time Delivery** Small particles injected locally in the tumor vicinity infiltrate gradually the lymphatics, representing a tool for lymph node metastases, and locoregional adjuvant therapy, for breast cancer for example. In this model the size and choice of the carrier are of fundamental importance to avoid clogging of small lymphatic vessels. For this purpose magnetic systems would be a good choice (see below).

Polymer gels have been designed for controlled release and as systems for modulated delivery. The hydrophobic–hydrophilic balance of a gel carrier can be modulated to provide useful diffusion characteristics for periods up to months. Current polymer network drug delivery systems incorporate the pharmaceutical agent by imbibition, equilibrium partitioning after the network is formed, before or after polymerization depending on the drug stability to UV light. Reference [88] gives a more extensive review of the features of these devices.

**New Materials Evaluated as Carriers: Thermoresponsive or Oxidation-sensitive Materials** The preparation and characterization of “intelligent” core–shell nanoparticles has been described. Thermoresponsive, pH-responsive and biodegradable nanoparticles of poly(D,L-lactide)-*graft*-poly(N-isopropyl acrylamide-*co*-methacrylic acid) have been developed as a core–shell type nanoparticle with high drug loading capacity. A hydrophilic outer shell and a hydrophobic inner core, with a phase transition above 37 °C, have been prepared. Heating above the phase transition temperature or pH modification caused leakage of the drugs, demonstrating the potential of these nanoparticles as drug carriers for intracellular delivery of anticancer drugs [89]. Monodisperse polymeric nanoparticles of polyacrylic/isopropyl acrylamide, prepared by seed-and-feed method, displayed inverse thermogellation at 33 °C. Therefore, drug–polymer mixtures that are liquids at room temperature become a gel at body temperature without chemical reaction, allowing the sustained release of drugs [90]. Oxidation-sensitive polymeric nanoparticles of crosslinked polysulfides have also been developed as oxidation-sensitive vehicles for hydrophilic or hydrophobic drugs able to release drugs in the more oxidative environment of cancer and inflammation [91].

#### 7.4.9

##### Superparamagnetic Iron Oxide Nanoparticles (SPIONs) as Magnetic Drug Nanovectors

Nanovectors able to both detect cancer and deliver drugs have also been developed, mainly using the outstanding superparamagnetic properties of iron-oxide nanoparticles. Superparamagnetic iron oxide nanoparticles (SPIONs) are usually used as

magnetic nanovectors since their superparamagnetic properties, depending on their nanoscale size, make them magnetic in the presence of an external magnetic field, but no magnetic remanence remains after removal of this external field. Magnetic nanoparticles offer additional attractive possibilities in biomedicine since their magnetic properties allow them to be manipulated by an external magnetic field gradient, further improving chemical and biological drug delivery strategies, in addition to magnetic resonance imaging (MRI) contrast enhancement detection of their sites of localization. Previous experiments using this approach have been performed by some groups with magnetic particles or magnetic liposomes, ranging from 10  $\mu\text{m}$  to 100 nm, loaded with chemotherapeutic agents [92–94]. Some positive effects were obtained, in particular a decreased general toxicity, due to lower dosages, of the agents. This approach has the advantage of being non-invasive and efficient.

Biocompatible superparamagnetic nanoparticles have been developed for *in vivo* biomedical application, mainly in magnetic resonance imaging [63, 95, 96], and have been only preclinically evaluated in the tissue-specific release of therapeutic agents [97]. Dextran-SPIONs have been used in gene transfer experiments in a human bladder cancer cell line [98]. SPIONs combined with albumin [99] or as liposomes with antibodies targeting Her2 have been used for combination of antibody therapy with hyperthermia [53]. Surface modification of the PEG film of SPIONs with folic acid decreased their uptake by mouse macrophages and increased their uptake by human cancer cells [100]. Anionic SPIONs, coated with albumin, were taken up by cells [101], and anionic to cationic surface charge in the acidic lysosomal compartment may allow escape from the endo-lysosomal compartment to the cytosol [102]. Dextran-coated SPIONs of 150 nm, but not of 10 nm, were taken up by macrophages involving type I and II scavenger receptor SR-A-mediated endocytosis [103]. For the latter application, the internalization of nanoparticles into specific cells is the critical step, but is limited by non-specific targeting and a low efficiency of internalization of the endocytosed ligands grafted on the nanoparticles [104]. Clearly, this step needs to be improved to enhance efficiency. Few published studies have addressed the uptake by cells or the cell-surface binding of functionalized superparamagnetic nanoparticles [105]. Therefore, a firm theoretical foundation of magnetic drug targeting is still lacking.

Interactions of magnetic nanoparticles with cells may have an impact on cell functions. Macaque T cells labeled with monocrystalline SPIONs following adsorptive pinocytosis or receptor-mediated endocytosis and which localized in the cytoplasm did not cause any measurable effects on T cell functions [106]. Conversely, transferrin magnetic nanoparticles localized to the cell membrane without inducing endocytosis, but this surface localization induced the expression of several genes of the cytoskeleton and cell signaling pathways [107].

## 7.5 Targeting

Detecting and treating cancer by targeted means at the earliest possible stage of cancer will improve the quality of life and the life expectancy of patients. The use of nanoparticles has a bright future towards achieving these goals. Probably the

most promising features of nanovectors are related to the possibility of modifying their properties, mainly their surface, to achieve organ-, tissue- and cell-specific and -selective delivery of anticancer drugs, to increase drug efficacy and decrease side effects, and ultimately improve the quality of life and survival of patients. Technical problems of developing targeting nanoparticles include the increased complexity/size of the nanoparticles, as well as the increased risks of adverse reactions, while advantages include the fact that more drug will reach the target, selectivity is increased, the delivery of multiple agents at the same site will become possible for targeted combination therapies, and the ability to bypass biological barriers.

Cancer targeting using drug-loaded nanovectors may be achieved in three ways:

1. Using the tissue characteristics of cancer, mainly the leaky vessels associated with many human cancers – what has been called passive targeting.
2. Using the characteristics of cancer cells, mainly increased metabolism and active cell proliferation, and *active circumstantial targeting*.
3. Using molecular markers overexpressed by either cancer cells or cancer-associated cells, mainly the neo-angiogenic endothelium of cancer tissue, and *active molecular targeting*.

Active targeting of drugs to cancer is probably the most challenging biotechnological approach. To achieve these goals it will be necessary to:

1. Define valid targets: markers of tumor and tumor-associated cells and vasculature.
2. Develop the necessary chemistry to bind drugs to nanovectors: validate synthetic routes.
3. Release the drugs at the right place and time from the carrier: develop intelligent linkers.
4. Achieve intracellular delivery: define cell penetration means and organelle addresses.

The greatest challenge in designing strategies for targeting is to define the optimal targeting system, able to selective bind to tumor or tumor-associated cells, then to trigger internalization of the drug cargo (for a more extensive review see Ref. [24]). Most studies have used a modification of the nanoparticle surface, e.g.,

- covalently-linked antibodies,
- tumor vascular markers (RGD and integrins, VEGF-R, EGF-R),
- and permeation-enhancing agents.

The endothelium is a very attractive tissue for drug targeting using nanoparticles in cancer. Surface properties of the nanocarrier may provide passive–active targeting to endothelium, e.g., polystyrene nanoparticles arrest in bone marrow endothelium, followed by receptor-mediated endocytosis [108], while polysorbate 80-coated nanoparticles arrest in the blood–brain barrier vasculature [16, 28]. Cationic lipo-

somes are internalized within 1 h in endothelial cells, according to an organ- and vessel-specific manner [109], and these effects are likely mediated by vessel-type specific properties. Recent approaches have also provided information concerning specific molecules expressed by the various endothelia. Issues to consider in targeting tumor vasculature include the fact that tumors are poorly perfused, tumor vasculature destruction is not enough to totally destroy tumors, that high intratumoral osmotic pressure will result from antiangiogenic therapies, and it has to be considered that the destruction of tumor vasculature will also result in the loss of access to the tumors.

### 7.5.1

#### **Passive Targeting**

Passive targeting utilizes tissue features that are characteristics of cancer, mainly the defects of the cancer vascular system, enhanced permeability and retention time of tumor vasculature and tissue [24], avoiding trapping in the RES, or kidney clearance. Heterogeneity of blood flow in a tumor is also a challenge, but the leakiness of tumor vasculature and the poor lymphatic drainage of human cancers may be advantageous, allowing an enhanced permeation and retention (EPR) effect. Following systemic administration, drug delivery devices to solid tumors must be transported through blood vessels, across the vascular wall into the surrounding tissues, and through the interstitial space within a tumor. These processes are determined both by the characteristics of the drug and of the delivery system, and by the biological properties of tumors. Functional and morphological differences exist between normal and tumor-associated blood and lymphatic vasculature, offering therapeutic opportunities and windows for the delivery of therapeutic agents [110, 111].

Tumors smaller than 2–3 mm in diameter receive nutrients, oxygen, etc. from the surrounding host tissue by diffusion and do not develop their own vasculature, and will not be targeted by passive targeting. The growth of tumors results in the development of their own vascularization, which is more heterogeneous and heterogeneously distributed, larger, tortuous and permeable than that of normal tissue, depending on the tumor. In a tumor, defects in tumor vasculature result in increased resistance to flow, lower blood flow and decreased perfusion of tumor tissue. In tumors the lymphatic system, which returns the interstitial fluid to blood circulation, is defective. The lack of lymphatic drainage in solid tumors also results in decreased water clearance and the retention of high molecular weight components (>40 kDa), but at the price of increased interstitial pressure and decreased extravasation from blood vessels. The extravasation of molecules is accompanied by fluid movement across the leaky vessel walls by passive diffusion or convection, dependent on the hydrostatic and osmotic pressure differences between blood and interstitial space. Small molecules mainly diffuse whereas large molecules are transported by convection/pressure differences. In a tumor, convection is directed out of the tumor. Macromolecules, extracellular matrix and cell density are important factors in the repartition of therapeutic agents in the tumors.

Thus, in cancer, blood perfusion is heterogeneous, the vascular wall frequently is collapsed and the intratumoral hydrostatic pressure high; therefore, nanoparticle distribution is unpredictable. Passive diffusion of nanoparticles (20–150 nm) at sites of vascular leakage in cancer is possible. Drug release, near the cancer, by the carrier must follow extravasation and drug therapeutic dosages must be achieved. The release rates depend on both the drug and chemical and biophysical properties of the nanomaterials and on the biological characteristics (pH, redox, etc.) of the tissue where the drugs has to be released and be active. Drug release from the nanocarrier remains an issue – some polymeric materials do not allow drug release at levels and rates that are compatible with those necessary for treatment efficacy.

## 7.5.2

### Active Targeting

Actively targeted treatment of cancer and tumor-specific targets include nanoparticle delivery systems selective either for cells forming tumor angiogenic vessels and stroma or tumor cells.

#### 7.5.2.1 Targeting Cancer-associated Cells

Human cancers are heterogeneous entities, made of several different cell types: the tumor cells, the normal cells from which tumor cells have evolved, the cells forming the normal and the tumor-associated vascular system, fibroblasts and tumor-associated fibroblasts, and immune cells and cancer-associated immune-cells (mainly macrophages and lymphocytes). Theoretically, all these cells may be useful for drug targeting, but presently the cells forming the tumor vasculature have been evaluated in most experimental approaches.

**Targeting Cancer Vasculature** The molecular signature of the endothelial surface is tissue- and disease-specific, allowing one to direct functionalized nanoparticles to selected sites through vascular markers, via appropriate ligands, receptors, and enzymes. Drugs in cancer may be targeted using angiogenesis-associated molecules, such as the receptors for VEGF/VPF, bFGF, PDGF, or proteases associated with invasion, such as the matrix metallo- and serine-proteases. The use of angiogenesis inhibitors as drugs, including IFN $\alpha$ ,  $\beta$ , or  $\gamma$ , thrombospondins, TIMPs, and anti-VEGF antibody (Avastin), has been investigated. The inhibitors approach allows one to combine drug targeting and anti-angiogenic therapy. Gene therapy using liposome and poly(*N*-vinyl-2-pyrrolidone) delivery [112, 113] with the integrin  $\alpha v \beta 3$  and lipid-based cationic nanoparticles to target a mutant of Raf [114] has been shown to be a potential approach only in animal models. A web site exists that lists the clinical trials and molecules under evaluation [24].

**Macrophages** In cancer, macrophages have been used in the detection of lymph node metastasis with SPIONs (see Section 7.4.9). The targeting of tumor-associated macrophages for therapy has been little attempted to date, but might in

the near future become an option since these cells are involved in cancer progression. The lessons gained from knowledge acquired of immune, inflammatory, infectious and vascular disorders may be important.

#### 7.5.2.2 Targeting Cancer Markers

To achieve active targeting and drug delivery to the right cells based on molecular recognition processes, including ligand–receptor and antibody antigen, high expression at the tumor cell-surface of cancer-specific molecules is to be used. However, such molecules are frequently cancer-type specific and not expressed by all cancer cells in human cancers, resulting in resistance mechanisms. Pro-drugs, whose activation depends on specific biological properties of cancer cells, can also be useful in achieving treatment selectivity. Among these approaches, peptidase- or acid-sensitive linkers have been evaluated. For example, adriamycin conjugated to PEG via a linker containing Ala-Val, Ala-Pro, Gly-Pro sequences that can be cleaved by proteolytic enzymes displayed tumor cell selectivity [115]. Liposomes may be destabilized by enzymes, e.g., phospholipases or proteases, which are highly expressed and secreted in many cancers; depending on the lipid composition and structure, pH changes or the high redox potential associated with the cancer environment can also be useful for this purpose.

To achieve these goals, the methods of assembling recognition molecules on the surface of nanoparticles, through adsorption or chemical linkages, must be developed and validated. The surface density, orientation, presentation, spacing, and conformation of ligands on the surface of nanoparticles are crucial for the success of the ligand–receptor binding and, therefore, targeting and drug delivery. Particle stability, aggregation, and degradability may become problematic. If intracellular delivery of therapeutics is the goal, the choice of the ligand–receptor pair is of the utmost importance (phagocytosis, endocytosis, lipid rafts, receptor-mediated, etc.) for efficiency of internalization, the cellular localization of the nanoparticle payload, and the pattern of activation of cell signaling pathways.

These approaches may bypass multidrug resistance systems, but drug release from the carrier in a biological situation is still a major problem.

**Folate and Folate Receptor** One of the most investigated approaches involves the folate receptor, which is expressed at the surface of many cancer cells. Targeting may be obtained with folate linked to PEG to target folate receptors overexpressed on cancer cells, such as ovarian, lung, colorectal cancers, and internalization of the nanocarrier by this receptor [116]. Folate-PEGylated cyanoacrylate nanoparticles have been developed [104] and high affinity was achieved, probably due to increased multivalent interaction of folate-nanoparticles with the clustered folate receptors on the cell surface. As a consequence, increased internalization of encapsulated drug was achieved. Monodisperse (10 nm) magnetite nanoparticles, derivatized with PEG-folate, were more efficiently taken up than PEG or folate nanoparticles by breast cancer cells [117]. Folate-mediated uptake of folate-conjugated albumin nanoparticles (mean diameter 70 nm) prepared by a coacervation method and chemical crosslinking has been demonstrated in ovarian SKOV3 cancer cells

[118]. Polyamidoamine (PAMAM) dendrimers, <5 nm, conjugated to folic acid and methotrexate as anticancer agent were injected i.v. into folate receptor-positive human KB tumor-bearing immunodeficient mice. The folate-derived dendrimers concentrated in the tumor and methotrexate was internalized into tumor cells. The anti-tumor activity of methotrexate was increased and toxicity markedly decreased, allowing a tumor drug dosage not possible with the free drug [49].

**Antibodies** Targeting via monoclonal antibodies (listed in Table 7.1 of [24]) has been attempted, either as direct therapeutic agents or as carriers for drug delivery systems, to exploit differences between the expression of the corresponding antigens in cancer and normal cells [119].

Breast cancers express high levels of estrogen and EGF receptors, and prostate cancers express androgen receptors, which can also be used to achieve targeting. The ERB-2 receptor, a growth factor receptor belonging to the EGF receptor family, is overexpressed in about one-quarter of human breast cancers. An experimental study has used commercial liposomal doxorubicin, incubated with an anti-ErbB2 antibody coupled to modified PEG, to induce faster and greater tumor regression [120]. Chemical conjugation of mitoxantrone-loaded nanospheres and anti-C-erbB-2 monoclonal antibodies to nanospheres (665 nm mean diameter) prepared by an emulsion heating solidification technique displayed selective binding to breast cancer cells [121]. The conjugation of an anti-EGF receptor monoclonal antibody to colloidal gold nanoparticles increased their selectivity toward cancer cells versus non-cancer cells, suggesting their utility in both detection and targeted drug delivery [52]. Interaction of immunotargeted nanoshells, optically active nanoparticles, whose relative dimensions allow either the scattering or absorption light and, therefore, the imaging or photothermal destruction of target tissue, has been demonstrated in Her2-positive breast cancer cells [122].

**Carbohydrates** Liver cells express asialoglycoprotein, a galactose ligand, that has been evaluated as a target for primary or metastatic liver cancers. Nanoparticles based on biotinylated diamine-terminated PEG and using the galactose moiety of lactobionic acid as targeting agent and A11-transretinoic acid as drug have afforded a constant drug release *in vitro* over one month [123, 124].

**Transferrin Receptors** Transferrin receptors are overexpressed at the surface of many tumor cells, and have been used for liposomes or PEGylated liposomes of doxorubicin or cisplatin for intracellular targeting of tumor cells [125].

### 7.5.3

#### **Intracellular Drug Delivery**

Nanoparticles (nanovesicles, nanocontainers, liposomes) are generally internalized into cells via fluid phase endocytosis, receptor-mediated endocytosis or phagocytosis, resulting in the potential delivery of the nanoparticles in different cell compartments [125–128]. Efficient cytoplasmic delivery of drugs is important for drugs

whose action is intracellular, and sustained cytoplasmic delivery of drugs with intracellular receptors can only be envisioned using biodegradable nanoparticles [129].

Nanoparticle made from poly(DL-lactide-co-glycolide) can rapidly (of the order of minutes) escape the endo-lysosomal compartment, in intact form, after internalization, and reach the cytoplasm [102]. This escape mechanism is related to the anionic to cationic surface charge in the acidic environment of endosomes-lysosomes. pH-Sensitive liposomes have been designed using phospholipids/pH-sensitive polymethacrylate [130, 131], which become unstable at the acidic pH of lysosomes. Therefore, to date most approaches have involved pH effects between cellular compartments and surface-functionalized drug-loaded nanoparticles. Chitosan nanoparticles uptake was inhibited by chlorpromazine, suggesting clathrin-mediated endocytosis [132]. Wheat-germ agglutinin-PLGA nanoparticles were taken up by lung carcinoma cells according to a receptor-mediated, caveolae-dependent mechanism [133]. Exocytosis and intracellular retention are also factors that may control the efficacy of cellular delivery. A study using PLGA nanoparticles has shown that uptake is an endocytic, concentration, time and energy-dependent process [134]; however, a large proportion of the endocytosed nanoparticles were excreted from cells by an energy-dependent exocytic process as early as 30 min later [134].

Nanoparticle surface manipulations may be performed to increase cytoplasmic delivery, in particular with protein-transduction domain peptides [54, 135, 136] such as HIV-TAT peptides, or poly-Arg. These effects are related to the interaction of positively charged peptides with negatively charged heparan sulfate proteoglycans and sialic acid-containing glycoproteins, resulting in cell internalization of the complex by lipid-raft pinocytosis [137]; this is receptor independent, and then destabilization of the complex and release into the cytoplasm of the nanoparticle payload arises without fusion with lysosomes. However, cytotoxicity issues of the carrier have been raised.

Gene transfer by carrier destabilization via surface charge modification has also been used. Negatively charged nucleic acid material is adsorbed onto cationic polymeric nanoparticles, such as poly(ethyleneimine), and the complexes then undergo endocytosis. In the low pH of endosomes, the polycation-nucleic acid complexes are then released into the cytoplasm. Virus- or bacterial toxin-mimicking nanoparticles have been also used to achieve membrane disruption or forced-internalization. The viral components are intercalated between the lipid bilayer of 150 nm vesicles, and the structure is destabilized at the acidic pH of lysosomes. Gold particles modified with nuclear localization signal peptides were able to target the nucleus [96].

#### 7.5.4

#### **Development of the Necessary Chemistry: Synthetic Routes and Linkers for Conjugation**

Active targeting requires that selective ligands for defined tumor or tumor-associated cell markers are presented in adequate configuration and concentration

at the surface of nanoparticles. But this means that reactive groups must exist at the surface of nanoparticles for chemical coupling. PEG has been widely used to coat the surface of polyester or poly(alkyl cyanoacrylate), delaying phagocytosis by macrophages, and making them compatible for passive targeting by the increased vascular permeability associated to cancer [126, 138]. Polysaccharide (e.g., chitosan) coating may be a valuable alternative to PEG for this purpose, having the additional advantages of providing targeting by themselves for saccharide cell surface receptors, of being biocompatible and biodegradable [84], and being able to control the interactions with cells:

1. Dextran, pullulan and glycolipid, or sialic acid, decrease macrophage uptake;
2. hyaluronic acid provides bioadhesive properties;
3. functionalized dextran allows vascular targeting;
4. galactose-containing copolymer achieves liver targeting;
5. polysaccharide modified by vitamin H and biotin improved cancer targeting.

Preparation methods include (reviewed in Ref. [84]):

1. Adsorption on preformed nanoparticles. This depends on the relative polysaccharide and nanoparticle surface characteristics and chemical composition: hydrophobic, hydrophilic, covalent photopolymerization.
2. Incorporation during nanoparticle preparation: nano-coprecipitation or emulsion solvent evaporation (water–organic solvent) and stabilization with a surfactant (PVA or modified dextrans), diafiltration and sequential layering.
3. Copolymerization: alkyl cyanoacrylate chain elongation under basic conditions, or radical polymerization. A stabilizing agent (dextran) may be necessary and is important for particle characteristics, drug release.
4. Using preformed copolymer: polysaccharide backbone grafted with preformed polyester chains, and a core–shell structure.

In many situations, drugs have to be linked to the nanocarriers via *linkers*, several of which have been evaluated (Table 7.3).

## 7.6

### Overcoming the Mechanisms of Resistance to Therapy of Cancers

One important mechanism of resistance of tumors to treatment involves the poor distribution of drug into the tumor, high intratumoral osmotic pressure and/or short residence times at the tumor site. Another problem associated with cancer chemotherapy is the concentration of the active compounds to be reached in the tumor tissue at the expense of massive toxicity to the rest of the body, representing an obstacle to effective anti-tumor therapy. Most drugs currently used are active on cells in the process of cell division or proliferation. However, at any given time, a proportion of tumor cells are in a resting state and are, therefore, irresponsive to

Tab. 7.3. Some examples of linkers.

Linker	Ref.
Peptides	
Peptidyl spacers designed for cleavage by the lysosomal thiol-dependent (cysteine) proteases (Gly-Phe-Leu-Gly)	153, 154
Glu-Lys (cleaved with bovine trypsin)	155
Leu, Ala or Leu-Ala	154
Trp-Ser-Gln	156
Valine (less prone to ester hydrolysis)	157
Chemical	
4-Acyl-oxy-3-carboxybenzyloxy moiety (recognized by a specific lipase)	155
C4-Chain spacer tetramethylenediamine (TMDA, MW = 88)	158
Diaminated poly(ethylene glycol) (PEG, MW 3400)	158
Ester linker, formed between a hydroxyl-containing drug and a mercaptoacid	159
Ethylene glycobis(succinimidylsuccinate) (EGS): used to link particles having amino groups with each other via an ester linkage	160
Glutaraldehyde (crosslinker)	161
N-Hydroxysuccinimidyl active ester linker (synthesis with dianhydride)	74
Phenylacetyl derivatives, phenylacetamide moiety	162, 155
Scissile linkers	155
Succinic acid, glutaric acid	163
3-Sulfanylpropionyl	159
4-Sulfanylbutyryl	159
Triazene	164, 165
Dual linker systems	166
Coupling agents for peptide synthesis:	115
1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDCI) N-succinimidyl 3-(2-pyridyldithio) propionate (SPDP) N-hydroxysuccinimide N,N'-methylene bis-acrylamide	

the drug. Thus it is necessary to maintain the drugs for a long period at the tumor site. Nanoparticles with long, controlled drug release may thus ameliorate this defect in anticancer treatment.

A second important mechanism of resistance of cancer cells to therapeutic drugs is the simultaneous resistance mechanisms linked to ATP-driven efflux pumps (MDR, Pgp) able to efflux positive drugs (such as doxorubicin) out of cells. Resistance may appear at the onset of therapy, or later during treatment. It is mainly linked to ATP-driven cell membrane efflux pumps on the tumor cells or the tumor-associated vascular cells, or as detoxifying enzymes expressed by these cells. Increased efficacy of PIHCA-doxorubicin was dependent on an increased adsorption of nanoparticles to the cell surface, and to increased diffusion of doxorubicin forming ion pairs between the drug and cyanoacrylic monomer degradation product [139]. This effect was initially observed with cyanoacrylate polymers. Inhibitors of Pgp (verapamil, amiodarone, cyclosporine), or the encapsulation of drugs into colloidal carriers, shield drugs from Pgp, which recognizes drugs associated to the membrane but not in the cytoplasm. Inhibitors for pumps, or for detoxifying enzymes, may be co-administered, or anticancer drugs delivered using nanoparticles able to overcome the resistance of pumps. Since the amino sugar of doxorubicin is a substrate for Pgp, doxorubicin was covalently coupled to PEG-poly(Asp) (MW 14 400 and 3500 kDa, respectively) block copolymer before micelle formation or to gelatin, but without success, probably due to poor diffusion of the drug out of the carrier. Co-encapsulation of the Pgp inhibitor cyclosporin with doxorubicin into PICBA inhibited efficiently growth of doxorubicin-resistant tumor cells, by continuous and simultaneous release of both drugs by polymer biodegradation [140, 141]. Doxorubicin encapsulated in poly(alkyl cyanoacrylate) PIHCA nanoparticles was able to kill Pgp-positive tumor cells, but not PIBCA nanospheres, which are more rapidly degraded and do not enter cells [139, 142–144]. This effect requires direct contact between the carrier and tumor cells and was mediated by poly(alkyl cyanoacrylate) degradation products, which formed ion-pairs with the drug, and the doxorubicin concentration was increased in tumor cells. Pgp remains active. The same effect was obtained by encapsulating doxorubicin in the core and expressing cyclosporin A at the surface of the nanoparticles. Pluronic block copolymer may inhibit the efflux pumps (MDR/P-glycoproteins), and their gene expression, on the endothelial cells forming the blood–brain barrier (BBB) [145, 146] that protects the brain from unwanted chemicals, but which are also involved in the resistance of brain tumors to chemotherapeutic agents. Therefore, they may be of interest in the treatment of brain cancer only if they can be made selective to tumor-associated endothelium.

## 7.7 Toxicity Issues

For more extensive reviews see Refs. [5, 6]. Nanoparticles interact differently with organs, tissues and cells than do larger particles made of the same components.

Therefore, the evaluation of toxicity performed with larger particles cannot be extrapolated to nanoparticles without control. The hazards of inhaled micro- and nanoparticles in air pollution are well established, epidemiological and toxicological studies have coherently demonstrated pro-inflammatory and prothrombotic adverse effects in diverse organs. There is virtually no toxicological data available, for patients, researchers or medical workers concerning the new types of nanoparticles under development for drug delivery. Size and surface modification may modify biocompatibility and biodistribution, and a combination of drugs, devices and biological agents may behave differently than each agent separately – therefore combination approval must be obtained from drug control agencies. The exact mechanisms of interaction of nanovectors and cells have been determined in very few situations. Therefore, coordinated studies will be rapidly needed to address these issues. Nanostructures can minimize solubility and stability problems, and improve the negative impact of drugs to collateral non-tumoral tissues and organs. However, nanomaterials themselves may be cytotoxic [147, 148] or induce and/or potentiate cell death [149, 150] or immunogenic reactions, or nanoparticle aggregates may clog small blood vessels. For example, micelles of cisplatin differently induced gene expression than cisplatin alone [149], and degradation products from poly(L-lactic acid) were cytotoxic for immune cells [150].

Gene therapy with viruses has had poor success and many problems have been linked to immunogenic reaction to the viral vector constituents, and random integration in the genome. Therefore, cationic nanoparticle vectors have been designed to complete viral vectors. Polycations are cytotoxic for cells, inducing mitochondria-mediated necrosis and/or apoptosis or membrane destabilization and pore-formation mediated by interactions of polycations with negatively-charged cell-surface glycoproteins or actin [151]. The interactions of cationic polymers with mitochondria need to be better understood, in particular with the proteins of the bcl-2 family. Hypersensitivity reactions secondary to complement activation and induced by infusion of PEG-modified liposomes [152] may be a potential problem with these materials. Careful design of the polymer formulation and surface functionalization is needed to reduce these side effects. Therefore, nanoparticle design and polymer formulation and functionalization for gene therapy *in vivo* must be carefully optimized before such treatments can be envisioned.

To gain wide acceptance of nanovectors as anticancer delivery agents, the following toxicity issues need to be addressed:

- The ultimate biological fate of nanomaterials, and their degradation products, particularly non-biodegradable nanomaterials such as functionalized poly(ethylene glycol).
- The immunological and pharmacological activities and toxicities.
- Possible interferences with cellular machineries, gene expression, protein processing.
- Short- and long-term consequences of exposure to nanovectors.
- How *in vitro* studies translate to *in vivo* application.

## 7.8

### Conclusions

In summary, medical benefits can be expected within the next 10 years from the branch of nanotechnology named “Nanomedicine”. However, for drug delivery, nanocarriers have to become smarter, and the biophysical, biochemical and biological processes and the mechanisms associated with the interaction of nanoparticles with living tissue, at large, must be understood in detail to design optimized materials for defined therapeutic goals. This includes carrier stability, targeting, extracellular and intracellular drug release mechanisms, overcoming mechanisms of resistance to biological barriers and to anticancer agents, and understanding the immunogenic reaction mechanisms of the nanodevices, and toxicity issues in great detail. The future of nanomedicine will in part depend on the rational design of smart nanoparticles.

#### 7.8.1

##### Opportunities and Challenges of Nanomedicine in Cancer

1. Passive targeting effects can enhance the amounts of drug at tumor sites, but circumstantial or active targeting can be designed to improve the selectivity and specificity of drug delivery; therefore, combining these approaches may greatly increase the quality of cancer treatment.
2. Targeted drug delivery systems can improve the therapeutic index of approved drugs.
3. New drugs that are macromolecules, proteins, peptides, oligonucleotides or plasmids will need such delivery systems to achieve an efficient local concentration.
4. Externally activated (ultrasound, irradiation, magnetic field, photodynamic therapy, etc.) drug delivery of therapeutic agents can be designed to control the timing of drug delivery and administration schedules, without multiple injections.
5. Overcoming of the biological barriers:
  - Including tight junctions (BBB) and epithelial barriers.
  - Using permeation enhancers: tight junction opening agents, osmotic shock.
  - Avoiding the RES: using surface modification of nanoparticles, e.g., by poly(ethylene glycol)s.
  - Controlling sensitization reactions: protein-dendrimers are highly immunogenic.
  - Overpassing intratumoral increased osmotic barriers: limit to the diffusion of nanoparticles and drugs.
6. Challenges also include the control of drug release and bioavailability at the tumor site, enhancing selective targeting, and achieving controlled and efficient intracellular delivery, together with acceptable toxicological hazards.

Therefore, an ideal nanovector should look as shown in Fig. 7.2. One representation of the ideal goal is an injectable nanoparticle for targeted drug delivery, without, or with highly reduced, collateral toxicity, and with a reporter device.

**Fig. 7.2.** Ideal drug delivery nanovector, containing a reporter system (SPION), a targeting agent (T) linked to the polymer, and a drug linked to the polymer via a releasing linker.

# Nanoparticles for Thermotherapy

*Andreas Jordan, Klaus Maier-Hauff, Peter Wust, and  
Manfred Johannsen*

### 8.1

#### Introduction

The biological effectiveness of heat in treating cancer has been known for decades and many of the corresponding molecular mechanisms are understood. Elevation of tissue temperature to above 40–41 °C is termed hyperthermia. It alters the function of many structural and enzymatic proteins within cells as a function of time and temperature, which in turn alters cell growth and differentiation and can induce apoptosis [1, 2]. Modest temperature rises are particularly effective against cells that tend to be resistant to radiation, cells in the S phase of the cell cycle and nutrient-deprived, low pH hypoxic cells [3]. Hyperthermia inhibits repair of sublethal radiation damage and also induces increasing radiosensitivity due to tumor reoxygenation [4, 5]. Treatments with tissue temperatures above 46 °C are termed thermoablation and have direct cytotoxic effects.

Thermotherapy is a physical therapy with fewer limitations than chemotherapy or radiotherapy and is typically used in combination with both of these therapies [6–8]. This allows a greater number of repeated treatments without accumulation of toxic side effects.

Although successful clinical trials have been conducted, thermotherapy is not yet established in clinical routine. This discrepancy probably derives from technical limitations in achieving effective temperature distributions in the depth of the human body rather than from a general lack of biological effectiveness [9].

Common thermotherapy techniques use different energy sources for generating heat in body tissue: Electromagnetic waves radiated by antennas (radiofrequency- or microwave-hyperthermia) [10, 11], ultrasonic sound [12, 13], magnetically excited thermosteds as well as tubes with hot water [14, 15]. For reviews see Refs. [16, 17].

The major problem with all present conventional thermotherapy systems is achieving a homogenous heat distribution and deep regional therapeutic temperatures in the treated tumor tissue. According to this hypothesis, treatment failure results from an insufficient temperature rise in parts of the tumor, enabling tumor

regrowth. However, excessive intratumoral temperatures might on the other hand induce damage of adjacent structures.

The heating of tissues using magnetic nanoparticles as a new treatment modality for interstitial thermotherapy has the potential to overcome these shortcomings.

When describing the properties of magnetic nanoparticles for thermotherapy, one has to consider that the magnetic properties are influenced to a large extent by the size and shape of the particles. Although there has been much progress regarding nanoparticle synthesis, the control of particle size and shape on the nanoscale level remains a synthetic challenge. Nevertheless, nanoscaled particles have several advantages over larger particles that favor their application in biomedicine. One advantage arises because particles change their magnetic properties when entering the size regime below approximately 20 nm, giving rise to distinct mechanisms of heating in alternating magnetic fields.

The use of magnetic nanoparticles for heating purposes was investigated comprehensively by Jordan et al. in 1993 [18]. Different studies have revealed that the specific absorption rate (SAR) of magnetic nanoparticles depends strongly on the diameter of the particle core [19–22]. In general, the heat production of magnetic nanoparticles in alternating magnetic fields can be attributed to hysteresis and relaxation losses, the latter being more pronounced in particles below 20 nm. Hysteresis losses play a role in larger particles, which consist of more than one magnetic domain and magnetization reversal occurs due to motions of the domain boundaries. In this case, the energy produced is proportional to the coercivity of the particles [19]. Magnetic fluids are dispersions of ultrafine magnetic particles, which are mostly superparamagnetic, meaning that each particle has only a single magnetic domain. For these so-called subdomain particles (SDP), coercivity is zero and magnetization reversal is only possible by relaxation processes. In alternating magnetic fields heat can be produced by two distinct relaxation mechanisms, Brownian and Néel relaxation. The first can be attributed to the rotation of the single-domain particle, which is related to the Brownian motion. The second corresponds to rotation of the magnetization vector in the crystal, if the particle is considered to be immobile [18].

To date, all magnetic nanoparticles intended to be used *in vivo* are composed of magnetic iron oxides. The main reason for this is their low toxicity and the known pathways of metabolism. The only two clinically relevant materials used are magnetite ( $\text{Fe}_3\text{O}_4$ ) and maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ). The crystal structures of both oxides are based on a cubic dense packing of oxide atoms, but they differ in the distribution of Fe ions in the crystal lattice. Magnetite is the most common ferrite and has an inverse spinel structure,  $\text{Fe}_{(\text{II})}\text{Fe}_{(\text{III})}_2\text{O}_4$ .

Pure iron-oxide nanoparticles have a high tendency to agglomerate and thus to build larger structures even in the absence of a magnetic field, which has a strong influence on the biomedical and magnetic properties of the particles. To prepare magnetic fluids for biomedical applications, the iron-oxide particles have to be coated with a protecting shell that prevents agglomeration. Furthermore, the protecting shell is responsible for the interaction of the particles with its surrounding (e.g., tumor tissue) and can provide functional domains that are useful for the cou-

pling of biomolecules or drugs to the surface. Common shell materials are polymers such as dextran, starch or poly(ethylene glycol).

Most techniques established so far concerning the use of magnetic particles for thermotherapy are basically based on direct instillation of magnetic fluids into the tumor tissue followed by exposure to an externally applied alternating magnetic field.

Ferromagnetic embolization hyperthermia is another technique for the local application of nanoparticles, in which the arterial supply of certain body regions is used as a pathway to carry magnetic particles directly into the tumor area.

## 8.2

### Thermotherapy following Intratumoral Administration of Magnetic Nanoparticles

Magnetic particles suspended in a carrier fluid can be injected directly into tumor tissue and subsequently be heated in an alternating magnetic field.

The history of magnetic particles for selective heating of tumors had already begun in 1957, when Gilchrist et al. used magnetic particles a few micrometers in size for inductive heating of lymph nodes in dogs [23].

In 1979, Gordon et al., for the first time, used magnetic fluids of dextran-coated magnetite-particles (often referred to as “dextran-magnetites”) for hyperthermia of implanted mammary tumors of rats [24]. After systemic application of the nanoparticles with a core size of up to 6 nm and exposition to an alternating magnetic field, the authors demonstrated histological evidence of tumor necrosis after intratumoral temperature increases of 8 °C.

Direct injection of microscaled ferromagnetic particles into renal carcinomas of rabbits and subsequent hysteresis heating in an alternating magnetic field was reported by Rand et al. in 1981 [25]. They measured tumor surface temperatures of 55 °C, leading to destruction of most of the treated tumor tissue within 3 days.

Direct injection of “truly nanoscaled” magnetic particles into tumors was first reported by our group in 1997 [26]. We studied single high dose thermotherapy on intramuscularly implanted mammary carcinoma of mice. Dextran-coated magnetite particles with a core size of approximately 3 nm were injected intratumorally 20–30 min before excitation and trapped by magnetic targeting (50 mT), which yielded a 2.5-fold enhancement of the intratumoral iron concentration. An intratumoral steady state temperature of 47 °C was maintained for 30 min with whole-body alternating magnetic fields of 6–12.5 kA m<sup>-1</sup> at 520 kHz. The study demonstrated that a single high thermal dose was able to induce local tumor control in many of the treated animals within 30 days after therapy. Histological examinations of tumor tissue after thermotherapy showed widespread tumor necrosis. Tumor growth after thermotherapy was heterogeneous; some tumors did not show evidence for regrowth after 50 days whereas others had grown rapidly. This was most probably due to inhomogeneities of the intratumoral particle distribution, which was also confirmed qualitatively by magnetic resonance imaging (MRI).

In 2002 Hilger et al. injected colloidal suspensions of coated nanoparticles with

average total particle sizes of 10 nm and 200 nm into human breast adenocarcinoma implanted into immunodeficient mice (4–18 mg magnetite per 100 mg tumor tissue) [27]. During exposure to an alternating magnetic field temperature increases between 12 and 73 °C in circumscribed areas within the tumor could be induced (termed “magnetic thermal ablation”). Histological examination revealed the presence of early stages of coagulation necrosis in the treated tumor cells.

Ohno et al. have investigated a new type of magnetite for interstitial hyperthermia [28]. They inserted stick-type carboxymethylcellulose-magnetite containing nanoparticles ( $\text{Fe}_3\text{O}_4$ , average particle size approximately 10 nm) stereotactically into gliomas of rats and exposed the animals to an alternating magnetic field. This investigation revealed a characteristic spreading of the magnetite particles through the tumor after three heat treatments and an approximately three-fold prolongation of survival time.

Groups at the University of Nagoya in Japan have developed “magnetic cationic liposomes” (MCLs) with improved adsorption and accumulation properties and demonstrated the efficacy of this approach in several animal tumor models:

Induction of antitumoral immunity to rat glioma by intratumoral hyperthermia using these particles was investigated by Yanase et al. in 1998 [29]. For intratumoral hyperthermia, the cationic liposomes containing magnetite ( $\text{Fe}_3\text{O}_4$  core with approximately 10 nm diameter) were directly injected into glioma tissue transplanted subcutaneously into the thigh of rats. Three subsequent treatments in an alternating magnetic field led to killing of the tumor cells and to the induction of a host immune response, which could be demonstrated by suppressed tumor growth after rechallenge with glioma cells 3 months later. In similar experiments using the same tumor model and the same particles, published one year later [30], complete tumor regression was observed in about 90% of the animals.

Le et al. have described successful tumor control (over two weeks) after hyperthermia of 43 °C using immuno-targeted magnetoliposomes [31].

In 2003, Ito et al. investigated the effect of intratumoral hyperthermia in combination with an immunotherapy of melanoma in mice [32]. After direct injection of MCLs into the tumors, the animals were exposed to an alternating magnetic field that raised the tumor temperature up to 43 °C; 24 h later, in a second treatment, interleukin-2 (IL-2) or granulocyte macrophage-colony stimulating factor (GM-CSF) was injected directly into the melanomas. In 75% (receiving IL-2) and 40% (receiving GM-CSF) of the animals treated by both therapies complete regression of the tumors was observed, while no tumor regression was observed in mice receiving only one of the treatments.

In 2005, Tanaka et al. investigated the therapeutic effects of tumor-specific hyperthermia using MCLs combined with an immunotherapy (intratumorally injected immature dendritic cells) on mouse melanoma [33]. Complete regression of tumors was observed in 60% of the mice and the cured animals rejected a second challenge of melanoma cells.

Kawai et al. have used the same liposomes to heat prostate cancer cells injected subcutaneously into the flank of rats [34]. They reported on tumor regression after generating intratumoral temperatures of 45 °C in an alternating magnetic field.

Carcinoma of the prostate represents an attractive target for minimally invasive, interstitial treatments due to its relatively easy accessibility via the transrectal or transperineal route.

To explore the potential of magnetic nanoparticle thermotherapy in an orthotopic prostate carcinoma, we have carried out experiments using the Dunning R3327 tumor model (MatMyLu-subtype), an established rat model developed to study prostate cancer progression [35]. This model resembles the human prostate with respect to physiological blood supply and local growth and may thus allow a more accurate analysis of the effects of a local hyperthermia treatment than a heterotopic model. In a preliminary *in vivo* evaluation, the feasibility and good overall tolerability of this technique in prostate cancer could be demonstrated [36].

Thermotherapy was carried out using an alternating magnetic field applicator system for small animals, operating at a frequency of 100 kHz and variable field strength of 0–18 kA m<sup>-1</sup>.

Thermoablative temperatures of 50 °C were achieved at a field strength of 15 kA m<sup>-1</sup>. Iron measurements were carried out to determine the percentage of nanoparticles present in the prostate tumors at different time points following intratumoral application. Without thermotherapy, 7 days after injection of magnetic fluid into the rat prostates, 53% of the injected amount of iron oxide was still present in the prostates. At 4 and 13 days after application 79% and 64%, respectively, of the injected amount of iron was still retained in the prostates after two sequential thermotherapy treatments. This difference in iron content between untreated and treated animals was attributed to the so-called “thermal bystander effect”, which describes a hyperthermia-induced spread of coated nanoparticles in the target tissue, where they seem to escape rapid removal by macrophages [26]. This effect could also be demonstrated by means of histopathology. After magnetic fluid application alone, a loose distribution of nanoparticles within the tumor tissue with deposits in capillaries could be seen in sections of rat prostate tumors, whereas homogeneous distribution and co-localization of nanoparticles with necrotic areas could be demonstrated in animals that had undergone thermotherapy.

In a further systematic *in vivo* analysis using a more concentrated magnetic fluid containing approximately 112 mg-iron mL<sup>-1</sup>, as well as a slightly modified aminosilane-based coating, intraprostatic temperatures of 70 °C could be achieved at a maximum magnetic field strength of 18 kA m<sup>-1</sup> in the same tumor model [37]. Up to 0.5 mL of magnetic fluid per mL of tumor volume was injected into the prostate tumors in these experiments. The animals received two thermotherapy treatments carried out 48 h apart to avoid heat shock protein-induced thermoresistance. At a constant field strength of 12.6 kA m<sup>-1</sup>, mean minimal intratumoral temperatures during the first and second thermotherapy sessions were 41.2 and 41.4 °C, respectively, whereas mean maximal temperatures were 54.8 and 54.2 °C (averaged over 12 animals). In this study, animals were sacrificed on day 20 after tumor cell inoculation (10 days following the first thermotherapy treatment) to compare tumor weights in the treatment and control groups and for iron measurements. A significant inhibition of prostate cancer growth of 44–51% over controls

was demonstrated in the thermotherapy group. Mean iron content of the prostates of treated and untreated control animals was 81.6% and 83.7%, respectively, whereas 7.6% and 2.3% of the injected dose of iron was found in the liver. No detectable amount of iron was found in the blood stream. While thermal treatment itself had a significant impact on intratumoral distribution and stable deposition of nanoparticles in the previous pilot study, no such effect was observed using the modified magnetic fluid. In fact, intratumoral deposition of the MFL AS particles was the same with or without thermotherapy treatment. Histological analysis revealed a co-localization of nanoparticles with areas of necrosis, but a rather inconsistent pattern of intratumoral distribution, which appeared less homogeneous than with the previously used magnetic fluid preparation.

Further experimental studies have investigated the effect of combined magnetic nanoparticle thermotherapy and external irradiation in the Dunning tumor model [38].

Mean maximal and minimal intratumoral temperatures obtained in these experiments were 59 (centrally) and 43 °C (peripherally) during the first thermotherapy and 55 and 42 °C, respectively, during the second of two treatment sessions. Combined thermotherapy and radiation with 20 Gy was significantly more effective than radiation with 20 Gy alone and reduced tumor growth by 88% versus controls, achieving an equal tumor growth inhibition as irradiation alone with 60 Gy. As in the previous experiments, sequential heat treatments were possible without repeated injection of magnetic fluid. The mean iron content in the prostates on day 20 was 88% of the injected dose of ferrites, whereas only 2.5% was found in the liver.

In conclusion, thermotherapy using magnetic nanoparticles achieved significant growth inhibition, but not tumor control or eradication in the orthotopic Dunning tumor model of the rat. The results of preclinical evaluation of magnetic nanoparticle thermotherapy suggest that this technique may, in principle, be suitable for both local hyperthermia and thermoablation of prostate carcinoma, since the desired treatment temperatures can be freely selected by modulating the magnetic field strength [39].

However, for complete thermal ablation of the prostate, homogeneous infiltration of the whole prostatic tissue with magnetic nanoparticles would be required and high magnetic field strengths would have to be applied. In view of the synergistic effects of hyperthermia and radiotherapy, a combination of magnetic nanoparticle thermotherapy with irradiation may also be an attractive option for the treatment of prostate cancer.

In a rat model of glioblastoma multiforme we could also demonstrate the high efficacy of our new technique, leading to an up to 4.5-fold prolongation of survival [40]. The animals received two thermotherapy treatments within 48 h after a single stereotactic injection of the magnetic fluid into the tumor. Intratumoral temperatures between 43 and 47 °C correlated well with prolonged survival. As in our prostate tumor model, the application of aminosilane-coated nanoparticles led to the formation of stable deposits in the brain, thus allowing for repeated magnetic field treatments without repeated applications of the particles.

### 8.3

#### Ferromagnetic Embolization Hyperthermia

Another technique of using magnetic nanoparticles for thermotherapy is ferromagnetic embolization hyperthermia, in which a feeding artery is used to carry ferromagnetic particles into a tumor.

The technique seems to be well suited for the treatment of hepatic malignancies due to the differences in blood supply of hepatic tumor cells and normal liver parenchyma. Liver tumors mainly derive their blood supply from the hepatic arterial system, while the normal liver parenchyma receives most of its blood supply from the portal venous system [41]. Hence any substance infused into the arterial system will have the potential to preferentially target liver tumors [42].

Several preclinical studies have reported on arterial embolization hyperthermia of liver cancer.

Moroz et al. have demonstrated successful ferromagnetic embolization hyperthermia of rabbit hepatic carcinomas after arterial infusion of magnetic nanoparticles suspended in lipiodol [43, 44].

In 1994, Mitsumori et al. tested the thermotherapeutical properties of dextran-coated magnetite particles suspended in lipiodol or in degradable starch microspheres [45]. The study reported an increase of over 12 °C after 10 min of heating after embolization of the renal artery and selective heating of the embolized kidney by exposure to an alternating magnetic field. The authors followed up this work with a study in 1996 [46], in which hepatic carcinoma-bearing rabbits were arterially infused with the same sub-domain sized particles (75 nm in diameter with a 7.4 nm magnetite core). Slight tumor temperature increases were recorded *in vivo*.

In a study performed by Minamimura et al. a novel preparation of microspheres incorporating a dextran magnetite complex was used for arterial embolization and inductive hyperthermia of liver tumors in rats [47]. Tumor temperatures of around 43 °C were maintained for 30–40 min and three days after treatment the increase of tumor volume in the treated animals differed significantly from that of the control groups.

Jones et al. have achieved positive temperature differences between tumor and normal liver and consequent therapeutic responses in experimental rabbit liver tumors after arterially infused ferromagnetic microspheres [48]. Heating to over 42 °C for 20 min by exposure to an alternating magnetic field resulted in large areas of tumor necrosis 14 days after treatment.

After arterial infusion of iron-oxide particles suspended in lipiodol into rabbit hepatic carcinoma, Moroz et al. have found that an iron concentration of 2–3 mg per gram of tumor was necessary to produce heating rates up to 11.5× greater than those in adjacent normal liver parenchyma [43]. The authors reported a mean tumor to normal liver iron concentration ratio of 5.3.

Further work by this group employing the same tumor model and infusion regimen has shown that large hepatic tumors are more amenable to thermotherapy after arterial embolization than small tumors [44]. The authors concluded from their data that, for a given tumor iron concentration, larger tumors heat at a

greater rate than small tumors, owing to poorer tissue cooling and better heat conduction in the necrotic regions of large tumors.

In a later study the authors investigated the clearance of ferromagnetic particles from the liver [49]. The normal liver of pigs was arterially embolized with  $\gamma$ - $\text{Fe}_2\text{O}_3$  particles (150 nm) suspended in lipiodol and polymer microspheres (32  $\mu\text{m}$ ) containing ferromagnetic particles suspended in 1% Tween-water. Both types of particles were extensively phagocytosed in the liver and there was no significant reduction in the hepatic iron concentration in either treatment group 28 days after infusion. The suspension of 150 nm ferromagnetic particles in lipiodol was too vaso-occlusive for use in hepatic tissue, while the suspension of 32  $\mu\text{m}$  spheres was safe and well tolerated.

Although few preclinical studies have been described, arterial embolization hyperthermia has demonstrated encouraging results. The technique seems to be particularly well suited for the treatment of hepatic malignancies. Potential advantages are a very selective local heat deposition and a more homogeneous tissue temperature distribution than other hyperthermia techniques.

#### **First Clinical Experiences with Thermotherapy using Magnetic Nanoparticles: MagForce Nanotherapy**

The pathways developed so far for thermotherapy using magnetic nanoparticles have in common that they deliver the magnetic material directly into or adjacent to the tumor tissue. To facilitate cellular uptake by tumor cells, the particle coatings often were modified with targeting ligands such as antibodies or peptides.

Magnetic fluids can be instilled into tumor tissue percutaneously under CT, ultrasound or fluoroscopy guidance. Owing to inductive excitation of the nanoparticles this technique allows very precise heating of almost every part of the body.

A major advantage of direct intratumoral application of the particles is the good control of deposition, leading to high concentrations of the magnetic material within the tumor while healthy tissue can be spared. The magnetic fluid can be distributed in very small portions and, therefore, almost continuously within the targeted area. Therefore, the requirement of maximal heat deposition within the target area while sparing neighboring healthy tissue can be met.

MagForce Nanotherapy, formerly designated magnetic fluid hyperthermia, has been developed at Charité – University Medicine Berlin over the last 15 years. Our preclinical studies have demonstrated that this innovative approach has the potential to improve heating capabilities with certain cancer types and thus overcome existing prejudices against routine application of heat to treat cancer.

It is the first nanotechnology-based local thermotherapy to enter clinical trials.

Beginning in 2003, we started four different clinical studies to investigate the feasibility of our new thermotherapy approach on different tumor entities.

The magnetic fluid MFL AS used in these studies is manufactured by MagForce Nanotechnologies, Berlin, and consists of superparamagnetic iron-oxide nanopar-

**Fig. 8.1.** Thermotherapy treatment of a glioblastoma multiforme patient in the magnetic field applicator MFH<sup>®</sup> 300F (MagForce Nanotechnologies, AG, Berlin, Germany).

ticles in aqueous solution with an iron concentration of  $2 \text{ mol L}^{-1}$ . The iron oxide core is covered by an aminosilane-type shell and has a diameter of approximately 15 nm. The particles generate heat in an alternating magnetic field by Brownian and Néel relaxation processes.

Thermotherapy is performed in a magnetic field applicator (MFH<sup>®</sup> 300F, MagForce Nanotechnologies, AG, Berlin, Germany), generating an alternating magnetic field (100 kHz) and a variable field strength of  $0\text{--}18 \text{ kA m}^{-1}$  (Fig. 8.1). This applicator meets the safety and practicability criteria for medical use imposed by the respective European authorities. Owing to its universal design, it can be used for treatment of malignancies in every location of the human body. Fixation or anesthesia of the patients during treatment is not necessary.

Minimally invasive measurement of treatment temperatures is carried out by fiber-optic thermometry probes as part of the therapy system.

#### 8.4.1

##### **Feasibility Study on Thermotherapy using Magnetic Nanoparticles in Recurrent Glioblastoma Multiforme**

From March 2003 to June 2004 we performed the world's first phase I trial on tumor thermotherapy using magnetic nanoparticle, with 14 glioblastoma multiforme patients.

Malignant gliomas (anaplastic astrocytoma and glioblastoma multiforme, WHO grades III and IV, respectively) have an incidence of approximately 5 in 100 000 per year and represent approximately 40% of primary brain tumors in adults, with 50% of them belonging to the most malignant phenotype, glioblastoma multiforme. Clinically, they are highly problematic due to their widely invasive nature, which makes complete resection almost impossible. Median overall survival after first-line therapy does not exceed 12–15 months [50, 51] and no significant in-

crease has been achieved over the last decade, despite modern diagnostics and treatments with surgery, radio- and chemotherapy.

All patients of our trial received stereotactic injection of the magnetic fluid into the tumor area. Before starting thermotherapy, the position of the instilled nanoparticles was determined by computed tomography (CT). These data were matched to presurgical MR images using specially designed software (MagForce NanoPlan®, not commercially available), thus allowing calculation of the expected heat distribution within the treatment area in relation to the magnetic field strength [52].

The preoperatively planned and neuro-navigationally guided procedure led to an almost atraumatic instillation of the magnetic fluid and rise of intracranial pressure could be avoided by slow injection of the magnetic fluid.

Patients received 4–10 thermotherapy sessions where intratumoral temperatures of 42–49 °C could be measured; body temperatures increased by 1.0–1.5 °C.

All patients tolerated the instillation of the nanoparticles without complications and side effects such as headache, nausea, vomitus or allergic reactions were not observed. Neurological deficits or infections did not occur.

As documented by CT-scans and thermometry measurements, a high stability of the nanoparticle deposits can be assumed. In fact, reproducible intratumoral temperatures could be achieved during the therapy, even several weeks after administration.

Data of the trial concerning overall survival and time to progression suggest that intracranial thermotherapy using magnetic nanoparticles can be safely applied with therapeutic temperatures and without side effects [53]. A phase II study is in progress to evaluate the efficacy of this treatment approach.

#### 8.4.2

#### **Feasibility Study on Thermotherapy using Magnetic Nanoparticles in Recurrent and Residual Tumors**

Another phase I trial started in February 2004, which enrolled 21 patients suffering from non-resectable and pre-treated local relapses of different tumor entities (e.g., rectum, ovarian, prostate, and cervix carcinoma as well as soft tissue sarcoma). All patients received thermotherapy in combination with radio- or chemotherapy [54].

The objectives of the study were treatment planning, application and subsequent control of magnetic fluid distributions in circumscribed lesions (<4–5 cm) and, furthermore, assessment of safety, quality and feasibility of the heating patterns achieved *in situ*.

Patients with metallic implants <30 cm from the treatment area had to be excluded. Teeth amalgam fillings or gold crowns had to be replaced by ceramics if involved in the treatment field (head and neck, upper thorax). Metallic clips or seeds several millimeters long and <1 mm in diameter were permitted due to their very low power absorption capacities.

Two principally different techniques for the instillation of the magnetic fluid were evaluated.

**Fig. 8.2.** Thermotherapy using magnetic nanoparticles of a patient suffering from metastases of a cervical carcinoma. Three-dimensional reconstruction of a pelvis sliced by a CT scan: The calculated temperature

distributions (isotherms) during thermotherapy decrease from orange to blue. White spots within the colored lines show the magnetic nanoparticle deposits.

The first strategy implied a prospective planning of the “ideal” nanofluid distribution on the basis of a three-dimensional CT dataset performed in treatment position. This dataset is then transferred via the radiological information system into a software platform to calculate the temperature distribution during thermotherapy within the treatment area (Fig. 8.2).

The second implantation technique consisted of intraoperative injection under visual control. In this case prospective planning is not possible, because after tumor debulking an individual (non-resectable) tumor rest or an area at risk (R1/2-situation) has to be infiltrated. Cervical cancer recurrences at the pelvic wall (after primary treatment) are typical clinical examples.

Nanofluid concentration in the target area was claimed to be as high as possible. In these patients a retrospective planning based on a post-operative CT dataset was performed.

Direct temperature measurements via implanted catheters were suitable to estimate a mean perfusion and to calculate the temperature distributions in and around the target volume.

Tolerated H-fields were limited by local discomfort to 3–6 kA m<sup>-1</sup> in the pelvic region and up to 7.5 kA m<sup>-1</sup> in the upper thorax.

From our experience with brain tumor patients we know that magnetic fields of 10–14 kA m<sup>-1</sup> are technically achievable and tolerated well. The H-field limitations are related to the periphery of the body where the accompanying electric fields and the current densities are highest. The larger the cross section, the lower the tolerated H field strength (comparing pelvis with head). However, treatment-limiting

hot spots arise from skin folds, where the current path narrows and the current density, therefore, increases.

We also observed relative temperature maxima at tissue boundaries such as the anal sphincter and pelvic floor. These locations were, however, never treatment-limiting during our study, but are a typical problem during RF hyperthermia, where the E-fields are considerably higher.

One particular advantage of MagForce Nanotherapy is the option to plan the magnetic fluid distribution prospectively and to control the heat distribution thereafter to a high degree of reliability, thus increasing the safety of the application significantly.

Another major advantage of the new treatment is that, owing to the stability of the nanoparticle deposits, it can be repeated over weeks without additional injection of the magnetic fluid. This enables multimodal treatment concepts.

The heat treatments were tolerated well with only moderate side effects. The follow-up showed encouraging results for severe oncological diseases. Several strategies are available to further improve the effectiveness of treatment, e.g., to elevate the H-field (after modification of the applicator) or to increase the amount of magnetic fluid in the target.

#### 8.4.3

#### **Feasibility Study on Thermotherapy using Magnetic Nanoparticles in Recurrent Prostate Carcinoma**

Despite much progress in the development of hyperthermia application and treatment planning systems for prostate cancer, clinical hyperthermia of this deep-seated organ is still a challenging problem [55].

Reported mean intraprostatic temperatures obtained with conventional heating methods have been between 40 and 42 °C, rarely reaching or exceeding the critical temperature of 43.0 °C, where a measurable cytotoxic effect is documented for various cell types [56, 57].

The first published report on thermotherapy treatment of human cancer using magnetic nanoparticles describes the preliminary experience with this technique in patients with locally recurrent, radioresistant prostate cancer [58]. In this investigation, treatment planning based on computerized tomography of the prostate preceded intraprostatic application of magnetic fluid. The number and position of magnetic fluid depots required for sufficient heat deposition was calculated according to the anatomy of the prostate and the estimated SAR of magnetic fluids in prostatic tissue. Nanoparticle suspensions were injected transperineally into the prostate under transrectal ultrasound and fluoroscopy guidance and six weekly treatments were delivered in an alternating magnetic field. Temperatures of up to 48.5 °C with a minimum of 40.0 °C were achieved in the prostate during the 1st treatment at a field strength of 4–5 kA m<sup>-1</sup>, whereas during the 6th treatment, intraprostatic temperatures between 42.5 and 39.4 °C were recorded by means of invasive thermometry. Maximum and minimal temperatures, respectively, measured in the urethra were 42.4 and 38.0 °C whereas in the rectum 42.1 and 37.9 °C were

recorded. Treatment was well tolerated without anesthesia. Since the injected magnetic fluid depots appear as signal-intense areas on the CT-scan, it could be documented that nanoparticles are retained in the prostate well beyond the treatment interval of 6 weeks. Thus, further applications of magnetic fluid are unnecessary for effective thermal treatments and at least hyperthermic temperatures can be achieved many weeks following intratumoral injection of nanoparticles.

Further refinement of the technique appears necessary regarding several important aspects. Firstly, the intraprostatic application and homogeneous distribution of nanoparticles appeared suboptimal due to fibrotic changes induced by the previous radiotherapy and may be improved. Most importantly, however, only one-third of the available power was used in these first clinical treatments, since an increase of magnetic field strength beyond  $5 \text{ kA m}^{-1}$  led to substantial patient discomfort in the perineum and the groin. This may be due to accompanying electric fields and current densities, which are highest in skin folds and at areas with the largest cross-sectional volume such as the pelvis. Since SAR increases quadratically with the magnetic field strength, significantly higher treatment temperatures can be achieved in the prostate by applying higher magnetic field strengths. Interposition of devices for focusing of the magnetic field may improve tolerability of treatment in the future. Furthermore, non-invasive temperature calculations based on evaluation of CT data are another area of ongoing research.

A phase I study evaluating feasibility, toxicity and quality of life during hyperthermia using magnetic nanoparticles, involving ten patients with radio-recurrent prostate carcinoma, is nearing completion. Preliminary clinical results suggest that thermotherapy using magnetic nanoparticles may be suitable for thermoablation of the prostate, since intratumoral temperatures well above  $44^\circ\text{C}$  were achieved at low magnetic field strengths. However, further technical developments regarding the magnetic field applicator may be necessary to fully exploit the potential of this technique as a monotherapy. In addition, this treatment modality may also be combined with interstitial or external irradiation in patients with localized prostate cancer.

## Ferromagnetic Filled Carbon Nanotubes as Novel and Potential Containers for Anticancer Treatment Strategies

*Ingolf Moench, Axel Meyer, and Albrecht Leonhardt*

## 9.1

### Introduction

Especially during recent years, the discovery of various species and modifications of carbon nanotubes (CNTs) have stimulated research on their applications, including in human medicine. The success of these applications depends significantly on the physical, chemical and biological properties of the CNTs and their modifications. For application in the human body, CNTs must be pure and biologically inert.

The development and testing of novel and alternative therapeutic concepts against cancer are needed, especially for advanced tumor types where no curative conservative treatment option is established. Attractive novel and potential tools for anticancer treatment strategies are nanoparticles (e.g., for hyperthermia) and nano-scaled tubes (e.g., for targeted drug release).

Here, we propose novel types of functionalized and ferromagnetic filled multi-walled CNTs (fff-MWCNTs) with various advantages for application in human medicine, especially in anti-tumor therapeutic concepts. These structures represent multifunctional nano-scaled containers for possible use in different medical treatments, including (a) magnetically guided hyperthermia, (b) heat-inducible drug delivery/carrier and stepwise drug release and enhancement systems, (c) internal tracer/drug carrier systems for the detection and/or (d) combinational applications with conservative treatment modalities. Such fff-MWCNT containers are schematically illustrated in Fig. 9.1. These structures combine the advantages of ferromagnetic containers (for hyperthermia or other mechanisms of heat transfer) with those from a broad spectrum for encapsulations and modifications within the carbon tube as well as outside.

Presently, human prostate cancer (PCa) – the most abundant tumor in men – with the well-known limitations of conventional therapies serves as an attractive model object for developing and optimizing treatment concepts based on and/or associated with fff-MWCNTs. First, a short overview and a clinical introduction about this tumor entity are given, followed by the different methods and techniques of synthesis and characterization of the MWCNTs, including novel techniques for their modification and functionalization. The treatment concept pro-

Fig. 9.1. Schematic of a multifunctional nanocontainer. (Modified from Ref. [232].)

posed will be realized by principles of nanotechnology; therefore, the magnetic properties of nano-scaled objects and materials are introduced. Furthermore, we discuss the relevant parameters for and mechanisms of heat transfer as well as of the specific absorption rate.

Recent knowledge of modified MWCNT will be summarized, including our own results for synthesis strategies for fMWCNT, (bio)functionalization for the *in vitro* and *in vivo* transfer into different cellular systems and the accumulation in target cells and tissues. Future steps in the development of these nanocontainers are also discussed. These containers must fulfill numerous criteria, especially basic safety and efficacy requirements, before being used in humans.

For a potential future application *in vivo*, fundamental issues that need to be resolved include the homogeneity (uniformity of the carbon multi-wall sidewall, grade and composition of the ferromagnetic and additional filling materials) and purity of the MWCNT at the various stages of intrinsic and extrinsic functionalization.

This chapter describes the feasibility of different applications using MWCNTs, e.g., as heat mediators for hyperthermia of solid tumors. The extraordinary potential of the proposed MWCNTs is shown by their functionality as multiple containers. These therapies are based on heat dissipation in the ferromagnetic filling material of the MWCNTs. Therefore, the requirements for the heat transfer of the nanocontainer are related to those of the hyperthermia. Thus, the material requirements were derived from the knowledge of hyperthermia but are not limited to this application field. For this reason it is difficult to present a complete and comprehensive overview of all modifications and variants of functionalized MWCNTs, and so for technical and medical reasons the focus here will be on novel types of fff-MWCNTs and the model system of prostate cancer.

## 9.2

### Prostate Cancer

#### 9.2.1

#### Incidence, Risk Factors and Diagnostic Criteria

Prostate cancer (PCa) is the most commonly diagnosed cancer in men of western countries. However, except for the risk factors of age, race, geographic dependence,

and family history of PCa, the etiology of this tumor entity remains poorly understood. PCa is primarily a tumor of older men. The incidence rate for men over the age of 65 is about 20-fold greater than that for men between 50 and 54. Less than 1% of PCa are diagnosed in patients in their first three decades of life. About 2–3% of all male deaths are attributable to PCa.

A familial history of PCa, *per definitionem* an affected father or brother with an association with at least a two-fold increase of disease, remains a consistent and important risk factor. About 40% of PCa cases are estimated to have a genetic component. However, PCa is a outstanding example of a tumor entity characterized by tumorbiological and genetic heterogeneity (reviewed in Ref. [1]). The prostate of a man diagnosed with PCa contains an average of five apparently independent lesions [2], and this multifocality is independent of familial history.

In the general population of the U.S., the risk of PCa is highest in African-American men, being approximately double that of their Caucasian counterparts. Moreover, Caucasians and African-American men in the U.S. have a PCa incidence that is 5–50× greater than that of Japanese men residing in Japan, and the incidence of PCa on Japanese immigrants to the U.S. is four times that of their native Japanese counterparts. This marked racial and cultural disparity indicates that dietary factors might affect PCa onset and growth.

As a serum tumor marker, prostate specific antigen (PSA), a serine protease belonging to the human glandular kallikrein family, has revolutionized the detection and management of PCa like no other marker in the history of oncology. With early identification of PCa using serum PSA, less than 10% of PCa with distant metastases are now diagnosed, a stage with five-year survival of only about one-third.

A patient's serum level of PSA, clinical tumor stage and Gleason grade provide valuable information to clinicians. The Tumor-Node-Metastases (TNM) classification system is used for the staging of PCa, whereas the Gleason score system is used for histologic grading characterizing the aggressiveness of this malignancy. Classification of PCa is based on size, invasion of the prostate capsule, and clinical stage. PCa develops in two different regions of the gland, with about 80% being found in the periphery, whereas the remaining cancers are found in the periurethral region, termed transitional zone (Fig. 9.2).

Primary PCa growth is characterized by an extremely heterogeneous and multifocal pattern. Initially, the tumor growth is an androgen-dependent and mediated by the androgen receptor. Despite an initial sensitivity, PCa become more or less quickly androgen-independent. Then the PCa becomes metastatic and, finally, hormone refractory [3].

The entity of PCa represents a significant public health problem and underscores the need for the development of improved diagnostic markers [4] as well as of treatment modalities.

### 9.2.2

#### Treatment Options, Outcome and Limits

The serum marker PSA improves the detection of clinically important tumors without significantly increasing the detection of unimportant tumors; most PSA-

**Fig. 9.2.** Staging modality section of the prostate. The prostate gland with a branched structure can be divided in four distinct regions that reveal a different incidence of PCa: the anterior zone is purely fibro-muscular, the central zone contains the ejaculatory ducts (8% of cancers), the transitional zone (25% of cancers) is characterized by two lateral lobes, together with the periurethral glands, and the peripheral zone gives rise to 67% of cancers.

detected tumors are curable using current techniques, but there is no cure for metastatic disease. Treatment options, mostly radical prostatectomy, external beam radiation and brachytherapy, have become increasingly used to manage localized disease.

Contemporary methods of radical prostatectomy for patients with clinically localized disease are generally associated with excellent outcomes (reviewed in Ref. [5]). The cancer specific survival 10 years after radical perineal prostatectomy for patients with organ confined disease is approximately 90%. Crude survival rates at 10 and 15 years after surgery were similar to those of age-matched men from the general population without PCa. However, about 30–50% of patients thought to have organ-confined PCa at the time of surgery are later found to have disease beyond the prostate based on a careful review of the surgical specimen [5].

Neoadjuvant therapy with hormonal ablation has been evaluated in several studies and resulted in reduced positive surgical margins, and decreased volume of the PCa, equivalent to a pathological down-staging [6].

Virtually all recurrent clinical and metastatic diseases are preceded by a rising PSA, and only a few sporadic cases of recurrence have been reported in the absence of a detectable serum PSA. Biochemical failure is defined as either the persistence of detectable PSA after surgery or the development of detectable PSA in those with previously undetectable postoperative level.

For advanced disease, ablating androgenic hormones is the mainstay of therapy (reviewed in Ref. [7]), and will result in tumor response in about 80% of men.

For men considered to be at high-risk of treatment failure after local therapy alone, multimodal treatment strategies, for instance the combination of radiotherapy followed by hormonal therapy, may result in improved cancer-control out-

comes. The benefit of neoadjuvant or adjuvant hormonal and/or chemotherapy followed by radical prostatectomy in high-risk patients is unclear but is the subject of ongoing or planned Phase III clinical trials. These studies will help to examine the role of multimodal treatment strategies in these high-risk patients.

In summary, alternative therapeutic strategies are needed for the treatment, especially, of locally advanced and metastatic PCa.

### 9.2.3

#### **MWCNT Model**

Figure 9.1 depicts a schematic diagram of a multifunctional nanocontainer that is possibly applicable for future anticancer therapy. The main component is a multi-wall carbon nanotube, filled with a ferromagnetic material, with an external diameter of 20–60 nm and a length of approx. 100–10 000 nm, as required. The case is made up of a pre-defined number of graphene layers (2–20), which guarantee an extremely high chemical stability. The external case is already filled during production. Iron [8–12], nickel [11], cobalt [13, 11], or FeCo [11, 14] may be used as ferromagnetic materials. The deposits can grow without a substrate in powder form [8, 9] or on substrates [10, 12], which is of particular technological advantage. Of these materials, we favor iron as a filling material for future application in antitumor therapy, owing to the possible toxic side effects of Ni, Co or FeCo alloys. Even at this early stage, the ff-MWCNT can be put to practical use as part of a therapy. One particularly notable consideration is magnetic particle hyperthermia. The basic effectiveness of this therapy and the biological compatibility of the material system have been confirmed in animal testing (mice). With regard to superparamagnetic particles (SPM, see Chapter 8) also discussed for these applications – using magnetite and maghemite – the different mechanism for heat generation must be born in mind.

The primary field of application is the single “magnetic particle hyperthermia” (MPH) or in combinations with other treatment modalities. Therapeutic efficacy and the biocompatibility of ff-MWCNTs have been confirmed in cell culture and animal experiments in recent years by our group.

For these applications and in comparison with other nanoparticles, especially superparamagnetic particles containing magnetite or maghemite (see Chapter 8), the function of ff-MWCNTs is based on a completely different mechanism of heat induction.

Apart from the basic functionality (for hyperthermia), the container system proposed allows a broad spectrum of further applications. Since the ferromagnetic filling is often partial and the ff-MWCNTs can be opened after synthesis, a secondary filling with an additional agent and a subsequent defined closing is applicable. The agents could be (a) enhancer substances for hyperthermia, (b) chemotherapeutics with better efficiency at higher temperatures (e.g., cisplatin). Furthermore, minimized sensors can be integrated for contact-free measurement of local temperatures. The inclusion of rare elements for the localization of ff-MWCNT within the body has been suggested.

The opened ff-MWCNT is re-closed by the chemical reconstruction of the carbon tube or by addition of foreign materials such as heat-inducible and biocompatible polymers. Moreover, specific functionalization increases the accumulation within the target tissue and can stimulate the uptake by the target cells [15]. The proposed nanocontainers are suitable (a) alone for hyperthermia, (b) as adjuvant therapeutics or (c) alone or in combination with other nanoparticles (e.g.,  $\gamma\text{-Fe}_2\text{O}_3$  as SPM) for heat-inducible drug-releasing containers.

### 9.3

#### Carbon Nanotubes

##### 9.3.1

##### General Remarks

After detailed systematic studies of very thin carbon filaments in a high-resolution transmission microscope Iijima reported the existence of SWCNT and MWCNT in 1991 [16, 17]. Since then there have been intensive investigations into the synthesis, structure and properties of these new nanostructured materials. Their unique electrical, thermal, optical and mechanical properties have already generated great interest for applications in many different fields. They have shown increasing potential for use as field emission devices, nanoscale transistors, tips for scanning microscopy or components for composite materials [18]. Moreover, CNTs filled with ferromagnetic metals such as Fe, Ni, or Co represent a fascinating new material. Owing to their size and enhanced magnetic coercivities these carbon-covered ferromagnetic nanowires have significant possibilities in different areas too. They can be used in magnetic recording media or, as individually filled ff-CNTs, as sensors for magnetic force microscopy [19]. In addition to pure CNTs, derivative nanotubes with attached chemical or biochemical groups have been prepared that should find applications in biomedicine [20].

Two types of CNTs can be distinguished, single-walled (SWCNTs) and multi-walled (MWCNTs). They can be described as cylindrically shaped molecules made of rolled up single or multilayer sheets of graphitic planes. Typical diameters are approximately 1 nm for a SWCNT and 10–100 nm for a MWCNT and a length reaching up to the centimeter-range (Fig. 9.3). Besides catalytic chemical vapor deposition (cCVD) [21, 22], electric discharge [17, 23] and laser ablation methods [24], various types of plasma-enhanced chemical vapor deposition methods [25–27] are practicable and controllable methods for the preparation of CNTs.

The electrical and electronic properties of carbon nanotubes depend on their geometrical structure and, for SWCNTs, on the so-called chirality. SWCNTs can be either metallic or semiconducting. CNTs are among the strongest and most resilient materials in nature.

The properties of MWCNTs strongly depend on the structure of their shells. Especially, the electrical conductivity varies between nearly metallic and insulator. The quality of shells depends on the synthesis method used.

**Fig. 9.3.** Schematic and TEM images of SWCNT (single-walled carbon nanotubes) bundles and MWCNT (multi-walled CNT carbon nanotubes). (Modified from Ref. [233].)

Both SWCNTs and MWCNTs consist of two regions: the first is the sidewall of the tube and the second is the cap of the tube. By using different chemical and physical methods, the end caps can be opened and caps and sidewalls can be derivatized with different functional groups, radicals or molecules. Such manipulable nanotubes are well suited for application in biology and/or medicine. With a special material as filling (e.g., a ferromagnetic metal) CNTs can play an important role as a multifunctional nanocontainer in the diagnosis and therapeutic treatment of different diseases.

The next section describes the synthesis of f-MWCNTs and shows the unusual magnetic properties and possibilities of functionalization and manipulation (open, fill, close).

## 9.3.2

**Preparation and Structure of Filled Multi-walled Carbon Nanotubes****9.3.2.1 Synthesis of Ferromagnetic Filled Multi-walled Carbon Nanotubes**

f-MWCNTs can be synthesized by various methods. We classify two general versions: the first is an “*in situ* method”, in which the formation of the CNTs and their filling with different elements or compounds take place simultaneously. The other method is a “step by step process”: synthesis of empty CNTs – opening the tubes by chemical treatment – depositing and diffusion of filling material using different methods, mostly by wet chemical techniques – and, finally, closing the filled nanotubes by redeposition with a polymer or other carbon-containing phases (post-filling method).

In the following we only deal with “*in situ* techniques” for which there are physical and chemical methods. A physical, promising method is the “arc discharge”. This method delivers long, relatively continuous nanowires of many different elements, e.g., transition metals (Cr, Ni, Re, Au) rare earth metals (Sm, Gd, Dy, Yb) and other elements (S, Ge, Se, Sb) [28, 29]. The alternative, well-established method for synthesizing CNTs filled with metals as Fe, Co or Ni is catalytic chemical vapor deposition (cCVD). Different groups world-wide have used this method in a similar way.

With the suitable precursors, cCVD can deliver well-defined MWCNTs with a relatively high grade of filling and on a large scale, especially with elements of the iron triad. Compounds of the organometallic complex family “metallocenes” are such precursors. They have a “sandwich structure” of two parallel cyclopentadienyl rings and a metal in the center between these rings [ $M(C_5H_5)_2$  with  $M = Fe, Co, Ni$ ]; they are solid at room temperature, readily applicable, soluble in different organic solvents but also show suitable decomposition behavior in the temperature range 600–1150 °C. Pyrolysis of these metallocenes (Fe, Co, Ni) has been analyzed by Dyagileva et al. [30]. They showed that the decomposition is a complex process of homogeneous–heterogeneous nature of a series of consecutive, parallel and catalytic reactions.

Thus, the synthesis process of ff-MWCNTs, based on the decomposition of metallocenes, will also be catalytically determined and, consequently, a support (substrate) covered (completely or partially) with an active catalyst material will promote the formation of filled nanotubes.

In principle, all known methods for manufacturing (Fe,Co,Ni)-filled CNTs have the same basic concept. Figure 9.4 shows a typical synthesis (two-band) reactor, as used by different groups of researchers.

Sen et al. reported the first experimental results for the synthesis of f-MWCNTs [31]. The pyrolysis of metallocenes (ferrocene, cobaltocene, nickelocene) was carried out in a quartz tube located in a two-stage furnace system. In a typical experiment a defined quantity of a metallocene was placed in a quartz boat, placed inside a furnace and a mixture of argon and hydrogen passed through the quartz tube (in some experiments acetylene is used as additional gas-phase component). The furnace temperature was increased to 200 °C, leading to the generation of the met-

**Fig. 9.4.** Typical two-band furnace for the synthesis of filled carbon nanotubes, based on the decomposition of metallocenes. (Modified from Ref. [12].)

allocene vapor, which was carried by the Ar/H<sub>2</sub>-stream into a quartz tube maintained at 900 °C in a second furnace. Depending on the deposition conditions, partially filled CNTs were unoriented or aligned deposited on the quartz tube walls, and no substrate was positioned in the reactor. Sen et al. have recognized that this method is a real alternative to previously known methods (arc discharge) [31].

Grobert et al. at Cambridge University (Kroto's group) has synthesized iron and Invar (iron/nickel alloy) f-CNTs in an aligned structure by using a mixture of ferrocene and fullerene (C<sub>60</sub>) in the temperature range 900–1050 °C [9]. For the first time, the Cambridge group could also show the enhanced magnetic properties in such iron nanowires inside the CNTs. Later, Grobert used the aerosol-technique for the decomposition of ferrocene [32]. Here, a benzene solution containing ferrocene is nebulized by an aerosol generator in an argon flow and is injected in the reactor through a nozzle directly (Fig. 9.5).

In a further study the same group have prepared aligned, partly filled MWNTs (30–130 μm long) in high yield by using a compressed gas Ar driven atomizer

**Fig. 9.5.** Aerosol-technique for the injection of ferrocene in the deposition zone. (Modified from Ref. [32].)

[33]. They demonstrated that the yield of filling is proportional to the ferrocene concentration, but complete filling could be not achieved.

In 2002, Satishkumar et al. from Rao's group observed, besides increased coercivity, Barkhausen jumps with  $5 \text{ emu g}^{-1}$  steps in Fe-filled CNTs [34]. The ff-MWCNTs were prepared by pyrolysis of ferrocene along with acetylene. Selected area diffraction patterns of the nanowires show spots due to (011) planes of an  $\alpha$ -phase, the ferromagnetic modification of iron. Additional X-ray investigations revealed  $\gamma$ -Fe and, as the minor phase, cementite ( $\text{Fe}_3\text{C}$ ).

In our laboratory we have synthesized ff-MWCNTs on precoated substrates [10, 12]. On oxidized Si-wafers, thin layers (few nm) of the iron triad group (the catalyst material) have been deposited by using the sputter technique. Before beginning the deposition process, the pre-coated substrates were annealed at 900–1000 °C, directly in the deposition apparatus for a short time (few minutes). The annealing yielded some nm-sized islands on the substrate surface, which act as a source for nanotube growth. Hence, both iron from the surface in a solid or liquid-like state and the iron from the gas phase (ferrocene pyrolysis) deliver the material for the filling, causing a higher yield of filling than obtained by the groups of Kroto and Rao. With the higher filling yield the magnetic properties were also improved. The aligned-grown nanotubes show a pronounced magnetic anisotropy, with the easy axis perpendicular to the substrate plane and parallel to the axis of the aligned MWCNTs. Coercivity for the magnetic field direction perpendicular to the substrate amounts to  $44.56 \text{ kA m}^{-1}$  ( $\mu_0 H = 56 \text{ mT}$ ) compared with  $19.89 \text{ kA m}^{-1}$  (25 mT) for the direction parallel to the substrate. For comparison, the coercivity of bulk iron amounts to  $0.072 \text{ kA m}^{-1}$  (0.09 mT).

X-Ray diffraction analysis indicated the presence of bcc-Fe ( $\alpha$ -Fe), fcc-Fe ( $\gamma$ -Fe) and, as minor phase,  $\text{Fe}_3\text{C}$  with a relatively strong  $\langle 011 \rangle$  texture. An annealing process below the transition temperature of  $\gamma$ -Fe to  $\alpha$ -Fe led to an increase of the ferromagnetic phase ( $\alpha$ ) and an enhancement of magnetization saturation [35]. Similar results could be realized in the same group for Co- and Co/Fe-filled MWCNTs. In the latter, the filled material enhanced coercivities to about  $103.5 \text{ kA m}^{-1}$  (130 mT) [14, 36].

Recently, our group has explored various means of improving the deposition procedure in regard to increasing the grade of filling and the abundance of ff-MWCNTs. We have also investigated aligned and relatively small, short f-CNTs that are suitable for special applications.

Figure 9.6 illustrates a so-called two-stage reactor. It shows a first conveyor belt system for a constant and reproducible transport of the ferrocene precursor. The ferrocene is dissolved in cyclopentane and dropped on the moving band continuously. In the first part the solvent is vaporized and the ferrocene is transported alone in the reactor at a defined temperature and constant transport velocity. In the deposition reactor a second moving band, populated with Fe-precoated substrates is positioned. In principle, such an apparatus can work continuously [37]. By using this equipment, very strong aligned f-MWCNTs can be synthesized with extremely high magnetic anisotropies and coercivities. The tube lengths are linearly dependent on the concentration of ferrocene in the solvent cyclopentane and

Fig. 9.6. A two-stage reactor for continuous deposition of filled carbon nanotubes. (Modified from Ref. [37].)

range between a few  $\mu\text{m}$  to 40  $\mu\text{m}$ . In contrast, the diameter of filled nanotubes is independent of ferrocene concentration and constantly in the range  $< 10\text{--}50\text{ nm}$  [inner (Fe-wire) diameter] and 20–180 nm (outer tube diameter).

### 9.3.2.2 Crystallographic Structure of Core Material in Filled Multi-walled Carbon Nanotubes

Some research groups have determined the structure of the core material in f-MWCNTs. Detailed results exist about Fe-filled tubes, which we only report on here. Figure 9.7 shows typical TEM images of CNTs with a partial and a complete

Fig. 9.7. Partly and completely filled multi-walled carbon nanotubes (MWCNT).

iron filling. The core material seems to be homogeneous. But which crystallographic phases does this material consist of? Several studies have investigated the X-ray-diffraction patterns of Fe-filled carbon nanotubes synthesized by cCVD in the temperature range 830–900 °C [33, 38, 39]. In most cases, the body-centered cubic phase of iron ( $\alpha$ -Fe) is the main component of the core material and is  $\langle 100 \rangle$ -textured along the tube axis.

Only Che et al. have reported that the filling material is amorphous if the cooling rate is very high after the synthesis process [40]. A post-annealing leads to crystalline  $\alpha$ -iron. In addition, Pichot et al. have shown that inside their aligned grown MWCNTs face-centered cubic iron ( $\gamma$ -Fe) is the dominant phase, with a  $\langle 110 \rangle$  texture parallel to the tube axis [41]. Finally, if the argon transport gas contains small amounts of oxygen (~1%) it is also possible that the filling consists of iron oxides such as hematite or magnetite [42]. These partly contrary results deserved detailed study. Recently, Kim and Sigmund have examined the crystallographic structures and orientations of iron nanowires inside carbon nanotubes with and without heat treatments at various temperatures [43]. The core material was found to consist of both bcc- and fcc-iron, in general, with their ratio dependent on the post-annealing temperature (without post-annealing and at room temperature the ratio  $\gamma/\alpha$  is  $<1$ ; after post-annealing at 1000 °C the ratio is near 1.0 and at 1400 °C approx. 2.3). Interestingly, the high temperature  $\gamma$ -Fe remains stable in a large quantity at room temperature. The reason why is explained below. The bcc-structure of iron is oriented in the  $\langle 001 \rangle$  or  $\langle 111 \rangle$  directions, while the fcc-structure is aligned only in the  $\langle 110 \rangle$  directions, along the axis of CNTs.

Besides the two modifications of iron a third phase, the thermodynamically unstable iron carbide phase  $\text{Fe}_3\text{C}$ , is often detected as a core material component. This phase plays a decisive role in the growth of empty and filled carbon nanotubes [44, 45]. Both Kim [43] and Shaper [45] have found that the iron carbide is enriched in the tips of the aligned CNT, and Shaper concluded that this iron carbide is an important intermediate in the catalyst-mediated growth of the tubes.

The application of iron-filled CNTs as nanomagnets requires complete filling with ferromagnetic iron, namely the bcc-phase  $\alpha$ -Fe.

As reported, at a synthesis temperature of 850–920 °C the core material consists of  $\alpha$ - and  $\gamma$ -Fe in various ratios, depending on the temperature, and a small amount of  $\text{Fe}_3\text{C}$ . Comparison with the Fe–C phase diagram shows that we do not have a thermodynamically stable state. The  $\gamma$ -Fe and  $\text{Fe}_3\text{C}$  cores are in a “frozen” state. Therefore, for the paramagnetic  $\gamma$ -phase to be transformed into the ferromagnetic  $\alpha$ -phase, a post-annealing process at a temperature below the eutectic line at 723 °C is needed. However, the  $\gamma \rightarrow \alpha$  transformation is connected with a 9% volume dilatation and if the  $\gamma$ -Fe is in a tight contact with the carbon shells it cannot expand and transform into  $\alpha$ -Fe because of the high elastic modulus of CNTs. Nevertheless, such a post-annealing has been realized at 645 °C for 20 h by our laboratory [46]. After this treatment the fcc-phase was completely transformed into the bcc-phase, as proved by X-ray diffraction.

Investigations of the crystallographic structures of core material, especially filled with iron, have led to differing views on the growth mechanism of empty and filled MWCNTs.

### 9.3.2.3 Growth Mechanism of Multi-walled Carbon Nanotubes

The growth mechanism of MWCNTs, especially of filled MWCNTs is still under discussion. However, some experimental facts are certain. First, growth is always carried out by a catalytically determined process, which means that a catalyst material is absolutely necessary. Secondly, tubular MWCNTs grow by a vapor–liquid–solid (VLS) mechanism with the catalyst particle in a liquid-like constitution, in contrast to the bamboo-like structures produced with a solid catalyst particle (VSS growth mechanism, see Fig. 9.8) [47, 48].

When a CNT is grown on a substrate, two types of growth modes are observed: so-called tip growth and the base or root growth mode (Fig. 9.9). The actual mode depends on the contact forces between the particle and the substrate. Strong adhesion promotes the base or root growth mode – it is often observed on plain substrates.

**Fig. 9.8.** Tubular MWCNT with a spherical catalyst (a, b) and a bamboo-like nanotube with a conic-shaped catalyst (c, d). (Modified from Ref. [230].)

Fig. 9.9. Tip and root growth modes of a CNT (carbon nanotube) on a substrate [231].

The diameter of the growing nanotubes depends on the size of catalyst particle on the substrate and on the size of a stable catalyst particle on the Young contact angle between substrate and particle. Figure 9.10 shows an example.

Catalytic acting metals are mainly the iron triad group, i.e., iron, cobalt and nickel. Thus, metallocenes of these elements are used as precursors for the synthesis of CNTs. An effective, well-known method for the preparation of tubular MWCNTs is the injection method [49, 50] using ferrocene dissolved in a hydrocarbon (e.g., xylene or benzene). This mixture is injected in the hot zone of the reactor chamber. By spontaneous decomposition of both ferrocene and xylene a rapid and aligned growth of MWCNT is performed on the reactor walls or on a used substrate.

Dyagileva et al. have investigated the decomposition behavior of (Fe, Co, Ni)-metallocenes and ascertained that their thermal stability decreases in the order  $Cp_2Fe > Cp_2Co > Cp_2Ni$  [30]. Furthermore, ferrocene decomposes mainly into  $H_2$  and  $CH_4$  above  $500^\circ C$ , in contrast to the Co- and Ni-metallocenes, which mainly decompose to give cyclopentadiene ( $C_5H_6$ ) and less  $H_2$  and  $CH_4$ . This decomposition behavior of ferrocene is advantageous for growth because by hydrogen formation the Cp-complex is completely cleaved and carbon is released for tube shell growth. The hydrogen produced additionally reduces fresh ferrocene in the

Fig. 9.10. Calculated Young contact angles for Fe and Co on oxidized silicon. Iron has a lower surface energy and a lower viscosity than cobalt. (Modified from Ref. [54].)

gas flux and inhibits oxidation of the iron and carbon. In fact, Dormans has observed the reduction of ferrocene at between 673 and 1173 K in a hydrogen atmosphere, whereas no decomposition was detected up to 1173 K in helium [51].

Consequently, the first step of the CNT growth mechanism is the homogeneous gas-phase decomposition of ferrocene:

As additional carbon feedstock the solvent xylene or benzene is used in the injection method. For the hydrocarbon xylene, a derivative of benzene, Endo et al. have considered two gas-phase and four surface reactions and found very good agreement between experimentally determined and calculated production rates of MWNTs allowing for these six elementary equations [52].

Xylene reacts with the hydrogen formed by ferrocene decomposition to afford toluene which then yields benzene:

These four hydrocarbons (xylene, toluene, benzene, methane) will decompose on the catalyst particle surface, and Eqs. (2) and (3) are named as the second step in the growth mechanism of MWNTs.

Promotion of reactions according to Eqs. (1–3) is always observed on the walls of the reactor chamber or on an inert substrate, positioned in the hot zone of the oven, because a heterogeneous reaction, two-dimensional nuclei formation, is always energetically favored. At relatively low temperatures (820–850 °C) such heterogeneous reactions are exclusively dominant.

It is assumed that the iron particles impinge on the substrate and solve the carbon. The solved carbon diffuses through the particles and precipitates again as tube shells. As mentioned above, a tip or root growth mode can be observed, depending on the adhesion forces on the exclusive substrate material. Wafers composed of oxidized silicon are often as substrates. The tip growth mode is often realized on such materials, where the catalyst material is deposited by a sputter technique on the substrate before nanotube growth is started. Nanometer-sized droplets are subsequently formed by a thermal pre-treatment of these very thin sputtered layers (a few nm thick) in either an argon or hydrogen atmosphere [12, 52]. The subsequent CNT growth is affected by the introduction of a catalyst-free hydrocarbon in the reaction chamber. In contrast, using spray pyrolysis of ferrocene dissolved in a hydrocarbon, spontaneous deposition on the reactor walls leads to base growth [53].

Normally, a grown MWCNT has only one catalyst particle on either the base or tip. The core of tube is hollow and free of inclusions.

By using the ferrocene pyrolysis technique with and without an additional hydrocarbon the synthesized carbon nanotubes show a partial filling with catalyst mate-

Fig. 9.11. Continued growth of partially filled carbon nanotubes. (Modified from Ref. [234].)

rial; the tubes exhibit multiple particles or wires along the middle of the tube (Fig. 9.11).

Investigations aiming to explain this phenomena have shown that the root or base growth mode is a suitable model for describing the growth of such partially ff-MWCNTs [50, 52, 53]. Figure 9.12 shows the initial state schematically. Short catalyst-containing tubes deposit on the reactor wall or on the substrate. The tubes always show an open tube end (root growth). With continued growth the gas-phase delivered carbon and iron particles can fall into these open tube ends. Simultaneously, carbon dissolves in the particle and graphite precipitation occurs into the wall of the CNT, thereby increasing the tube length. The particle is deformed due to the squeeze of the tip. As the distance between the open tube end and the catalyst particle increases, it becomes harder for carbon to reach this particle. After a defined time, a new iron particle falls on the open end and growth is continued. The model explains not only the growth of partially filled tubes but also the growth of very long tubes.

Is it possible to influence the yield of filling by deposition conditions? Cer-

Fig. 9.12. Initial state of growth of partially filled carbon nanotubes when using the spray technique with continuous catalyst addition. (Modified from Ref. [53].)

tainly, the catalyst addition rate plays an important role. This addition rate can be increased by a higher Fe/carbon ratio in the gas phase (ferrocene decomposition without hydrocarbon) or by first and additional catalyst particles on the substrate. Using latter method we have reached a filling yield of nearly 50 vol% [46]. In doing so, we could prove that both the catalyst material from the substrate and from the gas phase participates in the filling of nanotubes. Furthermore, the deposition of filled tubes using cobaltocene as catalyst and a carbon feedstock was realized on an iron pre-coated substrate. The result was a carpet of aligned Fe/Co filled MWCNTs. The iron could be detected in the tips of tubes, meaning that it diffused into the Co filling material that was delivered from the gas phase.

As mentioned above, the open tube end model can explain the rapid growth of super long MWCNTs. Nevertheless, with longer deposition times the growth rate decreases and more Fe particles and no nanotubes are formed [11, 54]. This means that although new catalyst material is supplied again and again the catalytic reaction at a tube material will be ever more deactivated. This effect of catalyst deactivation is well known and is indicated by an overcoating of the iron particles with an amorphous carbon layer. It is caused by a momentary supersaturation of carbon on the surface of the catalyst particle due to too high a carbon supply from the gas phase.

### 9.3.3

#### **Post-treatment: Opening, Filling and Closing of MWCNTs**

The application of ff-MWCNTs as multifunctional nanocontainers (for instance in the medicine) requires the ends of these tubes to be opened, further filled with drugs or agents and, finally, re-closed (cf. Fig. 9.1).

The opening process of both SWCNTs and MWCNTs is relatively well controlled. This procedure is often connected with a necessary purification of the synthesized nanotube material. CNTs are effectively purified and opened by an oxidation process, either by a treatment in an oxidizing atmosphere at increased temperature ( $O_2$  annealing or treatment in a  $O_2$ -containing Ar-plasma [55–57]) or by a wet-chemical post-treatment in an oxygen acid ( $HNO_3$ ) [58, 59].

Tsang et al. first published the method of wet-chemical opening with  $HNO_3$  in 1993 [60, 61] and today this method is used by many research groups. However, all these procedures, which are primarily developed for the purification of CNTs, i.e., as means of eliminating of amorphous carbon and metal particles, are very aggressive. They not only remove the ends of the carbon nanotubes, they also damage parts of the tube walls. Such defects in the tube walls reduce the mechanical properties and limit the application fields. Recently, Raymondo-Pinero have reported on the simultaneous purification and opening of MWCNTs by using of solid NaOH [62]. By such a solid–solid reaction between NaOH and as-grown carbon nanotubes the MWCNTs will be purified and opened without defects in the tube shells (Fig. 9.13).

The next necessary step for the construction of a nanocontainer is to fill the opened carbon with the desired agents, drugs or sensor materials. In principle,

**Fig. 9.13.** TEM images of carbon nanotubes: (a, b) as grown and (c, d) after reaction with NaOH at 800 °C for 1 h. (Modified from Ref. [62].)

this is generally possible because the hollow interior can serve as a nanometer-sized capillary.

Ajayan and Iijima could already show in 1993 that CNTs can be filled with molten material through such a capillary action (Pb and Bi melts) [63]. By using a simple wet chemical method (suspending the CNTs in a nitric acid solution containing nickel nitrate), Tsang et al. have filled the CNTs with Ag [61]. In 1996, Chu et al. described a two-step method for filling CNTs with silver and gold metal with a high grade of filling [64]. Ugarte et al. have studied in detail the wetting and capillarity by metal salts by a similar two-step method [65]. First, nanotubes were opened by oxidation in the air and, subsequently, nanotubes were immersed in molten salt (e.g.,  $\text{AgNO}_3$ ).

Wu et al. have successfully prepared Fe-Ni alloy nanoparticles inside carbon nanotubes by wet chemistry [66a]. Using nitrates of iron and nickel, filling lengths of up to 50 nm were reached. Gao and Bando have developed a special nanothermometer by filling carbon nanotubes with liquid gallium [66]. Gallium has one of the greatest liquid ranges of any metal and has a low vapor pressure and a high thermal expansion coefficient. Such a thermometer can be used over a wide temperature range.

Besides filling with metals or salts, CNTs can be also filled with oxides [67, 68]

and halides [69, 70]. Recently, CNTs have been filled controllably with fluorescent particles by immersion in liquid ethylene glycol, by the complementary action of capillary forces and evaporation of the liquid [71]. In addition, Korneva et al. have described a simple capillary action technique to fill CNTs with paramagnetic iron oxide particles using commercial ferrofluids (particle size  $\sim 10$  nm) [72].

Both of the latter results show important progress and that filling a CNT with solid particles (up to 10 nm diameter!) is generally possible. This is one of the most important requirements for filling CNTs with drugs or agents and thus for possible application as a nanocontainer to transport these drugs to specific locations in the human body.

After the post-filling process it is necessary to re-close the nanotubes. This can be achieved by reaction with different reagents such as ethylene glycol or by treatment with benzene or another hydrocarbon vapor in a reducing atmosphere of argon and hydrogen at increased temperatures [73].

Another possibility is an additional thermal treatment with a biocompatible monomer that will polymerize at higher temperatures.

## 9.4

### Magnetism in Nano-sized Materials

#### 9.4.1

##### General Remarks

The principles suggested here for putting the multifunctional nanocontainer to use can only really become effective when it is produced on a nm scale. Understanding the difference between bulk and nm materials and the changes in properties they cause is the main condition for appreciating how magnetic materials can be used in biomedical applications [74, 75]. To better understand the special uses of ferromagnetic materials, especially those with geometric forms at the nm scale, some fundamental magnetic parameters, and dimension-related changes where necessary, must be briefly elaborated. These relations are, however, highly complex and extensive, meaning that only some selected challenges can be briefly described at this point. For complementary, continuing deliberations, reference should be made to the relevant standard works on magnetism [76–80], and to studies that deal specifically with physical characteristics specific to nanoscale arrays of ferromagnetic materials [81–86]. For an immediate understanding of the problem, we explain briefly some of the parameters necessary for the suggested therapy plan using a nanocontainer to be effective. In particular, these include those that affect heat development by AC heating. Magnetic reorientation is responsible for losses in ferro- or ferrimagnetic materials such as ff-MWCNT. The reorientation depends on the type of demagnetization process. These processes are determined by intrinsic magnetic properties such as magneto crystalline anisotropy and magnetization, on the one hand, and extrinsic properties such as shape, particle size and aspect ratio on the other hand. The size and shape dependence of  $H_c$  are well known.

$H_c$  will be maximized when the size reaches a critical low size (single domain particle). In the same way, it can be enhanced for particles having large aspect ratios [75]. To study these dependences in detail, the challenge of producing uniform nanomagnets must be solved. To prepare nanomagnets, complex technologies are often used, not only based on conventional thin film or CVD technology but also on a combination of wet chemical methods and special technology. One technique that has proved particularly valuable is the electrolytic deposition of ferromagnetic materials in the pores of suitable substrates (e.g.,  $\text{Al}_2\text{O}_3$ ) [82–85, 87, 88].

Another point that needs to be explained is that the preferred ferromagnetic metals (iron, cobalt and nickel) are, for example, susceptible to oxidation [89–92] and that the oxides may have different magnetic characteristics than the pure metal. If the characteristics of nanoparticles with diameters of  $<100$  nm are to be determined and used, the volume/surface ratio detrimental to oxidization must be considered here. The improvement of biocompatibility is often the reason why nanoparticles are coated with paramagnetic materials. For this purpose, Al or  $\text{Al}_2\text{O}_3$  [93–95], Au [96], Si or  $\text{SiO}_2$  [97–99], and other materials are discussed. Several groups suggest the use carbon [92, 100–104]. In the case of the ff-MWCNT, protection from oxidation is guaranteed by the carbon [9]. Even a small number of graphene layers provide excellent protection against chemical changes. The magnetic characteristics do not change over a long time, even in unfavorable conditions [9]. For example, Fe-filled MWCNTs can be stored in acids and brines [105] with no demonstrable reaction and thus no demonstrable change in their magnetic characteristics. This avoidance of oxidation is acquired at the cost of possible limited biodegradability, however. Nonetheless, these external cases/coatings can also indirectly have an (sometimes positive) effect on the magnetic qualities, e.g., by mechanical stresses [106], even if these case materials are paramagnetic by nature. As well as the applications described here, magnets in the desirable single-domain state generally demonstrate a wide range of potential uses in biomedicine [107], if the challenges of production can be solved.

#### 9.4.2

#### Magnetization in Nano-sized Materials

Ferromagnetism is the result of an ordered alignment of the atomic magnetic moments. Fe, Co, Ni and their alloys are the most important substances of this material class. Ferromagnetic materials are materials that can remain magnetized after application of an external magnetic field. This external field is typically applied by another permanent magnet, or by an electromagnet. If the temperature of a ferromagnetic material is raised above a certain point, called the Curie temperature ( $T_c$ ), the ferromagnet loses its long-range magnetic order that establishes the spontaneous magnetization and becomes simply paramagnetic [108].

The magnetic behavior of a ferromagnetic material can be illustrated in a plot of the magnetization ( $M$ ) versus the applied field ( $H$ ). For ferromagnets, which are the focus of this work, the “hysteresis loop” [109] is the most evident distinction. The remnant magnetization ( $M_r$ ), the saturation magnetization ( $M_{\text{sat}}$ ) and the co-

Fig. 9.14. Typical hysteresis loop ( $M$  vs.  $H$ ) for ferromagnetic materials.

ercive field ( $H_c$ ) are important magnetic properties (Fig. 9.14).  $M_r$  is the magnetization of the sample in the absence of an external applied field and is often used in relation with  $M_{\text{sat}}$  (i.e.,  $M_r/M_{\text{sat}}$ ).  $H_c$  is the applied field in the direction opposite to the current magnetization direction, which is necessary to bring the global magnetization to zero [79]. This does not imply that  $M = 0$ , but the magnetization breaks up into domains that are magnetically oriented such that the integration over the entire sample disappears. Table 9.1 shows the values of some magnetic characteristics for bulk Fe, Co and Ni.

In contrast to bulk material, enhanced values of the coercivity have been obtained for ferromagnetic nanoparticles [110, 111] or nanowires encapsulated inside a carbon envelope, where the coercivity reaches tens of millitesla [9]. Generally, the origin of this phenomenon is related to the small size and the single domain nature of the encapsulated metal crystals [9].

#### 9.4.3

#### Influence of the Dimensions on the Magnetization Distribution

Without a magnetic field applied, a piece of a ferromagnet often assumes a state with global magnetization vanishing. Such behavior indicates the presence of domain closures inside the material. The overall magnetization  $M_{\text{overall}}$  of the magnetic object is given by Eq. (4).

$$M_{\text{overall}} = \frac{1}{V_{\text{overall}}} \sum_i M_i V_i \quad (4)$$

where  $M_i$  and  $V_i$  are the magnetization and the volume of the domain, respectively, and  $V_{\text{overall}}$  is the volume of the ferromagnet.

**Tab. 9.1.** Some magnetic characteristics of the ferromagnetic elements Fe, Co and Ni (bulk and nano-sized materials).

		Fe (bcc)	Co (hcp)	Ni (fcc)
Bulk material				
Curie-temperature	$T_c$ ( $^{\circ}\text{C}$ )	770	1131	355
Saturation magnetization	$M_s$ ( $\text{emu cm}^{-3}$ )	1710	1422	484
First anisotropy constant	$K_1$ ( $\text{erg cm}^{-3}$ )	$4.6 \times 10^5$	$45 \times 10^5$	$-0.5 \times 10^5$
Exchange constant	$A$ ( $\text{erg cm}^{-1}$ )	$2.5 \times 10^{-6}$	$1.3 \times 10^{-6}$	$0.86 \times 10^{-6}$
Coercive field (bulk)	$H_c$ ( $\text{A m}^{-1}$ )	71.6	795.8	159.2
Nano-sized material				
Coercive field (nano-sized)	$H_c$ ( $\text{A m}^{-1}$ )	31 830 [96] 127 337 [54] 99 470 [11] 21 200 (par.) [136] 37 900 (perp.) [136] 6446 [110] 49 800 [111] 9700 [166] 24 020 [166] 270 572 [171]	55 900 [111] 47 100 [36]	1190 [172] 1800 [111]
Critical diameter	$D_{cr}$ (nm)	32 ( $l/d \approx 3$ ) [84] 45 ( $l/d \approx 2$ ) [86] 85 ( $l/d \approx 5$ ) [86] 140 ( $l/d = 10$ ) [86]	28 ( $l/d \approx 3$ ) [84] 140 ( $l/d = 10$ ) [86]	64 ( $l/d \approx 3$ ) 600 ( $l/d = 10$ ) [86]

Figure 9.15(a) depicts a ferromagnet consisting of many domains with an overall magnetic moment ( $M_{\text{overall}}$ ) equal to zero. At zero applied fields, a domain circuit or closure is created to approach the lowest energy state and the minimum demagnetizing field [78]. In the following, we consider the changes in domain state that depend on the diameter of the ferromagnetic material ( $D_p$ ) relative to the critical diameter  $D_{cr}$  for a single domain state.

When  $D_p$  of a magnetic nanowire is larger than  $D_{cr}$ , the creation of more magnetic domains or a strong non-uniform magnetization ( $\nabla M \neq 0$ ) allows a more stable lower energy state. When  $D_p$  is less than the critical single domain diameter, the magnetization of the nanowire is almost uniform ( $\nabla M \approx 0$ ) and spreads along the wire axis (Fig. 9.15b). Micromagnetic calculations for magnetic nanowires with an aspect ratio (length/diameter) of  $\approx 3$  have shown the following dependence:

**Fig. 9.15.** Magnetization in magnetic elements: (a) multi- and (b) single-domain particle. (Modified from Ref. [84].)

$$D_{cr} \approx 3.5 \frac{\sqrt{A}}{M_s} \quad (5)$$

where  $A$  is the exchange constant (Table 9.1). Estimated  $D_{cr}$  for Fe, Co and Ni are 32, 28 and 64 nm, respectively. The critical diameter should also increase with increasing aspect ratio (length/diameter). These dependences for Fe, Co, and Ni have been determined by Sun et al. using micromagnetic calculations [86]. They reported critical diameters (Fe) of  $\approx 45$  nm (aspect ratio = 2),  $\approx 85$  nm (aspect ratio 5) and 140 nm (aspect ratio 10).

Figure 9.16 shows several magnetization configurations and their respective hysteresis curves, which depend on the nanowire diameter. Magnetic nanowires with a diameter significantly larger than  $D_{cr}$  break into domains of uniform magnetization to approach the lowest energy state (Fig. 9.16a). The overall remnant magnetization of this multidomain state is negligible. When the nanowire diameter decreases down to  $D_{cr}$ , the formation of a domain wall will not be energetically favored and no domains are formed. In this case, the magnetization is non-uniform. Such a magnetization configuration is called a “flower” [112] (Fig. 9.16b).

Another configuration observed in this type of magnetic material is the “vortex” structure. There is a flower–vortex transition that depends on the particle size and the aspect ratio. Micromagnetic calculations for Ni nanowires (aspect ratio < 3) made by Ross et al. point to the existence of a “flower-state” magnetization for small diameters [113]. As the diameter increases, a gradual transition to a “vortex” state occurs.

For ff-MWCNTs with filler diameters of 10–70 nm and aspect ratios of 1  $\rightarrow$  100 (Fig. 9.7), from the point of view of magnetism we are in the transitional area from

a) many domains    b) "flower" domain    c) single domain    d) superparamagnetic

**Fig. 9.16.** Schematic magnetization configuration and hysteresis loops of ferromagnetic materials of different sizes. (Modified from Ref. [84].)

single domain to “flower/vortex” structures. For specific applications it seems of advantage, in the long run, to aim for a single domain structure. However, to carry out alternating field heating with this single domain material, taking into consideration the limiting values for magnetic fields in medical applications, a specific alteration is necessary; seen from the point of view of the maximum values attained on the material we synthesized, it is a *reduction* of  $H_c \leq 15 \text{ kA m}^{-1}$  (18.8 mT).

When the nanowire diameter is  $< D_{cr}$ , the magnetization is almost uniform and is oriented along the wire axis (Fig. 9.16c). In this case, the hysteresis loop for the direction along the nanowire axis has the form of a rectangle. As the nanowire size continues to decrease within the single domain range, another critical threshold is reached, at which the remnant magnetization and the coercivity go to zero. When this happens, the material becomes superparamagnetic (Fig. 9.16d). Superparamagnetism occurs when the wire becomes so tiny that random thermal vibrations at room temperature cause them to lose their ability to hold their magnetic orientation, resulting in a spontaneous reversal of the magnetization. The geometric dimensions at which this transition from the ferromagnetic to the superparamagnetic state takes place are known as the superparamagnetic limit (SPL). For

iron [114, 115] and carbon-wrapped Fe wires [116], arranged in an array, these dimensions have been estimated at <10 nm.

#### 9.4.4

#### Anisotropy and Interaction

Magnetic anisotropy is another characteristic evident from the hysteresis. This is described as the tendency of a ferromagnetic material to have a preferential direction, “easy axis”, of magnetization [80]. For Fe, which has a bcc structure, the (100) axis is the easy axis, whereas the (110) and (111) axes correspond to the medium and hard axis, respectively. The anisotropy of magnetic nanowires is usually determined by the form of the ferromagnetic material and its crystal structure. In our experience, the crystal structure of the filler is a given fact. As described above, ff-MWCNT filler consists mainly of monocrystal  $\alpha$ - or  $\gamma$ -Fe. The  $\gamma$ -Fe phase can be transformed into ferromagnetic  $\alpha$ -Fe(110) by subsequent heat treatment.

In addition to the magnetocrystalline anisotropy, the preferential direction of magnetization can be determined by the shape of the material (i.e., a wire prefers the easy axis to be along its large dimensions) – shape anisotropy. The essential anisotropy contribution in thin metal nanowires is the shape anisotropy with the easy axis of magnetization parallel to the wire axis [117]. This anisotropic contribution can be decisively influenced by production technology, by means of the filler diameter and length. The shape anisotropy of a ferromagnetic nanowire is determined by the stray field energy of each nanomagnet, the decisive factor being the stray field vector  $\mathbf{H}_D$ , which determines the easy magnetic direction. According to Eq. (6) the local stray field energy density  $E_D$  is lowest when  $M$  points in the direction of the stray field determined by the nanomagnet.

$$E_D = -\frac{1}{2}|\vec{H}_D| \cdot |\vec{M}| \cdot \cos\beta \quad (6)$$

To estimate the stray field energy, the conventional model of Stoner and Wohlfarth is often drawn upon [118]. This model assumes that the cylinder (ff-MWCNT filler) can be approximately represented by a homogeneously magnetized rotationally symmetric ellipsoid. The aspect ratio of a Stoner–Wohlfarth particle,  $a = l/D_p$ , is decisive for its shape anisotropy energy. With further simplifications, such as presuming an aspect ratio of  $\gg 1$  and the orientation of the magnetic moment along the axis, the effect of the stray field can be described in a simplified manner as an additional anisotropy field  $H_D$  of the shape anisotropy.  $H_D$  is given by Eq. (7).

$$H_D = 2\pi M_{\text{sat}}\{1 + 3/a^2[1 - \ln(2a)]\} \quad (7)$$

This means it is possible to determine the magnetic field necessary to rotate the magnetization in the axis  $180^\circ$ . In the borderline case of infinitely long nanowires,  $H_D$  approaches the value given in Eq. (8).

$$H_{D,\infty} = 2\pi M_{\text{sat}} \quad (8)$$

The model of Stoner and Wohlfarth drawn upon here can only describe a simple estimation, but clearly shows the principal influencing variables.

For  $H_D$  we examined a single nanomagnet. When a collection of several nanowires is involved, they affect each other interactively.

In terms of material production, a distinction must be made here between the conditions of the production of ff-MWCNTs on a substrate and the conditions of ff-MWCNTs in tumor tissues. Whereas magnetic nanowires on a substrate are very closely packed in great numbers, once they are detached and transferred into the tissue they spread out. The magnetostatic interaction of the nanomagnets with the external field is described by the *Zeeman* therm.

$$E_{\text{zee}} = -HM_{\text{sat}}V \cos \Phi \quad (9)$$

In Eq. (9),  $\Phi$  is the angle between the magnetic field and the magnetization. When the magnetic field is realized along the easy axis of the nanomagnet, the hysteresis loop is rectangular. The coercivity  $H_c$  is equal to the anisotropy field ( $H_A$ , Eq. 10).

$$H_A = \frac{2K_u}{M_{\text{sat}}} \quad (10)$$

In evaluating the magnetic properties of nanomagnets like ff-MWCNTs we have to differentiate between the properties of structures arranged on a substrate and disordered in a tissue. Here it is meaningful to appropriate an ensemble of non-interacting and randomly oriented Stoner–Wohlfarth particles. Averaging over all possible spatial direction results in a hysteresis loop characterized by  $M_r = 0.5M_{\text{sat}}$  and  $H_c = 0.48H_{\text{sat}}$ . Hysteresis losses are reduced by a factor of  $\approx 0.25$  in comparison with the aligned situation [119, 120]. These differences mean that the hysteresis loops of a single material can be markedly different on the substrate (after production) and after being transferred to biological systems. For further examination of this problem, reference should be made to the relevant technical literature.

#### 9.4.5

#### Magnetic Reversal

The mechanisms of magnetic reversal are also important for future therapy options using ff-MWCNTs. What is of significance here is the relative size of the nanomagnets expressed by the  $D_p/D_{\text{cr}}$  ratio (as in Fig. 9.16). To turn the magnetization in a nanomagnet around  $180^\circ$ , a reversal field,  $H_{\text{SW}}$ , is necessary. This field depends mainly on the stray fields and the anisotropic contributions. For the magnetic reversal of particles with the dimensions examined here, a homogeneous rotation is mostly discussed [86, 118] or, by Curling's rotation [86, 121], an inhomogeneous rotation. The magnetic bipolar moments remain in parallel alignment in the case of homogeneous rotation during magnetic reversal. They rotate to the new orientation together. This mechanism is often adopted for mesoscopic, single-

domain ferromagnets with a uniaxial anisotropy. The accompanying magnetization curve is rectangular when the external magnetic field  $H_{\text{ex}}$  is parallel to the axis of the nanomagnets; it is a linear function of the external field in the case of a perpendicular field direction. Curling's inhomogeneous rotation is discussed for  $D_p \geq D_{\text{cr}}$ , i.e., for flower structures, for example. At the ends of the ferromagnetic cylinder, vortex structures are expected to form and then spread out across the cylinder as the opposing field increases. In practice, especially when a very high number of nanomagnets are spatially randomly dispersed and interact with one another, magnetic reversal can not be satisfactorily described using a model. It must be assumed that all energy contributions according to Eq. (11) are moving towards a common minimum;  $E_K$  is the magnetocrystalline anisotropic density,  $E_A$  is the exchange energy density,  $E_{\text{zee}}$  is the magnetostatic energy density (*Zeeman* energy), and  $E_D$  the stray field energy density.

$$E_{\text{ges}} = E_K + E_A + E_{\text{zee}} + E_D \quad (11)$$

#### 9.4.6

#### Magnetic Properties of Filled Multi-walled Carbon Nanotubes

The effects described above are crucial for ff-MWCNTs as a material system, which is the central element of the proposed multifunctional nanocontainer. In evaluating the magnetic properties, we must take into account the following aspects:

1. The fillers are mainly produced in a monocrystalline form (Fig. 9.17). They may exist not only as  $\alpha$ -Fe but in some cases also as  $\gamma$ -Fe or  $\text{Fe}_3\text{C}$ . In the present case,  $\alpha$ -Fe is the desired ferromagnetic phase. A transformation of  $\gamma \rightarrow \alpha$  is partly possible using temperature treatment. The higher volume of the  $\alpha$ -phase may in some cases change the mechanical stress state. By this means the shape of the magnetization curve and  $H_c$  could sometimes be influenced.

Fig. 9.17. TEM image and SAED pattern of a partly filled Fe-MWCNT.

2. Consideration must be given to variation in the level of filling in general, the filler diameter and the length of the ferromagnetic nanoparticles (aspect ratio  $1 \rightarrow 100$ , see Fig. 9.7). Because of these, both single domain and flower/vortex states may be achieved in nanotubes from one batch.
3. During therapy, the ff-MWCNTs are no longer arranged parallel to one another in the form of up to  $10^9$  tubes per  $\text{cm}^2$ , but face in all directions in a statistically even manner. This affects the way the ff-MWCNTs interact magnetically.
4. The number of carbon shells can vary considerably, which is another reason why the influence of mechanical stresses on magnetic properties can not be ruled out.

These few points suffice to make it clear that many different variables must be considered when evaluating the magnetic properties of ff-MWCNTs. Much fundamental research is still necessary for a complete understanding of these relations. Rising to this fascinating challenge is important not only for the biomedical applications discussed but also for a whole array of other interesting applications.

CNTs filled with most different materials have numerous applications in different areas. These unique nanostructured materials with a nanowire as material inside and the carbon shell around are receiving increasing attention. The closed CNT saves the sensitive core material by their relatively chemically inert carbon shells against oxidation or reduction. Therefore, the material will open up new applications, e.g., in nanoelectronics. ff-MWCNTs have attracted increasing interest. "Saved magnetic wires" are fascinating objects in itself, revealing unusual magnetic properties [122, 123], e.g., they will find application as magnetic electrodes in future molecular spintronic devices or as new material for high-density magnetic recording media [124]. As already mentioned, one very interesting application area is their utilization as magnetic nanoparticles in medicine, as material for hyperthermic therapy of cancer tissues.

The major advantage of filled CNTs is that their catalyst materials, the metals of the iron triad group (Fe, Co, Ni), are ferromagnetic over a wide temperature range. Thus, the catalyst and the necessary ferromagnetic material are identical (Section 9.3.2.1).

All three metals are suitable for hyperthermic application at temperatures up to  $45^\circ\text{C}$  as they are all ferromagnetic in this temperature range.

Nevertheless, the ferromagnetic properties of the filling material are determined by the presence of the ferromagnetic Fe-phase ( $\alpha$ -Fe). Therefore, the synthesis temperature is one of the most important parameters. Conforming with the phase diagram, unsurprisingly, at a synthesis temperature of  $850^\circ\text{C}$  the Fe filling consists of both para- and ferromagnetic iron and, particularly in the presence of carbon, iron carbide too. Complete transformation into the ferromagnetic phase is not possible, because the transformation of paramagnetic (fcc lattice) into the ferromagnetic phase (bcc lattice) is associated with a 10% volume dilatation. Iron tightly embedded in the nanotube would cause a permanent strain on the carbon shells; however, that is not possible due to the high elastic modulus of CNTs. The alternative is, necessarily, destruction of the nanotubes.

Several groups have investigated the magnetic properties of ff-MWCNTs. Figure

**Fig. 9.18.** Typical hysteresis loops of Fe-MWCNTs grown on a silicon substrate (parallel = magnetic field parallel to the substrate on which the Fe-MWCNTs are in perpendicular positions).

9.18 shows a typical hysteresis loop of an ff-CNT carpet on a silicon substrate. The measurements always reveal a uniaxial magnetic anisotropy with the easy axis along the tube axis. The magnetic characteristics saturation magnetization ( $M_{\text{sat}}$ ) and coercivity ( $H_C$ ) depend not only on the synthesis parameters and the  $\gamma/\alpha$ -Fe ratio, as mentioned above, but also on the alignment level, the diameter and the length of the CNTs on the substrate (Fig. 9.19). For instance, Satishkumar et al. have found that these magnetic properties are significantly dependent on the used hydrocarbon [34] (Table 9.2). This is because of the different diameters, lengths and alignment levels produced as a result of the significantly different growth rates obtained with different hydrocarbons. The higher the growth rate the stronger the alignment. With elongation of the aligned CNTs the magnetic anisotropy increased. This means that the aspect ratio determined the magnetic anisotropy too (so-called shape anisotropy). This phenomenon causes the extremely high coercivities observed in such CNT carpets.

Table 9.3 summarizes experimentally determined coercivities parallel to the tube axis. The values were determined using superconducting quantum interference devices (SQUID), an alternating gradient magnetometer (AGM) and a vibrating-sample magnetometer (VSM). As can be seen, the single values differ greatly, but are always higher at low temperature. In addition, the coercivities are far higher than in bulk material [ $H_{C(\text{Fe-bulk})} = 0.072 \text{ kA m}^{-1}$  (0.09 mT),  $H_{C(\text{Ni-bulk})} = 0.159 \text{ kA m}^{-1}$  (0.2 mT) and  $H_{C(\text{Co-bulk})} = 0.796 \text{ kA m}^{-1}$  (1 mT)]. This is due to the shape anisotropy and to the aligned arrangement of the CNTs on Si substrates.

Figure 9.19 illustrates clearly that at a strong alignment the anisotropy and the  $H_C$  values are very high in contrast to the case of sub-optimal alignment, where the shape anisotropy is weak and the  $H_C$  values are identical. This very interesting behavior is typical for arrangement on a substrate. After removal from the sub-

**Fig. 9.19.** Comparison of hysteresis loops of strong and sub-optimal aligned fCNT on Si-substrates. Left: strong, optimal alignment; right: sub-optimal alignment.

strate the ff-MWCNs lose their alignment. To study this effect, the removed nanotubes were transferred into human cancer cells [15] on a sample holder substrate. Figure 9.20 shows a typical hysteresis loop for this situation. The measured curves for magnetic fields in the  $x$ ,  $y$ , and  $z$  directions are almost identical. This is most likely due to the statistical random orientation of the ff-MWCNTs. The  $H_{c_s}$  for the individual directions in  $\text{kA m}^{-1}$  are  $H_{c_x} = 18.35$  (23 mT),

**Tab. 9.2.** Magnetic properties of Fe-filled carbon nanotubes obtained from the pyrolysis of ferrocene–hydrocarbon mixtures.

$H_{cy} = 18.43$  (23.1 mT) and  $H_{cz} = 18.83$  (23.6 mT). These values give the relation  $H_{c\_perpendicular}/H_{c\_parallel} \approx 1.02$ , which is significantly smaller than for parallel aligned nanotubes on a Si substrate.  $H_{c\_par}/H_{c\_perp}$  for ff-MWCNTs grown on a wafer lies in the range 1.8–6. The magnetic characteristics determined for ferromagnetic filled nanotubes in cells and tissues are much more representative for

Fig. 9.20. Hysteresis loop of Fe-MWCNTs in cancer cells on a sample holder substrate.

applications in therapy than those obtained for ff-MWCNTs on a substrate. Our data – based on hysteresis loops, holographic experiments (Fig. 9.21) and MFM measurements – strongly suggest that *single* nanotubes can display switching behaviors as single-domain element. Because of the large number of tubes in an issuing batch it is possible to find different filling diameters and different aspect ratios. In the present state of technology, you can produce particles with an aspect ratio in the range  $1 \rightarrow 100$  in one batch (Fig. 9.7). The fraction of single domain and flower/vortex structures is not well-defined. The present state of technological knowledge is insufficient to predetermine the fraction of single domain and flower/vortex structures in one batch. Remarkably, concerning Fe-MWCNTs there is a gap in the evidence regarding the general transferability of results, because either 1 or  $>10^4$  tubes have been evaluated. It is a challenge to transfer the results from one area to another. Study of the intermediate area should be expanded experimentally. Detailed investigations would be important in addressing these issues.

## 9.5

### Heat Generation

#### 9.5.1

##### General Remarks

When exposing materials in alternating magnetic fields, apart from the qualities of the materials, the geometric conditions and the frequency applied, we may in some

cases also have to take into account several heating principles, which differ due to their individual dependency on frequency ( $f$ ) and modulation ( $\hat{B}$ ) [120, 125–127]. The possible heating principles do not generally all occur at the same time in the different applications. What are principally seen are relaxation losses, dielectric losses, hysteresis losses and eddy current losses. In the technical literature, different formulae are sometimes used for the dependencies that apply, according to whether the work is of a magnetic or biomedical nature. Here, we mainly use the formulae that have become established in the biomedical literature. For hyperthermia using superparamagnetic (very small) particles, Rosenszweig has refined a model that was originally developed to describe dielectric dispersion in polar liquids [128].

For small field amplitudes, and assuming minimal interactions between the particles, the response of the magnetization to an AC field can be described in terms of its complex susceptibility  $\chi = \chi' + i\chi''$ . Both parts,  $\chi'$  and  $\chi''$ , are frequency dependent. The out-of-phase  $\chi''$  components result in heat generation, given by Eq. (12) [128].

$$P_{\text{spm}} = \mu_0 \pi \chi'' H^2 \quad (12)$$

This can be interpreted physically as meaning that if  $M$  lags  $H$  there is a positive conversion of magnetic energy into internal energy. This simple theory compares favorably with experimental results, e.g., in predicting a square dependence of  $P_{\text{spm}}$  on  $H$ , and the dependence of  $\chi''$  on the driving frequency.

As this heating principle does not play a decisive part in the ferromagnetic particles we favor, for further considerations and a detailed description of the dependencies reference should be made to Chapter 8 (Jordan et al.) of this book. Another principle considered is that of dielectric losses. These result in Eq. (13).

$$P_{\text{d}} \approx c_1 f^3 \hat{B} \quad (13)$$

For a concrete example of the application of ff-MWCNTs in alternating magnetic fields  $<20 \text{ kA m}^{-1}$  ( $<25.1 \text{ mT}$ ) with frequencies of up to 250 kHz (the operating range we prefer for ferromagnetic filled nanocontainers) the dielectric losses and the energy transfer in the tissue are also not the determining factor. They are only of importance for far higher frequencies [129–134]. In the application suggested here, the heating of ferromagnetic materials (e.g., ff-MWCNTs) with dimensions above the superparamagnetic limit, the determining heating principle is assumed to be that of heating by hysteresis losses. The general view is that the such losses are determined according to Eq. (14).

$$P_{\text{FM}} = \mu_0 f \int H dM \quad (14)$$

Apart from the frequency used, the area under the magnetization curve is also an

especially decisive factor in heat transfer. Equation (14) is sometimes also used in the form of Eq. (15).

$$P_{\text{FM}} \approx c_2 f H_c B_r \quad (15)$$

From this it can be seen that the hysteresis losses of different materials can be compared using the material parameters  $H_c$  and  $B_r$ . To achieve the high heat transfer desirable in the application of hyperthermia, it appears expedient to choose a material with a high  $H_c$  and a high  $B_r$ . However, in this case, notably, the application of very high magnetic fields is not possible for medical reasons (meaning hard magnetic materials can be considered only to a limited extent) and, physiologically, not all possible materials can be used. For example, the elements cobalt and nickel and their alloys, which are often used for magnetic materials, must be considered toxic and therefore questionable [135]. For this reason we prefer to discuss the use of iron as a possible material. The magnetic parameters that characterize iron have been investigated in many studies and determined with great precision. The coercivity of bulk Fe is considered verified at  $0.072 \text{ kA m}^{-1}$  ( $0.09 \text{ mT}$ ). As described above, the dimensionality of the ferromagnetic materials has a significant influence on the parameters examined [9, 19, 136]. In Fe-CNTs synthesized by our group, as the filler mainly consisted of single-domain particles, and because of the shape anisotropy, we were able to verify values from  $103.45 \text{ kA m}^{-1}$  ( $130 \text{ mT}$ ) [11]. This rise by a factor of  $>1300$  compared with the  $H_c$  of the bulk material has a direct influence, according to Eq. (15), on the energy transfer that can be achieved and is therefore of fundamental importance. Pure iron can only be considered as a possible material for hyperthermia when there is a rise of  $H_c$  compared with the bulk material values and in particular when the *shape* of the magnetization curve is specifically modified. Iron with any other magnetic configuration (multi-domain particles) does not allow sufficient energy transfer [137]. Furthermore, the demands on the magnetizing field concerning the field strength needed also depend on the  $H_c$  and  $B_r$  of the material to be re-magnetized. For an isotropic dispersal of magnetically uniaxial particles,  $B_r \approx J_s/2$ , where  $J_s$  is the saturation polarization. The magnetic field amplitude should fulfill the condition of Eq. (16) in order for the material to be nearly entirely re-magnetized (see also Ref. [120]).

$$H_{\text{ext}} > H_c + \frac{1}{3} \mu_0 J_s \quad \text{with } \mu_0 = 4\pi \times 10^{-7} \text{ Vs m}^{-2} \quad (16)$$

The magnetic reversal losses of various hard magnetic materials have been studied [138]. At a diameter of  $30 \mu\text{m}$ , the particle size was such that eddy current losses are no longer negligible. Nonetheless, it was still possible to show that the conditions of Eq. (16) must be fulfilled to achieve high-performance yields. In Ref. [120] this is also confirmed for the use of magnetite.

According to Eq. (15), as well as the aspect that can be technologically influenced (shape of magnetization curve), the energy transfer is linearly dependant on the frequency of the alternating field applied.

As well as the alternating magnetic field losses discussed above, one last sub-

stantial contribution in particular must be considered, namely energy transfer due to eddy current losses that occur. This heating, known technically as inductive heating, occurs when conductive materials – even non-magnetic ones – are subjected to an alternating field. Several important parameters, including conductivity, essentially determine the possible energy transfer. As the human body also possesses an appreciable degree of electrical conductivity it too can be heated according to this principle. Considering these losses is extremely important as they directly determine the boundary conditions of the alternating field heating actually desired. For inductive heating, both the geometric dimensions and electrical conductivity are determining factors. There are great differences between the factors to be considered. While ff-MWCNTs are geometrically very small ( $10^1$  nm) and exhibit very high electrical conductivity, biological tissue displays only low electrical conductivity, but the dimensions of a real patient are significant ( $10^8$  nm). For this reason, both systems reach the limiting values when considered as a whole and both materials connect differently. It therefore seems advisable to examine these cases separately, taking that of ff-MWCNTs first. In the usual technical discussions on inductive heating, the losses that occur are generally described by Eq. (17).

$$P_{\text{eddy}} \approx c_3 f^2 \hat{B}^2 d^2 \sigma_e \quad (17)$$

In Eq. (17),  $f$  is the frequency,  $\hat{B}$  the working induction,  $\sigma$  is the penetration depth, and  $c$  is a parameter that depends on the materials and geometry;  $d$  represents the work-piece diameter.

An essential difference between the heating methods discussed here is the frequency dependency of the energy transfer. Whereas alternating field losses increase linearly with frequency during magnetization reversal processes, the square of the frequency is a determinant of eddy current losses. Figure 9.22 presents these

Fig. 9.22. Variation of both hysteresis losses and eddy current losses with frequency. (Modified from Ref. [204].)

**Tab. 9.4.** Dependence of the degree of efficiency on the ratio  $d/\sigma$  ( $d/\sigma = 0.4\text{--}8$ ). (Modified from [204].)

$d/\sigma$	8	6	4	2	1	0.6	0.4	0.0001 (Fe-MWCNTs)
Degree of efficiency (%)	95	85	65	30	10	4	1	$\ll 1^*$

\*  $\ll 1$  is a postulation, but the value could not be determined experimentally.

ratios for iron with large geometric dimensions. Clearly, above approx. 70 kHz – i.e., in the area of interest for a therapy – the eddy current losses very quickly come to dominate in the case of electrical conductivity *and* dimensions on a mm level. A special feature of inductive heating is that energy transfer tends to occur more in the outer areas of the work piece. Because of the skin effect, eddy current flow is mostly on the surface of the material. The depth at which the energy density drops to  $1/e = 0.368$  is known as the current penetration depth. Some 86% of the energy is transformed between the edge of the work piece and  $\sigma$ , and the rest heats lower-lying layers.

The penetration depth itself depends on the electrical conductivity of the material to be heated. For energy transfer to be very effective, the geometric conditions must be optimally adjusted. The most important (influencable) parameters here in particular are the work-piece diameter  $d$  and the construction of the coil system. Once the boundary conditions, which can be technically altered, have been optimized, the ratio work-piece diameter  $d$  to penetration depth  $\sigma$  is of decisive importance for the energy transfer that can be achieved. Table 9.4 illustrates the effect of this parameter on energy transfer. Whereas energy transfer still reaches 10% at a  $d/\sigma$  ratio of 1, at a ratio of 0.4 it already drops to 1%. When Fe-containing ff-MWCNTs are used a  $d/\sigma$  ratio of  $\approx 10^{-4}$  is achieved. Figure 9.23 illustrates these dependencies. The figure 9.23(a) shows a screw with a diameter of 10 mm 10 s after start of AC-heating. The induced increase in temperature was  $>500$  K. Moreover, the so-called “skin” effect is clearly seen. The large temperature difference was mediated by the high electric conductivity and the nearly optimal geometry. Figure 9.23(b) shows a substrate placed at the same site ( $10 \times 10$  mm) with aligned Fe-MWCNTs. In this case and under the same conditions no change in temperature was found. The difference between the two cases is based on the geometry because both consist of the same material (Fe).

Gilchrist et al. have already dealt with this challenge in their fundamental publication describing the initial application of magnetic particle hyperthermia [130]. They were able to show that, in metallic powders, the eddy current loss becomes negligible at a level of  $<5$   $\mu\text{m}$ . With the ff-MWCNTs the diameter of the magnetic particles is not 5  $\mu\text{m}$  but only 0.015  $\mu\text{m}$ . This seems to verify the assumption that eddy current heating does not dominate in nanoparticles of this dimension; an as-

**Fig. 9.23.** Schematic images and photographs of AC-heating experiments using iron in the cm- (a) or nm-range (b).

sumption shared by other authors [120, 125, 128, 139]. Taking these results into consideration, we conclude that for hyperthermia using Fe-containing MWCNTs, eddy current losses are negligible and magnetic alternating field losses can be assumed to dominate.

The other borderline case with eddy current heating is the direct heating of human tissue. In the biomedical literature, the modification of the Eq. (17) written as Eq. (18) has become established [131, 133, 140], where  $\sigma_T$  is the conductivity of tissue and  $r$  is the distance from the central axis of the body.

$$P_{\text{tissue}} = \frac{\pi^2 \mu^2 \mu_0^2 \sigma_T r^2 (f^2 H_0^2)}{2} \quad (18)$$

Equation (18) is valid only for  $H_0 = \text{const}$  and  $\sqrt{(\omega\sigma\mu_0 r_{\text{max}})} \ll 1$  [135]. Biological tissue fulfills this condition because of its low electrical conductivity.

In principle, this heating method can also be used to treat patients. It has not become established as defined localized heating, e.g., in lower-lying tissue, is only possible to a very limited extent. Instead, the objective is to concentrate the heat precisely in the tumor tissue. For thermoseed treatment, Stauffer et al. called for a performance ratio of at least 10:1 [131].

When therapy focuses on magnetization reversal heating it is, therefore, wise to find ways to minimize eddy current heating. According to Eq. (18)  $r$ ,  $f$  and  $H$  are the alterable parameters. As the square of the radius is a determinant of performance rate, an undesirably high level of heating is most likely to occur if the body is surrounded by the coil system at its widest point (the chest cavity). The problem is then lessened if treatment can be carried out in the extremities with far smaller radii. Theoretical calculations and experiments have shown that an  $H \times f$  product of  $\leq 4 \times 10^8 \text{ A m}^{-1} \text{ s}^{-1}$  can be safely applied when treating tumors in the chest cavity. Higher values can be achieved if the radius can be reduced. Hilger et al., for example, specify an  $H \times f$  product of  $1.5 \times 10^9 \text{ A m}^{-1} \text{ s}^{-1}$  when treating breast cancer (coil diameter 150 mm) [141]. For this very important boundary value to be determined with certainty, however, in our opinion too few experimental data are as yet available.

### 9.5.2

#### Requirements for the Development of Materials for Hyperthermia and Magnetism

The use of magnetic nanoparticles in hyperthermia goes back to Gilchrist et al., who treated different tissue samples with particles of  $\gamma\text{-Fe}_2\text{O}_3$  (20–100 nm) in a magnetic field of up to  $20 \text{ kA m}^{-1}$  (25.1 mT) and a frequency of 1200 kHz [130]. Since then, numerous different materials and technical boundary conditions have been proposed.

The concept of locally and contact-free heating in the tumor tissue itself by raising the temperature up to  $>42 \text{ }^\circ\text{C}$  for 30 min to influence apoptosis and/or to destroy the tumor is fascinating, but requires reproducible conditions for particle production as well as reproducible heat dispersal in the tumor. At the same time, the therapeutic effects on humans depends on the actual conditions in the appropriate target tissue and organ. In particular, heat transport in different kinds of tissue and the differing blood supply in the organs mean that only limited theoretical predictions can be made. What is more, the temperature rise required for long-term therapy success has been estimated at varying levels. Hilger et al., for example, have suggested implementing temperatures around  $55 \text{ }^\circ\text{C}$ , the thermoablative level, when treating breast cancer, as when the temperature is limited to  $44 \text{ }^\circ\text{C}$  approx. 50% of the tumors recur [142].

Since the pioneering work of Gilchrist et al. [130] various materials have been suggested for hyperthermia using magnetic nanoparticles. These can be classified conveniently according to their magnetic condition at the temperature of application ( $41\text{--}55 \text{ }^\circ\text{C}$ ). There is a differentiation between:

1. Particles that are in a superparamagnetic state under the application conditions due to their geometric dimensions or their physical properties. These include  $\text{Fe}_3\text{O}_4$  (magnetite) or  $\gamma\text{-Fe}_2\text{O}_3$  particles (maghemite) with *small* dimensions

and

2. Particles that are in a ferri- or ferromagnetic state under the application conditions due to their geometric dimensions or their physical properties, e.g.,  $\gamma\text{-Fe}_2\text{O}_3$  particles (maghemite) of *large* dimensions, multidomain ferrite or ferromagnetic materials.

Several interesting studies have been carried out using materials of these two groups [120, 130, 137, 140–156]. This summary of different studies can not be complete. It reflects the different goals concerning the material and the heating mechanism. Many different materials – such as alloy-based systems – have been used by other groups. Our focus is directed towards pure iron or some iron compounds.

Another interesting alternative option in terms of heat generation, although with geometric dimensions at the  $\mu\text{m}$  or  $\text{mm}$  scale, is:

3. “Self-regulating thermoseeds” with a Curie temperature of  $>42$  to approx.  $57^\circ\text{C}$  [157–160], i.e., above the Curie temperature these materials change their properties and the energy transfer is greatly reduced. This strategy shows that self-regulation mechanisms can be achieved by optimizing material properties – here the Curie temperature – in a targeted manner. If the AC losses of these types of alloys can successfully be raised considerably in moderate fields, then this principle of temperature limiting could also be of interest for magnetic particle hyperthermia.

Materials can only be sorted into categories (1) and (2) above as suggested because the materials of one composition can be placed in either group solely on the basis of their geometric dimensions. For maghemite and magnetite particles, it is not always possible to state unequivocally that the material is in a superparamagnetic state. The division does, however, take into account the fact that the mechanism for heat transfer is fundamentally different [120, 161], meaning that different steps must be taken to selectively develop the material. Based on this division, we now confine this review to particles with ferromagnetic properties. With regard to superparamagnetic nanoparticles, which are very important for hyperthermia, the reader is referred to Chapter 8 by Jordan et al., which describes this point in detail.

As the first, simplest application of ff-MWCNTs – note that this principle only applies here – we begin from a therapeutical point of view by focusing on the treatment of urological carcinomas, including PCa. These are diseases that are, statistically, more likely to occur in later life. It must be taken into account that quite a substantial number of patients may already be fitted with metal implants, e.g., hip prostheses. This means that the use of high frequencies is only possible and/or

practical in a limited way due to the occurrence of eddy current heating [129, 132, 133, 157]. For this reason, within the limits of the admissible  $H \times f$  product [133, 141], we focus our attention on higher fields and not the commonly-implemented higher frequencies. According to the conditions described in Section 9.5.1, high frequencies produce eddy current losses on a mm scale, and thus possibly very high temperatures (Fig. 9.23) that can result in serious health problems.

For the successful therapeutic application of magnetic particle hyperthermia, the key data contained in Table 9.5 must be taken as a starting point. In the last few years, superparamagnetic material (SPM) particles have increasingly been discussed, as they are attributed with better heat generation. This judgment is based on the magnetic values of the materials in a multidomain state [137]. The production, for instance, of Fe nanoparticles that are, magnetically, in the desirable single domain or flower condition constitutes a technological challenge. For example, Fe

<sup>b</sup> Quality: high grade.

<sup>c</sup> Quality: best grade.

as a favored material is susceptible to oxidation [89] and at this particle size a substantial proportion of the volume has been transformed into Fe oxides. Furthermore, iron is pyrophoric [162], meaning that conventional production techniques such as milling, which is often used in industry, can only be used to a limited extent and/or after further technological measures have been taken. Only the much-used wet-chemical, dry-chemical methods or thin film technologies, sometimes with the implementation of extra protective coatings where applicable, have led to any obvious progress [92, 102, 111, 163–171]. Materials with unusual magnetic properties are described in these studies.

These materials have also been rendered interesting for this kind of application by alternative nanotechnology processes. Natural nanostructures, such as magnetotactic bacteria, are not the focus of our interest. Using these particles, a defined influencing of the magnetic properties is hardly possible. Useful magnetic nanostructures can also be obtained by the production of ff-MWCNTs using CVD, affording  $> 1000\times$  higher  $H_c$ s, magnetization properties that are more favorable to this kind of application compared with bulk material, and permanent oxidation protection. However, notably, the characteristics of the nanoparticles are always partly determined by structure and by production-caused contamination, mechanical stresses, etc.

Several parameters play an important role in optimizing a material; some parameters affect, negatively or positively, optimization of the magnetic properties. For example, the nickel nanoparticles encapsulated in graphite by Hwang et al. showed distinctly lower  $H_c$ s than in bulk material [172]. Pirota et al., however, showed from the example of magnetic-phase multilayer microwires at the  $\mu\text{m}$  scale that by adding another coating to the microwires the hysteresis loop could be clearly improved towards single-domain characteristics [106]. Thus, production technology is of decisive importance, and the hysteresis loops can and must be adjusted. On the basis of these methods of influencing magnetic parameters and their effect on heat generation, it must again be underlined that the therapeutic method we suggest using the multifunctional nanocontainer is only made possible when the entire system, or the decisive parameters, is optimized (not maximized).

Taking as a basis an  $H \times f$  product of  $1.5 \times 10^9 \text{ A m}^{-1}\text{s}^{-1}$  [141], the maximum that can be applied during therapy, a magnetic field that can usefully be applied is at most approx.  $20 \text{ kA m}^{-1}$  (25.1 mT). As the hysteresis loop must be modulated to exceed  $H_c$  for heat to develop, seen from this angle it appears pointless to try to achieve  $H_c$ s higher than  $100 \text{ kA m}^{-1}$  (125.3 mT), even though this is possible with the ff-MWCNTs (Table 9.3). The point is much rather to influence the shape of the magnetization curve, as in Fig. 9.24, with an  $H_c$  of approximately  $15 \text{ kA m}^{-1}$  (18.8 mT). To do this, it is advantageous to provide a material in a single domain state. This, again, means that the aim should be a Fe filler diameter of between approx. 10 nm ( $< 10 \text{ nm SPL}$ ) and approx. 32 nm [84] or approximately 45 nm [86] (no single-domain particles). As mentioned above, the higher values depend on the aspect ratio. The given values are representative for  $d/l \leq 3$ . For favorable shape anisotropy, the particles should have a length/diameter ratio of  $\geq 2$ , requiring a

Fig. 9.24. Schematic of well- and ill-conditioned hysteresis loops for medical applications (e.g., hyperthermia).

nanoparticle length of at least 20–60 nm. Furthermore, as high a magnetization as possible should be guaranteed. Based on these benchmark figures, high heat dispersion is possible in the case of single-domain-ff-MWCNT. However, this remains a distant goal.

Our data strongly suggests that *single* ff-MWCNTs can display switching behaviors as a single-domain element. Because of the large number of tubes in an issuing batch the fraction of single domain and flower/vortex structures is not well-defined. The present state of knowledge is insufficient to determine the optimal conditions (single domain, flower/vortex or mixing) for heat generation. To answer this question the conditions of the therapy must be considered.

Single-domain elements can generate a large amount of heat only in magnetic fields  $H_{\text{ext}} > (H_c + \Delta H)$ . From a medical viewpoint, the therapy might need be performed in a low magnetic field. Under this condition the application of another type of ff-MWCNTs could be advantageous. Detailed investigations are important in further answering these questions.

The ff-MWCNTs described at present are, most likely, not yet entirely in a single-domain state. Because of the magnetization behavior and the varying diameters, we must assume that significant proportions of the materials are in a flower/vortex condition. Nonetheless, considerable heat dispersion could be proved.

### 9.5.3

#### Specific Absorption Rate (SAR)

A characteristic parameter is necessary to evaluate the effectiveness of a material system. For hyperthermia two processes must be considered. In principle, we have to evaluate the process of heat generation. It is determined by the loss power or specific heating power of the material. We also have to consider the process of heat absorption by a biological tissue. The specific absorption rate (SAR), the mass-normalized rate of energy absorption by a biological body, in  $\text{W g}^{-1}$ , has become

the most important parameter in characterizing the effectiveness of a material system in hyperthermia. It is determined according to Eq. (19) [140, 173], where  $c$  is the specific heat capacity.

$$\text{SAR} = c \, dT/dt \quad (19)$$

For water,  $c_{\text{water}} = 4.118 \text{ J g}^{-1} \text{ K}^{-1}$ . For better comparability with different magnetic materials, some groups have used a particular SAR that is related to the active magnetic component [174–177]. This SAR of iron is given by Eq. (20), with  $m_{\text{tot}}$  the total mass of the specimen, and  $m_{\text{Fe}}$  the mass of the iron content.

$$\text{SAR}_{\text{Fe}} = \text{SAR}(m_{\text{tot}}/m_{\text{Fe}}) \quad (20)$$

This means the specific absorption rate  $\text{SAR}_{\text{Fe}}$  allows comparison of the efficiencies of different types of magnetic particles. In the description of our own material, we use this type of evaluation too.

With ff-MWCNTs, magnetic reversal losses are assumed to dominate for the mechanism of heat generation. On account of the opinion sometimes raised in the literature that sufficient heat transfer is not possible by this means with compatible magnetic fields [137, 139], it seems expedient to start with a calculated estimate. According to Eq. (21), the amount of heat generation per unit volume can be obtained by the frequency multiplied by the area of the hysteresis loop [75, 139].

$$P_{\text{FM}} = \mu_0 f \int H \, dM \quad (21)$$

Here, the substantiated assumption is made that the magnetization curve in the area examined is not dependent on frequency.

Under these conditions,  $P_{\text{FM}}$  can be readily determined from quasi-static measurements of the hysteresis loop [120, 139, 150] using an AGM, VSM or SQUID. To make these estimates, Fe-MWCNTs were transferred into tumor cells [15] and washed, and 50 000 cells were separated using fluorescence-activated cell sorting (see below). A defined volume of this solution was transferred onto a suitable substrate material. The magnetic properties of samples of this kind were studied by recording hysteresis loops in an alternating gradient magnetometer (AGM, 2900 MicroMag). As well as measuring complete hysteresis loops (major loops) the minor loops, which are decisive for the conditions of application, were also determined. For this purpose, when recording individual minor loops the maximum magnetic fields were limited to  $H_{\text{max}} \text{ (kA m}^{-1}\text{)} = 0.796, 1.591, 9.549, 12.732, 15.915, 39.788, 59.683, 79.577, 119.366, 159.155, 198.943, 397.887, 238.732, 318.310, 477.464, 557.042, 636.620, 716.197, \text{ and } 795.775 \text{ (1 mT–1 T)}$ . Typical magnetization curves are presented in Fig. 9.25. Notably, the curves shown here are not those of Fe-containing ff-MWCNTs in parallel alignment on substrates, but of Fe-containing ff-MWCNTs at a random spatial orientation in tumor cells. Where a parallel magnetic field orientation is mentioned this means, in this case, parallel to the substrate and no longer parallel to the tube axis. Because of the random ori-

**Fig. 9.25.** Hysteresis loops of Fe-MWCNTs in cancer cells. Outermost line: major loop; inner lines: minor loops.

entation, to some extent an averaging-out of all the spatial axes takes place. This is reflected in the directional dependence of the magnetization curves, which is now only weak. By determining the areas of the magnetization curves and multiplying them with an assumed frequency, the energy dissipation calculated for each magnetic field was estimated at  $0.796\text{--}796 \text{ kA m}^{-1}$  ( $1 \text{ mT}\text{--}1 \text{ T}$ ). For the calculated frequency, we drew upon the limiting frequencies of 50 and 1200 kHz generally accepted in the literature as well as our favored frequency of 250 kHz. Figure 9.26 shows the results obtained. Based upon quasi-stationary measurements, sufficiently high energy losses can already be achieved with magnetic fields of  $10 \text{ kA m}^{-1}$  ( $12.5 \text{ mT}$ ). Energy losses  $> 250 \text{ W (g-}\alpha\text{-Fe)}^{-1}$  are, however, only to be expected for this material from above  $30 \text{ kA m}^{-1}$  ( $37.7 \text{ mT}$ ). Although fields of  $20 \text{ kA m}^{-1}$  ( $25.1 \text{ mT}$ ) at 1200 kHz [130] or  $45 \text{ kA m}^{-1}$  ( $56.4 \text{ mT}$ ) at 53 kHz [153] have been used for hyperthermia treatments, lower magnetic fields are often preferred, in the range of the recommended  $f \times H$  product of  $4.85 \times 10^8$  [133] to  $1.5 \times 10^9 \text{ A (m s)}^{-1}$  [141]. The range of possible combinations of frequency and magnetic field that result from this fit in with the range defined as acceptable for clinical applications by Pankhurst et al. [139],  $f = 50\text{--}1200 \text{ kHz}$  and  $H = 0\text{--}15 \text{ kA m}^{-1}$  ( $0\text{--}18.8 \text{ mT}$ ). Based on these first fundamental assertions on the possible achievement of high energy losses by magnetic reversal, in a further step the SAR was also determined experimentally.

Determination by measurement often takes place using a calorimetric (time-resolved) method, with certain boundary conditions concerning technology and/or

Fig. 9.26. Variation of specific absorption rate ( $SAR_{Fe}$ ) of Fe-MWCNTs with magnetic field (lines: calculated from hysteresis loops; symbols: experimental measurements).

measuring techniques due to the high-frequency alternating fields. As illustrated in Fig. 9.27, the set-up we used consists of a high-frequency generator with an impedance matching network and the magnetic coil system. Water-cooled copper tubes are wound into a coil system (e.g., 4–10 turns, diameter of bore 20–100 mm,  $l = 60$ –120 mm) in which the sample to be examined is placed. The sample must have good heat insulation and the coils must be sufficiently cooled. The sample in the coil system is heated by applying an alternating magnetic field. The temperature change per time unit is determined using an appropriate device. Fiber-optic systems such as the FLUOROPTIK® Thermometer have proven effective for high-frequency magnetic fields: these metal-free systems are not affected by the alternating magnetic field and eddy current effects do not occur. With these systems, the temperature can be measured *in situ*. The output resolution and the accuracy also meet the demands posed, at  $0.001\text{ }^{\circ}\text{C}$  and  $\pm 0.2\text{ }^{\circ}\text{C}$  respectively.

Another notable point is that the magnetic field amplitudes are often determined by measuring the coil current and then calculating  $H$ . This is possible with sufficient precision in the case of coil geometries, which are generally simple. For the simplest case of a single circular conductor loop with radius  $R$  in the  $x$ - $y$  plane (if the origin is the center of the circle) we obtain Eq. (22) for the field components in the  $z$  direction, with  $I$  the current passing through the conductor.

Fig. 9.27. Experimental setup for time-dependent calorimetric measurements.

$$H_z = \frac{1}{2} IR^2 \frac{1}{(R^2 + z^2)^{3/2}} \quad (22)$$

Clearly, for  $z \gg R$  the field decreases at about  $1/z^3$ , and therefore outside the coil there is only slight stress on the tissue during treatment. For therapy the field is of importance within a long coil. It applies to Eq. (23), where  $n$  is the number of turns and  $l$  is the length of the coil.

$$H = \frac{nI}{l} \quad (23)$$

Initial attempts to determine the SAR experimentally used water, physiological salt solution and agarose gel blocks, to each of which was added a defined quantity of ff-MWCNTs. Heat insulation of the sample is extremely important, as mentioned above. When simple glass vessels were used we observed a distinct time dependency of the determined SAR. As shown in Fig. 9.28, the values vary from about  $750 \text{ W (g-}\alpha\text{-Fe)}^{-1}$  (30 s measuring time) up to  $150 \text{ W (g-}\alpha\text{-Fe)}^{-1}$  (900 s measuring time). We ascribe these differences to an unfavorable ratio of sample volume/sample surface at the time and, in particular, to heat conduction from the sample into the sample vessel. After the geometry of the materials used was optimized and heat conduction was minimized, this problem was reduced. It was possible to increase the accuracy and to realize the well-known  $t$ - $T$  characteristics. The initial slope was used to determine the SAR.

Figure 9.26 shows the SAR obtained by experiment under these altered conditions at a frequency of 250 kHz, depending on the magnetic field strength for the mid-quality material used for the quasi-static measurements. The figure also shows the SAR curves calculated for this material. The material used was from

**Fig. 9.28.** Variation of specific absorption rate ( $SAR_{Fe}$ ) of Fe-MWCNTs with time ( $H = 30 \text{ kA m}^{-1}$ ). Different colors represent data points from independent experimental series.

one batch but was not that used for the magnetic measurements. Clearly, the values obtained by experiment in a magnetic field area of up to about  $28 \text{ kA m}^{-1}$  ( $35.1 \text{ mT}$ ) tend to be lower than expected from the quasi-static measurements. What is more, there is distinct scattering of the measured results in all magnetic fields. We ascribe this scattering to instrument-related problems in controlling the HF current, as when the HF transmitter was at full drive, values were determined that could easily be reproduced. The SARs determined by experiment at  $34 \text{ kA m}^{-1}$  ( $42.6 \text{ mT}$ ) came out at 286, 280, 286, 292, 286, and 292  $\text{W (g-}\alpha\text{-Fe)}^{-1}$  in a series of measurements, for example. At the level of magnetic fields  $<12 \text{ kA m}^{-1}$  ( $<15 \text{ mT}$ ) it was not yet possible to obtain any sufficiently firm measured values. One reason could be the switching behavior of single-domain particles. To throw light on the real cause, further equipment-related improvements and basic studies of the switching characteristics of *individual* ff-MWCNTs must be carried out. The results already gathered by experiment, however, tend to confirm the expected course. In the range that can be applied in therapy, up to approximately  $20 \text{ kA m}^{-1}$  ( $25.1 \text{ mT}$ ), we were able to verify SARs of  $\leq 100 \text{ W (g-}\alpha\text{-Fe)}^{-1}$  for this not yet optimized material. However, clearly, far higher values could be obtained in the range  $>30 \text{ kA m}^{-1}$  ( $37.6 \text{ mT}$ ). From this, central questions emerge concerning:

1. The maximum  $H \times f$  product that is possible to use;
2. how these values appear in relation to the superparamagnetic particles;
3. whether the present situation achieved is sufficient for treating urological tumors.

Fig. 9.29. Grain size dependence of the loss power density for small ellipsoidal particles of magnetite ( $H = 6.5 \text{ kA m}^{-1}$ ). (Modified from Ref. [120].)

Table 9.5 lists typical SARs for the most important material systems, magnetite and maghemite, as well as for iron. The differing values for the frequencies and magnetic fields must be taken into account when comparing the results. Even after numerical correction of the SARs to “standard frequencies” and “standard magnetic fields” in accordance with the known dependences given by Eqs. (12) or (15), a great deal of scattering still clearly takes place within each material system. One reason for this can be found in the dependence of the energy loss on particle diameter and working frequency. As shown by Hergt et al. (Figs. 9.29 and 9.30), when using superparamagnetic nanoparticles, a distinct reduction in energy transfer achieved can be expected, even from a deviation of around  $\pm 1 \text{ nm}$  from the op-

Fig. 9.30. Dependence of magnetic loss power density on particle size for magnetite ( $H = 6.5 \text{ kA m}^{-1}$ ). (Modified from Ref. [120].)

Fig. 9.31. Power requirements of magnetic nanoparticles. (Modified from Ref. [120]; 3 curves.)

timal diameter [120]. With ferromagnetic particles up to the superparamagnetic limit, however, only a relatively minor change occurs depending on the diameter. Here too, the marked influence of technology on the results that can be obtained is apparent. As has already been established, controlling heat conduction in the tumor and the surrounding tissue is of decisive importance in connection with the SAR achieved. The group of Andrä, Hergt and Hilger [141, 143, 178] have stated more precisely results [143] for the range of thermoablation ( $T = 51\text{--}55\text{ }^\circ\text{C}$ ). The calculations imply that the specific heating power needed to achieve the required rise in temperature in the tumor goes up sharply as the diameter of the tumor falls. With thermoablation, the target is a temperature difference of 15 K.

Figure 9.31 shows the specific heating power required for this for three different concentrations of magnetite, depending on the tumor diameter. The low and high concentrations of  $0.001$  and  $0.1\text{ g cm}^{-3}$  are approximately the limiting values that are usefully applicable in practice. From the graphic representation, the required specific heating power clearly varies by several orders of magnitude, depending on the concentration of particles achieved. According to this, for an average particle concentration of  $0.01\text{ g cm}^{-3}$  and  $100\text{ W g}^{-1}$  (Table 9.5), tumors from a diameter of about 1 cm can be treated. By analogy, a higher particle concentration results in a size of 4 mm. These observations apply to the range of thermoablation. For hyperthermia, the proportions are slightly more favorable due to the lower temperature difference required. As only slight differences can be made to the heat conductivity conditions in the tumor tissue, one urgent task for materials development is to raise the performance of the material. The heat condition problem, on the one hand, and the amount of heat generated by a few magnetic nanoparticles inside a biological cell, on the other hand, are the background for the discussion: Is hyperthermia on a cellular level possible [137, 141, 179]?

Fig. 9.32. AC-heating using model tissue: (a) Muscle tissue containing Fe-MWCNTs (black), (b) muscle tissue: before and after AC-heating.

Taking as a basis the SARs for Fe-containing ff-MWCNTs at the *level used in therapy* of approx.  $100 \text{ W (g-}\alpha\text{-Fe)}^{-1}$ , the minimum SARs postulated in the literature to achieve the necessary temperature rise in the tissue, it can be concluded that this ferromagnetic material in a single-domain state should be suited for the treatment of a diagnosed PCa with an extension of at least several millimeters. Assuming this to be the case, experiments have been made in heating model systems. Beef was used as a model substance for the first heating experiments (specimen  $7 \times 7 \times 7 \text{ mm}$ ). Fe-MWCNTs were injected into this tissue (see Fig. 9.32a) and the sample was heated (at  $H = 20 \text{ kA m}^{-1}$  and  $f = 250 \text{ kHz}$ ). Figure 9.33 shows the temperature curve within the muscle tissue ( $43 \text{ }^\circ\text{C}$  after 7.5 min AC-heating). By compari-

Fig. 9.33. Temperature development during AC-heating.

son, without an injection of Fe-MWCNTs no temperature difference was measured for at least 15 min after the start of magnetic induction. Figure 9.32(b) shows typical photographs of model specimens/tissues before and after AC-heating. Based on these results, further experiments were carried out on cell cultures, tissue and organ samples and animals.

### Study Results for *In Vitro* and *In Vivo* Applications of ff-MWCNTs

#### 9.6.1

#### Efficient Endocytosis *In Vitro*, Lipid-mediated Could Enhance the Internalization Rate and Efficiency

Using different types of ff-MWCNTs we have studied the uptake by different urologic cancer cell lines. In cell culture experiments an efficient delivery into human EJ28 bladder cancer cells after complex formation of the ff-MWCNTs with cationic lipids was detected [15]. Our original conclusion was that the lipid is necessary for efficient uptake of ff-MWCNTs by cancer cells in our settings. However, systematic investigations of several cancer cell lines indicated that the ff-MWCNTs with different sizes (1–10  $\mu\text{m}$  long) were also internalized without lipid addition. Therefore, we hypothesized that lipid addition *in vitro* can stimulate the internalization, probably via endocytosis. Internalization by cancer cells under optimal growth conditions *in vitro* guarantees an efficient transfer in the cytoplasm of most of the cells. Our data implicate a potential direct association between the proliferating capacity of the individual cell type and the rate of internalization, which is in accordance with an active uptake mechanism. Further analyses should clarify this point in more detail because of its potential importance for the development of future therapeutic concepts.

Using TEM we have detected clusters of ff-MWCNTs mainly in the cytoplasm of the PCa model cell line PC-3. This uptake had no influence on the cell viability quantified by WST-1-assay in the first three days after short-term (4 h) treatment with ff-MWCNTs. These data confirm several reports for unfilled SWCNT [180–186] and also indicate that ff-MWCNTs appear non-toxic once internalized into mammalian cells of malignant (PCa and bladder cancer cells) and non-malignant origin, and without adverse effects to cell viability.

Beside the intracellular detection of ff-MWCNTs in the form of clusters or bundles the association with cells was further evaluated by flow cytometry. The results indicate that clusters of ff-MWCNTs are detectable in solution by FSC-SSC scatter flow cytometric analyses (FACS) (Fig. 9.34). They can be discriminated from cancer cells because of their higher granularity and smaller size (cf. Fig. 9.34b). After addition of ff-MWCNTs in serum-free culture medium to the cancer cells for 2 h, FACS analysis revealed a high percentage of cells characterized by a larger granularity, indicating an association between cells and ff-MWCNTs. Cells with internalized ff-MWCNTs and those with ff-MWCNTs at their surface can not be differenti-

**Fig. 9.34.** Representative results of flow cytometric analyses of human PC3 cells without MWCNT transfection (b). In comparison, 4 h after incubation of cells with Fe-MWCNTs (c) the granularity and size of the cells have increased. Remarkably, bundles of Fe-MWCNTs are also detectable in solution (a).

ated by this technique. However, the detection of a broad spectrum of increasing granularity confirms the TEM studies, showing that cancer cells have internalized different amounts of ff-MWCNTs. Moreover, on repeating the flow cytometry two days later, the same percentages of cells associated with ff-MWCNTs were found. Summarizing these experiments, clearly, by addition to the culture medium an intracellular accumulation of ff-MWCNTs takes place within a few hours, especially as cytoplasmic localized aggregates (Fig. 9.35). In addition, cell-associated and internalized ff-MWCNTs have the same magnetic properties as ff-MWCNTs in solution without cells.

A pilot animal study has checked the distribution of Fe-MWCNTs in mice [187, 188]. Briefly, male mice at 8 weeks of age were narcotized, and different doses of ff-MWCNTs were injected once intraperitoneally (i.p.) or intravenously (i.v.; via the tail vein). The animals were sacrificed 20 h after treatment. Tissue samples of different organs were conserved for TEM and histological analyses. Mice without treatment were used as controls. The remaining but treated animals were observed over a period of 150 days. For several mice of this treatment group, the injections were repeated. All animals survived and showed no abnormalities in their behavior or food consumptions. Remarkably, one mouse with a five-fold injection over a period of 3 months was treated with a total of >1 g ff-MWCNTs per kg of body weight.

In sacrificed animals, large agglomerates of ff-MWCNTs were detected at various organs in the retroperitoneum for the i.p. treatment but not in the i.v. treatment group. This indicates that most of the intraperitoneally administrated ff-MWCNTs is retained within the retroperitoneum over several weeks. Interestingly, the macroscopically visible agglomerates were attached in most cases to the surface of organs and penetrated to the peripheral zone of different organs, including kidney and liver. So, remarkably, magnetic force was transferred to the organs (Fig. 9.36).

The amount of magnetic material required to produce the appropriate temperature for hyperthermia or thermoablation depends to a large extent on the method of *in vivo* administration. Intra- or peritumoral injection or deposit allows for sub-

**Fig. 9.35.** Representative TEM photographs showing the internalization of ff-MWCNT by the PCa cell line PC-3. Black structures represent an accumulation of Fe-MWCNTs. (a) One large complex with many single CNTs was detected within the cytoplasm (magnification  $\times 7000$ ); (b) intracytoplasmically localized

CNTs with different grades of ferromagnetic filling (dark) (magnification  $\times 12\,100$ ); (c) different types of complex formation within the cytoplasm of PC-3 cells containing many CNTs (4 h after incubation, magnification each  $\times 7000$ ).

stantially greater amounts of magnetic material to be concentrated in a tumor than do other methods employing intravascular, intradermal or intraperitoneal administration and/or targeting. A general assumption is the concentration of at least 5 mg of the magnetic material within 1 cm<sup>3</sup> of target (tumor) tissue.

### 9.6.2

#### Production of Two Types of ff-MWCNTs for *In Vivo* Application

ff-MWCNTs can be synthesized by two different types of CVD. The first, solid source CVD (SSCVD), uses a simple quartz-tube gas flow reactor inside a two-zone furnace system [12]. Ferrocene,  $\text{Fe}(\text{C}_5\text{H}_5)_2$ , is sublimated in the first zone at about 150 °C. Decomposition is then realized in the second, the hot, zone at about 830 °C in an Ar flow on oxidized Si-wafers.

The second CVD system (so-called liquid source CVD, LSCVD) consists of a band evaporator with continuous action and a hot wall reactor with a tape on which the precoated substrates are positioned. This tape can be moved through the hot zone of the reactor. Here the ferrocene is solved in cyclopentane and drops continuously on the moving band evaporator. At 45 °C the solvent evaporates, at 270 °C the ferrocene is completely sublimated and, finally, the vapor is transported into the CVD reactor. At 900 °C the precursor decomposes and ff-MWCNTs are deposited on the precoated substrates directly. The CVD system has been described in detail previously [189].

Therefore, this method has the important advantage of producing filled nanotubes continuously and is, thus, favorable for a large-scale application.

The nanotube material was investigated by scanning (SEM, XL 30, Philips) and transmission electron microscopy (TEM; TECNAI F30 with GiF 200). Thermal gravimetric analysis (TGA, RUBOTHERM) in an Ar/O<sub>2</sub> atmosphere up to 450 °C was used to determine the thermal stability and the filling grade of the nanotubes (oxidation of nanotubes up to the remaining Fe<sub>2</sub>O<sub>3</sub>). Alternating gradient magnetometry (AGM) revealed the ferromagnetic behaviors of the filled nanotube-ensembles on the Si-substrates.

Depending on the deposition conditions, the length, structure, filling grade and the magnetic properties of the CNTs varied. Here, two different batches of ff-MWCNTs were used. One batch was synthesized by SSCVD, affording ff-MWCNTs about 10 μm long (type 1), with a filling yield of 25–30 wt.%. The ff-MWCNTs of

**Fig. 9.37.** SEM image of Type 1 ff-MWCNTs used for administration studies in mice.

the other batch (type 2), produced by LSCVD, were about 15  $\mu\text{m}$  long (Fig. 9.37), with filling yields of 30–35 wt.%. Both types had the same diameter distribution, i.e., 10–30 nm (inner) and 20–130 nm (outer). The number of carbon shells ranged between 20 and 100.

### 9.6.3

#### Outlook/Next Steps in Evaluation of these ff-MWCNTs

The future goal is the design and optimization of biofunctionalized ff-MWCNTs for different anticancer applications (Table 9.6). These multifunctional nanocontainers are finely regulated regarding the site of action, the temperature induced by external magnetic field application, and the step-by-step release of different drugs. In addition to therapeutic applications, nanocontainers could also be functional units for diagnostic and therapeutic monitoring purposes. They fulfill all the criteria for nanoscaled mediators of anticancer treatment with an optional intrinsic sensoric unit. The latter can function both for the detection of small tumor lesions as well as for the control of therapeutic effects. Note that either all of the individual characteristics can be incorporated in a single MWCNT species or a combination of different species with various behaviors can be synthesized, produced on a large scale, and applied under standardized conditions.

In our view, a variable experimental model is needed to test these possibilities. Therefore, we suggest a chamber model for the administration and characterization of *in vitro* and *in vivo* effects using a standardized device (Fig. 9.38).

Potential applications (Tables 9.6 and 9.7) of improved functionalization of ff-MWCNTs include:

1. Selective tumor-targeting by coupling of specific antibodies to the sidewall or the ends of ff-MWCNTs.
2. The formation of complexes with suitable lipids for better internalization of ff-MWCNTs inside target cells and tissues.

**Purposes for the experiments with the model chamber:**

- Objects of analyses: solution with different species of fff-MWCNT, adherente growing normal and cancer cell lines, slices of explanted model tissues (normal & malignant prostate from mouse or rat) including xenografts, organ bathes, or whole animals (mouse, rat)
- Study of the intrinsic magnetic properties of ff-MWCNT and fff-MWCNT in aqueous solution & within tissue slices
- Targeting, selective labeling & detection of tumor cells
- Study and optimization of different treatment modalities (microscopy, measurements within the chamber, external temperature control): intracellular intratumoral hyperthermia, drug release, combinational therapies

**Fig. 9.38.** Principle of the chamber used to analyze the interaction between ff-MWCNTs and tissues or organs.

3. Conjugation with other nanomaterials (nanoparticles, nanotubes, nanowires) characterized by other intrinsic biological, chemical or physical properties for an enhanced effect in diagnosis and treatment of malignant tumors.
4. Biofunctionalization and/or labeling of the ends of CNTs.
5. Potential as dual container (intrinsic chambers) and cargo system (functionalization, e.g., conjugation at the sidewall and at both ends of ff-MWCNTs).

Kam and coworkers have described recently the overall potential of functionalized CNT for anticancer therapies in general because of the intrinsic advanced physical and biological properties of these nanomaterials [185]. They reported that short ( $\approx 150$  nm long and  $\approx 1.2$  nm in diameter) and unfilled HIPCO-SWCNT solubilized in the aqueous phase by noncovalently and strongly adsorbing either fluorescently labeled 15-mer oligonucleotides (ODN) or phospholipid-PEG-grafted folic

Type of functionalization	Methods and results	Ref.
Drug/vaccine delivery Delivery of nucleic acids and proteins	Crossing the cell membrane and cytoplasmic accumulation enhance the immune (ab) response against peptides with no cross-reactivity to CNT, SWCNT as molecular cargoes into cells by noncovalently and non-specifically bound proteins to the nanotube sidewall and intracellular delivery by endocytosis, delivery of plasmid DNA by binding and condensation onto ammonium-functionalized SWCNT and MWCNT and onto lysine-functionalized SWCNT, selective targeting and destruction of tumor cells	180, 182–186, 190–193, 207–212
Usage as new types of biosensors based on DNA or proteins	Examples: CNT functionalized with PNA bind DNA containing a complementary sequence, nanoassembly by DNA–DNA interaction	213–220
Complement activation and protein adsorption	Description only for SWCNT and double-wall CNT	221
Imaging of cells, use in atomic force microscopy	By covalent linkage to visible-wavelength fluorophores or as Pluronic SWCNT fluorophores through near-infrared microscopy	180, 181, 192, 222, 223
Enzyme immobilization, usage as ion channel blockers		224, 225
Molecular electronics	Formation of nanoassemblies useful as molecular switches	226–229

acid were internalized inside folate-overexpressing HeLa cancer cells by simple incubation in cell culture medium at 37 °C (Fig. 9.39). This was in contrast to the results of the same experiment at 4 °C, which indicated that uptake is based on receptor-mediated and energy-dependent endocytosis. The SWCNT were heated by external near-infrared laser pulses, resulting in an intracytoplasmic release of ODN

**Fig. 9.39.** Selective targeting and killing of tumor cells using functionalized SWNT. After internalization of modified SWCNT via folate receptor (FR) binding on FR expressing tumor cells laser radiation induces selective tumor cell death. (Modified from Ref. [191].)

from the SWCNT and translocation into the nucleus. Note that radiation of the aqueous SWCNT solution ( $25 \mu\text{g mL}^{-1}$ , without cells) by an 808 nm laser ( $1.4 \text{ W cm}^{-2}$ ) continuously for 2 min caused heating to  $\approx 70^\circ\text{C}$ . The authors suggested that the SWCNTs can act as tiny “heaters” in living cells overexpressing the receptor molecule (folate receptor) targeted by the functionalized SWCNTs. Selective targeting and induction of necrosis of HeLa cells was observed after the same laser pulse treatment, without harming receptor-free normal cells. Dying cells released the ODN cargoes and were mixed with cell debris in black aggregates.

The same properties should be transferred and adapted to our *fff*-MWCNT model because of the intrinsic heating function of the ferromagnetic filling. In general, new PCa-specific antigens recognized by PCa-specific receptors can be applied for a selective *fff*-MWCNT-based hyperthermia in the histologically remarkably heterogeneous PCa tissue containing also receptor-negative stromal and normal prostatic cells.

A major advantage of using *ff*-MWCNTs would be the external control available for localization and intrinsic heating. Note that the finely-regulated, slow and controlled induction of heating should also improve the internalization of *fff*-

MWCNTs by target cells that did not primarily take them up; this implies a possible multiplicity of anticancer therapeutic efficacy once or in multiple treatments: stepwise (a) heating, (b) improvement of uptake within the target tissue, (c) release of drug from the container at a defined temperature, (d) repeating the hyperthermia as secondary local treatment and release of other drug classes by realization of higher temperatures than at the time of primary hyperthermia.

Biocompatibility is a major concern when introducing a therapeutic agent inside the human body. For different, mainly short and pure, species of unfilled SWCNT no adverse or toxic effects have been reported by various groups on testing the cellular viability and the proliferation [180–182, 184–186, 190].

Studies with SWCNTs indicate that simple mixing of oxidized SWCNT with solutions of various types of proteins resulted in covalent and non-covalent bonds to the sidewall [191]. The sidewall was functionalized with oxygen-containing groups by refluxing and sonication of SWCNTs in nitric acid. Interestingly, the adsorption of proteins with a molecular weight of  $\leq 80$  kDa (bovine serum albumine and cytochrome c) on SWCNTs imparts hydrophilicity to the CNTs. The spontaneously formed nanotube–protein conjugates were internalized by different cell types of non-malignant as well as malignant origin. While single proteins were unable to cross the cell membranes by themselves, SWCNTs efficiently traffick protein cargos inside the cells. An energy-dependent endocytosis mechanism for the uptake of the conjugates was proposed [191].

However, other mechanisms as the dominant internalization processes *in vitro* have also been discussed recently in the literature, including uptake of the CNTs by insertion and diffusion through cellular membrane phagocytosis [181, 182, 184, 190, 192]. The detailed uptake mechanisms and efficacy for the different target and non-target cells should be evaluated in various animal models.

Kam et al. have further described the release of internalized conjugates with SWCNTs and proteins from endosomes by adding the membrane-passing base chloroquine to the culture medium [191]. The functionality of adsorbed protein was shown for cytochrome-c because, after release of this protein from the endosomes, cells died by active apoptosis (mediated by the delivered cytochrome c).

Recently, derivatization of unfilled MWCNTs with N-protected amino acids based on a cycloaddition reaction to the external sidewall was described by Georgakilas et al. [193]. The modified MWCNTs had a lower solubilization than functionalized SWCNTs. However,  $12 \text{ mg mL}^{-1}$  of functionalized MWCNTs gave a clear solution in water. The authors conclude that this result represents the basis towards the synthesis of peptide-based CNTs.

Other reports have shown the interactions between SWCNT (HiPco tubes) and nucleic acids. Refs. [194, 195] describe the extremely strong binding of short single stranded DNA (oligonucleotide) by  $\pi$ -stacking. The binding of the oligonucleotide was realized by helical wrapping with right- and left-hand turns or simply by adsorption at the sidewall with linearly extended structures. This DNA coating of bundled SWCNTs was effectively dispersed in water by sonication. Moreover, subsequent functionalization was made by labeling one terminus of the oligonucleotides with biotin.

Ammonium-functionalized SWCNTs and MWCNTs facilitate the delivery of plasmid DNA in different murine [180, 196]. Complexes of DNA and unfilled, ammonium-functionalized MWCNTs formed aggregates  $>4 \mu\text{m}$  and possessed a planar lattice structure, whereas the double-stranded plasmid molecules formed a planar structure with MWCNTs buried within. Compared with SWCNTs, the sidewall of MWCNTs had a higher charge density and an increased surface, resulting in a closer DNA association with the MWCNTs. The authors found  $>96\%$  of plasmid DNA is condensed by ammonium-functionalized MWCNTs at a charge ratio of 1:1.

Future developments in this fascinating application spectrum will depend on whether the specific synthesis methods and, afterwards, the defined functionalization for CNTs of a desired structure can be realized (Tables 11.6 and 11.7). According to the planned therapeutic application of fff-MWCNTs, the focus should be on the stepwise shortening of the length of the sidewall, the definition of a feasible amount of sidewall. In addition, the dependence of chemical reactivity on the detailed MWCNT structure is particularly interesting.

As well as investigation of the general toxicities of ff-MWCNTs, the principal biodistribution has been studied in a mouse model for the i.v. and i.p. administration route. For biological TEM analyses, different organs were fixed immediately after removal from sacrificed mice by fixating them in glutaraldehyde. Ultrathin slices were prepared as described recently by us [187]. Additionally, other samples of the same tissues were also collected, fixed in formaldehyde and embedded in paraffin for routine H&E staining and subsequent histological analyses.

The major goal of these studies was to investigate the short-term accumulation and distribution of the containers within the body. Furthermore, by histopathological investigations potential toxic effects after single or multiple *in vivo* administrations were assessed.

Recent results of both TEM and histological light microscopy studies indicate that aggregated to form clusters, independently of the localization site *in vivo* [187]. The aggregation can be observed even macroscopically after sonication and during injection. Therefore, the ff-MWCNTs can reach different tissues by diffusing through capillaries. The cluster sizes, detected by TEM, ranged from 0.5 to several microns. The structure of these clusters was identical to those found in cell culture incubation experiments. From the calculated sizes each cluster, mainly detected intracellular, may consist of several to hundreds or thousands of individual ff-MWCNTs. Remarkably, the tendency of *in vivo* formation of such large clusters did not influence the health conditions of the animals, and did not reduce survival. All animals ( $n = 14$ ) treated with different dosages of MWCNTs of both subtypes (once or several times) survived 150 days.

In several animals injected once with one of both types of ff-MWCNTs, the CNTs were detected within different cell types of different organs, including lung, heart, liver, colon or accumulated within the tissues (Fig. 9.40). Only in the minority of TEM positive samples were individual ff-MWCNTs found.

Moreover, after i.p.-injection low amounts of bundled ff-MWCNTs were also detected in feces. This observation needs further detailed investigation.

**Fig. 9.40.** Representative results of ff-MWCNTs detected by TEM analysis in different mouse organs 20 h after injections (i.v. or i.p.). (a) Lung section collected 20 h after i.v. injection of type 2 (mouse No 8, 9 weeks of age); magnification  $\times 7000$ . (b) Liver section collected 20 h after i.v. injection of type 1 (mouse No 4, 9 weeks old); magnification  $\times 7000$ . (c) Diaphragm section derived from

the same mouse as (b); magnification  $\times 7000$ . (d) Colon section collected 20 h after i.p. injection of type 1 (mouse No 6, 9 weeks old); magnification  $\times 7000$ . (e) Same as (d) but at magnification  $\times 32\,000$ . (f) Heart section collected 20 h after i.v. injection of type 1 (mouse No 3, 9 weeks old); magnification  $\times 4700$ . (g) Faeces collected 20 h after i.p. injection of type 1 (mouse No 15, 9 weeks old).

Other animals injected once or several times with doses of approximately 100–400  $\mu\text{g}$  ff-MWCNTs per injection survived more than 150 days without any indication of toxic or other adverse events. Analysis of the body weight indicated no influence of the administration of ff-MWCNTs on health condition.

Moreover, for example, several animals were sacrificed 6 weeks after first injections and analyzed by an experienced pathologist for potential alterations caused by the accumulation of ff-MWCNTs. In general, 6 weeks after the first injection ff-MWCNTs were detected cell-associated in most cases. Several microphotographs revealed an association of ff-MWCNTs accumulation with macrophages.

No formation of giant cells or granuloma was detected, indicating the absence of inflammation signs. The unrestricted localization of bundles and clusters of ff-MWCNTs was not associated with encapsulation of the accumulated tubes within the different tissues and organs. Especially in lung tissue specimens, the clusters were found near the alveolae and beside microvessels (Fig. 9.41). Interestingly, after i.p.-administration, in some cases tubes were also detected in the lung but in significantly lower amounts and number than after the i.v. administration.

**Fig. 9.41.** Detection of Fe-MWCNTs by H&E-stained histological slices of different mouse tissue 6-weeks after i.v. or i.p. administration. Black structures represent an accumulation of

Fe-MWCNTs. Lung section at a magnification of (a)  $\times 100$ , (b)  $\times 1000$ , (c)  $\times 10000$ , and (d) with accumulation of ff-MWCNTs in the alveole at  $\times 1000$ .

**Tab. 9.8.** Temperature developed during AC-heating in mouse tissue containing Fe-MWCNTs.

Time (min)	Mouse muscle ( $T/^\circ\text{C}$ )	Kidney from mouse ( $T/^\circ\text{C}$ )
0	28.0	29.2
5	40.5	40.0
10	42.6	40.7

The determined long-term accumulation of ff-MWCNTs in different organs and tissue indicated the biocompatibility of this compound over several weeks without dramatic toxicity. The comparable patterns of accumulation between short- and long-term treated animals showed the injected ff-MWCNTs can accumulate within hours and persist in these depot tissues without encapsulation.

Partially needle-like formations of bundles were detected. In the liver, low numbers of clusters of ff-MWCNTs were localized at the sinus.

In an additional experiment series the principle of ff-MWCNTs-mediated hyperthermia was tested using freshly explanted mouse tissue specimens. At seven months of age, one untreated mouse was sacrificed, and one kidney and muscle from the leg ( $5 \times 3 \times 3$  mm) was collected for heating analyses. After injection of approximately 10–20  $\mu\text{L}$  of freshly sonicated 0.9% saline containing type 1 ff-MWCNTs ( $20 \mu\text{g} \mu\text{L}^{-1}$ ) the heating potential was tested immediately using the device described in Section 9.5.3. A magnetic field of  $20 \text{ kA m}^{-1}$  was realized at a frequency of 230 kHz. The explanted tissue specimens were incubated in the magnetic field. The temperature was measured in the centre of the treated specimens at the beginning, after 5 and 10 min (Table 9.8). Remarkably, for both explanted tissues an increase of  $>10$  K was detectable after 10 min of treatment with  $<400 \mu\text{g}$  of ff-MWCNTs. In comparison with control experiments (applying the same magnetic field for equivalent tissue specimens without injections of ff-MWCNTs) the heat injection clearly confirmed our working hypothesis that ff-MWCNTs are useful for hyperthermia purposes. These pilot experiments *ex vivo* clearly showed that doses of lower than the mg range of ff-MWCNTs can mediate an intrinsic temperature shift to  $>40^\circ\text{C}$  after a couple of minutes of treatment.

The traditional approaches to hyperthermia, including radiofrequency, microwave and ultrasound, showed only limited efficacy in clinical studies because of (a) mediating of inhomogeneous temperature conditions, (b) difficulties in focusing in the target tissue, and/or (c) relatively high absorption of the heat by the intratumoral capillaries and connective tissues. The prostate as the target organ for local treatment primary PCa represents an extraordinary example because of the anatomy of the pelvis and the high perfusion of this gland.

Jordan et al. (Magforce GmbH, Berlin) have developed amino-silane-coated iron-oxide superparamagnetic nanoparticles with a mean diameter of 15 nm.

Aqueous ferromagnetic fluid (nanoparticles at a concentration of  $120 \text{ mg mL}^{-1}$ ) were injected directly in the target tissue and subsequently heated by intracellular hyperthermia. The particles were taken up efficiently by endocytosis. The so-called magnetic fluid thermotherapy (MFH) was proposed in principal as suitable for both local hyperthermia and thermoablation of PCa, since the intratumoral temperature conditions can be selected over a broad range by modulating the magnetic field. Moreover, in contrast to E-field dominant systems used for regional hyperthermia, the boundaries of differently conductive tissues do not interfere with power absorption in the MFH treatment.

In a subsequent animal study using orthotopically implanted MatLyLu-cells (Dunning R3327 model), magnetic fluid ( $200\text{--}400 \mu\text{L}$ ) was injected into the prostate tumors ( $0.5 \text{ mL per cm}^3$  of tumor). Immediately after injection, an AC field was applied ( $100 \text{ kHz}$ ,  $0\text{--}18 \text{ kA m}^{-1}$ ; gradually increased field strength from 45% to 70% over a period of 17 min, heat treatment at 70% field strength for 30 min) using the MFH 12-TS (MagForce Nanotechnologies GmbH, Berlin) [197, 198]. By intratumoral temperature control, the authors described mean maximal temperatures of up to  $58 \text{ }^\circ\text{C}$ . The observation that  $>85\%$  of the nanoparticles were retained in the prostate 10 days after injection indicates that repeated thermal treatment is possible. Afterwards, external radiation of  $20 \text{ Gy}$  was applied. Combined thermoradiotherapy resulted in a higher inhibition of tumor growth than radiation with the same dose alone. The combinational treatment was as effective in tumor growth control as radiation therapy alone with a three-times higher dose.

Recent data from a phase I clinical study has been used to evaluate the toxicity and tolerability of MFH using a novel hyperthermia- and thermoablation-system (MFH 300F) [174] in PCa patients [147]. To our knowledge, this is the first report of the clinical application of interstitial hyperthermia using magnetic nanoparticles in the treatment on human carcinomas. A patient with locally progressive growing PCa following a high dose brachytherapy received a total of  $12.5 \text{ mL}$  of magnetic fluid in 24 depots (each of  $0.5 \text{ mL}$ ) in the prostate (intraperineal injection under rectal ultrasound control and fluoroscopy guidance) with an approximate volume of  $35 \text{ mL}$ . Thermotherapy was applied using an initial magnetic field strength of  $2.5 \text{ kA m}^{-1}$ , which was gradually increased to  $5 \text{ kA m}^{-1}$ , and was kept constant for one hour. Five subsequent MFH applications took place at weekly intervals. The maximum intra-prostatic temperatures determined ( $48.5$  and  $42.2 \text{ }^\circ\text{C}$  during the first and second treatment, respectively) achieved were in the thermoablative range.

It was assumed that for sufficient heating of the prostate gland, and ideally a homogenous distribution of the nanoparticles field strength of  $10 \text{ kA m}^{-1}$  toxicity,  $0.2 \text{ mL}$  of the magnetic fluids per  $\text{mL}$  of tissue volume is necessary to guarantee an  $\text{SAR}_{\text{tissue}}$  of  $300 \text{ W kg}^{-1}$ . However, the measured particle distribution within the tumor tissue was sub-optimal and must be improved.

As side effects, the patients experienced local pain several times (especially when the field strength was  $>5 \text{ kA m}^{-1}$ ) and moderate bladder spasms occurred after the first treatment cycle.

Moreover, in this report the authors also described preliminary experiences in

glioblastoma and recurrent soft-tissue sarcomas of the ongoing phase I study. Interestingly, the particles are retained in the PCa tissue for at least several weeks.

The authors conclude that this observation represents an important pre-requisite for the clinical application of MPH in locally advanced PCa.

In comparison, an aqueous solution of ff-MWCNTs *per se* represents a homogeneous population of particles based on the principles of their synthesis. This could be a major advantage over superparamagnetic particles for a cost-effective clinical use as thermal transmitters.

This development of nanoscaled containers, including the proposed fff-MWCNTs, opens a new chapter in the field of anticancer therapeutic concepts based on nanotechnology. Further steps of evaluation and optimization must undergo very different and detailed tests to ensure their therapeutic efficacy and mechanical stability and safety after local implantation or systemic injection. Progress in medical device technology is strongly linked to progress in material science technology, and new combinations of different materials that have been developed for different application in human medicine have influenced the design, and also the structural, chemical and biological properties of CNTs.

### Acknowledgments

The authors thank Brigitte Hamann for TEM and Dr. M. Haase (both from the Institute of Pathology, Technical University Dresden) for histopathological studies, and Dietmar Meiler (IFW Dresden) for expert technical assistance. We thank Dr. Gerd Hammermann (HAMSTEIN-Consult, Dresden, Germany) for helpful cooperation and Systemanix GmbH (Dresden, Germany) for support. Furthermore, we are thankful to Kai Krämer, and to Dr. Vladimir Novotny for participation and support in animal experiments. The ff-MWCNTs were synthesized and characterized by Dr. Manfred Ritschel, Radinka Kozhuharova-Koseva, Dr. Silke Hampel and Christian Müller. The magnetic measurements were performed by Dr. Dieter Elefant. We thank Kai Krämer and Vicky Rutschmann-Will for critical language editing. The project was generously supported by Prof. Dr. M.P. Wirth (Head of the Department of Urology, Technical University Dresden) and by Prof. Dr. B. Büchner (Head of the Institute for Solid State Research; IFW Dresden).

## 10 Liposomes, Dendrimers and other Polymeric Nanoparticles for Targeted Delivery of Anticancer Agents – A Comparative Study

Yong Zhang and Dev K. Chatterjee

### 10.1 Introduction

Cancer management through chemotherapy, surgery and radiotherapy often fails because of high toxicity and poor target selectivity. Nanotechnology, through the synthesis and modification of nanoparticles, has the potential to overcome these barriers by providing drug molecule stability in circulation, reduced toxicity and better targeting of tumors.

Several excellent reviews deal with the anti-tumor activities of nanoparticles. A look at recent ones in this fast changing field shows that most have tackled the wider issue of nanotechnology as a tool against cancer. In an excellent review, Ferrari has dealt with the whole field of cancer nanotechnology, including *in vitro* diagnostics as well as *in vivo* targeting [1]. In a very recent review Jain (of Jain PharmaBiotech in Switzerland) has focused on the field of “nanobiotechnologies” and its effect on drug delivery in cancer [2]. The same author has also reviewed nanotechnology in the setting of the diagnostic clinical laboratory [3]. Another recent review, by McNeil, deals more widely with the ramifications of nanotechnology for the biologist [4]. A similar review by Fortina et al. details the uses and promises of nanobiotechnology in the whole field of molecular recognition, mainly for enhanced *in vitro* molecular diagnostics [5]. As these and other examples show, most reviews deal either with the wider aspects of nanotechnology or with different subsets.

This chapter focuses specifically on the targeting of drug-loaded nanoparticles to tumor sites. This is perhaps the most important aspect of anticancer therapy with nanoparticles. However, even with a wish to limit ourselves to detailing the means of targeting nanoparticles and discussing and comparing current reports about the three major types of nanoparticles, we find it imperative to include short introductions, wherever applicable, so that even recent entrants to the field can peruse this chapter.

Nanoparticles that are currently under consideration as drug delivery vehicles can be considered to be of three major types: liposomes, dendrimers and other polymeric nanoparticles. When modified with certain chemicals, mainly poly(ethylene

glycol), they enjoy long circulation times and selectively accumulate at tumor sites due to an enhanced permeation and retention (EPR) effect. When a targeting ligand or antibody is attached this selectivity is enhanced. Suitable targets include antigens of the neo-angiogenic process associated with tumor growth, altered antigens specific for tumors (tumor specific antigens) and growth factor receptors such as transferrin and folic acid receptors. Drugs delivered to the site include conventional anti-neoplastic drugs such as doxorubicin and paclitaxel, and also other biological response modifiers such as cytokines and antibodies. Corporate interest in the future of this technology has resulted in a few start ups that have already marketed a few anti-tumor nanoparticles formulations; hope for a better future is appreciably high.

Section 10.2 deals with the effectiveness of chemotherapy and other conventional therapies and discusses their limitations in halting tumor growth. We introduce the concept of targeted drug delivery in Section 10.3 and elaborate on targeting ligands in Section 10.4. Section 10.5 deals with the achievements of each of the three major types of nanoparticles. Section 10.6 wraps up the review with a look at the overall picture that is emerging and ends on an optimistic note.

## 10.2

### Cancer Chemotherapy: so Far, but not so Good

The fundamental differences between cancer cells and normal human cells are still not clear. None of the empirically developed anti-neoplastic drugs in conventional use appear to involve a mechanism or target that is completely unique to the cancer cell. They appear to achieve some degree of selectivity in their action by acting on certain characteristics that are found altered in cancerous tissues as compared to normal ones. These include a rapid rate of cell division, differences in the rate of uptake of or the sensitivity to the drug in different types of cells, and occasional presence in the cancer cells of hormonal responses characteristic of the original cells from which they developed.

All cells undergo divisions in a cyclical manner. This cell cycle has been divided into several phases. Very broadly, cells can undergo DNA synthesis (S phase) and mitotic and cytokinetic activity (M phase) while dividing; or can be in a dormant non-dividing state ( $G_0$  phase). Anti-neoplastic drugs can be broadly classified according to whether they are cycle sensitive or insensitive. Cycle sensitive agents act on dividing cells, during the M or S phase, and have first-order kinetics and exponential dose–response curves. They are highly active on rapidly dividing tumor cells, but fail to kill cells that are dormant or dividing slowly.

The selection of drugs for a particular cancer depends on several factors: the type of cancer, the stage and grade of the tumor, the condition of the patient, and the ability to afford the therapy. The selected regimen may aim for palliation, i.e., reduction in the severity or extent of the disease, or remission, i.e., complete absence of cancerous growth clinically and with laboratory tests. Current cancer therapy suffers from the serious disadvantage of high toxicity to the patient's normal body

tissues. The effectiveness of therapeutic regimens has to be balanced against their side effects. Poor selectivity for cancer cells by the anticancer drugs is the underlying cause.

The major reason for poor selectivity is the relative paucity of marker molecules that will unequivocally distinguish neoplastic from non-neoplastic cells. Most cancer chemotherapeutic drugs interfere with the mechanism of cell division. Some cancers are intrinsically highly drug-sensitive, such as childhood acute lymphoblastic leukemia (ALL), Hodgkin's disease, some non-Hodgkin's lymphomas, and testicular cancer. For these, relatively lower doses of chemotherapy may be effective. However, for most other cancers, promiscuous interaction of significant amounts of potent drug molecules with normal cells cannot fail to have serious consequences. The immune system, hematopoietic system and the internal lining of the gastrointestinal tract are the major sufferers as they have the highest cell turnovers. Side effects of therapy can be acute or delayed. Acute complications include nausea, vomiting, diarrhea, anorexia, allergic reactions and anaphylaxis. Delayed toxicities include myelosuppression, which can cause neutropenia and repeated infections, anemia from multiple causes, and hemorrhagic manifestations from thrombocytopenia. As a consequence of all these, and perhaps other unknown causes, the patient may develop a severe form of cachexia that is almost exclusively found in advanced cancers.

To avoid or reduce toxicities, several approaches have been adopted. Supportive therapy in cancer aims to reduce the specific toxicities of the drugs. Potent antiemetics for gastrointestinal toxicities, diuretics for nephrotoxic agents such as cisplatin, anti-histaminics for allergic reactions, and the more recently introduced recombinant therapies such as erythropoietin and GM-CSF to treat myelosuppression are a few examples. Another is the use of several drugs at lower doses for a single cancer, rather than a single drug in high doses. Multidrug regimens, or protocols, have become the norm in cancer treatment. This is advantageous because the anticancer effects of the drugs will be additive when the drugs have different mechanisms of action, while the side effects will be distributive if their toxic effects are on different cells. Combination of a cycle-specific and non-specific drug may prevent tumor resistance by killing actively dividing as well as dormant cells. Combination chemotherapy also suppresses drug resistance, which is another major drawback of conventional chemotherapy.

Drug resistance, or the lack of responsiveness to the chemotherapeutic agent, can be due to several causes. The drug may not be reaching the tumor site at effective concentrations, either because of poor blood flow, or even after reaching the site may not achieve high enough concentration in the cell due to poor absorption, metabolic degradation, or rapid excretion from the cell (pharmacokinetic resistance). Failure to achieve total cell kills result in cytokinetic resistance: a population of survivors serve as source for repeated proliferation of the tumor. Tumor cells can evolve under these conditions to develop biochemical resistance by altering uptake and target molecules, developing or upgrading drug metabolism and excretion pathways, increasing the intracellular concentration of the drug-affected molecule, or incorporating protective genetic changes.

When multidrug regimens are not effective on their own, they are supplemented with radiotherapy and surgery. Unfortunately, radiotherapy also has the same depressive effect on the immune system and dividing cells, and results in nausea, vomiting, diarrhea and anemia. Surgery in early stages in some cancers can be curative, with only limited associated morbidity and very low fatality. However, most deep-seated cancers in the body are detected after they have metastasized, while some cancers, notably those of intracranial origin, are not easily approachable surgically, and carry high mortality and morbidity risks. Various ingenious combinations of the above, such as adjuvant (and neo-adjuvant) chemotherapy and radiotherapy with surgery to reduce tumor size or treat disseminated tumor cell nests, have been used to maximize the benefit to the patient.

In recent years, in recognition of the limited success of “classical” chemotherapy to treat cancers, several new methods have been investigated. Most important among them are gene therapy for correcting the altered genetic profile in cancer cells; and the biologic response modifiers that aim to enhance the innate anti-tumor immunity of the human body. Nonspecific immune modulators like BCG (for bladder cancer) and cimetidine (for melanoma) have shown limited efficacy. Better results have been obtained with the introduction of lymphokines and cytokines (IL-1, IL-2, TNF and more recently CCL21). These are natural human molecules produced in minute quantities for the purpose of signaling among immune cells. However, nonspecific use of these cytokines, especially IL-2 and TNF, has shown unacceptable levels of toxicity. This is primarily because of the short half-lives of these small molecules. To achieve acceptable levels inside the tumor micro-environment, very high doses need to be introduced: a common theme in cancer therapy regimens. A way to increase the stability of these molecules in circulation, along with the means to target them to selective neoplastic tissue, has become the current need.

### 10.3

#### **Nanoparticles and Drug Delivery in Cancer: a new Road**

##### 10.3.1

##### **Importance of Nanoparticles in Cancer Therapy**

Nanotechnology, especially nanoparticulate drug delivery systems, may provide the solution to the problems facing current cancer therapy. Nanoparticles can be defined as spherical (or spherical-like) particles with at least one dimension less than 100 nm [6]. The history and technology involved in nanoparticle synthesis can be found elsewhere (e.g. [6]). Nanoparticles, along with liposomes and block copolymer micelles, form the group of submicron sized colloidal systems used as targeted drug delivery vehicles (Fig. 10.1). Their small size allows intravenous administration without the risk of embolization, and passage through capillary vessels [7] and mucosae [8], while affording special properties of large surface

**Fig. 10.1.** Types of nanoparticulate drug delivery systems and their common targeting methods. Left to right: Liposomes with enclosed drug molecules; other polymeric nanoparticles, and dendrimers.

area, significant surface properties, greater solubility (especially for oil-based drugs) and better tissue adhesion [9].

Nanoparticles can have several roles in cancer therapy. They can be useful in targeting the tumor and achieving local therapeutic concentration of the toxic drug while keeping circulating levels of free drug fairly low, thus reducing systemic toxicity. They can stabilize lipophilic drugs in circulation, and help them enter previously inaccessible regions of the body like the central nervous system by crossing the blood–brain barrier, and treat previously untreatable tumors and reach “tumor sanctuaries”. They can increase the circulatory period of drugs by controlled release, thus overcoming the toxicity associated with initial high concentrations in periodic doses. They can also, conceivably, overcome multidrug resistance by a combination of these effects [6]. Apart from their therapeutic benefits, nanoparticles – as fluorescent nanoparticles and quantum dots – can also help in the early detection of tumors.

Therapeutic effects of nanoparticles can be achieved by “physical”, “chemical” or “biological” means. Physical means include the recently developed methods of hyperthermia and magnetic therapy. Chemical means include the delivery of more conventional chemotherapeutic drugs to the tumor sites. Biological response modifiers like immunotherapeutic agents are also gaining favor.

It is debatable whether the term “nanoparticles” applies only to the more recently developed polymeric nanoparticles or if, applying the definition in a broader sense, it should encompass block copolymer micelles and liposomes. Taking the emerging field of targeted drug delivery to cancer as the leit motif of this chapter, and acknowledging the significant roles played by both these types of “nanoparticles” in the development of this important branch of cancer therapeutics, we have included short subsections on both. The reader will thus get a better overview of the current state of knowledge and can peruse the reference section to further his/her interest. However, henceforth, we use the term “nanoparticles” in the narrower sense of polymeric spherical coiled particles, whether modified or unmodified.

## 10.3.2

**An Overview of Targeting Methods**

In this chapter we concentrate on the methods and materials by which nanoparticles are targeted to neoplastic tissue. Targeting can be loosely defined in this context as any means that increases the specificity of localization of nanoparticles in tumor cell masses. Targeting does not intrinsically imply improved sensitivity but, as we shall see, the different methods employed to increase the specificity allow administration of higher doses of the drugs, thus also favorably increasing sensitivity. Also, as mentioned earlier, the ability of nanoparticles to cross the blood–brain barrier and other impediments to conventional therapy increases its volume of distribution. This also results in increased sensitivity.

Targeting can be divided into two major types – passive and active. Passive targeting involves modifications of nanoparticles that increase the circulation time without addition of any component/involvement of any method that is specific to the tumor; increased circulation time helps in accumulation of the particles in the tumor by an EPR effect described below. Active targeting of tumors can be divided into “physical” and “chemical/biological” targeting. Physical targeting involves directing magnetic nanoparticles to tumor sites under the influence of an external magnetic field. Chemical/biological targeting involves the modification of nanoparticles’ surfaces with tumor-specific ligands.

Notably, any of these methods can be used in conjunction with others. For example, common modifications for passive targeting, such as PEGylation, are frequently used with more “active” modifications like antibodies. The methods are almost independent of each other, and can be judiciously combined to increase the effectiveness of the drugs.

This chapter does not deal extensively with the magnetic therapy of cancer and induced hyperthermic killing of tumor cells (see Chapters 5, 8 and 9). However, in keeping with the idea of overviewing the whole field of targeting, we have incorporated a short discussion of physical targeting by magnetically directing particles to tumor tissues.

## 10.4

**Means to the End: Methods for Targeting**

## 10.4.1

**Passive Targeting**

Here we must make a clearer distinction between what can be described as “active” and “passive” targeting. In general terms, a targeted drug can be defined as one modified in a fashion that allows its preferential uptake in the desired cells/tissues, in this case cancer. Evidence has been provided that many nanoparticles, especially long circulating ones, will show a preferential distribution to cancer sites over healthy tissues, even without any specific targeting molecule. This was demon-

**Fig. 10.2.** The enhanced permeation and retention (EPR) effect accumulates nanoparticles to tumor sites without active targeting.

strated for the first time by Matsumura and Maeda [10]. This is likely due to the increased vasculature of these regions, larger fenestrations in the capillary walls for rapid delivery of nutrients, general disordered architecture that is symbolic of the neoplastic process, and the reduced lymphatic drainage in these regions. All these factors lead to the enhanced permeation and retention effect (EPR) [11, 12] (Fig. 10.2). This fortuitous distribution has been taken advantage of by numerous researchers in designing targeted drug delivery systems. As an example, in a recent study tamoxifen was encapsulated in poly(ethylene oxide)-modified poly( $\epsilon$ -caprolactone) (PEO-PCL) nanoparticles and administered to a murine model of breast cancer [13]. The poly(ethylene oxide) (PEO) coating made it a “stealth nanoparticle”, i.e., able to avoid detection by the body’s MPS system for a considerable time. The PEO surface modified nanoparticles showed significantly increased levels of accumulation within tumor with time than did the native drug or surface unmodified nanoparticles. An earlier effort by one of the authors to incorporate tamoxifen in nanoparticles for preferential uptake by estrogen receptor (ER) positive breast cancer cells had been shown to be successful *in vitro* [14]. However, to translate that success *in vivo*, a long-circulating nanoparticle was necessary. Another current example is the incorporation of cisplatin in liposomal formulations [15] with poly(ethylene glycol) (PEG) coating for gastric tumors: in preclinical and clinical trials, this formulation has been demonstrated to have longer half-life in circulation without the attendant side effects.

This targeted distribution of nanoparticles, together with the controlled release of anticancer drugs, can bring about a type of “passive” but effective targeted delivery. The other type of targeting is by specific ligand–receptor interaction. Possibly,

better specificity and sensitivity can only be achieved by this more “active” means. However, the introduction of a biological entity on the surface of the nanoparticle can create several problems: the size and complexity will increase, with attendant complexities of synthesis and characterization; the biomolecule may react adversely with the immune system or any of the other myriad proteins in the blood and tissues. This may give rise to unpredictable adverse reactions.

However, potential advantages include the ability to deliver larger amounts of drug per target biorecognition event; increase selectivity by including more than one type of targeting molecule, better avoidance of barriers by using different avoidance methods and the ability to administer “localized integrated combination therapy” by including multiple drugs in the same nanoparticle [1].

A method for enhancing this passive delivery to the cancer using nanoparticles is by the use of pH- and heat-sensitive nanoparticles. The fact that the pH in the region of cancerous growth is lower than in the rest of body, while the temperature is raised locally because of enhanced metabolism and ongoing inflammation, has been used to design pH-responsive nanoparticles: a lower pH causes enhanced drug release. Wei et al. have given a recent example of this [16]. The temperature- and pH-sensitive amphiphilic polymer poly(*N*-isopropylacrylamide-*co*-acrylic acid-*co*-cholesteryl acrylate) [P(NIPAAm-*co*-AA-*co*-CHA)] was synthesized and used to encapsulate paclitaxel in core-shell nanoparticles fabricated by a membrane dialysis method. The spherical nanoparticles are below 200 nm and have a pH-dependent lower critical solution temperature (LCST). *In vitro* release of paclitaxel from the nanoparticles was responsive to external pH changes, and was faster in a lower pH environment.

#### 10.4.2

#### Magnetic Targeting of Nanoparticles

Magnetic drug targeting has been defined as “the specific delivery of chemotherapeutic agents to their desired targets, e.g., tumors, by using magnetic nanoparticles (ferrofluids) bound to these agents and an external magnetic field which is focused on the tumor” [17]. This type of tumor targeting is aimed at concentrating the toxic drug at the cancer, hence enhancing its efficacy and reducing systemic side effects from high doses.

Gilchrist et al. described the first magnetic nanoparticles in 1957 [18]. These are generally 10–200 nm in diameter, magnetic or superparamagnetic and usually composed of iron oxide, magnetite, nickel, cobalt or neodymium; of these, magnetite ( $\text{Fe}_3\text{O}_4$ ) and maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ) are more biocompatible and preferred. Iron oxide is degradable in the body and has been shown to be safe for *in vivo* applications [6]. However, to be effective, magnetic nanoparticles should demonstrate high magnetization for external magnetic field control and should exceed linear blood flow rates of  $10 \text{ cm s}^{-1}$  in arteries and  $0.05 \text{ cm s}^{-1}$  in capillaries. For this purpose, particles composed of, for example, 20% magnetite require a field of 0.8 Tesla. Tissue depth is a limiting factor in active targeting, with deeply localized tumors being hard to access.

Lubbe et al. have utilized a complex of 4-epirubicin bound to ferrofluids in the treatment of squamous carcinoma of the breast or head and neck [19]. They used a field of 0.5–0.8 T at the tumor site while infusing the particles. Results showed accumulation in tumors in 6 of 14 patients with reduced toxicity, a transient rise of serum iron, but no demonstrable damage to kidney or hepatic function. Alexiou et al. have used mitoxantrone complexed to 100 nm ferromagnetic particles against VX2 squamous cell carcinoma among rabbits to demonstrate the superiority of intra-arterial infusion to other routes of delivery, especially the intravenous route where the particles are removed from circulation by the reticulo-endothelial system [20]. They have also demonstrated that circulating mitoxantrone becomes concentrated at the tumor tissue when complexed to ferrofluids; a higher concentration of the complexed drug (compared to the free drug) is achieved at the tumor site using only a half to one-fifth dose [17]. The drug mainly resides in the intraluminal space, the tumor interstitium and peritumoral area (region surrounding the tumor  $\leq 1$  cm). Other researchers have investigated ferrous nanoparticles in glioblastoma (a tumor of the brain), and demonstrated that these particles effectively cross the blood–brain barrier [21].

The clinical applications of magnetic drug targeting have been reviewed in more detail [22].

#### 10.4.3

#### **Ligands for Active Targeting**

Cancer cells arise from normal cells through a complex series of genetic events. Unlike infectious agents like bacteria, they largely share the same proteins as normal cells. However, some proteins are found in much larger numbers on cancer cells than in normal cells [23]. These overexpressed antigens are called tumor-associated antigens (TAA). Some proteins derived from normally silent genes or mutated forms of normal proteins are found exclusively on cancer cells. These are known as tumor-specific antigens (TSA). The obvious targets for targeted cancer therapy are TSAs. However, TSAs are often difficult to characterize for a particular tumor. When found, they are usually not extensive, i.e., they are not found in all patients affected by the tumor, nor are they found in all the cells in a particular tumor in the same patient. The aberrantly expressed tumor specific antigens are produced by aberrant glycosylation in glycolipids, glycoproteins, proteoglycans, and mucin [24]. For example, the glycosylation pattern of MUC1 membrane mucin of breast cancer epithelial cells differs from normal breast epithelial cells, possibly as a result of changes in expression of glycosyltransferases [25]. TAG-72 is a mucin-like tumor-associated glycoprotein [26] that is found in some epithelial tumors. Melanoma cells aberrantly express GM3 ganglioside on their surface [27]. Gastrointestinal cancer cells abnormally express LeX antigens [28].

Tumor-associated antigens are often growth factor receptors on the tumor that are overexpressed to meet the rapidly dividing neoplastic cells' demands. A classic example is folic acid and congeners. These are low molecular weight pterin-based

**Fig. 10.3.** Cancer cell antigens are targeted with monoclonal antibodies; ligands such as folic acid and transferrin also show specificity.

vitamins essential for carbon metabolism and *de novo* nucleotide synthesis. The presence of elevated levels of folate receptors has been demonstrated from epithelial tumors of various organs such as the colon, lungs, prostate, ovaries, mammary glands, and brain [29–40]. These present attractive targets for drug delivery. Another promising tumor receptor target is Her2<sub>neu</sub>, also known as c-erbB-2. This is a transmembrane protein with an epidermal growth factor receptor that possesses intrinsic tyrosine kinase activity [41–43]. The normal human Her-2<sub>neu</sub> proto-oncogene is frequently found to be overexpressed in breast and ovarian cancers among others. Its level may correlate with the metastatic potential of the cancer cells [44, 45].

Another such membrane-associated tumor antigen is the transferrin receptor. This is overexpressed in different types of cancers [46]. The levels may also correlate with the malignant potential of these cells [47] (Fig. 10.3).

The presence of various other tumor antigens has been demonstrated: membrane-associated Carcinoembryonic antigen; CD10 or CALLA in leukemias, melanomas and myelomas [48, 49]; CD20 in B cell malignancies [50]; etc. Many others are being recognized routinely. They all represent potential goals for targeted drug delivery.

#### 10.4.3.1 Monoclonal Antibodies against Tumor-specific Antigens

Specific targeting became a possibility with the discovery of monoclonal antibodies in 1975 [51]. As the name suggests, these are antibodies derived from a single clone of cells. They can be mass produced in the laboratory from a single clone and recognize only one antigen. Monoclonal antibodies are usually made by fusing a short-lived, antibody-producing B cell to a fast-growing cell, such as a cancer cell. The resulting hybrid cell, or hybridoma, multiplies rapidly, creating a clone that produces large quantities of the antibody. It was hoped that monoclonal antibodies would be able to target specific antigens on the surface of cancer cells, and initially

raised high hopes for targeted cancer therapy. Animal-origin monoclonal antibodies such as murine antibodies were strongly immunogenic; to avoid this, chimeric antibodies [52] and humanized antibodies [53, 54] were produced. More recently, completely human monoclonal antibodies and single-chain human antibody fragments [55] have been introduced for immunotherapy and targeted drug delivery.

Antigen targets for monoclonal antibody therapy (or for any other targeted anti-cancer therapies) must have the property of specificity, i.e., present only on the cancer cell surface and be absent from the surfaces of all normal cells; they should be extensive, i.e., present on all the cells in a given tumor, preferably on all such tumors in every patient; there should not be any mutation or structural variation of the antigen; and they should be preferably involved with a critical function of the cell, so that adaptive response of the cancer to therapy by losing the antigen can be prevented [56]. However, naturally, such a perfect antigen is rarely, if ever, found. Several good candidates have been discovered, and monoclonal antibodies against these have been marketed. Examples include anti-CD20 antibody for relapsed/refractory CD20 positive B-cell non-Hodgkin's lymphoma and low-grade or follicular-type lymphoma, anti-CD53 antibody for relapsed/refractory AML, and anti-CD52 antibody for B-cell chronic lymphocytic leukemia [56, 57]. Recently, Zhou et al. have utilized BDI-1 monoclonal antibodies to target highly toxic to bladder cancer cells *in vitro* [58]. To improve therapeutic efficacy and decrease toxicity, we prepared arsenic trioxide-loaded aluminates immuno-nanospheres [As<sub>2</sub>O<sub>3</sub>-(HAS-NS)-BDI-1] targeted with monoclonal antibody (McAb) BDI-1 and tested its specific killing effect against bladder cancer cells.

**Identifying Monoclonal Antibodies** One strategy to identify ideal targets for monoclonal antibodies is to select the internalizing antibodies from phage libraries; accordingly, two antibodies to the breast cancer cell line SK-BR-3 which bind to ErbB2 have been identified [59]. Nielsen et al. have demonstrated the use of single-chain Fv (scFv) antibodies for internalization of nanoparticles in target cells [60]. The antibodies were recovered from a non-immune phage library and the scFv specific for ErbB2 (F5) was re-engineered and attached to liposomes. Doxorubicin loaded in these immunoliposomes was selectively active on ErbB2 positive breast cancer cells and showed targeted cancer cell cytotoxicity.

Liu et al. have described a method to map the "epitope space" of a tumor using monoclonal antibody libraries [61]. The expressed epitopes on the cell surface, which constitute the "epitope space", is essential to targeted drug delivery. This is "highly complex, composed of proteins, carbohydrates, and other membrane-associated determinants including post-translational modification products, which are difficult to probe by approaches based on gene expression" [61]. The authors used monoclonal antibody libraries against prostate cancer cells and identified over 90 antibodies, which bind to the cancer cells selectively, with little or no binding to normal human cells. This approach does not attempt to identify the tumor-specific antigens, but rather takes a functional approach to the problem of tumor-target identification.

**Fig. 10.4.** Monoclonal antibodies against cancer were originally used either by themselves (A) or attached to drug molecules (B). However, attachment to nanoparticles (C) provides longer circulation times and lower toxicity.

**Monoclonal Antibodies and Nanoparticles** Monoclonal antibodies were initially hailed as therapy for cancers in their own right (Fig. 10.4). To introduce more cancer cell killing ability, they can also be conjugated with anticancer drugs. This complex can also be formulated as a prodrug, which is cleaved to release the anticancer agent at the cancer site. Usually, the link between the molecules would be peptidase cleavable, in order to separate inside the cancer cell. However, such formulations are not very stable *in vivo*, and may undergo early cleavage. The absence or reduction of cleavage at the site will, clearly, lower the potency of the anticancer agent.

The greatest difficulty in using monoclonal antibodies for cancer therapy is their rapid clearance from the bloodstream by the immune mechanisms of the body. Li et al. have estimated that <0.01% of the administered dose of antibodies reaches the target sites [62]. This has two serious drawbacks: firstly, monoclonal antibodies are relatively costly, and a large dose of the therapy becomes prohibitively expensive; secondly, the excess antibody can have serious toxic effects on rest of the patient's body. As we discussed in the introductory section on chemotherapy, this problem, in various proportions, dogs all current therapies of cancer. Hence, monoclonal antibodies by themselves provide no advantage over general anticancer drugs. Attachment of the molecules to nanoparticles circumvents some of these problems.

#### 10.4.3.2 Targeting the Angiogenic Process

Judah Folkman discussed one of the prime candidates for targeted cancer therapy, angiogenic factors, in 1989 [63]. Cancer cells require a significant amount of nutrition to keep growing and reproducing. To obtain this they promote the ingrowth of capillary vessels into the tumor site. This is known as angiogenesis. Tumor cells secrete chemicals that promote angiogenesis. Since active promotion of angiogenesis is unnecessary in most body cells, the associated antigens are of interest

in targeted therapies. The anti-VEGF (vascular endothelial growth factor) drug Avastin® has shown moderate effectiveness in several solid tumors. This has led to a gene-therapeutic approach to anti-angiogenesis using liposomes [64] and cationic nanoparticles [65]. In the latter, an integrin-targeting ligand was used for specific delivery of a mutant Raf gene, and selectivity was demonstrated.

Hallahan et al. have described novel targets that depend on targeting radiation-induced neoantigens in the cancer microvasculature [66]. They demonstrated the presence of an RGD-containing amino acid sequence in phage-displayed peptides obtained from irradiated tumors. This peptide binds to integrins. Immunohistochemical examination confirmed the presence of the fibrinogen receptor integrin in irradiated tumors. Targeting this receptor by fibrinogen-containing nanoparticles showed enhanced anti-tumor effects.

The Intradigm Corporation (MD, USA) has utilized the RGD sequence attached to PEG to target their siRNA-containing nanoparticles to the integrins present in the tumor microvasculature [67]. The siRNA provide potent selective gene inhibition with high specificity. They delivered siRNA-inhibiting vascular endothelial growth factor receptor-2 (VEGF R2) expression and, thereby, tumor angiogenesis to a mouse tumor model using PEI-PEG nanoparticles. The siRNA was found to be active in a highly cell-selective manner. They demonstrated that selectivity could be incorporated in the drug itself, along with the ligand–receptor interaction.

Nucleic acid conjugates have been favored as targeting ligands for their exquisite specificity for the targeted molecule. Farokhzad et al. have utilized nucleic acid ligands (aptamers) to target cells expressing prostate-specific membrane antigen, a tumor marker for prostate cancer acinar epithelial cells [68]. They created PEG-containing PLA nanoparticles that bind to aptamers by surface negative charge. These aptamer conjugated nanoparticles showed 77× greater uptake by the cancer cells than unmodified nanoparticles.

Other efforts [69] have demonstrated nanoparticle targeting to angiogenic epithelium using the  $\alpha_v\beta_3$ -integrin, which is found on endothelial cells. Anti-angiogenic effects were demonstrated in mouse models of melanoma and adenocarcinoma.

#### 10.4.3.3 Folic Acid and Cancer Targeting

Perhaps the most interesting molecule to attract attention for its targeting abilities in recent times is the humble folic acid. Most normal human cells take up this molecule in its reduced form (Fig. 10.5). One of the notable exceptions is the

Fig. 10.5. Molecular structure of folic acid.

luminal sides of the gut endothelial layer, which take up the folic acid present in food, convert it into folate, and release it into our bloodstream. Many types of cancer cells, however, take up folic acid in its oxidized form. Since intravenously administered nanoparticles will only come into contact with the abluminal side of the gut epithelium, selectivity for tumor cells is very high. As mentioned above, several endothelial tumors (e.g., derived from the ovaries, mammary glands, colon, lungs, prostate and brain) possess elevated levels of folic acid receptors on their surface [29, 30, 32, 33, 36–40]. Already, a large body of research has accumulated regarding the use of folic acid receptors as cancer targets. Since folic acid, the natural choice for ligand to the folic acid receptor, can be quite easily coupled to the nanoparticle surface, it has been used for targeting these to cancer cells.

Hattori and Maitani have reported *in vitro* studies of folate-linked nanoparticles in human cancer cells [31]. They synthesized DC cholesterol–Tween 80 nanoparticles with incorporated folate-PEG conjugates for steric stability and targeting. The nanoparticles were complexed with plasmid DNA. They showed enhanced uptake in human oral cancer cells by a folate-dependent route. Human prostate cancer cells also showed high uptake of the nanoparticle–DNA complexes. However, based on their results, the authors suggest that the route of uptake may be different for the two cell types.

Oyewumi and Mumper have reported the cellular uptake, distribution and tumor retention of folate-coated and PEG-coated gadolinium nanoparticles in mice models of human nasopharyngeal carcinomas [34]. While this was more for imaging than therapeutic purposes, their results also indicate the efficacy of using folate as a targeting agent. Baker et al. at the Center for Biologic Nanotechnology, University of Michigan Medical School have focused on the use of dendrimers as targeted delivery vehicles (described in detail later). They used folic acid as targeting element to deliver a triplex-forming growth-inhibitory oligonucleotide to breast, ovarian and prostate cell lines [35]. A very recent example of folic acid receptor targeting in squamous cell carcinoma has been demonstrated by Santra et al. [70], who employed a novel technique that uses fluorescent silica nanoparticles (FSNPs) to detect overexpressed folate receptors.

Folic acid targeting to cancer cells has also been demonstrated in our own Cellular and Molecular Bioengineering Laboratory in the National University of Singapore. Although the use of folate as a targeting agent has been extensively reported, little has been done to continuously track the intracellular delivery of nanoparticles grafted with folate using imaging techniques such as confocal microscope. This is possibly due to the short lifetime of most biological fluorescent labels. The problem has been tackled using quantum dots (QDs).

QDs have several advantages over conventional fluorescent dyes and proteins like the Green Fluorescent Protein. They exhibit a strong fluorescence emission, a broad absorption spectra and a narrow, symmetric emission spectrum, and are photochemically stable. The most exciting finding is that QDs also exhibit a wide range of colors, which is exquisitely controlled by their size; a broad absorption spectra means that a series of different-colored dots can be activated using a single laser. These properties of QDs raise the possibility of using them to tag biomole-

cules with an optical coding technology. This can, for example, create QD bar codes, and the use of six colors and ten intensity levels can theoretically encode one million biomolecules. Techniques have been developed to incorporate QDs into polymer beads, to solve problems relating to their surface chemistry. In general, quantum dots exhibit water insolubility, poor biocompatibility, and low chemical stability in physiological media; encapsulation in polymer nanoparticles can reduce these problems. In their work, Zhang et al. have incorporated luminescent CdSe/ZnS QDs into polystyrene (PS) nanoparticles grafted with carboxyl groups using an emulsion polymerization method. Nanoscale QD-incorporated PS nanoparticles (30 nm diameter) were separated by centrifugation at high speed in viscous solution.

Finally, the nanoparticles were modified with folic acid on their surface and their intracellular uptake into NIH-3T3 (an immortalized epithelial cell line) and HT-29 (colon cancer epithelial cell line) cells was investigated using a confocal laser scanning microscope.

For nanoparticles without a folate cover, fluorescence was observed in the cytoplasm of the cells but not in the nuclei of most cells, indicating that the nanoparticles have difficulty in reaching the nuclei on their own. After surface modification of the nanoparticles with folic acid, fluorescence appeared in the nuclei of some cells (Fig. 10.6). This suggested that intranuclear uptake of the nanoparticles may be affected by the folic acid attached to the surface.

It took three hours of incubation for the PS-encapsulated QDs with folate-modified surfaces to spread throughout the cytoplasm of cells. Folic acid modified nanoparticles first attached to the folate receptors expressed on the cell membrane after 0.5 h incubation. After 1 h, more fluorescence was found on the cells' membranes and some fluorescence spots were already seen in the cytoplasm, indicating early migration of the nanoparticles into cells. After 1.5 h, more fluorescence was observed inside the cytoplasm. Throughout the observation period, fluorescence was seen on the cell membranes. This can be explained by the fact that internalized nanoparticles were rapidly replaced by nanoparticles from the surrounding media. This seems to argue in favor of a receptor-mediated endocytosis process. In contrast, slight cytoplasmic fluorescence was observed with unmodified nano-

particles, and did not change throughout the observation period. This uptake was possibly by non-specific endocytosis of the PS beads by the cells.

#### 10.4.3.4 Transferrin as a Targeting Ligand

Approximately 3 mg or 0.1% of body iron in the adult male circulates in the plasma as an exchangeable store. Essentially all circulating plasma iron normally is bound to an 80 kDa glycoprotein called transferrin. Plasma transferrin is synthesized by the liver and secreted into plasma. It has two homologous N-terminal and C-terminal iron-binding domains [71] (Fig. 10.7). This iron-protein chelate serves three functions: it makes iron soluble under physiologic conditions, it prevents iron-mediated free radical toxicity, and it facilitates transport of iron into cells. Transferrin is the most important physiological source of iron for red cells [72]. The liver synthesizes transferrin and secretes it into the plasma. Transferrin is a suitable ligand for tumor targeting because of the upregulation of its receptors in many cancers [46] in which their levels correlate with the malignant potential [47].

Insert Therapeutics (California, USA) have reported transferrin based targeting. They demonstrated tumor targeting in mice by transferrin-modified nanoparticles containing DNAzymes (short catalytic single-stranded DNA molecules) [73]. They synthesized  $\beta$ -cyclodextrin polymer-DNAzyme nanoparticles. Steric stabilization was obtained by adamantane-PEG conjugates complexed to the surface by adamantane-cyclodextrin interaction. Transferrin was included for targeting transferrin receptor expressing tumors. While the uptake of unmodified nanoparticles was demonstrated *in vivo* in nude mice, transfer modification was demonstrated to be necessary for intracellular delivery of the DNAzyme.

Previously, the same group demonstrated [74] the uptake of transferrin-modified cyclodextrin-adamantane inclusion complex nanoparticles to leukemia cells, which was competitively inhibited by excess free transferrin.

#### 10.4.3.5 Other Targeting Ligands

Another targeting molecule used is biotin (vitamin H). Na et al. have incorporated this molecule into a hydrophobically modified polysaccharide, pullulan acetate, loaded with adriamycin [75]. The biotinylated nanoparticles exhibited very strong adsorption to the HepG2 cells, while the unmodified nanoparticles showed no significant interaction. Uptake was confirmed by confocal microscopy. While the degree of interaction increased with increasing vitamin H content, drug uptake by the nanoparticle was inversely related to the vitamin H content.

Various other ligands have been studied as probable candidates for targeted drug delivery in tumors. These include antibodies against tumor-associated antigens [76], lectins [77], and glycoproteins [78]. Recently, Yu et al. from Japan have detailed the use of the surface antigen (sAg) of the hepatitis B virus to accomplish liver-specific delivery of genes and drugs. They describe the association of approximately 110 molecules of this protein to form a polymeric capsule (which they call a "BioNanoCapsule" or BNC) with an average diameter of 130 nm. The nanoparticles that were produced delivered emerald green fluorescent protein (EGFP) to human hepatoma cells [79].

## 10.5 Targeting with Different Types of Nanoparticles

### 10.5.1

#### Liposomes in Cancer Targeting

Currently, the most exciting event in targeted drug delivery systems is undoubtedly the ongoing clinical trial of the world's first tumor-targeted gene delivery vector, Rexin-G™, marketed by Epeius Biotechnologies Corporation. This nanoparticle formulation combines a proprietary vector system with a proprietary anticancer gene controlling cell cycle. The company website claims that "when given by intravenous infusions, Rexin-G™ has been shown to eradicate remote metastatic cancers in mice and to arrest cancer growth with shrinkage and necrosis of solid tumors in humans – determined by CT Scan and MRI – without eliciting systemic side effects." The first clinical trials were started in 2003 in Manila, Philippines; and following FDA approval shortly thereafter, clinical trials were started in New York from April, 2005 for metastatic pancreatic and colon cancer. Initial reports are favorable and results of ongoing studies are eagerly awaited [3, 80, 81].

In this context, a few words regarding immunoliposomes are in order. In our initial classification of colloid based systems, we separated nanoparticles from liposomes and block copolymer micelles. Many authors consider them part and parcel of the same package [1, 82]. Hence, in the interest of topicality and completeness, we consider both in some measure.

Liposomes (and, in some instances, micelles) have long been used for targeted delivery of drugs. Of all the proposed nanoparticulate drug delivery systems, liposome-based agents, particularly liposomal anthracyclines, have had the greatest impact on oncology to date [82]. These lipid based formulations have several advantages as drug carriers: they are amphiphilic, hence allowing the carriage of lipophilic drugs in plasma; they fuse with cell membranes and transfer their load inside cells; and they can be embedded with targeting molecules like antibodies on their outer surface. They have been likened to the Trojan horse in Greek mythology: the cancer cells fuse to the liposomal membrane and takes up the contents of the liposome, which contains the anticancer formulations (the company that is conducting the liposomal targeted-gene delivery trials has been appropriately named after Epeius, the maker of the original Trojan horse).

Several problems have dogged liposomal drug delivery systems from its conception and implementation. These include a short half-life in circulation, instability *in vivo*, and lack of target selectivity. Liposomes are removed rapidly from the circulation by the reticulo-endothelial system (RES) [83]. Stability and circulation times were increased, as in nanoparticles, by the introduction of a steric stabilizer on the surface, usually PEG [84]. Like other nanoparticles, enhanced passive uptake of liposomes has been demonstrated with longer circulation times. PEGylation has increased therapeutic efficacy of the liposomal formulations [85, 86]. These innovations, affording longer and stable circulation times, have resulted in approval of some liposomal formulations for clinical use [87]. The passive increase of lipo-

somes in cancer sites was recognized as a means of delivering toxic, poorly soluble drugs. Liposome-encapsulated doxorubicin was approved for use in Kaposi's sarcoma more than a decade ago. Formulations are available now for breast and ovarian cancers. The most recent instance deals with liposomes encapsulating cisplatin; this has been demonstrated in preclinical and phase 1 clinical trials in humans to have almost negligible nephrotoxicity, ototoxicity and neurotoxicity, which are the major side-effects of free cisplatin in circulation [15].

Improved target selectivity has been demonstrated using ligands and antibodies. Active targeting of liposomes using ligands for tumor-associated receptors, and antibodies against tumor-associated antigens, has been investigated as a means of improving selectivity. Liposome-antibody complexes (immunoliposomes) have received most attention [88]. The problem of rapid removal by the RES is compounded by the attachment of antibodies [89, 90]. However, PEGylation has created a generation of "stealth" immunoliposomes that can effectively hide from the RES for long periods. In this context, immunoliposomes can be classified into two groups based on the relation of the antibody to the PEG group on the liposomal surface: antibody coupled to lipid head group 76 and antibody coupled to the distal end of PEG [91]. The latter composition has been considered to be better for efficient antibody-target coupling because of the absence of interference from PEG chains [92]. At optimal compositions of both types of formulations, antibodies do not interfere with PEG function and long circulation times have been demonstrated; conversely, PEG does not interfere with antibody function, and active targeting is unimpaired. Immunoliposomes complexed with PEG have been successfully demonstrated for *in vivo* targeting of brain [93] and lung [91] tumors.

Immunoliposomes with cancer targeting antibodies have been shown to be cytotoxic to cancer cells *in vitro* [94]. However, this did not translate to *in vivo* success. This was because not all antibodies used to target the cancer cells result in uptake and internalization of the liposome. The use of more specific internalizing antibodies aided in uptake and cytotoxic effects *in vitro*. As an example, the anticancer antibody anti-ErbB2 did not increase cytotoxicity of the liposome [95]; but when the anti-ErbB2 Fab fragment was used, the liposome was internalized and had high efficacy of cancer kill [96, 97]. More recently, scFV (single-chain Fv) antibodies against ErbB2 have been utilized for cancer targeting with doxorubicin-loaded liposomal formulations. The antibodies are selected from a phage display library, and demonstrate higher internalization efficacy [98–100]. Ongoing research by Park et al. at UCSF comprehensive cancer centre [82, 101] aims to develop immunoliposomes with antibodies targeted to HER 2, overexpressed in breast cancer, and EGFR, overexpressed in several cancers such as lung, pancreas and prostate. The targeted liposomes have been loaded with anticancer drugs like doxorubicin and vinorelbine. The loaded immunoliposomes have shown increased effectiveness and reduced toxicity compared with conventional chemotherapy.

The issue of internalization can be circumvented by a two-step method to release the anticancer drugs from the liposome near the tumor. This antibody-directed enzyme pro-drug therapy (ADEPT) involves first administering an enzyme-antibody conjugate that preferentially targets cancer cells, followed by administration of a

non-toxic prodrug that is activated by the bound enzyme and releases the toxic product close to the cancer cells [102]. An improvement of the ADEPT method using immunoliposomes to carry the enzyme shows greater stability in the body and has been tested pre-clinically [103].

#### 10.5.1.1 Beyond Immunoliposomes

Similar to the development of nanoparticles, scientists have looked beyond monoclonal antibodies as a means of targeting liposome to cancer. This was to avoid the intrinsic immunogenic nature of antibodies, their high cost, and the ease of procurement of ligands for overexpressed growth receptors on the tumor surface. Folic acid coupled liposomes have been developed and tested against various cancer cells both *in vitro* and *in vivo* [85, 104, 105]. Transferrin has also been evaluated as a targeting ligand for anticancer drug carrying liposomes [106].

Targeting with transferrin and folic acid has also been used to deliver anticancer genes to tumor cells. Cationic liposome–DNA complexes (lipoplexes) that are formed spontaneously by charge interaction exhibit the best gene-transfer efficiency. However, cationic liposomes were found to be unsuitable for active cancer cell targeting. Hence, a new anionic liposome–polyplex (anionic liposome-entrapped polycation-condensed DNA, LPD-II) was introduced for the gene therapy of cancer. Cationic lipoplexes containing liposomes and DNA were better internalized and transfected when transferrin was conjugated [107] and demonstrated selectivity for myeloblast cells [108], adenocarcinomas and squamous cell carcinomas [109]. Folic acid has also been used for tumor targeting the LPD-II polyplexes [110]; and systemic administration of anticancer gene therapy for selective uptake in squamous cell carcinomas of the head and neck, and breast cancer xenografts have been demonstrated [109].

### 10.5.2

#### Dendrimers

Block copolymers or dendrimers were described as far back as 1985. Initial studies elucidated the physical and chemical properties of these new materials. However, their entry into the field of targeted cancer therapy is relatively recent.

Dendrimers are globular macromolecules that have a “starburst”-like shape, with multiple branches radiating from a central core. The stepwise synthesis of dendrimers makes it possible to fine-tune its highly regular branched structure with defined peripheral groups and adjust physical properties such as the high molecular weight and low polydispersity index. Dendrimers have several advantages over polymeric nanoparticles derived from linear chains. Dendrimers are multivalent: several different drug molecules, targeting agents and other groups can be attached in a predefined fashion. Dendrimers have low polydispersity: all the synthesized molecules have molecular weights within a narrow range; this makes their behavior highly reproducible. Dendrimers have a globular rather than random coil structure, which could lead to better biologic properties [111]. Various types of

**Fig. 10.8.** PAMAM dendrimers are the most common dendrimer nanoparticles currently used in drug delivery. (Source: <http://www.dendritech.com/pamam.html>)

dendrimers have been synthesized. The most common is the polyamidoamine (PAMAM) dendrimers developed by Tomalia and coworkers [112] (Fig. 10.8), which uses a divergent growth approach. Other types include polypropyleneimine dendrimers [113], polyaryl ether dendrimers [114] and peptide-based dendrimers, such as polylysine-based ones [115].

Passive targeting can be achieved by dendrimers having long circulation times. Unlike polymeric micelles, dendritic unimolecular micelles maintain their structure at all concentrations because of the covalent linkage [111]. This increased stability has the disadvantage that drug release from the central core cannot be controlled. This can be circumvented by attaching the drug molecule covalently to the periphery of the radiating arms of the dendrimer molecule. The amount of drug conjugated can be controlled by the number of generations (which increases the length of the radiating arms) and the release can be ensured by making the drug-dendrimer linkage easily degradable. Attachment of cisplatin to PAMAM dendrimers has been demonstrated by Duncan et al. [116]. Another of type of passive

targeting that utilizes the lowered pH of the intracellular endosomal and lysosomal microenvironment for drug release has been demonstrated [117]. Doxorubicin was conjugated to hybrid dendrimers using hydrazone linkages; these are stable at normal physiologic pHs, but break down after uptake in the mildly acidic endosomes and lysosomes. They demonstrate longer circulation times and toxicity to several tumors [118].

Active targeting of dendrimers using folic acid conjugates has been demonstrated by Frechet and coworkers [119] using dendrimer folate and dendrimer methotrexate conjugates. Quintana et al. have created analogous PAMAM–methotrexate conjugates with degradable amide and ester linkages [35]. Folic acid conjugation enhanced cellular uptake of these compounds, resulting in increased cancer cell cytotoxicity and efficacy of the anticancer drug as compared with the free drug *in vivo*.

Dendrimers have enormous potential in targeted drug delivery systems because of their reproducibility, controlled synthesis, and multivalent structure, which ensures incorporation of different functions like targeting, imaging and multidrug delivery. However, relatively less literature is available on these exciting molecules and they suffer from lower circulation times and drug release rates than those of more established nanoparticles and liposomes, and their biodistribution is still being investigated. With time and experience, these technical obstacles will, hopefully, be solved and they will have an even wider impact on targeted drug delivery.

### 10.5.3

#### **Other Polymeric Nanoparticles**

Historically, nanoparticles were first introduced by Birrenbach and Speiser [120]. They were later developed to become drug delivery systems as a substitute for liposomes. Initial formulations were made by emulsion polymerizations [120]. However, later methods were developed (like phase separation, controlled gelation, etc.) that made use of preformed polymers with already characterized physicochemical properties. This allowed better control over the properties of the nanoparticles.

The most common polymers used as core material for polymeric nanoparticles are poly(alkyl cyanoacrylate), poly(lactide) derivatives and chitosan. However, several other materials have also been investigated, as noted in other volumes of this series. Recently, Gilbert et al. have developed fluorescent virus-like nanoparticles (fVLPs) from fusion protein VP2 and GFP that may serve as a model for the development of vehicles that can be designed for the delivery of large biomolecules to cancer cells [121]. These are taken up with high efficiency and transferred to the nucleus using the microtubular network. In another very recent example, Mo et al. have developed a novel lectin-conjugated isopropyl myristate (IPM)-incorporated PLGA nanoparticle for the local delivery of paclitaxel to the lungs [122].

Nanoparticles can be nanospheres or nanocapsules, the basic difference being that nanospheres have a matrix structure, while the capsules have a core-and-shell structure. While a wide range of sizes are available and have been tried, generally,

the particles should be less than 100 nm in diameter [123]. The greater surface area of the nanoparticles allows attachment of targeting molecules and anticancer agents; alternatively, the drug may form the core of the nanocapsule with a polymeric shell.

Nanoparticles as vehicles of targeted drug delivery enjoy several advantages. Primarily, the attachment of different molecules to the same platform confers bi- and multi-functionality. This is important because conjugating targeting molecules directly to the anticancer drug may cause decreased functionality of either or both. Nanoparticles can be modified to incorporate not only two but more functions. One of could report the presence of the tumor using, for example, quantum dots.

Secondly, attachment to the nanoparticle surface increases the stability of molecules. This is particularly important with peptides, nucleic acids (like anti-HA-*ras* [124]) and anti-Ewing sarcoma [125] and small proteins (like antibodies), which are easily removed from the circulation in the free form. It is also important for carrying poorly soluble drugs (e.g., muramyl tripeptide cholesterol [126]) in significant quantities without the usual side effects. Controlled release can be achieved to ensure a long-term, high level of the drug without encountering the loading dose problem. This has been shown in the use of doxorubicin-loaded nanoparticles. Doxorubicin can cause acute and chronic cardiomyopathy at high levels. By attachment to nanoparticles, high levels of doxorubicin were achieved in the circulation, with reduced cardiac levels and, consequently, less toxic effects and increased effectiveness against the metastatic cancer.

Chemotherapy fails *in vivo* even when the cancer is shown to be highly sensitive to the drug *in vitro* because of cellular “sanctuaries”. For example, the recurrence of acute lymphoblastic leukemia has been attributed to cell nests in the CNS. Intravenous drug formulations fail to cross the blood–brain barrier. Nanoparticles, however, can accomplish this feat, perhaps by trans-cellular movement after endocytosis by the endothelial cells. Some examples of this include the use of polysorbate 80-coated nanospheres to deliver Kytorphin, turbocurarine NMDA antagonist and doxorubicin to the brain. Polysorbate 80 adsorbs apolipoprotein E from the circulation and becomes attached to the low-density lipoprotein receptors on the endothelial surface.

The major drawback of nanoparticles is their propensity to be taken up by the macrophages lodged in the organs of the mononuclear phagocytic system (MPS). After intravenous administration, most of the nanoparticles accumulate in the spleen and the liver, and to a lesser extent in the bone marrow. Steric stabilization has been devised to avoid this. The attachment of PEG to the nanoparticle surface allows them to “hide” from the MPS and stay longer in circulation, eventually finding their way to the targeted regions. Poloxamine has been proposed as an alternative to PEG for producing steric stabilization.

In fact, PEG-coated poly(cyanoacrylate) (pCA) nanoparticles – made by a copolymer inculcating both – have such a long circulating time that they penetrated the brain more than any other modifications, including coating by polysorbate. This uptake was increased in pathological situations with, presumably, higher blood–brain barrier permeability.

Modeling of nanoparticle delivery and effects has raised the question of “diffusional instability”. Vittorio Cristini et al. have shown that the delivery of cytotoxic agents to tumors, particularly anti-angiogenic drugs, might fractionate the lesion into multiple satellite neoplasms [127]. This is likely due to the rearrangement of the sources of oxygen and nutrient supply because of the anti-angiogenic therapy.

The other difficulty is the issue of control. Especially with synthetic methods derived from microencapsulation techniques, there may be considerable difficulty in encapsulating the drug and then controlling its release after encapsulation.

To summarize, a nanoparticle designed for targeted delivery of anticancer agents will have three essential components: (a) the capsule or matrix or core that provides the platform to bind or contain; (b) the drug or anticancer agent, which binds on the surface; and (c) the targeting molecule. This whole arrangement must be made immune from the attacks of the immune system by steric stabilization, usually by the attachment of PEG to the surface.

Mauro Ferrari has labeled these modified nanoparticles as “nanovectors” [1]. The name is appropriate as an indication of their function as carriers of large therapeutic payloads to target sites. He points out that while antibody conjugated therapies can only deliver single molecules of drug per recognition event, nanovectors can deposit a much larger amount. This makes nanoparticles particularly attractive when dealing with toxic drugs.

In the described tripartite arrangement, an optimum combination of matrix, drug and surface recognition element is required. As stated above and described elsewhere, many matrix polymers have been tested for their drug uptake and surface modification abilities (for a review see Ref. [128]). Targeting has ranged from “active” targeting, using antibodies, radiation-induced vascular neo-antigens, folic acid receptors and transferrin, to passive targeting that depends on surface modification with PEG and enhanced fenestrations of tumor vasculature to selectively deliver the drug.

The role of the surface-modified matrix and the targeting molecule is to effectively deliver the drug to the target site. For this, they must provide stability to peptides and others drugs with short half-lives in circulation, avoid uptake by the MPS or RES, circumvent the endothelial and blood–brain barrier, be non-toxic to normal body tissues and, finally, deliver the drug to the tumor cells, avoiding the enhanced osmotic pressure in tumor regions [129] and ensuring uptake and action.

However, a nanoparticle may have yet further uses. As demonstrated by Baker et al., dendrimer-based nanoparticles can be modified to not only avoid obstacles and target tumors but also to “report” on the presence and extent of the tumor by the means of an attached “reporter” molecule, in this case fluorescein [35]. In a similar vein, Loo et al. have demonstrated the dual functional ability of immunotargeted nanoshells for integrated cancer imaging and therapy [130]. They define nanoshells as “a novel class of optically tunable nanoparticles that consist of a dielectric core surrounded by a thin gold shell”. The relative dimensions of the shell thickness and core radius allow nanoshells to either scatter and/or absorb light over a broad spectral range, including the near-infrared (NIR). The NIR is a wavelength region that provides maximal penetration of light through human tissue. Thus,

with attachment of suitable antibodies, these nanoshells offer the opportunity to design vehicles that provide, in a single nanoparticle, both diagnostic and therapeutic capabilities.

Targeting can be enhanced or achieved by other factors, too. One of these is the use of drugs that act preferentially on tumor cells. While most conventional chemotherapeutic drugs now in use have greater or lesser degrees of tumor selectivity (usually by targeting the rapid proliferation of tumor cells), greater selectivity may be achieved by using siRNA that are specific for tumor antigens (see below). Another type of targeting, demonstrated by Potineni, et al. [131], describes a method to utilize pH differences to release drugs at tumor sites. They demonstrated the *in vitro* release of the anticancer drug paclitaxel by biodegradable poly(ethylene oxide)-modified poly( $\beta$ -amino ester) nanoparticles. This can theoretically be reproduced at cancer sites, which have high metabolic rates and altered pH.

## 10.6

### Conclusion

As far back as the late 19<sup>th</sup> century, Paul Ehrlich (1854–1915) – Nobel laureate for Physiology or Medicine in 1908 for his pioneering work in immunology and chemotherapy and for the discovery of the first effective therapy for syphilis – propounded and popularized the concept of a “magic bullet”. This is a drug that targets and destroys diseased cells selectively, to the exclusion of all others, like a bullet that finds its mark every time. His invention, preparation 606, later called Salvarsan, was highly effective against syphilis and harmless despite a large arsenic content. This drug was also found to be successful in curing several other diseases. Indeed, it seemed that a “magic bullet” had indeed been found [132]. We, of course, realize that despite its effectiveness, arsenical-based therapy of syphilis can not accurately qualify for the label of magic bullet. Indeed, for years scientists have searched in vain for such a drug for cancer, but as our understanding of the complexities of the cancer cell and the diverse nature of the neoplastic process grows, more than one researcher has denounced this concept as an unachievable objective. The search for the magic bullet for cancer has become a sort of Holy Grail for cancer researchers worldwide – to be sought for, but not to be found. Each new advance and discovery in this field has been accompanied by hopes that finally the grail has been found, but in all cases these hopes have been shattered by the realities of failure rates. On the bright side, very large strides have been made in cancer treatment, and average life expectancy after detection has increased for most cancers, and several treatments have chalked up impressive cure rates.

The field of nanotechnology was famously introduced by another Nobel laureate, Richard P. Feynmann, in his lecture “There is plenty of room at the bottom” at the annual meeting of the American Physical Society at the California Institute of Technology in 1959. Many nanotechnology researchers consider this talk to be the inspiration for their work. Feynmann, in this lecture, proposed two challenges to future nanotechnologists, but neither, however, was related to the field of biology.

Lipid based formulations, especially liposome encapsulated doxorubicin, first raised visions of a route to the magic bullet. However, it was still just a drug modification that allowed the transfer of toxic but effective drugs in the serum. The introduction of monoclonal antibodies suddenly made active targeting an attractive possibility. However, the high cost of these antibodies, the large amounts needed to counter their rapid removal from circulation, and the single molecule of drug they carried, all presented technical difficulties for their widespread use. An ant can carry 10–20× its body weight of food; imagine how ineffective it would be if it could carry only a mouthful at a time! Nanoparticles – introduced in the 1970s – seemed to be the probable replacement for liposomes. However, they soon came up against the same problem that monoclonal antibodies faced: they were rapidly cleared from circulation by the mononuclear phagocytic system in the liver and spleen. Scientists innovatively tried to turn this drawback into an advantage, by using nanoparticles to target the liver specifically, e.g., to transfect genes to produce essential proteins, but in the end the goal of targeted delivery seemed to be as far away as before.

The discovery of the steric stabilization effect of poly(ethylene glycol) (PEG) solved that major problem. While “PEGylating” nanoparticles increased their circulation time dramatically, it also reaped an unexpected harvest. The local environment of the tumor supports extravasation of nanoparticles through large endothelial fenestrations and disordered neoplastic tissue architecture. Their retention is ensured by a low lymphatic drainage. This enhanced permeation and retention (EPR) effect had a dramatic influence on the distribution of long-circulating nanoparticles: they collected at tumor sites to the exclusion of other body tissues even without any “active” targeting molecules. Long time of circulation and the EPR effect ensured that nanoparticles circumvented the blood–brain barrier, with important implications for the treatment of resistant tumors with cell sanctuaries in the brain.

Innovations continue to increase almost daily. Not satisfied with costly monoclonal antibodies for tumor targeting, researchers have turned to such mundane molecules as folic acid, transferrin and biotin for enhanced selective uptake in tumors. Folic acid in particular has a relatively long history of tumor targeting abilities, and preferential uptake in a large number of solid tumors.

The drug carried to the tumor site is not restricted to the more traditional doxorubicins and paclitaxels. There had been considerable interest in a possible gene therapy of cancer. Indeed, at one time it had been hyped as the elusive “magic bullet”. *In vitro* studies have conclusively demonstrated repetitively the effectiveness of this approach against a wide variety of cancer. The obstacle had always been an appropriate vehicle that can effectively deliver sufficient amounts of the gene to the cancer cells. Direct injection of the naked DNA into muscle cells (the so-called “gene gun”) showed considerable uptake and expression. But for the ultimate delivery vehicle, man decided to trust the vector that Nature’s evolutionary process has skillfully crafted over millions of years for this very purpose: viruses. Initial experiments with harmless adenoviridae *in vitro* promised success; however, clinical trials (to supplement the mutated p53 in ovarian cancer) failed to demonstrate any

advantage over conventional therapy [133]. On September 17, 1999, eighteen-year-old Jesse Gelsinger died during a gene therapy clinical trial for ornithine transcarbamylase (OTC) deficiency, a rare metabolic disorder that is marked by dangerous levels of ammonia in the bloodstream. He died after a vector injected into his liver triggered an immune response that led to multiple organ failure. This incident seemed to ring the death knell to virus-delivered gene therapy.

Gene therapists turned to non-viral means of delivery – the obvious solution appeared to be nanoparticles. They can be modified to carry biological macromolecules, are themselves harmless, and can help protect the gene from the immune system till the cancerous tissue is reached. The complex of genetic material, especially siRNA, and targeted nanoparticle vector brought together a double selectivity process: the targeting ligand ensures selective uptake to cancer cells, and the siRNA ensures that even if some non-cancerous cells have taken up the particle, only the cancer cells are affected.

The excellent results with nanoparticulate gene vector complexes brought back the old nanoparticle workhorse, liposomes, to the forefront. Ease of DNA uptake by the cationic liposomes, and their uptake by fusion to membranes, ensures efficient transfection. With added targeting ligands, the complex promises to be the answer to many cancer therapy problems. Another nano-sized colloidal drug delivery system made its entry into the field more recently: block copolymer micelles or dendrimers.

With nearly all the components finally at hand, the assembly of the actively targeted nanoparticle against cancer was but a matter of time. Several such complexes have already shown promise. In a natural spin off, several start-up companies have already begun early research into human applications. Endocyte, Inc. has taken up folic acid as their solution, while Baker has established the Center for Biologic Nanotechnology at the University of Michigan to espouse the cause of dendrimers. Arguably the most exciting is the performance of Epeius Biotechnologies Corporation's liposomal based active targeting system that delivers genetic material to treat several cancers, including pancreatic head carcinoma, which has one of the worst prognoses among all neoplasms.

It may be that nanoparticles fail to provide us the “magic bullet” against all cancers. However, if current interest, effort and progress in the field of nanoparticulate targeted drug delivery systems are any indication, we may be heading towards an era of more effective chemotherapy with less morbidity and higher cure rates.

# Colloidal Systems for the Delivery of Anticancer Agents in Breast Cancer and Multiple Myeloma

*Sébastien Maillard, Elias Fattal, Véronique Marsaud, Brigitte Sola, and Jack-Michel Renoir*

### 11.1

#### Introduction

The success of cancer treatments depends on an active drug concentration at the tumor sites. In fact, drug dispatch remains the objective of clinicians and drug delivery has been the subject of a tremendous amount of research during the past four decades [1, 2]. Indeed, most used anticancer drugs have great toxicity, including for normal tissues, and it is crucial to minimize massive damage to the rest of the body after their administration. Moreover, despite poor water solubility, owing to a high hydrophobicity, some chemotherapeutic drugs were initially given orally. However, drug administration, particularly for antitumor drugs, increasingly required intravenous perfusion, leading to a poor amount reaching the tumors and to important side effects because high doses are often administered. This poor specificity creates a toxicological problem that constitutes a serious obstacle to effective antitumor therapy. Thus, a crucial problem remains the addressing of the drug to the site of action, i.e., being more tumor selective.

Undoubtedly, intravenous administration of anticancer drugs could be of great help but it remains limited by the capture of the drug by macrophages of the mononuclear phagocytes system (MPS), leading to drug destruction in the liver, spleen, lung and bone marrow. If the propensity of MPS macrophages for endocytosis/phagocytosis provides an opportunity to deliver efficiently therapeutic agents to these organs, the targeting of non-MPS organs remains a priority. One strategy consists of associating antitumor drugs with colloidal systems engineered to resist the MPS and to increase the selectivity of drugs towards cancer cells while reducing their toxicity towards normal tissues. Various injectable delivery systems, nanoparticles, emulsions and liposomes (conventional drug delivery systems, CDDS), have been developed but only a few are clinically used. To avoid their recognition by opsonins (immunoglobulins, proteins from the complement) and their degradation by the MPS organs, hydrophilic polymers may be grafted [2, 3] at the surface of these colloidal systems [4, 5], rendering them capable of long circula-

tion times in the blood stream, thus constituting “Stealth” drug delivery systems (SDDS) [6].

Another important issue is the capacity of formulations to cross the vascular endothelium (extravasation process). Vascularization of solid tumors is heterogeneous, with regions of necrosis and other areas that are densely vascularized in order to supply the tumor cells with nutrients for tumor growth. The formation of new capillaries from pre-existing vessels (angiogenesis) also contributes to tumor growth. Tumor blood vessels present various abnormalities (increased tortuosity, deficiency in pericytes, aberrant basement membrane formation [1, 7]) that result in an enhanced permeability of tumor vasculature. This enhancement is thought to be regulated by various mediators, such as vascular endothelium growth factor (VEGF), nitric oxide, prostaglandins and metalloproteinases [8, 9]. Macromolecules cross tumor vessels through open gaps (interendothelial junctions and transendothelial channels), vesicular endothelial organelles and fenestrations [10]. The pore size cut-off of various solid tumor models usually lies in the range 380–800 nm [2, 9–13], which is compatible with the extravasation of SDDS.

Thus, to deliver therapeutic agents to tumor cells following i.v. injection one must: (a) avoid the opsonization process and resulting destruction by the MPS; (b) realize a stealth formulation incorporating high amounts of drug; (c) dispatch a high and active drug concentration at the tumor level; (d) overcome drug resistance mechanisms. This chapter focuses on two types of cancer, which differ in the sort of cells they affect and in their morphology, i.e., breast cancers and multiple myeloma, and we describe how new antiestrogen drug delivery devices strongly inhibit tumor growth in xenograft models.

Besides their essential function in female reproduction, estrogens exert various responses in target cells, including promotion of tissue differentiation, morphogenesis, mitogenic activity and development of the mammary gland. They are also beneficial hormones in the regulation of bone mineral density, through effects on the osteoclast/osteoblast balance, in the prevention of atheromatous plaque, and in the nervous system. Importantly, they are also implicated in oncogenesis and maintenance of some tumor growth. In fact, estrogens are regulators of several proto-oncogenes coding for nuclear proteins [14]. Estrogens act on cells via interaction with two types of intracellular receptors, ER $\alpha$  [15, 16] and ER $\beta$  [17–19]. Like all steroid hormone receptors, ERs are trans-acting transcription enhancer factors that are activated by binding of their ligands. They become, therefore, capable of interacting with specific cis-acting enhancer elements that are usually located with the 5'-flanking regions of target genes. This classical mechanism of action was thought for many years to be unique. However, following recent findings reporting the membrane localization of ER, “non-genomic” mechanisms involving mitogen-activated protein kinase (MAPK) activation have emerged [20, 21].

Half of breast cancers are intrinsically estrogen sensitive and, therefore, respond to antiestrogens [22, 23]. To treat these estrogen-dependent cancers, pharmacologists have aimed to develop antiestrogens, i.e., compounds capable of blocking the effects of estradiol without displaying any estrogenic activity on their own. Numer-

**Fig. 11.1.** Structure of the most commonly studied antiestrogens: The most commonly used SERMs (Tamoxifen and raloxifen) and three pure antiestrogens (ICI 182,780, RU 58 668 and EM 800) are shown. Among them

only ICI 182,780 (Faslodex®), by deep i.m. oily injection in tamoxifen-resistant breast cancers. RU 58 668 development has been stopped and EM 800 is in phase II clinical trials [183, 184].

ous molecules (Fig. 11.1) behave both as agonists or antagonists of estradiol, depending on the tissue, the promoter and the type of the ER [22, 24]. These compounds have been classified as “selective estrogen receptor modulators” (SERMs). Recently, a few compounds able to bind ER and to abrogate all effects of estrogens in a competitive manner have been elaborated [24]. These so-called “pure antiestrogens” were expected to be very useful for estradiol-dependent cancer treatment. In addition to their ability to inhibit all the effects of estradiol, one other important characteristic is their capacity to target ERs to proteasome-mediated degradation in human breast cancer cells [25–27]. On the basis of this property, “pure antiestrogens” have been called selective ER down-regulators (SERDs). However, recent findings in various cancer cell lines prompted reconsideration of this notion, because it has been observed that any kind of antiestrogen, both SERMs and “pure antiestrogens”, behave as inducers of transcription through the activating protein 1 (AP<sub>1</sub>) pathway [28–30].

Multiple myeloma (MM) is a B-cell malignancy characterized by the clonal expansion of tumoral plasma cells in the bone marrow. This accumulation of malignant cells synthesizing immunoglobulins results in hyperproteinemia, renal

dysfunctions, bone lesions and immunodeficiency [31]. This pathology, which accounts for 2% of all cancer deaths per year in occidental countries, remains largely incurable despite novel therapeutic approaches involving the targeting of both MM cells and the bone-marrow environment [32]. Previous studies have established that both ER $\alpha$  and  $\beta$  isotypes are expressed in some MM cells [33–36]. Surprisingly, and differing strongly from breast cancer cells, estradiol as well as SERMs and SERDs induce a decrease of MM cell proliferation, and at a micromolar concentration preclude a classical recruitment of ERs. However, SERMs and SERDs induce breast cancer and MM cell cycle arrest as well as apoptosis. Therefore, they all can be considered as potent anticancer drugs.

Other work relating to the use of anticancer drug delivery systems has shown the importance of this approach in developing new anticancer treatments. However, most work describes the use of drug delivery systems containing highly cytotoxic drugs devoid of specific cellular target, leading to ubiquitous effects and high toxicity [37, 38]. A physicochemical DDS containing an anticancer drug implies knowledge of the physicochemical properties of the drug, its exact mechanism of action in the pathology to be treated, and the physiology of the pathology itself. Here, we point out the importance of delivering a molecule endowed with a very specific intracellular target.

Thus, we focus first (Section 11.2.1) on the importance of estrogens in breast cancer development. The different roles of estrogens will be discussed by presenting the classical ER-ligand and ERE-dependant, ERE-independent, ER-ligand independent, and “non-genomic” pathways. Knowledge of these precise mechanisms has led to the use of various families of antiestrogens (AEs), the properties of which differ (Section 11.2.2). The benefits of AE encapsulation, to improve anti-tumoral activities *in vivo* and to limit side effects, are discussed in Section 11.2.3.

In Section 11.3, we focus on another pathology, multiple myeloma (MM), describing current treatments and new biological therapies as well as the promising use of AEs.

Whatever the concerned pathology, we will develop in Section 11.4 the requirement for a specific drug delivery system. Thus, the use of passive targeting long-circulating drug delivery systems in different types of xenografts are detailed, such as nanoparticles for breast cancer (Section 11.4.1) and liposomes for MM (Section 11.4.2). Finally, we discuss the potential improvement of these systems on acquiring a specific tumoral recognition element (Section 11.4.3).

## 11.2

### Hormone Therapy in Breast Cancers

Two important general ways have been imagined for eliminating the mitogenic activity of estradiol in estrogen-dependent breast cancers: blocking the site of an estrogenic specific target (the estradiol receptor) or blocking the synthesis of estradiol. For the first case, antiestrogenic compounds are used, and for the second case aromatase inhibitors have been developed [39].

## 11.2.1

**Molecular Mechanisms of Estrogen Action in Breast Cancers****11.2.1.1 Classical ER-ligand and ERE-dependent Mechanism**

The general mechanism by which estrogens transduce their mitogenic activity results from their binding to the two nuclear receptors from the steroid/thyroid superfamily of transcription factors, ER $\alpha$  and ER $\beta$  [40, 41]. In addition to binding estrogens with a high affinity, ERs bind to specific DNA sequences called estrogen responsive elements (EREs), possess defined activating functions (AF1 in the N-terminal domain and AF2 in the ligand binding domain), and interact with various protein partners [22, 24, 42–44]. In target cells unexposed to estradiol (E<sub>2</sub>) or growth factors, ER $\alpha$  is part of a large complex in which molecular chaperones such as heat shock proteins (hsp) and co-chaperones are present (for a review see Ref. [44]). The major chaperones that favors the efficient folding of ER $\alpha$  are hsp90 and hsp70 [44–47]. Another important partner of this supramolecular complex is p23 [48, 49], a N-terminal interacting client protein of hsp90 [50], the overexpression of which decreases the transactivation capacity and ligand binding of ER $\alpha$  [51]. In fact, this p23 is a prostaglandin-E<sub>2</sub> synthase and its degradation is an apoptosis indicator [52, 53].

Following E<sub>2</sub> binding, a change in ER $\alpha$  conformation occurs, promoting the dissociation of hsp90 and other proteins from the molecular chaperone complex. Phosphorylation of ER $\alpha$  increases in response to estradiol binding prior to transcriptional enhancement [54]. This rapid process leads to dimerization of ER $\alpha$ , to its tight association with the nucleus [55] and to its interaction with specific nucleotide sequences of the specific EREs in gene promoters. This leads to enhancement of transcription through the recruitment of co-activators, some of which carry a histone acetyl transferase (HAT) activity (Fig. 11.2A), like SRC<sub>1</sub> and CBP/p300 [41, 56, 57]. Histone acetylation leads to chromatin opening and to repositioning of nucleosomes [58]. Other modifications of the ER state and of some co-regulators and the specific DNA sequences (like phosphorylations, methylation, ubiquitination, acetylation) also take place in the sequentially and processivity of transactivation [O'Malley, B. W., NURSA e-journal (2003) 1, ID# 3.11052003.1; ISSN 1550-7629]. This interaction of ER with DNA leads to activation of transcription [40, 42]. Recently, the concept of a “transcriptional clock” that directs and achieves the sequential and combinatorial assembly of 46 co-activators at a specific E<sub>2</sub>-inducible (pS2) promoter in human breast cancer MCF-7 cells was defined [59, 60]. Following the pS2 promoter transactivation, the E<sub>2</sub>-ER complex is polyubiquitinated, leading to its proteasome-mediated destruction [60, 61].

With binding of a SERM, cofactors different from those recruited upon E<sub>2</sub> binding associate with the ER $\alpha$ /DNA complex (Fig. 11.2A). Co-repressors, such as N-COR, SMRT and REA (specific for ER $\alpha$ ), are present in these complexes [56, 57, 62]. The co-repressors are associated with a histone deacetylase activity (HDAC), which re-compacts chromatin followed by nucleosome re-positioning, leading to blockade of transcription of specific genes. It has also been proposed that, in the absence of ligand, ER $\alpha$  could be sequestered in complexes containing

**Fig. 11.2.** Mechanisms of action of estradiol and antiestrogens: (A) In the classical genomic mechanism of ER, the inactivated receptor (1) is sequestered in a supramolecular chaperone complex (organized around hsp90, p23 and immunophilins). E<sub>2</sub> binds to inactivated ER, changes its conformation, promotes both its phosphorylation by different kinases and its release from the molecular chaperones, helps in the sequential recruitment of a set of co-activators, among which are histone acetyl transferases (HAT), which modify the chromatin structure en route to transcription. When a SERM like OH-tamoxifen (OHT) binds to ER (2), the induced conformational change and the phosphorylation state of ER differ from

those induced by E<sub>2</sub> binding. Co-repressors instead of co-activators are recruited, among which are histone deacetylases (HDAC), which re-compact the chromatin and preclude interaction with the basal machinery of transcription (BMT) at an ERE, allowing activation of the polymerase and leading to inhibition of the transcription. With an AP<sub>1</sub>-containing promoter, the SERM-ER $\beta$  complex activates transcription while the E<sub>2</sub>-ER complex inhibits AP<sub>1</sub>-mediated transcription. If a SERD like RU or Faslodex complexes with ER $\alpha$  (3) a delocalization of ER and its fast proteasome-mediated destruction occurs, precluding binding to DNA.

these repressors (or some of them), maintaining the receptor in an inactive state [63].

#### 11.2.1.2 ERE-independent Pathway

In addition to the classical transactivation pathway that results in binding of the  $E_2$ /ER $\alpha$ -complex to EREs, tamoxifen and other SERMs also activate target genes (like collagenase gene) through binding at an activating protein-1 (AP-1) site; this is observed in uterine cells but not in breast tumor cells [28]. It occurs through direct binding of ER- $E_2$  complex to the heterodimer c-fos/c-jun at AP-1 binding sites and is mainly mediated via ER $\beta$ , the major ER form in the endometrium (Fig. 11.2B). Remarkably, the pharmacology of ER ligands bound to ER $\beta$  is reversed at an AP-1 element. Bound to ER $\beta$ , the antiestrogens, including the “pure antiestrogens” Faslodex® and RU 58668 (RU) (Gougelet, A., Marsaud, V., Renoir, J.-M., in preparation), act as transcriptional activators and  $E_2$  behaves as a transcription inhibitor. These features may explain the incidence of uterine cancers following long-term tamoxifen treatment of  $E_2$ -dependent breast cancers, and could be involved in the acquisition of tamoxifen resistance in breast tumors [24]. Similarly, other genes containing GC-rich promoter sequences are activated via an ER-SP1 complex [64, 65].

#### 11.2.1.3 ER-ligand-independent Pathway

There is accumulating evidence that ER-mediated transcription activation occurs also in the absence of ER-ligand binding in response to cell surface growth factor receptors and the intracellular signaling cascades that they activate [66–68]. Indeed, growth factors or cyclic adenosine monophosphate (cAMP) activate intracellular kinase pathways, leading to phosphorylation and activation of ER at ERE-containing promoters in a ligand-independent manner, possibly via p42/44 MAPK activation [69–71]. Similarly, phorbol-12-myristate-13-acetate (PMA) through the stimulation of adenylate cyclase also increases the ER-mediated transcription. Therefore, the genomic activity of ER can be induced by numerous different stimuli, ER agonists themselves but also activators of various kinases of the EGF receptor family as well as activators of PI3-K, PKA and PKC [54]. These variable processes target ER to different sequences present in  $E_2$ - and/or PMA-inducible promoters to affect gene expression. However, the crosstalk between the classical activation  $E_2$ -dependent pathways and other pathways has considerably helped our understanding of the complicated multifaceted mechanism of action of estrogens.

← (B) ER $\alpha$  can also be rapidly phosphorylated on Ser118 by the MAPKinase pathway following activation of the EGF receptor which, through the Ras,Raf, MEK, ERK cascade, leads to an ERE-dependent, ER-ligand-independent transactivation activity, or an ERE-independent, ER-ligand-independent-PI3K/AKT-dependent activation process. The “non-genomic” activation process by which ER $\alpha$  can be

activated proceeds through binding of  $E_2$  to a cytosoluble ER bound to caveolin-1, to translocation of the caveolin-1/ER $\alpha$  complex to the membrane, leading to association with a caveolin-1 receptor (CR), allowing contact with small G proteins, which acts to activate the MAPK cascade and gene expression without any DNA binding of ER $\alpha$ .

#### 11.2.1.4 “Non-genomic” Pathway

Besides this general and well-accepted genomic mechanism (representing direct or indirect binding of ER to DNA), estrogens may induce effects occurring within minutes (“non-genomic effects”), which is incompatible with a process requiring DNA and transcription (Fig. 11.2B). For instance, estrogen-induced vasodilatation is rapid and relies on the activation of nitric oxide synthase by a mechanism involving trimeric G proteins [72] and Akt via the PI3-K pathway [73]. Direct interaction between ER and PI3-K has been demonstrated [74]. Rapid activation by E<sub>2</sub> of protein kinase C in MCF-7 ER-positive (ER+) cells as well as in other human breast cancers lacking ER is membrane mediated and inhibited by tamoxifen [75]. Several groups have reported that E<sub>2</sub> induces a rapid activation of MAPK/ERK in breast cancer cells [76–78] as well as a rapid non-transcriptional activation of PI3-K [79]. However, this E<sub>2</sub>-induced activation of both MAPK and PI3-K in human ER+ breast cancer cells such as MCF-7 and ZR75.1 has been severely criticized by several laboratories, who have questioned the non-genomic mitogenic activity of E<sub>2</sub> [80–83]. In fact, it is now accepted that a small amount of ER $\alpha$  exists as a functional non-traditional G-protein coupled receptor (GPCR) at the plasma membrane [78, 84–86]. Such a membrane localization of ER $\alpha$  is thought to be the consequence of the S522A mutation, which convert the receptor into a dominant-negative form [86]. This GPCR is now known as the endoplasmic reticulum GPR30 [84], which under direct E<sub>2</sub> binding results in intracellular calcium mobilization and synthesis of phosphatidylinositol 3,4,5-triphosphate in the nucleus [87].

#### 11.2.2

#### Differential Activity of Antiestrogens

Evidently, from several reports emanating from various laboratories, an efficient way to inhibit the E<sub>2</sub>-mediated mitogenic effects in breast tumors could be the suppression of the biological activity of ER. This is possible through different pathways that block ER-mediated transcription, as realized with SERMs and SERDs, but also by inhibiting ER protein expression. Introduced as a new approach for targeted therapy with few side effects compared with traditional cytotoxic chemotherapy, hormone therapy is based on the use of non-steroidal antiestrogens, the archetype of which is tamoxifen (Tam), which has been used clinically with success since the 1970s. Initially investigated in the late 1960s these antiestrogens are partial estrogen antagonists or SERMs (Fig. 11.1).

In terms of breast cancer growth, Tam as well as several other SERMs are anti-estrogenic, whereas they exert estrogen-like actions in bone, the cardiovascular system, and in the regulation of circulating low density lipoproteins (LDL) [22, 23]. Unfortunately, the SERMs are agonist in the uterus and can enhance the growth of human endometrial tumors implanted into immune deficient mice [88]. SERMs such as tamoxifen and raloxifen induce an accumulation of ER $\alpha$  in breast cancer cells [25–27, 89, 90]. In contrast to tamoxifen, both ICI 182,780 (Faslodex®) and RU 58668 treatment of human breast cancer cells results in rapid delocalization

and a fast destruction of endogenous ER $\alpha$  through the 26S proteasome pathway [25–27, 61, 86, 89, 90]. Such pure antiestrogen-induced down-regulation of ER $\alpha$  expression takes place in a nuclear compartment from which ER $\alpha$  is difficult to extract [27, 78, 91] and is recovered with the nuclear matrix [55]. The CSN5/Job1, a subunit of the COP9 signalosome, is involved in ligand-dependent degradation of ER $\alpha$  by the proteasome [92]. Interestingly, any alteration of the activity of various kinases known to affect signaling involved in cell cycle progression targets ER $\alpha$  to the 26S proteasome-mediated degradation [27]. Similarly, several co-activators involved in the activation of ER-mediated transcription are also degraded through the proteasome pathway [61]. Contrarily to ER $\alpha$ , ER $\beta$  stably expressed in ER-negative MDA-MB-231 cells is more slowly degraded by the SERDs than the ER $\alpha$  isotype and still conserves a high expression level [93].

In addition to SERDs, hsp90 inhibitors are also able to trigger ER $\alpha$  to proteasomal degradation [94]. Both N-terminal hsp90 ligands such as geldanamycin and radicicol, as well as C-terminal hsp90 ligands such as novobiocin, target not only ER $\alpha$  but also ER $\beta$  [93] to degradation through the proteasome pathway. Thus, destabilization of steroid receptors by hsp90-binding drugs constitutes a ligand-independent approach to hormonal therapy of breast cancer [95, 96]. In general, any compound with high inhibitory ability of the activity of one (or more) of the proteins implicated in the mechanism of action of ERs could be a potential anti-cancer drug (SERDs for ER $\alpha$ , HDAC inhibitors, proteasome inhibitors, hsp90 inhibitors, immunosuppressors, p23 inhibitors).

### 11.2.3

#### The Need to Encapsulate Antiestrogens

We have already mentioned the large spectrum of activity of SERMs. Actually, their use in postmenopausal women treated for estrogen-dependent breast cancer is based on a daily oral administration of Tam (20 mg day<sup>-1</sup>). Sometimes, detrimental side effects occur, leading often to hot flushes and more rarely to endometrium cancers (1–2%). Nevertheless, tamoxifen is still clinically used and, in addition, it is of benefit for osteoporosis and cardiovascular disease due to its agonistic activity in bones and vessels. Pure antiestrogens were first reported nearly 20 years ago [97]. Nevertheless, concern about the increased risk of osteoporosis and coronary heart disease, as well as problems with drug delivery, is similar to that caused by aromatase inhibitors developed as an alternative strategy for antiestrogen therapy [98]. Delivery of these molecules to their site of action at the desired rate is a challenge because their transport through compartmental barriers (endothelium or epithelium) in the body is inefficient and/or because they are rapidly metabolized. For controlled release or for site-specific delivery, new delivery systems will be required (as only oral tablets and an oil solution for i.m. injection of Faslodex® are currently available). Furthermore, alkyl estradiol derivatives are difficult to synthesize, and their oral bioavailability is very low. Therefore, a targeted drug delivery system of both SERMs and SERDs for breast cancer treatment could be of benefit.

### 11.3

#### Multiple Myeloma

Despite new insights into the biology of MM, the major prognostic for such pathology was not significantly improved. Thus, for several years, research into novel approaches, implying new therapeutic targets, has increased. We focus here on the new biological strategies and, particularly, on the promising outcomes of the estrogens and antiestrogens regimen.

##### 11.3.1

#### Current Treatments

Addition of glucocorticoids (which trigger apoptosis) to the oral alkylating agent melphalan [melphalan-prednisone (MP) regimen] constituted the mainstay of therapy for many years, although remissions were rare (<5%) and median survival did not exceed three years. Addition of other alkylating agents such as anthracyclines and vinca alkaloids to MP did not improve patient survival. The further developed therapeutic management of MM for the last two decades has mainly involved regimens based on the use of glucocorticoids (dexamethasone) and cytotoxic chemotherapeutic drugs [99, 100]. The standard therapy for MM, at least for younger patients, is considered to be autologous peripheral blood stem cell (PBSC)-supported high-dose melphalan [101].

##### 11.3.2

#### New Biological Therapies for MM Treatment

The need for efficient therapy has become obvious and several new agents seem very promising [102, 103]. Among them, SU 5416 [104], an inhibitor of VEGF-induced MM proliferation, and thalidomide, an inhibitor of tumor necrosis factor (TNF $\alpha$ ) and VEGF production, which is in phase II trials, could be of great interest [105–107]. As many regulators of cell proliferation or apoptosis are degraded by the ubiquitin-proteasome pathway, proteasome inhibitors such as bortezomib (PS-341) [108–111] (Velcade; Millennium, Cambridge, MA) may be promising. Inhibiting the Ras/Raf/MAPK signaling pathway with farnesyltransferase inhibitors like R115777 [112–114] or promoting growth arrest and apoptosis by HDAC [115] and 2-methoxyestradiol [116, 117], which induce apoptosis in numerous cancers by producing reactive oxygen species as well as hsp90 ATPase inhibitors, are other areas of clinical development. All these drugs/inhibitors represent potential anticancer agents [93, 95, 96] alone and in combination with dexamethasone or other drugs. However, they are highly toxic and great care must be given to their administration so as to avoid healthy tissues. For example, the strong cardio-toxicity of anthracyclines must be suppressed as much as possible. This has been successfully realized with the incorporation of doxorubicin in numerous stealth liposomes. Among them caelix/doxil [118] is actually clinically used for different cancer therapies (breast, ovary, myeloma) alone or in combination with vincristine and

dexamethasone [119]. Liposomal vincristine and liposomal cisplatin have also been clinically evaluated on various cancers [120]. Despite progress in delineating the activity of such regimens, at either conventional or high dose, MM has remained incurable. No substantial improvement of the median survival was obtained, even from new promising attempts.

### 11.3.3

#### **Incidence of Estrogens and Antiestrogens on Multiple Myeloma**

Both isotypes of ER have been identified in several MM cell lines as well as in cells isolated from patients [33–36], and both SERMs like OH-tamoxifen, the active metabolite of tamoxifen, and two pure antiestrogens (Faslodex® and RU 58668) have been shown to block the cell cycle progression of MM cells and to induce apoptosis [34, 36, 121]. Interestingly, 4-OH-tamoxifen-induced apoptosis in several ER-positive MM cells is a mitochondrial process [121]. Such an event, in conjunction with the high doses needed to obtain apoptosis in these MM cells (as compared with lower doses giving the same effect in ER-positive breast cancer cells), raised the question of the ER specificity of antiestrogens in MM. Even if the pathway(s) that conduct MM cells to apoptosis under antiestrogens is (are) not totally elucidated at present, this has prompted us to evaluate the efficacy of liposomal formulations loaded with RU in a xenograft model of MM.

## 11.4

### **Colloidal Systems for Antiestrogen Delivery**

#### 11.4.1

##### **Nanoparticles Charged with AEs in Breast Cancer**

The first strategy employed to obtain a controlled release of the 11 $\beta$ -alkylestradiol derivatives manufactured by Schering was the use of a polyacrylate-based matrix transdermal system [122, 123]. Pretreatment of the skin with a fluid permeation enhancer of propylene glycol–lauric acid should enhance absorption of transdermally administered antiestrogens. Drugs that permeate easily through the skin must be small molecules with moderate lipophilicity. Nanoparticles for intravenous administration of drugs have since been developed. Because the usefulness of conventional nanoparticles is limited by their rapid and massive capture by macrophages of the MPS after i.v. administration, different nanoparticle devices have been considered to target tumors that are not localized in the MPS organs. Several studies have been devoted to the development of so-called “stealth” particles, which are “invisible” to macrophages [6, 124]. These stealth nanoparticles are characterized by a prolonged half-life in the blood compartment, allowing them to extravasate in pathological sites like tumors or inflamed regions with a leaky vasculature [125, 126]. The size of the colloidal carriers and their surface characteristics are the keys for the biological fate of nanoparticles, since these parameters can prevent

**Fig. 11.3.** Schematic structures of colloidal systems used for antiestrogen incorporation: Nanospheres (A), nanocapsules (B) and liposomes (C) are the drug delivery systems used to encapsulate antiestrogens. Nanospheres are composed of a polymeric matrix in which the ligand (●) can be encapsulated; nanocapsules consist of the same polymer surrounding an oily core, allowing solubilization of hydrophobic

compounds. PEG-PLA or PEG-PLGA or PEG- $\epsilon$ -caprolactone copolymers were also used. Liposomes (C) made of various phospholipid compositions containing a water core were also employed. The antiestrogens were presumed to be located in the lipid bilayer. Tumor recognition molecules are shown as shaded triangles (A and B), and the ligand and antibody as shaded solid Vs (C).

their uptake by the MPS. A high curvature, small size (<100–200 nm) and a hydrophilic surface (as opposed to the hydrophobic surface of conventional nanoparticles) reduce opsonization and subsequent clearance by macrophages [2, 124].

A major breakthrough came with the use of hydrophilic polymers [poly(ethylene glycol) (PEG), poloxamines, poloxamers, polysaccharides] to coat the surface of nanoparticles [6, 127] (Fig. 11.3). Such coatings provide a dynamic “cloud” of hydrophilic and neutral chains at the surface of the particles, repelling plasma proteins and avoiding opsonization. Two ways have been used to introduce hydrophilic polymers at the surface of nanoparticles: either adsorption of surfactants or the use of branched copolymers [6, 127–130]. The second strategy, consisting of the covalent linkage of amphiphilic copolymers, is generally preferred for obtaining a protective hydrophilic cloud on nanoparticles, as it avoids the possibility of rapid coating desorption upon dilution or after contact with blood components. This approach has been employed with poly(lactic acid) (PLA), poly(caprolactone) and poly(cyanoacrylate) polymers, which were chemically coupled to PEG [125, 131–134]. This type of DDS has been used to incorporate antiestrogens in the studies described here.

The “pure antiestrogen” RU 58 668 [135, 136], referred as to RU below, is highly hydrophobic and could be trapped in the lipidic skin layer, avoiding its access

to targets localized in other tissues. Colloidal particles may be used as drug carriers to obtain a site-specific drug delivery. The vascular endothelium in solid tumors is discontinuous [10], and nanoparticles are able to cross this discontinuous endothelium in a process called extravasation. Such a strategy has been already employed in the case of Tam, but the drug release was too fast and its loading too low to obtain significant effects *in vivo*. In fact, poly( $\epsilon$ -caprolactone) and poly(MePEGcyanoacrylate-co-hexadecyl cyanoacrylate) nanoparticles failed to encapsulate Tam correctly, with a maximum loading efficiency of 64% and most of the drug being adsorbed onto the particle surface [137–139]. In contrast, the highly promising pure antiestrogen RU has been successfully incorporated with a high loading efficiency in polyester-PEG nanospheres [140]. These small nanoparticulate systems (~150–200 nm) showed reduced drug release *in vitro*, and reduced protein adsorption in the presence of serum, two features compatible with increased persistence in blood [141]. These parenteral delivery systems inhibited estradiol-promoted tumor growth *in vivo* that correlated with an arrest of cell cycle proliferation in MCF-7 cells [142]. Accumulation of these nanoparticles in tumor sites following i.v. administration has been demonstrated by the use of radioactive polymer [142].

The recent antiestrogen-containing formulations we have synthesized represent, to our knowledge, the first drug delivery systems loaded with an antiestrogen that have been successfully evaluated biologically in animal models. They are made of copolymers that are organized as nanospheres or nanocapsules (Fig. 11.3); in the latter case, the antiestrogen is solubilized in an oily core. Two types of copolymers were employed, affording nanoparticles with a small size that is compatible with good extravasation (Table 11.1). Tamoxifen-loaded PEG-poly(alkyl cyanoacrylate) (PEG-PACA) nanospheres contained only a small amount of drug ( $1.8 \mu\text{g mL}^{-1}$ ) [137], whereas RU-loaded PEG-poly(lactic acid) (PEG-PLA) nanocapsules (NC) and nanospheres (NS) contained at least  $3\times$  more drug ( $5$  and  $33 \mu\text{g mL}^{-1}$ , respectively) [140, 142]. In addition, PEG-PLA nanoparticles are devoid of any intrinsic toxicity, which is not the case for the PACA-based copolymer [143, 144]. RU-charged PEG-PLA nanoparticles in MCF-7 cells show greater toxicity than free RU, and flow cytometry experiments have revealed a strong increase of MCF-7 cells in apoptosis after treatment with RU-loaded NS and NC. Interestingly, following i.v. administration to mice bearing MCF-7 breast cancer xenografts, nanospheres loaded with RU were highly efficient at inhibiting  $\text{E}_2$ -induced tumor growth at a dosage 50 to  $100\times$  lower than that at which free RU is active [142, 145] (Fig. 11.4). Comparatively, RU-loaded nanocapsules possessed a strong potency to reduce the  $\text{E}_2$ -induced tumor growth in this model as well as in xenografts of MCF-7/ras tumors [142]. They also prolonged the anti-uterotrophic activity of RU [142] at a low dose.

Tamoxifen-loaded PEG-PLA nanospheres also possess a high potency for inhibiting  $\text{E}_2$ -induced growth in MCF-7 tumors (Fig. 11.4). Analysis of the cell cycle proteins and proteins involved in apoptosis in tumor extracts from mice injected with nanospheres or nanocapsules containing RU indicated that both cyclin dependent

**Tab. 11.1.** Physicochemical characteristics and biological parameters of antiestrogen-loaded colloidal systems. The size and zeta potential of nanospheres nanocapsules and liposomes loaded with either RU or OH-Tam are indicated, together with the encapsulation rates of the drugs. Interestingly, the change in zeta potential for nanoparticles loaded with OH-Tam indicates that some drug is located at their surface, unlike RU-nanoparticles and liposomes.

Half-lives were determined following a 24 h-treatment of MELN cells with E<sub>2</sub> (0.1 nM) in the presence or not of 0.5 nM RU; results represent the times at which 50% luciferase expression was inhibited. Empty liposomes had no effects [154]. nd: not defined.

**Fig. 11.4.** Tumor evolution of MCF-7 breast cancer xenografts i.v. injected with RU- and OH-Tam-nanospheres. Bi-weekly i.v. injections of RU-PEG-PLA nanospheres (NS) and of 4-OH-Tam-PEG-PLA nanospheres ( $12 \text{ mg kg}^{-1} \text{ week}^{-1}$  each) were performed in mice ( $n = 10$  per group) bearing MCF-7 tumors (ranging

from  $0.8$  to  $1 \text{ cm}^3$ ). Identical amounts of free antiestrogen in 5% glucose were i.v. injected as controls. All groups received  $0.5 \text{ mg-E}_2 \text{ kg}^{-1} \text{ week}^{-1}$  following skin deposition of an  $\text{E}_2$  solution in ethanol. Tumors were measured each week.

kinase inhibitors  $\text{p}21^{\text{WAF-1/CIP1}}$  and  $\text{p}27^{\text{kip1}}$  (CDKIs) were dramatically augmented (Ameller, T., Marsaud, V., Legrand, P., Renoir, J.-M., manuscript in preparation). This was not seen in tumor extracts from mice having received encapsulated 4-OHT. This finding supports the concept that delivery of RU incorporated in long-circulating formulations is able to arrest tumor growth by a mechanism in which both CDKIs are overexpressed [142]. This agrees with the need for an elevated level of  $\text{p}27^{\text{kip1}}$  for cells to remain quiescent, an effect produced by pure antiestrogens in human breast cancer cells [146] but not by SERMs such as 4-OHT. Additionally, immunological analysis of MCF-7 cells tumors exposed to both nanospheres and nanocapsules containing RU revealed a strong destruction of the  $\text{ER}\alpha$  content, contrary to tumors exposed to nanospheres loaded with OH-Tamoxifen. In the former, TUNEL experiments indicated a strong apoptosis while a weaker one was detected in the latter. These data correlate with the proteasome-mediated degradation of  $\text{ER}\alpha$  under RU, concomitantly with apoptosis induction.

Finally, s.c. administration of trapped RU in mice bearing MCF-7 tumors was as efficient as the i.v. route at the same dose of RU (Fig. 11.5). This finding led to the hypothesis that nanospheres could behave like a reservoir from which the drug could diffuse and release slowly in the interstitium before reaching the tumor. In that case it is intriguing that the efficiency was similar to that obtained by i.v. More research is necessary to elucidate this mechanism, in particular to find out how the administration of an antiestrogen through a stealth DDS affects its pharmacokinetics and biodistribution as well as its bioavailability.

**Fig. 11.5.** Tumor evolution of MCF-7 breast cancer xenografts s.c. injected with RU-nanospheres and RU-nanocapsules. Bi-weekly subcutaneous injection of PEG-PLA-RU loaded nanocapsules and of PEG-PLA-RU-loaded nanospheres [containing, respectively,  $2 \times 10^{-5}$  M ( $0.3 \text{ mg kg}^{-1} \text{ week}^{-1}$ ) and  $5 \times 10^{-4}$  M RU ( $4.3 \text{ mg kg}^{-1} \text{ week}^{-1}$ )] was performed in nude mice bearing MCF-7 tumors ( $n = 8$  mice per group), in addition to  $0.5 \text{ mg kg}^{-1} \text{ week}^{-1}$  by skin deposition. Free RU at the highest concentration was s.c. injected at  $4.3 \text{ mg kg}^{-1} \text{ week}^{-1}$ . Control group received only  $E_2$ .

#### 11.4.2

#### Liposomes Charged with RU 58668 in MM

Several liposomal formulations have been elaborated for the delivery of highly cytotoxic anticancer drugs such as doxorubicin and platinum-based agents [4, 147–151]. These formulations utilized liposomes capable of circulating with very long half-lives (referred to as sterically stabilized liposomes) [152, 153] that avoid the opsonization process when injected in the blood stream. Similarly to nanoparticles, opsonization is reduced by coupling phospholipids to hydrophilic polymers such as PEG. PEG-liposomes can be injected either intravenously or subcutaneously.

From *in vitro* experiments, we have established that high antiestrogen amounts are able to trigger cell cycle arrest in MM cells as well as to induce apoptosis [121, 154]. We then incorporated RU in liposomes known to have a better incorporation capacity than nanoparticles. Table 11.1 summarizes the physicochemical characteristics of the different formulations obtained and their biological properties in terms of drug loading and *in vitro* release. At least  $10\times$  more RU was incorporated into liposomes of EPC/DSPE-PEG<sup>2000</sup> than in nanospheres of PEG-PLA. Coupling of PEG did not modify any of the characteristics of liposomes but addition of cholesterol enhanced vesicle stability of the liposomes and strongly decreased the RU re-

lease measured *in vitro*. RU release from liposomes was comparatively faster than that of RU from nanoparticles (Table 11.1). Flow cytometry experiments carried out on various MM cell lines (LP1, NCI-H929, RPMI8226, OPM-2 and U266) exposed to increasing amounts of RU revealed that in all MM cells RU blocks the cell cycle progression in the G0/G1 phase and/or induced apoptosis (except in OPM-2). This occurred at up to 5  $\mu\text{M}$  RU, a concentration far above (100 $\times$ ) that at which the antiestrogen induced apoptosis in breast cancer ER+ cancer cells. Interestingly, the extent of apoptosis in cells exposed to RU-loaded liposomes is strongly augmented in all MM cells (Fig. 11.6).

Intravenously injected in a RPMI8226 MM xenograft model, RU-charged liposomes inhibited strongly the tumor growth even when injected at 12 mg kg<sup>-1</sup> week<sup>-1</sup> in a single injection (Fig. 11.7). Conversely, free RU at this dose had no effect, as well as empty liposomes. This suggests that the release of RU is slow and that its potency in inhibiting the growth of the MM tumor is enhanced by incorporation in the liposome system. Another interesting observation made in RPMI8226 xenografts was the enhanced anti-angiogenesis activity following RU-charged liposomes (Maillard, S., Gauduchon, J., Gouilleux, F. Marsaud, V., Connault, E., Opolon, P., Fattal, E., Sola, B., Renoir, J.-M., submitted for publication), which is consistent with the inhibition of VEGF by RU in the MM cells (our unpublished work) as well as in human breast cancer cells [155, 156], an effect mediated by ER $\alpha$  contained in the endothelium membranes. In addition, in all of the MM and breast cancer xenograft models we used, no apparent toxicity (liver, lung, bone) was noticed. Interestingly, the size of the xenograft uteri injected with RU-PEG-PLA nanospheres was not decreased, contrary to that of healthy mature mice having received RU at 12 mg kg<sup>-1</sup> week<sup>-1</sup> for at least 5 weeks (RPMI8226 xenografts) and 4.3 mg kg<sup>-1</sup> week<sup>-1</sup> (MCF-7 xenografts) [142, 145, 154]. This strongly suggest that, although being passive, some tumor targeting is produced when stealth DDS are employed.

### 11.4.3

#### Tumor-targeted Drug-loaded Colloidal Systems

Targeting of drugs to specific tissues of the body has been the major focus of research in recent decades in an attempt to improve selectivity in cancer treatment. The PEG stabilizing effect results from local surface concentration of highly hydrated groups that sterically inhibit both hydrophobic and electrostatic interactions of various blood components at the carrier surface [152, 153, 157]. “Active targeting” of either nanoparticles or liposomes is generally attempted by conjugating ligands, to the carrier surface, that possess high affinity for the tumor cells [158]. Several types of ligands have been used, including antibody fragments [159–161], vitamins [162–164], glycoproteins [165], peptides (RGD-sequences) [166], and oligonucleotides aptamers [158]. The concept is actually over 25 years old, but only small improvements have been obtained. In fact many difficulties are encountered. The major one, besides the complexity of such conjugation chemistry, is the dilemma of preserving the stealth property of the formulation, by leaving enough

**Fig. 11.7.** Tumor evolution of multiple myeloma xenografts i.v. injected with RU-liposomes. RPMI8226 xenografted nude mice received, or not, a weekly injection of free RU or RU-loaded liposomes (12 mg per kg per

week of RU) or unloaded liposomes at the same lipidic concentration as that containing RU. Tumor volume was measured and tumor evolution plotted as a function of the time of injection. \* $p < 0.01$  with regard to control.

free PEG chains grafted at the surface, while also obtaining enough tumor grafted ligand molecules capable of binding to the tumor cell receptors (Fig. 11.3).

In some cases, “active targeting” may take advantage of the overexpression of a membrane receptor. This is, in particular, the case with breast cancer cells that are insensitive to antiestrogens because they are ER-negative. In that case, a tyrosine kinase membrane receptor of the EGFR family, HER2-Neu or Erb-B2, is overexpressed [24]. Overexpression of Erb-B2 remains a major risk factor in non-metastatic breast cancers treated with high-dose alkylating agents and autologous stem cell transplantation. The activity of Erb-B2 is blocked by a specific antibody, herceptin (trastuzumab), which enhances tumor necrosis factor-related apoptosis-inducing ligand-mediated apoptosis in breast and ovarian cancer cell lines [167]. In MM cells, Erb-B2 is also overexpressed, representing a major risk [168]. Then, coupling trastuzumab on PEG chains of PEGylated nanoparticles and liposomes loaded with an antiestrogen could be of great benefit for breast cancers and MM since both the “piloting” grafted recognition molecule and the encapsulating drug

**Fig. 11.6.** Flow cytometry: NCI-H929 MM cells (50% confluence) were grown and exposed or not to RU ( $1 \mu\text{M}$ ) free or encapsulated, or to empty liposomes (at the same lipid concentration as that used in RU-loaded liposomes) for various periods. Cells ( $10^4$ ) were then analyzed by FACS. Cell cycle profiles and the percentage of cells in the sub-

G1 fraction obtained without treatment (control) are indicated in panels A, E, I for 24, 48 and 72 h, respectively. Panels B, F, J show the same parameters obtained after treatment with free RU. Similarly, panels C, G, K and D, H, L show the profiles obtained for cells treated with RU-loaded liposomes and unloaded liposomes, respectively.

can conduct tumor cells to apoptosis. Several sterically stabilized anti-Erb-B2 immunoliposomes have been synthesized to date [161, 169–173], all of which seem promising.

Another interesting and simple molecule to couple at the end of PEG chains is folic acid [174, 175]. Several malignant cells, including KB3-1 cells, endometrial Ishikawa cells and also some MM cells (but, unfortunately, not breast cancer cells), overexpress a folate receptor [176] that mediates internalization. Folate linked to PEGylated cyanoacrylate nanoparticles show a ten-fold higher apparent affinity for the folate membrane receptor than free folate does. The particles represent a multivalent form of free folic acid and the folate receptor(s) is (are) often disposed in clusters [175]. As a result, conjugated nanoparticles could display a multivalent and hence stronger interaction with the surface of the malignant cells [177]. Moreover, confocal microscopy has demonstrated that folate nanoparticles, compared with non-conjugated nanoparticles, were selectively taken up by the folate receptor-bearing KB3-1 cells, but not by MCF-7 cells. In the former case, the folate nanoparticles were located in the cell cytoplasm, as a consequence of receptor-mediated endocytosis [176]. Very recently, the improved therapeutic response of folate-nanoparticles charged with methotrexate demonstrated a marked decrease in toxicity and increase in antitumor capacity [178].

## 11.5

### Conclusions and Perspectives

The potential use of pure antiestrogens in anticancer therapy leads again to the question of how they must be administered to avoid side effects. Altogether, the data obtained with AE-loaded colloidal systems demonstrate that drug delivery of this type of anticancer drug either i.v. or s.c. administered enhances the apoptotic activity of the drug, decreases the side effects and behaves as long-lasting delivery systems, although probably acting through different process. For example, while it is likely that PEGylated nanoparticles concentrate at tumor sites via a passive targeting, liposomes are believed to deliver the encapsulated RU through an endocytosis process (Fig. 11.8). Several novel drug delivery systems for steroid hormones have been developed, including intra-uterine delivery systems, implants and steroid-loaded vaginal rings [145]. However, what is needed for the delivery of anticancer drugs in general, and for antiestrogens in particular, is a specific targeting of tumor cells with maximum avoidance of normal cells. The challenge is not to reach the pathological cells with a high dose of drug but rather to incorporate at these sites the optimal drug concentration necessary to completely inhibit the activity of the target. If this condition is attained, little of the drug will be disseminated at other sites of the organism, thus minimizing undesirable side effects.

In fact, another way to inhibit ER $\alpha$  activity has emerged recently from Gustafsson's group, who have described ER $\beta$  as a potent dominant negative variant of ER $\alpha$  [179, 180]. This has been confirmed by other groups [181, 182]. Thus, delivery of the cDNA encoding ER $\beta$  or of silencing RNA directed against ER $\alpha$  concomi-

**Fig. 11.8.** Antiestrogen-release mechanisms from colloidal systems. The antiestrogen (●) is located inside the lipid bilayer of liposomes (A), which are internalized in lysosomes in cells capable of endocytosis. The drug is then released in the cell after degradation of the lysosomes. In nanospheres and in nano-

capsules (B) the antiestrogen is trapped in the polymer matrix and/or in the oily core; they also can be submitted to endocytosis as in (A). The encapsulated drug can be released near the tumor cells, allowing its passive diffusion. In both cases, an increased intracellular antiestrogen concentration occurs.

tantly with RU could be a helpful approach since it can reduce, on the one hand, the activity of ER $\alpha$  and, on the other hand, destroys the ER $\alpha$  protein itself, preserving ER $\beta$ .

The results obtained are encouraging and we strongly believe that the drug delivery approach is promising not only for the administration of antiestrogens in estrogen-dependent breast cancers and MM but also for the delivery of much more toxic anticancer agents such as taxol, thalidomide, bortezomib, VEGF inhibitors, farnesyltransferase inhibitors, histone transferase inhibitors and hsp90 inhibitors.

### Acknowledgments

We greatly appreciate the support of the Ligue Nationale contre le Cancer (Cher, Indre and Manche departments Comities), P. Van de Velde for the gift of RU 58 668 and the SCEA of IGR (Villejuif, France) for animal experiments.

## Contents

<b>Preface</b>	<i>XVII</i>
<b>List of Authors</b>	<i>XXI</i>
<b>1 Dendrimers in Cancer Treatment and Diagnosis</b>	<b>1</b>
<i>Srinivasa-Gopalan Sampathkumar, and Kevin J. Yarema</i>	
1.1	Overview 1
1.2	Introduction 1
1.3	Basic Properties and Applications of Dendrimers 3
1.3.1	Structural Features and Chemical and Biological Properties 3
1.3.1.1	Basic Features of Dendritic Macromolecules are Inspired by Nature 3
1.3.1.2	Comparison of the Properties of Dendrimers and Conventional Synthetic Polymers 5
1.3.1.3	Comparison of the Properties of Dendrimers and Proteins (a Biological Polymer) 6
1.3.2	Dendritic Macromolecules Possess a Wealth of Possible Applications 8
1.4	Methods for Dendrimer Synthesis 10
1.4.1	History and Basic Strategies 10
1.4.1.1	Cascade Reactions are the Foundation of Dendrimer Synthesis 10
1.4.1.2	Dendrimer Synthesis has Expanded Dramatically in the Past Two Decades 12
1.4.2	Strategies, Cores, and Building Blocks for Dendritic Macromolecules 12
1.4.2.1	Dendrimers are Constructed from Simple “Building Blocks” 12
1.4.2.2	The Synthesis of Dendrimers Follows Either a Divergent or Convergent Approach 13
1.4.3	Heterogeneously-functionalized Dendrimers 13
1.4.3.1	Basic Description and Synthetic Considerations 13
1.4.3.2	Glycosylation is an Example of Surface Modification with Multiple Bioactivities 14
1.5	Dendrimers in Drug Delivery 15
1.5.1	Dendrimers are Versatile Nano-devices for the Delivery of Diverse Classes of Drugs 15

VIII | Contents

1.5.2	Dendritic Drug Delivery: Encapsulation of Guest Molecules	16
1.5.2.1	Dendrimers have Internal Cavities that can Host Encapsulated Guest Molecules	16
1.5.2.2	Using Dendrimers for Gene Delivery	16
1.5.2.3	Release of Encapsulated “Pro-drugs”	17
1.5.3	Covalent Conjugation Strategies	17
1.5.3.1	Dendrimers Overcome many Limitations Inherent in Polymeric Conjugation Strategies	17
1.5.3.2	Dendrimer Conjugates can be Used as Vaccines	19
1.5.3.3	Release of Covalently-delivered “Pro-drugs”	19
1.5.4	Fine-tuning Dendrimer Properties to Facilitate Delivery and Ensure Bioactivity	20
1.5.4.1	Delivery Requires Avoiding Non-specific Uptake	20
1.5.4.2	“Local” Considerations: Contact with, and Uptake by, the Target Cell	21
1.5.5	Drug Delivery: Ensuring the Biocompatibility of Dendritic Delivery Vehicles	22
1.5.5.1	Biocompatibility Entails Avoiding “Side Effects” such as Toxicity and Immunogenicity	22
1.5.5.2	Water Solubility and Immunogenicity	22
1.5.5.3	Inherent and Induced Toxicity	23
1.6	Dendrimers in Cancer Diagnosis and Treatment	24
1.6.1	Dendrimers have Attractive Properties for Cancer Treatment	24
1.6.2	Dendrimer-sized Particles Passively Accumulate at the Sites of Tumors	24
1.6.3	Multifunctional Dendrimers can Selectively Target Biomarkers found on Cancer Cells	25
1.6.3.1	Methods for Targeting Specific Biomarkers of Cancer	25
1.6.3.2	Targeting by Folate, a Small Molecule Ligand	26
1.6.3.3	Targeting by Monoclonal Antibodies	26
1.6.4	Dendrimers in Cancer Diagnosis and Imaging	28
1.6.4.1	Labeled Dendrimers are Important Research Tools for Biodistribution Studies	28
1.6.4.2	Towards Clinical Use: MRI Imaging Agents	28
1.6.5	Steps Towards the Clinical Realization of Dendrimer-based Cancer Therapies	29
1.6.5.1	The Stage is now set for Dendrimer-based Cancer Therapy	29
1.6.5.2	Boron Neutron Capture Therapy	29
1.6.6	Innovations Promise to Speed Progress	30
1.6.6.1	“Mix-and-Match” Strategy of Bifunctional Dendritic Clusters	30
1.6.6.2	Towards Therapeutic Exploitation of Glycosylation Abnormalities found in Cancer	31
1.6.6.3	Towards Targeting Metabolically-engineered Carbohydrate Epitopes	31
1.7	Concluding Remarks	33

	Acknowledgments	33

<b>2</b>	<b>Nanoparticles for Optical Imaging of Cancer</b>	<b>44</b>
	<i>Swadeshmukul Santra and Debamitra Dutta</i>	
2.1	Introduction	44
2.2	Cancer Imaging Techniques	46
2.2.1	Computed Tomography (CT) Scanning	47
2.2.2	Magnetic Resonance (MR)	47
2.2.3	Positron Emission Tomography (PET)	47
2.2.4	Single-photon Emission CT (SPECT)	48
2.2.5	Ultrasonography (US)	48
2.3	Optical Imaging	48
2.3.1	Basics of Optical Imaging	48
2.3.2	Optical Imaging Techniques	49
2.3.3	Optical Contrast Agents	50
2.4	Nanoparticles for Optical Imaging	51
2.4.1	Why Nanoparticles for Optical Imaging?	51
2.4.2	Development of Nanoparticle-based Contrast Agents	53
2.4.2.1	Quantum Dots	53
2.4.2.2	Gold Nanoparticles	57
2.4.2.3	Dye-doped Silica Nanoparticles	61
2.5	Optical Imaging of Cancer with Nanoparticles	65
2.5.1	Active Targeting	65
2.5.2	Passive Targeting	66
2.5.3	Cancer Imaging with Quantum Dots	66
2.5.4	Cancer Imaging with Gold Nanoparticles	68
2.5.5	Cancer Imaging with Dye-doped Silica Nanoparticles	69
2.6	Other Nanoparticle-based Optical Contrast Agents	70
2.7	Conclusions and Perspectives	70
	Acknowledgments	72

<b>3</b>	<b>Nanogold in Cancer Therapy and Diagnosis</b>	<b>86</b>
	<i>Priyabrata Mukherjee, Resham Bhattacharya, Chitta Ranjan Patra, and Debabrata Mukhopadhyay</i>	
3.1	Introduction	86
3.2	Medicinal use of Gold: A Historical Perspective	87
3.3	Application of Gold Nanoparticles in Cancer	88
3.3.1	Angiogenesis and Cancer	88
3.3.1.1	Agents that Inhibit Endothelial Proliferation or Response	90
3.3.1.2	Agents that Block Activation of Angiogenesis	91
3.3.1.3	Agents that Block Extracellular Matrix Breakdown	91
3.3.1.4	Unique Anti-angiogenic Properties of Gold Nanoparticles	91

3.3.1.5	Gold Nanoparticles Inactivate VEGF165	92
3.3.1.6	What is the Mechanism of Action?	93
3.3.1.7	Effect of Gold Nanoparticles on the Activity of VEGF165, VEGF121, bFGF and EGF	94
3.3.1.8	Effect of Gold Nanoparticles on Signaling Events of VEGF165	94
3.3.1.9	Effect of Nanogold on Downstream Signaling events of VEGF165	95
3.3.1.10	Effect of Gold Nanoparticles on Migration of HUVEC Cells	95
3.3.1.11	Effect of Gold Nanoparticles on Angiogenesis <i>in vivo</i>	95
3.3.1.12	Gold Radioisotopes in Cancer Treatment	96
3.3.2	Application of Gold Conjugates in the Treatment of Cancer	96
3.3.2.1	Gold–TNF Conjugate in Cancer Therapeutics	96
3.3.2.2	“2 in 1” System in Cancer Therapeutics	97
3.4	Biocompatibility of Gold Nanoparticles	99
3.4.1	Cellular Adhesion Effects	99
3.4.2	Local Biological Effects	99
3.4.3	Systemic and Remote Effects	99
3.4.4	Effects of the Host on the Implant	100
3.4.5	Addressing the Biocompatibility of Gold Nanoparticles using DNA Microarray Analysis	100
3.4.6	Internalization of Gold Nanoparticles by HUVECs	101
3.4.7	Nanogold Particles do not Alter Global Pattern of Transcription by HUVEC Cells under Serum-free Conditions	101
3.4.8	Nanogold Particles do not Alter the Global Pattern of Transcription by HUVECs in Near-normal Culture Conditions	103
3.5	Synthetic Approaches to Gold Nanoparticles	105
3.5.1	Chemical Methods	105
3.5.2	Physical Methods	105
3.5.3	Biological Methods	106
3.6	Nanotechnology in Detection and Diagnosis with Gold Nanoparticles	106
3.6.1	Cancer Detection	106
3.6.2	Detection in DNA	107
3.6.2.1	Single-mismatch Detection in DNA	107
3.7	Future Direction	109

## Preface

Two volumes (6 & 7) in the ten-volume series *Nanotechnologies for the Life Sciences* have been dedicated to the application of nanotechnology in cancer. The first of these two has captured nanotechnological approaches for the treatment of cancer and is already published. I do hope you had a chance to read it. This is the second of the pair, bringing out the utility of nanotechnology in developing tools and materials for sensitive and early diagnosis of cancer. These two volumes are timely as it is projected that cancer will be the leading cause of death, overtaking heart diseases, in the near future. One of the major goals of the American Cancer Society is early and sensitive detection of cancer. It is astonishing to note that the five year survival rate for breast cancer patients, if the cancer is diagnosed at localized stage, is 97.5%. Currently only 63.5% of breast cancers are diagnosed at the localized stage and there is no sensitive diagnostic tool for detecting micro-metastases, where the survival rate is less than 30%. Having made only limited progress in early and sensitive diagnosis of cancer using traditional methods, a paradigm shift in our approach is required in order to develop imaging agents and diagnostics for detecting cancer in its earliest and pre-symptomatic stage when it can be treated most easily. Needless to say, nanotechnology is offering this new approach and investigations reported so far demonstrate its immense potential. Since these investigations are being published in a very broad range of journals, this book provides a unique collection of consolidated and up-to-date information on nanotechnological diagnostic tools for the detection of cancer.

It is my pleasure to present, on behalf of the eminent contributors, the 7<sup>th</sup> volume in the series, entitled *Nanomaterials for Cancer Diagnosis*. The uniqueness of nanotechnological approaches in the battle against cancer is a distinct possibility to create technologies for simultaneous diagnosis and treatment of cancer. Therefore, you will find some of the chapters covering both these aspects while focusing primarily on diagnosis. I am grateful to all the contributors who made this book into a comprehensive source of information on the impact of a variety of nanomaterials on a number of diagnostic tools. A book of this magnitude is not possible but for their scholarly contributions. At this point, I also would like to gratefully acknowledge the support of a number of others, especially my employer, family, friends and Wiley VCH publishers for this timely publication.

The book is divided into eleven chapters, encompassing a number of diagnostic approaches for cancer through use of a variety of nanomaterials such as dendrimers, quantum dots, gold nanoparticles, dye-doped silica nanoparticles, superparamagnetic iron oxide nanoparticles (SPIONs), liposomes, fullerenes, carbon nanotubes, nanowires, nanorods, and so on.

The book begins with a chapter reviewing the progress that has been made to date on dendrimers – nano-sized, radially symmetric molecules with well-defined, homogeneous and monodisperse structure consisting of tree-like arms or branches – and dendrimer-based nanomaterials in the diagnosis and treatment of cancer. The authors, Srinivasa-Gopalan Sampathkumar and Kevin J. Yarema from the Johns Hopkins University in Baltimore, USA, have done an excellent job in collating pertinent information on how several different attributes of dendrimers are being utilized to fine-tune their biological activity in order to obtain effective solutions to long standing problems in diagnosis and treatment of cancer. The chapter, *Dendrimers in Cancer Treatment and Diagnosis*, is valuable for all those interested in acquiring knowledge on this exciting and most promising class of nanomaterials in cancer nanotechnology. The second chapter, *Nanoparticles for Optical Imaging of Cancer*, has been contributed from the laboratories of University of Central Florida in Orlando, USA. Authors Swadeshmukul Santra and Debamitra Dutta provide a broad overview on various existing cancer-imaging techniques followed by a detailed description on optical imaging in general and nanoparticle-based optical imaging in particular. This chapter will provide readers with all the necessary information that is required for them to obtain a grasp of this exciting and continuously evolving field of nanoparticle-based optical contrast agents. More specifically, readers will have an opportunity to obtain a broader perspective on applications of quantum dots, dye-doped nanoparticles, gold nanoparticles, phosphors & fluorescent polymer particles as potential contrast agents in optical imaging of cancer. Of all the nanomaterials with optical properties, gold nanoparticles are the most widely investigated materials and therefore, a complete chapter is dedicated to the utility of gold nanoparticles in cancer diagnosis. The third chapter, *Nanogold in Cancer Therapy and Diagnosis*, a contribution from the laboratories of Debabrata Mukhopadhyay from Mayo Clinic Cancer Center in Rochester, USA, brings out the importance of gold nanoparticles in cancer diagnosis and therapy. The authors also have reviewed relevant information on synthetic methods, biocompatibility and the mechanism of action of gold nanoparticles.

Moving from nanomaterials-based optical imaging techniques for diagnosis of cancer, the next three chapters describe investigations into utilization of magnetic nanoparticles for enhancing the sensitivity of detection of tumors using magnetic resonance imaging (MRI). Of the existing non-invasive diagnostic tools such as Computed Tomography (CT), Positron Emission Tomography (PET), Single Photon Emission CT (SPECT), Ultrasound (US) and optical imaging, MRI appears to be the most promising and sensitive technique. It is gaining more importance with the discovery of nanomaterials-based contrast agents. Researchers from the Washington University Medical School in St. Louis, USA, contributed the fourth chapter wherein an overview of the MRI technology and principle targeting mechanisms

are described, followed by a detailed discussion on the application of superparamagnetic and paramagnetic nanoparticles. The chapter, *Nanoparticles for Magnetic Resonance Imaging of Tumors*, brings out clearly the differences between the superparamagnetic nanoparticles, which are mainly SPIONs and paramagnetic nanoparticles belonging to groups such as liposomes, perfluorocarbon nanoparticles, fullerenes, and others. The chapter contributed by Tillmann Cyrus, Shelton D. Caruthers, Samuel A. Wickline, and Gregory M. Lanza also provides up-to-date information on rapidly evolving hybrid technologies using quantum dots for non-invasive imaging with MRI and intraoperative direct visualization. While the fourth chapter provides an overview of nanomaterials being developed for MRI, the fifth chapter primarily focuses on superparamagnetic iron oxide nanoparticles. This chapter, *Magnetic Resonance Nanoparticle Probes for Cancer Imaging*, contributed by Young-Wook Jun, Jung-tak Jang, and Jinwoo Cheon from Yonsei University in Seoul, Korea, reviews recently developed biocompatible magnetic nanoparticles and their utilization in molecular MRI. The final chapter on the application of SPIONs in MRI, the sixth chapter in the book, is from the laboratories of Carola Leuschner, Pennington Biomedical Research Center at Baton Rouge, USA. Being one of my close collaborators and having closely associated with the development of Leutenizing Hormone and Releasing Hormone (LHRH)-conjugated SPIONs, I can confidently say that this chapter is very unique and provides readers with all the information that is available on LHRH-conjugated magnetic nanoparticles. The chapter, *LHRH-conjugated Magnetic Nanoparticles for Diagnosis and Treatment of Cancers*, provides an elaborate account of the role of LHRH and LHRH receptors in malignant tissue. The central theme of the chapter is a description of comparative advantages of LHRH-SPIONs with other targeting agents in targeting specifically primary tumors and metastases, thereby demonstrating the potential for LHRH-SPIONs in dramatically improving the sensitivity of MRI.

Switching gears from nanoparticles, chapter seven written by Pu Chun Ke and Lyndon L. Larcom from Clemson University in Clemson, USA, is a testimony to the ever-increasing number of applications of carbon nanotubes. Not surprisingly, single-walled carbon nanotubes (SWNTs) have already shown promise in cancer diagnosis and therapy and have distinct advantages over multi-walled carbon nanotubes (MWNTs). The chapter, *Carbon Nanotubes in Cancer Therapy and Diagnosis*, captures up-to-date information available in the literature on functionalization for solubility and biocompatibility, cytotoxicity, gene and drug delivery, and sensing of cancer cells utilizing SWNTs. Following this chapter, Kiyotaka Shiba from the Cancer Institute of the Japanese Foundation for Cancer Research in Tokyo, Japan, has brought out a thorough review on the application of “non-spherical” nanomaterials in cancer treatment and diagnosis. The theme of this 8<sup>th</sup> chapter, truly reflected in the title *Nanotubes, Nanowires, Nanocantilevers and Nanorods in Cancer Treatment and Diagnosis*, is the current status of carbonaceous as well as non-carbonaceous nanotubes, nanowires, and nanorods with respect to their potential applications in cancer diagnosis and treatment. In the ninth chapter, *Multifunctional Nanotubes and Nanowires for Cancer Diagnosis and Therapy*, authors Sang Bok Lee and Sang Jun Son from the University of Maryland at College Park, USA, describe in detail

the importance of carbon nanotubes, nanotubes and nanowires composed of artificial peptides, and template-synthesized silica and magnetic nanotubes in general for various biomedical applications and in particular related to cancer. The authors demonstrate that tubular nanomaterials have several advantages over spherical nanoparticles, especially when multifunctionality is needed as nanotubes have distinctive inner and outer surfaces that can be modified and utilized differently, enabling them to be equipped with the right function in the right position.

The last two chapters of this volume are testimony to the breadth of nanotechnological approaches for cancer diagnosis. The penultimate chapter, *Nanoprobe-based Affinity Mass Spectrometry for Cancer Marker Protein Profiling*, provides an overview on a recently developed technique – nanoprobe-based affinity mass spectrometry (NBAMS) – for the screening of normal individual and cancer patients. The chapter is a contribution from the Institute of Chemistry and Genomic Research Center of the Academia Sinica in Taipei, Taiwan, authored by Yu-Ju Chen and co-workers. This chapter provides fundamental principles in mass spectrometry and the detection method in NBAMS, in addition to details of the design, workflow and performance of NBAMS. The final chapter is presented by Thomas Ludwig from Yale University at New Haven, USA. The author points out some of the challenges in cancer diagnosis by focusing on local, nanoscale processes for in vitro and in vivo diagnostics. The chapter, *Nanotechnological Approaches to Cancer Diagnosis: Imaging and Quantification of Pericellular Proteolytic Activity*, is an interesting chapter on how development of improved nanotechnology enabled methods that are likely to provide real-time high-resolution imaging and quantification of local enzymatic activities will play a major role in the design of new drugs and the understanding of basic principles in tumor cell invasion.

This book concludes the two volumes dedicated to cancer nanotechnology. I do realize that there are some topics that have not been covered and also some topics that have been covered are not exhaustive enough. I am hoping that the next edition of this book series will fill these gaps and also will take into consideration suggestions from the readers. I am looking forward to hearing from you.

As I end this preface, I am pleased to note that the first six volumes of the ten volume series have already been published and the next four volumes are in print. I am also pleased to know that the *Nanotechnologies for the Life Sciences* in general is being well received.

**Dendrimers in Cancer Treatment and Diagnosis**

*Srinivasa-Gopalan Sampathkumar, and Kevin J. Yarema*

## 1.1

**Overview**

Dendrimers are nano-sized, radially symmetric molecules with well-defined, homogeneous and monodisperse structure consisting of tree-like arms or branches. Over the past two decades since the term “dendrimer” was formally defined, research interest in these molecules has gradually evolved from a primary focus on overcoming purely synthetic challenges to include aesthetic and theoretical perspectives, and, more recently, with the ongoing flurry of “nanobiotechnology” advances, to develop practical and commercial applications for these elegant nano-devices. Today, a critical mass of knowledge exists to synthetically control the physicochemical properties of dendrimers and thereby govern their ensuing biological behaviors. These fundamental scientific advances, coupled with practical methods to covalently conjugate a wide range of bioactive molecules to the surface of a dendrimer or encapsulate them as guest molecules within void spaces, provide a highly versatile and potentially extremely powerful technological platform for drug delivery. This chapter recaps synthetic advances in dendrimer construction and summarizes the many features of these fascinating macromolecules that endow them with favorable properties for drug delivery applications. Finally, with this enticing technology having matured to the point where it is ready to confront “real-world” challenges, a synopsis is outlined of the prospects for exploiting dendrimer-based nanodevices for one of the most intractable medical challenges, the diagnosis and treatment of cancer.

## 1.2

**Introduction**

The discovery, design, and development of anticancer therapeutic agents have proven to be remarkably intractable despite intense efforts at the research and clinical levels over many decades. A brief consideration of the challenges facing an

anticancer drug illustrates some of the reasons for frustratingly-slow progress: first the drug must be able to seek out subtle changes that distinguish a transformed cell from the other 200 or so types of healthy cells found in the body and then provide a sufficiently high dose of a toxic agent to kill the cell. The difficulty of this task is amplified by the potential metastasis of cancer cells to widely-spread niches throughout the body, each with unique properties. Furthermore, to successfully cure a patient, each and every cancer cell must be eradicated because even one in a thousand – often harboring latent resistance – can re-grow into a second tumor refractory to therapeutic intervention.

Readers of this chapter, contained within a volume devoted to the development of novel cancer therapeutics, do not require convincing of the difficulty of combating cancer and this issue will not be labored here. Instead, this chapter provides a broad overview of dendrimer-based nanotechnologies for the treatment of cancer with a consideration of their synthesis, the encapsulation and covalent attachment of drugs, and various strategies used for tumor specific targeting, imaging, and therapy. The discussion of specific topics begins with a description of the basic properties of dendrimers in Section 1.3 to highlight how these molecules lie at the interface between conventional synthetic polymers and the archetypical nano-sized biological polymers, proteins. Section 1.4 briefly outlines the synthesis of dendrimers; exhaustive review articles (referenced therein) provide a wealth of synthetic detail beyond the scope of this discussion. This chapter aims to provide the reader with the knowledge that, by control of design parameters, the attributes of dendrimers can be tuned to incorporate the most desired features of synthetic polymers and proteins and, thereby, gain exquisite control of biological activity.

Upon having established that dendrimers are synthetically-tractable, biologically-compatible nano-devices, their unique suitability for drug delivery will be delineated in some detail in Section 1.5. Specific topics covered include the alternative drug-carrying strategies of encapsulation (Section 1.5.2) and covalent conjugation (Section 1.5.3), as well as design features needed to ensure bioactivity of the drug (Section 1.5.4) and the biocompatibility of the dendrimer (Section 1.5.5). Finally, with the multi-disciplinary set of tools required for dendrimer-based drug delivery now reaching maturity, this area of investigation is undergoing transformation from the developmental stage to “real-world” applications. Accordingly, Section 1.6 discusses the prospects for using dendrimer-based nanotechnologies to overcome arguably the most difficult biomedical problem now faced, the diagnosis and treatment of cancer. In particular, the general properties of dendrimers that make them attractive for cancer treatment will be outlined in Section 1.6.1, with a specific benefit – exploitation of the enhanced permeability and retention effect that allows passive accumulation at the sites of tumors – discussed in Section 1.6.2. The ability of dendrimers to serve as a technological platform for multifunctional nano-devices that include targeting, imaging, and/or cytotoxic modalities is discussed in Section 1.6.3 and their prospects for diagnosis and therapeutic applications are given in Sections 1.6.4 and 1.6.5, respectively. Finally, Section 1.6.6 gives a brief synopsis of innovations that promise to speed progress in the near future.

Together – while broader in scope than the typical discussion of dendrimers, drug delivery, or cancer therapy – this chapter provides an integrated look at the many considerations required for successful application of dendrimers for cancer therapy. For a more-in-depth consideration of any particular sub-topic, the interested reader is urged to consult the many original research reports and review articles cited throughout.

## 1.3

### Basic Properties and Applications of Dendrimers

#### 1.3.1

##### Structural Features and Chemical and Biological Properties

###### 1.3.1.1 Basic Features of Dendritic Macromolecules are Inspired by Nature

Dendritic structures, characterized by hyperbranched subunits, are widely found in nature. Indeed, the word dendrimer is based on the Greek words “dendron” meaning “tree” or “branch” and “meros” meaning “part” [1, 2]. Taken literally, similarities with dendrimer macromolecules are illustrated by a tree, where the leaves of a tree are maximally displayed on a highly-branched scaffold to maximize their accessibility to the outside world to optimize functions such as light harvesting. The branches of a tree can modify the environment within them, similarly the core/interior encapsulated within a dendrimer can provide a sheltered microenvironment with tailored chemical properties and reactivities [2]. In addition to actual trees, Nature has scaled dendrimeric structures down to the multi-centimeter level (the intricate neural pathways found in the brain), the millimeter level (ice crystals and snowflakes), and yet further to the micron level (the dendritic outgrowths of neurons). At a molecular, “nano-size” level, dendrimer-like molecules, such as branching polysaccharides, provide an elegant solution to a cell's need to stably store high energy molecules like monosaccharides; the presence of many chain ends allows the rapid release of large numbers of glucose monomers when needed [3].

Unlike Nature, which provides dendritic structures in a range of sizes from real trees to the namesake molecular nano-sized structures, this chapter focuses exclusively on dendritic macromolecules that are of a synthetically tractable scale and appropriate for cancer therapy. Starburst® clusters [4], made of poly(amidoamine) (PAMAM) units, are arguably the most-thoroughly characterized and extensively-utilized dendrimers [5]. A basic characteristic of these molecules is their layered composition – known as “cascades” or “generations” [1] (Fig. 1.1). The overall shapes of dendrimers range from spheres to flattened spheroids (disks) to amoeba-like structures, especially in cases where surface charges exist and give the macromolecule a “starfish”-like shape [6].

The exact morphology of a dendrimer depends both on its chemical composition (the chemical composition of PAMAM dendrimers is shown in Fig. 1.1) as well as on the generation number, as exemplified by PAMAM where the lowest generation

**Fig. 1.1.** Schematic representation of a generation G4 dendrimer with 64 amino groups at the periphery. This dendrimer starts from an ethylene diamine core; the branches or arms were attached by exhaustive Michael addition to methyl acrylate followed by exhaustive aminolysis of the resulting methyl ester using ethylene diamine [36]. This sequence of reactions was applied in an iterative fashion to increase the level of

generations. The periphery of successive generations is marked by grey circles, starting from G0, G1, G2, G3 and G4. Of note, distinctive features of dendrimers, including the densely-packed membrane-like arrangement of surface functional groups, the formation of internal cavities, and the condensation into globular structures (not shown), are typically manifest at the G4 stage (and amplified in successive generations, Table 1.1).

structure (e.g., G0 and G1) have highly asymmetric shapes and possess open structures compared with higher-generation structures that first appear to be disk-like and then progress to increasingly spherical geometries [5] as they assume globular structures with a significant reduction in hydrodynamic volume [7]. In addition to sphere-like dendrimers – based on a “dot-like” core (Fig. 1.1) – increasing interest is developing in cylindrical dendrimers that are based on “rod-like” cores. These interesting spin-off macromolecules have been compared with spaghetti because they can be rigid like the uncooked form of this pasta or highly flexible like the cooked form; these properties can be tuned based on the chemical composition and density of packing of the dendritic branches [6]. Additional features of dendrimers are discussed below, by comparison with the two classes of molecules they are most often likened to, i.e., “conventional” synthetic polymers and, the most extensively studied biological polymer, proteins.

### 1.3.1.2 Comparison of the Properties of Dendrimers and Conventional Synthetic Polymers

Dendrimers have both similarities and differences when compared with traditional polymers. One similarity is the vast diversity in the basic monomeric building blocks used to create both classes of molecules and to provide the final macromolecular products with a wide range of chemical, mechanical, and biological properties. Until recently, polymer chemistry has been focused on the production of linear polymers that often have a degree of branching or crosslinking; this property, however, is dramatically limited by comparison to dendrimers whose entire identity is wrapped up in their hyperbranched character. Interestingly, highly-branched polymers of the same material can be vastly different from conventional polymers of a similar molecular weight and composition; in particular, as dendritic macromolecules progress in size, usually when becoming larger than the third generation (G3), they assume globular structures and occupy considerably smaller hydrodynamic volumes than linear polymers [1].

When dendrimers condense into globular structures, a feat rarely achieved with linear synthetic polymers, their many termini become fixed into an outwards orientation and also form a densely packed, membrane-like surface (Fig. 1.1). This structural arrangement provides numerous attachment points for covalent conjugation of bioactive molecules on the surface as well as enclosed cavities for occlusion of guest molecules within the dendrimer. This tight packing ultimately results in the reaching of a critical branched state – known as the “starburst effect” [4] – where growth of the dendritic macromolecule is dramatically hindered by steric constraints [8] (this state is reached at G10 or G11 for PAMAM, Table 1.1). Dendrimers also have dramatically different rheological properties than conventional polymers; viscosity tends to increase continuously with molecular mass for linear macromolecules whereas the intrinsic viscosity of dendrimers goes through a maximum at approximately the fourth generation and then declines [8, 9]. Finally, dendrimers have a negligible degree of polydispersity because, unlike classical polymerization that is random in nature and produces molecules of various sizes, the size of dendrimers can be carefully controlled during synthesis. Under ideal condi-

**Tab. 1.1.** Generation by generation specifications for PAMAM Starburst® dendrimers. (Adapted from Ref. [5].)

Generation	Physical or structural parameter			
	Molecular weight (Daltons)	Diameter (Å)	Surface groups (-NH <sub>2</sub> )	Radius of gyration (Å)
G0	517	15	4	4.93
G1	1430	22	8	7.46
G2	3256	29	16	9.17
G3	6909	36	32	11.2
G4	14 215	45	64	14.5
G5	28 826	54	128	18.3
G6	58 048	67	256	22.4
G7	116 493	81	512	29.1
G8	233 383	97	1024	36.4
G9	467 162	114	2048	46.0
G10	934 720	135	4096	55.2
G11	1 869 780	167	8192	68.3

tions, preparations of dendrimers are monodisperse, which is to say they have one molecular weight instead of the range, over tens or even hundreds of kDa, often seen for traditional synthetic polymers. Indeed, the homogeneity and uniformity of dendrimers of successive generations becomes strikingly obvious as shown by the tunneling electron microscopy (TEM) images for G5 to G10 PAMAM (Fig. 1.2) [10].

### 1.3.1.3 Comparison of the Properties of Dendrimers and Proteins (a Biological Polymer)

As discussed above, dendrimers have unusual, often dramatically different, characteristics compared with conventional synthetic polymers. In fact dendritic molecules have often been compared with proteins, which are the workhorse biological polymers. Both classes of macromolecules are globular, are composed of precisely controlled monomeric units, have defined architectures, are of comparable size (Table 1.1), and have surfaces with chemically-reactive sites that can be endowed with biologically-compatible ligands found on proteins (such as glycosylation, Section 1.4.3.2). Moreover, the interior of a dendritic molecule, reminiscent of a protein, can harbor unique microenvironments, providing behaviors like redox chemistry, molecular recognition, ligand and substrate binding, and catalysis [11, 12]. The ability to create and exploit isolated nanoenvironments within a dendritic shell is derived from two main properties of a dendrimer. First, dendritic macromolecules adopt a semi-globular or fully globular character containing internal void

**Fig. 1.2.** Transmission electron microscopy (TEM) of PAMAM dendrimers. Dendrimers were positively stained with aqueous sodium phosphotungstate and imaged by conventional TEM: (a) G10, (b) G9, (c) G8, (d) G7, (e) G6, (f) G5. The scale bars indicate 50 nm, and a

small amount of G10 has been added as a focusing aid for G6 and G5. (Reprinted with permission from Jackson and coauthors [10]. Copyright 1998 by the American Chemical Society.)

spaces once they reach the fourth generation in size (Fig. 1.1) [8], enabling the encapsulation of protein-like functions, including catalysis [13, 14]. Second, these molecules have molecular flexibility and can undergo deformations, leading to rudimentary “lock and key” molecular recognition of the type vitally important to protein functions [15, 16].

Molecular recognition between molecules is a fundamental process in biology and chemistry without which life could not exist. The concept of molecular recognition, based on complementarity between the receptors and substrates, is very similar to the “lock and key” function first described by Emil Fischer over 100 years ago. In biology, the “lock” is the molecular receptor such as a protein or enzyme and the “key” can be regarded as a substrate such as a drug or ligand that is recognized to give a defined receptor–substrate complex [15]. In proteins, molecular recognition is largely driven by non-covalent forces such as hydrogen bonding, electrostatics, van der Waals forces,  $\pi$ - $\pi$  interactions, solvent-dependent interactions including hydration forces, and conformational energy [17]; notably, all of these parameters can be controlled in dendrimers through synthetic design. The inherent ability of dendrimers to achieve molecular recognition of biological features, if it can be successfully developed to a level of sophistication where it can be exploited for the recognition of the surface biomarkers that distinguish cancer

cells from healthy cells (Section 1.6.3), has important – and extremely beneficial – implications for drug delivery (Section 1.5).

Although sharing many superficial features, a close inspection reveals important differences between dendrimers and proteins. For example, remaining on the topic of deformability and flexibility, the linear, folded chain of a protein is more tightly packed but also has a greater *potential* for flexibility (when a comparison is made between the fully folded and unfolded states of a peptide chain) than is possible for the branches of a dendrimer. Only a small proportion of the potential flexibility of a protein, however, is usually available for “induced fit” interactions because the extensive unfolding of a protein is highly thermodynamically unfavorable. By comparison, although the extensive covalent bond networks within a dendrimer prevents complete unfolding under any condition, this arrangement does provide sufficient flexibility to allow dramatic – albeit somewhat thermodynamically unfavorable – deformations fairly readily [18]. Next, to consider dendrimer surfaces in comparison with proteins, synthetic dendritic macromolecules can be given a significant repertoire of tunable characteristics not found on natural proteins; this feature has greatly propelled the development of practical applications for these molecules. In particular, the surface of a protein contains a relative sparse complement of chemically reactive and accessible functional groups because most amino acid side chains are buried with the globular structure of the protein. By contrast, virtually all of the termini of dendritic branches, which can be customized with a wide range of chemical functionalities (Fig. 1.3), are oriented outward and are highly accessible on the surface of the dendrimer (Fig. 1.1). The consequent ability of a dendrimer to be functionalized with far more surface groups than a protein of comparable size [1, 19] has provided impetus to their widespread use as drug delivery vehicles.

### 1.3.2

#### **Dendritic Macromolecules Possess a Wealth of Possible Applications**

Within the past decade, the success of chemists in synthesizing mimics of natural dendrimers with a plethora of interesting physicochemical properties at the nanoscale has spurred efforts to find practical uses for these versatile nanodevices. Now that efforts to synthesize these molecules have reached fruition, there is a pleasing circularity that certain applications mirror natural processes considering that dendritic molecules were initially inspired by nature. In a dramatic example, a primary function of the leaves of real trees is for light harvesting; now, synthetic dendrimers have been created with highly-efficient light-harvesting antennae as well [8, 20]. Similarly, the dendritic network of hairs found on the Gecko foot that allows amazingly strong attachment to many types of surfaces through van der Waals forces [21] has led to efforts to create new forms of adhesives that are unaffected by the roughness, smoothness, wetness, or other macroscopic properties of the surface while providing strong but reversible adhesion. In addition to these two examples, many novel applications such as the exploitation of organometallic dendrimers as quantum dots for imaging, the solubilization of hydrophilic dyes in

**Fig. 1.3.** Structural options for dendrimer-based drug delivery. Dendrimers can be synthesized with neutral surfaces (1) and positive (2) or negative (3) charges at the periphery; moreover, dendritic macromolecules, generally when larger than G3, can harbor non-covalently encapsulated guest/drug molecules [4 and discussion in Section 1.5.2]. An alternative strategy for drug delivery is through covalent conjugation of ligands ("A" in 5) to the surface of the dendrimer (Section 1.5.3). The versatility of dendrimers for drug delivery is illustrated by considering that "A" could be a targeting

ligand (Section 1.6.6.3) and the active drug could be encapsulated within the same macromolecule (6). Synthetic strategies are now available for providing dendritic clusters with extremely high densities of surface ligands (7) and for providing more than one type of surface ligand, either in a random orientation (8), or in blocks (9). The latter dendrimers are now being exploited in sophisticated cancer cell targeting (Fig. 1.4) and drug release (Section 1.5.3.3) strategies where A, B, and C can be any combination of targeting agents, drugs, contrast agents, or functional groups that improve pharmacological properties.

apolar dendritic “solvents” [22], use as chemical catalysts, and in electronics as insulated molecular wires, light-emitting diodes, or fiber optics [12, 23, 24] have been reported. Besides their use for drug delivery and cancer therapy, the many emerging chemical, synthetic, research, and industrial uses for dendrimers are outside the scope of this article and will not be discussed further; the interested reader can consult chapter articles [1, 2, 11].

## 1.4

### Methods for Dendrimer Synthesis

#### 1.4.1

##### History and Basic Strategies

The ability to create homogeneous molecules with defined dendritic architecture and novel physicochemical properties at the sub-nano to nano-size scales occurred in chronological synchrony with the wide-spread application of nanobiotechnology to biology and medicine. Consequently, the parallel development of synthetic chemical methodology and the ever-increasing application of nano-tools in biomedicine triggered an explosive growth in the new field of dendrimer synthesis. This growth is evidenced by a cursory search for “dendrimers and synthesis” in the Web of Science database, which reveals that ~2000 articles have been published on this topic since 1986. Clearly, a full discussion is beyond the scope of this report; excellent accounts and review articles on the synthesis of dendrimers by pioneers of the field have appeared at regular intervals [25–32] and are cited throughout this chapter. Nonetheless, a working knowledge of the chemical properties of dendrimers is critical to successfully devise efficacious therapeutic strategies with these versatile, but temperamental, macromolecules (as described in detail in Sections 1.5 and 1.6). Accordingly, we next provide an outline of the basic strategies and building blocks employed in dendrimer synthesis, with an emphasis on families of dendritic molecules that possess special properties – such as possessing cavities in their interiors suitable for host–guest complexation similar to enzyme–substrate complexes or displaying several functional groups on their surface appropriate for sophisticated drug delivery strategies – relevant to the field of biology and medicine.

##### 1.4.1.1 Cascade Reactions are the Foundation of Dendrimer Synthesis

Although the term “dendrimer” was coined by Tomalia and coworkers less than two decades ago, the basic cascade or iterative methods that are currently employed for synthesis were known to chemists much earlier. For example, similar schemes form the basis of solid phase peptide synthesis. In turn, biology has long exploited similar iterative strategies in biochemical synthetic pathways; one example is provided by fatty acid biosynthesis [33]. Focusing on dendrimers, these macromolecules are constructed by performing simple chemical reactions in a repetitive or iterative manner by using small building blocks. In 1978 Vögtle and coworkers re-

## A. Cascade synthesis of polyaza compounds by Vögtle and coworkers (1978)

## B. Divergent synthesis of poly(amidoamine) dendrimers (PAMAM) by Tomalia and coworkers (1986)

## C. Convergent synthesis of aryl ether dendrimers by Fréchet and coworkers (1990)

**Fig. 1.4.** Synthetic approaches to dendrimers. (A) Cascade reaction sequences developed for the synthesis of “non-skid-chain like” polyaza macrocyclic compounds [34]. (B) Divergent approach – synthesis of radially symmetric PAMAM dendrimers using ammonia as the trivalent core; the generations are added at each synthetic cycle (two steps), leading

to an exponential increase in the number of surface functional groups [36]. (C) Convergent approach – synthesis of dendrons or wedges or branches that will become the periphery of the dendrimer when coupled to a multivalent core in the last step of the synthesis [40].

ported a similar approach, termed as cascade reactions, for the construction of nonskid-chain-like poly-aza macrocyclic molecules with well-defined architectures. Cascade synthesis is defined as “reactions where a functional group (e.g., amine) is made to react in such a way as to appear twice in the subsequent molecule or product” [34] (Fig. 1.4A). In the first step of the synthesis a primary or secondary amine was reacted with excess acrylonitrile in a Michael reaction to obtain a product with two arms [bis(2-cyanoethyl)amines]. In the second step the nitrile groups were reduced using cobalt(II)/sodium borohydride to generate a new set of primary amine groups on both arms. The newly generated amino groups were then subject to identical reaction sequences iteratively to obtain the desired oligo-amine compounds.

In 1985 Newkome and coworkers reported the synthesis of cascade molecules consisting of hydrocarbon core and shell with alcohol groups on the surface. These synthetic efforts were inspired by the Leuwenberg model of arboreal design; hence they named their synthetic macromolecular tree-like molecules “arborols” (Latin: arbor = tree). Interestingly, characterization of these molecules showed they could be considered to be unimolecular micelles possessing cavities for encapsulation [35], a property that foreshadowed today’s efforts to use dendrimers for the delivery of encapsulated small molecule drug candidates (Section 1.5.2).

#### 1.4.1.2 Dendrimer Synthesis has Expanded Dramatically in the Past Two Decades

In 1986, Tomalia and coworkers coined the now popular name “dendrimers” (Greek: dendron = branch or tree-like) for radially symmetric branched molecules and reported the application of cascade synthesis for the synthesis of starburst dendrimers [36]. These researchers obtained homogeneous dendrimers by using a synthetic sequence of two simple reactions: (a) exhaustive Michael addition of ammonia to methyl acrylate and (b) exhaustive aminolysis of the resulting tri-ester derivative by ethylene diamine. The acrylate addition and aminolysis were repeated in an iterative manner, with excellent yields in each step, to prepare various molecules with increasing molecular weight and generations (Fig. 1.4B). The products with ester groups at the exterior were defined as  $G(m + 0.5)$  generations and those with amine groups at the exterior were defined as  $G(m)$  (Fig. 1.1). This simple methodology is both powerful and versatile as it provided the ability to synthesize dendrimers with various surface properties. For instance, the ester groups could be hydrolyzed to present negatively charged carboxylate functional groups at the periphery or the amine groups could be protonated to present positive charges at the periphery. Electron micrographic studies showed the dendrimer with carboxylate groups of generation,  $G = 4.5$ , to be highly monodispersed with a diameter of  $88 \pm 10 \text{ \AA}$ , compared with the theoretical value of  $\sim 78 \text{ \AA}$ . These dendrimers, when covalently attached to a polymeric backbone, were called “starburst polymers” or, less commonly, “cauliflower polymers” [7, 28].

### 1.4.2

#### Strategies, Cores, and Building Blocks for Dendritic Macromolecules

##### 1.4.2.1 Dendrimers are Constructed from Simple “Building Blocks”

In terms of synthesis, dendrimers can be constructed by using simple chemical reactions and building blocks reminiscent to the modular assembly of “LEGO” toys. Due to the ease, simplicity and repetitive nature of the synthetic methods, dendrimers based on organic, inorganic and organometallic molecular building blocks with greater than hundred different compositions are currently known, and new designs continue to be reported at a fast pace. In general, dendrimers consists of three major regions – (a) an initiator core, (b) a shell with extending arms or branches made of building blocks and (c) the exterior or outer-most surface groups on the termini of the branches.

There are innumerable ways of designing dendrimers [37–39]. For instance, the symmetry of the initiator core (Fig. 1.1) can be varied by using a wide range of molecules, which have included ammonia,  $\alpha,\omega$ -diaminoalkanes, tri-substituted benzene, oligo- or polyalcohols, nucleic acids, amino acids, lipids, carbohydrates, or heteroatoms; many additional permutations are possible, e.g., the number of branching units in the initiator can be increased (tri- or tetra- or higher valency cores have been reported). Once the core moiety has been selected, options for the synthesis of the dendritic branches are equally numerous as various types of building blocks can be used, either singly or in combination with each other in the same dendritic macromolecule. The lengths of the dendritic arms, the nature of the surface, and the display of terminal functional groups can all be customized.

#### 1.4.2.2 The Synthesis of Dendrimers Follows Either a Divergent or Convergent Approach

Dendrimers can be synthesized by two major approaches. In the divergent approach, used in early periods, the synthesis starts from the core of the dendrimer to which the arms are attached by adding building blocks in an exhaustive and step-wise manner. This process provides dendrimers with incrementally increasing generation numbers. However, only one type of reaction can be performed at each step, giving a uniform display of only one functional group on the exterior surface; moreover, defects in successive generations can arise due to incomplete reactions or steric hindrance (Fig. 1.4B).

In the convergent approach, pioneered by Fréchet and coworkers [40], synthesis starts from the exterior, beginning with the molecular structure that ultimately becomes the outer-most arm of the final dendrimer (Fig. 1.4C). In this strategy, the final generation number is pre-determined, necessitating the synthesis of branches of the various requisite sizes beforehand for each generation [31]. Small branches or dendrons are synthesized starting from the building blocks containing surface groups; these assemblies are then condensed with a multivalent core. This approach is versatile in the sense that branches of different molecular composition can be linked to a single core molecule, introducing regional variations on the final dendrimer (Fig. 1.3); this strategy also minimizes the introduction of defects at various stages of synthesis.

### 1.4.3

#### Heterogeneously-functionalized Dendrimers

##### 1.4.3.1 Basic Description and Synthetic Considerations

By simultaneously conjugating appropriate targeting moieties, drugs, and imaging agents to dendritic polymers, “smart” drug-delivery nanodevices can be developed to target, deliver, and monitor the progression of therapy. For example, as will be described in greater detail below, a dendrimer intended for cancer therapy needs to be functionalized with the drug itself, display a moiety for targeting to the tumor cells, as well as include surface groups designed to improve the pharmacological

properties (e.g., to ensure water solubility, avoid non-specific uptake or immunogenicity). Several synthetic strategies – primarily the convergent method discussed above (Section 1.4.2.2) – have been developed that enable multiple species to be added to a dendritic surface in an ordered manner [41] and thereby achieve multiple functionalities within the same dendritic nanodevice (Fig. 1.3). The ability to create multi-functional nanodevices based on dendritic scaffolds, however, remains a challenging endeavor because conjugating several types of different molecules to a dendrimer is likely to change its physicochemical properties and resulting biological activity. Practically, additional synthetic steps required to fine-tune bioactivity and remedy bioincompatibility if it arises may render the whole process cost-inefficient at best and, more troublesomely, lead to loss of product uniformity, thereby negating a key benefit of dendrimers, i.e., their monodisperse, fully defined nature [42].

#### 1.4.3.2 Glycosylation is an Example of Surface Modification with Multiple Bioactivities

An outstanding demonstration of the synthetic power of decorating the surface of dendrimers with “interesting” molecules comes, once again, by way of comparison of these nanodevices with proteins. Proteins, which have had the opportunity to evolve biocompatibility and systemic functions in multicellular organisms over hundreds of millions of years, have found it advantageous to decorate their surfaces with complex carbohydrates when they are displayed on the cell surface or secreted into the extracellular milieu. In the past few years, it has become clear that these sugars play many key roles in molecular recognition over short distances, such as interactions with the extracellular matrix and with neighboring cells, as well providing system-wide communication (e.g., almost all protein hormones are glycosylated). When developing dendritic nanotools requiring bioactivity similar to that found in proteins, including the ability needed by a drug candidate to seek out and evoke responses at a specific but far-removed cell type in the body, it is wise to learn from nature and consider the inclusion of sugars to be an important design parameter.

The ability to provide dendrimers with oligosaccharide coatings has been facilitated by the many functional groups that can be displayed on the surface and function as chemical handles for covalent attachment of a second group. A pioneering example of sugar display on a dendritic scaffold was provided by the unusual nine-carbon sugar sialic acid [43, 44]. This sugar, when displayed on human cells, serves as a critical binding epitope for the influenza virus. The virus, however, does not bind to soluble sialic acid, or sialic acid appended to a conventional polymer. Because these forms of sialic acid do not serve as effective binding elements, they are unable to act as a molecular decoys [45] and prevent the virus from binding to its real target, sialic acid on the human cell. By contrast, when sialic acid was conjugated to the surface of a dendritic polymer, it functioned as an effective and efficient binding decoy [46, 47], opening the door to the development of new diagnostic devices and novel anti-viral therapies [48, 49]. The molecular basis of the preferential recognition of sialic acid by the influenza virus when this sugar was

displayed on a highly structured dendritic scaffold was traced to the “cluster glycoside effect” [50]. Over the past decade it has become firmly established that carbohydrate-based recognition depends on multiple simultaneous interactions to increase specificity and affinity [45, 51]. The demonstration that dendrimers provide an ideal synthetic platform for the appropriate display of carbohydrates to achieve the cluster glycoside response [52–54], along with improved methodology to synthesize glycoconjugated-dendrimers [43, 55], has driven the expansion of this approach from a single monosaccharide to a sugar-amino acid couple (the Tn antigen, which is *N*-acetylgalactosamine linked to serine [56]) to disaccharides (lactose [57] and the T-antigen [58]), and, finally, to tetrasaccharides (the sialyl Lewis X epitope [59]).

## 1.5

### Dendrimers in Drug Delivery

#### 1.5.1

#### Dendrimers are Versatile Nano-devices for the Delivery of Diverse Classes of Drugs

A successful drug must perform the demanding tasks of selectively recognizing and binding to a molecular target, then triggering an appropriate biological response, all the while possessing pharmacological properties that render it “drug-like”. In some cases, nature has supplied compounds – such as aspirin or penicillin – that can be used directly as drugs but the more common situation is that many otherwise promising therapeutic agents are not successful in the clinic because of their poor pharmacological properties. The properties of dendrimers, in particular the synthetic ability to provide them with many different biological properties, along with their capacity to carry conjugated surface molecules or encapsulated guest molecules, make them immediately attractive as potential vehicles for drug delivery.

Drug delivery efforts are complicated by the diversity of molecules that hold potential therapeutic or diagnostic value; briefly reviewing three classes of drug candidates based on size demonstrates the wide applicability of dendrimers to drug delivery. First, regarding “small molecules”, many low molecular weight drug candidates are limited by poor solubility in aqueous environments or, if they are soluble, face rapid elimination from the bloodstream through filtration in the kidney. In the past, efforts have been made to modify the molecule itself, often following the “rule-of-five” guidelines developed by Lipinski to raise awareness of the properties and structural features that render molecules more or less “drug-like” [60]. Dendrimers present an attractive alternative strategy to the redesign of the drug because they allow unfavorable properties of a small molecule, such as insolubility, to be overcome by the larger characteristics of the macromolecule. An approach for improving the pharmacological properties of higher molecular weight drug candidates, analogous to Lipinski’s guidelines for the modification of small molecule drugs, has been applied for protein therapeutics such as recombinant antibodies

and protein toxins used in cancer treatment. In these cases, the amino acid sequences of recombinant proteins have been “humanized” by genetic engineering to avoid immunogenicity [61, 62] and their glycosylation patterns have been modified to increase serum half-life [63, 64]. These efforts, undertaken with actual proteins, illuminate design features that can benefit the development of protein mimics, dendrimers. In particular, the “humanizing” experiments show that small changes, such as the substitution of a single amino acid for another, can avoid significant problems like undesired systemic immune responses. In the same manner, small changes in the surface properties of dendrimers, such as the addition of poly(ethylene glycol) (PEG), can avoid unwanted immunogenicity. Finally, even extremely large therapeutic candidates, notably plasmids or naked viral DNAs used for non-viral gene delivery that are well beyond the size of traditional drugs, are also benefiting from dendrimer-assisted delivery. The next section outlines specific approaches for the delivery of both small and large drug candidates by dendrimers.

### 1.5.2

#### **Dendritic Drug Delivery: Encapsulation of Guest Molecules**

##### **1.5.2.1 Dendrimers have Internal Cavities that can Host Encapsulated Guest Molecules**

The flexible branches of a dendrimer, when constructed appropriately, can provide a tailored sanctuary containing voids that provide a refuge from the outside environment [2] wherein drug molecules can be physically trapped [65] (Figs. 1.1 and 1.3). Encapsulation of hydrophilic, hydrophobic, or even amphiphilic compounds as guest molecules within a dendrimer [66] can be enhanced by providing various degrees of multiple hydrogen bonding sites or ionic interactions [65, 67] or highly hydrophobic interior void spaces [68, 69]. A wide variety of molecules have been successfully encapsulated inside dendrimers. In early experiments, compounds used to demonstrate the “guest molecule” concept included easy-to-visualize dye molecules such as rose bengal [66] and Reichardt’s dye [69] as well as pyridine [65] and peptides [67]. More recently, actual drugs, including 5-fluorouracil [70], 5-amino salicylic acid, pyridine, mefenamic acid and diclofenac [65], paclitaxel [71, 72], docetaxel [73], as well as the anticancer agent 10-hydroxycamptothecin [69], have been successfully encapsulated. Together, these results demonstrate that encapsulation is a general strategy for the delivery of low molecular weight compounds by dendrimers. This method is anticipated to be of particular value when display of the bioactive molecule on the surface of the dendrimer induces unwanted immunogenicity or reduces biocompatibility (Section 1.5.5).

##### **1.5.2.2 Using Dendrimers for Gene Delivery**

The delivery of small molecules complexed as guest molecules in internal void spaces of dendrimers is, at least in retrospect, intuitively obvious. By contrast, the delivery of extremely large macromolecules, such as MDA-sized plasmid DNA for non-viral gene therapy, is counter-intuitive because the encapsulation of a “guest” molecule many times the molecular weight of the dendrimer itself appears impos-

sible. Nonetheless, experimental evidence had demonstrated that gene delivery strategies also benefit from the participation of dendrimers [74]. For example, from its original discovery of efficacy for gene delivery [75], the fractured form of PAMAM, known as Superfect™, is now a commercially-available transfection agent for *in vitro* applications [76]. Typical approaches to optimize dendritic gene delivery for *in vivo* use have involved the surface modification of a PAMAM backbone, either with arginine [77] or hydroxyl groups [78]. Alternatively, the results reported by Kim and coworkers, who demonstrated improved gene delivery with a novel PAMAM-PEG-PAMAM triblock copolymer, show that construction of dendrimers composed of new building blocks is warranted [76]. Although still in their infancy, there are efforts afoot to exploit dendrimers for the delivery of smaller nucleic acids such as antisense oligonucleotides and short interfering RNAs (siRNA); the success of these applications is likely to depend on the continuing development of novel materials for dendrimer synthesis [79].

### 1.5.2.3 Release of Encapsulated “Pro-drugs”

Once a dendrimer carrying an encapsulated drug reaches the intended site of action, the guest molecule generally must be released to gain bioactivity. Indeed, a concern is that the active drug would “leak” out prematurely, thereby reducing the amount available for the intended therapeutic intervention, or more ominously, result in systemic toxicity. Reassuringly, early experiments showed that the close packing of dendritic branches on the surface of the macromolecule (Fig. 1.1) effectively formed a “membrane” that reduced diffusion to immeasurably slow rates [66]. In other cases, the release of encapsulated guest molecules was relatively faster, occurring over a few hours, apparently through hydrolytic degradation of the dendrimer in aqueous conditions [65]. The observation that guest molecules could be liberated at different rates demonstrated that viable opportunities exist to tailor the release for either slow or rapid delivery (Fig. 1.5). At present, additional control of delivery rates is being sought; for instance, the ability of a dendrimer to instantaneously release its entire drug payload upon reaching its cellular target would be valuable. Promising steps in this direction are being taken by the development of pH-sensitive materials [65], the fine tuning of hydrolytic release conditions, and the selective liberation of guest molecules on the basis of their size or shape [80].

## 1.5.3

### Covalent Conjugation Strategies

#### 1.5.3.1 Dendrimers Overcome many Limitations Inherent in Polymeric Conjugation Strategies

The strategy of coupling small molecules to polymeric scaffolds by covalent linkages to improve their pharmacological properties has been under experimental test for over three decades [81–84]. Unfortunately, conventional linear polymers typically used in these efforts are plagued by inherent properties that render them distinctly “un-drug-like”, including high polydispersity and size distributions, a

**Fig. 1.5.** Requirements for dendrimer-based, cancer-targeted drug delivery. (a) Dendrimers with multiple surface functional groups (Section 1.4.3) can be directed to cancer cells by tumor-targeting entities that include folate or antibodies specific for tumor-associated antigens (TAAs). (b) The next step is intake into the cell, which in the case of folate

targeting occurs by membrane receptor-mediated endocytosis (Section 1.6.3.2). (c) Once inside the cell, the drug generally must be released from the dendrimer, which, for the self-immolative method (Section 1.5.3.3), results in the simultaneous disintegration of the dendritic scaffold (d).

lack of defined structure, and a low density of drug payload per unit volume or mass. Properties of dendrimers that overcome these problems include monodispersity that results in the ability to select the precise sizes of nanoparticle required to a specific application (Table 1.1), a fully defined structure that allows the presentation of attached conjugates in a defined architecture, a high ratio of drug payload to volume, and enhanced control over drug release rates. Unsurprisingly, based on these many beneficial features, a wide range of biologically active molecules have

already been covalently attached to dendrimers. These conjugates range from small molecule drugs, such as ibuprofen [85], fluorescent and radioactive imaging agents (Section 1.6.4), oligonucleotides, oligosaccharides and peptides, as well as much larger molecules such as monoclonal antibodies (Section 1.6.3). Biologically active molecules attached to dendrimers can have two fundamentally different relationships to the host molecule. In some cases, exemplified by vaccine applications, there is no need to liberate active drug from the dendrimer (indeed, the success of antibody production usually depends on the unique display characteristics achieved by conjugation to the dendrimer). In most cases, however, the conjugated dendritic assembly functions as “pro-drug” where, upon internalization into the target cell, the conjugate must be liberated to activate the drug.

### 1.5.3.2 Dendrimer Conjugates can be Used as Vaccines

Most low molecular weight substances are not immunogenic; consequently, when it is desired to raise antibodies against small molecules, they must be conjugated to a macromolecule. In the past, natural proteins have commonly been used as carriers to generate antibodies to small molecules; now an alternative strategy using dendrimers has been demonstrated. In particular, unmodified PAMAM dendrimers that fail to elicit an antibody response on their own become haptized upon protein conjugation and generate a dendrimer-dependent antigenic response [86, 87]. A specific example of this technique is provided by the dendrimeric presentation of antigenic HIV peptides, which proved superior to other multimeric presentation strategies, such as conjugation to dextran [88]. Notably, the immunogenicity of dendrimer conjugates is not limited to peptides antigens; in one study antibodies were produced against densely penicilloylated dendrimers that were subsequently used for the diagnostic testing of patients with potential allergy to  $\beta$ -lactam antibiotics [89]. Finally, although carbohydrate-conjugated dendrimers (Section 1.4.3.2) are typically non-immunogenic [1], antibodies can be successfully elicited against cancer-specific oligosaccharides displayed on a dendritic scaffold, offering a method for generation of a new class of cancer vaccines (Section 1.6.6.2).

### 1.5.3.3 Release of Covalently-delivered “Pro-drugs”

Similar to encapsulated guest molecules that generally require release from the void spaces of a dendrimer to gain bioactivity (Section 1.5.2.3), a covalently delivered dendritic conjugate must also be cleaved within the target cell to regenerate the active cytotoxic agent (Fig. 1.5). At the same time, to ensure systemic non-toxicity, the covalent linker must be stable in circulation [90]. Several strategies are being pursued to ensure the successful cleavage and activation of the pro-drug in the target cell or tissue while avoiding systemic release. These include activation by low pH found in endosomal vesicles, installation of enzyme-cleavable ester linkages into the linkers that attach the pro-drug to the dendritic macromolecule, or disulfide bonds that are liberated in the reducing environment of the endoplasmic reticulum, photoactivation, or sensitivity to ultrasound [1].

Briefly returning to the benefits of dendritic clusters over conventional polymers for drug delivery, problems with the delivery of covalent conjugates when conven-

tional polymers, such as poly(lactic acid) (PLA) or its copolymer with glycolide (PLGA), are used include a lack of sustained drug release [91]. Generally, these and other linear, randomly oriented polymers have an initial burst where as much as 50% of drug is released followed by a dramatic drop-off. An advantage of dendrimers is that their release rates are more consistent, which has been demonstrated by polylactide-PAMAM dendrimers [91] and dendrimer-platinite [92]. Consistent release from dendrimers is likely an inherent feature of their defined three-dimensional structure as their sites of drug attachment are continuously exposed to solvent, compared with random polymers where conjugated pro-drug moieties can be internalized randomly. The unique architectural features of dendrimers offer additional elegant strategies to gain exquisite control over release of active drug. In particular, the production of dendrimers functionalized with catalytic antibodies [68] has spurred the development of dendrimers capable of “self-immolation” [93–95].

Self-immolative dendrimers provide an attractive potential platform for multi-drug delivery. To briefly explain, these unique assemblies have the ability to release all of their tail units (i.e., the active drug) through a self-immolative chain fragmentation, which is initiated by a single cleavage at the dendrimer’s core [96]. The first generation of dendritic prodrugs was demonstrated by Shamis and coworkers who synthesized doxorubicin and camptothecin as tail units and designed a retro-aldol retro-Michael focal trigger provided by action of the catalytic antibody 38C2 [94]. This method showed a dramatic increase in toxicity to tumor cells upon bioactivation of the pro-drug compared with tests done in the absence of the activating antibody. This technology, when fully developed into a complete chemical adaptor system that combines a tumor-targeting device (Section 1.6.3), a pro-drug, and pro-drug activation trigger, provides a sophisticated platform for future research efforts and the development of drugs for *in vivo* use [93].

#### 1.5.4

### Fine-tuning Dendrimer Properties to Facilitate Delivery and Ensure Bioactivity

#### 1.5.4.1 Delivery Requires Avoiding Non-specific Uptake

From the initial entry into the body, a drug candidate confronts many barriers and diversions on its route to the site of intended bioactivity. Uptake by oral ingestion is ideal for patient comfort and, while still largely speculative for dendrimers [97], there is now evidence that uptake occurs in the rat gut [98]; this route is enticing based on an increasing recognition that nanoparticle uptake across the gut is largely governed by the physicochemical properties and surface chemistries of oral drug delivery vehicles [99]. Typically, to get to the target site in the body, the drug candidate must avoid becoming trapped with the extracellular matrix, which has been shown to hinder cellular uptake and reduce the efficiency of other nano-sized delivery vehicles [100]; instead entry into the bloodstream is generally required for transit to the intended site of action.

Once in the bloodstream, either by successful navigation of an oral route or through direct injection, dendrimers below a certain size are at risk of filtration

and removal by the kidney. This pitfall, however, can be avoided by ensuring that sufficiently large dendrimers are used. Indeed an important design feature and overriding impetus to use dendrimer delivery vehicles is to prevent the filtration of these drug candidates by the kidney. A second, off-target “trap” for dendrimers has been identified in a study that showed sequestration of dendrimers in the liver and spleen, in part due to their surface properties and in part due to their size [101]. As discussed elsewhere, both of these parameters can be controlled with exquisite sensitivity for dendritic macromolecules, allowing longer residence times in the blood (the longer the serum half-life, the greater the opportunity to reach the intended site of action).

#### 1.5.4.2 “Local” Considerations: Contact with, and Uptake by, the Target Cell

Once a dendrimer has successfully entered the bloodstream and has been designed to minimize undue accumulation in non-target organs or tissues, it still faces the challenge of seeking out and interacting with its targeted site of action. The diversity of cell surface targets available for a nanodevice to bind to is vast; here we limit ourselves to specific examples related to cancer (Section 1.6.3). We will jump ahead to the point when a dendrimer has made “first contact” with a cell and reflect on how it interacts with the membrane. In this regard, there are provocative studies with PAMAM polymers that suggest that binding to the cell surface is facilitated by the deformable properties of dendrimers [15, 16, 18] (Section 1.3.1.3). Cell-binding induced deformations, if they prove real, have important implications for drug delivery. For example, the flattened forms of dendrimers lose their internal voids where guest molecules – such as drug payloads – are sequestered [6]. If this step occurs too soon, i.e., outside of the target cell, the drug might be ineffective, whereas if it occurs at the right moment, i.e., in the cytosol for cytosolic-acting drugs, it would provide an additional design parameter to exploit in the drug release process (Section 1.5.2.3). Notably, the deformations proposed to occur upon the interaction of a dendrimer with a cell, where the dendrimer shifts from a canonical “spherical” shape to a flattened disk with a significant loss in volume, have been most-extensively investigated at the dendrimer–mica interface. Clearly, the plasma membrane of a cell shares few biophysical characteristics with an extremely flat and rigid surface of mica, therefore, combined with the thermodynamically unfavorable aspects of the putative shape change, the extrapolation to drug delivery in biological systems should not be overstated. Encouragingly, shape changes also have been observed – but not thoroughly characterized – for dendrimers encountering the air–water interface, which is a better model for biological systems. Regardless of the current lack of concrete information, the intriguing nature of this potential mechanism for cell targeting and drug release merits its discussion here and also warrants further experimental investigation.

Once a dendrimer is in contact with a cell, there is strong experimental evidence that the exact surface properties of the dendrimer influence cellular uptake [102]. Therefore, the ability to modulate the chemical properties of a dendrimer provides additional options for controlling the uptake of a dendritic drug delivery device into a cell and even partitioning pro-drug release into specific organelles. To elaborate

by briefly recapitulating a series of elegant experiment from the Banaszak Holl group, these researchers used a battery of assays, ranging from dye leakage to atomic force microscopy, to demonstrate that G5–G7 PAMAM dendrimers disrupt lipid bilayers and form holes large enough (5–40 nm) to account for dendrimer internalization. Moreover, the hole formation could be tuned by the exact size of the dendrimer, as well as surface chemical properties. To be specific, G7 amine-terminated PAMAM initiated hole formation while its G5 counterpart did not. The smaller G5 dendrimer, however, did expand holes at existing defects; by contrast, acetamide terminated G5 PAMAM neither initiated hole formation nor expanded existing defects [102, 103]. The mechanism of hole formation in membranes by PAMAM was proposed to involve the removal of lipid molecules from the membrane to form aggregates consisting of a dendrimer surrounded by lipid molecules [103]. Once inside a cell, there are early indications that the precise properties of a dendrimer can influence subcellular trafficking. Eventually, if these processes can be better understood and controlled, their exploitation for drug delivery will be very attractive considering that some entities, such as dendrimer-delivered ibuprofen, need to only gain access to the cytosol [85], whereas other class of drugs, such as dendrimer-delivered plasmid DNAs, have the more-demanding task of reaching the nucleus [104].

#### 1.5.5

### **Drug Delivery: Ensuring the Biocompatibility of Dendritic Delivery Vehicles**

#### **1.5.5.1 Biocompatibility Entails Avoiding “Side Effects” such as Toxicity and Immunogenicity**

To briefly reiterate, properties of dendritic polymers important for drug delivery include negligible polydispersity, a high-density payload of pro-drug, and the ability to selectively release the active form of drug precisely at its intended site of action. Although dendrimers are capable of each of these tasks, their advantages are for naught if the final dendritic complex is not “biocompatible.” Biocompatibility, a broad term with numerous meanings, will be considered here from three perspectives, water solubility, lack of immunogenicity, and toxicity.

#### **1.5.5.2 Water Solubility and Immunogenicity**

The first two biocompatibility issues mentioned above, namely water solubility and immunogenicity, are closely related insofar as highly-hydrated macromolecules tend to be less immunogenic. With dendrimers, there are many options available to overcome difficulties that arise in these areas. For example, solubility can be readily adjusted by surface modifications to surface chemistry or by the addition of conjugated ligands (Section 1.5.3, Fig. 1.3). Moreover, dendrimers such as the commonly used G3, G5, and G7 PAMAM clusters are not inherently immunogenic [105]. Derivatized PAMAM such as the G4D-(1B4M-Gd)<sub>62</sub> magnetic resonance imaging (MRI) contrast dendrimer, however, can become immunogenic (which is not surprising considering the deliberate efforts to render small molecules immunogenic through presentation on a dendritic scaffold). This problem –

once again tying together the concepts of solubility and immunity – was overcome in one study by conjugation of poly(ethylene glycol) (PEG) to the surface of the dendrimer. Notably, PEG also had the positive effect of decreasing non-specific clearance from the blood, likely due to the increased hydration and resulting solubility of the particle [106].

### 1.5.5.3 Inherent and Induced Toxicity

A basic issue in drug delivery is the avoidance of non-specific, systemic, or off-target toxicity. At its simplest this issue, when applied to dendrimers, involves the biological effects of the material used to construct the polymer. Ideally, the building blocks themselves, as well as their degradation products upon delivery and release of the drug payload, are non-toxic. One strategy is to directly use natural biological molecules, such as carbohydrates [59, 107], amino acids and peptides [108], nucleic acids [109–113], or lipids [114, 115] as the building blocks. To provide additional synthetic flexibility, while maintaining biocompatibility, an increasing number of biologically compatible and generally-regarded as safe (GRAS) materials are being used in dendrimer construction. Examples include dendritic polyglycerol [116], melamine [117]; phosphate [118], polyglycerols [39], a polyester dendrimer based on poly(ethylene oxide) that has tunable molecular weights and architectures [84], and dendrimers composed of citric acid and poly(ethylene glycol) [65].

The pioneering PAMAM-based dendrimers illustrate a second issue beyond inherent toxicity of the material or breakdown products, namely “induced” toxicity. The PAMAM family (Table 1.1), although not explicitly designed for biocompatibility, was found to be non-toxic when generations 1 through 5 were tested [105]. Evaluation of G7 dendrimers, however, showed potential biological complications, including dose-dependent toxicity [105], thereby illustrating that, while the basic material of PAMAM is inherently non-toxic, deleterious outcomes could be “induced” by factors such as the size or structure of the nanodevice. Smaller generation, non-toxic, dendrimers are sufficient for some applications but larger clusters are needed to fully exploit the enhanced permeation and retention (EPR) effect important in the treatment of cancer with macromolecular therapeutics (Section 1.6.2); consequently, toxicity cannot simply be avoided by restricting use to small, safe-sized particles. Instead, one strategy devised to avoid toxicity was the re-design of the building blocks of PAMAM-based material [76, 119] while another strategy involved the development of completely new polymeric backbones [120].

The selection of “safe” building blocks to avoid deleterious effects in dendrimer construction is unlikely to prevent all problems. To illustrate, even very safe building blocks, such as amino acids, can be highly toxic or immunogenic when assembled into large macromolecules – in this case proteins – in the “wrong” way. Indeed, the toxicity of dendrimers could be the result of several factors beyond the simple properties of the unloaded scaffold. For instance, with cancer drugs intended to kill cells, systemic toxicity could result if the drug is taken up by the wrong cellular target (i.e., a healthy cell or tissue, rather than a cancer cell or tumor) or if the nanodevice was “leaky” (i.e., if the pro-drug was released systemically before reaching the target cell). Fortunately, many strategies exist for prevent-

ing toxicity, including directing a drug to its intended site of action by targeting moieties (Section 1.6.3) and developing sophisticated release strategies (Section 1.5.3.3). Problems that arise from the surface properties of the conjugated dendrimer can be ameliorated by masking the surface with something as simple as PEG or, in more advanced schemes, by coating with sugars or peptides to make glycodendrimers or peptide dendrimers, respectively (discussed in Ref. [121]) to mimic proteins naturally found in circulation (Section 1.4.3.2).

## 1.6

### Dendrimers in Cancer Diagnosis and Treatment

#### 1.6.1

##### Dendrimers have Attractive Properties for Cancer Treatment

Cancer epitomizes the challenges faced during drug delivery: an anticancer drug must be able to seek out subtle changes that distinguish a transformed cell from the other 200 or so types of healthy cells found in the body and then provide a sufficiently high dose of a toxic agent to selectively kill the cell while not harming its healthy neighbors. Therefore, even though dendrimers can be endowed with many favorable properties for drug delivery (Section 1.5), an ultimate challenge – ergo, a “real-world” test – of these versatile nano-devices will be whether they can successfully meet the formidable tasks of diagnosing and treating of malignant disease. As described in Section 1.7, although significant work remains in several areas, prospects now appear bright for dendrimer-based approaches to cancer treatment.

#### 1.6.2

##### Dendrimer-sized Particles Passively Accumulate at the Sites of Tumors

To begin the discussion of properties that make dendrimers attractive vehicles for cancer treatment, we revisit the concept that encapsulation (Section 1.5.2) or covalent linkage (Section 1.5.3) of small molecule drug candidates to a dendrimer enhances the pharmacological properties of the drug. In cancer chemotherapy, these desirable size-based features are reinforced by the enhanced permeability and retention (EPR) effect that improves the delivery of macromolecules to tumors. The EPR effect is based on unique pathophysiological features of a solid tumor, such as extensive angiogenesis resulting in hyper-vascularization, limited lymphatic drainage, and increased permeability to lipids and macromolecules. These features, which help ensure adequate nutrient supply to meet the metabolic requirements of rapidly growing tumors [122, 123], can be turned to the tumor’s disadvantage by the use of nano-sized therapeutic agents.

The EPR effect was discovered when selective accumulation of the SMANCS conjugate (styrene-maleic anhydride-neocarzinostatin) was observed at the site of tumors while similar accumulation was not seen with neocarzinostatin alone

[124, 125]. The EPR response was subsequently demonstrated for similarly-sized liposomes, thereby establishing that this effect was largely a function of particle size and did not solely depend on the chemical or biophysical properties of the macromolecule. Specifically, in one study optimal tumor delivery occurred for liposomes having a size distribution between 70 and 200 nm in diameter [126]. An independent study showed efficacy for liposomes loaded with daunorubicin in the same size range; specifically, those ~142 nm in diameter exhibited an inhibitory effect against Yoshida sarcoma whereas smaller (~57–58 nm) and larger (~272 nm) liposomes had weaker or no effect [127]. Over time, cautionary notes were raised that tempered initial enthusiasm for exploiting the EPR effect for cancer treatment. For example, the porosity of the vasculature in tumors can be highly variable even with a single vessel that can be leaky to one size of particle in one region but not in another [128]. Experimentally addressing this issue was complicated by the size polydispersity of traditional nanoparticles used to exploit the EPR effect, which were typically either lipids or conventional polymers that rendered a significant proportion of intended drug inactive. Fortunately this issue – the ability to match exact and uniform sizes needed to target an individual tumor – is highly tractable with dendrimers because selection of an exactly-sized entity is possible (Table 1.1) compared with the large size distributions that plague liposome and most polymeric materials [42].

The ability to construct monodisperse populations of dendrimers in the size range needed to exploit the EPR effect is an encouraging step towards the passive exploitation of tumor properties. Once the basic issue of size was resolved, however, secondary challenges (and opportunities) arose from observations that the chemical properties of the nano-sized particle can play significant roles in modulating the EPR effect. By way of a specific example, “conventional” polymeric materials showed efficacy at a smaller size range, occurring at ~60 nm for both water-soluble and hydrogel forms of poly(vinyl alcohol) (PVA) [129], whereas almost identically-sized 57 nm egg phosphatidylcholine (EPC)-liposomes were ineffective [127]. As reported above, liposomes about twice this size showed maximal efficacy, so it was not unexpected that the EPC-liposomes were ineffective. Interestingly, however, hydrogenated egg phosphatidylcholine (HEPC)-liposomes in this size range (specifically, 58 nm) were active [127], illustrating that the exact chemical properties of the material is a critical design parameter. In this respect, the many options for dendrimer “building blocks”, as well as the ability to further tune surface properties provide many opportunities to endow dendrimers with favorable “passive” properties for tumor targeting.

### 1.6.3

#### **Multifunctional Dendrimers can Selectively Target Biomarkers found on Cancer Cells**

##### **1.6.3.1 Methods for Targeting Specific Biomarkers of Cancer**

As discussed above, dendrimers can achieve passive EPR-mediated targeting to a tumor simply by control of their size and physicochemical properties. Passive tar-

getting, which localizes the nano-particle in the close vicinity of a cancer cell, can be immediately useful for diagnostic purposes (Section 1.6.4) or for the delivery of radioisotopes capable of killing any cell within a defined radius. In general, however, most delivery strategies require that the anticancer agent directly attached to, or be taken up by, the target cell. The ability to append more than one type of functionality to a dendrimer (Fig. 1.3) allows the inclusion of ligands intended to bind specifically to cancer cells in the design of a multi-functional drug-delivery nanodevice (Fig. 1.5). Although a wide range of targeting ligands have been considered, including natural biopolymers such as oligopeptides, oligosaccharides, and polysaccharides such as hyaluronic acid, or polyunsaturated fatty acids [90, 130], discussion here is limited to folate, which is an exemplary small molecule tumor-targeting agent [42], as well as monoclonal antibodies directed against tumor associated antigens (TAAs).

#### 1.6.3.2 Targeting by Folate, a Small Molecule Ligand

Folate is an attractive small molecule for use as a tumor targeting ligand because the membrane-bound folate receptor (FR) is overexpressed on a wide range of human cancers, including those originating in ovary, lung, breast, endometrium, kidney and brain [131]. As a small molecule, it is presumed to be non-immunogenic, it has good solubility, binds to its receptor with high affinity when conjugated to a wide array of conjugates, including protein toxins, radioactive imaging agents, MRI contrast agents, liposomes, gene transfer vectors, antisense oligonucleotides, ribozymes, antibodies [131, 132] and even activated T-cells [133]. Upon binding to the folate receptor, folate-conjugated drug conjugates are shuttled into the cell via an endocytic mechanism, resulting in major enhancements in cancer cell specificity and selectivity over their non-targeted formulation counterparts [131, 132]. Recently, folate has been enlisted in an innovative dendrimer-based targeting schemes ([42, 134], Section 1.6.6.1).

#### 1.6.3.3 Targeting by Monoclonal Antibodies

Of the many strategies devised to selectively direct drugs to cancer cells, perhaps the most elegant (and demanding!) is the use of monoclonal antibodies that recognize and selectively bind to tumor associated antigens (TAAs) [135–138]. TAA-targeting monoclonal antibodies have been exploited as delivery agents for conjugated “payloads” such as small molecule drugs and prodrugs, radioisotopes, and cytokines [139, 140]. The field of “immunotherapy” envisioned almost a hundred years ago, and given renewed impetus a quarter century ago by the development of monoclonal antibody technologies, has nonetheless progressed erratically over the past two decades as many pitfalls have been encountered [139]. Current prospects remain mixed but hopeful; optimistically, progress marked by commercial interest with companies providing their immunotherapeutic drug candidates with flashy trademarked names, such as “Armed Antibodies™” [141]. Similarly, the rosy opinion that this field is “on the verge of clinical fruition” has been published recently [142]. Perhaps, more realistically, one recent synopsis

holds out “hope” for a major clinical impact for this strategy within the next 10 years [136].

Although a detailed discussion of the many pitfalls encountered in immunotherapy efforts is beyond the scope of this chapter, one key issue – readily addressed by dendrimers – is the requirement that an extremely potent cytotoxic drug be used in targeted antibody therapy. This point is illustrated by the fact that the greatest progress in this field has occurred for immunotoxins, which are antibody–toxin chimeric molecules that kill cancer cells via binding to a surface antigen, internalization and delivery of the toxin moiety to the cell cytosol. In the cytosol, protein toxins, such as those from diphtheria or pseudomonas, catalytically inhibit a critical cell function and cause cell death [143]. The high potency of immunotoxins for killing cancer cells is dramatically illustrated by ricin, where the catalytic activity of this ribosome-inactivating enzyme allows a single immunotoxin conjugate to kill a cell upon successful uptake and trafficking to the site of action [144, 145].

A drawback of immunotoxins is their significant immunogenicity, which limits repeated use [136]; from a broader perspective, their repeated use is made necessary by difficulties in providing a sufficiently high drug load to eradicate all cancer cells despite the high potency of conjugated toxin. An alternative approach of radioimmunotherapy, where high energy radionuclides are conjugated to TAA-targeting antibodies, also shows promise [146] but suffers from indiscriminate toxicity (the surrounding healthy tissues, as well as off-target tissues, become irradiated in addition to the target cancer cells). A third possible approach for immunotherapy, the conjugation of commonly-used small molecule drugs to TAAs, is hindered by the relatively low potency of most low molecular weight therapeutics. To illustrate this point, ~10 000 TAAs occur on a typical cancer cell [101], making this number the upper limit for the number of targeting antibodies that can bind to the cell. The widely used anticancer drug cisplatin, to give one example, requires internalization of at least 50× this level of drug molecules for therapeutic efficacy.

A numerical analysis of the cisplatin example presented above indicates that each tumor-targeting antibody would have to be modified with a large number of small molecules to be effective as an anticancer drug (in this case, roughly 50 cisplatin molecules upon superficial analysis). Modification of an antibody with multiple radioisotopes, toxins, or even small molecules to increase the efficacy of cell killing, however, diminishes or eliminates the inherent specific antigen-binding affinity of an antibody. Therefore, to maximize drug loading while minimizing the deleterious effects on the biological integrity of the host antibody, an attractive approach is to use a linker molecule, such as a dendrimer, that can be highly conjugated (or internally loaded) with drug while modifying only a single site on the surface of the antibody [147]. Methodology to covalently attach antibodies to dendrimers that preserve the activity of the antigen–antibody binding site [148, 149], e.g., by chemical modification of their carbohydrates and subsequent linkage to PAMAM [150], has opened the door for the inclusion of dendrimers in immunotherapy [151, 152], thereby enhancing the future prospects of this chronically “almost-there” strategy.

## 1.6.4

**Dendrimers in Cancer Diagnosis and Imaging****1.6.4.1 Labeled Dendrimers are Important Research Tools for Biodistribution Studies**

The synthetic ability to attach both a tumor-targeting antibody and a potent payload of anticancer drugs to the same dendritic molecule provides a platform for multi-functional nano-scale drug delivery devices (Fig. 1.5). Before this technology can be applied in the clinic, however, its safety and efficacy must be demonstrated; towards this end, fluorescently-modified dendritic conjugates have been used extensively to characterize cell targeting, surface binding, uptake and internalization, and even sub-cellular localization [85, 151, 152]. The radiolabeled counterparts appropriate for animal studies have allowed detailed examination of the biodistribution of dendrimers. Several radio-isotopes have been conjugated to dendrimers, including  $^3\text{H}$  [153],  $^{14}\text{C}$  [105],  $^{88}\text{Y}$  [154],  $^{111}\text{In}$  [154, 155], and  $^{125}\text{I}$  [98, 149, 156–158]. These studies have established that the chemical and physical properties of dendrimers can be tuned to favor distribution to or away from specific organs and, ultimately, to achieve favorable biodistribution to tumors. The methods used in these experiments, however, typically requiring post-administration dissection of the host animal to allow the analysis of organ sequestration and tissue distribution of the radioisotope, are clearly not applicable to clinical practice. Instead, they have served as an important stepping stone along the path towards non- or minimally-invasive diagnostic procedures, which are proceeding mainly by the development of MRI contrast agents.

**1.6.4.2 Towards Clinical Use: MRI Imaging Agents**

Upon successful demonstration of the selective accumulation of dendrimers at the sites of tumors in animal models, a natural extension of this approach was to substitute gadolinium for the previously-tested isotopes or fluorophores. Gadolinium ( $^{153}\text{Gd}$ ) is the best known and most extensively utilized magnetic resonance (MR) contrast agent [159, 160] and has previously been shown to be valuable for the improved diagnosis of cancer [161, 162]. Importantly, the *in vivo* efficacy of gadolinium is greatly enhanced when used as part of a macromolecular system [159]; in the past, attempts to create macromolecular gadolinium platforms have included the conjugation of chelators for this metal to both proteins [163] and conventional polymers [164]. These efforts have met with mixed (but generally limited) success. By contrast, Kobayashi and Brechbiel report that, by conjugating gadolinium to dendrimers, the unique properties of these polymers, such as exquisite size control, allowed selective targeting and imaging of the kidney, vascular, liver, or tumors [159]. Of note, tumor specific targeting and accumulation of gadolinium contrast agents is possible by use of either the folate receptor [165] or TAAs [159]. A drawback of the initial PAMAM-based MR contrast agents was their long residence time in the body; this problem, however, can be met by modifying both the surface properties [106] and basic chemical composition of the dendrimer. Specifically, diaminobutane (DAB) dendrimer-based chelators were more rapidly excreted from the

body, illustrating that the development of clinically-acceptable dendrimer MR platforms is realistic [166].

### 1.6.5

#### Steps Towards the Clinical Realization of Dendrimer-based Cancer Therapies

##### 1.6.5.1 The Stage is now set for Dendrimer-based Cancer Therapy

The use of dendrimers for cancer treatment is still in its infancy with few, if any, applications successfully translated to the clinic. Consequently, their use as diagnostic agents constitutes both an important goal in and of itself, and also a valuable “baby step” towards the ultimate goal of curing cancer. As discussed, the process of actual killing cancer cells entails the complicated process of drug uptake followed by release of the drug into the cytoplasm or nucleus and is clearly a more demanding process than cell surface labeling, or even localization to the vicinity of the tumor, sufficient for diagnostic purposes. Nonetheless, in some cases, the transition from imaging to therapy will be closely linked, as evidenced by efforts now underway to combine antibody-targeted MR imaging nanoparticles with the delivery of antiangiogenic genes intended to inhibit the vascularization to the V2 carcinoma model in rabbits [167]. Another promising strategy – boron neutron capture therapy – has undergone impressive development over the past decade and is presented next as a successful demonstration of the promise of dendrimer-based cancer therapies.

##### 1.6.5.2 Boron Neutron Capture Therapy

Cisplatin-based therapies illustrate the need for multiple conjugations of small molecules – estimated at 50 for this platinum drug – to a targeting antibody (Section 1.6.3.3). While some efforts are underway to use dendrimeric strategies for platinum drug delivery [168], an even more demanding situation, where thousands of ligands are required per targeting antibody, is provided by boron neutron capture therapy (BNCT). Accordingly, BNCT will be discussed here as an illustrative example of how dendrimers can help overcome high hurdles in the development of innovative cancer therapies. As a brief background, BNCT is based on the nuclear reaction that occurs when boron-10, a stable isotope, is irradiated with low energy ( $\leq 0.025$  eV) or thermal neutrons to yield alpha particles and recoiling lithium-7 nuclei. A major requirement for the success of BNCT is the selective delivery of a sufficient number of boron atoms ( $\sim 10^9$ ) to individual cancer cells to sustain a lethal  $^{10}\text{B}(n, \alpha) \rightarrow ^7\text{Li}$  capture reaction [169, 170]. Considering that the maximal number of antigenic sites per tumor cell is in the range of 100 000, and more commonly only  $1/10^{\text{th}}$  that level, an a priori calculation suggests that each targeting antibody must be linked to at least 2000, but preferably closer to 5000, boron atoms [101]. Clearly, a single TAA-targeting antibody cannot be directly conjugated at this level and conventional polymers – e.g., polylysine conjugated with  $\sim 1700$  boron derivatives and linked to a targeting antibody – caused the antibody to lose *in vivo* tumor localizing properties [171]. By contrast, when a

PAMAM dendrimer was used for polyvalent boron conjugation, the linked antibody maintained immuno-recognition (although *in vivo* tumor targeting remained problematic because the conjugated dendrimer had a strong propensity to mis-localize in the spleen and liver) [101]. Over the decade since these pioneering efforts were first reported, continued progress has been made to solve problems such as off-target tissue localization, which was traced to the size of the dendrimer and presence of a large number of amine groups on the surface of PAMAM, by exploiting the versatility of dendrimer chemistry. In short, the re-design of boronated, anti-body-targeted dendrimers has culminated in the successful treatment of gliomas in the rat [158, 169, 172] and laid the foundation for translation of this technology into clinical tests in the foreseeable future.

#### 1.6.6

### Innovations Promise to Speed Progress

#### 1.6.6.1 “Mix-and-Match” Strategy of Bifunctional Dendritic Clusters

Two lessons are immediately apparent from the dedicated efforts to bring dendrimer-based BNCT to fruition. One is that dendritic technologies, while still at an early developmental stage, hold tremendous promise and merit continued investigation. The second is that the coupling of one treatment modality (BNCT) with one targeting strategy (antibodies to a specific type of glioma) required a staggering amount of effort. The growing realization that cancer is hundreds, if not thousands, of unique diseases at the cellular and molecular level, suggests that a commensurate number of therapeutic strategies are needed. The diversity of targeting strategies (which are not limited to folate and TAAs discussed here), coupled with the many “payload” possibilities (beside radioisotopes, boron, and cisplatin discussed here) used to diagnose and kill cancer cells, means that there are literally tens of thousands of individually customized therapies required to fully confront the myriad clinical manifestations of cancer. The sobering reality is that, if each of these customized treatments will require a decade long effort by a large team of researchers and clinicians, the large problem of cancer treatment will not be solved for a long time.

Choi and coworkers [134] have come up with an innovative mix-and-match scheme that promises to offset this gloomy prediction. These researchers have recently reported a cancer-targeting strategy that is reminiscent of the antibody-toxin/immunoconjugate strategy where distinct, but linked, entities are used to first recognize and bind and then subsequently modify a cancer cell. Their strategy, however, has great potential to improve on both the “targeting” and “payload” aspects of cancer therapy by, at first seemingly paradoxically, completely dividing these functions into separate dendritic clusters (Fig. 1.6). The key to this approach was to include a DNA “zipper” on each dendrimer that allows the targeting cluster, composed of folate-derivatized PAMAM in proof-of-concept experiments [173], to be readily combined with the imaging or drug-carrying dendrimer by way of the complementary DNA strand [134]. It can be envisioned that the production of libraries of dendrimers targeted to different cancer-specific biomarkers can be pro-

**Fig. 1.6.** DNA–dendrimer conjugates as potential cancer targeting imaging agents or therapeutics. (Adapted from Ref. [189].) Differentially functionalized dendrimers covalently conjugated to complementary deoxy-oligonucleotides can readily form duplex combinatorial nanoclusters that possess

cancer cell-specific ligands hybridized to an imaging agent or drug. Cell-specific targeting ligands (e.g., folic acid in one study) are appended to Dendrimer A, and Dendrimer B is conjugated with an imaging agent or drug [134].

duced by a “mix-and-matched” strategy by combining “off-the-shelf” targeting and drug clusters as needed [42]. Development of easily-customizable nanomedicine platforms that exploit the facile duplex DNA formation for the generation of hybrid nano-clusters, thus circumventing the tedious synthesis of multiply-functionalized dendrimers, offers hope that the next ten years will witness rapid expansion of dendrimer technologies that build on the painstaking advances of the past decade.

#### 1.6.6.2 Towards Therapeutic Exploitation of Glycosylation Abnormalities found in Cancer

Aberrant glycosylation, where the patterns of complex carbohydrate glycoforms found on the surfaces of cancer cells are dramatically different from those on healthy cells, is a hallmark of cancer [174–178]. Efforts to exploit these changes therapeutically, however, have long been stymied by the difficulty of controlling these complex and diverse molecules in an artificial synthetic setting. Today, with new technologies such as dendrimers that provide a platform for physiologically-relevant display of carbohydrates, new vistas are opening up for exploiting these molecules to intervene in malignant disease. Promising – but still early-stage – efforts in this direction include the presentation of oligosaccharides found only in cancer cells [53, 56, 58, 179–181] on a dendritic scaffold (Section 1.4.3.2) for vaccine development (Section 1.5.3.2).

#### 1.6.6.3 Towards Targeting Metabolically-engineered Carbohydrate Epitopes

As discussed above, one area of rapidly-expanding investigation is the abnormal glycosylation associated with the cancer cells; in particular dendrimeric scaffolds provide a unique platform to control the multimeric carbohydrate presentation needed to enact the “cluster glycoside effect” [45, 50, 51], which is crucial for tar-

getting diseased tissues found in malignant diseases [1, 24]. Another approach to exploiting glycosylation for the treatment of cancer is through “chemical biology” strategies, such as the ability to express non-natural sialic acids on the cell surface through the use of *N*-acetylmannosamine (ManNAc) analogs [49, 182, 183] (Fig. 1.7). By appropriate design of the ManNAc analog, sialic acids, which are interesting nine-carbon sugars often overexpressed on cancer cells [175], can be provided with a “chemical handle” – such as a ketone, azide, or thiol [184–186] – for tar-

Fig. 1.7. Chemoselective targeting of drug-loaded dendrimers to the cell surface. (A) Overview of sialic acid engineering. (a) A dendrimer can encapsulate and assist the delivery of *N*-acetylmannosamine (ManNAc) analogs, such as the thiol-containing sugar “ManNTGc” (shown as “\*”) into a cell (Section 1.5.2). (b) Once inside the cell, ManNTGc can be metabolically converted into CMP-Neu5TGc, a compound that serves as a sugar-nucleotide needed for the glycosylation process (c) where “Neu5TGc” a non-natural form of sialic acid, is installed into cell surface glycoconjugates. Overall, this process replaces

natural sialic acids, such as “Neu5Ac”, with their thiol-containing counterparts (d), which can then be targeted by dendritic assemblies such as the bifunctional “targeting” and “payload” clusters shown in Fig. 1.6. (B) Details of the “chemoselective ligation reaction” required for targeting the appropriately derivatized dendrimeric assembly to the cell. In this case, a maleimide-conjugated targeting capsule will selectively interact with the sialic acid-display thiols to covalently bind the dendrimer to the cell surface via thio-ether bond formation.

geted delivery of a second agent such as the ricin A-chain used in immunotoxins [187] or small molecule anticancer drugs [188]. Dendrimers offer assistance at several steps in this process of translating early-stage anticancer strategies like “sialic acid engineering” from the laboratory to clinical relevance. An enticing proposition is that the starting material – ManNAc, which like all sugars has notoriously poor pharmacological properties – can be made “drug-like” by encapsulation (or covalent ligation). Subsequently, after display of the target epitope on the cell surface, which is a modified thiol-bearing sialic acid in the case shown in Fig. 1.7, this can benefit from the high local density of dendritic display of maleimide to increase the rate of drug binding to the cell surface, which occurs over an unacceptably long period of several hours for current covalent coupling schemes [188]. This strategy, under evaluation in our laboratory, coupled with a high drug payload on the DNA-hybridized cluster (Fig. 1.6), provides renewed impetus for the already promising application of sugar-based therapeutic approaches to cancer. A particularly attractive aspect of this approach is that  $\sim 10^8$  sialic acids exist on cancer cells, greatly improving prospects to deliver adequate levels of drug to achieve therapeutic efficacy compared with TAA-targeting schemes (Section 1.6.3).

## 1.7

### Concluding Remarks

Dendrimers, chemically-defined entities with tunable biological properties, have advanced over the past two decades to the point where they stand on the cusp of major contributions to the treatment of cancer in a meaningful way. Although, as has been apparent by the many instances cited throughout this chapter where gaps in knowledge still remain and that must be plugged before dendrimers are ready for wide clinical use, their extreme versatility combined with the extensive research efforts now underway are sure to add sophistication to drugs already in use as well as spur the development of entirely new classes of anticancer therapy.

# Nanoparticles for Optical Imaging of Cancer

*Swadeshmukul Santra and Debamitra Dutta*

### 2.1

#### Introduction

The word “cancer” comes from the Latin word for crab. Historically, an ancient physician from Greece noticed the resemblance of the swollen mass of blood vessels around a malignant tumor to the shape of a crab and so named the disease. The malignant tumor is also seen to adhere to surrounding tissues that it can seize upon in a stubborn manner, similar to a crab.

Human cancer consists of more than 200 different diseases [1] in which cells multiply at an exponential growth rate in an uncontrolled fashion. This abnormal growth rate leads to the formation of a lump, called malignant tumor. Gradually the tumor tissue grows and invades the adjacent tissues and organs, obstructing normal physiological functions. In some cases, the cancerous cells can detach from its origin and migrate through circulation to different parts of the body, forming a new tumor site. This is termed as cancer metastasis. Over a period of time, malignant tumors cause malfunctioning of various organs, which turns fatal.

According to the American Cancer Society’s annual report [2], about 570 280 people are expected to die of various cancers in the year 2005 in the United States of America (USA). During the last century, cancer has slowly advanced to become the leading cause of death for patients below the age of 85 in USA, despite rapid advances in global cancer research towards the understanding of cancer biology in the past several decades.

The formation of malignant tumors is associated with six different cellular characteristics [3, 4], each of which is unique for cancer development. These characteristics are self-sufficiency in growth signals, evading apoptosis (a process by which a cell is “commanded” by the environment to die), insensitivity to anti-growth signals (an inherent mechanism for preventing undesirable cell growth), sustained angiogenesis (a process of growth of new blood vessels), tissue invasion and metastasis and limitless replicative potential.

Cancer can develop in any living organ or tissue in the body. The part of the body in which the cancer first develops is referred to as the primary site. The most common cancer developing sites include the skin, lungs, female breasts, prostate, co-

lon and rectum, and corpus uteri. The secondary site refers to the body part where metastasized cancer cells grow and form secondary tumors. Even if a cancer has spread to another part of the body, it is always described with respect to the primary site. For example, advanced breast cancer that has spread to the lymph nodes under the arm and to the lungs is always considered breast cancer.

The diagnosis of cancer means an attempt to accurately identify the anatomical site of origin of the malignancy and the type of cells involved. The presence of cancer may be preliminarily suspected by some other disease-like symptoms. For example, weight loss and abdominal pain can be caused by stomach cancer or an ulcer. However, to confirm the diagnosis of cancer, a biopsy (removal of tissue for microscopic evaluation) is usually done. Biopsies can provide information about histological type, classification, grade, potential aggressiveness and other information that may help determine the best treatment. A biopsy together with advanced imaging technologies, can not only confirm the presence of cancer, but also can pinpoint the primary and secondary cancer sites.

Early cancer diagnosis, in combination with the precise cancer therapies, could eventually save millions of lives. The diagnosis of cancer at the early stage is extremely challenging and has been an active research area of great interest in current times. If the tumor is located near the body's surface, a tissue sample can be easily retrieved for a biopsy (removal of tissue for microscopic evaluation) and the tissue abnormality can be confirmed at the cellular level. However, if the tumor mass is inaccessible for a biopsy, one has to then rely upon the existing imaging techniques for the detection of the tumor location. Existing diagnostic non-invasive imaging techniques such as Computed Tomography (CT), Magnetic Resonance (MR), Positron Emission Tomography (PET), Single Photon emission CT (SPECT), Ultrasound (US) and optical imaging are effective for macroscopic visualization of tumors. However, none of these techniques are sensitive enough for the diagnosis of abnormalities in the microscopic level. Substantial research efforts are being made for the development of better cancer imaging techniques. Of them, optical imaging has shown a great promise with respect to the image resolution [5]. The feasibility of developing optical imaging technique for the sensitive detection of cancer has been recently demonstrated [6, 7] using nanoparticle-based highly sensitive optical contrast agents.

This chapter provides a knowledge base platform to readers interested in learning about nanoparticle technology and its implications in diagnostic cancer imaging. An overview of existing cancer imaging techniques with special emphasis on optical-based imaging techniques has been incorporated. Optical imaging has strong potential in becoming an attractive alternative to existing cancer imaging techniques. Optical imaging is a highly sensitive, non-invasive, non-ionizing, relatively inexpensive and simple technique. With the aid of better contrast agents, this imaging technology could be transferred to a clinical setup for human applications for early cancer diagnosis in the near future. Recent developments which are directly associated with the improvement of optical image contrast, such as the use of sophisticated laser technology, highly sensitive charged-coupled device (CCD) technology and powerful mathematical modeling of light propagation through the

biological systems, have been integrated into the imaging components. However, presently, significantly limited numbers of appropriate *in vivo* optical contrast agents are available. Therefore, there is a great demand of developing highly sensitive, stable and clinically safe *in vivo* optical contrast agents.

Nanoscience and nanotechnology is an interdisciplinary research area that brings various traditional disciplines such as chemistry, physics, materials science, biomedical, molecular biology, and many others together under one umbrella. Several edited books [8–12] on nanoscience and nanotechnology include the development of various nanoparticles such as metals, semiconductors, etc. for biological applications. Several review articles [5, 7, 9, 13–22] have recently reported advance research highlights on optical-based contrast agents [15–17, 21], some of which emphasize nanoparticle-based optical contrast agents [7, 18–20, 22] for bioimaging. However, none of these articles captured thoroughly recent developments on nanoparticle-based optical contrast agents suitable for cancer imaging. In this chapter, we made every effort to provide extensive details of nanoparticle-based contrast agents developments, including separate sections on nanoparticle design, synthesis strategies, nanoparticle dispersion, surface modification, bioconjugations and cancer imaging applications. We hope that this chapter will be useful for students, teachers, research scientists, general audiences who are interested in learning more about early cancer diagnosis and others. We have attempted to explain each section and sub-section of this chapter in a simple manner so that readers could easily grasp the general strategy of various nanoparticle-based optical contrast agent development.

Since the field of cancer imaging is expanding rapidly, we start with an introduction to highlight the contents of this chapter (Section 2.1). Section 2.2 briefly overviews various existing cancer-imaging techniques, allowing readers to understand merits and demerits of these techniques. Section 2.3 describes the basics of optical imaging, optical imaging techniques and optical contrast agents. This chapter provides a clear understanding of the merits and challenges of developing optical-based imaging techniques and contrast agents. Section 2.4 details recent advances in nanoparticle-based optical contrast agents. While Section 2.4.1 provides the reasons for developing such contrast agents, Section 2.4.2 provides some literature review on the development of nanoparticle-based various contrast agents such as quantum dots, dye-doped nanoparticles and gold nanoparticles. Various cancer imaging applications using nanoparticles are reviewed in Section 2.5. Section 2.6 covers some miscellaneous nanoparticles such as up-converting phosphors, fluorescent polymer particles, etc. that are potential contrast agents. Section 2.7 provides concluding remarks and the perspectives of nanoparticle-based optical imaging of cancers.

## 2.2 Cancer Imaging Techniques

Some of the major imaging techniques routinely used in hospital setup for cancer imaging in humans are briefly described below.

### 2.2.1

#### **Computed Tomography (CT) Scanning**

The detection components of a typical CT scanner include the X-ray tube, detectors, image reconstruction computer and visual display monitor. The X-ray tube generates a beam of X-rays that are made to pass through the body of the patient. The detectors are positioned to absorb the X-rays coming out through the body. While processing the information, the reconstruction computer takes into consideration that X-rays passing through denser tissues like bones are attenuated to a higher extent than those passing through softer tissue such as lungs. Thus the X-ray beams of varying strengths that come out from the body create a differential profile. This profile is measured by the detectors and finally imaged by the display monitor. The complete setup rotates around the patient and acquires about 1000 snapshots for every 360° rotation, when a slice is completed. After each rotation, the information from the detectors is collected together and processed by the computer to construct a two-dimensional image (slice) on the display monitor. Image resolution is on the order of 50–100 μm with data acquisition time varying from 5 to 30 min. Recently, there have been continuing efforts to merge the CT modality with other modules like nuclear imaging modalities, which have limited spatial resolution, to generate better images.

### 2.2.2

#### **Magnetic Resonance (MR)**

In this technique, patients are placed in a strong electromagnetic field that causes the hydrogen atoms of water molecules present in the body fluid to align with the field. A short, powerful radio signal is then sent through the body at a desired level (slice) perpendicular to the original field. Hydrogen atoms with similar frequencies resonate with the radio signal and get excited. When the radio signal is switched off, the excited atoms will release their excitation energy in the form of radio waves and return to their normal state. The time taken for the hydrogen atoms to release their energy is characteristic of the physical properties of the tissue. These radio waves are detected and the time taken is measured and analyzed by a computer to construct an image of the tissues. Usually, it is difficult to distinguish tumors from normal tissues in the body using an MR image. Therefore, patients are injected with contrast agents that selectively highlight the tumors. Standard MR images (1.5 Tesla, the magnetic field strength) provide a spatial resolution of 1 mm, which could be increased to about 10 μm with certain modifications.

### 2.2.3

#### **Positron Emission Tomography (PET)**

In this technique, a positron-emitting isotope ( $^{11}\text{C}$  or  $^{18}\text{F}$ ) is attached to a biological molecule that has an affinity to tumor cells and introduced into the patients. The decaying isotopes emit positrons, which collide with a nearby electron and annihilate to release  $\gamma$ -rays. These rays are detected and analyzed by a computer. The po-

sition of the tumor in the body can be located by tracking the density of the positrons in a particular region.

#### 2.2.4

#### **Single-photon Emission CT (SPECT)**

This imaging technique is similar to PET, except that the SPECT isotope itself emits a single  $\gamma$ -ray instead of a positron. This technique is very inexpensive when compared with PET. However the spatial resolution is not as good as PET.

#### 2.2.5

#### **Ultrasonography (US)**

In this form of imaging, ultrasonic sound waves are sent through the body. The waves are partially reflected from the interfaces of different tissues. The intensity of reflected waves depends on the density of the tissues. The time taken for the reflected wave to reach the detector gives a measure of the depth of the tissue location. The advantage of ultrasonography is that the images are generated in real time with very high temporal resolution. However, ultrasonic waves cannot travel through bone and therefore cannot detect tissues behind bony structures such as the brain behind the skull.

### 2.3

#### **Optical Imaging**

##### 2.3.1

#### **Basics of Optical Imaging**

Optical imaging is a sensitive, non-invasive, non-ionizing (clinically safe) and relatively inexpensive technique that has strong potential for diagnostic cancer imaging. Two major components are associated with an optical imaging system: an imaging component and an optical contrast-enhancing component (i.e., contrast agent). Recent advances in optical imaging have utilized sophisticated laser technology, highly sensitive charged-coupled device (CCD) technology and powerful mathematical modeling of light propagation through the biological systems; all these developments have formed a solid basis for the imaging component. Molecular fluorescent probes have been successfully used as optical contrast agents for imaging various cancer tissues in the past [5, 15–17, 23–27]. However, the sensitivity of the contrast agent has become the major obstacle in obtaining a high-resolution image. Again, *in vivo* deep tissue optical imaging has been limited because of the low penetration depth of the light in the ultraviolet (UV) and visible spectral range (the approximate tissue penetration depth is about 1–2 mm). Near-infrared (NIR) light in the spectral range 650–900 nm can, however, penetrate much deeper (up to several centimeters) into the tissue and skull [5, 15]. This is due to the relatively low absorption of tissue components (water and hemoglobin)

in the NIR spectral range. Therefore, the development of an NIR-based optical imaging system has attracted tremendous attention in the cancer imaging community in recent years.

For developing optical-based imaging system, it is important to understand how light interacts with biological tissues. Simply, a tissue can interact with light photons by absorption, scattering and reflection. Since biological tissue represents a complex system in terms of light propagation, it is expected that the optical image would be somewhat distorted. A robust mathematical modeling is thus necessary to improve image quality. Again, all biological tissues somewhat autofluoresce upon interaction with the light in the UV and visible spectrum. The tissue autofluorescence originates from the natural tissue fluorescent molecules such as nicotinamide, flavins, collagen, and elastin [25]. To develop a robust optical imaging system it is thus important to address all sorts of light interaction with tissue as well as tissue autofluorescence.

### 2.3.2

#### Optical Imaging Techniques

Optical-based imaging methods such as confocal imaging, multiphoton imaging, microscopic imaging by intravital microscopy or total internal reflection fluorescence microscopy have been used traditionally to image fluorescence events that originates *in vivo* from surface and subsurface region. Recently, advanced imaging technologies that use photographic systems with continuous or intensity-modulated light and tomographic systems have shown great potential for deep tissue imaging. With the aid of highly sensitive contrast agents such as nanoparticles, it may be possible to transfer optical imaging technology to human application. There are several potential optical imaging techniques, such as reflectance fluorescence imaging and fluorescence-mediated molecular tomography (FMT), that use the diffuse component of light for probing molecular events deep in tissue samples. These techniques are briefly described below.

In a typical reflectance imaging technique, a simple “photographic method” is used where the light source and the detector reside on the same side of the imaging object (e.g., an animal). This technique is currently used for *in vivo* assessment of fluorescent dyes [such as green fluorescent proteins (GFP), bioluminescent molecules, etc.]. In a reflectance imaging system, the light source can be either an appropriate laser for the target fluorescent molecules or a white light with the appropriate low-pass filter. The laser excitation source is preferable because it provides a narrow and well-defined spectral window ( $\pm 3$  nm) when compared with white light ( $\pm 10$  nm). A high-sensitivity CCD camera is usually used as detector. Reflectance imaging has been successfully used to image cathepsin B [28], cathepsin D [29], matrix metalloproteinase 2 (MMP-2) [30], using activatable probes that are dark in the native (quenched) state and fluoresce upon interaction with a specific enzyme. This technique has been used for the elucidation of MMP-2 (a biomarker) expression levels in two different breast cancers, MMP-2 positive human HT1080 fibrosarcoma and MMP-2 negative BT20 mammary adenocarcinoma [31]. A NIR probe was activated upon interaction with both the tumors. The level of MMP-2

expression was directly related to the number of probe molecule activation. As expected, great probe activation was found in human HT1080 fibrosarcoma. Reflectance imaging technique has also been used for targeting cell-surface receptors *in vivo* using peptide-NIR dye conjugate [26, 32] and for studying gene expression [33]. Reflectance imaging is a simple, fast and highly sensitive imaging and screening technique for capturing surface fluorescent events *in vivo* or in excised tissues. This imaging system can be, inexpensively, made portable for the laboratory bench. However, this technique has several limitations. Firstly, the technique will allow imaging of a few millimeters thick tissue. As a result, the appearance of deeper lesions is significantly blurred. Secondly, quantitative information cannot be extracted from the reflectance imaging technique. For example, the surface appearance of a small structure with high dye loading that is located in a deeper tissue could be similar with a larger structure of low dye loading that is closer to the surface.

Fluorescence-mediated molecular tomography is a powerful technique to resolve and quantify deep tissue fluorescence signal. This technique, usually termed as diffuse optical tomography (DOT) utilizes advanced photon sources, a detection system and rigorous mathematical modeling of light propagation in tissue. The DOT technique uses multiple projections and measures light around the boundary of the illuminated body followed by a complex mathematical modeling to construct the three-dimensional tomographic image. This technique has recently been applied clinically for imaging tissue oxy- and deoxy-hemoglobin concentration and blood saturation [34–37]. Based on the same principle, fluorescence molecular tomography (FMT) has been developed where measurements of fluorescent molecular probes at both the emission and excitation wavelengths were considered. The FMT technique has been recently used for imaging cathepsin B activity in deep tissue structure of 9L gliosarcomas [38–40]. An optical imaging system that can image both reflected light and fluorescence light to generate multi-spectral digital imaging of tissue morphology from a large field of view with mm resolution has also been developed [21]. Readers are encouraged to read a few recent review articles [5, 21, 41] that describe the topic on optical imaging techniques.

### 2.3.3

#### **Optical Contrast Agents**

Optical tissue contrast agents are used in biological systems (e.g., cells, tissues, etc.) to enhance the optical contrast by virtue of their contrast enhancing properties (e.g., fluorescence, scattering, etc.). Tissue contrast agents, for example, are capable of reducing the background signal and improving the image resolution. Fluorescent molecular contrast agents, mostly organic fluorescent compounds, possess high extinction coefficient and quantum yield and have the potential to drastically suppress tissue autofluorescence and hence background signal. Effective delivery (loading) of these contrast agents to the target tissue has also been realized to be one of the most important factors for achieving better image contrast, other than its intrinsic fluorescent characteristics (extinction coefficients, quantum yield, etc.). The concentration of contrast agent per unit volume of target tissue would

determine the signal strength. Therefore, a higher loading of contrast agent is always desirable for better image resolution and hence in obtaining a sharp marginal contrast between the normal and the pathological (e.g., a tumor) tissues.

A few important features of contrast agents have to be kept in mind prior to using or developing new contrast agents for diagnostic cancer imaging. Firstly, contrast agents with the excitation and emission band maxima in the NIR range (650 to 900 nm) are highly preferable for deep tissue imaging. Secondly, contrast agents should have a high extinction coefficient for effective absorption and a high quantum yield for obtaining strong fluorescence signal. Thirdly, they should be photostable and should not have any photo-sensitizing effects (i.e., photodynamic effect causing the damage of cellular DNA and hence cell death; also termed as photo-sensitized cell death). Fourthly, contrast agents should be hydrophilic so that an aqueous-based formulation can be easily made. Fifthly, contrast agents should have low toxicity so that they can be administered safely. Lastly, for cancer imaging, contrast agents should be attached to appropriate cancer specific delivery systems (e.g., antibodies, peptides, folates, etc.) for targeting.

Organic fluorescent contrast agents, although studied extensively for various bio-imaging applications [42], starting from cellular to tissues to whole animal fluorescence imaging have, however, several limitations for them to be considered as robust contrast agents. Firstly, organic fluorescent contrast agents (dyes) rapidly undergo photobleaching. As a result, the fluorescence signal fades away when exposed to the excitation light source (particularly when a laser is used for the excitation), limiting sensitive detection of the target. Secondly, fluorescent dyes are usually hydrophobic. To make aqueous-based formulation, chemical modifications (e.g., sodium salt) are often required that sometimes compromises their spectral characteristics. Thirdly, a handful of fluorescent compounds have been shown to possess low toxicity. Lastly, a few dyes have excitation and emission bands in the NIR spectral range (e.g., cyanine dyes). Another class of fluorescent contrast agents is fluorescent proteins. Fluorescent proteins such as green fluorescent protein (GFP) represent one class of imaging marker genes (IMG, artificial genes) with an optical signature where GFP is the transcriptional product of IMG. The GFP-based optical imaging has been successfully used to study various gene expressions *in vivo*. For example, human and rodent tumor cell lines, transected with GFP, could be visualized *in vivo* for monitoring tumor growth and metastasis [43–45]. The major drawback of GFP is limited penetration depth since the tissue can highly absorb the green emission of GFP.

## 2.4 Nanoparticles for Optical Imaging

### 2.4.1 Why Nanoparticles for Optical Imaging?

Nanoparticle (NP)-based contrast agents present a whole new class of robust nanometer size (between 1 and 100 nm) particulate materials that has strong potential

for optical imaging of cancer. The use of NPs for bioimaging applications has several advantages.

Firstly, the sensitivity of the optical imaging could be greatly improved using nanoparticle-based contrast agents. A classic example is the fluorescent quantum dots (Qdots) and their applications in cancer imaging [6, 13, 21, 46–65]. Qdots are usually crystalline cadmium sulfide (CdS) and cadmium selenide (CdSe)-based semiconductor particulate materials. They are small (<5 nm) and bright, having a broad excitation band but a narrow emission band. Dye-doped nanoparticles (NPs) such as dye-doped silica [66–69], dye-doped polymer particles [70–72], present another class of materials for sensitive cancer detection. In dye-doped NPs, each particle carries thousands of dye molecules, thus greatly enhancing the fluorescence signal. Dye-doped NPs are usually smaller (about two to three orders of magnitude) than cells, which make them suitable for cellular application. Gold nanoparticles have been well studied and have also been used for sensitive cancer cell imaging [21, 47, 73–75]. They possess a strong surface plasmon band that originates from efficient light scattering by the nanosize particles.

Secondly, nanoparticle-based contrast agents have better photostability than traditional organic dye-based contrast agents. This has tremendous potential for sensitive and real-time monitoring of cancer progression (e.g., monitoring cancer growth and metastasis). Photostable nanoparticles will allow non-invasive imaging of cancer tissue multiple times for monitoring tumor growth and also the effect of cancer drugs during cancer therapy. For example, Qdots are extremely photostable. The effective surface passivation of Qdots with a wide bandgap material such as zinc sulfide (ZnS) or zinc selenide (ZnSe) makes them photostable. In dye-doped NPs, dye molecules remain encapsulated by the particle-matrix that protects them from photobleaching. This is because the particle-matrix can, somewhat, prevent the penetration of oxygen molecules that cause dye degradation. Usually, Qdot materials are more photostable than dye doped NPs. Gold nanoparticles efficiently scatter light and, therefore, do not fade away via photobleaching process [76–78].

Lastly, multiple imaging modalities can be integrated into nanoparticle-based contrast agents (also called as multifunctional nanoparticles [79–88]), making them suitable for imaging using multiple modalities (such as fluorescence, X-ray, MRI, etc. [86, 89, 90]). This would have great importance for *in vivo* cancer imaging applications. Once labeled with the multimodal contrast agents, tumors could be imaged non-invasively using a CT scan or MRI for the pre-surgical assessment. During the surgical procedure, tumor tissue could be directly visualized in real-time by the optical property (e.g., fluorescence) of the contrast agent. This mode of tumor visualization would provide direct guidance to surgeons for the effective tumor resection, enabling them to demarcate the boundary between the tumor and normal tissues. Nanoparticle surface is usually modified to obtain multiple functional groups/ligands to improve aqueous dispersibility, specific targeting (e.g., cancer targeting), biocompatibility, etc. [6, 20, 66, 67, 84, 86, 89–95].

Nanoparticles-based contrast agents have strong potential for early cancer diagnosis since they are bright and photostable. For *in vivo* cancer diagnosis, NIR-based nanoparticle contrast agents will be required. The following sub-sections describe

in detail the design, synthesis, surface modification, and cancer targeting of various nanoparticle-based contrast agents (e.g., Qdots, dye-doped NPs, gold, etc.).

#### 2.4.2

#### Development of Nanoparticle-based Contrast Agents

A robust nanoparticle design is the key step for the synthesis of highly sensitive optical contrast agents. In a typical nanoparticle-based optical contrast agent design, the optical core is encapsulated by an intermediate coating followed by an outermost layer containing appropriate functional groups for bioconjugation. Figure 2.1 shows a general schematic representation of nanoparticle design. For cancer labeling, these particles are then attached to cancer cell targeting agents (e.g., folates, antibodies, etc.). The resulting nanoparticles can be used as cancer imaging probes (Fig. 2.2).

##### 2.4.2.1 Quantum Dots

Fluorescent Qdots are ultra-small (2–8 nm diameter) semiconductor nanocrystals, having broad absorption band with narrow and symmetric emission band (full-width at half-maximum  $\sim 25\text{--}40$  nm), that typically emit in the visible to NIR spectral range [7, 18, 96]. Qdots absorption is associated with the promotion of electrons from the conduction band to the valence band when the excitation energy exceeds that band gap energy between two electronic bands (semiconductor band gap), resulting in the formation of an electron–hole pair, called an exciton. In con-

**Fig. 2.1.** Schematic representation of core–shell nanoparticle design. The nanoparticle core (e.g., quantum dot, gold nanoparticle, dye-doped silica nanoparticle, etc.) is the primary source of an optical signal. The intermediate shell (e.g., ZnS surface passivation followed by polymer/silica coating,

pure/hybrid silica coating, etc.) is designed to protect the nanoparticle core. The outermost shell contains appropriate surface functional groups (e.g., carboxyls, amines, thiols, etc.) for biomolecule/ligand (e.g., antibodies, peptides, proteins, sugars, folates, etc.) attachment.

**Fig. 2.2.** Schematic representation showing a typical nanoparticle-based cell-labeling strategy. In this strategy cancer-targeting agents (e.g., folates, antibodies, etc.) are coated onto nanoparticle surface. The resulting coated particles are capable of recognizing cancer cells.

trast to organic fluorescent molecules, the absorption probability of Qdot nanocrystals increases at shorter wavelengths (higher energy), resulting in a broadband absorption spectrum. When the Qdot is smaller than the Bohr exciton radius (which is typically a few nanometers), the quantum confinement effect is observed in such nanocrystals [97]. In this situation, Qdot energy levels are quantized, with values directly related to the Qdot size. Qdot emission is due to a radiative recombination of an exciton, which is characterized by a long lifetime [98] ( $>10$  ns), leading to the emission of a photon in a narrow and symmetric energy band. These spectral characteristics of Qdot materials are different from a typical organic fluorescent molecule with red-tailed broad emission band and short fluorescence lifetimes. In comparison to traditional fluorescent molecules (fluorophores) or fluorescent proteins (e.g., GFP), Qdots have several attractive optical features that are desirable for long-term, multi-target and highly sensitive bioimaging applications. Some of the major optical features of Qdots are described below.

(a) Large molar extinction coefficient: Qdots are highly sensitive fluorescent agents (or fluorescent tags) for labeling cells and tissues. Unlike organic fluorescent compounds, Qdots have very large molar extinction coefficients [99], typically of the order of  $0.5\text{--}5 \times 10^6 \text{ M}^{-1} \text{ cm}^{-1}$  which means that Qdots are capable of absorbing excitation photons very efficiently (the absorption rate is approximately 10–50 $\times$  faster than organic dyes). The higher rate of absorption is directly correlated to the Qdot brightness and it has been found that Qdots are approximately 10–20 $\times$  brighter than organic dyes [100–102], allowing highly sensitive fluorescence imaging.

(b) Excellent photostability: Qdots are several thousand times more photostable than organic dyes. This feature allows real-time monitoring of biological processes over a long period.

(c) Much longer lifetime: Qdots are highly suitable for time-correlated lifetime imaging spectroscopy. This is possible due to the longer excited state lifetime of Qdots (about one order of magnitude longer than that of organic dyes), allowing effective separation of Qdot fluorescence from the background fluorescence. This will improve the image contrast by reducing the signal-to-noise ratio dramatically [103, 104] in the time-delayed data acquisition mode.

(d) Large Stokes shift: Unlike in organic dyes, the excitation and emission spectra of Qdots are well separated (i.e., large Stokes shift value; up to 400 nm, depending on the wavelength of the excitation light). This allows further improvement of sensitivity of the detection by reducing the high autofluorescence background often seen in biological specimens [6].

(e) Multiple targeting capability. The wavelength of Qdot emission is size dependent. This is a unique feature of Qdot materials in comparison to organic fluorescent dyes. The size dependent emission of Qdots allows imaging and tracking of multiple targets simultaneously using a single excitation source. This feature is particularly important in tracking a panel of disease-specific molecular biomarkers simultaneously, allowing classification and differentiation of various complex human diseases [105].

The development of Qdot-based fluorescent probes involves a multi-step process: synthesis, surface capping and bioconjugation. Each step is described below in detail.

**Qdot Synthesis** Qdot nanocrystals are made out of hundreds to thousands of atoms that typically belong to group II and VI elements or group III and V elements in the periodic table. For example, CdSe, CdTe, and ZnSe are group II–VI semiconductor Qdots, whereas InP and InAs Qdots are group III–V semiconductors. The Qdot emission can be continuously tuned from 400 to 2000 nm by changing both the particle size and chemical composition. Herein, we briefly describe two robust synthesis techniques that produce high quality Qdots.

**Hot Solution-phase Mediated Qdot Synthesis** This is most popular technique of synthesizing high quality Qdots. Typically, Qdots are synthesized at elevated temperature in high boiling point non-polar organic solvents. Bawendi's group have reported [106] the synthesis of highly crystalline and monodisperse (size distribution 8–11%) CdSe Qdots using high-temperature growth solvents/ligands (mixture of trioctylphosphine/trioctylphosphine oxide, TOP/TOPO). A combination of TOPO and hexadecylamine can also be used [96]. The purpose of using hydrophobic organic molecules as mixed solvents or as a solvent/ligand mixture is two-fold. The mixture serves as a robust reaction medium and also coordinates with unsaturated metal atoms on the Qdot surface to prevent the formation of bulk semiconductors. Following a similar synthesis strategy, Qu et al. have reported the formation high

quality CdSe nanocrystals having fluorescence quantum yields as high as 85% at room temperature [107].

**Reverse-micelle Mediated Qdot Synthesis** The reverse micelle synthesis of high quality CdS:Mn/ZnS core-shell Qdots has been reported [86, 89, 90, 108–110]. Reverse micelles [also called water-in-oil (W/O) microemulsion system] are an isotropic, thermodynamically stable homogeneous mixture of oil, water and surfactant molecules where the surfactant capped (stabilized) water droplets remain uniformly dispersed in the bulk oil phase. The water droplets serve as a tiny reactor (nano-reactor) for the synthesis of Qdots. This is a simple procedure that does not require extreme reaction conditions such as high temperature or high pressure. This is a robust method that allows room temperature synthesis of monodisperse Qdots at normal atmospheric pressure. Yang et al. have reported the synthesis of manganese-doped cadmium sulfide core and zinc sulfide shell (CdS:Mn/ZnS) Qdots using AOT (dioctylsulfosuccinate sodium salt, a surfactant)/heptane (an oil)/water reverse micelle system [90, 108, 109]. The bright yellow emitting CdS:Mn/ZnS Qdots are small (average Qdot size was 3.2 nm) and highly photostable.

**Qdot Surface Passivation and Aqueous Stabilization** Effective surface passivation of the Qdot nanocrystal core with wide bandgap semiconductor materials (shell) is extremely important [100, 111] for the following reasons. For example, with cadmium selenide/zinc sulfide (CdSe/ZnS) core-shell Qdots, the epitaxially matched ZnS layer effectively passivates the surface defects of the CdSe core [100, 108, 112], protects the core from oxidation, prevents leaching of highly toxic Cd<sup>2+</sup> ions, and also drastically improves the quantum yield by reducing surface defects (that act as exciton traps, leading to non-radiative recombination processes). Surface passivation with silica is effective for the CdSe core [90, 113, 114] nanocrystals.

TOP/TOPO-capped Qdots prepared using hot solution phase mediated synthesis route are hydrophobic. For biological applications, however, it is necessary to obtain aqueous dispersible Qdots. Therefore, phase transfer from the organic (e.g., toluene, hexanes, chloroform) to aqueous solution is usually performed by surface functionalization with hydrophilic ligands. There are three major routes to surface functionalization. Firstly, the “cap exchange” route that involves replacement of TOP/TOPO capping with bifunctional ligands. The bifunctional ligands [102, 115–118] have two functional moieties, Qdot surface anchoring (e.g., thiol) and hydrophilic moieties (e.g., hydroxyl, carboxyl). Secondly, the formation of a hydrophilic silica shell [86, 89, 90, 101, 108, 119] that encapsulates the Qdot. Lastly, the over-coating of TOP/TOPO-capped Qdots with amphiphilic “diblock” and “triblock” copolymers and phospholipids [6, 64, 120–124].

Notably, Qdots capped with mono-mercapto ligands have short shelf-lives, about a week, due the weak (dynamic) thiol-ZnS interaction [125], although polydentate thiolated ligands (containing more than one thiol groups) afford better stability (from a week to a couple of years) [116, 118, 125]. Applying a silica shell over the Qdots has several advantages with respect to long-term stability (shelf-life) and bio-

compatibility. Also, a silica coating remains stable upon pH fluctuation (below pH 8) and a further coating with a multifunctional hybrid silica is possible using appropriate silane reagents [86, 89]. The polymer/phospholipid encapsulation is also robust in terms of long-term stability. Both the silica and the polymer/phospholipid coating increase the particle size (~20–30 nm). However, Yang et al. reported the W/O microemulsion-mediated synthesis of silica-overcoated CdS:Mn/ZnS Qdots [90] where the silica shell thickness was approximately 2–3 nm.

**Qdot Bioconjugation** Qdot bioconjugation represents the attachment of biomolecules (e.g., proteins, antibodies, peptides, DNA, etc.) to the Qdot surface, forming a hybrid structure, interfacing both the inorganic and the biological materials, for targeting to biological systems such as cells, tissues, etc. either specifically or non-specifically. Qdots are comparable or slightly larger than many proteins. For example, a 510 nm green-emitting Qdot size is comparable to GFP and a 650 nm red-emitting Qdot size is comparable to DyRed (a red-emitting fluorescent protein) [126]. Medintz et al. have shown that about 15–20 maltose binding proteins ( $M_r \sim 44$  kDa) can be conjugated to a single 6-nm Qdot [127]. There are three major ways to attach proteins to Qdot surface. Firstly, using carbodiimide [e.g., EDC, 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide] coupling chemistry, carboxylated Qdots are covalently conjugated to the protein molecules through the formation of stable amide bond. Secondly, disulfide bonds can be formed between Qdot surface sulfur atoms (from the ZnS surface) and peptides containing cysteine residues [128, 129]. Histidine-expressing proteins [130] or peptides containing polyhistidine residues [131–133] can also be directly attached to the Zn atom on the Qdot surface. Lastly, engineered proteins containing positively charged domains can be non-covalently adsorbed onto the negatively charged Qdot surface via electrostatic interaction [116, 134, 135]. Although various bioconjugation strategies have been tested, none of them can control the ratios of proteins per Qdots. There is certainly a lack of experimental tools with which to discern the orientation of a protein immobilized on a Qdot surface. For specific targeting, it is highly desirable that the delivery proteins (e.g., antibody) are properly oriented and fully functional. The Qdot bioconjugation step is, therefore, extremely important in obtaining success in bioimaging.

#### 2.4.2.2 Gold Nanoparticles

For over 30 years, nanometer-sized gold particles have been used to stain cells and tissue samples for electron microscopy. The basic principle of interactions between gold particles and biomolecules, like proteins, has been well studied for immunocytochemical staining applications. Although nanosize metals like gold and silver do not fluoresce they can effectively scatter light due to the collective oscillation of the conduction electrons induced by the incident electric field (light). This is known as “surface plasmon resonance” [20]. Thus, colloidal gold particles exhibit a range of intense colors in the visible and NIR spectral regions.

Gold nanoparticles, because of their strong SPR properties, have attracted considerable attention in bioimaging in recent years. The SPR signal originates from

the collective oscillation of conduction electrons upon interaction with absorption photons [136]. The SPR frequency depends on various factors, e.g., particle size [137] shape [138–140], dielectric properties [141, 142], aggregate morphology [143–146], surface functionalization [147, 148] and the refractive index of the surrounding medium [149–152]. Gold nanoparticles have high absorption [146, 151, 153] and scattering cross section [154, 155]. For example, the absorption cross section of a 5 nm diameter gold particle is about 3 nm [156] at a wavelength of 514 nm [136], which is about two orders of magnitude higher than that of organic fluorescent molecules at room temperature. The scattering cross section of gold nanoparticles is much larger than polymeric spherical particles of similar size, especially in the red region of the spectrum, i.e., red to NIR range, having potential in deep tissue imaging. For example, using composite core–shell gold (dielectric silica core and gold shell) particles, it is possible to tune the scattering from 600 to 1200 nm [141]. Due to excellent biocompatibility [157–159], gold nanoparticles have been widely used in immunohistochemistry (gold-based staining) and in ultra-sensitive DNA detection assays [146, 160, 161]. However, a few literature reports are available on gold nanoparticle-based cancers imaging.

**Gold Nanoparticle Synthesis** Various methods have been reported for the synthesis of gold nanoparticles. There are two general approaches (so-called “top-down” and “bottom-up”) that primarily categorize most reported synthesis strategies.

Synthesis of gold nanoparticles by employing laser ablation technique is an example of a “top-down” approach, where the embryonic (nascent) particles are formed from the ionized gold atoms via nucleation and growth processes. The challenge still remains how to stabilize particles in the solution phase. Using a surfactant-based capping agent (sodium dodecylsulfate, an ionic surfactant), Kondow et al. have successfully stabilized ultrafine (~5 nm) particles [162]. The capping agents, in general, control the particle size and size distribution, prevents particle aggregation, and stabilize particle solution (such as in aqueous-based medium).

In the “bottom up” approach, gold nanoparticles and gold nanocomposites (e.g., composite of gold and silica) have been chemically synthesized by reducing gold precursors. Various reduction methods have been reported. The major synthesis routes are as follows.

(a) Reduction of gold precursors (e.g., hydrochloroauric acid,  $\text{HAuCl}_4$ ) using appropriate reducing agents, such as citrate [163–166], sodium borohydride [167], ascorbic acid [168], etc. The citrate reduction of the gold(III) ions has been widely used. While sodium citrate reduces  $[\text{AuCl}_4]^-$  ions in hot aqueous solution, it forms a colloid. The reported average particle size is about 20 nm. Both the citrate ions and the oxidation products (e.g., acetone dicarboxylate) act as capping agents [163–165]. In conjunction with citrate ions, amphiphile surfactants have also been used that allowed particle size tuning upon varying the gold/stabilizer ratio [166]. A two-phase synthesis of gold nanoparticles (the Brust–Schiffrin method) has been reported in which a phase-transfer agent (tetraoctylammonium bromide) is used to transfer  $[\text{AuCl}_4]^-$  ions from an aqueous phase to an organic phase (tol-

uene) containing alkanethiol stabilizer. The Au(III) in organic phase is reduced by the addition of aqueous sodium borohydride. The resulting Au clusters are then capped immediately by alkanethiols. The Brust–Schiffrin method produces monodisperse particles (approx  $1.4 \pm 0.4$  nm) in the diameter range 1.5–5.2 nm [167, 169].

(b) Microemulsions [170–172], copolymer micelles [173], reversed micelles [172], surfactant, membranes, and other amphiphiles have been widely used for the synthesis of stabilized gold nanoparticles. Wilcoxon and coworkers have studied the synthesis of gold nanoparticles formed in aqueous media and in reverse micelles, using chemical and photolytic reduction [174]. The chemical reduction method was achieved using reduction agents such as hydrazine, sodium borohydride, and metallic sodium. The advantages of using reverse micelles for the synthesis of gold nanoparticles are (i) it produces monodisperse particles, (ii) particles remain coated by surfactant molecules that prevent particle aggregation surrounding the molecule and (iii) the size of the nanoparticles can be easily varied by changing reaction parameters such as concentrations of the reagents, water-to-surfactant molar ratio, temperature, time allowed for ripening of particles, etc.

(c) Another popular, long standing, method is the seed mediated route [175]. Indeed, the use of preformed metallic seeds as nucleation centers in nanoparticle synthesis has a long history [175–182]. Various references are available on the seed mediated growth of gold nanoparticles and also of gold nanorods [183–189]. Further nucleation during the “growth” part of the reaction often leads to non-uniform size distribution [190, 191]. The presence of seeds appears to cause additional nucleation (sometimes referred to as secondary nucleation) [184]. The step-by-step particle enlargement is considered more effective than the one-step seeding method to avoid additional nucleation [192]. More recently a modification of seed mediated method was used by Loo et al. [193] to achieve gold coating on the silica nanoparticles. Gold shells were grown using the method of Duff et al. [194]. Briefly, small gold colloid (1–3 nm) was adsorbed onto the aminated (amine functionalized) silica nanoparticle surface. More gold was then reduced onto these colloid nucleation sites using potassium carbonate and HAuCl<sub>4</sub> in the presence of formaldehyde. Gold shell particles have been used for whole blood immunoassay [195], photothermal tumor ablation [196] molecular imaging in live cells [197] and for cancer imaging and therapy [198].

(d) Reduction of gold precursors using a combination of appropriate reducing agents and radiation such as UV [188, 199–201], ultrasound [202–207], heat [208–210].

The UV irradiation method has been used to prepare gold nanoparticles [188, 199, 200, 211, 212], including when in synergy with micelles [211] or seeds [188]. The “gold seed particles” are prepared photochemically by UV irradiation, preferably in the presence of a neutral micelle of a non-ionic surfactant, Triton X-100 [poly(oxyethylene) iso-octyl phenyl ether] [201]. The seed particles subsequently grow by successive addition of metal ions and, again, exposure to UV irradiation under the same experimental conditions.

Several reports are available on the sonochemical synthesis (chemical synthesis using ultrasound radiation) of gold nanoparticles [202–207]. The general mecha-

nism of reduction is briefly described here. When a solution is exposed to ultrasound radiation of sufficient intensity it produces a cavitation field made up of a large distribution of vapor and gas-filled bubbles, which pulsate continuously. When the pressure inside the bubble falls below the vapor pressure of the liquid the bubble fills with vapor and grows. At a certain point when the pressure turns positive the bubble collapses, resulting in extreme temperatures and pressures in the interior. The localized hot point causes ionization of molecular species present within the interior of the collapsing bubble. For water vapor, this dissociation results in the production of H and OH radicals [213]. The radicals produced in the interior of the bubble can then diffuse into the bulk solution and reduce metal ions, yielding nanosized metallic particles such as gold nanoparticles.

Gold has also been fabricated by employing thermolysis [208–210] of organic derivatives of gold. This novel strategy involves the reductive elimination of thiolate ligands with simultaneous attachment of an organic moiety on the growing nuclei [210].

**Surface Functionalization and Bioconjugation** As mentioned in the previous section, gold nanoparticles have been widely used as immunostaining agents for labeling cell, tissue section, blots, etc. In general, protein conjugated gold nanoparticles are mostly used as labeling probes. Although the actual mechanism of macromolecule (e.g., proteins) binding to gold particles is poorly understood, some of the accepted mechanisms are [214]:

- (1) Protein binding via electrostatic (ionic) interaction. Negatively charged gold nanoparticles can bind to positively charged protein domains via electrostatic interactions.
- (2) Protein binding via hydrophobic interaction. Hydrophobic domains present in the protein structure can interact with the metal surface of the particle.
- (3) Protein binding via chemical interaction. Protein molecules containing sulfhydryl ( $-S-H$ ) groups can chemically interact with the gold atoms. This is also called dative binding.

Other biomolecules, such as protein A, antibodies, lectins, avidins (or streptavidins), etc., have also been conjugated to gold nanoparticles to be used as sensitive probes. Some of the binding strategies are described below.

**Protein A–Gold Conjugate** Protein A–gold conjugates are generally prepared by adsorbing protein A onto the gold surface. Following a similar method, many other immunoglobulin binding proteins can also be attached to gold nanoparticles. These probes have been used as “universal” probes for labeling cells, tissue sections and various blots. In a typical tissue labeling experiment, primary antibodies are specifically targeted to the tissue antigens. In the following step, protein A–gold conjugates bind to the antibodies. The advantage of this labeling technique is that the same protein A–gold conjugate can be used for various immunochemical procedures.

**Antibody–Gold Conjugate** Antibody–gold conjugated probes are prepared by coating antibodies directly on to the gold nanoparticle surface. These probes have been successfully used for the detection, localization and quantification of antigens on the target specimens. This is a powerful technique for detection of pathogens, intracellular foreign substances, monitoring cellular metabolic processes, etc.

**Lectin–Gold Conjugate** Lectin-coated gold nanoparticle probes have been used for the detection of sugar-binding receptors that are expressed on the cell membranes. Lectin molecules have specific carbohydrate binding sites. In this assay, a specific carbohydrate molecule is sandwiched between the lectin molecule and the cellular receptor. The objective of this assay is to localize glycoproteins, glycolipids, etc. on cell surfaces.

**Avidin (or Streptavidin)–Gold Conjugate** Avidin–gold conjugated probes have been used to localize, detect and quantify biotin molecules. This assay is similar to protein A–gold complex-based assays except that the primary antibodies are attached to biotin molecules.

#### 2.4.2.3 Dye-doped Silica Nanoparticles

Amorphous silica (silicon dioxide) nanoparticles that are produced via Stober's sol–gel [67, 215, 216] or microemulsion technique [66, 68, 91, 93, 217–225] have recently found applications in the area of bioimaging. Unlike Qdots or gold nanoparticles, silica does not have inherent strong fluorescence that can be exploited for sensitive imaging applications. However, silica nanoparticles can be made fluorescent by incorporating fluorescent dye molecules inside the silica matrix (dye-doping). Another approach could be attaching fluorescent dye molecules (via covalent binding) on the silica surface.

For bioimaging applications, it is preferable that dye molecules remain encapsulated by the silica matrix for the following reasons. Silica-based nanoparticles exhibit several attractive features, e.g., silica is water dispersible and is resistant to microbial attack. The size of silica particles remains unchanged by changing solvent polarity (i.e., resistant to swelling) and, therefore, silica porosity remains unaltered in a wide selection of solvents, including aqueous-based neutral and acidic solutions. A silica matrix is optically transparent, allowing excitation and emission light to pass through efficiently. Moreover, fluorescent dyes can be effectively entrapped inside the silica particles. The spectral characteristics of the dye molecules remain almost intact. Silica encapsulation provides a protective layer around dye molecules, reducing oxygen molecule penetration (which causes photodegradation of dye molecules) both in air and in aqueous medium (in the latter case dissolved oxygen). As a result, photostability of dye molecules increases substantially compared with bare dyes in solution. Amorphous silica appears to be a biocompatible [22] and non-toxic [23] material, and has potential biological applications.

The surface of a silica particle can be easily modified to attach biomolecules such as proteins, peptides, antibodies, oligonucleotides, etc., using conventional silane-based chemistry. For example, carboxylated silica nanoparticles can be covalently

attached to the amine groups of proteins, antibodies etc. through the formation of stable amide bond [216]. Peptides containing a cysteine residue (through a  $-S-H$  group) can be attached to the aminated silica nanoparticles [89] through (SPDP) coupling chemistry.

A general synthesis strategy of fluorescent silica nanoparticles is the incorporation of organic or metalloorganic dye molecules inside the silica matrix [66, 93, 226–231]. For example, a metalloorganic dye, tris(2,2'-bipyridyl)dichlororuthenium(II) (Rubpy), has been entrapped inside silica nanoparticles using a reverse microemulsion-based synthesis approach [66] where the positively charged Rubpy molecules were electrostatically bound to the negatively charged silica matrix. Dye-doped silica-based imaging probes are non-isotopic, sensitive and relatively photostable in the physiological environment. Additionally, the interaction potential of the silica surface can be easily manipulated to facilitate the interaction with cells [232–234]. Due to these novel features, functionalized silica nanoparticles (FSNPs) have found widespread applications in bioanalysis and bioimaging applications.

**Synthesis** There are two reported synthesis routes to dye-doped silica nanoparticles: Stober's sol-gel method and the reverse microemulsion method.

**Stober's Method** In a typical Stober's method, alkoxysilane compounds [e.g., tetraethylorthosilicate (TEOS), tetramethylorthosilicate (TMOS), various TEOS or TMOS derivatives, etc.] undergo base-catalyzed hydrolysis and condensation in an ammonia-ethanol-water mixture, forming a stable alcohol. This method has been widely used for synthesizing both pure and hybrid (when more than one silane compound are used, such as dye-doped silica particles) silica nanoparticles with particle diameters ranging from a few tens to several hundreds of nanometers (sub-micron size). Following Stober's protocol with a slight modification, fairly monodisperse organic dye doped fluorescent silica nanoparticles have been synthesized. Since organic dyes are normally hydrophobic, doping them inside the hydrophilic silica matrix is not straightforward. Typically, a reactive derivative of organic dye (e.g., amine-reactive fluorescein isothiocyanate, FITC) is first reacted with an amine-containing silane compound (e.g., APTS), forming a stable thiourea linkage. Then FITC conjugated APTS and TEOS are allowed to hydrolyze and condense to form FITC conjugated silica particles. Note that particles so formed will have some amount of bare dye molecules on the particle surface that is covalently attached. These bare dyes, due to their hydrophobic nature, will somewhat compromise the overall particle aqueous dispersibility and, also, they will be prone to photobleaching. Therefore, an additional coating with pure silica is usually applied around the dye-conjugated silica nanoparticles. Using Stober's method, bulk amounts (kilograms) of silica particles can be easily produced in a typical laboratory setup.

**Reverse Microemulsion (W/O) Method** This method is used for the synthesis of pure silica, as well as inorganic and organic dye-doped silica nanoparticles. Figure 2.3 shows a schematic representation of dye-doped silica nanoparticle synthesis steps. The W/O microemulsion is a robust technique for producing monodisperse

**Fig. 2.3.** Scheme of a water-in-oil (W/O) microemulsion mediated synthesis of dye-doped silica nanoparticles. (A) An immiscible mixture of water and oil (bulk phase). Upon addition of an appropriate surfactant, a W/O microemulsion is formed (B), where each tiny water droplet (nanosize water pool) is stabilized in the bulk oil phase with a surfactant coating (C). In reality each nanosize

water droplet serves as a nanoreactor for the synthesis of nanoparticles (D). The nanoparticle core (shown as filled circles), intermediate shell (inner ring) and outermost shell (outer ring) of the dye-doped silica nanoparticles are constructed in modular fashion by adding appropriate silane-based reagents at various stages of the synthesis process.

particles in the nanometer size range (tens to a few hundred nanometers). Figure 2.4 shows a typical transmission electron microscopic image of dye-doped silica nanoparticles synthesized using the W/O microemulsion technique. The W/O microemulsion is an isotropic, single-phase system that consists of surfactant, oil (as the bulk phase) and water (as nanosize droplets). Each surfactant-coated water droplet that is stabilized in the oil phase serves as an individual nanoreactor for the synthesis of silica nanoparticles. The water droplets undergo rapid and spontaneous collision and coalescence (fusion followed by separation) processes. As a result droplet contents (e.g., water-soluble reagents) are mixed together and chemical reactions (e.g., precipitation, hydrolysis and condensation reactions, etc.) take place. The surfactant present at the interface of oil and water nanodroplet is responsible for the thermodynamic stability of the W/O microemulsion system. Nucleation and growth processes are carried out inside the confined spherical volume of the nanoreactor. Varying the water-to-surfactant molar ratio and the dynamic properties of the microemulsion system helps to control the size of the nanoparticles.

**Fig. 2.4.** Typical transmission electron microscopic image of dye-doped silica nanoparticles about 100 nm in size. Particles were synthesized using the water-in-oil (W/O) microemulsion technique. As expected, nanoparticles were highly monodisperse,

confirming that the W/O microemulsion is a robust technique for the synthesis of dye-doped silica nanoparticles. This technique can be easily adopted to produce other types of nanoparticles such as quantum dots and multimodal nanoparticles.

The fluorescence brightness of dye-doped silica nanoparticles can be improved by incorporating high-quantum-yield organic dyes having large absorption coefficients. In other words, brighter probes will improve the image resolution if encapsulated fluorescent dyes do not experience substantial photobleaching during imaging.

**Surface Functionalization and Bioconjugation** For bioimaging (e.g., cancer imaging), it is highly desirable that dye-doped silica nanoparticles are appropriately surface modified with cancer targeting molecules such as cancer specific antibodies, folates. This surface modification involves a few steps. Firstly, the particle surface should be modified to obtain appropriate functional groups such as, amines, carboxyls, thiols, etc. Secondly, using suitable coupling reagents, nanoparticles are attached to the bio-recognition molecules (such as antibodies, folates, etc.). Lastly, bioconjugated particles are targeted to cancers. Note that all these steps are usually carried out in aqueous-based solutions. A few bioconjugation methods are briefly mentioned below.

- (1) Bioconjugation with carboxylated particles. This is one of the most common bioconjugation techniques to immobilize protein molecules on silica nanoparticles. The surface of the nanoparticle is modified to obtain carboxyl groups ( $-\text{COOH}$ ) by using a carboxylated silane reagent. Biomolecules such as proteins, antibodies, etc. containing free amine functional groups are then covalently attached to the carboxyl functionalized nanoparticle, using carbodiimide-coupling chemistry [235].
- (2) Bioconjugation with aminated particles: Many cancer cells overexpress folate receptors. Cancer targeting with folate-conjugated nanoparticles has been

recently reported [67]. Folates are chemically attached to aminated silica nanoparticles using carbodiimide chemistry.

- (3) Bioconjugation with avidin–biotin binding: Avidin is a protein molecule that contains four specific binding pockets for biotin molecules. A strong binding affinity exists between avidin and biotin molecules, which is comparable to covalent binding. Avidin-coated nanoparticles are typically attached to biotinylated molecules such as antibodies, proteins, etc. [236].
- (4) Bioconjugation through disulfide bonding: Sulfhydryl-modified nanoparticles are conjugated to disulfide-linked oligonucleotides (e.g., DNAs). In this method, oligonucleotides are attached to nanoparticles through di-sulfide bond formation [237].
- (5) Bioconjugation using cyanogen bromide chemistry: Nanoparticles with hydroxyl groups (such as silica) can be activated with cyanogen bromide to form a reactive  $-OCN$  derivative of the nanoparticles. The  $OCN$  derivative then readily reacts with proteins (via amine groups), forming a “zero-length” bioconjugate as there is no spacer between the particle surface and the protein molecule [66].

## 2.5

### Optical Imaging of Cancer with Nanoparticles

Here we discuss the use of nanoparticle-based optical contrast agents in *in vitro* and *in vivo* experiments to image cancerous tissues. These nanoparticle-based contrast agents should provide a new gateway to characterize cancer at the molecular level. As we have already realized, these ultra-sensitive and specific probes provide a viable alternative to rapidly and non-invasively image the uptake, distribution and binding of nanoparticles to tumors. To establish the widespread use, it is important to understand the delivery, interaction and recognition mechanism of these contrast agents with cancer cells.

Various delivery vehicles with varying specificity have been used to target cancer tissues, mainly for drug delivery applications, some of which are folates, antibodies, lectins, growth factors, cytokines, hormones and low-density lipoproteins. Obviously, most of these carriers can be similarly used for molecular imaging applications. These can be broadly classified [6, 238] as active and passive targeting.

#### 2.5.1

##### Active Targeting

This refers to the conjugation of targeting ligands to nanoparticles to provide preferential accumulation into the tumor antigens and blood vessels with high affinity and specificity. This relies on specific interactive forces between lectins–carbohydrate, ligand–receptors and antibody–antigens [214].

Lectins can recognize and bind to glycoproteins that occur on the surface of cells. These proteins can bind to certain carbohydrates in a specific manner. Direct

and reverse lectin targeting have made use of these specific interactions to receptors or antigens expressed by the plasma membrane.

Folate receptor-based interactions are an excellent example of ligand–receptor based active targeting. Folate receptors are overexpressed on the surface of various cancers like those of the brain, ovary, kidney, breast and lungs. Confocal microscopic studies have demonstrated the selective intake and receptor-mediated endocytosis of folate-conjugated nanoparticles by tumor cells.

Antibody-mediated tumor targeting has been performed for detecting the presence of antigenic moieties on the surface of cancer cells. Tumor targeting ligands like monoclonal antibodies are attached to nanoparticles to target the specific receptors. These moieties are minimally present on the surface of normal tissues. Only certain antigens are actually tumor-specific and are referred to as tumor-specific antigens.

### 2.5.2

#### **Passive Targeting**

This mode of targeting particles to tumors includes strategies like using the enhanced permeation and retention (EPR) effect, use of a unique tumor environment and a direct local delivery of imaging agents to tumors.

In the EPR strategy, nanoparticles with a hydrophilic surface and diameter < 100 nm are made to accumulate at the tumors. The nanoparticles are engineered to prevent their uptake by the reticuloendothelial system, resulting in faster circulation and enhanced targeting ability in the physiological environment.

Various researchers have demonstrated the strategy of exploiting the unique tumor environment to trigger the release of therapeutic drugs. The drug is conjugated to tumor specific ligands and remains inactive till it reaches its target site. On reaching the tumor, the linkages are hydrolyzed either by the enzymes present, or by a change in pH and the drug is released by the nanoparticles.

Sometimes the imaging agents can be locally delivered to avoid its systemic circulation. But this is a challenging procedure as it involves the precise delivery using injections or surgical procedures that can be frequently cumbersome.

### 2.5.3

#### **Cancer Imaging with Quantum Dots**

Surface-functionalized quantum dots have been used to image various tumor cells and tissues in *in vitro* and *in vivo* experiments. Some of the different cell lines that have been used are human mammary epithelial tumor (MDA-MB-231) [239], human breast cancer (MDA-MB-435S [240], MDA-MD-435 [129], MCF 7 [240], and SK-BR-3 [64]), human prostate cancer [6], squamous carcinoma [19, 241] B16 melanoma (skin cancer) [56], human neuroblastoma (SK-N-SH) [242], colon tumor (SW480) [240], lung tumor (NCI H1299) [240], and bone tumor (Saos-2) [240] cells.

In 2002, Parak and coworkers used water-soluble [119] siloxane-coated quantum dots of two different sizes (2.8 and 4.1 nm cores), functionalized with thiol and/or amine groups, to label human mammary epithelial tumor cells (MDA-MB-231) [239]. These Qdots emitted at 554 and 626 nm, respectively, and were more photo-stable than ordinary organic dyes. Confocal microscopic images verified the presence of nanocrystals ingested rapidly inside the cells, and not on the surface. The quantum dot crystals were found in the perinuclear region of the cells even after a week. Almost at the same time, Ackerman and coworkers [129] incubated human breast carcinoma MDA-MD-435 cells with peptide coated quantum dots. These cells were then injected into mice to create tumor grafts. The mice were imaged 8–12 weeks after tumor inoculation. Although quantum dot probes were not detected inside the mice, *in vitro* tests showed that peptide-coated Qdots could specifically target tumor cells. Wu et al. have used streptavidin-conjugated commercial Qdots, QD 560 (emission maximum 560 nm) and QD 608 (emission max. 608 nm), to detect Her2 cancer markers on the surface of human breast cancer cells (SK-BR-3) [64]. The nanocrystals effectively labeled the cancer cells with negligible affinity to normal cells.

Recently, Nie and coworkers [6] have developed multifunctional nanoparticle probes (2.5 nm radius core protected by a 1-nm TOPO cap with 2-nm polymer coating and 5 nm PEG/affinity ligand shell) for imaging. The quantum dots were used for *in vivo* imaging to target to tumor sites either through a slow passive targeting process or a more efficient active targeting process. Squamous carcinoma cells have been labeled with quantum dots conjugated to epidermal growth factors (EGF) [19, 241]. These probes with a broad fluorescence peak in the NIR at 770 nm can specifically bind and activate the EGF receptors [241] of cancer cells in C3H mice [19]. Similarly dihydroxyliipoic acid (DHLA)-capped quantum dots can be efficiently delivered into B16 melanoma (skin cancer) cells [56]. The melanoma cells were labeled with the Qdots and injected into live mice to track tumor cell extravasation. The Qdots did not pose a detectable threat [56] to the labeled cells or the host animal and behaved as “inert fluorescent tags.” Quantum dots have also been used to detect integrin  $\alpha_v$  subunits in human neuroblastoma cells (SK-N-SH) [242] and label mouse lymphocytes (EL-4 cells derived from murine T-cell lymphoma) [243].

*In vivo* imaging to map sentinel lymph nodes (SLN) in rats and pigs has also been achieved using Qdots [238, 244, 245]. The presence of lymph node metastases is an early warning signal for breast and lung cancer. NIR nanocrystals with oligomeric phosphine coating (for solubility in aqueous buffers) was used to guide a surgeon during cancer surgery.

A new quantum dot based tool, called “Quantum Dot Phagokinetic Track assay” has been developed [240] to quantify the invasive potential of different tumor cells. When cancer cells move through a bed of Qdots, they engulf the nanocrystals and leave behind a phagokinetic trail depleted in Qdots. Cells with higher metastatic potential engulf more Qdots and leave a clearer trail than those with weak metastatic potential. Seven different cancerous and non-cancerous cell lines were used

to compare the different invasive potentials, including breast epithelial MCF 10A, breast tumor MDA-MB-231, MDA-MB-435S, MCF 7, colon tumor SW480, lung tumor NCI H1299, and bone tumor Saos-2. This assay rapidly discriminates between invasive and non-invasive cancer cell lines with greater sensitivity than the conventional Boyden chamber invasion assay.

#### 2.5.4

#### Cancer Imaging with Gold Nanoparticles

Gold bioconjugates have been used for vital imaging of precancerous and cancerous cells by researchers for *in vitro* and *in vivo* experiments. The unique optical property of the metal in the nanosized range has been used for detecting breast carcinoma cells (SK-BR-3) [246] breast cancer markers like HER2, oral epithelial live cancer cells (HOC 313 clone 8 and HSC 3) [73] and neoplastic cervical biopsies [75].

Gold nanocages <40 nm can be used for specific targeting of breast cancer cells [246]. Gold-bioconjugates with surface plasmon resonance peaks at 800 nm were synthesized and used to label breast cancer cells (SK-BR-3) that overexpresses epidermal growth factor receptor 2 (EGFR2 or HER2). Primary antibodies (monoclonal anti-HER2 antibody from mouse) were immobilized on the SK-BR-3 cells. Secondary antibody (e.g., anti-mouse immunoglobulin G or IgG) conjugated gold nanocages were added to the cancer cells bound with anti-HER2 antibodies and imaged. A gold nanoshell based contrast agent [198] has also been used to image breast cancer cells. The nanoshell consists of a dielectric core surrounded by a thin gold shell. The dimensions were maintained to obtain an optical scattering peak in the NIR region at around 800 nm. In this case, anti-HER2 was attached to a PEG linker, and then attached to the nanoshell surface using a sulfur-containing group. The nanoshells successfully detected the HER2-positive SKBr3 breast adenocarcinoma cells.

SPR scattering imaging or SPR absorption spectroscopy can be used with antibody-conjugated gold nanoparticles for imaging oral epithelial living cancer cells *in vivo* and *in vitro* [73]. Two malignant oral epithelial cell lines (HOC 313 clone 8 and HSC 3) and a non-malignant cell line (HaCaT) were incubated with the gold nanoparticles. The cell cytoplasm contained dispersed and aggregated forms of the colloidal gold nanoparticles, with non-specific uptake for malignant cells. The gold nanoparticles conjugated to monoclonal anti-EGFR antibodies specifically and homogeneously bound to the cancer cell with enormously greater affinity than to non-cancerous cells. A relatively sharper SPR absorption band with a redshifted maximum was obtained for specific binding compared with that obtained for noncancerous cells.

Sokolov and coworkers [75] have reported the use of gold bioconjugates with monoclonal antibodies against EGFR for the real-time vital optical imaging of precancerous cells and tissues. Cervical epithelial cancer cells (SiHa cells) and 3D tissue constructs and normal and cancerous cervical biopsies were used for *in vivo*

imaging. They have shown the topical delivery of gold conjugates for imaging the whole epithelium.

### 2.5.5

#### Cancer Imaging with Dye-doped Silica Nanoparticles

Dye-doped silica nanoparticles have been used for *in vitro* imaging of cancer cells. Researchers have demonstrated their use in labeling human leukemia [66, 92, 93], HepG liver cancer [68], human oral carcinoma [67] and lung carcinoma cells [91, 217]. Figure 2.5 shows a confocal image of human lung cancer cells labeled with folate-conjugated FITC-doped 100-nm silica nanoparticles. Tan and coworkers have used 60-nm dye-doped silica nanoparticles, doped with Rubpy dye to label human leukemia cells [66, 92, 93]. Similarly, He and coworkers [68] have reported a method to recognize HepG liver cancer cells using FITC-APTS-doped silica nanoparticles. More recently, FITC-APTS-doped folate-conjugated silica nanoparticles were used to target overexpressed folate receptors in human oral carcinoma [67] and lung carcinoma cells [91, 217]. The dye-doped silica nanoparticles were covalently attached to folic acid molecules by a carbodiimide coupling reaction. The affinity of folate immobilized conjugates for folate receptors on the cancer cell surface were utilized for imaging [67]. The nanoparticles were detected using fluorescent techniques and imaged using a confocal microscope.

**Fig. 2.5.** Folate conjugated FITC-doped 100-nm silica nanoparticles were targeted to human lung cancer cells. Confocal microscopic images (left: fluorescence, right: transmission) showed that folate-conjugated nanoparticles successfully labeled cancer cells. This nanoparticle-based cancer labeling strategy

could be extended further to image other type of cancer cells that overexpress folate receptors. Note that nanoparticles were taken up by the cancer cells via receptor-mediated endocytosis. The extracellular nanoparticle concentration was  $50 \mu\text{g mL}^{-1}$  and the incubation time was 2 h.

## 2.6

### Other Nanoparticle-based Optical Contrast Agents

Up-converting phosphors, dye-doped polymer particles are also considered as optical nanoparticle probes. However, application of these particles for cancer imaging is yet to be explored.

In up-converting phosphor nanoparticles both the absorber and the emitter ions are present in the crystal lattice. The absorber is excited by the energy of the infrared (IR) light source. The absorber transfers this energy to the emitter ion that emits a detectable photon. The up-conversion of light is caused by multiphoton process. The unique feature of converting IR light into visible radiation of the phosphors has shown great promise as a new type of fluorescence reporter for bioanalysis [247, 248]. Their emission bandwidths are generally very narrow (25–50 nm). There are several advantages of using up-converting phosphor technology (UPT) for bioanalysis. First, emission occurs at discrete wavelengths with a large anti-Stokes shift. Second, the emission is strong and does not fade away. Third, excitation wavelength is in the IR range, which reduces the background signal drastically by completely eliminating autofluorescence from the biological samples. Fourth, it has simultaneous detection capability for multiple target analytes. Fifth, the instrumentation requires low cost microscope modifications for IR excitation and visible emission. Zijlmans et al. have reported application of the phosphor probe for the sensitive detection of antigens in tissue sections or on cell membranes [248]. They conjugated phosphor [green-emitting ytterbium/erbium (Y.Yb.Er) $O_2S$  and a blue-emitting ytterbium/thulium (Y.Yb.Tm) $_2O_2S$ ] particles to NeutrAvidin (Pierce, Rockford, IL) first and then successfully targeted in a model system consisting of prostate-specific antigen in tissue sections and the CD4 membrane antigen on human lymphocytes.

Various fluorescent polymers particles have been reported for bioimaging applications, such as long-lifetime europium chelate complex-doped 107-nm polystyrene particles [249–251], fluorescein isothiocyanate labeled poly(butyl cyanoacrylate) nanoparticles [252], and fluorescent gelatin NPs [253]. Multimodal (fluorescent and paramagnetic) nanoparticles have been prepared where a NIR dye (Cy5.5) and iron oxide nanoparticles were co-doped in dextran particles. These particles were used in constructing quantitative 3D tomographic NIR fluorescence imaging combined with MR imaging to yield highly detailed anatomic and molecular information in living organisms [254].

## 2.7

### Conclusions and Perspectives

Early diagnosis can prevent cancer and possibly cure cancer patients. However, currently available techniques such as CT scan, MRI scan, PET scan, etc. are not sensitive enough to diagnose cancers at the early stage. The challenge is to develop sophisticated *in vivo* imaging techniques that could precisely detect the presence of a

few abnormal cells in the body. Optical-based imaging systems have potential for early cancer diagnosis. To achieve better resolution, a sensitive optical imaging system must be coupled with highly sensitive image-enhancing optical contrast agents. Unlike organic-based dyes, nanoparticle-based contrast agents such as quantum dots, gold nanoparticles, and dye-doped silica nanoparticles have shown great promise for highly sensitive optical imaging of cancers. As described in this chapter, most successful experiments were conducted *in vitro* using various cancer cell lines. So far, few animal experiments have been performed that demonstrate that quantum dots have strong potential for *in vivo* cancer imaging.

The future of nanoparticle-based *in vivo* optical contrast agents and cancer imaging will rely upon many factors.

Firstly, the toxicity of nanoparticles needs to be thoroughly investigated. There are no straightforward answers to the toxicity of quantum dots, gold- and silica-based nanomaterials. Cadmium ions from cadmium sulfide and cadmium selenide-based quantum dots are highly toxic to cells. Although effective surface passivation with zinc sulfide and further coating with polymer, silica, etc. can reduce the release of cadmium ions, the long-term fate of these materials is highly uncertain, especially under *in vivo* conditions. Gold- and silica-based materials are biocompatible substances. However, their long-term *in vivo* behavior in the nanoscale size regime is also uncertain. Again, these particles are not digestible, meaning that if they are not naturally cleared by the body, they will be accumulated somewhere. This might cause additional threats in terms of secondary toxic effect.

Secondly, the size of the particle would play a critical role. It is probably better to work with smaller particles, as they can be easily loaded intra-cellularly. Small particles (<10 nm) may be excreted naturally through the body (via kidney and spleen). Despite these advantages, smaller particles would have some limitations with respect to image resolution. As cancer cells divide rapidly, the concentration of particles in daughter cells will be diluted. As a result, image resolution will be compromised with time.

Thirdly, development of nanoparticles with NIR excitation and emission would be extremely important for deep tissue imaging. Tumors that are present in a deeper tissue area can be imaged using NIR nanoparticles. A few NIR quantum dots have been tested in animal models recently. However, little work has been performed on the development of NIR silica or gold nanoparticles.

Fourthly, nanoparticles with high extinction coefficients, quantum yields and photostability would be highly desirable for sensitive cancer imaging. Quantum dots are likely to be better candidates than gold- and silica-based nanoparticles. Further improvement towards effective surface passivation would be important. The spectral characteristics of gold nanoparticles are highly sensitive to the surface-capping agents and therefore, robust surface capping would be necessary for stable spectral output. As silica is porous, dye-doped silica nanoparticles would experience photobleaching as well as fluorescence quenching to some extent.

Lastly, effective surface modification and bioconjugation for nanoparticle delivery are highly desirable. No matter how robust the nanoparticles are, the ultimate image contrast would also depend on the nanoparticle loading efficiency. The selec-

tion of specific cancer targeting strategies would thus play a crucial role. We envision that this part of the research and development would attract substantial attention in the near future.

Nanoparticle-based optical contrast agents have a bright future in cancer imaging. However, the key is how to make them smart in all the aspects mentioned above for human applications. Although there is no straightforward route to such smart particles, research progress in this area over the last few years has been overwhelming.

## Acknowledgments

We acknowledge the Particle Engineering Research Center (PERC) at the University of Florida for the entire support. Both SS and DD express sincere thanks to Dr. Parvesh Sharma, PERC, for his generous help during the preparation of the manuscript.

### 3.1

#### Introduction

Cancer is the second leading cause of death in the United States. Nearly half of all men and a little over one-third of all women in the United States will develop cancer during their lifetimes. Today, millions of people live with cancer or have had cancer.

The uncontrolled division of cells is termed as cancer. Cancer cells are different from normal cells in that they continue to grow, divide and form new abnormal cells. Cancer cells usually accumulate in an organ to form solid tumors; however, non-tumor forming cancer of the fluid connective tissue, blood, also occurs such as leukemia. Cancer cells can travel to other parts of the body from their primary site of growth and this is called metastasis. Cancer can grow in various sites in the human body such as bladder, breast, colon, kidney (renal cell), lung, skin (melanoma), pancreas, prostate and thyroid [1]. Therapies differ considerably, depending upon the site and stage of tumor formation. Besides conventional treatments such as surgery, chemotherapy and radiation several other alternative approaches have been examined, such as laser therapy, photodynamic therapy, gene therapy, stem cell transplantation and anti-angiogenic therapy [2–5].

Due to the highly heterogeneous nature of the disease, the main challenge to cancer therapists today is to deliver drugs that can be specifically targeted to the different “hallmarks” of cancer growth. Unfortunately, common anticancer as well as new generation of anti-angiogenic or anti-stromal agents have several limitations: they are usually associated with high toxicity; several of them are non-specific and target both normal as well as malignant cells; have poor bioavailability; and last but not least, they have poor half-lives and fast clearance from the body. An ideal therapeutic approach in cancer would be to deliver multi-drugs specifically to the primary tumor, as well as to the site of metastasis and its micro-environment while simultaneously monitoring the prognosis through noninvasive approaches.

Recently, several groups, including ours, have shown that nanoparticles possess enormous potential to improve the efficacy of cancer treatment [6]. Hence, our long-term goal is to develop nanotherapeutics with multifunctional capabilities. This method of drug administration might significantly reduce the dosage of the drugs and this in turn may lead to better specificity, low toxicities, better bioavailability, in a targeted manner with real-time detection by non-invasive imaging. Our recent published and preliminary data support at least part of this hypothesis, as we have shown that when conventional anticancer drugs are loaded with gold-nanoparticles alone or in combination with other drugs such as an anti-angiogenic agent, the efficacy of each drug was intact or even better when tested in respective assays [7–9]. Our goal is to put together all the components to develop “*smart*” drug(s) that will target all the “*hallmarks*” of cancer growth and thereby inhibit tumor progression and metastasis. In this chapter, we emphasize potential targets of the angiogenesis component of the tumor and discuss the current standing with respect to nanotechnology.

### 3.2

#### Medicinal use of Gold: A Historical Perspective

Gold has a long history of use [10, 11]. The therapeutic use of gold can be traced back to the Chinese in 2500 BC. They were the first to prepare and use red colloidal gold as the “drug of longevity.” Red colloidal gold is still in use today in India in the form of Ayurvedic medicine for rejuvenation and revitalization during old age under the name of Swarna Bhasma (“Swarna” meaning gold, “Bhasma” meaning ash) [12]. Mahdihassan has explored the historical use of gold in eastern traditions, especially in India and China [13]. In India cinnabar-gold is known as “Makaradh-waja”. Makaradh-waja means emblem of god of fertility, a drug for vigor of youth [14]. Gold also has a long history of use in the western world as nerving, a substance that could revitalize people suffering from nervous conditions [12]. In the 16<sup>th</sup> century gold was recommended for the treatment of epilepsy [15]. At the beginning of the 19<sup>th</sup> century gold was the drug of choice for the treatment of syphilis [16]. Several books describing the medicinal use of gold came out at the beginning of 19<sup>th</sup> century [17–21].

The discovery by Robert Koch of the bacteriostatic effect of gold cyanide towards the tubercle bacillus marked the beginning of the modern day medicinal use of gold. Following Koch’s discovery, gold therapy for tuberculosis was introduced in the 1920s [22]. The major clinical uses of gold compounds are in the treatment of rheumatic diseases, including psoriasis, juvenile arthritis, palindromic rheumatism and discoid lupus erythematosus [23]. Gold compounds that were mainly used for the treatment of rheumatoid arthritis were gold thiolates (AuSR), where gold is unipositively charged. Sodium aurothiomalate and aurothioglucose are two prime examples of gold thiolates mainly used for rheumatoid arthritis. These drugs are water soluble and administered as deep intramuscular injection. Follow-

ing such injection these drugs get rapidly adsorbed and, at the same time, gold is rapidly cleared from the circulation and distributed to various organs such as kidney, liver, spleen and so on [22]. The adsorption of gold in the kidney causes nephrotoxicity, a major side effect. Other toxic reactions include mouth ulcers, skin reactions, blood disorder and liver toxicity [23–25]. To overcome the poor pharmacokinetics and toxicity, a second-generation gold drug, auranofin, was introduced in 1985 for arthritis [26–29]. The presence of phosphine ligands makes auranofin more lyophilic with better retention in the circulation. The adsorption of gold in the kidney was also reduced, with significant reduction in the nephrotoxicity.

The antitumor activity of cis-platin was discovered in 1969, prompting the discovery of other metal-containing antitumor drugs. Gold has also been included in the search on the basis of three rationales [30–33]: (a) both Pt(II) and Au(III) form analogous square-planar complexes with a  $d^8$  configuration of the central ions, (b) analogy to the immunomodulatory effects of gold(I) antiarthritic agents, and (c) complexation of known antitumor agents with gold(I) and gold(III) to produce compounds with enhanced activity. Auranofin showed activity against HeLa cells *in vitro* and P388 cells *in vivo*. This discovery led to the screening of many phosphine-containing gold drugs, of particular interest are bis(diphos)gold(I) complexes [34, 35]. These complexes showed promising antitumor properties but exhibited cardiovascular toxicity that precluded their use in clinical trials. The mechanism of action of these gold drugs is poorly understood. However, it is thought that, under biological conditions, gold(I) and gold(III) species are reduced to gold(0), which may be the active species. Hardly any report describes the use of gold nanoparticles as anticancer agent. However, recently we have shown, for the first time, the anti-angiogenic property of gold nanoparticles.

### 3.3

#### Application of Gold Nanoparticles in Cancer

The biological application of gold nanoparticles began almost three decades ago in the form of immunogold staining procedure. Since then, gold nanoconjugates have been extensively used to detect cellular components using electron microscopy as an indirect passive component. However, the use of these gold nanoparticles for *in vivo* drug delivery has never been described. This section discusses the application of “naked” gold nanoparticles as well as in the form of their nanoconjugates in the treatment of cancer.

##### 3.3.1

#### Angiogenesis and Cancer

Angiogenesis, the formation of new blood vessels from existing one's, plays an important role in the growth and spread of cancer. New blood vessels “feed” the cancer cells with oxygen and nutrients, allowing these cells to grow, invade nearby

tissue, spread to other parts of the body, and form solid tumors [36]. In the early 1970s Dr. J. Folkman first showed that solid tumors are angiogenic and require vascularization for growth [37, 38]. The central concept that tumor growth is “angiogenesis dependent” is well accepted today, with more than 2500 scientific reports showing angiogenesis linked to tumor growth. Angiogenesis is tightly regulated by a balance between endogenous proangiogenic growth factors like Vascular Endothelial Growth Factor (VEGF), Placental Growth Factor (PLGF), Platelet Derived Growth Factor (PDGF), Tumor Growth Factor-beta (TGF- $\beta$ ) and Angiopoietin-1 (Ang-1) and antiangiogenic factors like thrombospondin-1 (TSP-1), somatostatin, endostatin, angiostatin, interleukins, interferons and tissue inhibitors of matrix metalloproteinases (TIMPs) [39, 40]. In this chapter we briefly discuss angiogenesis in relation to cancer to provide a basis for understanding the fabrication and targets for nanodrug synthesis and use. For a detailed review on angiogenesis and cancer please refer to Refs. [1–44]. The angiogenic response in the microvasculature is associated with changes in cellular adhesive interactions between adjacent endothelial cells (ECs), pericytes, fibroblasts, and immune mediators express many different cytokines and growth factors that react with other cells or extra cellular matrix (ECM) components to affect EC migration, proliferation, tube formation, and vessel stabilization. During tumor growth this balance is disrupted and the scale tips towards the tumor-secreted angiogenic growth factors that interact with their surface receptors expressed on ECs (Fig. 3.1).

Folkman has propounded the idea that inhibiting angiogenesis could inhibit the growth of tumors [41]. Since then considerable effort has been invested in the discovery of agents that block the development of tumor vasculature. Yet only recently have the differences between the vasculature of the normal tissue and the tumor been realized. The tumor vasculature is strikingly tortuous, vessels have poor pericyte cover and numerous shunts, making it often difficult to distinguish between arterioles and venules. Blood flow through the tumor capillaries is sluggish and sometimes stationary, leading to the entire microenvironment, including red blood cells and endothelium, being highly hypoxic [42–44].

Although the idea of targeting and disrupting tumor vasculature as an anti-cancer therapy has been around for sometime, experimental evidence of efficacy was absent until Burrows et al., targeted the toxin ricin to the tumor vasculature in a mouse neuroblastoma model [45]. Since then several different antiangiogenic agents have been developed and used to treat cancer. These include drugs that directly target specific molecules involved in neo-vessel formation, such as antibodies to VEGF, or others that indirectly inhibit endothelial cell function like inhibitors of matrix metalloproteinase (MMP) breakdown [46, 47]. Other strategies include the use of cytotoxic drugs such as thalidomide that appear to have both antiangiogenic as well as tumor cell killing properties; however, the specific mechanism of action of these drugs is not known [48, 49]. Camptothecin analogs, 9-amino-20(*S*)-camptothecin, topotecan, CPT-11, are inhibitors of topoisomerase I and also decrease tumor angiogenesis [50]. Paclitaxel, a microtubule inhibitor, has shown anti-proliferative action in *in vivo* models [51, 52].

**Fig. 3.1.** Schematic diagram showing the role of angiogenesis in tumor growth and blood vessel formation.

#### 3.3.1.1 Agents that Inhibit Endothelial Proliferation or Response

Such targets include endoglin, integrins, dominant negative receptors and agents that prevent the release or activation of FGF. Direct administration of endogenous angiogenic inhibitors such as angiostatin, endostatin, and gene therapy using DNA that encodes for angiogenesis inhibitors, including angiostatin and platelet factor 4, are being evaluated. Administration of synthetic angiogenic inhibitors that specifically prevent endothelial cell division include derivatives of fumagillin, such as TNP-470 [53, 54]; combrestatin phosphate, which induces apoptosis in proliferat-

ing endothelial cells and causes tubulin destabilization [55]; and vitaxin, which is a humanized monoclonal antibody to alpha5-beta3 integrin present on endothelial cell surface, and EMD 121974 a small molecule blocker of alpha5-beta3 integrins [56–58].

### 3.3.1.2 Agents that Block Activation of Angiogenesis

Interferon alpha has demonstrated a 30% response rate in patients with AIDS-related Kaposi sarcoma and has been shown to be active in the treatment of hemangiomas, chronic myeloid leukemia, myeloma, melanoma, lymphoma and renal cell carcinoma [59–61]. SU5416, a small molecule blocker of VEGF-receptor2 signaling, is in Phase II clinical trial for metastatic colorectal cancer, non-small cell lung cancer and von Hippel-Lindau disease [62]. SU6668, a small molecule blocker of VEGF, FGF and PDGF receptor signaling, is in Phase I trial for selected advanced tumors [63]. Humanized monoclonal antibody to VEGF is now in clinical trials for several cancers, including metastatic renal cancer, advanced prostate cancer, non-small cell lung cancer, colorectal cancer and other solid cancers [46].

### 3.3.1.3 Agents that Block Extracellular Matrix Breakdown

Clinical trials have been ongoing for seven MMP inhibitors. Marimastat, a synthetic inhibitor that blocks TNF- $\alpha$  convertase, has shown clinical activity when combined with chemotherapy in colorectal, ovarian, prostate, gastric and pancreatic cancer [64]. Phase I studies with AG3340 in combination with other chemotherapeutic agents have been well tolerated in patients with advanced prostate and other solid tumors [65, 66]. Bay12-9566 and MM1270, synthetic MMP inhibitors, have undergone Phase I trials as single agents in pancreatic, ovarian and colorectal cancers [67, 68].

Although studies with antiangiogenic molecules have been elegant and results encouraging yet these advances should be viewed with cautious optimism as side effects that occur in some patients include hypertension, thrombosis, proteinuria, and even fatal hemorrhage. Therefore, selectivity, delivering drugs to specific targets on the tumor endothelium, has remained an obstacle in the development of better antiangiogenic therapy. Gold nanoparticles provide an avenue for targeted delivery of bioactive molecules to the tumor microenvironment by means of binding molecules such as antibodies that are specific for tumor-associated markers. Recent reports have demonstrated the potential utility of gold nanoparticles that served as a payload for delivery of DNA, proteins and imaging compounds to the tumor.

### 3.3.1.4 Unique Anti-angiogenic Properties of Gold Nanoparticles

Gold nanoparticles have been extensively used in biological applications due to their biocompatibility [69], dimensions (<50 nm), ease of characterization [70, 71] and their rich history of surface chemistry that can be easily exploited to better suit the needs of biomedical applications [72]. VEGFs are mitogenic for vascular endothelial cells [73] and act as potent angiogenic factors and blood vessel permeabilizing agents [73–76] *in vivo*. Four isoforms of VEGF containing 121, 165, 189 and

206 amino acids are produced from a single gene as a result of alternate splicing [76]. The 121 amino acid form of VEGF induces the proliferation of endothelial cells but, in contrast to VEGF 165, lacks the heparin binding ability [77]. Many anti-angiogenic approaches have been developed to block the interaction of VEGFs with their receptors in order to inhibit angiogenesis and tumor growth that include monoclonal antibodies targeting VEGF [78, 79] and the use of soluble decoy receptors blocking the binding of VEGF to its receptors [80]. We have shown, for the first time, that gold nanoparticles bind and inhibit the activity of Vascular Permeability Factor/Vascular Endothelial Growth Factor 165 (VPF/VEGF-165), an endothelial cell (ECs) mitogen and a prime mediator of angiogenesis that plays a tremendous role in pathological neo-vascularization, including rheumatoid arthritis, chronic inflammation and neoplastic disorders.

Gold nanoparticles used in this study were prepared by the reduction of aqueous chloroaurate ions with sodium and characterized using UV/Visible spectroscopy (UV/Vis), because of the presence of characteristic surface plasmon resonance band (Fig. 3.2), and transmission electron microscopy (TEM). The TEM image clearly showed that gold nanoparticles  $\sim 5$  nm in diameter were formed by this method (Fig. 3.3).

#### 3.3.1.5 Gold Nanoparticles Inactivate VEGF165

Whether gold nanoparticles had any effect on VEGF165 was tested on VEGF165-induced HUVEC proliferation. VEGF165 was pre-incubated with various concentrations of gold nanoparticles (67, 335, 670 nM) overnight at 4 °C and then added them to serum-starved HUVECs followed by [ $^3$ H]-thymidine incorporation. Gold nanoparticles inhibited VEGF165-induced proliferation ( $p < 0.0001$ ). However,

Fig. 3.2. UV/Vis spectrum of gold nanoparticles obtained by sodium borohydride reduction of tetrachloroauric acid.

**Fig. 3.3.** Transmission electron micrograph of gold nanoparticles obtained by borohydride reduction of gold salts.

gold nanoparticles did not inhibit non-heparin binding VEGF121-induced proliferation of HUVEC cells. Importantly, the gold nanoparticles were not toxic to HUVECs, where no inhibition in proliferation was observed in the only nano-gold treated samples compared to the control. Numerous examples of surface modifications of gold nanoparticles with alkanethiols aromatic thiols, and primary amines have been reported [81–85]. Such an ionic/pseudo-covalent reaction may explain the interaction between the gold nanoparticles and VEGF165 that led to the inhibition of its activity. However, the inability of gold nanoparticles to inhibit the activity of VEGF121 suggested that the presence of a heparin-binding domain was necessary to be inactivated by gold nanoparticles.

#### 3.3.1.6 What is the Mechanism of Action?

To prove that gold nanoparticles bind to the heparin-binding domain of VEGF165, gold nanoparticles at different concentrations (335, 670 and 1340 nM) were pre-incubated with VEGF165 overnight at 4 °C. VEGF165 was then precipitated from this complex with a saturating concentration of heparin-sepharose. In the absence of gold, all VEGF165 was bound to heparin-sepharose and was detected only in the precipitated fraction while none was detected in the supernatant fraction.

Heparin sepharose binds to the heparin binding domain of a heparin binding protein and precipitates it from the solution. The results of the pre-incubation experiments with heparin sepharose conclusively proved that VEGF165 in the supernatant fraction was in the gold-bound form and thus could not interact with the heparin-sepharose. From these results, it was concluded that gold nanoparticles inhibited VEGF165 from binding to heparin-sepharose because gold itself binds to VEGF165 through the heparin-binding domain. Signaling events of VEGF165 leading to proliferation were initiated by its association with cell surface receptors, mainly KDR, where the heparin-binding domain plays an important role. Pre-

incubation experiments with heparin sepharose clearly proved that blocking the heparin-binding domain of VEGF165 gold nanoparticles inhibited its association with KDR and, thereby, inhibited its activity.

Direct binding of VEGF165 to gold nanoparticles was confirmed by XPS analysis. The presence of a single Au  $4f_{7/2}$  peak at 83.9 eV clearly demonstrated only one form of Au present in solution and that it is Au(0) [86]. The presence of two sulfur peaks, at 162.7 and 167.1 eV, represented two chemically distinct sulfur species. The peak at 162.7 eV was assigned to gold-bound sulfur and that at higher BE was assigned to oxidized sulfur species such as in sulfones. The nitrogen 1s peak at 399.6 eV was likely due to unionized, non-protonated nitrogen [87]. However, the possibility of gold nanoparticles binding to VEGF165 through nitrogen as well could not be ruled out. Hence it was concluded that the direct binding of VEGF165 to gold nanoparticles occurred through sulfur and/or nitrogen, both present in the heparin-binding domain of VEGF165.

We have described earlier that angiogenesis plays a central role in the growth and progression of tumor [69, 70]. This process is also important for the promotion and maintenance of other diseases like neoplasia and rheumatoid arthritis [71]. As there are several reports that indicate that gold salts can retard the progression of rheumatoid arthritis [72], we reasoned that gold nanoparticles might also inhibit angiogenesis. Because VEGF/VPF [73, 74] and bFGF [75] are two critical cytokines for the induction of angiogenesis, we investigated whether nontoxic novel gold nanoparticles [76] being used at present in several biomedical applications can inhibit the functions of these two important proangiogenic growth factors.

#### **3.3.1.7 Effect of Gold Nanoparticles on the Activity of VEGF165, VEGF121, bFGF and EGF**

The effects of gold nanoparticles on the activity of VEGF165, VEGF121, bFGF and EGF were tested on two different cell lines, namely HUVEC (for VEGF165 and VEGF121) and 3T3 (for EGF and bFGF). The gold nanoparticles inhibited VEGF165-induced proliferation of HUVECs- and bFGF-induced proliferation of 3T3 cells but did not inhibit either VEGF121- or EGF-induced proliferation. Gold nanoparticles are not toxic to either cell line as no inhibition in proliferation was observed in the only nanogold treated samples compared with the control. The inhibition of proliferative activity of two heparin binding growth factors, namely VEGF165 and bFGF, by nanogold and its inability to inactivate non-heparin binding growth factors, namely VEGF121 and EGF, clearly suggested that the heparin-binding domain of VEGF165 and bFGF played the crucial role for their interactions with nanogold and, hence, inactivation.

#### **3.3.1.8 Effect of Gold Nanoparticles on Signaling Events of VEGF165**

With the addition of 335–670 nm nanogold, VEGF165-induced phosphorylation of VEGFR-2 was profoundly inhibited. However, at 67 nm nanogold ~40% inhibition of phosphorylation was evident [from densitometry quantitation using NIH Image software,  $p < 0.0001$ ]. Almost complete inhibition of VEGFR-2 phosphory-

lation was observed at concentrations of 335 and 670 nM nanogold. The results of receptor phosphorylation clearly suggested that nanogold binds directly to VEGF165 and inhibited its interaction with cell surface receptors hence inhibiting phosphorylation.

#### 3.3.1.9 Effect of Nanogold on Downstream Signaling events of VEGF165

To further support the hypothesis that nanogold binds to VEGF165 and inactivates its signaling capability, an intracellular calcium release experiment in HUVECs was performed. A gold concentration of 67 nM gave ~34% inhibition (determined by comparing the length of the upstroke of VEGF165 induced sample to the nanogold-treated samples) and complete inhibition was observed at 335–670 nM ( $p < 0.05$ ). The VEGF receptors on the HUVECs were still functional as evidenced by an increase in calcium release comparable to the control when VEGF was added after 300 s. These observations also clearly demonstrated that gold nanoparticles bind directly to VEGF165 and inhibited its signaling events but did not perturb the receptor functions.

#### 3.3.1.10 Effect of Gold Nanoparticles on Migration of HUVEC Cells

Nanogold inhibited VEGF165-induced migration of HUVECs. Rho A activity was also completely inhibited at 670 nM nanogold, further confirming the hypothesis that nanogold binds directly with the heparin binding growth factor through the heparin binding domain and inhibits its signaling activity.

#### 3.3.1.11 Effect of Gold Nanoparticles on Angiogenesis *in vivo*

The efficacy of nanogold in inhibiting VEGF165-induced permeability and angiogenesis *in vivo* was tested in a nude mouse ear model. Ad-VEGF injected mice treated with nanogold developed lesser edema than mice treated with Ad-VEGF only. As shown, 30 min after injection of Evan's blue dye into the tail vein of these treated mice, a decrease in permeability was also observed. In the MOT model, less fluid accumulation in the peritoneal cavity was observed in nanogold treated samples than in controls.

Taken together, our results showed that gold nanoparticles selectively inhibited VEGF165- and bFGF-induced proliferation of HUVECs and fibroblasts, respectively. In a similar fashion, nanogold also inhibited the activity of placental growth factor (PIGF) (unpublished results). Gold nanoparticles directly bind heparin-binding growth factors, presumably through cysteine residues of the heparin-binding domain, and inhibit growth factor mediated signaling. Gold binds strongly with thiols and amines [85–87]. Such an ionic/pseudo-covalent reaction may explain the interaction between the gold nanoparticles and VEGF that led to a decrease in its proliferative activity. Gold nanoparticles also inhibit VEGF-induced angiogenesis and permeability *in vivo* as well as causing lesser ascites fluid accumulation in a MOT model where VEGF/VPF activity is primarily responsible for fluid accumulation in the peritoneal cavity. Here, we mention, briefly, the toxicity of nanogold. Because metal poisoning is associated with renal and hepatic toxicities, we determined the effect of nanogold administration on liver and renal func-

tion tests. Normal mice were injected with same dose of nanogold as in MOT model intraperitoneally for 7 consecutive days. On day 8, the mice were sacrificed and serum was collected. There were no significant differences between serum levels of creatinine, blood urea nitrogen, bilirubin alkaline phosphatase, ALT (Alanine Aminotransferase) and AST (Aspartate Aminotransferase) between the nanogold treated and untreated control animals. This finding is significant because growth factor-mediated proliferation and angiogenesis have a central role in many pathological conditions, including neoplasia, rheumatoid arthritis and chronic inflammation. The low production cost and relative ease in modifying nanogold make them a feasible choice in future biomedical applications.

#### 3.3.1.12 Gold Radioisotopes in Cancer Treatment

Radioisotopes of gold have also long been used for the treatment of different types of cancer. A cumulative survival of 96.3% was achieved in the treatment of stage Ia ovarian cancer with radiogold [88]. In addition, Ehrlich ascites tumor has been prevented by intraperitoneal injection of colloidal  $^{198}\text{Au}$  [89]. In the treatment of limited epithelial carcinoma of the ovary, 104 patients received intraperitoneal radiocolloid [90]. Fifty six of these patients also received external beam radiation therapy to the pelvis. Five year actuarial no-evidence-of-disease survival rates were 95% for stage Iai, 82% for stage Iaii, 73% for stage Ib, 67% for Ic, 67% for Iia, 67% for Iib without gross residual tumor (GRT) and so on. Radioactive gold has also been used to prevent hepatic metastasis by intravenous administration [91]. Recently, gold nanoparticles have been used to increase radiotherapy in mice [92]. Mice bearing subcutaneous EMT-6 mammary carcinomas received a single intravenous injection of 1.9-nm gold particles (up to 2.7 g-Au per kg body weight). The gold content of the tumor elevated by this treatment to 7 mg-Au per g in tumor. The mice were then subjected to 250 kVp X-ray therapy for several minutes. The one-year survival rate was found to be 86% versus 20% with X-rays alone and 0% with gold alone.

### 3.3.2

#### Application of Gold Conjugates in the Treatment of Cancer

The biological application of gold nanoparticles began in 1971 when Faulk and Taylor invented the immunogold staining procedure [93]. Since then gold nanoconjugates have been extensively used to detect cellular components using electron microscopy. Mostly gold nanoconjugates were seen as passive components, used only to visualize different cellular components. However, the use of these gold nanoparticles for *in vivo* drug delivery has never been described. Recently, gold nanoconjugates have been used as more active components that can interfere with the biological activities [94–98].

#### 3.3.2.1 Gold–TNF Conjugate in Cancer Therapeutics

Recently, colloidal gold, a sol composed of nanoparticles of  $\text{Au}^0$ , has been used as a therapeutic for the treatment of cancer as well as an indicator for immunodiagnos-

tics. However, the use of these gold nanoparticles for *in vivo* drug delivery has not been described. The development of a colloidal gold (cAu) nanoparticle vector that targets the delivery of tumor necrosis factor (TNF) to a solid tumor growing in mice has been reported [99]. The optimal vector, designated PT-cAu-TNF, consists of molecules of thiol-derivatized PEG (PT) and recombinant human TNF that are directly bound onto the surface of the gold nanoparticles. Following intravenous administration, PT-cAu-TNF rapidly accumulates in MC-38 colon carcinoma tumors and shows little to no accumulation in the livers, spleens (i.e., the RES) or other healthy organs of the animals. Tumor accumulation was evidenced by a marked change in color of the tumor as it acquired the bright red/purple of the colloidal gold sol and was coincident with the active and tumor-specific sequestration of TNF. Finally, PT-cAu-TNF was less toxic and more effective in reducing tumor burden than native TNF since maximal antitumor responses were achieved at lower doses of drug.

### 3.3.2.2 “2 in 1” System in Cancer Therapeutics

Recently, our group has reported the fabrication of a “2 in 1” system containing functional anti-angiogenic agent and cytotoxic drug. Angiogenesis, the formation of new blood vessels from a pre-existing vessel, is a necessary step for tumor growth and metastasis [99–102]. This provides the basis for anti-angiogenic therapy – depriving tumor cells the nutrients essential for their growth by blocking their blood supply. Although this treatment may restrict tumor growth, anti-angiogenic therapy alone might not be enough to prevent tumor growth and cause increased cell killing. Therefore, to achieve maximal therapeutic benefit it is necessary to use anti-angiogenic agents in combination with other modalities such as anticancer drugs [103]. One of the problems in the use of anticancer drugs is that they have short half-lives, sometimes with extensive systemic toxicity [104]. When delivered in a gold-conjugated form, these molecules might have increased retention in the body with reduced systemic toxicity. VEGF-antibody attached on gold nanoparticles may facilitate delivery of the drugs to the site of tumor, as many tumors are known to produce VEGF [105, 106]. We hypothesize that use of a cytotoxic agent such as gemcitabine along with VEGF antibody will not only allow tumor cell killing but also give rise to more “normalized” blood vessels, resulting in better drug delivery [107]. This study employed a nano-composite system consisting of a nanogold core, bearing a functional anti-angiogenic molecule, VEGF antibody-2C3 (AbVF), and an anticancer drug, gemcitabine. This provides a unique “2 in 1” system where two components with different functions have been attached onto a single gold core, yet the functional activity of the individual components are retained.

To attach multiple components onto a single gold core, it is essential to determine the saturation concentration of the individual components [108]. The saturation concentration of AbVF was determined after incubating it with gold nanoparticles with increasing concentrations of AbVF for 30 min followed by treatment with 100  $\mu$ L of 10% NaCl solution to test for aggregation [109]. Gemcitabine was similarly attached to nanogold. Without any protection, gold nanoparticles aggre-

gate immediately upon addition of a 10% NaCl solution. The extent of aggregation, however, should decrease with increasing protection of the nanogold surface either by antibody or by gemcitabine. Increased stabilization of nanogold dispersions was observed with increasing concentrations of AbVF. In the absence of antibody but in the presence of NaCl, gold nanoparticles completely aggregated and, as expected, their absorbance dropped to zero [109]. Next, the saturation concentration of gemcitabine on gold nanoparticles was determined, similarly as above. Gold nanoparticles were incubated with different concentrations of gemcitabine for 30 min and their UV/Vis spectra were recorded. Absorbance of nanogold gradually increased with increasing concentrations of gemcitabine until it reached a maximum at  $20 \mu\text{g mL}^{-1}$ . According to the Mie theory, the observed shift in  $Y_{\text{max}}$  with an increase in plasmon resonance coincides with a rising dielectric constant of the medium surrounding the gold nanoparticles [110]. At doses higher than  $20 \mu\text{g mL}^{-1}$ , the absorbance of the nanocomposite gradually decreased, alongside a gradual increase in redshift in  $Y_{\text{max}}$ . This relationship, along with a broadening of the spectra, may be attributed to the aggregation of gold nanoparticles upon the addition of gemcitabine beyond the  $20 \mu\text{g mL}^{-1}$  limit. To attach both gemcitabine and AbVF on nanogold surface, incubation experiments were carried out below the 50% saturation concentration for AbVF and gemcitabine. Gold nanoparticles were first incubated for 30 min at room temperature with  $10 \mu\text{g mL}^{-1}$  of gemcitabine followed by another 30 min incubation with  $2 \mu\text{g mL}^{-1}$  of VEGF antibody. Aggregation tests were performed to confirm the attachment of both the components.

The functional activities of gemcitabine and AbVF were tested by *in vitro* cell culture assays. The activity of gemcitabine was tested on 786-O cells using a BrdU proliferation assay. The observed activity of gemcitabine combined with AbVF on nanogold surfaces was comparable to gemcitabine alone at the same concentration. In the control experiments with gold or AbVF alone or gold-AbVF, no inhibition 786-O proliferation was observed. Therefore, the inhibition in proliferation was due to the presence of gemcitabine within the nanocomposite and the presence of AbVF on the same nanocomposite did not exert any negative influence on the activity of gemcitabine.

The functional activity of AbVF was determined on VEGF165 induced calcium release in HUVEC cells. HUVECs release calcium into the cytoplasm when induced with VEGF165 [6]. AbVF attached to nanogold surfaces with gemcitabine inhibited calcium release more efficiently than the same dose of AbVF alone. At  $10 \text{ ng mL}^{-1}$ , almost no inhibition of VEGF165-induced calcium release was observed in the samples of AbVF alone but a moderate inhibition and delay was observed with AbVF in the nanocomposite form. At  $20 \text{ ng mL}^{-1}$ , moderate inhibition was observed in samples with only AbVF but complete inhibition of calcium release was observed for the nanocomposite. This suggested an optimal threshold concentration requirement for VEGF to be able to induce calcium release. To further confirm that the inhibition in calcium release was due to AbVF, the nanogold surface was blocked with gemcitabine and control mouse IgG. VEGF165-induced calcium release was not inhibited by this nanocomposite. From

the calcium release assay, it was concluded that AbVF retained its functional activity in the AbVF–gold–gemcitabine nanocomposite form and gemcitabine did not had no negative influence on the activity of VEGF antibody.

This study was a unique example of a “2 in 1” system where anti-angiogenic molecule, VEGF antibody and cytotoxic drug (gemcitabine) were attached on the same nanogold surface, with potential implication in cancer therapeutics.

### 3.4

#### **Biocompatibility of Gold Nanoparticles**

The biocompatibility of nanoparticles in general is discussed in detail elsewhere [110–114]. Here, recent efforts addressing the issue related to gold nanoparticles will be discussed briefly. The issue of biocompatibility arises when any foreign body is introduced inside the human body for medical purposes or otherwise [111–114]. In most general terms biocompatibility can be defined as “the ability of a material to perform with an appropriate host response in a specific application” or “the exploitation by materials of the proteins and cells of the body to meet a specific performance goal”. Interactions between the foreign body and the host can be classified in four general categories (a) cellular adhesion effects, (b) local biological effects, (c) systemic and remote effects, and (d) effects of the host on the implant.

#### 3.4.1

##### **Cellular Adhesion Effects**

The interaction of the foreign body, direct or indirect, weak or strong, specific or non-specific, receptor mediated or non-mediated with the host may influence the biocompatibility of the foreign body.

#### 3.4.2

##### **Local Biological Effects**

Local biological effects include cell viability, cell mitotic function such as proliferation, cell cycle phases, etc., plasma membrane integrity, toxicity and modification or normal wound healing.

#### 3.4.3

##### **Systemic and Remote Effects**

Systemic and remote effects include systemic toxicity (such as kidney failure, liver failure, etc.), elevation of unusual components in the blood, allergic, pyrogenic, carcinogenic and teratogenic responses.

## 3.4.4

**Effects of the Host on the Implant**

This mainly includes immune responses, such as inflammation, fibrosis, etc., around the implant, physical and mechanical effects, stability and biological degradation processes.

## 3.4.5

**Addressing the Biocompatibility of Gold Nanoparticles using DNA Microarray Analysis**

Nanotechnology is a rapidly evolving multidisciplinary branch of science involving systems and/or device manufacturing at the nano-scale level [115, 116]. Nanoparticle-aided strategies have been implemented to address a diverse array of issues, including drug delivery, targeting and monitoring of molecules/cells/tissues, and development of novel drug regimens [117–119]. A modified variety of nanoparticles, known as quantum dots, which are highly fluorescent semiconductor particles measuring roughly the size of an average protein, have been developed and shown to be valuable for monitoring metastatic tumor cells in an animal model [120]. These fluorescent quantum dots are reported to be active for over a month inside the body, allowing one to monitor migration and localization of the probe over a long period of time [121, 122].

Conceptually, nanoparticles can have effects, both desired and unintended, on an organism through acting directly and/or indirectly on individual cells. Since all investigations employing nanotechnology were performed related to specific questions, efforts to assess potential global effects remain virtually unanswered. However, some recent reports involving nanotechnology have generated widespread concerns regarding the effect of nanoparticles on the ecosystem and ultimately to human health [123–125]. Several recently published papers showed the toxicological effects of carbon nanotubes [126, 127]. It is, however, not known if all nanoparticles have similar biological effects; it is also not known if the same nanoparticle will have the same effect on different organisms. In fact, the overall consensus among scientists working on various aspects of nanoparticles is that very little is known about the potential impacts of nanoparticles on health and environment. Evidently, a thorough evaluation of the underlying issues needs to be systematically performed to distinguish reality from mere extrapolation of inadequate data. Metallic gold is known to be biocompatible; however, facts regarding the biocompatibility of gold nanoparticles are rare. Recently efforts have been made to address the biocompatibility issue of gold nanoparticles. Significant damage to the cell membrane was observed by cationically modified gold nanoparticles and they were shown to be moderately toxic, whereas anionic particles were quite non-toxic. A series of gold nanoparticles with various surface modifications were tested recently for uptake and acute toxicity in human leukemia cell lines. The authors concluded that although some precursor of nanoparticles might cause toxicity, the nanoparticles themselves are not toxic, further strengthening our findings [128]. The

effects observed in those cases may be due to the presence of the surface modifier and not because of the gold nanoparticles. To find out the effect of bare gold nanoparticles, our laboratory has focused on the genotropic effects of gold nanoparticles on normal human cell lines. We hypothesize that the overall physiology of a cell is equivalent to its global transcriptional profile. Consequently, we speculate that the expression signature of a cell in the presence or in absence of a given nanoparticle can generate valuable information regarding the potential effect of a nanoparticle on the target cell. However, a given nanoparticle can, possibly, interact with cellular components directly and elicit an effect or interact with non-cellular components first, which, in turn, may produce an effect on the target cell (an indirect effect). These so-called “direct” and “indirect” effects, if any, will need to be distinguished to ascertain the full spectrum of effects of nanoparticles on target cells (or on non-target cells). We have previously shown that gold nanoparticles effectively blocked the effect of vascular endothelial growth factor (VEGF)-mediated signaling by HUVECs (Human Umbilical Vein Endothelial Cells) and also inhibited angiogenesis *in vivo* in a mouse ovarian tumor model [10]. We have evaluated the potential direct effect of gold “naked” nanoparticles on HUVECs.

#### 3.4.6

##### **Internalization of Gold Nanoparticles by HUVECs**

To discern the effect of any nanoparticles on any cell lines, it is important to know the location of the nanoparticles, whether most of them are outside or inside the cells, and to find out if the nanoparticles change size upon internalization. To address the localization of gold nanoparticles, transmission electron microscopy was performed after incubating HUVECs with gold nanoparticles for 1 and 24 h under serum-free conditions and in the presence of serum. TEM clearly demonstrated the internalization of gold nanoparticles at both time points under such conditions, and no significant difference on the distribution of the gold nanoparticles was observed (Fig. 3.4). The size of gold nanoparticles did not alter significantly upon internalization. The distribution of gold nanoparticles under serum-free conditions and in the presence of serum was similar. No significant difference in the distribution of gold nanoparticles at 1 and 24 h was observed, confirming that 1 h incubation was enough for gold nanoparticles to be taken up HUVECs.

#### 3.4.7

##### **Nanogold Particles do not Alter Global Pattern of Transcription by HUVEC Cells under Serum-free Conditions**

Since serum contains a host of heparin-binding domain containing proteins, including growth factors, with which nanogold can potentially interact and block their functions [9], which, in turn, can have an (indirect) effect on cells in culture, it was necessary to exclude serum (FBS) in an attempt to evaluate a direct effect of gold nanoparticles on HUVECs. Therefore, cells were first cultured in serum-containing media until they were about 80% confluent, after which the cells were

**Fig. 3.4.** Internalization of gold nanoparticles by HUVECs, (a) internalization under serum-free conditions after 4 h incubation; (b) and (c) higher magnification images of (a). (d) Internalization of gold nanoparticles in the presence of serum after 4 h incubation; (e) and (f) higher magnification images of (d).

washed repeatedly with PBS to get rid of serum. The cells were then incubated in serum-free media for 24 h, after which gold nanoparticles were added and the culture continued for 1 and 24 h, respectively. Total RNA extracted from such cells was subjected to microarray analysis. The expression level of genes determined through microarray was subjected to Scatter plot analysis. The results indicated a strikingly similar pattern of gene expression at both 1 and 24 h by cells cultured with or without nanogold particles. The correlation coefficients were 0.98 for 1 h and 0.97 for 24 h, respectively. These observations strongly attest to the similarities

of gene expression, indicating that 5-nm gold nanoparticles have no effect on gene expression by HUVECs. It is possible that a small number of genes truly undergoing differential expression in the presence of gold nanoparticles were missed by the Scatter plot analysis. To eliminate this possibility, the microarray-based expression results were manually checked and seven genes were selected to show expression difference of at least 1.5 fold and having expression values of >300 either for control or for cells treated with gold. RT-PCR was performed for all these genes to validate their mRNA expression status in cells cultured with and without gold nanoparticles. The results showed no significant difference in the mRNA expression levels of any of the seven genes, supporting the observation made through Scatter plot analysis.

#### 3.4.8

#### **Nanogold Particles do not Alter the Global Pattern of Transcription by HUVECs in Near-normal Culture Conditions**

The lack of an effect of gold nanoparticles on HUVECs as observed under serum-free conditions could be due to the possibility that cells exposed to serum-free media preclude any potential effect of the gold nanoparticles on cell transcription. To eliminate this possibility, the first step was omitted completely (culturing cells in serum-free media for 24 h before adding gold particles) and confined incubation of cells with gold for up to 4 h. Briefly, cells were first grown in the presence of serum to near confluency, then repeatedly washed with serum-free media, nanogold particles were then added followed by incubation in serum-free media for 1 and 4 h.

RNA isolated from cells at indicated times (1 and 4 h after exposure to gold particles) was subjected to microarray analysis as above. Scatter plot analysis of the data showed no effect of gold particles on the global transcriptional pattern of HUVECs even when the cells were not exposed to serum-free conditions for a long time. Correlation coefficients obtained from these experiments were 0.995 for 1 h and 0.994 for the 4 h, further supporting this observation. The data was also manually scanned to identify cases of differentially expressed genes not evident in the Scatter plot analysis. Nine genes were identified based on the criteria mentioned earlier. RT-PCR was performed for these genes to validate their mRNA expression level in cells cultured with and without nanogold for 1 and 4 h. The RT-PCR results did not suggest any difference in the mRNA expression levels of these genes in HUVECs not exposed to serum-free conditions prior to adding nanogold in the culture, supporting the results from Scatter plot analysis. Thus, all of the experiments suggested a lack of a direct effect of gold nanoparticles on the transcriptional program of HUVECs.

Conceptually, any agent, physical, chemical or biological, can have an effect on a cell/organism; the magnitude of the effect, however, will depend on a diverse array of known and unknown parameters. Whether such an effect can be measured by

standard means depends on the resolution and sensitivity of a given method. We have previously shown changes in the level of gene expression due to the effect of sound waves on cultured cells [128, 129]. Thus, measurement of gene expression can document subtle intracellular changes caused by the extracellular environment of a cell. DNA-microarray has rapidly become a useful tool for measuring gene expression at the global level – this is, probably, because the resolution of the microarray can be very high (the one used in this study contains probes for virtually all known and predicted human genes) and the sensitivity is within an acceptable range.

However, with such a tool, we did not observe any effect (positive or negative) of gold nanoparticles on the global transcriptional pattern of HUVEC cells. Some genes selected by manual screening of the microarray data appeared to be differentially expressed between HUVEC cells cultured with and without gold nanoparticles. However, repeated RT-PCR failed to document differential expression for any of these genes. Thus, both RT-PCR and microarray-based results strongly suggest a lack of effect of gold nanoparticles on mRNA expression.

Recently, we have demonstrated that nanogold particles can not only bind to VEGF but also can inhibit VEGF-dependent HUVEC proliferation and ascites fluid accumulation in a mouse ovarian tumor model, illustrating a unique mechanism of deactivation of heparin binding growth factors by gold nanoparticles on a complex biological process [7]. Note that VEGF has cysteine residues on its heparin-binding domain, which can easily become conjugated with gold nanoparticles through covalent interaction, causing sequestration and/or inactivation of the growth factor [8]. Since, the experiments reported herein were not VEGF-dependent, no such indirect effect of nanogold should be expected (in agreement with our previous reports where we did not see any toxic effects of gold nanoparticles on HUVEC). The results presented in this study enabled some important inferences. First, although the results could not rule out subtle effects of 5-nm gold nanoparticles or effects beyond the time points investigated under conditions tested, 5-nm naked gold nanoparticles with no surface modifications may indeed have no direct effect on human cells. Second, gold nanoparticles of smaller size were expected to be more “active” than particles of larger size; however, it would be interesting to see if nanoparticles of different sizes with no surface modification have any significant direct effect on biological processes. Finally, since 5 nm nanoparticles appeared to have no effect (toxic or non-toxic) on HUVECs, such particles may be ideal to realize at least some of the promises of nanotechnology, assuming a similar effect of such particles on other types of cells. Notably, the potential genotropic effects of gold nanoparticles have been evaluated in this study; however, such particles may also exert non-genotropic effects (such as membrane protein cycling) on target cells. Such a possibility will need to be addressed to evaluate comprehensively the direct effect of nanoparticles on cell metabolism. We believe our approach provides a general experimental strategy for screening a diverse array of nanoparticles for their potential global effects on any type of target cells/tissues under diverse experimental conditions.

## 3.5

### Synthetic Approaches to Gold Nanoparticles

Even though this chapter focuses on the application of nanogold in cancer therapy and diagnosis, it would be incomplete without a description of the synthesis of gold nanoparticles, since the synthesis procedure may effect the properties of the gold nanoparticles and, hence, their application in the treatment of cancer. Here we describe briefly the general synthesis process for the preparation of gold nanoparticles. There are basically two synthetic methods: chemical and physical.

#### 3.5.1

##### Chemical Methods

In 1857, Faraday first reported the synthesis of gold nanoparticles by reduction of chloroaurate ions by phosphorous in carbon disulfide [130]. Among all the methods that are applied for the reduction of  $\text{HAuCl}_4$  to gold nanoparticles, the citrate reduction and borohydride reduction methods are most commonly used. The citrate reduction method, first introduced by Turkevitch in 1951, yields AuNPs approximately 20 nm in diameter [131]. Recently, it was shown that the size of AuNPs formed by the citrate reduction method can be controlled by the use of a stabilizer along with the reducing agent and by manipulating the ratio of gold salts to reducing agent/stabilizer [132].

In 1994, Brust and Schiffrin introduced a novel method for the synthesis of thiol-capped gold nanoparticles using sodium borohydride as a reducing agent [133]. Nanoparticles so-formed are thermally stable, air stable, with reduced dispersity and a size ranging from 1.5 to 5 nm. Spontaneous reduction of gold salts to gold nanoparticles by an inorganic matrix such as fumed silica has also been reported [134, 135]. These matrices not only reduce the gold salts to gold nanoparticles but also provide them with a solid support. Such conjugates exhibit interesting catalytic properties.

#### 3.5.2

##### Physical Methods

The most common physical methods for the synthesis of gold nanoparticles include UV, irradiation, NIR irradiation, sonochemical method, radiolysis and thermolysis. UV irradiation can improve the quality of the gold nanoparticles formed when it is used in the presence of micelles or seeds [136–139]. Near-IR irradiation produces a large size growth of thiol-stabilized gold nanoparticles [140]. The rate of  $\text{AuCl}_4^-$  reduction in aqueous solution as well as sizes of gold nanoparticles formed can be controlled by using an ultrasonic field of 200 kHz [141, 142]. Radiolysis has also been used to control the sizes of gold nanoparticles or when they are synthesized in the presence of radicals [143, 144]. Gold nanoparticles have also been produced by the thermolysis of gold salts [144, 145].

## 3.5.3

**Biological Methods**

Biological methods for the synthesis of nanoparticles have been reported recently. Some living microorganisms, such as fungus, can reduce metal salts to metal nanoparticles. Both extracellular and intracellular synthesis of metal nanoparticles have been reported using fungus [146, 147]. Cadmium sulfide nanoparticles has also been synthesized [148].

## 3.6

**Nanotechnology in Detection and Diagnosis with Gold Nanoparticles**

Nanotechnology [149] combined with biology is the most advanced technology both from an academic viewpoint and for commercial applications. The integration of nanotechnology with biology and medicine is expected to produce major advances in molecular diagnostics, therapeutics, molecular biology, and bioengineering [150–158]. Optical [159] and magnetic [160] properties of metals, semiconductors, polymers and magnetic nanoparticles, and quantum dots (small devices that contain free electrons and have typical dimensions between nanometers to micrometers – these tiny crystals glow when stimulated by ultraviolet light, e.g., ZnS, ZnSe, CdSe, CdTe, PbSe, etc.) are being used for DNA detection, cancer diagnostics, drug discovery and clinical therapy in biomedical research [121, 154, 161–179].

Among inorganic nanoparticles and quantum dots, colloidal gold nanoparticles have attracted significant research and practical attention in biology. Due to fascinating colors, size-dependent properties and dimensional similarities to biomacromolecule, these colloidal gold nanoparticles are widely used in biomedical research such as DNA detection [150, 177(b), 180], highly sensitive diagnostics [177(a), 181], thermal ablation and radiotherapy enhancement [182], as well as drug and gene delivery [183]. For instance, antibody-modified gold nanoparticles, when used for detection of prostate specific antigen, had an almost one million-fold higher sensitivity than a conventional ELISA-based assay [164]. Near-infrared radiation absorbing gold–silica nanoshells have been prepared and evaluated for thermal ablation of tumors after systemic administration [92, 182].

## 3.6.1

**Cancer Detection**

Sayed et al. have reported that binding gold nanoparticles to a specific antibody for cancer cells could make cancer detection much easier using a simple microscope [177(a)]. Their technique for detection of cancer cells is very simple, clean, faster, economically very cheap and eco-friendly/non-toxic.

They proposed that the very good scattering and light absorption properties of gold nanoparticles could be used to easily distinguish healthy from cancerous

cells with the help of a very simple microscope. Many cancer cells have a protein, known as Epidermal Growth Factor Receptor (EGFR), all over their surface, while healthy cells typically do not express the protein as strongly. By conjugating, or binding, the gold nanoparticles to an antibody for EGFR, suitably named anti-EGFR, they were able to get the nanoparticles to attach themselves to the cancer cells. When they added the conjugated nanoparticle solution to healthy cells and cancerous cells, they observed with a simple microscope that the whole cancer cell shines. In contrast, healthy cells did not bind to the nanoparticles specifically and, consequently, they did not shine.

In this promising technique, they found that the gold nanoparticles have a 600% greater affinity for cancer cells than for noncancerous cells. The gold nanoparticles that worked the best were 35 nm in size. Researchers tested their technique using cell cultures of two different types of oral cancer and one nonmalignant cell line. The shape of the strong absorption spectrum of the gold nanoparticles is also found to distinguish between cancer cells and noncancerous cells.

### 3.6.2

#### **Detection in DNA**

Several studies suggest that nanoparticle-based technology could enable sensitive detection of sequence variation in DNA [180]. Early studies demonstrated array-based DNA discrimination by allele-specific oligonucleotide hybridization using gold nanoparticle reporters containing bound oligonucleotides for hybridization to complementary targets [180(a)]. Detection was achieved by silver enhancement, resulting in deposition of silver on the surface of the nanoparticles, which enabled scanometric detection to define the location of the gold nanoparticles on an array [180(b)]. Attachment of a dye close to the surface of the nanoparticles via linkage to the oligonucleotide also enabled detection after silver enhancement by surface-enhanced Raman spectroscopy (SERS) [180(c)].

##### **3.6.2.1 Single-mismatch Detection in DNA**

Maxwell et al. have demonstrated the design and feasibility of bio-conjugated gold nanoparticles for recognizing and detecting specific DNA sequences in a single step [150]. According to their method, colloidal gold nanocrystals 2.5 nm in size have been used to develop a new class of nanobiosensors that can recognize and detect specific DNA sequences and single-base mutations in a homogeneous format. The 2.5-nm gold nanoparticles function as both a nano-scaffold and a nano-quencher (efficient energy receptor).

They proposed that single-stranded DNA is conformationally flexible. Conversely, two oligonucleotide molecules (oligos) are self-assembled in a constrained conformation (arch-like structure) on each gold particle (2.5 nm in diameter) A T6 spacer (six thymines) is inserted at both the 3' and 5' ends to reduce steric hindrance. In the assembled (closed) state, the fluorophore is quenched by the nanoparticle because of the stable arch-like structure. Upon target binding, the constrained conformation opens, the fluorophore leaves the surface because of the

structural rigidity of the hybridized DNA (double stranded), and fluorescence is restored. In the open state, the fluorophore is separated from the particle surface by about 10 nm.

In this novel method gold nanoparticles represent a new class of universal fluorescence quenchers that are substantially different from DABCYL (4,4'-dimethylaminophenylazobenzoic acid) and should find new applications in molecular engineering and biosensor development and homogeneous bioassays that are not possible by DABCYL.

In another method, Dubertret et al. have shown that gold-quenched nucleic acid probes (gold-oligonucleotide-dye) can be more sensitive than other probes currently available for mismatch detection. With their developed probes a point mutation can be selectively detected in the presence of random sequences even if only 1 out of 50 sequences has one mutation. They have developed a hybrid material composed of a 25-nucleotide long single-stranded DNA (ssDNA) molecule, a 1.4 nm diameter gold nanoparticle, and a fluorophore (an organic dye) that is highly quenched by nanoparticle through a distance-dependent process. This hybrid material can form the hairpin structure that brings the fluorophore and the gold particle in close proximity (within a few angstroms). In this conformation, the gold cluster quenches the fluorescence of the dye. Through sequence-specific hybridization to a single-stranded target DNA, the hairpin structure changes to a rod-like structure (on the right), which maintains the fluorophore and the quencher far apart and thus restores the fluorescence. They reported that 1.4-nm diameter gold nanoparticles are better than a conventional fluorescence quencher, such as DABCYL, because gold nanoparticles quench fluorescence as much as 100× better and have higher quenching efficiency than dyes emitting in the near-infrared region.

As well the above examples of the use of gold nanoparticles in cancer and DNA detection, numerous recent reports relate the biological applications of gold nanoparticles in imaging and in therapy [8, 184–193]. A few are described here very briefly.

Chen et al. have demonstrated a novel nanoshell-based all-optical platform technology for integrating cancer imaging and therapy applications [184]. Immunotargeted nanoshells are engineered to both scatter light in the NIR enabling optical molecular cancer imaging, and to absorb light, allowing selective destruction of targeted carcinoma cells through photothermal therapy. They have shown that dual imaging/therapy immunotargeted nanoshells can be used to detect and destroy breast carcinoma cells that overexpress HER2, a clinically relevant cancer biomarker.

Bioconjugated with antibodies, gold nanocages (<40 nm) have also been used for specific targeting of breast cancer cells [185]. These gold nanocages have a moderate scattering cross-section of  $\sim 8.10 \text{ \AA} \sim 10\text{--}16 \text{ m}^2$  but a very large absorption cross-section of  $\sim 7.26 \text{ \AA} \sim 10\text{--}15 \text{ m}^2$ , suggesting their potential use as a new class of contrast agents for optical imaging.

Surface-enhanced Raman scattering (SERS) studies have been reported on indocyanine green (ICG) on colloidal silver and gold nanoparticles, demonstrating a

novel optical probe for applications in living cells [186]. The ICG gold nanoprobe delivers spatially localized chemical information from its biological environment by employing SERS in the local optical fields of the gold nanoparticles.

Applications of nanostructures including gold nanoparticles in biodiagnostics have been thoroughly reviewed recently [187]. Prostate-specific antigen (PSA) is a valuable biomarker for prostate cancer screening. Huang et al. have developed a PSA immunoassay on a commercially available surface plasmon resonance biosensor [188]. They have developed a sandwich assay with gold nanoparticles for a major enhancement in sensitivity of PSA detection. The assay enables the detection of total PSA levels at clinically relevant concentrations. Gold nanoparticles can be used as an amplifying payload strategy for adenoviral cancer gene therapy [189]. Colloidal gold nanoparticles can be used as a versatile platform for developing tumor targeted cancer therapies [8, 190–192].

On the basis of theoretical and experimental results, a new dynamic mode – the bubbles-overlapping mode (BOM) – has been reported for the selective killing of cancer cells to whose cell membrane nanoparticles conjugated with specific antibodies have been attached [192].

### 3.7

#### Future Direction

Nanotechnology can be used in cancer detection and diagnosis. To improve cancer treatment, detection of cancer at an early stage is a very critical step. Presently, detection and diagnosis of cancer usually depend on molecular changes in cells and tissues that are detected by a doctor's physical examination or imaging expertise. Nanotechnology is uniquely promising as an early detection tool for cancer treatment for several reasons:

To successfully detect cancer at its earliest stages, scientists must be able to detect molecular changes even when they occur only in a small percentage of cells. This means the necessary tools must be extremely sensitive. The potential for nanostructures to enter and analyze single cells suggests they could meet this need.

Many nanotechnology tools will make it possible for clinicians to run tests without physically altering the cells or tissue they take from a patient. This is important because the samples clinicians use to screen for cancer are often in limited supply. Scientists would like to perform tests without altering cells, so they can be used again if further tests are needed.

Other technologies will focus on improved methods of reading the genetic code on single strands of DNA to detect errors that may contribute to cancer. Scientists believe nanopores, tiny holes that allow DNA to pass through one strand at a time, will make DNA sequencing more efficient. As DNA passes through a nanopore, scientists can monitor the shape and electrical properties of each base on the strand. Because these properties are unique for each of the four bases that make up the genetic code, scientists can use the passage of DNA through a nanopore to

decipher the encoded information, including errors in the code known to be associated with cancer.

To detect cancer, scientists can design beads containing quantum dots to bind to sequences of DNA that are associated with cancer. When the quantum dots are stimulated with light, they will emit their unique barcodes, or labels, making the critical, cancer-associated DNA sequences visible. The vast number of possible combinations of quantum dots means that scientists can create many unique labels, which can be used at the same time. This will allow scientists to look simultaneously at numerous regions of DNA. This will be important in the detection of cancer, which results from many different changes within a cell.

These technologies are in various stages of discovery and development. Experts believe that quantum dots, nanopores and other devices for detection and diagnosis may be available for clinical use in 5–15 years. Therapeutic agents are expected to be available within a similar time frame. Devices that integrate detection and therapy could be used clinically in about 15 or 20 years.

### Acknowledgments

This work was partly supported by NIH CA-78383 and HL-70567 and also by a grant from the American Cancer Society to DM. The authors are grateful to D. Lecy for her help in revising the manuscript.

# Nanoparticles for Magnetic Resonance Imaging of Tumors

*Tillmann Cyrus, Shelton D. Caruthers, Samuel A. Wickline, and Gregory M. Lanza*

### 4.1

#### Introduction

Molecular imaging with nanoparticulate agents represents a novel tool that will allow the detection of tumors and metastases in early stages that evade conventional imaging technologies. Several of these nanoparticulate agents are also undergoing development to deliver drugs locally, thus increasing therapeutic effects at the tumor site while minimizing systemic adverse effects that are often limitations of conventional chemotherapy. The combination of molecular imaging and local delivery of therapeutic agents is unique to nanoparticulate agents and regarding tumor detection and treatment will likely change the current medical paradigm of “see and treat” to a “detect and prevent” strategy. An overview of this technology is given here, focusing on particles that are available for non-invasive magnetic resonance imaging (MRI). Principle targeting mechanisms are described, followed by superparamagnetic nanoparticles, which create negative or dark contrast effects on MRI, and paramagnetic nanoparticles, which produce positive or bright contrast effects. Superparamagnetic nanoparticles all contain magnetic elements, mostly iron oxides, and are sub-classified according to molecular modifications and size. Paramagnetic nanoparticles differ substantially and thus are presented according to their principal groups, such as liposomes, perfluorocarbon nanoparticles, fullerenes, and others. Finally, hybrid technologies using quantum dots are presented, which allow non-invasive imaging with MRI and intraoperative direct visualization. As these technologies are rapidly evolving, particular emphasis is given to the most current developments.

### 4.2

#### Magnetic Resonance Imaging (MRI)

Originally developed as a noninvasive method using a magnetic field and radio waves to generate detailed images of the inside of the human body, MRI is based

on the principles of nuclear magnetic resonance (NMR). Atoms consist of protons, electrons, and often neutrons. All of these particles possess a spin. Depending on its composition, some nuclei have a net spin that, when placed in an external magnetic field ( $\mathbf{B}_0$ ), aligns with the external magnetic field, somewhat like a magnet with a north and south pole would. For a hydrogen nucleus, for example, there are two possible energy states: the lower energy configuration is parallel to the external magnetic field (e.g., N-S-N-S), and the higher energy state is anti-parallel (e.g., N-N-S-S). For a given nuclei, the energy of separation between spin states depends on the magnitude of  $\mathbf{B}_0$ . The parallel state is slightly favored, on the order of a few parts per million, and is described by Boltzmann statistics (as a function of the energy of separation and temperature). Thus, for about every one million nuclei, there is one extra aligned with the  $\mathbf{B}_0$  field resulting in a net magnetization pointing in the direction of the main magnetic field; these spinning nuclei do not perfectly align with  $\mathbf{B}_0$  but rather precess about it at their resonance frequency, also called the Larmor Frequency, which is defined as the product of the gyromagnetic ratio ( $\gamma$ ) of the nucleus and the external magnetic field. Typically, these individual “spins” are thought of collectively as a net magnetic vector, aligned with  $\mathbf{B}_0$ . Individual particles can undergo a transition from the lower to the higher energy state by absorbing a photon, and vice versa by emitting one. In MRI, the required frequency for this photon is in the radiofrequency (RF) range at the resonance or Larmor frequency, which is the product of the gyromagnetic ratio and  $\mathbf{B}_0$ . When exposed to RF energy at this frequency the nuclei change spin states and, when thought of *en masse*, can be represented by a net magnetic vector, which “rotates” away from the longitudinal axis, but returns to alignment once the external RF transmission is ceased. The rate of this return to equilibrium (known as longitudinal or spin–lattice relaxation) is exponential and can be described by the time constant T1. When the net magnetic vector is aligned with  $\mathbf{B}_0$ , an MR signal cannot be measured. But with the net magnetic vector “tipped” out of alignment, the component of the magnetization vector in the transverse plane ( $\mathbf{M}_{xy}$ ) can be measured as an MR signal (using an external RF antenna such as a coil of wire tuned to the correct resonance frequency). Since the individual spins comprising the net vector experience slightly different magnetic milieus, the spins have slightly different precessional frequencies and, thus, the magnitude of  $\mathbf{M}_{xy}$  (transverse magnetization) decays over time (independently of longitudinal relaxation). This signal decay is also exponential, with time constant T2. The detected signal, created by exciting the spins out of longitudinal alignment with  $\mathbf{B}_0$ , is the source for MR image generation is based on the absorption and emission of energy in the radiofrequency range of the electromagnetic spectrum. Hence, the signal in MRI results from the difference between the energy absorbed by the spins that make a transition from the lower energy state to the higher energy state and the energy emitted by the spins that simultaneously make a transition from the higher energy state to the lower one.

Although highly sensitive, NMR can only be performed on isotopes whose natural and biological abundance is high enough to be detected. The hydrogen in water

is an ideal atom in this respect. Its nucleus contains a single proton and has a large magnetic moment. Of the three hydrogen isotopes, the natural abundance of  $^1\text{H}$  is 99.985%. The  $^1\text{H}$  nuclei in water have an MR signal, and the human body consists primarily of water. While bones only contain about 22% water, muscle is 75% and blood up to 83% water, explaining the advantage of MR in imaging soft tissues including tumors. To generate an image, the MRI machine applies an RF pulse ( $\mathbf{B}_1$ ) at the specific resonance frequency of hydrogen. This excitation pulse is localized toward the area of the body that is of interest by simultaneously superimposing a secondary magnetic field, which is a function of position (i.e., gradient magnetic field). This gradient magnetic field causes the resonance frequency of hydrogen nuclei to vary as a function of position within the MRI magnet; thus, a finite “slice” of interest can be excited to give MR signal since the nuclei can absorb energy (to change spin state) only at their resonance frequency. As described earlier, once this RF excitation pulse is turned off, the  $^1\text{H}$  nuclei begin to return to equilibrium with  $\mathbf{B}_0$ . But while some transverse magnetization remains, the signal that will ultimately be reconstructed into the MR image can be detected. This signal is already localized upon excitation, via “slice selection,” in one dimension. The remaining two dimensions are encoded by quickly switching on and off other gradient magnetic fields before (phase encoding) and during (frequency encoding) the readout of the generated signal. By repeating this process multiple times, data is collected until the signal is completely spatially encoded and the final image can be reconstructed.

The signal intensity for each location in the image (volume element, or voxel) is dependent on multiple things, including the number of  $^1\text{H}$  nuclei present (proton density), and the T1 and T2 of the tissue present. T1 relaxation is characterized by the longitudinal return of the net magnetization to its ground state in the direction of the main magnetic field. It also depends on the main magnetic field strength, i.e., higher magnetic fields are generally associated with longer T1. T2 relaxation occurs when spins in the high and low energy state exchange energy but do not lose it to the surrounding area. Thus, transverse magnetization is lost. In pure water, T1 and T2 are approximately the same, but in biological tissues T2 is considerably shorter. These differences are exploited in conjunction with imaging sequence timing parameters to obtain either T1- or T2-weighted images.

Similarly to other imaging technologies, MR imaging benefits from the usage of contrast agents. Conventional MR contrast agents work by altering the local magnetic field and relaxation parameters in the tissue being examined. Superparamagnetic iron oxide particles, for instance, generate image contrast by shortening the MR relaxation times with a predominant effect on apparent T2 relaxivity, which leaves dark contrast effects (i.e., signal voids; Fig. 4.1). Paramagnetic particles such as gadolinium chelates, however, produce bright contrast in T1-weighted MR images (Fig. 4.2). The advent of nanoparticulate contrast agents afforded a dramatic improvement in imaging. These agents, which are described in this chapter, can passively or actively target epitopes within the body, enhance imaging, and, in some cases, even deliver drugs locally.

**Fig. 4.1.** T2-weighted MRI. (A) Conventional MRI and (B) MRI obtained 24 h after the administration of lymphotropic superparamagnetic nanoparticles. The accumulation of the iron-containing

superparamagnetic nanoparticles leads to a homogeneous decrease in signal intensity in a lymph node in the left iliac region (arrow). (Reproduced with permission from Ref. [27].)

### 4.3 Targeting Mechanisms

#### 4.3.1

#### Passive versus Active Targeting

Nanoparticulate agents concentrate within a site by passive and/or active targeting mechanisms (Fig. 4.3). Passive targeting refers to the accumulation within or the extravasation through a tumor neovasculature distinguished by a dismorphic, fenestrated architecture [1]. Vascular endothelial and basic fibroblast growth factors produced by tumors accelerate angiogenic sprouting with endothelial pores between 200 and 780 nm in diameter that entrap or permit extravasation of macro-

**Fig. 4.2.** T1-weighted MRI. (A) Conventional MRI and (B) MRI obtained 30 min after the administration of perfluorocarbon nanoparticles. C32 tumor in an athymic nude

mouse (arrow in A). Signal enhancement of angiogenic vasculature as detected by  $\alpha_v\beta_3$ -targeted paramagnetic nanoparticles (B).

**Fig. 4.3.** Schematic illustration of passive and active targeting with nanoparticles. (A) Passive targeting, via the enhanced permeability and retention (EPR) effect due to pathological endothelialization of angiogenic vessels in tumors, allowing the leakage of very small nanoparticles into the subendothelium and into the space between tumor cells. (B) Active targeting with very small ligand-targeted nanoparticles. These particles bind respective epitopes on tumor cells. (C) Active targeting with ligand targeted nanoparticles with nominal diameters  $> 150$  nm.

molecules and nanoparticles [2, 3], dependent on size. In many tumors, ineffective lymphatic drainage further contributes to the passive, local retention of nanoparticles [4]. This combination enhances the permeability and retention (EPR) effect [4, 5]. In some situations phagocytic cells, naturally responsible for particle clearance, ingest the agent while migrating into the tumors core.

Particles are removed from the circulation in a size-dependent hierarchy by the lung (largest), spleen, liver, and bone marrow (smallest). Opsonization (i.e., biological tagging) with blood proteins such as immunoglobulins, complement proteins, or non-immune serum factors can enhance macrophage recognition, phagocytosis, and further accelerate circulatory clearance. While complement fixation promotes liver sequestration, the presence of antibody Fc receptors favors splenic removal.

Active targeting encompasses ligand-directed, site-specific accumulation of nanoparticulate agents. Antibodies, peptides, polysaccharides, aptamers, and drugs, may be utilized to home nanoparticles specifically to cellular biomarkers. These ligands may be attached covalently (i.e., chemical conjugation) or non-covalently (e.g., avidin–biotin interactions) to the contrast agent. Further surface chemistry modifications, such as incorporation of surface poly(ethylene glycol) or crosslinking of surfactants, are employed to delay rapid systemic destruction or clearance of the agents. Homing-ligands increase contrast signal and therapeutic uptake in target organs beyond the concentrations achieved with passive approaches – benefits usually achieved with active ingredient dosages orders of magnitude less than what would be given in the clinic today.

#### 4.4

#### Superparamagnetic Nanoparticles

Superparamagnetic iron oxide nanoparticles generate contrast by shortening the MR relaxation times with a predominant effect on T2 relaxivity leaving dark or negative contrast effects (Fig. 4.1). These particles are categorized, based upon nominal diameter, into superparamagnetic iron oxides (SPIO, 50 to 500 nm) and ultra-small superparamagnetic iron oxides (USPIO, <50 nm). The variation in size results in different physicochemical and pharmacokinetic properties. SPIO nanoparticles with maghemite or magnetite cores have to be coated with molecules such as dextran, phospholipids, or poly(amino acids) to prevent aggregation. These particles passively localize to normal liver and spleen parenchyma, causing a loss of signal on MR images [6–12]. In contrast, pathological changes in the liver, such as benign tumors, primary hepatic carcinoma, or metastases, have decreased reticuloendothelial system (RES) function, thus avoiding absorption of SPIO particles and retaining their intrinsic signal intensity on MR images. The resulting MR images depict decreased MR signal intensity of the normal liver and spleen tissues and enhanced contrast of focal disease areas. Modifying SPIOs to allow targeting of asialoglycoprotein receptors on hepatocytes can further enhance absorption by native liver cells. These nanoparticles are coated with asialofetuin [13] or galactose [14, 15].

A water-dispersible oleic acid (OA)-pluronic-coated iron oxide magnetic nanoparticle formulation, which can be loaded with high doses of hydrophobic anticancer agents like doxorubicin, has recently been developed [16]. The formulation increased the average particle diameter of the iron oxide particles from 9.3 to 193 nm, but had no effect on the magnetic properties of the core. These nanoparticles demonstrated sustained intracellular drug retention and dose-dependent antiproliferative effect over a period of two weeks *in vitro*.

Ultrasmall particles of iron oxide (USPIOs) with a mean diameter of 10 to 50  $\mu\text{m}$  are cleared slower by the RES than SPIOs, thus increasing their intravascular half-life [17]. Moreover, their small size allows them to migrate through interendothelial junctions and capillary pores or fissures [18, 19] to potentially accumu-

late in the vascular wall. Such USPIOs are phagocytosed by macrophages in atherosclerotic plaque of WHHL rabbits in quantities sufficient to be detected by MRI [20], and have been shown to detect atherosclerotic plaque *in vivo* [21]. Extravasation of USPIOs has been imaged by MRI in the setting of capillary damage associated with infections [22] and inflammation [23], human ischemic stroke [23], angiogenesis associated with atherosclerosis [21], and neovascularity induced by solid tumors [24–26].

#### 4.4.1

#### Ligand-directed Targeting of Iron Oxides

Monocrystalline iron oxide nanoparticles (MION) have been developed to address the limitations of passive tissue accumulation and phagocytosis by macrophages and the RES system. These particles have an average core diameter of 3 nm and can be directly coupled to homing ligands to specifically target epitopes in the tissue of interest. An early clinical trial was based on MION without such ligands at the time [27]. Starting in 1999, patients with prostate cancer were selected to receive MION, delivering 2.6 mg kg<sup>-1</sup> body weight. The investigators were able to demonstrate non-invasive detection by MRI of clinically occult lymph node metastases.

Dextran-coated MION coupled to human holo-transferrin (Tf-MION) have been used to visualize transgene expression in a gliosarcoma mouse model *in vivo* [28]. In these experiments, the cellular uptake of MION was increased approximately 500% relative to control cells following overexpression of engineered transferrin receptor. In other experiments MION have been used to indirectly assess angiogenesis through estimates of blood volume distribution in brain tumors [29]. The targeting efficiency of iron oxide particles was further improved with the development of dextran crosslinked iron oxide (CLIO) particles [30]. These have since been used with various ligands, including e-selectin [31], a peptide sequence from the transactivator protein (Tat) of HIV-1 [32–35], and annexin V [36].

Another example of targeted iron oxide nanoparticles are SPIO coupled to humanized biotinylated monoclonal antibody (Herceptin) that was targeted to the human Her-2/neu (c-erb B-2) tyrosine kinase receptor expressed by human breast cancer cell lines [37]. This formulation yielded contrast proportional to the expression level of Her-2/neu receptors. Other investigators have employed polyacrylamide to encapsulate 10–15 crystals of iron oxide within the particle matrix, for blood pool imaging of gliomas [38]. Future applications of these nanoparticles may include direct targeting of ligands.

The combination of superparamagnetic and non-superparamagnetic nanoparticle technologies such as near-infrared fluorescent (NIRF) probes, which can be targeted to different proteases in tissues [39, 40], has also been employed. Upon phagocytosis by macrophages, detection is facilitated by light scattering with charge-coupled device (CCD) cameras [41] or fluorescence-mediated tomography (FMT) [42, 43]. CLIO-NIRF nanoprobe have been used to coincidentally localize axillary and brachial lymph nodes by MRI and NIRF imaging following intravenous

injection into C57BL/6 mice [44]. The utilization of CLIO-NIRF for non-invasive preoperative and subsequently intraoperative localization of brain tumors has also been established. In experiments with a Fisher 344 gliosarcoma model with stably green fluorescence protein expressing 9L glioma cells, non-invasive brain tumor localization of the superparamagnetic particles with MRI was followed later by intraoperative direct visualization of the fluorescent activity [45]. In conjunction with T2-weighted imaging, magnetite particles can be used to augment targeting through external field placement and create vibratory release of drug at localized sites [46]. One early agent pursuing this development path targets luteinizing hormone releasing hormone (LHRH) overexpressing breast cancer cells and releases a lytic peptide load when the particles fracture in response to magnetic field changes [47].

#### 4.4.2

#### Cell Tracking of Iron Oxides

Magnetic labeling of individual cells prior to reaching their target location allows advantage to be taken of the strong effects of iron oxide on T2 relaxation while increasing spatial resolution due to diminished background disturbance. The concept of cellular tracking became feasible once augmentation of cytoplasmic endocytosis of iron oxide particles was accomplished. An early example of this technology resulted from the exploitation of cell surface proteins, such as the transferrin receptor [48]. In these experiments, dextran-coated MION were incubated with CG-4 rat central nervous system glial precursor cells *in vitro* and then the cells were grafted into the spinal cord of rats. The migration, implantation, and remyelination process was imaged non-invasively by MR and corroborated by histology 10–14 days after transplantation. Subsequently, MION coated with various transfection agents have been used to nonspecifically label human mesenchymal stem cells, mouse lymphocytes, rat oligodendrocyte progenitor cells, and human cervical carcinoma cells [49]. Non-invasive tracking of human mesenchymal and neuronal stem cells has also been reported for iron oxide nanoparticles encapsulated within cationic dendrimers [50]. CD8+ T-cells have been labeled with CLIO derivatized with monoclonal antibodies in a mouse melanoma model [51], and stem cell homing to bone marrow has been tracked after labeling with CLIO coupled with HIV-Tat peptides. Particle uptake has been increased over 100-fold using such specific targeting conjugates [33, 52].

#### 4.5

#### Paramagnetic Nanoparticles

Paramagnetic nanoparticles produce “bright” contrast in T1-weighted MR images (Fig. 4.2). This allows subtle anatomical features to be discerned near the contrast agent. Nanoparticles can carry large paramagnetic payloads on the surface to provide adequate signal for noninvasive MR imaging at clinically relevant field

**Fig. 4.4.** Schematic illustration of a perfluorocarbon nanoparticle. Imaging agents such as gadolinium, targeting ligands, and drugs are covalently bound into the phospholipid monolayer. Phospholipids and drugs

within the nanoparticle surfactant exchange with lipids of the target membrane through a convection process after successful targeting. (Nominal particle diameter is 250 nm.)

strengths. Linking these nanoparticles with ligands to specific epitopes facilitates active targeting. Perfluorocarbon emulsions, dendrimers, fullerenes, and liposomes are the most prevalent paramagnetic nanoparticle technologies currently in various stages of development for clinical applications.

#### 4.5.1

##### Perfluorocarbon Nanoparticles

The large lipid surface area of perfluorocarbon (PFC) nanoparticles can be functionalized with magnetic labels for imaging, with homing ligands for specific tissue targeting, and with hydrophobic drugs for local delivery of treatment (Fig. 4.4). Due to the nominal size of the PFC nanoparticles (250 nm diameter), their utility is geared toward vascular-accessible targets, such as thrombosis, atherosclerosis, restenosis, and other angiogenic-dependent diseases, such as most tumors. Access beyond the circulation is sterically precluded, which prevents the unintended targeting of other cell types expressing the same biomarkers. Each nanoparticle can be coupled to several diverse ligands to afford polyvalent binding, which can amplify the signal from either microscopic pathology, where epitope concentrations are low, or where biologic temporal variation requires multiple bio-signature recognition for robustness. Binding to multiple ligands also enhances binding avidity and improves targeting, which also reduces the particle dissociation rate from the biomarker and provides more persistent MR contrast for convenient imaging in a clinical setting.

PFC nanoparticle emulsion technology offers the particular advantage of multimodal imaging. The inherent acoustic contrast of PFC nanoparticles allows detection of these emulsions when targeted and bound *in vivo* or *in vitro* due to the

markedly decreased speed of sound of the PFC core versus the surrounding water-like media [53, 54]. The high  $^{19}\text{F}$  concentrations of the perfluorocarbon provide a unique signal, which can be used for both imaging and spectroscopy. In addition, the integration of fluorine imaging with proton imaging provides an independent validation of the targeted contrast, quantitative assessment of biomarker concentration, and dosimetry of local therapeutic delivery.

For MRI imaging, each bound paramagnetic nanoparticle delivers 50 000 to 90 000+ gadolinium ions [55, 56]. These can be detected with low-resolution scans in routine clinical practice. The relaxivity of paramagnetic nanoparticles allows the calculation of “ionic relaxivity” with respect to absolute Gd concentration, and the determination of “molecular relaxivity” referring to the collective relaxivity of the entire paramagnetic nanoparticle. For applications with a 1.5 T scanner, perfluorocarbon nanoparticles have an ionic relaxivity of  $\sim 30 \text{ mM}^{-1} \text{ s}^{-1}$  and a molecular relaxivity of greater than  $2 \times 10^6 \text{ mM}^{-1} \text{ s}^{-1}$ , which is many fold greater than the ionic and molecular relaxivity of Gd-DTPA alone ( $\sim 5 \text{ mM}^{-1} \text{ s}^{-1}$ ) [57]. Due to this extraordinarily high relaxivity a voxel with as few as 100 pm of nanoparticles can be detected conspicuously with a contrast-to-noise ratio (CNR) of 5 [58]. Consequently, even single layers of cells can be imaged [59].

Various molecular epitopes, including high-density epitopes such as fibrin in thrombi and very sparse biomarkers such as integrins in neovascular beds have been targeted with perfluorocarbon nanoparticles. In angiogenic states,  $\alpha_v\beta_3$ -integrin is expressed on the luminal surface of activated endothelial cells and smooth muscle cells but not on mature quiescent cells. Nanoparticles targeted to  $\alpha_v\beta_3$ -integrin sensitively detect angiogenic endothelium at 1.5 T in New Zealand White rabbits bearing 12d Vx-2 tumors ( $<1.0 \text{ cm}$ ) [60]. In these experiments, the expression of  $\alpha_v\beta_3$ -integrin was obtained with MRI molecular imaging and paralleled by immuno-histochemical staining, which revealed an asymmetric distribution along the border of the tumor capsule where the popliteal fossa mass abutted the muscle border. The MRI signal from tumor vasculature was enhanced by 126% within 2 h of injection of  $\alpha_v\beta_3$ -integrin-targeted nanoparticles. Additional *in vivo* competition-blockade studies diminished targeted signal enhancement by more than 50%, which supports specificity of the  $\alpha_v\beta_3$ -targeted paramagnetic agent. In different experiments,  $\alpha_v\beta_3$ -integrin-targeted nanoparticles were administered systemically into athymic mice implanted with human melanoma xenografts (C-32, ATCC). The MR signal enhancement from the targeted angiogenic vasculature was apparent in 0.5 h and became progressively more prominent through the next 2 h (177%). Here too, *in vivo* competition studies and immuno-histology corroborated the specific localization of  $\alpha_v\beta_3$ -targeted nanoparticles (Fig. 4.5).

Recent studies have demonstrated the unique drug delivery capability of these agents to locally deliver antiangiogenic therapy through a process we term “contact facilitated drug delivery”. Atherosclerotic rabbits were treated with  $\alpha_v\beta_3$ -targeted paramagnetic nanoparticles including 0 or 0.2 mol% fumagillin. MRI signal enhancement averaged over all imaged slices from the renal artery to the diaphragm at 2-h post injection provided quantitative assessments of neovascular proliferation within the aortic wall. MR baseline aortic wall signal enhancement produced

**Fig. 4.5.** (A) Full slice baseline T<sub>1</sub>-weighted MR image (axial view) of an athymic nude mouse. (B) Full slice T<sub>1</sub>-weighted MR image (axial view) of athymic nude mouse 1 h after injection of targeted PFC nanoparticle. (C) Enlarged section of MR image (B). T<sub>1</sub>-weighted signal enhancement of angiogenic vasculature of early tumor at 1 h as detected by  $\alpha_v\beta_3$ -targeted paramagnetic nanoparticles (arrow). [Reproduced with permission from G. M. Lanza et al. *J. Nucl. Cardiol.* 11(6) (2004) 733–743.]

by  $\alpha_v\beta_3$ -targeted paramagnetic nanoparticles was heterogeneously distributed throughout the great vessel and averaged  $16.7 \pm 1.1\%$  and  $16.7 \pm 1.6\%$  in animals receiving fumagillin or control nanoparticles, respectively. Reassessment 7 days later of residual aortic angiogenic activity with  $\alpha_v\beta_3$ -targeted paramagnetic nanoparticles (no drug) revealed that MR signal enhancement in rabbits given  $\alpha_v\beta_3$ -targeted fumagillin nanoparticles was markedly reduced ( $2.9 \pm 1.6\%$ ;  $p < 0.05$ ), whereas the aortic wall enhancement from the control animals was unchanged ( $18.1 \pm 2.1\%$ ). The combination of MR molecular imaging with drug delivery permits local therapeutic concentrations to be estimated, i.e., rational drug dosing, by quantitative MR <sup>19</sup>F spectroscopy [58, 59]. Hence, targeted paramagnetic nanoparticles can serve as a platform to diagnose, treat, and monitor therapy.

#### 4.5.2

##### Liposomes

Liposomes were first described in 1963 following the demonstration that phospholipids in water form closed bilayer vesicles with an aqueous core [61, 62]. The size of these liposomes can reach  $>700$  nm, dependent on the size of the core components and the number of bilayers. Hydrophilic payloads may be stored in the inner aqueous core, hydrophobic ones can be embedded in the phospholipid bilayer and small proteins may be carried on the outer surface. The clinical potential of liposome technology was previously hampered by the short circulation half-lives secondary to rapid phagocytosis by macrophages of the reticuloendothelial

systems. However, the adoption of surface PEGylation and phospholipid crosslinking has helped to reduce the rapid *in vivo* destruction and clearance of liposomes [63–65].

Numerous studies have investigated various liposome formulations in their potential to target and treat cancer in animal models (reviewed in Ref. [66]). Using catheter-based techniques, liposome formulations were shown to deliver genes *in vivo* [67, 68] and, more recently, taking advantage of developments in molecular biology, liposome-mediated drug and gene transfer has been demonstrated for lipid prodrug liposomes [69], and small interfering RNA (siRNA) cationic liposomes [70, 71]. Several studies in humans have led to the approval of liposomal formulations based on doxorubicin, (Doxil™, ALZA Corporation, Tibotec Therapeutics, NJ) for treatment ovarian cancer and AIDS-related Kaposi's sarcoma, and daunorubicin (DaunoXome®, Gilead Sciences Ltd., UK) for the treatment of advanced Kaposi's sarcoma. Many more applications are being investigated in phase II trials [72, 73]. Generally, these liposomal agents accumulate in tumor tissues via passive targeting using the EPR effect. In the treatment of brain tumor models, direct injection and convection-enhanced delivery (CED) to overcome the blood–brain barrier have been employed [74, 75]. Because many cancer cells overexpress certain receptors compared with healthy tissues, avenues of active targeting with liposomes that have been fused with agonists to these receptors have been explored. For instance, liposomes have been fused with low-density lipoprotein (LDL) particles, thereby enhancing uptake into cancer cells, which frequently overexpress these receptors [76], and haloperidol-associated stealth liposomes have been used successfully to deliver genes to breast cancer cells [77].

MRI facilitated *in vivo* monitoring of a liposomal doxorubicin formulation utilizing MnSO<sub>4</sub> as the paramagnetic metal was recently investigated in a murine flank tumor model. This novel thermal-sensitive liposomal formulation took advantage of the relaxivity of Mn, which is similar to Gd. Visualization was possible within minutes following IV liposomal infusion as the temperature-sensitive particles entered the heated tumor, ruptured, and released MnSO<sub>4</sub> locally [78].

Rabbit adenocarcinoma neovasculature has been imaged with a newly developed  $\alpha_v\beta_3$ -targeted paramagnetic UV polymerized liposome. In these experiments, adequate tumor contrast was appreciated 24 h after injection [79], reflecting both the prolonged circulatory persistence of the nanovesicles and the time required to extravasate adequately into the tumor. After incorporation of cationic phospholipids into the polymerized bilayer, delivery of a mutant Raf gene to the neovasculature of M21-L melanoma was accomplished in athymic WEHI mice [80]. ATPmu-Raf, the mutant antisense gene, resulted in apoptosis of the tumor-associated endothelium and ultimately induced tumor regression.

#### 4.5.3

##### Fullerenes

Fullerenes, also referred to as buckyballs due to their characteristic geodesic structure, have unique physical, electrochemical, and photochemical properties [81]. These unique geodesic structures can be formulated to encapsulate gadolinium

atoms for imaging with MRI and have been functionalized for usage as receptor agonists and antagonists, free radical scavengers, and bactericidal agents [82]. Prolonged circulation, up to 48 h, has been demonstrated following intravenous injection for water-soluble gadolinium endohedral metallofullerenes [83, 84]. Recently, fullerene formulations have been developed that can influence proton relaxivities by manipulation of the pH [85]. A remaining challenge is the homing of paramagnetic buckyballs to important biochemical epitopes for molecular imaging at clinically relevant field strengths [86] as well as elucidation of their interaction with blood constituents, biodistribution, metabolism, and safety.

#### 4.5.4

##### **Nanotubes**

Ultrashort single-walled carbon nanotubes (20–100 nm), which are linear superparamagnetic “molecular magnets”, have been loaded with gadolinium ions for possible usage as MRI contrast agents. The relaxivities ( $\sim 170 \text{ mm}^{-1} \text{ s}^{-1}$ ) of these nanotubes are greater than for other gadolinium-based contrast agents currently in clinical use [87]. Studies are ongoing regarding the ideal length for biomedical applications, biocompatibility, and exploitation of the tube exterior to anchor targeting ligands and/or drugs.

#### 4.5.5

##### **Dendrimers**

Dendrimers are hyperbranched, structurally well-defined polymers. They are based upon polyamines, polyamides, or polyaryl-ether subunits, and have varying core structures such as carbohydrate or calixarene [88]. Paramagnetic polyamidoamine (PAMAM) and diaminobutane (DAB) dendrimers have been developed for MRI applications. Several spherically branched molecules [89] have been evaluated in several animal models to detect intratumoral vasculature [90] and lymph vessels [91–93] with high-resolution MRI on clinical 1.5 T MRI scanners. Blood pool imaging has been accomplished with conjugated dendrimers [94, 95]. However, conjugation with antibodies for targeting has tended to unfavorably alter their pharmacokinetics [96]. Recently, improved kinetics have been obtained with small molecule, e.g., folate, based targeting applications [97, 98]. Future formulations need to address the question of toxicity, which can be high, especially for dendrimers with cationic surface groups and amino-terminated dendrimers [99, 100]. The most promise for medical applications has been shown for anionic PAMAM dendrimers and hydroxy- and methoxy-terminated dendrimers [101–103].

## 4.6

### **Quantum Dots**

Semiconductor nanocrystals, also known as quantum dots, absorb light over a very broad spectral range, depending on the particle composition and size (typically 2–8 nm in diameter). This allows for the excitation of a broad spectrum of colors using

a single excitation laser wavelength [104]. When conjugated to targeting proteins such as transferrin or antibodies, these nanocrystals can bind to surface receptors on cells [105], be incorporated by cells [106], and even nuclear localization has been demonstrated [104]. Thus, their use for *in vitro* diagnostic applications has been extended to include *in vivo* small animal imaging applications. Recently, *in vivo* cancer targeting has been demonstrated in a mouse model growing human prostate cancer [107]. In these experiments, antibodies against prostate-specific membrane antigen were conjugated to nanocrystals, allowing for active targeting. Currently, linking quantum dots to therapeutic, e.g., anticancer, agents is being investigated for applicability. Unlike other nanoparticles, which can carry targeting ligands and therapeutic agents, semiconductor nanocrystals, due to their small size, will likely have to be conjugated to other nanoparticles to achieve specific targeting, while allowing for real-time imaging and drug delivery. The first such multimodality probes have recently been developed by integrating quantum dots with superparamagnetic nanoparticles [108, 109].

The main concerns with quantum dot technology, however, are biocompatibility, biodistribution, metabolism and biosafety. Nanocrystals can contain elements such as cadmium and indium and various techniques have been employed to make these particles more water-soluble and safer. One method is to modify the particles by growing a silica layer onto the surface of the quantum dots [110] or coating the dots with amphiphilic polymers [111, 112]. Another avenue of protecting the non-biocompatible elements of the quantum dots involves conjugation with targeting molecules [111, 112]. While polymer-encapsulated nanocrystals may be biocompatible for immediate imaging, the issue of toxicity during breakdown and elimination of these particles from the body requires further study.

## 4.7

### Polymer Nanoparticles

Nanoparticles formulated from poly(hydroxy acids) such as the copolymer of poly(lactic acid) (PLA) and poly(D,L-lactide-co-glycolide) (PLGA) have been investigated for localized drug and gene delivery [113, 114]. These particles are biodegradable, like absorbable suture materials, and result in a similar inflammatory response during degradation [115]. Drugs can be encapsulated into the nanoparticles during the emulsification process and are later released during the decay of the nanoparticle. Depending on size, the entire nanoparticle can be incorporated into cells through phagocytosis. Degradation kinetics, and thus drug release, can be adjusted by changing copolymer composition and molecular weights [116]. In recent experiments, transferrin targeted nanoparticles containing doxorubicin afforded prolonged survival in a murine prostate cancer model [117]. The particle size averaged 220 nm and the treatment was given as a single direct intratumoral injection into the subcutaneously grown prostate cancer in athymic nude mice. Sustained release of drug was observed, as compared with the paclitaxel Cremophor® EL formulation, and complete regression of tumor was observed with the higher nanoparticle associated paclitaxel dosage (24 mg kg<sup>-1</sup>) compared

with (in order of decreasing survival) lower dosage (12 mg kg<sup>-1</sup>), non-transferrin targeted paclitaxel nanoparticles, paclitaxel Cremophor® EL, or Cremophor® EL alone and control nanoparticles. These researchers took advantage of the over-expression of transferrin receptors by many tumors, yet the nanoparticles were still injected directly into the tumor in these experiments and systemic application may prove less effective since many normal tissues express transferrin receptors [118]. Recently shell-crosslinked nanoparticles derivatized with gadolinium were studied for their capability for polyvalent targeting [119]. These particles demonstrated large ionic relaxivities (~39 mM<sup>-1</sup> s<sup>-1</sup>) and a high molecular relaxivity of 20 000 mM<sup>-1</sup> s<sup>-1</sup>. Such particles have been conjugated with folate and shown to result in higher tumor uptake in small tumors overexpressing the folate receptor than controls [120]. Furthermore, folate nanoparticle uptake in the smaller tumors was competitively inhibited by excess folate, supporting ligand-based targeting.

#### 4.8

#### Conclusion

Nanoparticulate agents, such as superparamagnetic agents, perfluorocarbon nanoparticle emulsions, liposomes, fullerenes, dendrimers, are being intensively studied for various clinically relevant applications, particularly for magnetic resonance imaging (Table 4.1). The detection of tumor or metastasis development in the early stages appears feasible with nanoparticles targeted to unique or abundant epitopes on tumor tissues (Table 4.2). Nanoparticle-facilitated signal enhancement

Tab. 4.1. Nanoparticle classification.

Nanoparticles	Ref.	Nanoparticles	Ref.
Superparamagnetic		Paramagnetic	
SPIO	16, 37	PFC	53–60
USPIO	24–26		
MION	27, 28, 49	Liposomes	63, 66, 70–80, 121
CLIO	44, 45, 51		
PAM	38	Fullerenes	83–86
Magnetite	46, 47	Nanotubes	87, 122
Magneto-fluorescent			
NIRF	39–45	Dendrimers	89–95, 97–99, 102, 103
Fluorescent			
Quantum dots	107, 112	Polymer nanoparticles	114, 117, 119, 120

SPIO – Superparamagnetic iron oxides; USPIO – ultrasmall superparamagnetic iron oxides; MION – monocrystalline iron oxide nanoparticles; CLIO – crosslinked iron oxide nanoparticles; PAM – polyacrylamide magnetic nanoparticles; NIRF – near-infrared fluorescent nanoparticles; PFC – liquid perfluorocarbon nanoparticles.

Tab. 4.2. MRI applications of nanoparticles for cancer diagnosis and treatment.

Nanoparticle	Species/model	Cancer	Targeting: active (A); passive (P)	Treatment	Ref.
SPIO	<i>In vitro</i>	Breast and prostate cancer	P	Doxorubicin	16

will allow the imaging of tumors in size ranges that are undetectable with conventional imaging protocols. Importantly, delivery of drugs by nanocarriers specifically to tumor tissues will allow for localized therapy in dosage ranges that cannot be achieved with conventional systemic chemotherapy due to side effects. Ushering in the era of “personalized medicine” these nanoparticulate technologies will ultimately allow physicians to diagnose disease in asymptomatic individuals and treat pathology early and custom-tailored to the individual patient.

# Magnetic Resonance Nanoparticle Probes for Cancer Imaging

*Young-wook Jun, Jung-tak Jang, and Jinwoo Cheon*

### 5.1

#### Introduction

Inorganic nanoparticles exhibit unique optical, magnetic, and electronic properties arising from nanoscale quantum effect and are emerging as key materials for next-generation device applications [1]. When these nanoparticles are applied to biological systems, they have the potential to improve modern imaging techniques, such as X-ray imaging, computed tomography (CT), near-IR fluorescence imaging, positron emission spectroscopy (PET), and magnetic resonance imaging (MRI) [2–4]. Although such modern imaging techniques provide excellent anatomical information of living objects, they have difficulties in detecting molecular and cellular events. Considering that most biological processes and disease attacks are related to molecular and cellular events, precise observations of detailed biological processes are important [5, 6]. Inorganic nanoparticles, upon conjugation with biomolecular markers, can report such molecular and sub-cellular events. In addition, their nanoscale materials properties can lead to the significant enhancements in detection sensitivity and resolution.

Semiconductor quantum dots are a good example of such nanoparticle probes. Quantum dots exhibit better fluorescence properties, such as high quantum yield, multicolor emissions by single excitation, and high photo-stability, than conventional organic fluorophores [7–9]. Such enhanced properties have allowed the imaging of cell signaling, cell evolution, cell trafficking, and *in vivo* cancer detection [10–13].

In contrast, magnetic nanoparticles with unique superparamagnetism can serve as excellent probes in magnetic resonance imaging (MRI). MRI detects subtle change in the relaxation time of the proton nuclear spins of water molecules, which make up from 70 to 90% of most tissues. Although this is one of the most powerful medical diagnostic tools due to its non-invasive nature, multidimensional tomographic capabilities, and high spatial resolution [14], MRI has a lower sensitivity than other tools [6]. Such weakness can be significantly improved by using magnetic nanoparticle probes [15, 16]. Under an applied magnetic field, magnetized nanoparticles generate an induced magnetic field, which perturbs the mag-

**Fig. 5.1.** MR contrast effects of magnetic nanoparticles. Under an applied magnetic field ( $M$ ), magnetic nanoparticles are magnetized and generate an induced magnetic field ( $\delta M$ ),

which perturbs the magnetic relaxation processes of the proton in water molecules, which is reflected as dark MR contrast.

netic relaxation processes of the protons in water molecules surrounding the magnetic nanoparticles. This leads to a shortening of the spin–spin relaxation time ( $T_2$ ) of the proton, which results in darkening of the MR images (Fig. 5.1).

According to the outer sphere spin–spin relaxation formula of solvent protons by solute magnetic particles, the spin–spin relaxation time of the proton is given by Eq. (1), where  $\gamma_1$  is the gyromagnetic ratio of protons in water,  $m$  is the molarity of magnetic nanoparticles,  $r$  is their radius,  $N_A$  is Avogadro's number,  $\mu$  is the magnetic moment of the nanoparticle,  $\omega_s$  and  $\omega_1$  are the respective Larmor angular precession frequencies of the solute electronic and water proton magnetic moments, the functions  $j_n(\omega, \tau)$  are spectral density functions, and  $\tau (= r^2/D)$  is the time scale of fluctuations in the particle–water proton magnetic dipolar interaction arising from the relative diffusive motion ( $D$ ) of a particle and water molecules [17].

$$\frac{1}{T_2} = \left( \frac{32\pi N_A [M]}{405000rD} \right) \gamma_1^2 \mu^2 \{ 6.5j_2(\omega_s, \tau) + 1.5j_1(\omega_1, \tau) + j_1(0, \tau) \} \quad (1)$$

Therefore,  $T_2$  is shortened by increasing the magnetic moment of the nanoparticles. Recently, Cheon, Suh, and coworkers experimentally demonstrated such magnetic moment effects on  $T_2$  by elucidating the correlated nanoscale effects of iron oxide nanoparticles between size, magnetism, and  $T_2$  relaxivity [18]. Figure

**Fig. 5.2.** Nanoscale size effects of iron oxide nanoparticles on magnetism and induced magnetic resonance (MR) signals. (a) TEM images of Fe<sub>3</sub>O<sub>4</sub> nanocrystals of 4, 6, 9, and 12 nm. (b) Size-dependent T<sub>2</sub>-weighted MR images of iron oxide nanoparticles in aqueous solution at 1.5 Tesla. (c) Size-dependent MR images color-coded by T<sub>2</sub> values. (d) Graph of 1/T<sub>2</sub> relaxivity versus iron oxide nanoparticle size. (e) Magnetization of iron oxide nanoparticles measured by a SQUID magnetometer. (From Ref. [18], with permission.)

5.2(a) shows transmission electron microscopic images of highly monodispersed iron oxide nanoparticles, 4, 6, 9, and 12 nm. These magnetic nanoparticles exhibit size-dependent magnetic moments and as the nanoparticle size is increased from 4 to 6, 9, and to 12 nm, the mass magnetization at 1.5 T changes from 25 to 43, 80, and 102 emu (g-Fe)<sup>-1</sup> (Fig. 5.2e). Such a trend is clearly reflected in the T<sub>2</sub>-weighted MR images. The 1/T<sub>2</sub> relaxivity gradually increases from 56 to 106, 130, and to 190 M<sup>-1</sup> s<sup>-1</sup>, which is imaged by the gradual change of the MR contrast from white to black through gray (Fig. 5.2b–d).

Such effect of magnetic nanoparticles on MR contrast gives them the ability to report various biological events. For example, magnetic nanoparticles >30 nm have been used for phagocytosis imaging [19, 20]. When phagocytes uptake magnetic nanoparticles, they are imaged as dark contrast. But tumor cells without phagocytic ability are imaged as white contrast. By utilizing such an effect, liver metastasis [21, 22], spleen [23], and lymph node detection [24] have been performed.

In contrast, when smaller nanoparticles (e.g., 10 nm) can easily escape from phagocytes, magnetic nanoparticles, upon conjugation with a target specific biomolecule, can detect target tissues through molecular interactions between

nanoparticle–biomolecule conjugates and molecular markers expressed from target tissues [24, 25]. Various types of clinically benign iron oxide based magnetic nanoparticles [e.g., superparamagnetic iron oxide (SPIO)] have been explored, and imaging has been reported of infarct [26–28], angiogenesis [29], apoptosis [30], gene expression [31, 32], and cancer [18, 33–36]. However, MR signal sensitivity and specificity of nanoparticle probes to the target tissue are still unsatisfactory for clinical applications and further efforts are needed to make them better. This chapter briefly reviews recently developed biocompatible magnetic nanoparticles and their utilization in molecular MRI.

## 5.2

### Magnetic Nanoparticle Contrast Agents

For their successful utilization as molecular MR contrast agents, magnetic nanoparticles must fulfill the following requirements: (a) uniform and high superparamagnetic moment, (b) high colloidal stability under physiological conditions (e.g., high salt concentration and pH changes), (c) the ability to escape the reticuloendothelial system (RES), (d) low toxicity and biocompatibility, and (e) possession of functionality to be linked to biologically active species (e.g., nucleic acid, proteins). Since these properties are highly related to their size, stoichiometry, and surface structures, various types of iron oxide nanoparticles have been developed.

#### 5.2.1

##### Silica- or Dextran-coated Iron Oxide Contrast Agents

For conventional MR contrast agents, iron oxide nanoparticles are synthesized through the precipitation of iron oxide in an aqueous solution containing ferrous salt by adding an alkaline solution [37]. Such iron oxide nanoparticles are usually insoluble as-is and a coating material is required for them to be soluble in aqueous media. In early attempts to make them water soluble, silica was used as a coating material [38]. The size of the core magnetic iron oxide can vary between 4 to 10 nm and the total particle size varies from 10 nm to 1  $\mu\text{m}$ , including coating materials. Since these nanoparticles have a broad size distribution, further size sorting procedures, including differential centrifugation and dialysis, are required. A representative silica-coated iron oxide contrast agent is AMI-121 (generic name: Ferumoxsil), which is now commercially available as Lumirem<sup>®</sup> (Guerbet) and Gastromark<sup>®</sup> (Advanced Magnetics) (Table 5.1). The core is  $\sim 10$  nm-sized polycrystalline iron oxide and the hydrodynamic size is  $\sim 300$  nm. This agent is delivered orally and used for abdomen MRI [39].

Although silica-coated iron oxide nanoparticles are reasonably stable in aqueous media, they tend to aggregate in blood and, therefore, are inadequate for blood injection. To enhance the colloidal stability of iron oxide nanoparticles, another type of coating agent, dextran or carbodextran, has been developed [40] (Table 5.1). Since dextran possesses high colloidal stability against harsh physiological condi-

Tab. 5.1. Various silica- or dextran-coated iron oxide contrast agents.

Agent	Iron oxide core size (nm)	Total size (nm)	Coating material	Magnetization at 1.5 T (emu g <sup>-1</sup> )	T2 relaxivity (m <sup>-1</sup> s <sup>-1</sup> )	Blood half-life
AMI-121 <sup>[a]</sup> [36], Lumiren, Gastromark	10	~300	Silica	N/A	72	<5 min
AMI-25 <sup>[a]</sup> [38], Feridex Endorem	5–6	80–150	Dextran	78	98	~6 min
SHU 555A <sup>[a]</sup> [39], Resovist	~4.2	~62	Carbodextran	N/A	151	3 min
AMI-227 <sup>[a]</sup> [41], Combidex, Sinerem	4–6	20–40	Dextran	69.8	53	>24 h
MION [42–44], CLIO	2.8	10–30	Dextran	60–68	69	~10 h

<sup>a</sup>Commercialized.

tions, dextran-coated iron oxide nanoparticles can have good stability. Such nanoparticles are prepared through a co-precipitation method from aqueous solution containing ferrous salt and dextran by adding an alkaline solution [37]. There are three representative dextran-coated iron oxide nanoparticles: AMI-25 [Feridex<sup>®</sup> (Berlex Lab.) and Endorem<sup>®</sup> (Guerbet)], SHU 555A [Resovist<sup>®</sup> (Schering)], and AMI-227 [Combidex<sup>®</sup> (Advanced Magnetics) and Sinerem<sup>®</sup> (Guerbet)]. AMI-25 is composed of a ~5-nm iron oxide core and dextran coating materials. The total size is between 80 and 150 nm with a T2 relaxivity of ~98.3 mm<sup>-1</sup> s<sup>-1</sup> [41]. SHU 555A has an ~4.2-nm iron oxide core coated with carbodextran, with total size of ~62 nm; Resovist has a higher T2 relaxivity of 151.0 mm<sup>-1</sup> s<sup>-1</sup> [42] and has no known side effects after fast intravenous injection [43]. These magnetic contrast agents are generally trapped and accumulated by the reticuloendothelial cells in the liver with a short blood half-life of less than 10 min and, therefore, are used for liver imaging [20]. Compared with these two iron oxide contrast agents, AMI-227 has similar iron oxide core size (~5 nm) but a smaller overall size of 20–40 nm. Although AMI-227 has lower T2 contrast effects (T2 relaxivity of ~53 mm<sup>-1</sup> s<sup>-1</sup>), its smaller size provides a much higher blood half-life of ~24 h, which enables MR angiography and lymph node detection [44].

Smaller dextran-coated iron oxide nanoparticles, including monocrystalline iron oxide (MION) and its derivative, crosslinked iron oxide (CLIO) are composed of a ~2.8-nm core iron oxide and dextran shell with a total size of 10–30 nm [45–47].

**Fig. 5.3.** Synthesis scheme of magnetoferritin. Removal of ferrihydrite from native ferritin produces apoferritin and subsequent formation of magnetite nanoparticles inside apoferritin affords magnetoferritin. (From Ref. [49], with permission.)

Since these nanoparticles are relatively small and have a long blood half-life, and their surface can be readily linked with biologically active molecules, they are useful for *in vivo* molecular MRI of biological targets [45] (Section 5.3.1).

### 5.2.2

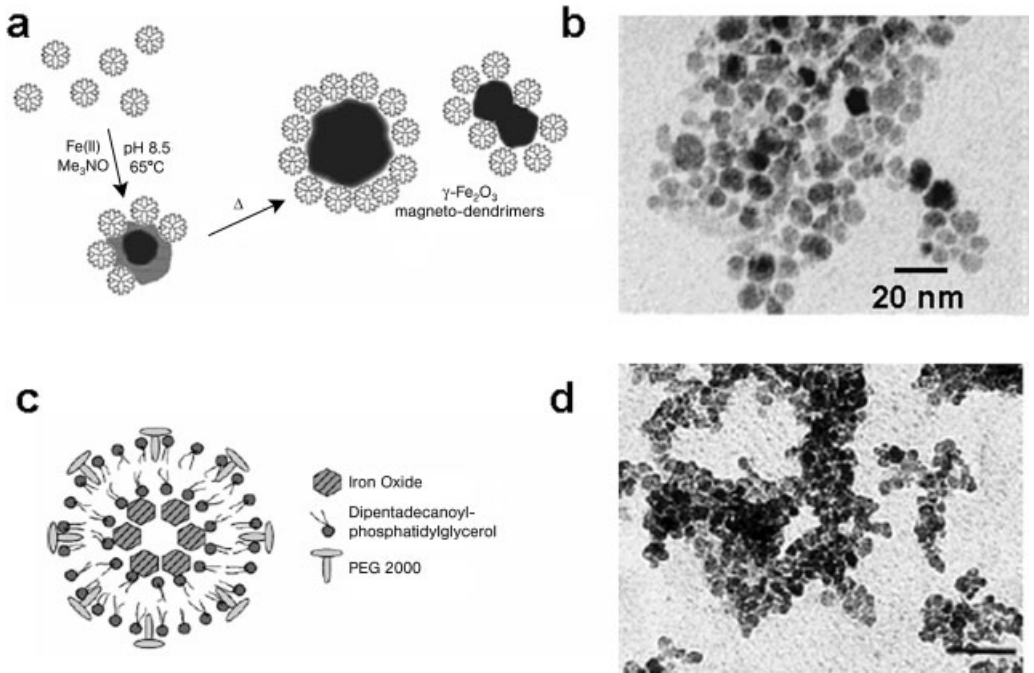

#### Magnetoferritin

Ferritin is a well-known iron storage protein used to sequester and store iron, which is composed of a  $\sim 6$  nm hydrated iron oxide, ferrihydrite ( $5\text{Fe}_2\text{O}_3 \cdot 9\text{H}_2\text{O}$ ), core and polypeptide apoferritin shell [48]. Ferritin has been used as an efficient synthesizer for other magnetic materials [49–51]. For example, magnetically less useful ferrihydrite can be replaced by iron sulfide or magnetite nanoparticles (Fig. 5.3) [49]. Researchers have also utilized magnetoferritin as contrast agents for MRI. Magnetoferritin possesses a reasonably high T2 relaxation of  $157 \text{ mM}^{-1} \text{ s}^{-1}$  [52]. Although magnetoferritin is expected to have high biocompatibility and colloidal stability in the blood when considering that they mimic naturally-occurring ferritin, actual results are contradictory. These magnetoferritin particles are rapidly cleared from the blood circulation (blood half-life of less than 10 min) by the reticuloendothelial system in the liver, spleen, and lymph nodes [52]. Therefore, magnetoferritins are only suitable for liver, spleen, and lymph-node detection rather than molecular imaging.

### 5.2.3

#### Magnetodendrimers and Magnetoliposomes

The unique pore structures and multiple functional end-groups of dendrimers make them useful as host materials in drug and gene delivery. Similarly, dendrimers can efficiently deliver magnetic nanoparticles to cells. Bulte, Frank, and coworkers have demonstrated carboxy-terminated dendrimer ( $G = 4.5$ ) coated iron oxide contrast agents [53, 54]. Typically, magnetodendrimers are synthesized through the pH-controlled reaction of a ferrous salt and a trimethylamine oxide

**Fig. 5.4.** Schematics and TEM images of (a, b) magnetodendrimers and (c, d) magnetoliposomes. (From Refs. [54 and 55], with permission.)

oxidant in a methanol/water mixture containing polyamidoamine dendrimers (Fig. 5.4a). The core size of the magnetodendrimers is 7–8 nm and they tend to aggregate to oligomers 20–30 nm in size (Fig. 5.4b). Magnetodendrimers show enhanced magnetic properties [saturation magnetism:  $\sim 94 \text{ emu (g-Fe)}^{-1}$ ] and a high T2 relaxivity of  $200\text{--}406 \text{ M}^{-1} \text{ s}^{-1}$  [53], compared with those of dextran-coated MION. Since dendrimers can be efficiently transfected to cells without any transfection agents, these magnetodendrimers can be used as labelers for cellular MR imaging and trafficking [53].

Similarly, liposomes, which are also widely used for drug and gene delivery, can be good coating materials to solubilize iron oxide nanoparticles. Liposomes have a bilayer assembly of surfactant molecules with a hydrophilic head and a hydrophobic tail. As shown in Fig. 5.4(c), the hydrophilic ends of the inner layer surfactants encapsulate the iron oxide nanoparticles and the hydrophilic head of the outer layer surfactant make them soluble in water. Bulte, Frank, and coworkers have reported that such magnetoliposome can be utilized for bone marrow MR contrast agents [55]. The iron oxide core size of the magnetoliposomes is  $\sim 16 \text{ nm}$ , and the entire size is  $\sim 40 \text{ nm}$  (Fig. 5.4d) with a T2 relaxivity of  $\sim 240 \text{ mM}^{-1} \text{ s}^{-1}$ .

## 5.2.4

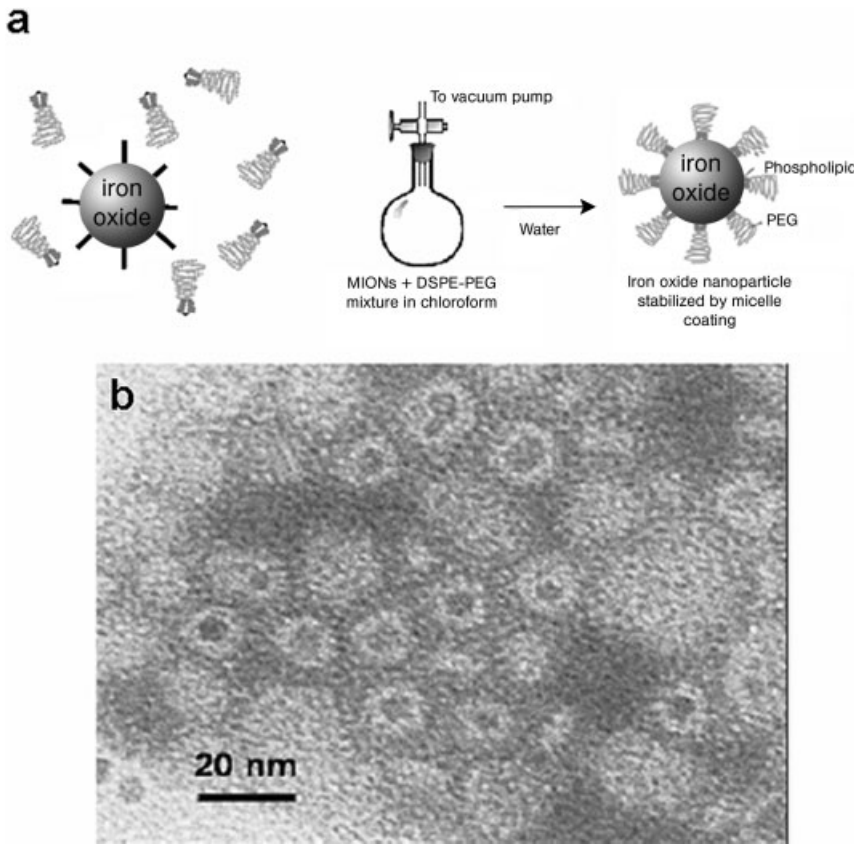

**New Type of Contrast Agent: Non-hydrolytically Synthesized High Quality Iron Oxide Nanoparticles**

With the exception of MION and CLIO, previously developed iron oxide MR contrast agents undergo rapid uptake by the reticuloendothelial systems (RES) and, therefore, are effectively for liver, spleen, and lymph node detection. Consequently, researchers have encountered difficulties when they are utilized for molecular MRI [19–23]. Successful molecular imaging requires high-performance magnetic nanoparticle systems that exhibit excellent magnetic properties, the ability to escape from the RES, and possess active functionality that can be linked with biologically active molecules [15]. Since magnetic properties of nanoparticles depend highly on the materials properties such as size, shape, stoichiometry, and crystallinity [18, 56, 57], it is critical to be able to control such properties. However, conventional water-phase protocols, which have been widely adopted for superparamagnetic iron oxide (SPIO) contrast agents, generally lack precise size-controllability and monodispersity, and afford poor crystallinity and non-stoichiometric compositions [37]. In contrast, nonhydrolytic high-temperature growth methods allow one to have size-controllability, high single crystallinity, and good stoichiometry [18, 57–60]. For example, the nanoparticle size can be easily controlled from 4 to ~20 nm with a very narrow size distribution ( $\sigma < 8\%$ ) by controlling the growth conditions [18, 57]. One difficulty that must be overcome before their utilization as MR contrast agents is obtaining water-solubility since nonhydrolytically synthesized iron oxide nanoparticles are soluble only in organic media. Various surface modification methods have been developed, including bifunctional ligand [18, 36, 61], micellar [62, 63], polymer [64–66], and siloxane-linking procedures [67, 68]. For example, nonhydrolytically synthesized nanoparticles can be transferred to aqueous media by overcoating the nanoparticles with poly(ethylene glycol)-(PEG)-ylated phospholipid micelles. Such a micellar coating strategy has been demonstrated with quantum dots [69], and Bao and coworkers have successfully extended this strategy to make water-soluble iron oxide nanoparticles (Fig. 5.5) [63]. The PEGylated nanoparticles can be further linked to cellular transfection Tat peptides and utilized for MR cellular labeling [63].

Bawendi and coworkers have proposed another approach to transfer iron oxide nanoparticles from organic to aqueous media by coating them with polymeric phosphine oxide ligands [70]. These polymeric ligands can tightly bind to the iron oxide nanoparticle surface through multidentate bondings (Fig. 5.6).

The siloxane linkage to a metal oxide surface is efficient and strong. Zhang and coworkers have successfully applied this strategy for the synthesis of water-soluble iron oxide nanoparticles [71]. Refluxing toluene solution containing triethoxysilyl-terminated PEG ligands and nonhydrolytically synthesized iron oxide nanoparticles provides iron oxide nanoparticles with high colloidal stability in aqueous media (Fig. 5.7).

The major advantage of these nonhydrolytic synthesized iron oxide nanoparticles, as mentioned above, is the precise size control with high monodispersity.

**Fig. 5.5.** (a) Synthetic scheme and (b) TEM image of poly(ethylene glycol) (PEG)-ylated iron oxide nanoparticles. (From Ref. [63], with permission.)

**Fig. 5.6.** Multidentate phosphine oxide ligand approach for the synthesis iron oxide nanoparticles. (a) The phosphine oxide functional groups bind to the surface of iron oxide and exposed PEG groups make them water soluble. (b) Iron oxide nanoparticles dissolved in water. (From Ref. [70], with permission.)

**Fig. 5.7.** Siloxane–poly(ethylene glycol) (PEG) coated iron oxide nanoparticles. Silanization of terminal ethoxysilane groups of the PEG ligand on top of iron oxide nanoparticles induces the formation of PEG-coated iron oxide nanoparticles. (From Ref. [71], with permission.)

Cheon, Suh, and coworkers have demonstrated such advantages for the synthesis of iron oxide MR contrast agents [18, 36, 61]. As shown by transmission electron microscopy (Fig. 5.8), nanoparticles obtained are  $\sim 9$  nm, with a narrow size distribution ( $\sigma < 8\%$ ). HR-TEM and X-ray analyses show that the nanoparticles are single-crystalline stoichiometric  $\text{Fe}_3\text{O}_4$ . Water-soluble iron oxide nanoparticles (WSIO) are then obtained by introducing 2,3-dimercaptosuccinic acid (DMSA) ligand onto the nanoparticle surface. This ligand endows the surface with high

**Fig. 5.8.** TEM image of  $\sim 9$ -nm  $\text{Fe}_3\text{O}_4$  nanoparticles.

**Fig. 5.9.** (a) Schematic of 2,3-dimercaptosuccinic acid (DMSA)-coated iron oxide nanoparticles. The carboxylic ends of DMSA bind to the surface iron oxide nanoparticles and are further stabilized through interligand disulfide crosslinkages. Remaining free thiol can be used for further

conjugation for biomolecules such as antibody. (b) Solubility test of as-synthesized (as-syn) and DMSA-coated iron oxide nanoparticles (WSIO = water-soluble iron oxide nanoparticles). (c) Stability test of WSIO in various concentrations of NaCl solution. (From Ref. [18], with permission.)

water-phase stability through (a) carboxylate chelate bonding to iron and (b) disulfide crosslinkages between the ligands (Fig. 5.9a) [18]. Furthermore, the remaining free thiol group of the ligand can be used to attach target-specific biomolecules. So-obtained  $\text{Fe}_3\text{O}_4$  nanocrystals with the DMSA ligand are fairly stable in water and phosphate-buffered saline (PBS) up to an NaCl concentration of 250 mM without any aggregation. These nanoparticles have been utilized as MR probes, upon conjugation with cancer targeting antibody, not only for the *in vitro* detection of cancer cells but also for *in vivo* imaging of cancer implanted in a mouse [18, 36] (Section 5.3.5).

### 5.3 Iron Oxide Nanoparticles in Molecular MR Imaging

When iron oxide nanoparticles are conjugated with biologically active materials (e.g., antibody), the resulting iron oxide–biomolecule conjugates possess dual functionalities of both the MR contrast enhancers and molecular recognition capability. These conjugates act as molecular imaging probes that can efficiently report on various molecular/biological events occurring in region-of-interest targets (Fig.

Fig. 5.10. Nanoparticle-assisted molecular MR imaging of biological systems.

5.10). Molecular MRI studies utilizing such iron oxide–biomolecule conjugates include the imaging of inflammation [72, 73], infarct [26–28], angiogenesis [29], apoptosis [30], gene expression [31, 32],  $\beta$ -amyloid plaques [74], and cancer [18, 33–36].

### 5.3.1

#### Infarct and Inflammation

For imaging of infarcts and inflammations, monocrystalline iron oxide (MION) nanoparticles are conjugated with specific antibodies through electrostatic interactions or covalent linkages by the reaction of potassium periodate-activated surface hydroxyl groups with lysine residues of antibodies. For example,  $R_{11}D_{10}$  antimyosin Fab was electrostatically conjugated to hydroxyl groups on MION surfaces for cardiac infarct imaging [27]. Since infarcted cardiac cells have increased porosity compared with normal cells, iron oxide–antimyosin Fab conjugates can efficiently be transported into damaged cells and recognize myosin. Figure 5.11 shows T2-weighted MR images of a mouse with cardiac infarct after injection of MION- $R_{11}D_{10}$  antimyosin Fab conjugates. The infarcted region is clearly observed as dark MR images, while no contrast effect was seen when unconjugated MIONs were administered. Such a targeting effect of MION- $R_{11}D_{10}$  antimyosin Fab conju-

**Fig. 5.11.** MR detection of (a, b) cardiac infarct and (c, d) inflammation of a mouse. After intravenous injection of iron oxide–antimyosin antibody, dark MR contrast in the infarcted area is observed. Similarly,

inflammation is not imaged at the control mouse but an inflammation site is clearly shown as dark contrast. (From Refs. [27 and 72], with permission.)

gates was evaluated through *ex vivo* immunohistological analyses through Prussian blue staining. Weissleder and coworkers further extended this strategy for the detection of inflammation by conjugating MIONs with polyclonal human immunoglobulin G. MION-IgG conjugates consistently detected the area of inflammation in T2-weighted spin-echo MR images (Fig. 5.11c,d), which was also further confirmed by a histological Prussian blue staining study [72].

### 5.3.2

#### Angiogenesis

Angiogenesis is a fundamental growth process of new blood vessels for development, reproduction, and wound repair. This process is also related to the progression of tumor growth. Therefore, the development of anti-angiogenic agents can be a potential pathway to efficient cancer treatment. Imaging of angiogenesis is also related to the cancer diagnosis and the evaluation of anti-cancer agents. Several molecular markers are involved in angiogenesis: vascular endothelial growth factor (VEGF), fibroblast growth factors (FGF), platelet-derived endothelial cell growth

**Fig. 5.12.** *In vitro* MR detection of E-selectin stimulated by interleukin-1 $\beta$ . (a) Without interleukin 1 $\beta$ , a white MR image is obtained from HUVEC treated only with CLIO–anti-E-selectin antibody. (b) In contrast, after

interleukin 1 $\beta$  and CLIO–anti-E-selectin are sequentially dosed to HUVEC, E-selectin expression is clearly imaged as a dark MR image. (From Ref. [29], with permission.)

factor (PD-EDGF), Tie-2 receptor, integrin, and E-selectin [75]. Among the various angiogenesis markers, VEGF, Tie 2 receptor, and integrin have been extensively studied [76–78]. Bogdanov and coworkers have reported that E-selectin expression in human endothelial cells can be imaged by using crosslinked iron oxide (CLIO)–monoclonal anti-human E-selectin antibody conjugate MR contrast agent [29]. When only CLIO–antibody conjugates are treated to endothelial cells with a low E-selectin expression level, an MR contrast effect is hardly detected (Fig. 5.12a). In contrast, treatment of cells with interleukin-1 $\beta$ , which stimulates the expression of E-selectin, followed by nanoparticle–antibody dosing results in a significant MR contrast effect (Fig. 5.12b).

### 5.3.3

#### Apoptosis

Apoptosis is an active process of programmed self-destruction of cells. In the early stages of apoptosis, the redistribution of phosphatidylserine in the cell membrane occurs and the detection of such processes can be an indicators of the programmed

**Fig. 5.13.** (a) MR imaging of apoptosis using the SPIO–C2 domain of synaptotagmin I. (b) T2-weighted MR images of (b, 1) water, (b, 2) SPIO–C2 conjugate, (b, 3) SPIO–BSA control conjugate, (b, 4) SPIO only treated apoptotic cells, and (b, 5) SPIO–C2 conjugate treated normal cells. *In vivo* MR images of tumors implanted in a mouse (c) before and (d) after drug treatment. (From Ref. [30], with permission.)

cell death. Representative binding proteins to phosphatidylserine are annexin V and synaptotagmin I. Although imaging of apoptosis using these antibodies has been already performed through radio-isotope techniques [79], the spatial resolution is only  $\sim 1\text{--}3$  mm and needs improvement. Brindle and coworkers have shown that conjugates of the SPIO and C2 domain of synaptotagmin I (C2-SPIO) can detect apoptotic cells through MRI with  $\sim 0.1$  mm resolution [30]. While there are no MR signals for nonspecific SPIO (BSA-SPIO) [Fig. 5.13b(3)], SPIO-only treated apoptotic cells [Fig. 5.13b(4)], and C2-SPIO treated normal cells [Fig. 5.13b(5)], C2-SPIO treated apoptotic cells [Fig. 5.13b(2)] clearly show dark MR contrast with a significant change in T2 ( $\Delta T_2 = \sim 90\%$ ). Further extension of this strategy to an *in vivo* animal study was also successful. When C2-SPIO was intravenously injected to drug-treated tumor-bearing mice, the nanoparticle conjugates are able to detect apoptotic regions with a significant MR signal change (Fig. 5.13c,d).

#### 5.3.4

##### Gene Expression

Gene expression is an emerging field in biomedical sciences, and the imaging of such expression is of importance. Although several approaches to detect *in vivo* gene expression have been performed through optical [80, 81] and radioisotope imaging techniques [82], there have been limitations such as low-penetration depth of light for optical imaging and poor spatial resolution of radioisotope imaging. Weissleder and coworkers have demonstrated that MR detection of transgene

expression of engineered transferrin receptor (ETR) in tumors is possible by using MION-transferrin (MION-Tf) contrast agents [32]. When MION-Tf is treated to the cells with various ETR expression levels, a gradual decrease in T2 is observed as the ETR expression levels of cells are increased due to proportional binding of MION-Tf conjugates to the expressed ETR. These workers also determined whether ETR expression can be detected in *in vivo* live mice with ETR positive tumors and ETR negative tumors. The results show that the MR contrast effect is only observed for ETR positive tumors (Fig. 5.14b–d). *Ex vivo* MRI of excised tumors shows more dramatic differences between these two tumors (Fig. 5.14e,f).

### 5.3.5

#### Cancer Imaging

Non-invasive detection of cancer in its early stages is of great interest since early detection of cancer can significantly increase the survival rate of patients. With conventional MRI techniques, the present detectable size of cancer is roughly  $\sim 1 \text{ cm}^3$ . If nanoparticle contrast agents can specifically recognize cancer cells through molecular interaction, selective enhancement of the MR signal of cancer cells can provide one with a way to clearly distinguish cancer from normal tissues. Tiefenauer and coworkers have reported that the detection of cancers is possible through such molecular recognition of superparamagnetic iron oxide (SPIO) nanoparticle–antibody conjugates [35]. Conjugation of poly(glutamic acid-lysine-tyrosine)-coated nanoparticles with anti-carcinoembryonic antigen (CEA) antibody is performed through a conventional sulfo-MBS crosslinking method. In the T2-weighted MR images, dark contrast is imaged at the CEA-expressed tumors, although the contrast difference is not highly pronounced (Fig. 5.15). Artemov and coworkers have utilized another approach to detect cancer cells [34]. Since the avidin–biotin interaction is strongly binding, avidin conjugated SPIO can efficiently detect biotinylated cancer specific antibodies that bind to the cancer cells (Fig. 5.16a). Their *in vitro* fluorescence-assisted cell sorting analyses and MRI confirm cancer detection (Fig. 5.16b). Au-565 cells with high expression of HER2/neu cancer markers are imaged as dark MR contrast, while no contrast effect is obtained from MDA-MB-231 cells with low HER2/neu expression.

Recently, Cheon, Suh, and coworkers have achieved highly efficient cancer targeting by using high quality, small-sized water-soluble iron oxide (WSIO) nanoparticle–antibody conjugates [36]. The WSIO nanoparticles have high magnetic momentum [ $\sim 100 \text{ emu (g-Fe)}^{-1}$ ] and small hydrodynamic size ( $\sim 9 \text{ nm}$ ), which are advantageous for both *in vitro* and *in vivo* cancer imaging. When these

nanoparticles are conjugated with Herceptin, they successfully detect cancer cells (SK-BR-3) as dark MR image (Fig. 5.17b) through molecular interaction between nanoparticle surface-bound Herceptin and HER2/neu cancer markers, compared with non-treated (Fig. 5.17a) and WSIO-irrelevant conjugate treated cells (Fig. 5.17c). This MRI result is also confirmed by an optical technique where vivid green fluorescence from the fluorescein (FITC) is clearly observed only for FITC-WSIO-Herceptin probe conjugate treated cells (Fig. 5.17d,e). Furthermore, WSIO nanoparticles enable the detection of various cell lines with different levels of HER2/

**Fig. 5.16.** *In vitro* MR detection of HER2/neu overexpressed cancer cells by using avidin-coated SPIO and biotinylated Herceptin. (a) Schematic and (b) MR images of SPIO–avidin conjugate treated cells (AU-565, MDA-MB-231, MCF-7). (From Ref. [34], with permission.)

**Fig. 5.17.** *In vitro* cancer detection using water-soluble iron oxide (WSIO)–Herceptin conjugates. MR images of (a) non-treated, (b) WSIO–Herceptin treated, (c) WSIO-irrelevant antibody treated breast cancer cells (SK-BR-3). (d) MR image of WSIO–Herceptin

conjugate treated cell lines with increasing expression levels of HER2/*neu* receptors: Bx-PC-3, MDA-MB-231, BT-474, and NIH3T6.7 cell lines. Control conjugates are treated to Bx-PC-3 cell lines. (From Ref. [36], with permission.)

neu cancer marker expression: Bx-PC-3, MDA-MB-231, BT-474, and NIH3T6.7 cell lines, which are arranged in the order of increasing HER2/*neu* expression level. T2-weighted MR signals of the cell lines treated with WSIO–Herceptin probe conjugates become darker as the expression level of the HER2/*neu* receptors is increased (Fig. 5.17f). Notably, the MR signal intensities of the cell lines treated with WSIO–Herceptin probe conjugates show a marked difference from that of control conjugates, indicating excellent specific binding efficiency of the probe conjugates.

These magnetic probes have been successfully extended to the *in vivo* detection of cancer cells implanted in mouse [36]. When these WSIO–Herceptin conjugates are intravenously injected into a mouse, they successfully reach and recognize HER2/*neu* receptors overexpressed from cancer cells which results in a significant MR contrast effect in the tumor sites, with a ~20% decrease in T2 compared with control experiments (Fig. 5.18a–c). In high-resolution MR images of WSIO–Herceptin conjugate treated mouse measured at 9.4-T MRI, a dark MR image initially appears near the bottom region of the tumor and then gradually grows and spreads to the central and upper region of the tumor as time elapses (Fig. 5.18d). They found that such a time-dependent MR signal change reveals the heterogeneous pattern of the intratumoral vasculatures, where the bottom side of the tumor has well-developed vascular structures.

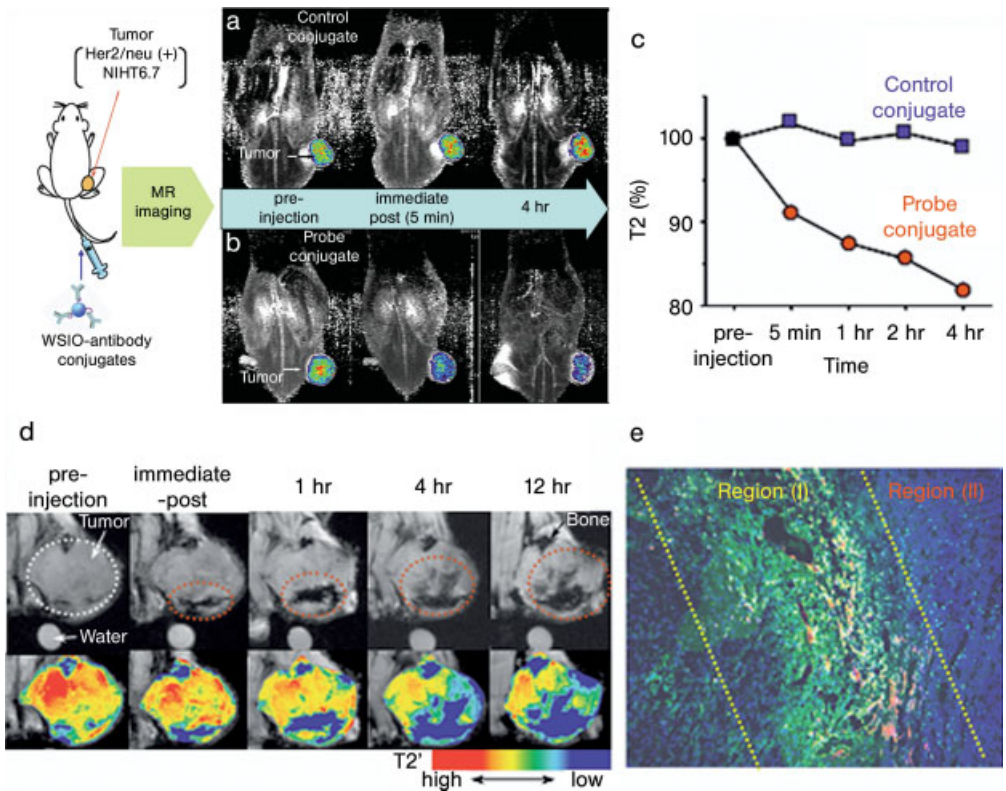

## 5.4

### Summary and Outlook

Although there has been much progress in the development of magnetic nanoparticle contrast agents for molecular MRI in the past few years, their successful utilization is limited to *in vitro* systems, except for a few *in vivo* cases. The main difficulties lie in their poor MR contrast effects and limited stability under *in vivo* conditions. The MR signal enhancing effect of conventional iron oxide-based nanoparticles is unsatisfactory, compared with other diagnostic tools such as fluorescence and PET, and needs to be improved. Therefore, it is important to develop new types of magnetic nanoparticle contrast agents that can significantly improve contrast effects. Since nanoparticles with higher magnetization values provide stronger MR contrast effects, the development of novel nanoparticles with superior magnetism is the first prerequisite. Concurrently, since the MR contrast effects of nanoparticles are strongly correlated with a material's characteristics in terms of their size, shape, composition, single crystallinity, and magnetism, it is important to have a good nanoparticle model system that can clearly describe the relationship between nanoscale material characteristics and MR contrast effects (Fig. 5.19a).

The next required step is to impart high colloidal stability and biocompatibility to the magnetic nanoparticles. As described in previous sections, various coating materials have been developed for such applications, but it is still necessary to develop general and more reliable protocols for tailoring nanoparticle surfaces with desired coating materials. Since a smaller overall size is advantageous for escaping the re-

ticuloendothelial system, the coating materials should be as small as possible while possessing high colloidal stability without any aggregation under physiological conditions (Fig. 5.19b).

The toxicity of magnetic nanoparticles is also a very important issue that needs to be resolved before clinical utilization. Although iron oxide nanoparticles have been regarded as clinically benign materials, potential cytotoxicity arising from their size, shape, and coating materials should also be examined, along with

**Fig. 5.19.** Nanoparticle-assisted molecular MRI. (b) Then, evaluation and optimization of materials properties such as magnetism, hydrodynamic size, and colloidal and biostabilities are important. (c) When these nanoparticles are conjugated

to biomolecules, the resulting nanoparticle–biomolecule conjugates possess the capabilities of both MR contrast effects and molecular recognition of target biosystems. (d) This enables molecular MRI that can report various biological events, such as pinpointing cancer diagnosis, cell migration, cell signaling, and genetic developments, with high sensitivity and specificity.

systematic guidelines for the nano-toxicity evaluation of newly developed novel nanoparticles.

Once novel nanoparticles with highly enhanced magnetism, small size, and high colloidal and biostability are developed, significant improvements in MR detection sensitivity and target specificity are expected (Fig. 5.19c,d). This can bring huge advances in current cancer diagnosis and biomedical imaging fields. For example, highly enhanced MR contrast of a biological target through the molecular recognition of such nanoparticle contrast agents will promise *in vivo* diagnosis of early-stage cancer with sub-millimeter dimension. In addition, many unrevealed

biological processes, such as *in vivo* pathways of cell evolutions, cell differentiations, cell-to-cell interactions, molecular signaling pathways, could be precisely monitored at the molecular level by using next-generation nanoparticle contrast agents.

# LHRH Conjugated Magnetic Nanoparticles for Diagnosis and Treatment of Cancers

*Carola Leuschner*

### 6.1 Introduction

Despite new discoveries of drugs and treatment combinations for cancer the mortality rate has not improved in recent decades. There is an urgent need to improve treatment and imaging in patients diagnosed with distant metastatic cancers. Cancer as a confined disease is treatable today; in contrast, distant metastatic disease outcome has not improved over the past 30 years and most patients succumb to this severe, devastating form of the disease. Furthermore, new drugs and contrast agents need to be developed to monitor the efficacy of response to treatments. Nanotechnology for treatment and diagnostics has been the focus of developmental research in the past 10 years and continues to grow exponentially. This thriving field of research focuses on materials that are on the nanometer scale, opening up new avenues that can lead to the development of highly specific compounds for treatment and imaging. Several reviews focus on the fabrication of nanoparticles for various applications, including encapsulation of drugs, and mainly summarize the latest developments for untargeted nanoparticles that are distinguishable by different coating materials, nanomaterials and various sizes and shapes. Nanoparticles open new opportunities to treat cancers by hyperthermia, to encapsulate drugs like doxorubicin, camptotecin or radiolabeled compounds that can be functionalized for higher specificity to reduce systemic exposure, and to deliver specifically nanoparticles to tumors, metastases peripheral organs and the brain.

The specific targeting of tumor cells and metastases has been more intensely under investigation. Several receptors overexpressed in cancer cells have been targeted. Although with different success with respect to specificity (some of these targets are also expressed in peripheral tissue), targeting of tumor cells can be surface binding only or by receptor-mediated endocytotic uptake of delivered compounds, which was observed to various extents, depending on the type of receptor.

Among targeting moieties on cancer cells, tumors and metastases the receptors for luteinizing hormone releasing hormone (LHRH) have been studied in detail since 1980.

The importance of LHRH receptors as specific targeting moiety for cancer treatments and diagnosis has become evident as peripheral organs express little or no receptors; however, most human cancer cells that belong to cancers of the highest incidence and death rates have tested positive for LHRH receptors. Most importantly, this chapter overviews specific targeting of nanoparticles using LHRH receptors for specific delivery, higher efficiency and faster accumulation of nanoparticles within tumor cells. Current applications in nanotechnology targeting the LHRH receptor for treatment and imaging will be explained and the latest findings and discoveries will be summarized for this highly important receptor.

Several reviews and book chapters have been published over the past decade that summarize LHRH receptors and their function in gonadal and pituitary tissues. This chapter tries to connect the current knowledge of LHRH and LHRH receptors in malignant tissue to specifically target nanoparticles through LHRH receptors to primary tumors and metastases. The current literature regarding LHRH receptors in malignancies will be reviewed and the latest findings in the development of targeted treatment and diagnosis will be discussed, with emphasis on nanoparticle construction and their consequences *in vitro* and *in vivo*.

## 6.2 Cancer

Cancer is the second leading cause of death, with 10.9 million newly diagnosed cases worldwide in 2005, claiming a total of 6.7 million lives [1]. In the USA, one in four deaths are caused by cancer [2].

Despite new drugs and treatment combinations for cancer the mortality rate has not improved in recent decades. Of 1 372 910 new diagnosed cases for all cancers in 2005 in the USA 570 380 Americans died [2]. The highest mortality rate of all occurring deaths in the United States in men and women was lung cancer, claiming the life of 28% of patients [3]. Since 1974 the survival rate has increased by only 13% as more sensitive diagnostic techniques have made very early detection of cancers possible. The yearly cancer death rates in men and women over the past 70 years has not improved despite new treatment regimens [1, 3]. The reason for this poor development becomes apparent in looking at the 5-year survival rates of cancer patients (Table 6.1, [4–29]).

Cancer death is dependent on the disease stage, whether the tumor is confined to the organ of origin and can be resected surgically, treated with radiation therapy or with systemic chemotherapeutics. The table clearly depicts the problem occurring in the distant, metastatic disease of cancer, which significantly reduces the 5-year survival rate of the patients to single digits compared with the organ-confined disease stage (Table 6.1).

This serious situation can be explained for prostate and breast cancers as examples: The second leading cause of cancer death in men is prostatic adenocarcinoma, and in women mammary carcinoma. Both cancers develop mixed popula-

**Tab. 6.1.** Occurrence of cancer by organ, survival rates in local and distant metastatic disease and their LHRH-receptor expression.

Cancer type	New cases	Deaths	5-year survival rate (%)		LHRH-receptors expressed (%)	Ref.
			Metastatic disease	Localized disease		
Lung	186 550	165 130	2.1	49	N.D.	
Prostate	230 110	29 900	34	100 (86% discovered)	86	4–7
Breast	217 440	40 580	23	97	52	8–12
Colon	106 370	56 730	9	90 (only 38% discovered)	Yes	13, 14
Pancreas	31 860	31 270	1.6	16	67	9, 15, 16
Ovary	25 580	16 090	30	94 (only 29% discovered)	80	17–21
Leukemia	33 440	23 300	64			
Non-Hodgkin's lymphoma	54 370	19 410	56	84	Yes	23
Esophagus	14 250	13 300	2.2	29.1	Yes	24
Liver	18 920	14 270	1.9	16.3	Yes	25
Uterine corpus (Endometrium) (Cervix)	40 320 10 370	7 090 3 710	26 17	96 92	80	18, 19, 26

Brain	18 400	12 690			Yes	29

1 368 030 newly diagnosed cancer cases in the USA in 2004, 563 700 Americans die. The numbers are stated for the most frequent cancer types for men and women combined [3].

Survival rates are given for patients with localized (malignancy entirely confined to the organ of origin) and distant (malignancy has invaded lymph nodes or organs remote from the primary tumor) disease.

tions of hormone (estrogen/androgen) dependent and independent cells, which are poorly to well differentiated, and have variable proliferation rates. The preferred treatment for men with organ-confined disease is radical prostatectomy, while in women it is mastectomy. Initially, patients are treated with radiation and/or chemotherapy (cyclophosphamide, doxorubicin, 5-fluorouracil) [30, 31], in addition to hormone ablation. Although androgen ablation in prostate cancer patients (LHRH agonists, Leuprolide) [32] leads to a reduction of the primary tumor, and to its partial regression, within 2 years the disease can re-emerge in a poorly differentiated, androgen-independent form, after which there is no therapy available to prolong the patient's life [33]. In breast cancer patients estrogen ablation is achieved by tamoxifen treatment [34] or ovariectomy. Surgical removal of the primary tumor is invasive and has side effects, depending on the area of resection, on the tumor (encapsulated or invasive), and can even lead to increased proliferation of metastases as single metastatic cells and dormant cancer cells start to proliferate [35]. At the time of diagnosis up to 70% of prostate cancer patients [36, 37] and 40% of breast cancer patients have already developed occult metastases [38]. Bone and lymph node metastases occur in 26% of prostate adenocarcinomas [39] and in 23% of breast cancer patients [38]. More than 70% of patients die from skeletal metastases [40]. Often removal of the primary tumor can promote metastatic growth, and dormant cancer cells can become secondary, often more aggressive, tumors [35].

Current treatments are palliative and can only prolong the life of patients, they do not cure patients. Often, high doses of chemotherapeutics administered systemically are necessary to achieve the pharmacological effective concentration. Even to maintain a state of remission in the disease a high dose chemotherapy is required over a long period [41]. Because of the high toxicity and poor specificity of currently used drugs, an increase in chemotherapeutic dosages is not desirable. The administration of high drug concentrations has disadvantages regarding side effects as chemotherapeutics not only destroy malignant tumors but also healthy tissue and organs, which eventually forces an end to such treatment. Often, patients in recurrent disease do not respond to chemotherapy. This is due to an acquired drug-resistance, which decreases the efficacy of chemotherapy. Dormant metastatic disease is not treatable with chemo- or radiation-therapy as these destroy only fast proliferating cells [38, 42, 43].

Currently used chemotherapeutic drugs are systemically active and cannot target single dormant cancer cells, or slow growing tumors [38, 44], because most chemotherapeutic drugs are not selective for cancer cells and destroy only rapidly dividing cells.

### 6.2.1

#### **Conventional Approaches to Cancer/Metastases Detection**

Sensitive non-invasive detection and monitoring tools are needed for early tumor detection and for monitoring disease progression, efficacy of treatment regimens and responses to treatments. Higher resolution and improved imaging techniques are needed to detect single, disseminated cancer cells or even small cancer cell

clusters in peripheral organs, bones and lymph nodes at the earliest stage before development of secondary tumors. Current detection methods are invasive and lack the sensitivity to detect micrometastases.

Clinically, metastases have been quantified by counting macroscopic nodules from biopsy specimen or tumor cell colonies in histological sections. The detection rates with these methods is 1–2% [45–47]. These approaches are invasive and lack the sensitivity necessary to detect micrometastases or single disseminated cells and cell clusters in peripheral organs. The use of immunocytochemistry techniques increased the detection rate of bone metastases in bone marrow aspirates up to 30% [48–50]. RT-PCR techniques (reverse transcriptase polymerase chain reaction) have been developed to detect cytokeratin 18 in bone marrow, with a sensitivity of a single cell in  $2 \times 10^7$  bone marrow cells [51]. Although these techniques are superior to histological examinations they involve invasive procedures and can take up to 7 days for a final diagnosis.

Non-invasive detection methods include X-ray, Mammography, Ultrasound, Magnetic Resonance Imaging (MRI), and nuclear imaging techniques such as Positron Emission Tomography (PET), SPECT (single-photon emission tomography) and Computed Tomography (CT). PET, SPECT and CT techniques require radiochemicals, which can have significant systemic toxicity. Unlike mammography and ultrasound, MRI and CT are independent of tissue depth. They exploit pure tissue–energy interactions and do not require isotopes. Mammography has high false positive rates (70%), whereas MRI is costly and ultrasound has a low spatial resolution and is dependent on tissue depth. The accuracy for detection of tumors from breast cancer by mammography was 36%, by ultrasound 33% and by MRI 77% [52, 53]. Contrast agents like ferrofluids enhanced the detection of tumors by 35% compared with unenhanced MRI (6%) or dynamic CT (14%). Intraoperative ultrasound detected liver metastases as small as 5 mm [54] and reduced false-positive diagnosis [55]. MRI can distinguish metastases from hemangiomas and cysts and is potentially valuable for the detection of occult metastatic disease in the sub-centimeter size [56, 57]. Micrometastases as small as 2 mm were detected; PET imaging for pelvic lymph nodes detected metastases as small as 6 mm [58].

Clinically used contrast agents for MRI are gadolinium chelates and iron oxide based particles (superparamagnetic iron oxide nanoparticles = SPIONs) [55, 59]. SPIONs have important advantages over gadolinium chelates: they have low toxicity (in some instances toxicities were reported at concentrations more than 100-fold above the clinically effective dosage [59]) and their detection limit in MRI is in the subnanomolar range, exceeding Gd imaging by a factor of 100 [60]. The accumulation and binding of the nanoparticles to the target cells was either absent or non-specific and, therefore, insufficient and limited the diagnostic applications to liver, spleen, and bone marrow, all of which are dependent on the reticulo-endothelial system (RES). In the past decade, contrast agents that enhance MR imaging have been used for imaging liver [61, 62], spleen [61, 62], gastrointestinal tracts, cardiovascular diseases, cancer [63, 64] and even lymph node metastases [65–67]. The contrast agent accumulated in healthy tissue and enhanced the resolution of MRI between malignant and healthy tissue [65–67].

### 6.2.2

#### **Current Chemotherapeutic Approaches and their Disadvantages in Cancer Treatments**

Currently used chemotherapeutic drugs are systemically active, have severe side effects and do not target specifically tumors or single dormant cancer cells. Most current chemotherapeutics interfere with the proliferation machinery of fast growing cells – they are not effective on slow growing tumors or dormant cancer cells [38, 43, 44]. Most chemotherapeutic drugs are not selective for cancer cells and do not discriminate between healthy and diseased tissue. However, because they interfere with the proliferation machinery of the cancer cells they show a relatively high efficacy on fast proliferating cells: Cyclophosphamide (Cytosan) destroys genetic material that controls tumor cell growth; methotrexate and 5-fluorouracil (5FU) are antimetabolites that interfere with cancer cell division; antimicrotubule reagents prevent cell division by acting on the microtubules, among them are paclitaxel (Taxol), docetaxel (Taxotere), vincristine (Oncovin), vinblastine (Velban); doxorubicin (Adriamycin) is a tumor antibiotic. To be effective these drugs need to enter, and accumulate in, the tumor cells. High systemic dosages are required to reach therapeutically effective concentrations at the tumor site, which causes severe side effects and peripheral tissue damage. Among the side effects are destruction of bone marrow cells, which impairs the production of erythrocytes, causes cardiotoxicity, nephrotoxicity, hepatotoxicity and hematotoxicity. Because bone marrow cells produce erythrocytes for oxygen transport, patients become anemic as a result of bone marrow destruction. Hematotoxicity includes the destruction of platelets needed for blood clotting and leukocytes to fight infections. Immediate side effects are nausea, alopecia, and fatigue. Longer lasting effects are the increased risk for infections, which persists until the immune system has recovered from the chemotherapy (4–6 weeks).

##### **6.2.2.1 Multidrug Resistance**

High-dose chemotherapy does not necessarily cure the patient. Many patients relapse. Cancer can recur after high-dose chemotherapy, often with a lack of response to further chemotherapy, which in turn leads to terminal disease even after several years of apparent disease-free state. This phenomenon is defined as multidrug-resistance (MDR) and is attributed to multiple mechanisms [68, 69].

Most cancers, like colon, kidney, breast, ovarian, prostatic, lung cancers, over-express the p-glycoprotein gene (also known as the multidrug resistance gene). Its gene product is the protein p-glycoprotein (Pgp), which is located in membranes, Golgi apparatus and nucleus [70, 71]. Pgp is a transmembrane efflux pump that actively excretes cytotoxic drugs of different molecular structure through an ATPase mechanism [72], thus decreasing intracellular drug concentrations. Modulators for Pgp pumps have been reported and include Verapamil, a compound that competes with the drug efflux pump.

During differentiation and progression, cancer cells can acquire the ability to remove the administered drug through such a pump mechanism. Other mechanisms include alteration of enzymatic activities like topoisomerase or glutathione

S-reductase activity, altered apoptosis regulation, altered transport or alteration of intracellular drug distribution due to increased sequestration of cytoplasmic vesicles [73].

The severity of side effects during administration of chemotherapeutic drugs and the occurrence of MDR emerges as non-responsive or refractory disease to chemotherapeutic drugs.

#### 6.2.2.2 Drug Delivery to Tumors

Tumor morphology is differently organized with normal tissue, to meet the physiological requirements for fast growth. Table 6.2 summarizes some of the key characteristics of tumor tissue compared with normal tissue. Consequently, tumor tissue shows certain characteristics that distinguishes it from normal tissue. Malignant tissues have adapted to their increased requirement of nutrients and oxygen by the following characteristics: angiogenesis, tortuous vasculature, leaky basement membranes, lack of lymphatic system (Table 6.2).

Fast growing tumors require high amounts of nutrients, which need to be transported to the fast growing tissues and metabolic waste products need to be eliminated at a higher rates than with normal cells. Newly growing tumors can only meet their nutrient requirements until an average tumor volume of  $2 \text{ mm}^3$ , beyond that the tumoral diffusion limit restricts further growth [74]. Further tumor growth requires the formation of neovasculature, a process called angiogenesis. The highly increased “fuel” requirement leads to specific morphologic characteristics in tumors vasculature, which is tortuous, chaotic and lacks the hierarchic

**Tab. 6.2.** Differences between tumors and normal tissues.

	Normal tissue	Tumor tissue
Cell growth	Low proliferation	High proliferation
Vasculature	No or little angiogenesis	High angiogenesis
	Normal proliferation	Chaotic
	None	High proliferation of endothelial cells
		Occlusions
	Not hypoxic	Hypoxic
	Low permeability	High permeability
Lymphatic system	Functional	Lacking
Interstitial pressure	Normal	High
Pore size (nm)	2–60	100–780

branching pattern found in normal vasculature [75–77]. The fast proliferating tumor cells causes occlusion of the capillary vasculature, which leads to hypoxia and eventually necrosis of tumor tissue [77]. The basement membranes of tumor vasculature is often aberrant, leading to leakiness and increased permeability [76, 78] to counterbalance the high oxygen and nutrient requirements for the fast proliferating tumors [79]. In addition the lack of lymphatic drainage system [80, 81] in conjunction with aberrant cell proliferation and occlusion of capillary vessels increases drastically the interstitial pressure in tumor tissue, which is filled with hyaluronate and proteoglycan-containing fluids. Ideally, removal of the drug from the interstitial into the intracellular compartment of the tumor cell would create the necessary concentration gradient to the plasma to allow further extravasation of the drug.

Increased interstitial pressure in the tumor tissue interferes with extravasation of the drugs, causing an increase in drug concentration in the tumor interstitium. The dense packing of tumor cells further reduces diffusion of compounds in solid tumors [41]. This phenomenon is explained by the enhanced permeability and retention effect (EPR) and is characterized by the accumulation of a compound in the interstitium. At this stage, further delivery of drug to the tumor cells is stagnant when the accumulation of the drug in the interstitium exceeds the drug concentration in the plasma [82, 83].

### 6.3

#### Nanoparticles as Vehicles for Drug Delivery and Diagnosis

The delivery of drugs using nanoparticles can improve current drug administration and treatment. Presently, nanoparticles are under development that can be used for hyperthermic destruction of tumor cells, may incorporate drugs that are slowly released, and at the same time protect the pharmaceutical compound from destruction, alteration in the plasma, and, moreover, opens a possibility to deliver highly lipophilic compounds.

Delivery of drugs through nanoparticles needs to take into account the *in vivo* distribution of systemically injected particles. The biodistribution and circulation time of contrast agents is determined by several factors, including size, charge, and surface chemistry [84, 85] (Fig. 6.1).

Charged particles are rapidly coated with plasma proteins, known as opsonization, aggregate and have an increased phagocytotic index [8, 86]. Opsonized particles and nanoparticles exceeding a diameter of 100 nm are easily recognized by macrophages of the reticuloendothelial system (RES) and preferentially delivered into liver, spleen, lymph nodes, microglia and bones, and reside and accumulate within the macrophages in these organs as fast as 5 min [87–93]. During this process nanoparticles are removed from the circulation and the drug is inaccessible to treat tumor tissues. Nanoparticles can be specifically designed for increased uptake by macrophages that deliver them through the RES system of liver (Kupffer cells),

spleen, lymph nodes (perivascular macrophages), nervous system (microglia) and bones (osteoclasts) [87, 88]. This clearance can occur within 0.5–5 min [90], thus removing the active nanoparticles from the circulation and prevent their access to the tumor tissue.

Coating of nanoparticles with polymers alters their distribution *in vivo*. For example, a hydrophilic coating increases the circulation time by preventing interaction with the RES.

Nanoparticles with a hydrophilic coating, neutral charge and that are <100 nm show characteristics that render them unrecognizable by the macrophage system [94]. These particles then access the tumor tissue through their hyperpermeable vasculature, accumulate in the interstitial compartment and are retained therein due to the lack of a functional lymphatic drainage (EPR effect) [83, 84, 95, 96]. If nanoparticles are biodegraded in the interstitium the drug can be released and enter the tumor cells through diffusion.

Nanoparticles can enter the tumor cells from the interstitial tumoral compartment. Depending on the surface and ligand characteristics the particles can enter by different pathways, among which are pinocytosis or endocytosis [97–99].

Figure 6.1 illustrates the different routes nanoparticles may encounter *in vivo*, depending on their size.

In summary, nanoparticles for the delivery of drugs to tumors offer an attractive possibility for avoiding obstacles that occur during conventional systemic drug ad-

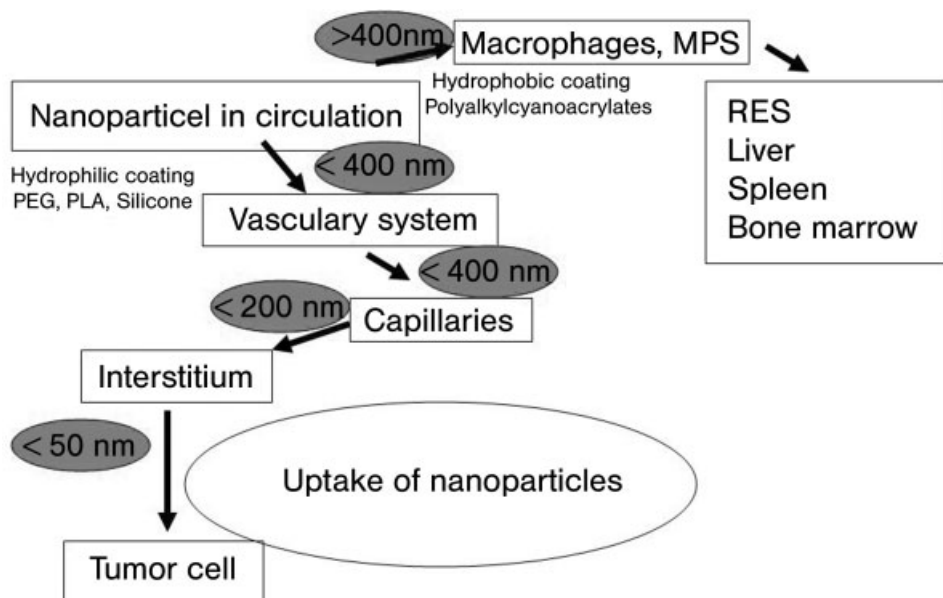

Fig. 6.1. *In vivo* distribution of nanoparticles by size.

ministration. However, new obstacles come into play, when nanoparticles are introduced into the system. The route of administration, particle size and composition, degradable coatings, biologically acceptable coatings, endocytosis properties, and stability in physiological salinity all determine the fate of nanoparticles. Nanoparticles injected into biological systems should not agglomerate to avoid not only macrophage uptake but, most importantly, thrombosis. The accumulation of nanoparticles at the target can be enhanced by either attaching ligands onto the surface of the nanoparticles or, in the case of magnetic nanoparticles, by using an external magnetic field.

### 6.3.1

#### **Targeting Tumor Cells**

Cancer therapy, ideally, should only destroy malignant cells, whether they are singly spread in the periphery or confined in an organ as a tumor. The conjugation of drug molecules with tumor specific ligands could facilitate targeting to the tumor cells and avoid uptake from normal cells: the normal cell would be spared and remain undestroyed whereas the tumor cells could accumulate and concentrate drug molecules, reaching the pharmacologically required concentration. This approach could overcome drug resistance, and side effects to vital organs can be eradicated or minimized through reduced systemic exposure. Malignant cells can be destroyed more effectively: even tumor cells inaccessible to surgery can be destroyed. The specific targeting of drug molecules can lower the plasma concentration and, at the same time, increase the efficacy through concentration of the drugs at the tumor cells.

The overall goal of active targeting is to increase the specificity of a drug to the tumor cells, to increase the concentration of the compound at the target cells and to incorporate and retain the drug or compound within the tumor cells (e.g., in the case of contrast agents). High efficiency internalizing and recycling receptors could improve cellular uptake through receptor-mediated endocytosis. This process is highly specific and efficient in cells expressing sufficient numbers of receptors and having sufficient receptor capacities.

Nanoparticles can be directed to the tumors by passive or active targeting. Passive targeting can be achieved by changing the size/hydrophobicity or other physicochemical characteristics of the newly designed nanoparticles to target the reticulo-endothelial system. Active targeting involves the direction of magnetic particles by using an external magnetic field or by using ligand-conjugated nanoparticles.

#### **6.3.1.1 Passive Targeting**

Passive targeting can be achieved by using nanoparticles of less than 100 nm size and free of charge, which determines the delivery to the tumors and metastases in peripheral organs through enhanced circulation time and at the site of the tumor cells through increased incorporation and concentration. The circulation time is

enhanced by hydrophilic coating of nanoparticles, whereas a hydrophobic coating ensures delivery to the liver and spleen. Examples for the delivery of nanoparticles through the RES include Endorem and AMI25, dextran-coated iron oxide nanoparticles of 62–150 nm diameter, which accumulated in liver and spleen after intravenous injection and have been clinically used for liver diagnostics as they accumulate up to 80% in the liver [100–102, 62]. Bone marrow imaging for tumor detection has been studied with AMI25 iron particles, which were delivered through the RES to the bone marrow [63, 64, 67]. Recently, occult lymph node metastases from prostate, bladder, breast, renal, penile, rectal and testicular cancer patients were diagnosed using dextran-coated nanoparticles (hydrodynamic size 30 nm) [65, 66]. This application exploits the difference between normal and malignant lymph nodes by delivering iron oxide nanoparticles through macrophages. In malignant lymph, nodes macrophages cannot infiltrate the tumor cells. Consequently, malignant lymph nodes do not accumulate macrophage delivered iron oxide nanoparticles.

Other examples of passive targeting include polyacrylcianoacrylate particles loaded with insulin, which have been orally administered into rats and were incorporated via the Peyer's patches in the intestinal lining into the lymphatic system [103], and the delivery of cucurbitan to cervical lymph nodes [104]. Gadolinium lipid nanoemulsions (70–90 nm) are an example of nanoparticles with increased circulation time. The nanoemulsion was synthesized from hydrogenated phosphatidylcholine, and gadolinium-diethylenetriaminepentaacetic acid (Gd-DTPA), which had been coated with polyoxyethylene to create a hydrophilic moiety. Bioavailability was determined for different routes of administration. Intravenous injection was advantageous over i.p. injections with respect to bioavailability, tumor retention and increased accumulation. Tumor accumulation was 49.7  $\mu\text{g-Gd}$  per g-tumor at 24 h compared with 21  $\mu\text{g-Gd}$  per g-tumor at 12 h in the i.p. treated groups. However, intravenous administration resulted in higher Gd accumulation in liver and spleen, lung and kidney compared with i.p. injected groups. Repeated injection with a two-fold enriched formulation led to 100  $\mu\text{g-Gd}$  per g-wt.-tissue [105]. The increased efficacy was due to prolonged circulation of the particles, reduced interaction with the RES, and reduced excretion of the compound Gd and increased retention in the tumor tissue. Polymeric nanoparticles (28 nm) prepared through polymer–metal complex formation between cisplatinum (CDDP) and poly(ethylene glycol)-poly(glutamic acid) block copolymers were tested for their efficacy in delivering cisplatinum to tumors. Lewis lung carcinoma bearing mice were injected i.v. with free CDDP (4 mg  $\text{kg}^{-1}$ ) or CDDP/m. CDDP/m had prolonged blood circulation time, and accumulated in the tumors 20-fold higher compared with free CDDP, whereas the accumulation in normal tissue was reduced [106]. These data clearly show the advantages of drug encapsulation and coating and size selection of nanoparticles with respect of increased bioavailability, increased target accumulation, and reduced accumulation in normal organs.

In the above applications the accumulation and binding of nanoparticles to the target cells was either absent or non-specific and, therefore, insufficient, and limited the diagnostic applications to liver and lymph nodes.

Not only drugs could be delivered to the tumors and cancer cells, but nanoparticles like iron oxide nanoparticles can also be used for imaging procedures.

#### 6.3.1.2 Active Targeting

In the past 5 years more attention has been paid to the identification and development of specific antigens and receptors that are unique to cancer cells. The ideal targeting moiety should be expressed on all tumor cells, including metastatic cells in the periphery, but not on healthy, normal cells. Targeting of nanoparticles or drugs has to meet the following characteristics:

- Specificity – to exclusively target cancer cells.
- Efficiency – faster uptake through receptor-mediated endocytosis, systemic delivered compounds concentrate on tumor cells, no involvement of peripheral tissues, faster delivery to tumor cells.
- Stability – the ligand should not be degraded.
- Functionality – receptor-mediated endocytosis, specific binding to tumor cells through receptors, facilitating increased uptake.
- Neutral surface coating – nanoparticles should not be recognized by macrophages.
- Increased retention through compartmentalization.

The decoration of nanoparticles with tumor targeting molecules, such as hormones, growth factors etc., can increase the efficacy of a treatment regimen by increasing the concentration of the drug at the tumor site, reducing the requirement of systemically administered drug for therapeutic efficacy, and can facilitate sustained intracellular retention of the drug. Antibodies for targeting malignancies have been approved and include Anti-CD 20 (Rituxan®, non-Hodgkins lymphoma), Anti-Her-2 (Herceptin®, metastatic breast cancer), Anti CD 33 (Mylotarg® myelogenous leukemia), and Gefitinib (Iressa®, non-small cell lung cancer) [107]. Other targets under intense investigation include antiangiogenesis compounds to specifically destroy tumor vasculature and eventually starve the tumor tissue. Angiogenesis is a complex process and the number of potential targets includes compounds for limiting endothelial proliferation, expression of angiogenesis inhibitors, and a decrease of angiogenesis stimulatory factors often secreted by tumor cells. The most prominent candidate for targeting vasculature is the vascular endothelial growth factor (VEGF) and an integrin for which antibodies have been developed for the use in conjugation in vascular imaging and tumor vasculature specific drug delivery.

Several specific receptors are overexpressed on tumor cells and have been identified and targeted with drug–ligand complexes or ligand–nanoparticle constructs. Some examples, which include lactoferrin [108, 109], ceruloplasmin [108, 109] and insulin [110], have been studied as targeting moieties; the ligands had strong surface binding on tumor cells, yet were not phagocytosed. High efficiency internalizing receptors could improve cellular uptake through receptor-mediated endo-

cytosis and increase dramatically the specificity of uptake in cancer cells, avoiding uptake in peripheral and healthy tissue.

Ligands that are endocytosed and recycled include transferrin [111–115], folate [116, 117], TGF alpha [118], nerve growth factor [119], Her2/neu [120], somatostatin, bombesin [121], steroid hormones, CD-8 [122], and HIV-1 tat [123, 124].

This chapter reviews in detail the use of Luteinizing Hormone Releasing Hormone (LHRH) as ligand to target the cancer cells. The following outline describes the characteristics and function of LHRH and its receptors regarding tumor treatment and detection.

Drugs delivered in conjugation with LHRH, studied over the past 20 years, include doxorubicin conjugates, studied intensely by Schally and co-investigators [22–24, 121, 125–129], lytic peptides conjugated to LHRH [8, 130], CPT-11 conjugated to LHRH and to pokeweed antiviral protein [159, 160]. Conjugates of lytic peptides or doxorubicin/doxorubicin derivatives with LHRH specifically target and destroy prostate, ovarian and breast cancer cells and their metastases, all of which express LHRH receptors *in vitro* and *in vivo* [22–24, 121, 125–130]. Metastases and disseminated cells derived from breast cancer xenografts of estrogen-independent MDA-MB-435S.luc cells, in the presence and absence of the primary tumor, have been detected, characterized and successfully targeted by CG/LHRH–lytic peptide conjugates [161–164, 318]. Schally et al. have treated several cancers with LHRH–doxorubicin conjugates and have developed a drug, which is currently in Phase III clinical trials (personal communication). These studies clearly demonstrate that tumors can be specifically targeted *in vivo* in experimental xenograft-bearing mice and rats. Moreover, in the above experiments none of the reported side effects of the free compounds were observed, suggesting increased specificity, targeting and efficacy with decreased systemic exposure. In studies using LHRH cytotoxic conjugates of doxorubicin the anterior pituitary did not show any permanent damage – complete recovery of pituitary function was observed [128, 129].

### 6.3.2

#### Detection of Tumors and Metastases using Nanoparticles

##### 6.3.2.1 Nanoparticles for Magnetic Resonance Imaging

The MRI signal in magnetic particles is created through the interaction of total water signal and the magnetic properties of longitudinal (T1) and transversal (T2) relaxivity.

MRI resolution can be increased by: (a) extending the scan time, (b) using high efficiency coils, (c) increasing field strengths, (d) increasing accumulation of contrast agent in cells or tissue, (e) compartmentalization of particles within the target cells, and (f) retention of particles.

To acquire the best image the signal-to-noise ratio must be optimized. An increase in field strength can cause neurological side effects like seizure, and/or cardiovascular effects. Clinically, MRI is conducted at 1.5 T, which is without side effects and well tolerated. MRI requires long imaging times, which can last up to 1 h. To enhance MRI sensitivities, contrast agents must accumulate in the target

cells, without leaking into surrounding tissue, at sufficient concentrations to increase relaxation times and must be retained within the tissue during the imaging procedure. In MRI, the signal can be amplified through an increase in intracellular concentration of the contrast agent [131, 132].

Clinically used contrast agents are paramagnetic gadolinium chelates (DTPA = diethyl tetraminepentaacetic acid) or ferrofluids. The use of superparamagnetic iron-based particles for magnetic resonance imaging has several advantages [133]:

Image enhancement with regard to relaxation time is greater in superparamagnetic particles – the change in T1 relaxation time is seven-fold, T2 relaxation time 16-fold, compared with gadolinium DTPA [134]. Gd is highly water-soluble and it is readily excreted, which allows only a short time for imaging and reduces cellular uptake [135, 136]. Superparamagnetic particles are less likely to aggregate because they lack remnant magnetization [137] and retain their physical characteristics even when chemically inert materials are attached [138]. Magnetite can adsorb or attach chemically to inert material without changing the characteristics of T2 relaxivity [138].

To significantly reduce relaxation time, gadolinium chelates have to be administered at high concentrations [139]. *In vitro*, increased Gd payloads resulted in increased T1 relaxivities and increased the resolution of fibrin clots [137]. In addition, superparamagnetic iron oxide particles have a much more favorable ratio of efficacy dose to LD<sub>50</sub>: 1/2400 compared with 1/50 for Gd-DTPA contrast agents [140]; in some instances toxicities were reported at concentrations 100-fold above the clinically effective dosage [139].

Monocrystalline Fe requires up to 1 mg of Fe per kg of tissue for MRI [141, 142]. In liver, up to 2.5 mg-Fe per kg of tissue showed a linear relationship with T2 relaxation [143]. Best imaging was obtained at 5–50 mg-Fe per kg of tissue sample [144]. A four-fold increase of the dose of superparamagnetic iron particles resulted in a decrease of signal loss by a factor of 10 [145].

Iron oxide nanoparticles are biologically safe and show no toxicity [139]. They are metabolized into elemental iron and oxygen by hydrolytic enzymes and the iron joins the normal body stores and is subsequently incorporated into hemoglobin. Iron homeostasis is controlled by absorption, excretion and storage. Acute toxicity has not been observed, in rats or human clinical trials. The administered iron was excreted over a period of four weeks [146]. Renal function, hepatic parameters, serum electrolytes, lactate dehydrogenase remained unchanged from baseline parameters after treatment with ferrofluids [146]. The elevation of serum iron levels persisted for a maximum of 48 h and caused no symptoms. In rats, 250 mg per kg of iron particles injected intravenously caused no side effects, in mice 350 mg kg<sup>-1</sup> were well tolerated [147].

In the past decade, contrast agents that enhance MRI have been tested for various applications, such as imaging of liver, spleen, gastrointestinal tracts, cardiovascular diseases and cancer detection. Administered systemically, the accumulation of unconjugated nanoparticles has been confined to liver, spleen, and bone marrow, all of which are dependent on the reticulo-endothelial system (RES), and did not directly accumulate in the tumor cells.

In these applications, the biodistribution of nanoparticulate contrast agents was exclusively determined by size, charge and surface chemistry (Fig. 6.1) [84, 85]. Systemically administered nanoparticles that are non-specific were incorporated by the MPS system, or they enter cells through endocytotic pathways involving clathrin-coated pit formation, sequestration and accumulation in vacuolar or lysosomal compartments of the cells [98, 99, 148]. Endocytotic cellular up-take of dextran-coated iron-oxide nanoparticles has been shown for tumor cells *in vitro* to range from 0.01 to 100 ng of iron per  $10^6$  cells within 1 h. In contrast macrophage uptake was about nine times higher [149, 150]. For example, occult lymph node metastases from prostate, bladder, breast, renal, penile, rectal and testicular cancer patients have been diagnosed using dextran-coated nanoparticles (hydrodynamic size 30 nm) [65, 66]. This application exploited the difference between normal and malignant lymph nodes by delivering iron oxide nanoparticles through macrophages. In malignant lymph nodes, macrophages could not infiltrate the tumor cells. Consequently, malignant lymph nodes did not accumulate macrophage-delivered iron oxide nanoparticles, and so they were not labeled.

The accumulation and binding of the nanoparticles to the tumor cells was either absent or non-specific and therefore insufficient and limited the diagnostic applications to liver and lymph nodes with limited sensitivity.

#### 6.3.2.2 Targeted Delivery of Nanoparticles to Increase Cellular Uptake for Higher MRI Resolution

Targeted delivery of nanoparticles can enhance the cellular accumulation of the contrast agent within the cancer cells, can increase the retention and thereby improve the resolution and specificity in imaging modalities.

The MRI signal can be amplified through an increase of the intracellular concentration of the contrast agent [131, 132]. Relaxation times in the acquisition of magnetic resonance imaging, i.e., the contrast of the image, increase with larger particles [151]. Compartmentalized particles and clusters have larger relaxation rates than free dispersed particles [152]. If the target cells are sufficiently loaded with iron oxide particles the MRI resolution can be as high as  $25\ \mu\text{m}$  [153].

This task requires specifically designed particles that concentrate in the target cells. A pre-requisite of the target cells is that they express high efficiency, internalizing, and functional receptors on their surface, to promote accumulation of the particles in the target cells, without leaking into surrounding tissue. Particle accumulation can be increased by targeting specific receptors on the cancer cells to facilitate receptor-mediated endocytosis of the delivered iron particle or to bind and accumulate the particles on the cell surface. Ideally, the injected nanoparticles should not be recognized by macrophages.

Examples for targeted uptake include dextran-coated monocrystalline iron oxide nanoparticles (MIONs) linked to transferrin [115] or to folate [116, 117].

Antibody-coupled paramagnetic liposomes targeting integrin  $\alpha V\beta 3$  of endothelial vascular cells greatly increased the MRI of angiogenic vasculature in rabbit carcinoma [154]. The  $\alpha V\beta 3$ -conjugated nanoparticles increased the signal enhancement

post-injection much faster than untargeted nanoparticle delivery (2 versus 24 h) [155, 156].

Dextran-coated nanoparticles have been conjugated to target Her2/neu receptors [158]. Folate-linked iron oxide nanoparticles accumulated in folate receptor expressing KB cells [116] and reached a maximal level of 75 pg-Fe per cell in BT20 breast cancer cell incubation and were poorly incorporated by macrophages [117]. CD-8 conjugated crosslinked iron oxide nanoparticles have been incorporated into T cells after 1 h of incubation at concentrations up to 100 pg-Fe per cell [122]. LHRH iron oxide nanoparticles coated with a silica shell specifically targeted and accumulated in MC-F7 human breast cancer cells *in vitro* [157]. Basically, the main purpose for targeted delivery of drugs or contrast agents is the improved specificity for a particular cell type, reduced requirement of the compound necessary to gain the desired effect, and the possibility to directly incorporate the desired compound into the target cells, and a sustained retention of the particles within the target cells. The design of nanoparticles carrying specific ligands reduces and avoids the uptake in non-target cells and tissue.

### LHRH and its Receptors

#### 6.4.1

#### The Ligand Luteinizing Hormone Releasing Hormone – LHRH

Luteinizing hormone releasing hormone (LHRH), also referred to as gonadotropin releasing hormone (GnRH), was purified 30 years ago and its isolation was honored with the Nobel Prize of Medicine that the laureates Schally and Guellerin received in 1977 for their discovery of peptide hormones in the brain.

LHRH is excreted from the arcuate nucleus of the hypothalamus into the pituitary gland in a pulsatile manner [165]. In gonadotrophic cells of the adenohypophysis, LHRH stimulates the release of luteinizing hormone and follicle stimulating hormone, which are released into the main body circulation and regulate the production of sex hormones (estradiol and testosterone) and, thereby, the function of normal reproduction in mammals, humans and mice. This relationship is called the pituitary/gonadal axis (Fig. 6.2). The pulsatile release of LHRH is crucial for maintaining its function on the pituitary/gonadal axis and ensuring the optimal function of reproductive organs and maintaining fertility [166–168]. Sustained administration of LHRH or its analogs to patients suppressed steroid hormone production and downregulated and desensitized the LHRH receptor in the pituitary [166, 167]. This observation was exploited for treatments of hormone-dependent cancers; steroid hormone suppression using Leuprolide, which binds to the LHRH receptor, stopped the release of testosterone and inhibited the proliferation of the cancers. Over the last 30 years more than a thousand LHRH agonists and

Fig. 6.2. Gonadal/pituitary axis and interaction of LHRH with gonadal function.

antagonists have been developed, and are used in the clinic to treat hormone-dependent cancers [169] (Table 6.3). The common mechanism of action is the ablation of hormones by administration of these pituitary acting antagonists. Suppression of gonadal steroid secretion reduced the growth of these hormone-dependent tumors (Fig. 6.2). Hormone ablation was considered to be the only mechanism of action for LHRH agonists, but recent identification of a second LHRH receptor and the expression of LHRH receptors in malignancies explained why LHRH also had a direct effect on the proliferation and metastatic behavior of cancers [12, 170–173].

In 1971, type I LHRH was isolated from the pituitary of pigs and its structure was revealed [174]. The gonadotropin hormone LHRH is also expressed in gonadal peripheral tissue like Leydig cells in the testes and ovarian cells as well as in numerous malignancies. The decapeptide LHRH is produced in numerous species with astonishing homology during evolution. To date 23 different forms have been identified with highly conserved sequences [170–181].

All these peptides consist of 10 amino acids and share at least 50% sequence identity, with the main differences occurring in amino acids 5–8 (Table 6.3) [170, 182–184]. The different isoforms of LHRH were named after the species of its isolation. Two different forms of LHRH coexist in vertebrates, LHRH I and LHRH II. LHRH I (mLHRH) has been isolated from the hypothalamus in pigs [174]; and

LHRH II (cLHRH) has been isolated from chicken [182] and from the forebrain of the teleost fish, the lamprey eel. LHRH III (lLHRH) has also been identified and characterized [183–185]. LHRH II has been conserved from fish to humans [170, 182–184]. In humans, LHRH II is synthesized in several extrapituitary tissues like kidney, bone marrow, and prostate at significant higher levels [186] and in the female reproductive tract such as placenta, endometrium, breast, ovary and granulosa cells [187–189].

LHRH hormones have manifold functions besides reproductive maintenance, including neuroendocrine (growth hormone release in fish), paracrine (placenta and gonads), autocrine (LHRH neurons, immune cells, breast and prostate cancer cells), neurotransmitter in central and peripheral nervous system (sympathetic ganglion, mid brain), energy and feeding behavior [175–178, 184, 190–194].

Direct effects of LHRH agonists and antagonists have been studied – most importantly, the antiproliferative effects of LHRH I on hormone-dependent and -independent tumor cells, including gonadal cancers like ovarian, endometrial, prostate and breast and non-gonadal cancers like melanoma. In endometrial, ovarian, breast and prostate cancers *in vitro* proliferation was inhibited by agonists and antagonists of LHRH I in a time and dose dependent manner [195–197]. Interestingly, the effects on LHRH agonists/antagonists seem to be different in tumor tissue of the reproductive tract, where LHRH antagonists have agonistic effects on the LHRH receptor type II [195]. Further functions of LHRH in gonadal malignancies and melanoma were antimetastatic, through effects on IGF-I, EGF and c-fos expression and antimetastatic-affecting matrix metalloproteinases, adhesion molecules, and plasminogen activator in prostate cancer cells [198].

#### 6.4.2

##### **Analogs of LHRH**

The highly conserved sequence of the amino (pGlu His Trp Ser) and carboxy (Pro Gly NH<sub>2</sub>) termini suggests that these amino acids are critical for receptor binding and activation. The amino terminus is involved in receptor binding and activation, whereas the carboxy terminus contains regions for receptor binding only. Structural changes in these particular amino acids created agonists and antagonists that had been clinically exploited for the stimulation of hormone production, for contraception and treatment of hormone-dependent cancers and diseases [170]. Substitution of amino acids at the amino terminal produced compounds with analogous antagonistic properties, including Cetrorelix and Ganirelix, which are currently marketed. Agonists on the market include Lupron, Zoladex, Sepprelin, Triptorelin and Buserelin (for sequences see Millar et al. 2004 [170]). Substitution of amino acid 6 by D-Gly enhances activity in the pituitary receptor [170] (Table 6.3). Table 6.3 lists amino acid sequences for various agonists and antagonists. Analogs of LHRH are applied for hormonal ablation, whereas antagonists (like Cetrorelix) seem to have antiproliferative effects on ovarian and endometrial cancers rather than the agonist Triptorelin.

## 6.4.3

**Receptors for LHRH**

LHRH affects the proliferation and metastatic potential of many cancers directly [171–173]. Autocrine/paracrine loops were identified and studied in breast cancer [199, 200], prostate cancer [201], ovarian cancer [202] and melanoma cell lines [172]. LHRH receptors not only are expressed in gonadal malignancies like prostate [4, 5, 203], breast [10], ovarian [204–208], endometrial cancers [26, 209], but have also been detected in several non-gonadal malignancies, such as laryngeal cancers [24] renal [28], pancreatic [15, 16], brain [29], melanoma [22, 27] liver [25], colon [13, 14, 210] and recently in non-Hodgkin's lymphoma [23] (Table 6.1). These findings suggest that there may be a connection between cancer and LHRH receptor expression. LHRH receptors are very widespread among malignancies rather than healthy tissues.

Consequently, LHRH seems to be a very appropriate candidate for specific targeting of malignancies. Most tumors overexpress LHRH receptors in much higher concentrations than normal tissue (where they can be entirely absent) [125, 211]. Non-malignant tissue of lung, liver, skeletal muscle, pancreas, other visceral organs and kidney express little or no LHRH receptors [11, 203, 212, 213].

Although LHRH-receptor transcripts detected in breast and ovarian cancers are identical to those in pituitary [214] the receptors may differ functionally. In binding studies [12], pituitary LHRH-receptors showed high affinity for agonists such as buserelin (nanomolar  $K_d$ ), whereas most LHRH-receptors in extrapituitary sites, including malignancies, have low affinity (micromolar  $K_d$ ) but show higher receptor capacities (Table 6.4).

For example, LHRH receptors were found in 57% of patients with pancreatic cancers and 67% in pancreatic inflammatory disease, compared with normal tissue with only 9% [16]. Pancreatic cancers showed low-affinity binding sites for LHRH in the membrane, and high-affinity binding sites in the nuclei [9]. In melanoma cells the LHRH receptor type I has high affinity/low capacity [172].

LHRH receptors have been cloned from mouse, rat, sheep, cow and human with an amino acid sequence homology of >85% [213–222]. The nucleotide sequence of LHRH receptors from breast, ovarian, endometrial and prostate cancers is identical to that of the pituitary receptor [5, 197, 213–215, 223–228].

The LHRH receptor belongs to the large superfamily of the seven-transmembrane domain receptors that bind G-proteins (G-protein binding receptors, GPBR) (Fig. 6.3) [229–232]. Typically, GPBRs contain a C-terminal cytoplasmic tail, which is lacking in the LHRH receptor type I. This C-terminal tail is phosphorylated by ligand binding and facilitates the binding of  $\beta$ -arrestins, G protein activation, desensitization and internalization of the receptor, and down-regulation via endocytosis and processing [233]. The internalization kinetics of LHRH-receptor type I [234] showed a 20-fold increase in uptake rate constants of the bound radioligand within 1 h compared with kinetics in wild-type TSH receptor, another member of the GBP receptor family (with cytoplasmic tail).

#### 6.4.4

#### Function–Signal Transduction Pathways

Signal transduction pathways activated by binding of LHRH to a tumor's receptor are quite different to the classical pituitary binding. The physiological significance of this remains under investigation (Fig. 6.4).

In the pituitary, binding of LHRH to its receptor (type I) initiates coupling to  $G_{\alpha q/11}$  binding followed by activation of phospholipase C (PLC), and hydrolysis

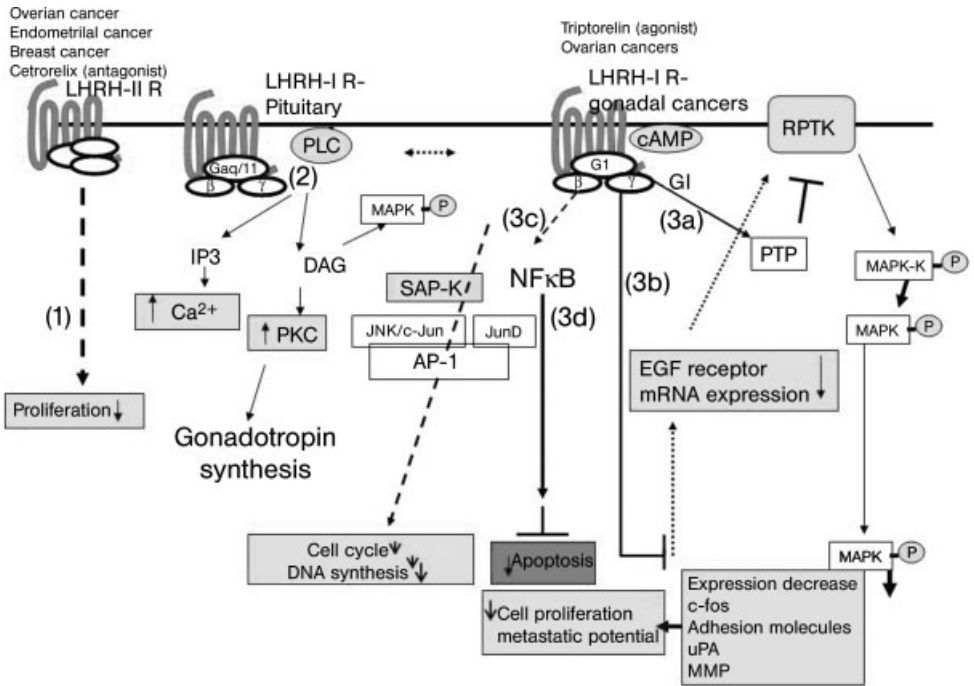

Fig. 6.3. Schematic of the human LHRH-receptor as an example of a seven-transmembrane receptor G protein binding receptor [170].

**Fig. 6.4.** Signal transduction pathways activated by LHRH-receptor binding in pituitary, gonadal and cancerous tissue. (1) Unknown signaling cascade leading to reduction of cell proliferation; (2) signal transduction pathway in pituitary for gonadal function; (3) signaling cascades for LHRH receptor I in malignancies: (3a) signaling resulting in decrease of cell proliferation

through MAP kinase pathway, (3b) signaling interferes with EGF receptor expression, (3c) signaling cascade that result in reduction of cell cycle and reduction of DNA synthesis, (3d) signaling cascade that reduces apoptosis. Abbreviations are defined at the end of this chapter. (Based on Ref. [207] with modification from Refs. [173, 206, 244, 245, 253, 281].)

of phosphoinositide to diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP3). These secondary messengers mobilize calcium from intracellular stores and activate PKC (protein kinase C) [235, 236]. LHRH also activates PLA2 (phospholipase A2), PLD and MAP-kinases (mitogen-activated protein), providing signals for gene expression for gonadotropin synthesis and secretion [235, 236]. The physiological function for this difference is unresolved.

Binding of LHRH to gonadal and receptors on cancer cells activates different signal transduction cascades. In malignant tissue, LHRH receptors have been suggested to regulate cell proliferation and the metastatic potential in tumors. LHRH receptor expression in tumors is associated with the phosphorylation of the epidermal growth factor receptor: the activated EGF receptor phosphorylates a protein corresponding to the LHRH receptor [237, 238]. Growth factor receptor expression can be reduced in the presence of LHRH most likely by phosphotyrosine phosphatase

tase (PTP), which in turn is connected to the G-protein  $\alpha_i$  in tumors [239, 240] (Fig. 6.4).

In cancer cells, LHRH receptor coupling occurred to multiple G proteins and the activation of multiple effectors has been reported. In prostate cancer cells, LHRH I binding facilitates the coupling of  $G\alpha_i$  protein [241], and human gynecological cancer coupling of  $G\alpha_q$  and  $G\alpha_i$  was demonstrated in ovarian and uterine cancer cells [20, 240].  $G\alpha_i$  coupling is prevalent in cancers, such as in ovarian [239, 240, 242], uterine leiomyosarcomas, uterine endometrial carcinomas and human prostate cancers [241]. Coupling to  $G\alpha_i$  protein is poorly understood and it is suggested that  $G\alpha_i$  activation underlies the antiproliferative effects of LHRH in cancers [240, 243].  $G\alpha_i$  coupling can be activated by both agonist and antagonists of LHRH, suggesting the involvement of an additional form of LHRH receptor distinct from the pituitary receptor type [239, 241]. Antiproliferative action in choriocarcinoma, benign prostate hyperplasia and human embryonic kidney cells, all of which express LHRH receptor type I, was demonstrated with agonists and some antagonists through activation of  $G\alpha_i$  coupling. The signal transduction resulted in activation of caspase and trans-membrane transfer of phosphatidylserine to the outer membrane, JNK and p38 [244].

In hormone-dependent tumors, binding of LHRH to its receptor decreased cyclic AMP levels, which is followed by an activation of phosphotyrosine phosphatase (PTP). This event interferes with the mitogenic signal transduction pathways, which normally activate growth factor cascades such as MAP kinase. The transcription is affected downstream, which include genes such as matrix metalloproteinases, urokinase plasminogen activator (genes for metastatic potency), c-fos (a protooncogene), and cell adhesion molecules. The overall result is reduction of proliferation and interference with the metastatic potential of the cancer cells.

Antagonistic LHRH analogs inhibited  $G\alpha_q/11$ -based signaling, suggesting that their antiproliferative effect on reproductive tumors could be dependent on ligand-selective activation on a  $G\alpha_i$  form of LHRH-receptor I through stress-activated protein kinase pathways (SAP-K) [244].

In hormone-dependent and -independent prostate cancers the antiproliferative effects of LHRH I were attributed through EGF and IGF receptor reduction initiated by different molecular mechanisms, dependent on hormone requirements of these types of cancer. In hormone-dependent prostate cancer cells LHRH I counteracts the stimulatory effects of epidermal growth factor (EGF) by decreasing the EGF receptors and insulin-like growth factors (IGF) [245, 281].

In breast, ovarian and endometrial cancers LHRH can bind to either  $G\alpha_q$  or  $G\alpha_i$ , the latter inhibiting proliferation. Emons et al. have found that endometrial and ovarian cancer cells PTP (phosphotyrosine phosphatase) are activated by LHRH/LHRH-receptor action, which counteracts the phosphorylation of EGF receptors, affects the growth factor signal transduction cascade (MAP-K, c-fos), and interferes with cell proliferation [239, 246–248] (Fig. 6.4). Positive correlation between EGF receptor activation and LHRH receptors were observed in various LHRH receptor expressing cancers [6, 24]. Consequently, EGF receptors can be downregulated to-

gether with LHRH receptors through LHRH-analogs or LHRH-targeting treatments [6, 249–251].

LHRH can influence apoptosis in cancer cells through activation of nuclear factor  $\kappa$ B [252, 253]: LHRH agonists can activate the cJun N-terminal kinase/activator protein 1 (AP-1) pathway, protein kinase C (PKC) or mitogen-activated protein kinase (MAPK/ERK) [20]. In contrast, when the antagonist cetorelix was tested in ovarian and endometrial cancer cells the antiproliferative effects were not mediated through LHRH receptor type I, suggesting binding to, therefore, LHRH receptor type II. The signal transduction pathway of LHRH II is still unknown [20].

#### 6.4.5

#### LHRH Receptor-mediated Uptake

Extensive internalization and downregulation of the receptor via endocytosis and processing has been studied and described in detail for the pituitary receptor [233]. Receptor internalization is highly influenced by the second intracellular loop of the seven-transmembrane receptor [254].

The COOH-terminal tail, which is lacking in the pituitary LHRH-receptor, determines the internalization and the recycling kinetics and causes resistance of the receptor to desensitization. Several examples of this observation have been reported. For example, deletion of the cytoplasmatic tail in TSH receptors decreased the internalization [255]. The chicken LHRH receptor showed rapid internalization that was dependent on the cytoplasmatic tail [256]. As mentioned earlier the pituitary LHRH receptor (type I) lacks the cytoplasmatic tail; however, the receptor still internalized and recycled, and is resistant to desensitization [257, 258]. These turnovers are much slower than with other GPCRs: While angiotensin II internalized 50–60% [259] and GRP receptors up to 80% [260, 261] of their agonists within 1 h, the LHRH receptor type I internalized only 26% [254]. This agrees with results for the LHRH-II receptor in the marmoset and rhesus monkey containing a C-terminal, cytoplasmatic tail that facilitated a more rapid internalization [262, 263].

Receptor-mediated endocytosis can be described with the four-compartment model [264] that includes (1) receptor endocytosis from cell surface to endosome, (2) recycling from endosome to plasma membrane, (3) receptor movement from endosome to lysosome for degradation, and (4) delivery of *de novo* synthesized receptors to the plasma membrane (Fig. 6.5). The classical pathway involves GPCR kinases,  $\beta$ -arrestin, clathrin-coated pits and GTPase dynamin.

As a representative mode for receptor internalization and recycling the process is described here for the type I receptor. Despite the lack of cytoplasmatic tail the LHRH receptor type I displays distinct characteristics described for other GPCRs that internalized via a clathrin-dependent mechanism, appeared to be independent of  $\beta$ -arrestin levels and recycled through an acidified endosomal compartment (Fig. 6.5).

LHRH incubation showed internalization of the ligand–receptor complex and redistributed into vesicular compartments [234]. The internalization was tempera-

Fig. 6.5. Receptor-mediated endocytosis and recycling of the receptor.

ture and time dependent and was suppressed at 4 °C; internalization was observed after 20 min and reached its maximum after 1–2 h.

The uptake mechanisms through LHRH receptors are cell type dependent and dependent on the type of LHRH receptor. In HeLa cells, internalization of the receptor was independent of dynamin; clathrin mediation was involved in the internalization of the receptor [265]. Receptor recycling to the plasma membrane in HEK 293 cells (human embryonic cells) was observed as early as 15 min and completed after 1 h. The intracellular pool of receptors was decreased by 68% due to reappearance of receptors at the plasma membrane. The reappearance of plasma membrane receptors was clearly due to recycling of the receptor rather than by *de novo* synthesis. Recycling of the receptors caused a loss of 10% of the initially detected surface receptors. When kinetics of LHRH and TSH (retained cytoplasmatic tail) receptors were compared, significantly lower rates were determined in HEK 293 cells for the endocytotic rate (16-fold), recycling (2.5-fold) and degradation rates (30-fold) for the LHRH receptor [234].

#### 6.4.6

#### LHRH Receptor Type II

The existence of two LHRH isoforms in human tissue led to a search for a second LHRH receptor in human tissue. These studies were supported by the following

observations: Effects on LHRH agonists/antagonists were different in tumor tissue of the reproductive tract, where LHRH antagonists have agonistic effects on the LHRH receptor type II. A recent study on human endometrial cancers and ovarian cancer cell lines demonstrated that the proliferation of these human cancer cells was dose and time dependent, but independent of the LHRH receptor I, suggesting the existence of a second LHRH receptor [206]. LHRH type II has been found in ovarian cancer cell lines [266] and had antiproliferative activity. In human malignant tumors *in vitro*, LHRH I agonists and antagonists inhibited the cell proliferation in a dose and time dependent manner. LHRH type II has antiproliferative effects on gynecological cancers to a much higher efficacy than triptorelin [267]. RTPCR and Southern Blot analysis showed the expression of LHRH receptor II mRNA in ovarian and endometrial cancer cell lines [266]. In addition, these cell lines responded to LHRH II with reduction in proliferation, to a much higher degree than with LHRH I or triptorelin [267]. In breast cancer cells the antiproliferative effects of Triptorelin (a LHRH-antagonist) and a LHRH II analog inhibited epidermal growth factor induced signal transduction and restored sensitivity to tamoxifen [313]. Recently, in a clinical study, primary and metastatic stromal sarcoma tested positive for LHRH receptor I and II expression using immunohistochemistry methods [209]. Interestingly, recurrent tumors had the highest levels in LHRH receptor I and II expression, suggesting a link between malignancy and LHRH receptors types [209].

Studies on human prostate cancer cells *in vitro* showed the existence of an 80-kDa protein that specifically bound to LHRH II in addition to the conventional LHRH I receptor. In this study, efficacy and function was studied and the authors found that a novel LHRH II antagonist completely inhibited Ca increase and induced, at high concentrations, cell death through apoptotic processes [268].

In ovarian and endometrial cancers, LHRH II is a more potent inhibitor for cell proliferation [252], receptors of type II have a higher sensitivity to LHRH II ligand [269, 270], and LHRH agonists and antagonists inhibited tumor growth [272]. Type II LHRH receptor has been cloned from monkeys and was highly selective to LHRH II [212, 263, 271]. To date, a functional form of the LHRH receptor type II has not been found in humans, although several observations suggest its existence. Therefore, it is referred to as a putative receptor. Millar found that the type II receptor was more widely distributed: mRNA for LHRH receptor-type II was found in numerous pituitary, brain, mammary glands, uterus, testes, prostate, seminal vesicles, thyroid, heart, pancreas and adrenal tissue, including ovarian and endometrial cancers [193, 212, 242, 268, 273]. In prostate cancer, a novel LHRH II binding protein was detected recently [268], suggesting the existence of a type II receptor in prostate cancer cells. In human pituitary and brain, immunoreactivity to the LHRH receptor type II was demonstrated [212].

Humans may be particularly unusual with respect to the LHRH control of their reproductive axis in that they possess two distinct LHRH precursor genes, on chromosomes 8p11-p21 and 20p13, but only one conventional LHRH receptor subtype

(type I LHRH receptor) encoded within the genome, on chromosome 4. A disrupted human type II LHRH receptor gene homologue is present on chromosome 1q12. In humans, on chromosome 1 and 14 in various tissues a gene for the LHRH receptor II was found, which is not expressed because it contained a premature stop codon [275, 276]. Evidence in support of this concept is available following the characterization of the chromosomal loci encoding the human type II LHRH receptor homologue, a rat type II LHRH receptor gene remnant (on rat chromosome 18) and a mouse type II LHRH ligand precursor gene remnant (on mouse chromosome 2) [277]. The lack of the C-terminal tail causes the type I LHRH receptor to be slowly internalized and to be resistant to desensitization [257, 258]. In contrast, type II LHRH receptors are rapidly internalized and desensitized, contain the c-Terminal tail, and activated a different signal transduction cascade [257, 278]. The LHRH type II specifically induces an intracellular  $Ca^{2+}$  increase that was inhibited by triptorelix in prostate cancers [268]; LHRH receptor type II was found in monkeys, prostate cancer cells show a  $G_{\alpha i}$  linked activation signaling cascade [241]. In ovarian cancer the LHRH-receptor II coupled to the  $G_{\alpha q}/11$  and activated extracellular signal regulated kinase (ERK1/2), but differs in activating p38 and mitogen-activated protein (MAP) kinase [19].

The above-summarized results and the fact that endometrial, ovarian, breast and prostate cancer cells have two types of LHRH binding sites (low- and high-affinity/low- and high-capacity) indicate the existence of a second LHRH receptor type. Only the high-affinity/low-capacity receptor type resembles the LHRH receptor type I form of the pituitary. There are reasons to believe that the low affinity binding site on these cancer cells is the putative LHRH receptor II. mRNA for the LHRH receptor type II is expressed in human endometrial and ovarian cancer cells. LHRH II was more potent in its antiproliferative effect than LHRH I agonists [19]. Leung et al. found similar results in ovarian cancers [273]. In pancreatic cancers the low-affinity receptor was located in the cell membrane, whereas the high-affinity receptor was in the nuclear membrane [9] (Table 6.4).

In summary, LHRH is a most appropriate ligand for targeting cancers, as there are receptors overexpressed in gonadal tissue, multiple cancers and pituitary. In addition, the LHRH receptor signal transduction pathway in tumor cells is different to normal cells in that the classical PLC/PKC pathway from pituitary is not activated by LHRH binding to a LHRH receptor in a tumor cell; multiple G protein subgroups can be activated. The LHRH binding activates signals to mitogenic signal transduction pathways related to growth factor receptors and tyrosine kinase activities as well as the activation of antimetastatic signals [247, 281].

The expression of LHRH II in malignant cells and tumors could be exploited by targeting even more specifically malignancies, increasing uptake through activation of tumor-specific signal transduction cascades and improving the intracellular delivery of nanoparticles conjugated with LHRH to highest efficiency.

The next section reviews the use of nanoparticles linked to LHRH for magnetic resonance imaging, treatment and drug delivery, with emphasis on specific properties of the *in vivo* use of these nanoparticles.

## 6.5 LHRH-bound Magnetic Nanoparticles

### 6.5.1 Synthesis and Characterization

The nanoparticles referred to here are superparamagnetic iron oxide nanoparticles (SPIONs) that were fabricated, by wet chemical synthesis, with amine groups on their surface, which facilitated the binding of LHRH through carbodiimide activation. The binding of LHRH or Hecate to SPIONs was confirmed by FTIR (Fourier-transformation infrared) spectroscopy and HPLC analysis. The SPION surface was saturated by the LHRH peptide, as FTIR spectral analysis of peptide bound magnetite nanoparticles revealed the absence of characteristic bands of  $-\text{NH}_2$  ( $3200$  and  $1625\text{ cm}^{-1}$ ) present in unbound nanoparticles [297, 300]. The LHRH-SPIONs were monodisperse under transmission electron micrographs and had an average diameter of  $10\text{--}20\text{ nm}$ . Both free SPIONs and LHRH-SPIONs retained the cubic spinel structure. Moreover, the particles remained superparamagnetic, regardless of binding to the ligand (Fig. 6.6). Unconjugated SPIONs showed a higher saturation magnetization than LHRH-SPIONs ( $M_s = 72.1$  compared with  $30.6\text{ emu g}^{-1}$ ). The coercivity for LHRH-SPIONs was greater than for SPIONs alone (Fig. 6.6). Zeta potential measurements revealed that SPIONs were positively charged ( $\zeta = 28.5 \pm 1.93\text{ mV}$ ), whereas LHRH-SPIONs were almost neutral ( $\zeta = -2.2 \pm 0.58\text{ mV}$ ). Similar values were reported by Shieh et al. [301] for nanoparticles of similar surface chemistry ( $\zeta = 23.3\text{ mV}$ ). Magnetic data were calculated per g of powder of both SPIONs and LHRH-SPIONs.

In another study LHRH conjugated nanoshells were prepared for treatment with hyperthermia. To increase the iron particle concentration within the tumor tissue,

**Fig. 6.6.** (A) TEM micrograph of LHRH-SPION nanoparticles. Inset: electron diffraction pattern. (B) Hysteresis and saturation magnetization at 300 K for LHRH-SPIONs (dashed line) and SPION nanoparticles (solid line).

Fig. 6.7. Nanoclinics for hyperthermia treatment [157].

nanoparticles were decorated with LHRH to target the cancer cells and increase the cellular accumulation. Bergey et al. have developed a specific targeting device [157]. The particle consisted of a silica shell (7 nm thick) that housed inside a magnetic core of  $\text{Fe}_2\text{O}_3$  (18 nm diameter), a two-photon optical probe and, on the outside, carried the ligand LHRH (DLys6) as targeting moiety; the optical probe served as a tracking device. The final particle diameter ranged between 20 and 50 nm – small enough to diffuse into tissue without destroying the cells. The ligands were covalently attached to the silica surface through spacer molecules (Fig. 6.7). In this nanoclinic, the ligands consisted of an analog of LHRH that has higher binding affinity to the LHRH receptor due to exchange of amino acid 6 into D-Lys.

### 6.5.2

#### Treatment using Hyperthermia

Tumor cells are more sensitive to temperatures above  $42^\circ\text{C}$  than normal cells [282, 283] and can be destroyed by increasing locally the temperature to  $41\text{--}42^\circ\text{C}$  for 30 min [284–287]. Magnetic particles generate heat when exposed to an alternating magnetic field (AMF) by hysteresis loss [287–289]. These exposures require high power to elicit heat.

The increase of temperature occurs during the thermal loss resulting from re-orientation of the magnetism of the magnetic material with low electrical conductivity [288]. The size of the magnetic particle, which can be controlled by appropriate synthesis methods, determines the heating potential, as nanoparticulate size compared with micro size and degree of dispersion reduces the required AC power [290, 291]. Specific absorption power rates (SAR) have been determined in suspensions of magnetite nanoparticles of various size and coating. SAR of dextran ferrites were  $180\text{--}210\text{ W (g-Fe)}^{-1}$  (120 nm), sonicated dextran ferrites ranged from 12 to  $240\text{ W (g-Fe)}^{-1}$ , uncoated ferro-suspension  $0\text{--}45\text{ W (g-Fe)}^{-1}$  (6–10 nm). Ultrasonification caused dispersion of agglomerated particles and can destroy in

part the dextran coating. Carboxymethyldextran magnetite particles (130 nm) had an SAR of  $90 \text{ W (g-Fe)}^{-1}$ . SAR data allow an estimate of the amount of particles necessary to heat human tissues [292, 293]. Ferrofluids directly injected into tumor tissue destroyed tumor cells after exposure to the magnetic field [289]. This effect was highly specific and cell destruction was only observed in cells containing the magnetic particles [294]. This process is known as magnetocytolysis.

Similar to the diagnostic magnetic resonance imaging approach, an increase in intracellular particle number and concentration increases the efficacy of tumor destruction through hyperthermia.

*In vitro*, LHRH expressing human breast cancer cells, MCF-7, and the receptor negative ovarian cancer cell line were incubated with nanoclinics linked to LHRH or nanoclinics alone. The LHRH-nanoclinic uptake was time dependent, and nanoshells accumulated within 30 min. In contrast, a human ovarian cancer cell line that did not express LHRH receptors did not incorporate LHRH-nanoshells.

LHRH decorated nanoparticles were eight times more potent in destroying MCF-7 cells. The number of lysed cells was linearly dependent on the magnetic field exposure time and the concentration of nanoparticles. The same nanoshells without LHRH resulted in comparable cell lysis in MCF-7 and UCI 107 cells. Up-regulation of LHRH receptors through EGF increased magnetocytolysis two-fold, whereas downregulation of receptors decreased the treatment effect 2.5-fold.

Several crucial observations were made that support the high specificity of these ligand-conjugated nanoclinics: (a) the LHRH-nanoclinics specifically entered the receptor-expressing MCF-7 cells; (b) nanoclinics without the ligand only incorporated particles to a significantly lower amount and were independent of the cell type used; and (c) LHRH-receptor positive MCF-7 cells incorporated higher amounts of LHRH-nanoclinics when LHRH receptors were upregulated through EGF, and lower amounts after downregulation of receptors. These data showed the importance of highly selective nanoclinic uptake.

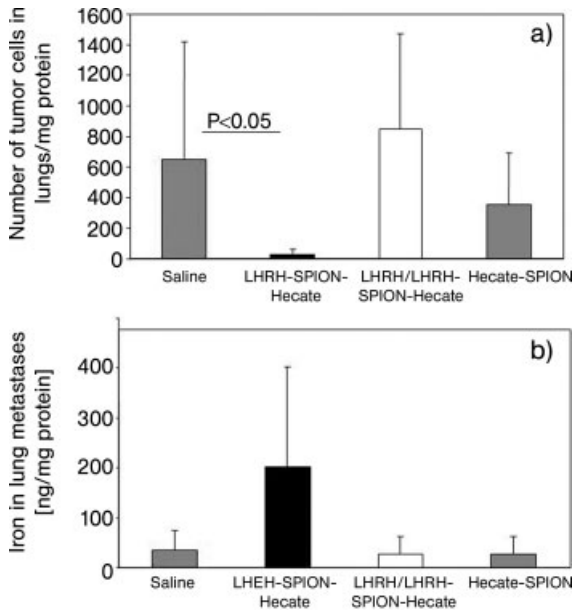

These studies demonstrated specific targeting of cancer cells and incorporation of magnetic nanoparticles conjugated to LHRH and showed *in vitro* accumulation of magnetic nanoparticles through receptor-mediated endocytosis. These results suggest that specific targeting can increase the efficacy of hyperthermic therapy and keep other organs unaffected.

### 6.5.3

#### Treatment using Lytic Peptides

##### 6.5.3.1 Destruction of Metastases through LHRH-SPION-Hecate

Recent studies on LHRH-SPIONs conjugated with Hecate, a membrane destroying peptide [6, 295, 315–317], resulted in tumor destruction and elimination of lung metastases in nude mice bearing LHRH receptor expressing MDA-MB-435S.luc breast cancer xenografts. Tumor bearing mice were injected once a week for 3 weeks with LHRH-SPION-Hecate conjugates in the presence and absence of LHRH, SPION-Hecate or saline. At necropsy tumor cells were determined in lung homogenates, and iron contents were also determined. In mice treated with

**Fig. 6.8.** LHRH-SPION-Hecate destroys lung metastases in MDA-MB-435S.luc tumor-bearing mice; co-injection with LHRH or Hecate-SPIONs does not destroy lung metastases (A). Iron is detectable in targeted treatment groups after 1 week (B).

LHRH-SPION-Hecate, tumor cell death occurred in primary tumors and lung metastases. Unconjugated SPION Hecate did not reduce the number metastatic cells in lungs (Fig. 6.8) or destroy the primary tumors when compared with saline controls. Iron oxide particles in the treated organs were still detectable 1 week after injections, suggesting that LHRH-SPION-Hecate may be useful in imaging and treating the cancer, most importantly serving as a monitoring tool for treatment response [318].

#### 6.5.4

#### Detection of Tumors and Metastases

##### 6.5.4.1 Targeted Delivery of SPION Contrast Agents for MRI

The development of iron oxide nanoparticles as a contrast agent for MR images requires high accumulation of nanoparticles in the cells of the target tissue. Relaxation times in the acquisition of magnetic resonance imaging, i.e., the contrast of the image, is increased with larger particles [151]. Compartmentalized particles and clusters have larger relaxation rates than free dispersed particles [152]. Highly efficient receptors were required on human breast cancer cells to increase the iron accumulation within the cells. Furthermore, the particles were designed to provide

target specificity, a long circulation time and low opsonization to escape macrophage recognition.

The following outline describes the development of LHRH-targeted nanoparticles to human breast cancer cells. The increase of cellular accumulation of iron oxide nanoparticles in LHRH receptor positive human breast cancer cells and their metastases iron oxide nanoparticles were developed, which carried LHRH as targeting moiety. Human breast cancer cells overexpress LHRH receptors. Recently, the targeted destruction of primary tumors and metastases had been shown in human breast cancer cells, MDA-MB-435S.luc, both *in vitro* and *in vivo* [8, 295–299].

#### 6.5.4.2 *In Vitro* Studies on Receptor-targeted LHRH-SPION Uptake

The accumulation of ligand conjugated and unconjugated SPIONs was compared in MDA-MB-435S.luc, TM4 mouse Sertoli cells to determine whether the iron accumulation was specific for individual receptors on the target cells (Fig. 6.9A). In

**Fig. 6.9.** (A) Iron uptake from SPIONs, LHRH-SPIONs and LHRH-SPIONs plus LHRH in LHRH receptor expressing breast cancer cells (MDA-MB-435S.luc) and receptor

negative mouse Sertoli cells (TM4). (B) Saturation kinetics in MDA-MB-435S.luc cells. (C) Incorporation of SPIONs or LHRH-SPIONs into THP-1 macrophages [297].

LHRH receptor overexpressing human breast cancer cells LHRH-SPIONs accumulated quickly and reached an intracellular iron concentration of  $452 \text{ pg cell}^{-1}$  whereas free SPIONs reached  $51 \text{ pg cell}^{-1}$  as the highest concentration (Fig. 6.9B). Blocking of the LHRH receptor significantly prevented LHRH-SPION uptake, suggesting that specific receptor-mediated uptake was the mechanism of uptake. Maximal concentrations within the breast cancer cells were reached within 1 h, whereas low temperature ( $4 \text{ }^{\circ}\text{C}$ ) prevented receptor-mediated iron uptake to less than  $1.1 \text{ pg cell}^{-1}$ . The mouse Sertoli cell line showed, at all concentrations, iron uptake between 29 and  $37 \text{ pg cell}^{-1}$  irrespective of LHRH conjugation (Fig. 6.9A).

Most importantly, macrophages incorporated significantly less LHRH-SPIONs ( $85 \text{ pg cell}^{-1}$ ) than free SPIONs ( $246 \text{ pg cell}^{-1}$ ) (Fig. 6.9C), suggesting that LHRH provided a coating as well a targeting moiety. This was expected as LHRH-SPIONs were neutral, while SPIONs were positively charged. Others have shown that neutral nanoparticles are less easily incorporated by macrophages than are charged nanoparticles, predicting an increased circulation time *in vivo* [86, 297–299].

TEM sections from human breast cancer cells *in vitro* showed that LHRH-SPION accumulation in the breast cancer cells resulted in cluster formation in the cytosol and the nucleus. In contrast, no iron particles were observed in cells incubated at  $4 \text{ }^{\circ}\text{C}$  [297–299]. Compared with other ligand conjugated nanoparticles LHRH-SPION uptake was highly efficient and resulted in the highest iron contents in LHRH receptor expressing cancer cells. Dextran-coated nanoparticles  $<10 \text{ nm}$  in diameter resulted in  $0.9\text{--}1.3 \text{ pg-Fe per cell}$  [120], whereas Her2/neu targeting of the same cells increased the uptake by a factor of 2.6 pg-Fe per cell. Folate-linked iron oxide nanoparticles reached a maximal level of  $75 \text{ pg-Fe per cell}$  in BT20 breast cancer cell incubation [117]. CD-8 conjugated crosslinked iron oxide nanoparticles were incorporated into T cells after 1 h of incubation at concentrations up to  $100 \text{ pg-Fe per cell}$  [122]. The targeted up-take of nanoparticles in cancer cells has been demonstrated for ferrofluids: dextran-coated Monocrystalline Iron Oxide Nanoparticles (MIONs) linked to transferrin resulted in a 10-fold increase in accumulation in rat glioma cells compared with free MIONs [111]. In contrast, human fibroblasts did not incorporate transferrin-linked MIONs; the particles were only bound to the membranes, but not internalized [302]. LHRH iron oxide nanoparticles coated with a silica shell specifically targeted and accumulated in MC-F7 human breast cancer cells *in vitro* [157].

Anionic maghemite chelate dimercaptosuccinic acid particles were incorporated in macrophages at up to  $6 \text{ pg-Fe per cell}$ , and in HeLa cancer cells up to  $40 \text{ pg-Fe per cell}$ , and showed saturation kinetics [152]. HIV-1 tat dextran-coated SPIONs were incorporated into CD34 cells up to  $30 \text{ pg cell}^{-1}$  [303, 304].

#### 6.5.4.3 *In Vivo* Studies on Receptor-targeted LHRH-SPION Uptake

When SPIONs and LHRH-SPIONs were injected intravenously into human breast cancer (MDA-MB-435S.luc) xenograft-bearing nude mice, up to 59.1% of iron particles accumulated in tumors of LHRH-SPION injected mice compared with 8% in groups injected with SPIONs (Fig. 6.10A, B). Lung tissue from tumor-bearing

**Fig. 6.10.** Relative iron distribution in human breast cancer xenograft-bearing mice after injection of SPIONs and LHRH-SPIONs. (A) Iron contents in organs and tumors after LHRH-SPION injection, (B) after SPION injection (100% = 5 mg-Fe per mouse). TEM micrographs (C) from lung section with metastases after LHRH-SPION injection and (D) after SPION injection [297].

mice, which contained significant numbers of metastatic breast cancer cells, accumulated up to 20% LHRH-SPIONs and only 2% SPIONs (Fig. 6.10A, B). Neither lungs nor livers of normal mice accumulated LHRH-SPIONs, suggesting that LHRH-SPIONs were not incorporated into macrophages *in vivo* as predicted from low *in vitro* macrophage uptake (Fig. 6.10). LHRH-SPIONs were either incorporated into tumors or metastatic cells or they were excreted as observed in normal mice. The high accumulation of SPIONs in the livers suggested that these particles were incorporated by macrophages and transported therein to the liver, where they accumulated to 55%.

Unconjugated SPIONs accumulated to 8% in tumors ( $p < 0.00006$ ), 55% in the livers, ( $p < 0.00006$ ), 2% in lungs, ( $p < 0.031$ ), and 3.3% in kidneys, ( $p < 0.33$ ) (Fig. 6.10B).

When lung sections from LHRH-SPION- and SPION-injected mice were stained for iron, only lungs from mice injected with LHRH-SPIONs tested positive [298, 299]. The iron contents of lungs correlated directly with the number of metastatic cells (Fig. 6.11) [297]. The average iron content per lung cancer cell was calculated to be  $77.8 \pm 23.5$  pg Fe per metastatic cell in lungs. Lung sections from tumor-bearing mice showed iron clusters in groups after LHRH-SPION treatment. No iron clusters were observed in SPION-injected groups (Fig. 6.10C, D).

The specific targeting of tumors and metastases and the low accumulation in the livers seemed to be a combination of ligand conjugation and physical characteristics of the LHRH-SPIONs. The LHRH-SPIONs had a sufficiently long circulation

Fig. 6.11. Linear relationship between the metastatic cells in lungs and the iron content in tissue [297].

time, similar to albumin-coated particles with neutral zeta potential [305]. Most important, neutral particles were less prone to accumulate in liver (20%) [86], because they showed the lowest opsonization and were, therefore, not recognized by macrophages of the RES. Coating nanoparticles with short peptides increased the colloidal stage and decreased the non-specific binding to fibronectin, an effect that was similar to PEG coating [274, 306]. It is highly likely that LHRH served as coating itself, considering the low liver accumulation of LHRH-SPIONs in normal (non-tumor) bearing mice.

The biodistribution and circulation time of contrast agents is determined by several factors, such as size, charge, and surface chemistry [84, 85]. Nanoparticles of hydrodynamic size greater than 50 nm, and hydrophilic surface and high charges are eliminated from the circulation within minutes by phagocytotic cells of the reticulo-endothelial system (RES). Therefore, the accumulation of such particles was observed in liver, spleen, bone marrow, and were less likely to accumulate in other organs such as breast tissue, lymph nodes, intestinal tissue or gonads [301, 307, 308]. Coating iron oxide nanoparticles of <50 nm diameter with poly(ethylene glycol) (PEG), sialic acid, neuraminic acid, mucin or glycoporphin increased the circulation time [309]. Dextran-coated nanoparticles of <50 nm were detected to 82% in the livers of rats after intravenous injection [310]. Ligand decoration with LHRH was highly superior in increasing SPION concentration in target cells lowering liver accumulation. Other *in vivo* studies delivered PEG-coated particles decorated with carcinoembryonic antigen, which resulted in 1% tumor, 54% liver and 22% spleen accumulation [309]. Transferrin-decorated MION particles accumulated in rat glioma cells, passing the blood–brain barrier, and were detectable in xenografts [311, 312].

#### Subcellular Distribution of LHRH and SPIONs in Tissues, Metastases and Tumors

The subcellular distribution of LHRH-SPIONs in tumors showed clusters of sub-microsize, which were absent in tumors of mice injected with SPIONs alone [296].

TEM images of the MDA-MB-435S.luc tumors, lungs, liver and kidneys confirmed previous observations. Sections containing LHRH-SPIONs were compared with those of mice injected with unconjugated SPIONs [296–298]. Iron oxide nanoparticles were detected in the cytoplasm of the tumor cells. The regions containing the nanoparticles were identified as iron in energy dispersive X-ray spectroscopy analysis; large nanoparticle clusters were formed in the breast cancer xenografts of nude mice injected with LHRH-SPIONs, whereas single nanoparticles were observed in the tumors of the mice injected with SPIONs. At higher magnification these clusters appeared to be monodisperse [296–298]. Similar observations were made in lung sections of tumor-bearing mice; lungs from mice injected with LHRH-SPIONs with metastases had iron particle clusters in their metastases (Fig. 6.10C). These clusters were absent in lung metastases of mice with SPION injections (Fig. 6.10D) [296–298]. TEM images from livers showed high iron accumulation in SPION injected groups, and no visible iron accumulation in kidneys of either LHRH-SPION or SPION injected groups [296].

In summary, the LHRH-SPION particles accumulated at high concentrations in cells expressing functional LHRH receptors. Neutral particles are less prone to accumulate in the liver due to escape from macrophages of the RES. LHRH-SPIONs were poorly recognized and incorporated into macrophages, which improves iron accumulation in tumors and metastases. Metastases incorporate specifically LHRH-SPIONs. Iron cluster formation suggests a good possibility to increase the relaxation times during MRI. LHRH has a dual function: coating and targeting.

**Enhancement of Magnetic Resonance Images in Tumors and Metastases** Preliminary magnetic resonance images of tumors and lung sections containing metastases have also been obtained from the 7 T animal MRI and were analyzed using acquisition of multiple orders of intermolecular multiple-quantum coherence (iMQC) in a multi-CRAZED sequence. The multi-CRAZED sequence is an imaging pulse sequence that consists of  $90^\circ$ -{delay  $\tau$ }-{gradient pulse, area  $GT$ }- $\Theta$ -{gradient pulse, area  $nGT$ }-{delay  $TE$ }- $180^\circ$ -{delay( $TE-n\tau$ )}acquisitions, that uses the difference in echo timing to acquire multiple echoes and results in up to five echoes that are separated by  $\tau$ , described as DQC ( $+/-2$  quantum coherence), SQC ( $+/-1$  quantum coherence) and ZQC (zero-quantum coherence) (Fig. 6.12 [314]). Tumors and lung sections containing metastatic cells have been analyzed using different acquisition modalities.

The images in Fig. 6.13(A, B) were obtained from tumor pieces of 1–2 cm of tumor samples with LHRH-SPION nanoparticles, while the images at the bottom correspond to 1–2 cm of tumor sample from mice, injected with saline. Due to the heterogeneity of tumor tissue, significant contrast differences are needed to reveal the presence of tumors or the attachment of the magnetic nanoparticles. Hence, classical MRI, such as the T2 images shown in Fig. 6.13(A) [314], did not reveal significant contrast differences between the tumors with or without LHRH-SPIONs, i.e., they did not overcome tissue heterogeneity. Increased contrast was observed in the T2\* image acquisition. Multi-CRAZED images show the contrast for each

**Fig. 6.12.** The multi-CRAZED sequence uses its echo timing to acquire multiple echoes that result in up to five echoes that are separated by  $\tau$ , described as DQC ( $\pm 2$  quantum coherence), SQC ( $\pm 1$  quantum coherence) and ZQC (zero-quantum coherence) [314]. The +SQC (+1 or single-quantum coherence) and MSQC ( $-1$  or single-quantum coherence)

images have primarily conventional contrast; the DQC ( $+2$ -quantum), ZQC (0-quantum) and MDQC (2-quantum) coherences have contrast from subvoxel variations in magnetization density or resonance frequency. Additional gradient pulses permit image acquisition in the standard way (single-line acquisition shown here) [314].

of the five images and resulted in enhanced contrast in LHRH-SPION-containing tumors for DQC and ZQC images (Fig. 6.13C).

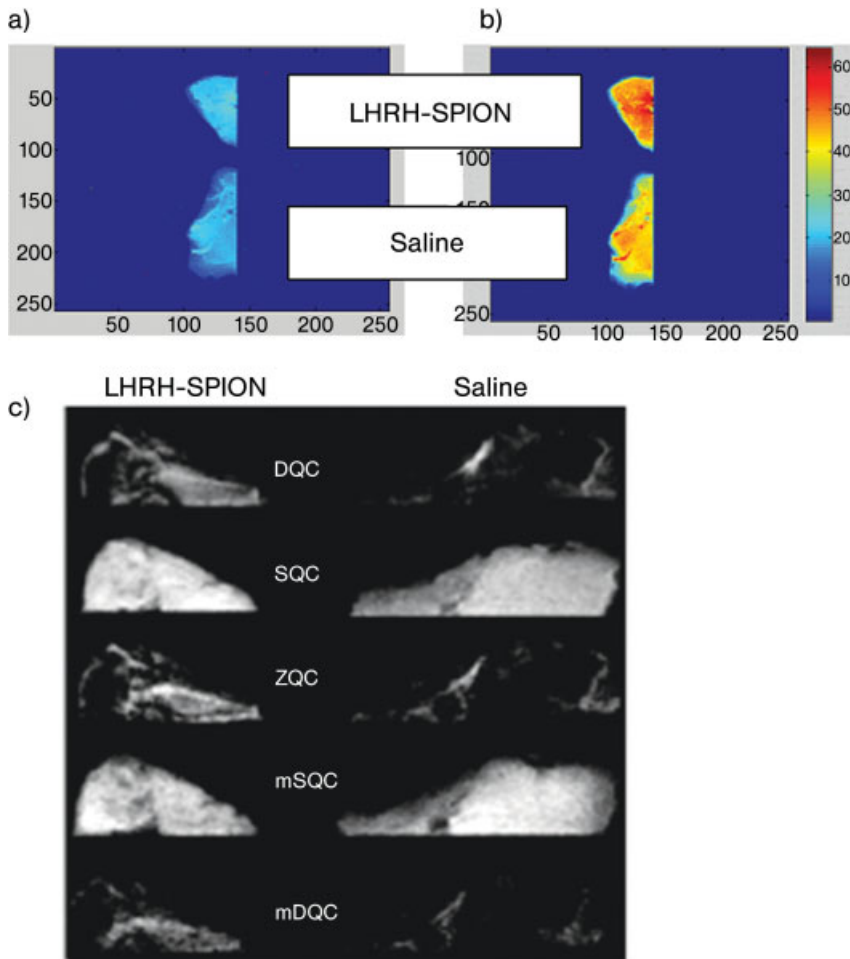

Similar results were obtained with sections from lungs containing metastases from mice injected with LHRH-SPIONs or saline (Fig. 6.14 [319]).

This may be due to the increased concentration of the LHRH particles and formation of clusters, as shown in the TEM image in Fig. 6.10(C). Such particle clusters should give rise to increased contrast due to increased magnetic moments, and their effects on the surrounding water molecules [314].

## 6.6

### Future Outlook

In summary, LHRH is a most appropriate ligand for targeting cancers, as there are receptors overexpressed in gonadal tissue, multiple cancers, their metastases and pituitary. In addition, the LHRH receptor signal transduction pathway in tumor cells is different to normal cells in that that the classical PLC/PKC pathway from the pituitary is not activated by LHRH binding to a LHRH receptor in a tumor cell, and multiple G protein subgroups can be activated. The LHRH binding activates signals to mitogenic signal transduction pathways related to growth factor receptors and tyrosine kinase activities as well as the activation of antimetastatic sig-

# Carbon Nanotubes in Cancer Therapy and Diagnosis

*Pu Chun Ke and Lyndon L. Larcom*

### 7.1

#### Overview

Integrating nanomaterials and biomedicine is a recent endeavor that aims to provide highly localized detection and treatment for cancers and diseases. Understanding the intricate interplay of nanomaterials and biological components and biological systems necessitates combining materials science, nanotechnology, physics, chemistry, biology, and biomedicine. The impact of this grand exploration touches areas of fundamental science and engineering, health care, and environmental control and protection. Recent advances in our understanding of carcinogenesis have led us to consider taking advantage of the special characteristics of both cancer cells and nanomaterials to detect and treat tumors. Integrating cancer therapy and nanomaterials captivates scientific imagination, offers new hope for human well-being, and unavoidably invites controversy and debate as experienced by many scientific and technological developments during their infancy.

Carbon nanotubes (CNTs) are mosaics of carbon atoms synthesized into cylinders of single or multiple layers [1]. The astonishingly simple and plain structures of CNTs transcend the most important classes of nanomaterials owing to their unsurpassed stiffness, easy accommodation of chemical and biological versatility, and rich quantum electronic properties [2–7]. Since their discovery a mere decade ago, CNTs have orchestrated a broad array of applications, including novel composites [8, 9], electrochemical sensors [10, 11], field emission [12, 13], memory, and nanoscale devices [14–16], just to name a few. In the rapidly growing field of biotechnology, CNTs have been utilized as platforms for ultrasensitive recognition of antibodies (Fig. 7.1, left) [17], as nucleic acids sequencers [18], and as bioseparators, biocatalysts [19], and ion channel blockers (Fig. 7.1, right) [20] for facilitating biochemical reactions and biological processes. Within the realm of nanomedicine, an emerging field of utilizing nanomaterials and nanostructures for medicine, CNTs have been transformed into scaffolds for neuronal and ligamentous tissue growth for regenerative interventions of the central nervous system and orthopedic sites [21–23], substrates for detecting antibodies associated with human autoimmune diseases with high specificity [24], and carriers of contrast agent aquated

Gd<sup>3+</sup>-ion clusters for greatly enhanced magnetic resonance imaging [25]. Once covalently or noncovalently attached by nucleic acids (DNA or RNA including short-stranded RNA for gene silencing) [26, 27], vaccines (e.g., B cell epitopes) [28], and proteins [29, 30], CNTs have shown to be effective gene and drug delivery vectors that may someday co-exist with or challenge conventional viral and particulate systems [31]. Selective destruction of cancer cells using functionalized CNTs as transporters and near-infrared (NIR) heat inducing agents, as reported by Dai's group [32], highlights research towards nanomedicine for cancer diagnosis and therapy.

To propel research in nanomedicine, the new “Nanotechnology for Cancer Diagnosis and Therapy” initiative was announced by the National Cancer Institute (NCI) in September 2005 [33]. Nanoscience with its implications for biomedicine has been highlighted as one of the “Priority Areas” of the National Science Foundation (NSF) [34] and in the “Roadmap” of the National Institutes of Health (NIH) [35]. It is not beyond our wildest dream that within the next decade or so we might be able to determine to what extent the atomic world obeys the laws of quantum mechanics, resolve the passionate debate between Drexler and Smalley on “the fat fingers” of nanobots and molecular assemblies [36], and witness how nature selectively embraces the “smart” creatures such as CNTs, buckyballs, dendrimers, quantum dots, and other nanoparticles offered by mankind.

This chapter reviews, for the first time to our knowledge, the state-of-the-art in cancer diagnosis and therapy from the perspective of single-walled carbon nanotubes (SWNTs). Through the introduction of these early developments we wish to present a panorama of how SWNTs can be used for biomedicine. There are many reasons for using SWNTs instead of multiwalled carbon nanotubes (MWNTs) as our model systems. They resemble nucleic acids in physical dimensions and present excellent platforms for biosensing and biocompatibility, as compared with viral

and particulate gene and drug delivery vectors. They possess an enormously high aspect ratio, which allows for efficient permeation of their attached drug loads through tissues and cells. Their large surface areas are able to carry many biomolecules to their respective targets for sensing, sequencing, and therapy. Their stability, flexibility, and non-immunogenicity may prolong the circulation and availability of attached drugs. Their hydrophobicity may facilitate interaction with cell membranes, and the rich electronic properties of SWNTs may open up new routes and methodologies for probing and imaging the states of cancerous tissues and cells.

Because nanotechnology is such a rapidly changing field and because nanomedicine is still in its very infancy, it is beyond our ability to grasp and thus to convey all of the exciting frontiers and aspects of this new science. Instead, we will elucidate only a few of these innovations in this chapter, which is organized into the following sections: Section 7.1 gives an overview; Section 7.2 covers SWNT modification for solubility and biocompatibility; Section 7.3 deals with diffusion of SWNT–biomolecular complexes; Section 7.4 covers gene and drug delivery with SWNT transporters; Section 7.5 deals with sensing and treating cancer cells utilizing SWNTs; Section 7.6 covers the cytotoxicity of SWNTs; Section 7.7 deals cancers and SWNTs; and Section 7.8 provides a summary.

## 7.2

### SWNT Modification for Solubility and Biocompatibility

Pristine SWNTs in aqueous solution form bundles due to the hydrophobic interactions, van der Waals attractions, and  $\pi$ -stacking among individual tubes. Bundle formation presents a major hurdle for the applications of SWNTs in biological systems and medicine. Solutions to this problem include two major routes, covalent and noncovalent modifications of SWNTs. Covalent modification of SWNTs involves esterification or amidation of acid-oxidized nanotubes and side-wall covalent attachment of functional groups [37–41]. These covalent schemes are often characterized by uncertainties in determining reaction efficacy and by undesirable modifications in the physical and chemical properties of SWNTs [28, 42, 43]. In comparison, the noncovalent modifications of SWNTs employ nonspecific attachment of proteins [17, 30], linear bio- and synthetic polymers [DNA, RNA, poly(vinyl pyrrolidone), polystyrene sulfonate], and surfactants [sodium dodecyl sulfate (SDS) etc.] [42–49]. Many surfactants, organic solvents, and residues, however, cause cytotoxicity [50] and/or other side effects that limit the biocompatibility of SWNTs. Developing alternative schemes is thus crucial for facilitating the full range of biological and biomedical applications for SWNTs and their derivatives.

#### 7.2.1

##### Chemical Modifications of SWNTs for Solubility

Chemical modification of SWNTs is an emerging research area in the fields of materials science and nanotechnology, and is pertinent to the biological applications

of SWNTs when it is deemed necessary to attach fluorescent tags, drugs, and proteins. These modifications include the functionalization of oxidized SWNTs and covalent modification of SWNTs. Organic chemistry plays a major role in these approaches.

#### 7.2.1.1 Functionalization of SWNTs through Oxidation

Functionalization of SWNTs utilizing acidic media (e.g., 3:1 mixture of concentrated sulfuric to concentrated nitric acids) may open the ends of the SWNTs and create functionalities suitable for further derivatization at these acid-induced defect sites. Long-chain alkylamines may be coupled with the carboxylic groups present on the surface of oxidized SWNTs. The coupling of organic acids with amines is a well-known reaction, but tends to proceed only at relatively high temperatures. This reaction is often facilitated by converting the acids into a more reactive moiety, usually a mixed anhydride  $R(\text{CO})\text{O}(\text{CO})R'$  or acid chloride  $\text{RCOCl}$ . The acid chloride is generally highly reactive, hydrolyzes upon exposure to air (or the humidity therein), and degrades back to carboxylic acid. Activation of the carboxyl moieties with thionyl chloride and their subsequent reaction with amines are feasible. Alternatively, oxidized SWNTs can be condensed directly with amines. Typically, the solubility of such modified SWNTs is approximately  $0.5 \text{ mg mL}^{-1}$  in organic solvents such as tetrahydrofuran or dichlorobenzene [51]. However, the electronic properties of these functionalized SWNTs are often deviated or even lost. In most cases, the SWNTs are greatly shortened [52].

Functionalization of SWNTs creates charge polarity to the tubes and may lead to their separation from pristine SWNT clusters in polar solvents. This separation is desirable since it breaks the persistent hydrophobic forces and van der Waals interactions among the tubes and renders SWNTs soluble, thus enabling their further incorporation by biological systems. This functionalization process also facilitates the characterization and purification of single SWNTs. The presence of the functional addends at the defect sites of oxidized CNTs can be monitored by either Raman or IR spectroscopy, which easily identify amide- or ester-bond formation. Regarding biosensing, oxidized SWNTs may, for example, react with an alkyl thiol with a subsequent chemical attachment to gold particles [52–54]. These SWNT–gold particle complexes can be used to construct microelectrode arrays. Potential applications of these microelectrode arrays include developing bio-electrochemical sensors and designing novel molecular-recognition electrodes [51].

One scheme that could lead to gene sequencing and recognition is the attachment of peptide nucleic acids (PNA) via N-hydroxysuccinimide (NHS) esters formed on carboxylated SWNTs, as demonstrated by Williams et al. [55] in 2002 (Fig. 7.2). There are several rationales for using PNA to construct such complexes. First, PNA molecules are uncharged DNA analogues that can be hybridized with complementary DNA, and these PNA attached SWNTs may be incorporated into larger electronic devices by recognition-based assembly. PNA treated SWNTs may also serve in biological systems as probes based on sequence-specific attachment. Second, PNA is compatible with the most convenient solvents such as DMF, though less soluble in aqueous solutions. Third, PNA is not susceptible to enzy-

**Fig. 7.2.** Attachment of DNA to carbon nanotubes. (a, b) *N*-Hydroxysuccinimide (NHS) esters formed on carboxylated SWNTs are displaced by PNA, forming an amide linkage. (c) A DNA fragment with a single-stranded, "sticky" end hybridizes by base-

pairing to the PNA-SWNT. (d, e) Atomic-force microscope (tapping mode) images of PNA-SWNTs. SWNTs appear as bright lines; the paler strands represent bound DNA. Scale bars: 100 nm; nanotube diameters: (d) 0.9 and (e) 1.6 nm [55]. (© Nature Publishing Group.)

matic degradation due to its synthetic status. Lastly, PNA-DNA duplexes are thermally more stable than their DNA-DNA counterparts because PNA is neutral and does not induce electrostatic repulsion. The higher thermal stability of PNA-DNA suggests that shorter sticky ends are required for room-temperature hybridization, which reduces nonspecific electrostatic interactions with metallic electrodes, or with silicon oxide, which is desirable for lithography [55].

#### 7.2.1.2 Functionalization of SWNTs through Covalent Modifications

Apart from oxidation, SWNTs also can be treated with dichlorocarbene, which can be induced by chloroform-sodium hydroxide interaction or phenyl(bromodichloromethyl)mercury [56, 57]. SWNTs react with molecular fluorine at 150–600 °C, and these derivatized SWNTs can be retrieved with hydrazine [51]. SWNTs functionalized through this procedure dissolve well in polar solvents, although the fluorine atoms may be substituted by alkyl groups for higher solubility [58]. Fluorination

can also shorten the SWNT to less than 50 nm [51, 59], which has broad implications should the permeation of nuclear membrane pores by SWNTs and their derivatives be desirable.

SWNTs may be functionalized through aryl diazonium chemistry [60], and be derivatized with C–C bonds by the electrochemical reduction of various diazonium salts. In addition, because the oxidative coupling of amines can result in their attachment to SWNT surfaces [51, 61], these nanotube-bound amine moieties have great versatility for use as gene and drug carriers.

Another covalent SWNT functionalization is derived from the chemical processing of fullerenes [62], which is accomplished by the addition of nitrenes, carbenes, or radicals. Functionalized SWNTs may also be constructed via electrophilic addition by adding chloroform to the side walls of SWNTs during a mechanochemical reaction with  $\text{AlCl}_3$ . Hydroxyl groups may replace the chlorine atoms, which then may be esterified to yield corresponding esters [51]. This method not only produces soluble SWNTs but also adds free functional groups for further linking to biomacromolecules.

Based on the methodology of 1,3-dipolar cycloaddition of azomethine ylides, Prato et al. have devised a route for covalently attaching pyrrolidine rings substituted with chemical functions to the side walls of SWNTs [63, 64]. They chose the triethylene glycol group as the N-substituent of the  $\alpha$ -amino acid due to its high solubilizing power. These SWNTs were soluble in chlorinated solvents, acetone, and alcohols but insoluble in diethyl ether or hexane. In particular, the solubility of these functionalized SWNTs in dichloromethane or chloroform was as high as  $50 \text{ mg mL}^{-1}$ , suggesting an average covalent attachment of one pyrrolidine ring to every one hundred carbon atoms of the SWNTs. Moreover, the covalent attachment of pyrrolidine rings to pristine SWNTs quenches their signature NIR band of van Hove transitions [51, 64]. Water-soluble SWNTs can also be obtained by exposing the tubes to N-substituted  $\alpha$ -amino acid with a terminated amino tert-butoxycarbonyl (Boc) protected group and paraformaldehyde. Upon treatment with gaseous hydrochloric acid, the N-Boc groups can be removed by treating the SWNTs with hydrochloric acid, which further releases the corresponding ammonium salts from the water-soluble SWNTs [51, 65].

### 7.2.2

#### **Noncovalent Modifications of SWNTs for Solubility**

Noncovalent solubilization of SWNTs has recently gained recognition partly due to the growing concern over the covalent schemes, including their induced alteration to and/or the loss of the mechanical and electronic properties of SWNTs. Noncovalent schemes are also attractive because of their relative ease of releasing load from the tubes, though this release may sometimes act against the purpose of application, causing uncertainties in quantifying gene and drug transfection. This route of solubilization schemes is unlimited to the field of organic chemistry and often embraces the contributions from researchers in materials sciences, biochemistry, and biophysics. Smalley's group first proposed the idea that SWNTs could be solu-

**Fig. 7.3.** Binding model of a (10,0) SWNT wrapped by a poly(T) sequence of ssDNA. (a) The right-handed helical structure shown here is one of several binding structures found, including left-handed helices and linearly adsorbed structures. In all cases, the bases (red) orient to stack with the surface of the

nanotube, and extend away from the sugar-phosphate backbone (yellow). (b) The DNA wraps to provide a tube within which the SWNT can reside, hence converting it into a water-soluble object [49]. (© Nature Publishing Group.)

bilized in aqueous media of amphiphilic molecules such as surfactants [45]. The hydrophobic moieties of the surfactants were hypothesized to interact through wrapping with the hydrophobic surfaces of the SWNTs. This interaction was understood to be facilitated by the van der Waals attractions between the surfactants and the SWNTs in close proximity. Zheng et al. extended this simple scheme to include biomacromolecules such as single-stranded DNA (ssDNA) for the solubilization of SWNTs and sorting of metallic nanotubes from semiconducting ones (Fig. 7.3) [49]. The underlining binding mechanism is the hydrophobic interaction between the nitrogenous bases of the ssDNA and the side walls of the SWNTs, attributed by the  $\pi$ -stacking of the nitrogenous bases and the  $\pi$ -electrons of the carbon atoms on the SWNTs. Poly(A) and poly(C) have lower dispersion efficiencies than poly(T), possibly because these nucleotides tend to strongly self-stack in solution and therefore have smaller free energies for binding to SWNTs. In addition to using nucleic acids, a few groups, most notably Dai's group at Stanford, have dispersed SWNTs in solutions of peptides and proteins such as bovine serum albumin (BSA) and streptavidin [17, 30]. These research efforts have formed the basis for creating biocompatible nanomaterials for biosensing and therapeutics. However, a direct comparison of the solubility from the noncovalent methods with that from the covalent schemes is unavailable, since most noncovalent studies were conducted through visualization rather than quantification.

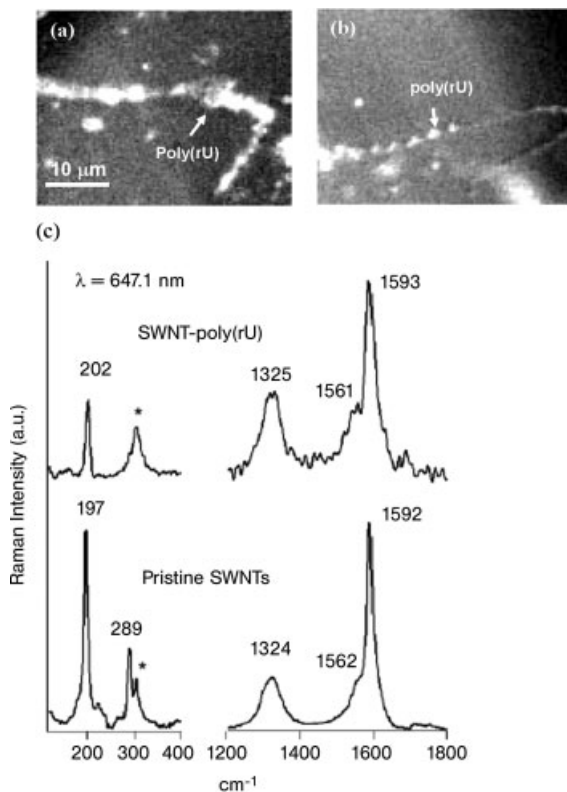

Recently, our group reported the solubilization of SWNTs using RNA polymers [66]. The structure of this RNA resembles that of ssDNA except that it possesses a hydroxyl group instead of a hydrogen atom at the 2' of their nucleotides. This structural difference, though seemingly minute, opens the door for many exciting applications, including using RNA as catalysts for inorganic particle growth and organic chemical reactions, and as agents for RNA interference (RNAi) for gene silencing. Using single-molecule fluorescence microscopy our group observed that poly(rU) RNA molecules, when exposed to SWNTs immobilized on a quartz substrate, bound to SWNTs instead of randomly distributing on the substrate. The surface property of this substrate changed from hydrophilic to hydrophobic during the chemical deposition of SWNTs. This suggests that  $\pi$ -stacking may dominate the hydrophobic interaction when nucleic acids are noncovalently attached to SWNTs (Figs. 7.4a, b) [46].

The binding induced changes in Raman spectra are shown in Fig. 7.4(c). The samples were prepared using the same protocol as described for fluorescence imaging except that the labeling was omitted to prevent the strong fluorescence signal of labeled poly(rU) from masking the Raman signal of SWNTs. The Raman spectra were excited with a 647.1 nm laser line and the laser power was maintained at approximately 1 mW to avoid heating. A Leica microscope equipped with a 50 $\times$  dry objective (NA = 0.75) was used to focus the laser beam at various spots on the pristine and poly(rU)-bound isolated SWNTs. The Raman scattered light was collected using an ISA Triax 550 spectrometer equipped with a liquid-nitrogen cooled CCD. The bottom spectrum corresponds to pristine SWNTs, while the top spectrum corresponds to poly(rU) bound isolated SWNTs. The frequency positions of the RBM, *D*, and *G* bands were determined from a Lorentzian line shape analysis. The characteristic RBM was observed between 190–290  $\text{cm}^{-1}$ , while the *G* band frequency was centered at 1593  $\text{cm}^{-1}$ . No significant shift in the peak positions was found in the spectrum of poly(rU) bound SWNT as compared with that of the pristine SWNTs, possibly because the charge transfer from the poly(rU) molecules to the SWNT was too minute to discern. The Raman spectrum of SWNT-poly(rU) hybrids exhibits a noticeable decrease in the intensity of the RBM band and a small enhancement in the *D* band intensity compared with the corresponding peaks of the spectrum for isolated SWNTs alone. These changes in Raman spectra are indicative of the effective binding of poly(rU) with SWNTs [46].

#### 7.2.2.1 Solubilization of SWNTs Using Lysophospholipids Enables Cellular Studies [67]

This section details a new approach for solubilizing SWNTs using single-chained phospholipids, or lysophospholipids. This approach is promising because it enables cellular studies using SWNTs and other nanomaterials. The potential applications of lysophospholipid solubilized SWNTs and their biofunctionalized derivatives include *in vivo* imaging, biosensing, and gene and drug delivery for biomedicine.

We first obtained pristine SWNTs using the arc-deposition method. The average diameter of the SWNTs was approximately 1.4 nm measured by Raman spectroscopy.

**Fig. 7.4.** (a, b) Fluorescence images of SWNT-poly(rU) hybrids. Individual poly(rU) molecules are visible as small blobs in (b) due to the relatively low concentration. SWNTs in both panels are over 50  $\mu\text{m}$  long. (c) Raman spectra collected at a laser excitation wavelength of 647.1 nm from pristine (bottom) and poly(rU) bound isolated SWNTs (top) on silicon substrates. Plots are normalized with respect to the amplitudes of the G bands. The asterisks at 305  $\text{cm}^{-1}$  correspond to the Raman lines of the silicon substrates [46]. (© American Institute of Physics.)

copy, with an average molecular weight of  $1 \times 10^6$  Dalton (Da), estimated from TEM. To measure the solubility provided by pure phospholipids, SWNTs were dispersed in phosphate-buffered saline (PBS, pH 7.4) containing phospholipids of varying amounts. After sonication for 1 h at room temperature, SWNTs were found to be completely solubilized by LPC 18:0 (Fig. 7.5), and by cell growth mediums (Fig. 7.6a). The weight ratio of solubilized SWNTs to LPC was approximately 1:10, corresponding to a molar ratio of 1:20 000 at saturation (Fig. 7.6b), indicating their high binding capacity. Comparable solubility of SWNTs was also obtained with LPA 16:0 (Fig. 7.5), and LPG 18:0 (Fig. 7.5), based on the same treatments.

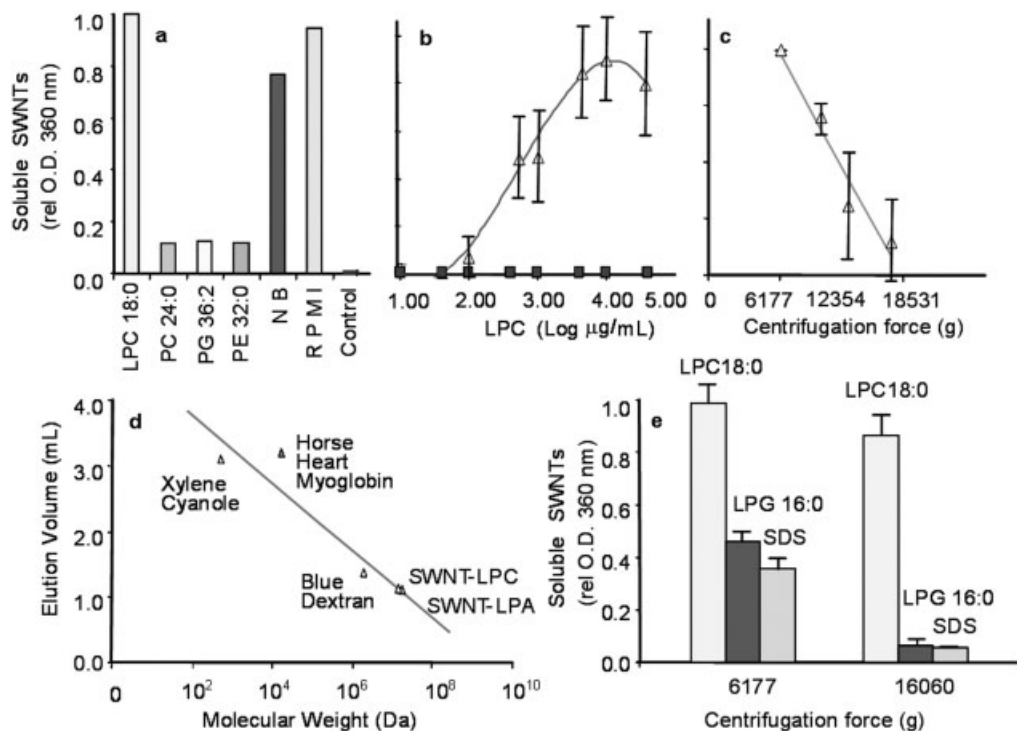

Approximately half of the soluble SWNTs were sedimented at 16 060g RCF at tip, based on measured optical densities (Fig. 7.6c), indicating their heterogeneous size

**Fig. 7.5.** Structures of lysophospholipids LPC 18:0, LPA 16:0, and LPG 16:0 and SDS. LPC: lysophosphatidylcholine; LPA: lysophosphatidic acid; LPG: lysophosphatidylglycerol. The numbers 18 and 0 in LPC 18:0 denote the total number of carbon atoms and the total number of double bonds, respectively, contained in the sum of the fatty acyl chains [67]. (© American Chemical Society.)

distribution. From elution volumes measured with chromatography, we estimated that the SWNT-LPC and the SWNT-LPA complexes had an average molecular weight of  $14 \times 10^6$  Da and  $18 \times 10^6$  Da, respectively (Fig. 7.6d). Since each SWNT carries approximately 20 000 LPC molecules and the molecular weight of each LPC is 523.7 Da, the “molecular weight” of each SWNT-LPC complex is estimated at  $11.5 \times 10^6$  Da, which agrees with our measured value of  $14 \times 10^6$  Da. The discrepancy is mainly caused by the heterogeneous size distribution of the SWNTs and the occurrence of small SWNT bundles.

Figure 7.6(e) compares SWNT solubility for LPC, LPG, and the surfactant SDS (Fig. 7.5), a routine solvent for SWNTs [45]. At 6177g RCF at tip, on a per molecule basis, LPC is approximately  $2.5\times$  more effective than SDS in dispersing SWNTs in PBS. At 16060g RCF at tip, LPC is approximately  $10\times$  more effective than SDS in dispersing SWNTs, possibly because the resulting micelles differ in size. This difference might be because LPC has a bulkier head group for interfacing with water and a longer acyl chain for binding with SWNTs. SWNTs with LPG are slightly more soluble than with SDS. Solubilization of SWNTs with lysophospholipids was also more effective than with nucleic acids [47, 49, 68], and was far more effective than with proteins [29, 39]. The aqueous SWNT-lysophospholipid solutions were exceptionally stable for months at room temperature, a promising feature in regards to possible applications in both biology and medicine.

**Fig. 7.6.** Characteristics of SWNTs solubilized with phospholipids. (a) Comparison of SWNT solubility with different aqueous phospholipid solutions and cell growth mediums, RPMI supplemented with 10% fetal bovine serum (FBS) and nutrient broth (NB). SWNTs (1 mg) were treated with phospholipids (10 mg) in PBS (1 mL) or growth medium (1 mL). After bath sonication at room temperature for 1 h and centrifugation for 3 min at 6177g, the absorbance was observed at 360 nm as a measure of the amount of SWNTs solubilized. The label “rel O.D.” on the y-axis denotes relative optical density. (b) LPC solubilized SWNTs. SWNTs (1 mg) were treated with increasing concentrations of LPC 18:0, sonicated, and centrifuged as above, with an absorbance observed at 360 nm. Filled triangles: SWNTs with LPC; filled squares: LPC

alone as a control for micelles. The latter showed negligible absorbance at 360 nm. (c) Sedimentation of LPC-solubilized SWNTs, prepared as above with SWNTs (1 mg) and LPC (10 mg). (d) Size-exclusion chromatography measurements of SWNT-LPC 18:0 (centrifuged at 16 060g for 3 min) and SWNT-LPA 16:0 complexes (centrifuged at 6177g for 3 min). A linear relationship between compound log(molecular weight) and elution volume in mL was established using xylene cyanole FF with blue color (538.6 Da), horse heart myoglobin with reddish color (16951.5 Da), and blue dextran with blue color ( $2 \times 10^6$  Da). (e) Comparison of SWNT solubility in LPC, LPG, and SDS solutions, prepared from SWNTs (1 mg) and detergents (10 mg) as above [67]. (© American Chemical Society.)

To probe the mechanism of SWNT-lysophospholipid binding, zwitterionic LPC and net negatively charged LPG at physiological pH were bound to SWNTs and imaged with TEM (Figs. 7.6a–c). One can see the formation of areas of tightly packed lysophospholipids in the dark/grey areas, our termed “lipid phase”, in

**Fig. 7.7.** TEM images of SWNT-LPC (a and c) and SWNT-LPG (b) complexes. Recorded with an Hitachi 7600 and stained with uranyl acetate. Numbers 1–4 in (a) and (c) correspond to (1) an isolated SWNT in the vacuum phase, (2) an LPC striation on an SWNT/SWNT bundle, (3) possibly an LPC micelle on the substrate in the lipid phase, and (4) an uncoated SWNT bundle in the vacuum phase. Note the less organized and wider striations of SWNT-LPG complexes in (b), as compared with those in (a) and (c) for SWNT-

LPC. Scale bar (a–c): 20 nm. (d) Hypothesized microscopic binding modes of LPC and LPG with SWNTs. The lysophospholipids are shown as truncated triangles, their head groups are at the base of the triangles, and the SWNTs are the inner circles and tubes. The left-hand side illustrates the proposed lipid spiral wrapping along the tube axis while the right-hand side shows their possible binding around the circumference of the tubes [67]. (© American Chemical Society.)

Figs. 7.7(a–c). The light/blank areas in Figs. 7.7(a–c) correspond to lysophospholipid free regions or our termed “vacuum phase”. In the lipid phase SWNTs are wrapped by striations of ~5 nm for LPC and 5–7 nm for LPG. Such organizations were previously reported for the binding of SDS and synthetic lipids on CNTs [69]. However, in the vacuum phase (Figs. 7.7a, c) SWNTs are practically naked, indicating that the binding of lysophospholipids to SWNTs is controlled by the local lysophospholipid environment rather than by specific interactions between lysophospholipids and SWNTs.

Neither LPC nor LPG binds to SWNTs in the vacuum phase, while both coat SWNTs in the lipid phase. LPC on an SWNT or an SWNT bundle displays such a consistent organized pattern along the tube(s) that striations remain approximately the same size (Figs. 7.7a, c). By contrast, the binding of LPG to SWNTs in the lipid phase does not follow the same pattern (Fig. 7.7b). The size and orientation of the

**Fig. 7.8.** Schematic representations of the mechanisms by which surfactants help disperse SWNTs. (a) SWNT encapsulated in a cylindrical surfactant micelle; right-hand side: cross section; left-hand side: side view.

(b) Half-cylinder adsorption of surfactant molecules on a SWNT. (c) Random adsorption of surfactant molecules on an SWNT [42].  
(© American Chemical Society.)

striations change along the axis of SWNTs. These differences could be related to the different lysophospholipid organizations shown in their respective backgrounds. Figures 7.7(a) and (c) show that the lipid phase of LPC is composed of many large objects of  $\sim 5$  nm, which are probably micelles, while the lipid phase of LPG is homogeneous, most probably composed of individual lysophospholipids. Another major difference in the binding of LPC vs. LPG in the lipid phase is the shape of the striations. The crests of striations are approximately 0.2 nm above the surface of SWNT(s) for SWNTs, while the clefts almost touch the surface of SWNT(s) for LPC.

There has been an ongoing debate on the binding mode of amphiphilic surfactants and cylindrical SWNTs [42, 43, 69]. Surfactants are hypothesized in the literature as adopting one of three configurations: (a) micelles; (b) half-cylinders; and (c) random adsorption (Fig. 7.8) [42]. The periodic wrapping in the lipid phase, as observed in our experiment, strongly suggests that the microscopic binding mode is the “half-cylinders” (Fig. 7.7d). Note that the macroscopic arcs formed by lysophospholipids along the SWNT axis are not semi-spherical but are extended arcs, because the ends of lysophospholipid tails within an arc can not occupy the same point and must be offset along the tube axis. Furthermore, LPC on SWNTs (Fig. 7.7a, c) exhibits macroscopic spirals possibly resulting from the wrapping of deformed lipid-composed long half-cylinder(s). In some cases, the step of the spiral is equal to the width of the half-cylinder; thus a single half-cylinder can provide a complete coating of the tube surface. For SWNT bundles, we observed binding with a larger step corresponding to double spiral wrapping. We also noticed that, in some cases, the ring binding mode and the rings were tilted with respect to the tube axis. As long as the tube diameter remains static, the wrapping mode is conserved along the tube. However, the wrapping mode may change when the bundle size varies (Fig. 7.7a). In contrast, the TEM images with LPG (Fig. 7.7b) exhibit alterations of the wrapping mode down the tube axis. In addition, the average width

of the LPG striations is noticeably larger than that of LPC (Fig. 7.7b vs. Fig. 7.7a) owing to a net negative charge of LPG head groups. A macroscopic configuration, like LPG head groups in consecutive half-cylinders, paired and in contact with weakly polarizable SWNT surfaces is energetically unfavorable. To reduce the repulsion between LPG head groups, the SWNT-LPG system must pay an “energy penalty” by distorting and/or broadening the striations (Fig. 7.7d, lower section). Indeed, our experimental data revealed that LPC bound better to SWNTs than LPG (Fig. 7.6e).

To confirm our observation, we tested double-chained phospholipids for their SWNT solubility. The phospholipids used were dimyristoylphosphatidylcholine (PC 24:0), which is zwitterionic at physiological pH; and 1,2-dioleoylphosphatidylglycerol (PG 36:2) and 1,2-dipalmitoylphosphatidylethanolamine (PE 32:0), both of which are negatively charged at physiological pH. None of the above phospholipids provided good solubility for SWNTs.

From a geometrical perspective the three-dimensional (3D) structures of lysophospholipids and detergent molecules can be approximated as cones (Fig. 7.7d). The packing of conical objects normally results in spherically shaped objects, e.g., micelles, due to their curvophilicity. In contrast, double-chained phospholipids are considered to be curvophobic [70], their 3D structures are approximated as cylinders and their packing assumes bilayers. Obviously, wrapping around a cylindrical object, i.e., an SWNT, is geometrically preferential for curvophilic lysophospholipids but not for curvophobic phospholipids.

The geometrical considerations further support the microscopic binding mode shown in Fig. 7.7(d). “Half-cylinder” wrapping is the only microscopic mode that results in semi-spherical curvature along the SWNT axis and SWNT circumference. In addition to the packing consideration, we calculated the average number of LPC necessary for coating an average SWNT, assuming tight packing and the LPC head group size of 0.6 nm. We found that “half-cylinder” binding will result in a lipids-to-tube ratio of 21 000:1 – in excellent agreement with our experimentally estimated ratio of 20 000:1.

Free lysophospholipids and micelles in SWNT-lysophospholipid solution were removed by filtration through 100 kDa *Microcon* (Amicon, Inc) centrifugation tubes and washed four times. The resulting lysophospholipid-free and micelle-free SWNT-LPC complexes were tested by *in vivo* bioassay using colon cancer (CACO-2) and macrophage (THP-1) cell lines. Each cell line was incubated in its own eight-well chamber slide (LabTek) for 48 h at 37 °C in a CO<sub>2</sub> incubator. Before treatment, cell adhesion was checked by differential interference contrast (DIC) microscopy using a Zeiss 135 Axiovert inverted microscope. Treatments ranging from 5 to 40 ppm of lysophospholipid-free and micelle-free SWNT-LPC complexes were added to each adherent cell line and incubated for 3 h at 37 °C in a CO<sub>2</sub> incubator. After incubation, control and treated cells were fixed with 4% paraformaldehyde for 30 min, washed in PBS and subjected to an APO-BrdU TUNEL assay (Invitrogen). This assay detects the onset of apoptosis by fluorescent detection of nuclear DNA fragments or DNA breaks. Cells were labeled with deoxythymidine analogue 5-bromo-2'-deoxyuridine-5'-triphosphate (BrdUTP) followed by the addi-

**Fig. 7.9.** Fixed CACO-2 cells incubated with SWNT-LPC for 3 h and examined for apoptosis by APO-BrdU TUNEL assay. Panels (a, b, e, f) show control cells and (c, d, g, h) show cells that have been incubated with 20 ppm of SWNT-LPC. The merged areas shows cells with intact plasma and nuclear membranes in control (f) and in treatments (h). PI staining revealed intact cell nuclei in control (a) and treated cells (c). Neither control (b) nor treated cells (d) appear apoptotic since there was an absence of anti-BrdU antibody labeled staining in the FITC channel. The DIC channel shows intact plasma membranes in both control (e) and treated cells (g). Scale bars: 20  $\mu$ m.

tion of Alexa-Fluor 488 labeled anti-BrdU antibody. Propidium iodide (PI) was used to image the total DNA content of cells. The prepared cells were imaged using a Zeiss 510 LSM confocal fluorescence microscope.

Our bioassays showed no loss of cell viability (Figs. 7.9 and 7.10) when both colon cancer cells (CACO-2) and macrophage (THP-1) cell lines were treated with 20–40 ppm of lysophospholipid-free and micelle-free SWNT-LPC. CACO-2 cell nuclei remained unaffected by treatment of 20 ppm SWNT-LPC (Fig. 7.9c), which was also the case for the macrophage THP-1 cell line treated with 40 ppm SWNT-LPC (Fig. 7.10c). Cell plasma membranes remained intact in both CACO-2 cells (Fig. 7.9e) and THP-1 cells (Fig. 7.10e), and the onset of apoptosis by Apo-BrdU TUNEL assay was not detected in either cell line (Fig. 7.9d and Fig. 7.10d). Motile THP-1 cells treated at 40 ppm SWNT-LPC exhibited elongated cell bodies (Fig. 7.10h), which is thought to be due to SWNT-LPC disruption of plasma membranes or cytoskeleton.

SWNTs, otherwise a collection of hydrophobic synthetic nanoparticles, have been solubilized in aqueous lysophospholipid solutions with extended stability. The biocompatibility of lysophospholipids is unsurpassed since they occur naturally in the cell membrane. The signaling capacity of lysophospholipids and the electronic property of SWNTs may be combined for disease detection. The strong absorbance of isolated SWNTs in NIR [44] can be utilized for noninvasive imaging and sensing. Furthermore, since the head groups of lysophospholipids can be functional-

ized with tags such as quantum dots, antioxidants, and monoclonal antibodies, this solubility method opens the door for utilizing nanomaterials for *in vivo* imaging, cancer diagnosis and therapy, and novel nanomedicines.

### 7.3

#### Diffusion of SWNT–Biomolecular Complexes

The enhanced elucidation of gene function in human health has led to the need for more effective and robust means for delivering therapeutic genes to target cells. While no single gene transfection method developed to date has been found to be optimal for all cells, SWNTs offer a promising alternative since they can be treated or functionalized for biocompatibility [30]. Recent biochemical assays and theoretical studies have indicated that the nonspecific binding of DNA with SWNTs is realized through the  $\pi$ -stacking between the bases of DNA and the  $\pi$ -electrons of carbon atoms as well as the hydrophobic interaction between the bases of DNA and the sidewalls of SWNTs [49, 71]. Helical wrapping of ssDNA on SWNTs is energetically favorable and sequence dependent [49, 71, 72]. While current efforts on interfacing SWNTs with nucleic acids have focused almost exclusively on DNA,

equal attention should be paid to RNA due to its biological significance. For example: (a) messenger RNAs (mRNAs) are the physical gene transcripts that are translated to functional proteins at the ribosomal level; (b) some RNAs act as enzymes to catalyze various cellular biochemical pathways, they serve as mediators for various organic reactions [73–76] and are often utilized as templates for the growth of inorganic-particles [77]; and (c) small interfering RNAs (siRNAs), which disrupt mRNAs prior to translation, will cause the silencing of a specific post-transcriptional gene's expression. The use of siRNA is a powerful research tool that has a pivotal role in deciphering the functions and interactions of thousands of unknown genes [78]. Albumin, in contrast, is one of the most abundant serum proteins present in the mammalian circulatory system, contributing over 80% of the colloid osmotic pressure [79]. Indeed, the nonspecific binding of SWNTs to BSA has been elucidated as a general phenomenon [17]. In this section, we introduce the first study by our group on the diffusion of SWNT-poly(rU) and SWNT-BSA hybrids, two of the most elementary synthetic biomolecular complexes. This study provides a physical guidance to gene delivery using SWNT as transporters.

Diffusion refers to the process by which particles intermingle as a result of their kinetic energy of random motion. It plays a central role in the transportation of small particles across cell membranes, in cytoplasm, and in nuclei. For the applications of gene and drug delivery, the innate hydrophobicity of SWNTs causes the tubes to aggregate or clump, presenting a major challenge for cellular studies. The addition of nucleic acids or proteins mediates the separation of pristine SWNTs through  $\pi$ -stacking and/or by decreasing the degree of hydrophobic interactions, thus markedly enhancing the solubility of the nanotubes. Further, nucleic acids and proteins can be labeled with fluorescent dye molecules and, consequently, SWNTs can be visualized when bound with these biomolecules. Single-molecule fluorescence microscopy (SMFM) has been utilized for the diffusion studies of phospholipids in biomembranes [80, 81]. Superior to confocal microscopy, wide-field SMFM simultaneously collects significant statistics without averaging or losing molecular individuality [80–82]. Unlike scanning electron microscopy (SEM) and crystallography, SMFM is non-invasive and is, therefore, suitable for *in vitro* and *in vivo* studies of biological processes.

In SMFM, the trajectories of fluorescently labeled biomolecules can be followed at nanometer resolution. Based on the displacement of the centre of mass (COM) of a molecule, the mean-square-displacement (MSD) [83] of the molecule can be obtained with Eq. (1), where  $x_i$  and  $y_i$  are the positional coordinates of the COM of the molecule in frame  $i$ , and  $n$  denotes the frame number with time interval  $\Delta t$ .

$$\text{MSD}(\Delta t) = \langle (x_{i+n} - x_i)^2 + (y_{i+n} - y_i)^2 \rangle \quad (1)$$

The diffusion coefficient  $D$  of the molecule undergoing a two-dimensional (2D) random walk is given as  $D = \text{MSD}/4\Delta t$ .

For diffusion studies, pristine SWNTs were first synthesized using the arc-deposition method [84]. The average diameter of the SWNTs was 1.4 nm, as confirmed by Raman spectroscopy and transmission electron microscopy. The sample

of SWNT-poly(rU) hybrids was prepared by modifying the protocol used by Zheng et al. [49], employing the following procedure. A mixture of poly(rU) ( $0.2 \mu\text{g } \mu\text{L}^{-1}$ , lyophilized polyuridylic acid, Midland, 500–2600 nucleotides) and SWNTs ( $0.01 \mu\text{g } \mu\text{L}^{-1}$ ) in TE buffer (10 mM Tris, 1 mM EDTA, pH 7.3) was first placed on ice and probe-sonicated at 10 W for 30 min (VC 130 PB, Sonics). The resultant SWNT-poly(rU) suspension was then centrifuged at 5000 rpm for 10 min to pellet the poly(rU)-wrapped and bare SWNTs. The supernatant of unbound poly(rU) was removed and the pellet resuspended in TE buffer. The sample was then labeled with OliGreen (Molecular Probes, absorption 500 nm, emission 520 nm), which fluoresces strongly only when bound to nucleic acids, and which specifically exhibits a large fluorescence enhancement when bound to the U bases in poly(rU). SWNT-BSA hybrids were prepared by the same procedure as that for the SWNT-poly(rU) hybrids, except labeling since BSA was pre-labeled with TRITC (Sigma, absorption 550 nm, emission 570 nm).

Binding of SWNTs and poly(rU) was analyzed by SEM (S4700, Hitachi), and a drop of the solution containing poly(rU) ( $0.2 \mu\text{g } \mu\text{L}^{-1}$ ) and SWNTs ( $0.01 \mu\text{g } \mu\text{L}^{-1}$ ) in TE buffer was dispersed on a silicon substrate after probe-sonication. The substrate was left to dry overnight then coated with chromium prior to imaging. An SEM analysis revealed that the average length of the SWNTs was approximately 400 nm with a standard deviation of 50 nm for the 50 hybrids examined. As shown in Fig. 7.11, poly(rU) molecules are seen bound at (a) the end or (b) midpoint of an SWNT(s). In Fig. 7.11(c), possibly two SWNT-poly(rU) hybrids are joined together. Figure 7.11 suggests that poly(rU) molecules remain bound to SWNTs even in dry conditions. However, the poly(rU) appear mostly as globules and no helical wrapping of poly(rU) on SWNTs is evident due to the possible lack of hydrogen bonds with water molecules [66].

Diffusing poly(rU), SWNT-poly(rU), and SWNT-BSA were imaged on an EPI fluorescence microscope. The excitation source of the microscope was a mercury lamp (PTI). Fluorescence was collected with a water immersion objective (Olympus,  $60\times$ ,  $NA = 1.2$ ) that was then focused onto a CCD camera (Roper, Cascade 512B). The imaging of poly(rU) and SWNT-poly(rU) was excited with blue light while that of SWNT-BSA was excited with green light. Approximately 100 poly(rU), SWNT-poly(rU), and SWNT-BSA hybrids were tracked, respectively, at a rate of six frames per second. The intensity of possible photoluminescence for isolated SWNTs [44, 85, 86] is expected to be much weaker than the fluorescence of the ultrasensitive OliGreen dye (approximately five bases of poly(rU) per dye) with a wavelength shifting to NIR. Our control experiments confirmed this phenomenon in which isolated SWNTs or SWNT hybrids were not visible without fluorescence labeling.

Figure 7.12(a) shows a fluorescence image sequence of an SWNT-poly(rU) hybrid diffusing in TE buffer with a time interval of 1.5 s. Figure 7.12(b) displays the corresponding 2D time trajectory of the SWNT-poly(rU) hybrid. The time interval between the consecutive steps is 0.167 s. The diamonds in the trajectory represent the COMs of the hybrid in individual image frames. The histogram of the bootstrap diffusion coefficients [87] as an ensemble was calculated for 1000 sam-

**Fig. 7.11.** SEM images of a poly(rU) molecule bound at (a) the end and (b) midpoint of an SWNT(s); (c) possibly, two SWNT-poly(rU) hybrids joined together. Scale bar: 100 nm. The SWNTs are seen individually or in very small bundles ( $\leq 10$  nm in diameter). Tertiary structures of the poly(rU) may prevent their

nitrogenous bases from fully binding to the SWNT sidewalls. However, limited by the instrument resolution ( $\sim 2.5$  nm), these fine structures were not clearly resolvable. The background structure is due to the chromium coating used to enhance image contrast [66]. (© American Institute of Physics.)

pling instances based on a linear fitting of the MSD versus time interval  $\Delta t$ . The stability/resolution of the imaging system was calibrated to be  $5 \times 10^{-5} \mu\text{m}^2 \text{s}^{-1}$  with fluorescence beads immobilized on glass slides. As shown in Figure 7.13, the diffusion coefficients  $D_{\text{SWNT-poly(rU)}}$  and  $D_{\text{SWNT-BSA}}$  of the SWNT-poly(rU) and the SWNT-BSA hybrids were measured to be  $0.374 \pm 0.045$  and  $0.442 \pm 0.046 \mu\text{m}^2 \text{s}^{-1}$ , respectively. The numbers after “ $\pm$ ” give the standard deviations of the means. By comparison, the mean diffusion coefficient  $D_{\text{poly(rU)}}$  of poly(rU) alone (inset of Fig. 7.13) was found to be  $0.661 \pm 0.110 \mu\text{m}^2 \text{s}^{-1}$ , almost twice that for the SWNT-poly(rU) hybrids due to their different conformations [66].

The diffusion coefficient of a small particle in solution, according to Einstein’s relation, can be described by  $D = k_B T / k_{\text{drag}}$ , where  $k_B$  is the Boltzmann constant,  $T$  is the temperature of the solution, and  $k_{\text{drag}}$  is the drag coefficient. For a rod-like particle,  $k_{\text{drag}} \propto \eta d$ , where  $\eta$  is the viscosity of the solution, and  $d$  is the longest dimension of the particle [88], which is approximately 400 nm for the SWNTs used in our diffusion experiment. The SWNT-poly(rU) hybrids, compared with SWNT-BSA, exhibit a relatively smaller mean diffusion coefficient that may be induced by the overhangs of the poly(rU) extruding from the ends of the SWNTs (refer to Fig. 7.11a). While the radius of gyration  $R_G$  of BSA is merely 3 nm [89], as opposed to an order of tens of nanometers for the  $R_G$  of poly(rU), the diffusion of SWNT-BSA is less affected. Here  $\Delta D$  is defined as the full-width at half-maximum for the distribution of diffusion coefficient. By Gaussian fitting,  $\Delta D_{\text{poly(rU)}}$  is found to be  $0.235 \mu\text{m}^2 \text{s}^{-1}$  (inset of Fig. 7.13), a broad distribution attributed to the length variation (500–2600 nucleotides), the instability, and the conformational changes of the poly(rU) molecules (in transient linear stretches, globules, and other tertiary structures).  $\Delta D_{\text{SWNT-poly(rU)}}$  and  $\Delta D_{\text{SWNT-BSA}}$  for the two hybrids obtained from the Gaussian fittings in Fig. 7.13 are  $0.092$  and  $0.094 \mu\text{m}^2 \text{s}^{-1}$ , respectively. In compar-

ison with poly(rU), the narrower distributions of the diffusion coefficients for the two hybrids possibly result from the rod-like structure of the SWNTs, which is expected to dominate the diffusion of the hybrids. Following Einstein's relation and based on the rule of error analysis, it can be derived that  $S_d = \bar{d}S_D/\bar{D}$ , where  $S_d$  and  $S_D$  are the standard deviations of  $d$  and  $D$ , and  $\bar{d}$  and  $\bar{D}$  are the means of  $d$  and  $D$ , respectively. Using the measured diffusion coefficients of SWNT-poly(rU), it can be calculated that the standard deviation  $S_d$  of the length of SWNT ( $d$ ) is approximately 48 nm. This deviation agrees with the SEM observation, which found a 12.5% deviation for the length distribution of the SWNT-poly(rU) hybrids. In that regard, a single-molecule diffusion study can be used as a measure for the structural information of SWNTs and their hybrids [66].

The measured mean diffusion coefficients suggest that a SWNT hybrid would take approximately 1–2 min to diffuse across a cell 10  $\mu\text{m}$  in diameter, consistent with the known diffusion coefficients of DNA and proteins within the cell's cytoplasm [89]. Faster diffusion can be achieved with SWNT hybrids prepared using extended probe-sonication. In future diffusion studies, the persistence length [90], a parameter that describes bending stiffness and flexibility, will be measured for SWNTs. The effect of the binding of nucleic acids and proteins on the persistence length of SWNTs will be also evaluated. These studies will provide knowledge on the flexibility of SWNTs in comparison with biomacromolecules, such as flexible double-stranded DNA, semiflexible actin filaments, or rigid microtubules. These diffusion studies on SWNTs can be extended to cell membranes and nuclei where hindered diffusion [81, 88] and reptation [88, 91, 92] may be significant. These studies facilitate, from a physical viewpoint, the applications of gene transfection using SWNTs as transporters.

#### 7.4

#### Gene and Drug Delivery with SWNT Transporters

Gene delivery and transfection, or the introduction and expression of foreign DNA, continue to draw strong interest because of their potential for gene therapy and disease prevention potential [93]. One of the greatest challenges for gene delivery is the physicochemical properties of DNA such as its negative charge and hydrodynamic volume. Transporters for DNA must be developed for gene delivery and gene transfection. Solutions to this problem have included viral (retroviral, lentiviral, and adenoviral) vectors and non-viral transfection vectors, including cationic lipids [94], polyethylenimine (PEI), and other cationic polymers [93, 95]. The viral transfection vectors have proven to be the most effective due to their natural ability to introduce foreign genetic information into cells. However, these viral vectors often provoke immune responses from cells, preventing successful gene delivery. Non-viral transfection vectors can avoid immune responses but are often hindered by low efficiency rates for nuclear membrane penetration and gene expression. Even though a few of the cationic polymers such as PEI boost relatively high efficiency rates for non-viral vectors, they exhibit cytotoxicity [96].

**Fig. 7.14.** EPI-fluorescence (A) and confocal microscopy (B) images of 3T3 cells incubated at 37 °C with 1 and 5  $\mu$ M concentration of CNT 1, respectively. EPI fluorescence microscopy images of 3T6 cells incubated at 37 °C

with 1 (C, D) and 5  $\mu$ M (E, F) concentration of CNT 2. The nucleus is stained with DAPI (C and E) [97]. (© The Royal Society of Chemistry.)

Since none of the current transfection vectors are ideal, alternative vectors must be sought through the exploration of new materials and methods, and SWNTs are one possibility. They possess versatile electronic and mechanical properties and have found numerous applications in both nanotechnology and materials science. Because SWNTs have a large surface area, stability, flexibility, and biocompatibility, they have excellent prospects for effective drug and gene delivery, and therapies [28]. Recently, Pantarotto et al. showed that fluorescently labeled SWNTs that covalently bind with bioactive peptides can penetrate cellular and nuclear membranes (Fig. 7.14) [97]. However, the mechanism for the translocation of SWNTs has yet to be determined and, therefore, can only be speculated upon. Shi Kam et al. have reported the appearance of SWNT–streptavidin conjugates within promyelocytic leukemia and T cells via the endocytosis pathway (Fig. 7.15) [98].

#### 7.4.1

#### RNA Translocation with SWNT Transporters

To explore the possibilities of SWNTs as transporters for gene delivery and transfection, we conducted a novel examination of the translocation of nucleic acid RNA polymer poly(rU) into breast cancer cells (MCF7). The non-specific binding

**Fig. 7.15.** (Top) Synthesis and schematic of various SWNT conjugates. incubation in a mixture of **4** (green due to SA) and the red endocytosis marker FM 4-64 at 37 °C (image shows fluorescence in the green region only); (c) same as (b) with additional red fluorescence shown due to FM 4-64 stained endosomes; and (d) same as (b) after incubation at 4 °C [98]. (© American Chemical Society.)

mechanism for SWNTs and poly(rU) in our study, as opposed to the covalent binding scheme by Pantarotto et al. and Shi Kam et al. in their respective peptide and protein delivery studies [97, 98], may offer more options and flexibility for the release of the load carried by SWNTs upon delivery. The sectioning property of confocal fluorescence microscopy in our study allows for axial discrimination of fluorescently labeled SWNT-poly(rU) hybrids on cell membranes, within either the cytoplasm, or the nucleus. In addition to confocal fluorescence imaging of SWNT-poly(rU) incubated with MCF7 breast cancer cells, we performed radioisotope labeling, cell enumeration, and an MTS [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulphophenyl)-2H-tetrazolium] assay, which measures

cellular metabolic activity through absorption. These additional studies quantitatively evaluate the direct cellular uptake and the cytotoxicity of SWNTs.

In our studies, SWNT bundles were synthesized using the arc-deposition method, with the dominant SWNT diameter of  $\sim 1.4$  nm [84]. SWNT bundles were probe-sonicated (VC 130 PB, Sonics & Materials) at 8 W for 90 min on ice in 10% FBS/PBS buffer. The SWNTs at a concentration of  $0.4$  mg mL<sup>-1</sup> were filtered through a  $0.45$   $\mu$ m filter before incubating with MCF7. Both the control cells and the cells treated with SWNTs were enumerated at 24, 48, and 72 h. The cell growth medium was RPMI supplemented with 10% FBS and 1% penicillin streptomycin. After the designated time of incubation, cells were released by trypsin-EDTA treatment (5 min) and counted with hemocytometry. Precautions were also taken to prevent contamination in preparing the SWNTs, including filtration to remove the bacteria and sterilization of the instruments in contact with the sample. The MTS assay was performed after treating MCF7 cells with various concentrations of SWNTs (0, 0.0125, 0.025, 0.05, 0.1, 0.125, 0.25, 0.5, and 1 mg mL<sup>-1</sup>). After 24 h of incubation, the growth medium was removed from the 96-well-plate and PBS (200  $\mu$ L) was used to wash the cells twice. RPMI-1640 medium without phenol red (approx. 200  $\mu$ L) and MTS (25  $\mu$ L) were added to each cell well, followed by incubation at 37 °C for 3 h. The absorbance in each well was measured using a spectrophotometric plate reader (Benchmark Microplate Reader, Bio-Rad) at a wavelength of 490 nm.

The translocation of SWNTs into cells was confirmed by radioisotope labeling assay. SWNTs were probe-sonicated in RPMI-1640 growth medium and incubated with radioactive [methyl-<sup>3</sup>H]thymidine overnight. The radioactively labeled SWNTs were collected by centrifugation and re-suspended in PBS before incubating with MCF7 cells. After incubation, the cells were released by trypsin-EDTA and re-collected as pellet by centrifugation. The pellet of MCF7 cells was thoroughly washed with PBS buffer twice to remove excess SWNTs and thymidine bound on the cell surface. The scintillation counts (Beckman Coulter, LS6500) read from the MCF7 cells, as opposed to those from the supernatants and the PBS washing buffer, yielded the translocation efficiencies of the radioactively labeled SWNTs at 1.3%, 6.3%, 10.7%, and 15.4% for incubation times of 0.5, 1, 2, and 4 h, respectively [67]. This result confirms that SWNTs alone can penetrate through cellular membranes with an increased efficiency over time, and concurs with the general understanding that cell membranes intake small hydrophobic particles.

For the imaging experiment, the SWNT-poly(rU) hybrids were prepared as follows. A mixture of poly(rU) ( $0.5$  mg mL<sup>-1</sup>) and SWNTs ( $0.125$  mg mL<sup>-1</sup>) in TE (10 mM Tris-HCl, 1 mM EDTA) buffer was probe-sonicated. From scanning electron microscopy and single-molecule diffusion studies, the prepared SWNT-poly(rU) hybrids were characterized in small bundles or isolated form with an average length of 400 nm [66].

To visualize the SWNT-poly(rU) hybrids, poly(rU) was fluorescently labeled with PI, which has an excitation peak at 535 nm and an emission peak at 617 nm. PI intercalates between the base pairs of nucleic acids, it is membrane impermeable, and is generally excluded by viable cells. To achieve fluorescent labeling, PI

(0.05 mL mL<sup>-1</sup>) in TE buffer was incubated with SWNT-poly(rU) hybrids at a volume ratio of 1:20 for at least 15 min. Excess PI and unbound poly(rU) were removed by cassette dialysis (Slide-A-Lyzer, 10,000 MWCO, Pierce) for a total of 36 h with three changes of buffer solution.

Approximately 10 000 MCF7 cells were deposited in each well of an eight-chambered slide to form a sparsely distributed layer of cells to ensure good exposure of cell membranes to SWNT-poly(rU) hybrids. Cells were directly cultured on the chamber glass slide using RPMI-1640 growth medium at 37 °C under 5% CO<sub>2</sub>. All cells were incubated for 24 h until an approximate 60% confluence was achieved. Twenty μL of PI, PI+poly(rU), or PI-labeled SWNT-poly(rU) hybrids (0.05 mL mL<sup>-1</sup>) was added to the chamber slide, and the cells were incubated for 2, 3, or 4 h. After incubation, the cells were washed twice with growth medium (200 μL) and kept in PBS (400 μL) before imaging with the confocal fluorescence microscope (LSM510, Zeiss, objective NA = 1.3, oil). Fluorescence from PI was collected in the TRITC channel, and the background was recorded from the bright-field channel of the microscope.

The confocal fluorescence images of the two controls, PI and PI+poly(rU), showed little to no fluorescence after incubation and the MCF7 cells appeared elongated and healthy (Fig. 7.16). In contrast, the PI control (Fig. 7.16a) showed one instance of intense fluorescence from a PI stained circular unhealthy cell. The minimal fluorescence intensity surrounding the cellular membrane for the PI+poly(rU) (Fig. 7.16b) was probably due to electrostatic interactions between the charged poly(rU) and cellular membrane.

The confocal fluorescence images of the MCF7 cells that were incubated with the SWNT-poly(rU) hybrids for 2 h showed translocation into the cytoplasm without accumulation of SWNT-poly(rU) hybrids on the outside of the cellular membrane. Figure 7.17 shows MCF7 cells appearing to retain the SWNT-poly(rU) hybrids after an incubation of 3 h. All the images were taken from a stack of slices scanned through the cells with a full scanning depth of approximately 10 μm and

**Fig. 7.16.** Control experiments showing little to no uptake of (a) PI, except in the dying circular cell, and (b) PI+poly(rU). Scale bar = 10 μm [68]. (© American Chemical Society.)

**Fig. 7.17.** Confocal fluorescence images of MCF7 cells incubated with  $0.05 \text{ mL mL}^{-1}$  of PI-labeled SWNT-poly(rU) for 3 h. Images (a)–(h) were acquired at different depths ( $z = 0.5, 1.51, 2.52, 3.53, 4.54, 5.55, 6.56, 7.57$

$\mu\text{m}$ ), across the z-axis normal to the chamber slide surface. The arrows point to the fluorescent spots where large SWNT-poly(rU) hybrids are localized. Scale bar =  $10 \mu\text{m}$  [68]. (© American Chemical Society.)

a scanning step of  $1.01 \mu\text{m}$ . Smaller red spots with low intensities as shown in Figs. 7.17(a–e) are thought to be small soluble SWNT-poly(rU) hybrids and/or PI-labeled poly(rU) dissociated from SWNTs after translocation. Their gradual disappearance (Figs. 7.17f–h) implies the uneven distribution of SWNT-poly(rU) hybrids in cytoplasm and/or possibly the defocusing of the hybrids. Figure 7.17(b) shows the uptake of an SWNT-poly(rU) hybrid in the cytoplasm, as indicated by the arrow. Figure 7.17(d) shows an instance of an SWNT-poly(rU) hybrid appearing in the vicinity of cell membrane; however, whether the exact location of the hybrid is within or on the cell membrane is unclear. In Figs. 7.17(f) and (g), the fluorescent spot was observed to co-localize with the nucleus, which supports the possibility that the SWNT-poly(rU) hybrid could have penetrated through the nuclear membrane. The observed fluorescence in Figs. 7.17(f) and (g) could also be from PI-labeled poly(rU) released from SWNTs due to dissociation kinetics and the change of pH between cytosol and nucleus [68].

The released nucleic acids may be used as templates for transfection at a later stage. Energetically, the fluorescence in the nucleus is unlikely to be from either free PI or PI dissociated from poly(rU) and then re-intercalated with the host

DNA or RNA. However, the binding dynamics of SWNTs and nucleic acids are beyond the scope of this chapter. The strong fluorescence in Figs. 7.17(f) and (g) fades gradually [Figs. 7.17(e) and (h)], which further indicates that the SWNT-poly(rU) hybrid was localized within the cell. From the depth information, we estimate that this large SWNT-poly(rU) hybrid is less than 2  $\mu\text{m}$  long. This length is consistent with that of the SWNTs obtained with probe sonication, confirming that the observed fluorescence was from the SWNT-poly(rU) hybrid. After 4 h of incubation the SWNTs were still present within the MCF7 cytoplasm and nucleus [68].

The uptake of the SWNTs-poly(rU) is hypothesized to be a result of amphipathic properties of both the cellular membrane and the SWNT-poly(rU) hybrids. Due to thermal agitation, lateral diffusion of phospholipids within the biomembrane may contribute to the translocation of SWNT-poly(rU) hybrids by allowing hydrophobic interactions between the hydrocarbon chains and SWNTs within the bilayer. The uptake of the SWNTs by the nuclear membrane is attributed to passive ratchet diffusion [99]. Cell mitosis might also play a significant role in the internalization of the SWNT-poly(rU) hybrids. During cell division, the nuclear envelope breaks down into multiple small vesicles early in mitosis, which may allow the translocation of SWNT-poly(rU) hybrids. In the telophase, the last mitotic stage, the nuclear envelope reforms, possibly incorporating the SWNT-poly(rU) hybrids. Once the SWNT-poly(rU) hybrids are within the MCF7 cells, it is possible that endosomes in the cytoplasm store SWNTs after poly(rU) translocation.

In summary, we have demonstrated the delivery of RNA polymer using SWNTs as transporters [68]. Translocation of SWNTs into MCF7 cells was confirmed by radioisotope labeling assay. Based on the sectioning property of confocal microscopy, fluorescently labeled SWNT-poly(rU) hybrids were found across the cellular and the nuclear membranes of MCF7 cells while the controls were excluded. Both cell growth and MTS studies have shown no cytotoxicity in either MCF7 breast cancer cells or d2C keratinocytes for concentrations up to 1  $\text{mg mL}^{-1}$ . These studies show the potential of using SWNTs as transporters for gene delivery, but further biophysical and biochemical studies must be conducted to better decipher the mechanisms of SWNT translocation across cellular and nuclear membranes. Assays on gene transfection using SWNT transporters need to be performed to move towards the final goal of gene therapy and disease prevention.

#### 7.4.2

##### **Gene Transfection with SWNT Transporters**

Limited literature is available on gene transfection with CNT transporters, with the only proofs of concept being reported by Pantarotto et al. [100] and Liu et al. [101]. The efficiencies of DNA transfection in mammalian cells were not optimal in these preliminary studies, yet they showed at least one order of magnitude enhancement over DNA alone.

Pantarotto [100] revealed that both SWNTs and MWNTs were covalently modified by pyrrolidine rings, each bearing a free amino-terminal oligoethylene glycol moiety attached to the nitrogen atom. The concentration of the functional groups

was 0.55 and 0.90 mmol g<sup>-1</sup> for functionalized-SWNTs and MWNTs, respectively. The presence of these functional groups led to a much increased solubility of the CNTs in aqueous solution. The electrostatic interaction of positively charged ammonium functionalized CNTs with the negatively charged phosphate backbone of plasmid DNA was confirmed by TEM. Plasmid DNA molecules, encoded with marker gene ( $\beta$ -galactosidase;  $\beta$ -gal) were seen adopting spherical, toroidal, or supercoiled structures 15–300 nm in diameter when exposed to the positively charged groups [100]. The varying degree of plasmid condensation could be related to the charge density, the hydrophobic character of the interaction, and the number of plasmid DNA molecules in the condensate [102]. Tighter packing of functionalized SWNTs was noticeable in regions of larger CNT bundles.

The interaction of functionalized CNTs with HeLa cells was also visualized by TEM. HeLa cells were incubated with ammonium functionalized CNTs at a concentration of 2.5 mg mL<sup>-1</sup> for 1 h and the mixture was then embedded in an epoxy resin. Solidified resin was sliced by an ultramicrotome and the slices were examined by TEM. CNTs were spotted inside the cells; higher magnifications provided more convincing evidence of their internalization. Nuclear localization and the translocation of CNTs through plasma cell membranes were also seen. The mechanism hereby was believed to be the binding of the cationic functional groups on the CNTs to the cell membranes, which could be facilitated by spontaneous insertion of the CNTs across the cell membranes. Subsequent translocation and diffusion of the functionalized CNTs within the intracellular space could occur following these nonendocytotic processes [100].

The ability of ammonium-functionalized SWNTs to enter cells and potentially reach their nuclei resulted in the delivery of plasmid DNA to CHO cells. Hypothetically, these functionalized SWNTs entered the cells via a spontaneous mechanism in which the tubes pierced through the cell membranes due to their enormous aspect ratio. This model is consistent with molecular dynamics simulations which predicted that hydrophobic CNTs with hydrophilic functional groups could spontaneously insert into a lipid bilayer. Both the hydrophobicity of SWNTs and the rapid lateral diffusion of lipids in the membrane bilayer could contribute to the uptake of SWNT-plasmid DNA complexes [100].

The rate of gene transfection depended on the charge ratio of the ammonium groups on the SWNT surface to the phosphate groups of the DNA backbone. Gene expression efficiencies 5–10 $\times$  higher than those without the presence of SWNTs were obtained when the charge ratio was maintained within the range of 2:1 to 6:1. Gene expression also increased with incubation time of up to 3 h and decreased thereafter. Although the measured transfection efficiency was far from optimal, functionalized SWNTs seem to offer ample opportunities for chemical and biological modifications than do cationic macromolecules such as peptides, dendrimers, and liposomes. The other significant advantage that functionalized SWNTs have over conventional gene and drug delivery methods is their significantly reduced cytotoxicity [100].

In the study conducted by Liu et al. [101], dendritic polyethylenimine (PEI), a most efficient and popular polymer for gene delivery, was grafted onto MWNTs to

anchor DNA. Carboxylic acid groups were first created on the side walls of the MWNTs by heating the tubes at reflux in 3 M nitric acid. The carboxylic acid groups were then transformed into acyl chloride groups by consecutive treatments of thionyl chloride and ethylenediamine [26, 57]. PEI was then grafted onto MWNTs based on the activated monomer mechanism or the activated chain mechanism. Protonated aziridine monomers or the terminal iminium ion groups of propagation chains were transferred to amines on the surface of the MWNTs to form PEI-g-MWNTs complexes. DNA encoded with pCMV-Luc gene was then immobilized securely onto the complexes through strong electrostatic interactions arising from the amines. The formation of DNA-PEI-g-MWNT complexes was confirmed by the total inhibition of DNA migration in gel electrophoresis [101].

The PEI obtained by cationic polymerization of aziridine had a dendritic structure that contained primary, secondary, and tertiary amines with a molar ratio of about 1:2:1 [103]. The polymer chemistry of the PEI should not have been affected by their grafting onto the surface of MWNTs. Grafted PEI with a high content of primary, secondary, and tertiary amines could function as anchor points for the immobilization of DNA onto the surface of MWNTs. Consequently, the migration of DNA was totally inhibited in gel electrophoresis when the weight ratio of PEI-g-MWNTs to DNA was about 4:1. By comparison, the control experiments using MWNTs and NH<sub>2</sub>-MWNTs showed little inhibition on the migration of DNA, even at a high weight ratio of 100:1. This is because the nonspecific adsorption of PEI on the surface of MWNTs did not facilitate the secure anchoring of DNA, possibly due to weak interactions between the PEI and MWNTs [101].

The PEI-g-MWNTs gene transporters created in the Liu study [101] yielded more encouraging results than the Pantarotto scheme [100], which used functionalized SWNTs. Figure 7.18 details a head-to-head comparison of transfection efficiency in human embryonic kidney 293 cells for DNA-PEI (25 kDa), DNA-PEI-g-MWNTs, and DNA alone. Under the optimal conditions, the transfection efficiency using PEI-g-MWNTs was three times higher than that using PEI, and, remarkably, four orders of magnitude higher than that using naked DNA. Transfection efficiencies using PEI-g-MWNTs in COS7 and HepG2 cells, under optimal conditions, were consistently 2½ times greater than efficiencies using PEI, and were much higher than efficiencies using DNA [101].

The mechanisms proposed and speculated upon in the literature for CNT uptake or their derivatives by cells include phagocytosis, endocytosis, insertion, or passive diffusion. Liu et al. [101] attributed DNA uptake to endocytosis because PEI-g-MWNTs, once labeled with fluorescein isothiocyanate and left incubating in cells for 1 h, significantly reduced their presence in cells with increasing temperature. The high transfection efficiency obtained using PEI-g-MWNTs was perhaps due to the secure anchoring of DNA onto the surface of MWNTs. The proton-sponge effect of the grafted PEI could allow the DNA-PEI-g-MWNTs complexes to escape easily from highly acidic endosomes or other vesicles in cells. The larger complexes of DNA-PEI-g-MWNTs could have improved the proton-sponge effect of PEI and facilitated a more effective sedimentation onto the cells [101].

**Fig. 7.18.** Transfection efficiency of PEI-g-MWNTs for DNA delivery relative to that of PEI and naked DNA in 293 cells. The level of pCMV-Luc gene expression is given in RLU per mg of protein for quadruplicate runs [101]. (© Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim.)

### 7.4.3

#### Gene Transfection with SWNT Transporters for RNA Interference

In addition to its fundamental roles in gene transcription and translation, RNA has been used for two decades to reduce (or interfere with) expression of targeted genes in various systems such as plants, fungi and higher organisms. This process, known as RNAi, is a natural defense mechanism that is thought to have evolved to protect organisms from viral diseases. Many viruses have a genetic blueprint made from RNA instead of DNA. The genetic information of many viruses is held in the form of double-stranded RNA and an enzyme known as Dicer first chops the double-stranded RNA of invaded viruses into small segments of genetic code of approximately 22 bases long. These segments, known as siRNAs, are surprisingly stable and, unlike ssDNA or RNA anti-sense oligonucleotides, do not need extensive modification to survive in tissue culture media or even within living cells. These newly formed siRNA then separate into single strands and some bind to intact lengths of single-stranded viral RNA. Finally, proteins target this tagged viral RNA and destroy it. As a result, RNAi shuts off key viral genes, potentially nipping infections in the bud. In theory, RNAi can be used to treat any disease such as cancer, which is an overactive gene or genes, or HIV, a virus with no cure and vaccine.

In one of the most exciting developments thus far, Dai's group reported gene silencing with SWNT delivered siRNA [104]. Phospholipids (PL) were adsorbed

onto SWNTs and the head groups of the PL were covalently linked by single-chained poly(ethylene glycol) (PEG, MW = 2000) with terminal amine or maleimide groups (PL-PEG-NH<sub>2</sub> or PL-PEG-maleimide). The PL-PEG bound to SWNTs via van der Waals and hydrophobic interactions between the fatty alkyl chains of the PL and the side walls of the SWNTs. Although double-chained PL molecules do not solubilize SWNTs, the presence of the PEG greatly increased the hydrophilic moiety of the PL-PEG-SWNT complexes, rendering SWNTs soluble in an aqueous solution. The amine or maleimide terminal on the PL-PEG immobilized on SWNTs was used to conjugate biofunctionalities such as DNA and siRNA. A crosslinker, sulfosuccinimidyl 6-(3'-[2-pyridyldithio]propionamido)hexanoate (sulfo-LC-SSDP), was attached to a thiol-containing biomolecule (X) to form SWNT-PL-PEG-SS-X (1-X). The biomolecule X was either 1-DNA (15-mer DNA with fluorescence label Cy3) or 1-siRNA. No disulfide linkage was employed in the control experiments [104].

In the study by Dai's group, biomolecules DNA or siRNA were transported by functionalized SWNTs into mammalian cells. SWNTs and their derivatives, after the cellular internalization of biomolecules, were believed to be allocated in endosomes and/or lysosomes. The disulfide bonds linking the biomolecules and the PL-PEI complexes were cleaved and the biomolecules were released by enzymes in lysosomal compartments whose pH (~5) is significantly lower than that of the cytosol (pH 7.2). Translocation of SWNT complexes across the cell membranes was believed to result from endocytosis [104]. Active releasing of endocytosed species from endosomes or lysosomes allows molecule cargoes to reach their intended destinations, thus preventing degradation inside the endosomes or lysosomes [105]. No effect on cell viability or proliferation was found by the presence of SWNTs in this study.

Both 1-siRNA and 2-siRNA were prepared where the siRNA was capable of silencing the gene encoding lamin A/C protein present inside the nuclear lamina of cells. HeLa cells were again used to incubate with 1-siRNA (50–500 nM) for up to 24 h. The concentration of SWNTs was 10 nM and cells of 40 000 per well in the presence of 5% FBS were fixed 48–72 h later. The cells were then stained with anti-lamin and fluorescently labeled secondary antibodies. The commercial transfecting agent lipofectamine (1 mg L<sup>-1</sup>) was used for comparison with the SWNT delivery system.

Minimal fluorescence was observed in the experiment (Fig. 7.19b) compared with that of the untreated control (Fig. 7.19a), indicating a significant reduction in the expression of lamin A/C proteins by 1-siRNA. The potency of RNAi was characterized using flow cytometry in the order 1-siRNA, 2-siRNA, and lipofectamine-siRNA, for a given concentration of siRNA (Fig. 7.19c). The higher silencing potency with 1-siRNA than 2-siRNA is possibly due to the release of siRNA from SWNTs by breaking their linking disulfide bonds. This released and subsequently more effective siRNA can then readily escape from endosomes or lysosomes. This two-fold increase in the silencing potency using 1-siRNA compared with lipofectamine was attributed to the high surface area of SWNTs for siRNA cargo loading, the high intracellular transporting ability of SWNTs, and the high degree of

**Fig. 7.19.** Confocal microscopy RNAi assay for (a) untreated control HeLa cells and (b) cells incubated with 1-siRNA, the latter showing a much weaker fluorescence than (a) due to silencing of the expression of lamin protein by RNAi. (c) Silencing efficiency of lipofectamin-siRNA (left-hand bars), 2-siRNA (middle bars) and 1-siRNA (right-hand bars) for 50 and 500 nM siRNA concentrations. Cells were fixed and stained with anti-lamin and a fluorescently labeled secondary antibody prior to analysis. The confocal images were captured at similar experimental settings for (a) and (b) [104]. (© American Chemical Society.)

endosome/lysosome escape owing to the breakage of the disulfide bond. Excellent siRNA delivery and silencing of the luciferase gene were also observed [104]. This study has shown great promise for using SWNT as molecular transporters for gene therapy.

#### 7.4.4

#### Drug Delivery with SWNT Transporters

This section reviews recent developments in drug delivery with SWNT transporters, and highlights the research by Pantarotto et al. on immunization with peptide-functionalized SWNTs for enhancing virus-specific neutralizing antibody responses [28], and the research by Dai's group on intracellular protein transport for inducing apoptosis and on the highly sensitive electronic detection of antibodies associated with human autoimmune diseases [106].

##### 7.4.4.1 Vaccine Delivery by SWNTs

Developing new and effective delivery approaches is of paramount importance for administering protective antigens. SWNTs could serve as excellent transporters for

the effective utilization of antigens that have previously been unable to induce adequate or appropriate responses, thus providing significant means of enhancing and modulating immune responses. In vaccine delivery, conserving the conformation of antigen is crucial. This conservation, in turn, yields the induction of antibody responses with the right specificity. Therefore, the presence of SWNTs should not change the biofunctionality of the antigen when they are linked together. Pantarotto et al. evaluated the capacity of mono- and bis-derivatized SWNTs to present B cell epitope from the VP1 coat protein of FMDV [107]. The knowledge obtained from this study served to enhance the neutralizing potential of the B cell epitope.

The chemical route for obtaining water-soluble SWNTs is based on the methodology described in Section 7.2.1.2. SWNTs were functionalized with a pyrrolidine ring through the 1,3-dipolar cycloaddition of azomethine ylides [108]. The amino-derivatized SWNTs were subsequently used to covalently link a series of peptides by different strategies. In one approach, B cell epitope, a peptide corresponding to the sequence 141-159 derived from VP1 protein of FMDV, was coupled to functionalized SWNTs, employing a selective chemical ligation to obtain the mono-conjugate 2 [28]. In another approach, functionalized SWNTs were covalently attached to two FMDV peptides to yield the bis-conjugate 3. The latter approach involved a derivatization of the free amino groups of SWNT 1 using an excess of Boc-Lys(Boc)-OH activated with DIC (diisopropylcarbodiimide) and HOBt (1-hydroxybenzotriazole) in DMF, and subsequent cleavage of Boc (tert-butyloxycarbonyl) with TFA (trifluoroacetic acid). The free amino groups were neutralized with DIEA (diisopropylethylamine) and coupled with *N*-succinimidyl 3-maleimidopropionate in DMF [108]. Excess reagent was removed by adding an amino-PEGA resin. The *N*-terminal acetylated FMDV 141-159 peptide, with an additional cysteine, was dissolved in water and linked to the two maleimido moieties [109]. Unreacted peptides were removed using a scavenger resin, and reverse-phase HPLC confirmed a peptide covalent bond formation to the SWNTs. The solubilities of the mono-conjugate 2 and the bis-conjugate 3, were 18.0 and 12.5 mg mL<sup>-1</sup>, respectively [28].

The activity of the FMDV 141-159 peptide was confirmed using a monoclonal assay. Anti-FMDV 141-159 peptide mAb was presented to a covalently linked anti-mouse Fc $\gamma$  antibody. SWNTs alone did not react with mAb, while free peptides, mono-conjugates 2, and bis-conjugates 3 all interacted with mAb in increasing masses [28]. However, an analysis of the three sensorgrams showed no difference in the association rate constants and only a small decrease of the dissociation rate constant for the bis-conjugate 3, which might be ascribed to the avidity of the bivalent reagent [28]. Thus both mono- and bis-conjugates preserve the conformation of their attached peptides.

An immunization protocol was tested on the coupling of nonimmunogenic peptides to SWNTs. Anti-peptide antibody responses were measured by ELISA using BSA-conjugated FMDV141-159 peptide as antigen (Fig. 7.20 left). The sensitivity of the ELISA was greater than that for the free peptides. The anti-FMDV 141-159 antibody response slightly increased when OVA was injected with the mono-conjugate 2. Using the bis-conjugate 3 as an immunogen (Fig. 7.20 left) also

**Fig. 7.20.** (Left-hand side): Anti-peptide antibody responses following immunization with peptides and peptide–SWNTs. Groups of BALB/c mice were co-immunized intraperitoneally with OVA and free FMDV 141-159 peptide, mono-conjugate 2, or bis-conjugate 3 in Freund's adjuvant emulsion. Serum samples collected 2 weeks after the booster immunization (on day 14 post priming) were screened by ELISA for the presence of antibodies using FMDV 141-159 peptide conjugated to BSA (solid bars), or control peptide conjugated to BSA (open bars), or

SWNT 1 functionalized with maleimido group without peptide (hashed bars) as solid-phase antigens. Data represent mean of  $\log_{10}$ (antibody titers) from five mice per group. (Right-hand side): Neutralization indices of serum samples of immunized mice. Serum samples were collected 2 weeks after the boost of mice co-immunized intraperitoneally with OVA and free FMDV 141-159 peptide, mono-conjugate 2, or bis-conjugate 3 in Freund's emulsion. Data represent the mean of antibody titers from five mice per group [28]. (© Elsevier Science Ltd.)

significantly elevated the anti-peptide antibody titers. Antibody responses were specific to the FMDV 141-159 peptides but not to the functional groups linking peptides to the SWNTs, because serum antibodies showed little reactivity to control peptides conjugated to BSA (Fig. 7.20 left). Both the peptide conjugates and OVA were sampled by antigen-presenting cells. Assistance from the OVA-specific T helper cells enabled the B cells to produce antibodies that recognized the FMDV 141-159 peptides. No anti-SWNT antibodies were detected (Fig. 7.20 left) [28]. The bystander help provided by the carrier (OVA) should be directed to the covalently

attached peptides and not to the SWNTs. This study indicated that SWNTs alone do not possess intrinsic immunogenicity.

Mono-conjugate 2 elicited virus-neutralizing antibody responses in mice (Fig. 7.20 right), which were significantly higher than those induced by the bis-conjugate 3 or the control free peptide. An increased number of epitopes at the surface of SWNTs enhanced the immunogenicity of the attached peptides while decreasing the neutralizing titers. It was hypothesized that both copies of the FMDV peptides of the bis-conjugate 3 assumed different conformations than that of their native state, thus failing to invoke antibody responses with the correct specificity [28]. The preferential induction of peptide-specific antibodies with enhanced virus neutralizing capacity using mono-conjugate 2, coupled with the non-responsiveness to the attached SWNTs, demonstrated the presentation of the attached peptides *in vivo*, suggesting their possible use as antigen delivery systems since no anti-carbon antibodies were elicited that could influence immune responses to their attached peptides.

#### 7.4.4.2 Protein Delivery by SWNTs

The Shi Kam and Dai study [106] explored protein delivery with SWNTs. The proteins used, including streptavidin (SA), protein A (SpA), BSA, and cytochrome *c* (cytc), were fluorescently labeled and bound to the side walls of SWNTs via a non-covalent and nonspecific mechanism (Section 7.2.2). Translocation of these proteins in mammalian cell lines, including HeLa, NIH-3T3 fibroblast, HL60, and Jurkats, cells was observed by confocal fluorescence microscopy. Endocytosis, an energy dependent internalization mechanism based on the engulfing of the foreign particles, was believed to be responsible since the uptake showed a distinct temperature dependence. For example, incubating the cells in protein-SWNTs conjugates at 4 °C yielded little uptake [106].

Cellular uptake of large proteins (molecular weight > 80 kDa) was poor, while the binding and intracellular protein transport by SWNTs appeared general for small- and medium-sized proteins [106]. Figure 7.21 compares the fluorescence level detected for cells incubated with proteins alone, and for cells incubated with protein-SWNTs; this suggests that while proteins in solutions were unable to traverse across cell membranes, SWNTs were able to transport protein cargoes inside cells possibly due to their hydrophobicity and high aspect ratio. SWNT-protein conjugates, once internalized within the cells, were found co-localized with red endocytosis endosome marker FM 4-64 [98], suggesting the confinement of the conjugates in endosomal lipid vesicles. Once within cells, the endosomes could fuse with lysosomes, and cause the degradation of the internalized species in the acidic lysosomes. To prevent lysosomal degradation, chloroquine was added to the cell medium during the incubation of cells in protein-SWNT conjugates to trigger an endosomal release of internalized molecules into the cell cytoplasm. Chloroquine is a membrane-permeable base that can localize inside endosomes and cause increases in pH. The resulting osmotic pressure led to swelling and eventual rupture of the endosomal compartments (Fig. 7.22). This phenomenon suggests that it is possible to create biological functionality for these internalized “cargo” molecules.

**Fig. 7.21.** Cell cytometry data for untreated HL60 cells (labeled as “control”), and for HL60 cells incubated in solutions of fluorescently labeled SA and SpA (a), and treated with the respective fluorescent protein–SWNT conjugates (b). Cells were incubated in protein–SWNTs solutions for 2 h [106]. (© American Chemical Society.)

HeLa and NIH-3T3 cell lines, known to undergo *cyt-c*-induced apoptosis [110], were used for intracellular transport of *cyt-c* with SWNTs and for apoptosis assay. After cell incubation in the *cyt-c*-SWNT conjugates, apoptosis was analyzed using fluorescently (FITC) labeled Annexin V. Annexin V-FITC is an efficient marker for early stage apoptosis as it binds to the phospholipid flipped from the inner to the outer leaflet of the plasma membrane during apoptosis. For NIH-3T3 cells in the presence of chloroquine and incubated, respectively, with *cyt-c*-SWNT conjugates and with *cyt-c* alone, the degree of Annexin V staining was characterized by both confocal microscopy (Fig. 7.23a, b) and cell flow cytometry (Fig. 7.23c). Significantly higher percentages of apoptosed cells were observed when incubated with *cyt-c*-SWNT conjugates than with *cyt-c* alone [106]. Figure 7.23(c; inset) shows the

**Fig. 7.22.** Endosomal rupture. Cells were incubated with (a) *cyt-c*-SWNT conjugate and (b) *cyt-c*-SWNT + 100  $\mu\text{M}$  of chloroquine at 37  $^{\circ}\text{C}$  and 5%  $\text{CO}_2$ . Confocal images were taken immediately after incubation and washing.

These images indicate the release of protein–SWNT conjugates from the endosome: overall green color across the cell in (b) vs. green individualized spots inside the cells in (a) [106]. (© American Chemical Society.)

**Fig. 7.23.** Apoptosis induction by cytochrome *c* cargos transported inside cells by SWNTs. (a) Confocal image of NIH-3T3 cells after 3 h incubation in 50  $\mu\text{M}$  cytochrome *c* alone (no SWNT present) and 20 min staining by Annexin V-FITC (green fluorescent). (b) Cell images after incubation in 50  $\mu\text{M}$  cytochrome *c*-SWNTs in the presence of 100  $\mu\text{M}$  chloroquine and after Annexin V-FITC staining. (c) Cytometry data of the percentage of cells undergoing early stage apoptosis (as stained by Annexin V-FITC) after exposure to 100  $\mu\text{M}$  chloroquine only (labeled “untreated”),

SWNT + 100  $\mu\text{M}$  of chloroquine, 10  $\mu\text{M}$  cyt-*c* + 100  $\mu\text{M}$  chloroquine, 10  $\mu\text{M}$  cyt-*c*-SWNT + 100  $\mu\text{M}$  chloroquine, and cyt-*c*-SWNT without chloroquine. Inset: representative confocal image of the blebbing of the cellular membrane (stained by Annexin V-FITC) as the cell undergoes apoptosis. Note that PI co-staining was used, and all data shown here excluded PI-positive cells and were recorded 4–5 h after exposure to chloroquine. The level of PI staining for all cells was a normal ~4–6% out of ~10 000 [106]. (© American Chemical Society.)

blebbing of the cellular membrane stained by Annexin V-FITC, a phenomenon associated with cells undergoing apoptosis.

To investigate the effect of endosomal release on the efficiency of apoptosis induction by cyt-*c* transported by SWNTs, cells were incubated in cyt-*c*-SWNT in both the presence and absence of chloroquine. Higher degrees of apoptosis were consistently observed for cells treated with cyt-*c*-SWNT in the presence of chloroquine (Fig. 7.23c). This higher degree of apoptosis is due to the more efficient endosomal releasing of proteins, suggesting that the cytochrome *c* bound and transported inside cells by SWNT carriers remained biologically active for apoptosis induction [106]. However, it is unclear if the functionality of cytochrome *c* was ob-

tained after detaching from the SWNTs, or if it remained effective even when proteins were still bound to the SWNTs.

#### 7.4.4.3 Biosensing by SWNTs

In a separate study by Dai's group [17], SWNTs were employed as biosensors for potential medical diagnostic and biological applications. In this scheme (Fig. 7.1 left), SWNTs were coated with U1A antigen-Tween conjugates and the immobilized antigens were recognized by 10E3 mAbs. The U1A RNA splicing factor is a prominent autoantigen target in systemic lupus erythematosus and mixed connective tissue disease, and detection of its autoantibodies by ELISA forms a clinical fluorescence assay. With SWNT sensors, binding can be monitored in real-time electronically without labeling, with the resulting sensitivity at a remarkable 1 nm or less.

Similar results were obtained with two other U1A-specific mAbs. In contrast, two different mAbs (3E6 and 6E3) specifically used for TIAR (a structurally related but different RNA binding protein autoantigen) failed to recognize the U1A splicing factor. This result compares favorably with fluorescence-based detection of immobilized antigens, where the limit of detection was found to be 2.3 nm [17]. In addition to offering a higher sensitivity, Dai's scheme also permitted sample preparation and detection to be performed in solution without protein denaturation. This study serves as a proof of concept that SWNT devices can detect clinically and biologically important interactions, with a potential for screening assays of mAb panels for use as reagents or therapeutics. Since the human proteome contains more than 300 000 different protein isoforms, methods for high-throughput screening of mAbs are crucial for their identification. Furthermore, multiplex analysis of autoantibodies may be performed with arrays of SWNT devices to diagnose patients with autoimmune diseases such as HIV, complementing or overtaking other recently developed techniques such as planar array-based methods [17].

## 7.5

### Sensing and Treating Cancer Cells Utilizing SWNTs

A milestone in the possible use of SWNTs to diagnose and treat cancer was recently reported by Dai et al. [32]. They demonstrated how several unique characteristics of SWNTs could be combined to serve the purpose of selectively causing cancer cell destruction. SWNTs functioned as multifunctional biological transporters for cargoes such as Cy3-DNA, various phospholipids, and folate moiety. The destruction of the cancer cells was due to the strong absorbance of translocated SWNTs in the NIR range (700–1100 nm) because of distinct first and second van Hove optical transitions (Fig. 7.24) [44].

*Ex vitro* studies showed an increase to approximately 70 °C after heating SWNTs of various concentrations for 2 min with continuous 808 nm laser light [32]. Heating was caused from optical stimulation of electronic excitations of SWNTs that was transferred to molecular vibration energies and heat. The transfer to molecular

**Fig. 7.24.** Semiconducting SWNTs electronic structure and density diagram of electronic states. Optical emission and excitation transitions are represented by solid arrows; dashed arrows show non-radiative relaxation of

the electron in the conduction band and of the hole in the valence band before emission [86].  
(© American Association for the Advancement of Science.)

vibration energies and heat has another interesting effect if pulsed NIR laser light is discharged. The pulsed optical stimulation of SWNTs seemed to cause the release of their cargoes, as demonstrated with confocal fluorescent images of Cy3-DNA-SWNT complexes (Fig. 7.25).

Perhaps more important than the demonstration of SWNT complex translocation is the preservation of cell viability. As previously shown, SWNT complexes below certain concentrations have no adverse affect on cell viability, and biological systems like cells experience limited or no damage because they are completely transparent to continuous NIR light. These two noninvasive aspects were combined to induce the destruction of cancer cells. Once cancer cells internalized SWNT complexes and were exposed to continuous NIR laser light, they experienced excessive heating and eventual death [32]. After exposure to this treatment, cells appeared round with aggregated SWNT complexes appearing within the growth medium (Fig. 7.26 left).

Another key issue involving cell viability in this experiment is the ability of cancer cells to selectively internalize SWNTs, thus ensuring that they can destroy harmful cells while preserving healthy ones. Specifically, SWNTs were conjugated with various phospholipids (PL), a poly(ethylene glycol) (PEG) moiety, and terminal folic acid (FA) group that provided specificity for this selective internalization (Fig. 7.27). Additionally, the preparation of cancer cells required some ingenuity

**Fig. 7.25.** NIR laser light excitation of Cy3-DNA-SWNT complexes causing DNA release and nuclear translocation. Confocal image of HeLa cells after 12 h incubation with  $2.5\text{--}5\text{ mg L}^{-1}$  Cy3-DNA-SWNT complexes and

radiation with six NIR pulses at 808 nm and intensity of  $1.4\text{ W cm}^{-2}$  for 10 s. Yellow coloring represents colocalization of green Cy3-DNA and red DRAQ5 in cell nuclei [32]. (© National Academy of Sciences.)

**Fig. 7.26.** Image of dead and aggregated cells after internalization of DNA-SWNT and continuous NIR laser radiation exposure for 2 min at  $1.4\text{ W cm}^{-2}$ . The dead cells show round and aggregated morphology 24 h after laser activated cell death. Black aggregates of

SWNTs are released from dead cells and could visually be seen floating. Raman data and SEM image of black aggregates ( $\times 36\,000$ ) confirm aggregates are SWNTs [32]. (© National Academy of Sciences.)

**Fig. 7.27.** Chemical structures of the cancer cell targeting scheme. (a) PL-PEG-FA and PL-PEG-FITC are conjugated with SWNTs and synthesized by conjugating PL-PEG-NH<sub>2</sub> with FA or FITC. (b) Diagram of selective internalization of PL-PEG-FA-SWNTs into folate-starved cells with increased folate receptors (FR). (c) No internalization of PL-PEG-FA-SWNTs into normal cells without folate receptors [32]. (© National Academy of Sciences.)

that included folate moiety starvation to increase the number of folate receptors on the membranes of these cells. SWNTs conjugated with folate moiety were selectively internalized by cancer cells with folate receptor markers, and then bombarded with continuous NIR laser, which heated these internalized SWNTs, which in turn destroyed the cancer cells. Whereas the folate-starved cancer cells were destroyed (Fig. 7.28), healthy cells without SWNTs complexes were transparent to the laser light and remained viable [32].

Though much more research is necessary, this study clearly demonstrated the amazing transporting potential for functionalized SWNTs to deliver both drugs and cancer therapies due to their unique chemical and optical properties.

## 7.6

### Cytotoxicity of SWNTs

Toxicity has been a controversial issue, shadowing the science of nanotechnology. An improved understanding of the cytotoxicity of SWNTs will undoubtedly benefit research on the biological and biomedical aspects of nanomaterials. An early study by Shvedova et al. determined that transition metal catalysts such as iron and nickel at SWNT concentrations of 0.06 mg mL<sup>-1</sup> and higher were toxic to human epidermal keratinocytes [111]. Indeed, inhaling SWNTs, perplexingly, caused the

**Fig. 7.28.** Images of SWNT complexes internalized by folate-starved cells. (Top): Confocal image showing the round cell morphology of dead cells. (Bottom): Confocal fluorescence image of SWNTs carrying two cargoes, PL-PEG-FA and PL-PEG-FITC,

internalized within folate-starved cancer cells. The green FITC fluorescence represents the internalization of SWNT with FA and FITC cargoes [32]. (© National Academy of Sciences.)

growth of granulomas in the lungs of rats, and in the total absence of such pulmonary biomarkers as inflammation, cell proliferation, and cytotoxicity [112, 113]. Another study by Colvin's group using the buckyball  $C_{60}$ , a cousin of SWNTs, revealed that nano- $C_{60}$  had a greater toxicity to human skin cells than  $C_{60}(OH)_{24}$  – the fullerene molecules containing most additional chemical groups on their surfaces. However, fullerene molecules with a higher degree of surface modification were far less toxic due to their inability to generate oxygen radicals [114]. Colvin et al. also found that the toxicity of water-soluble SWNTs to human dermal fibroblasts decreased as the functionalization of the tubes increased [115]. Their specific func-

Fig. 7.29. Cell growth curves for MCF7 cells without (control; left-hand bars) and with SWNTs ( $0.04 \text{ mg mL}^{-1}$ ). Incubation time was 72 h [68]. (© American Chemical Society.)

tionalizations included SWNT-phenyl-SO<sub>3</sub>X ratios of 18, 41, and 80 and SWNT-phenyl-(COOH)<sub>2</sub> with a carbon/-phenyl-(COOH)<sub>2</sub> ratio of 23. The cytotoxicity of unfunctionalized SWNTs was 200 parts per billion (ppb), ten times lower than unfunctionalized fullerenes, and modified SWNTs were found to be noncytotoxic. Therefore, while cell death did increase with dose concentration, it did not exceed 50% for concentrations of modified SWNTs up to 2000 ppm [115]. Pantarotto et al. supported this supposition, consistently finding that 90% of fibroblasts remained alive when incubated with SWNTs of  $5 \mu\text{M}$  [97]. Shi Kam et al. have reported that promyelocytic leukemia cells were viable when the SWNT concentrations were below  $1.25 \mu\text{M}$  [98].

Figure 7.29 shows cell growth for MCF7 cells both with and without SWNTs ( $0.4 \text{ mg mL}^{-1}$ ) [68]. A similar result was observed for d2C keratinocytes cells (data not shown). In both cases, no significant difference in growth was observed for SWNTs treated MCF7 or d2C cells over a 3 day period. The cell count for the MCF7 cells with SWNTs showed only a minimal decrease in the number of cells for day 2 and day 3; however, the overall trend mirrored the cell count for the control MCF7 cells. An MTS assay for cellular metabolism (Fig. 7.30) on the absorbance of MCF7 cells was performed on cultures without SWNTs (control) and with SWNTs of various concentrations. Absorbance was similar for the control cells (0.631) and for those of various concentrations of SWNTs (0.607 to 0.631). The highest concentrations of SWNTs (1 and  $0.5 \text{ mg mL}^{-1}$ ) have the largest drop in absorbance (0.024 and 0.021, respectively). However, at concentrations lower than  $0.5 \text{ mg mL}^{-1}$ , the absorbances have variances of less than 0.01. Our results suggest that SWNT of a concentration as high as  $1 \text{ mg mL}^{-1}$  has no effect on metabolism and cell viability, suggesting some general trends in biological responses to nanoparticles. Nonetheless, notably, a comprehensive risk assessment of SWNTs should go beyond cytotoxicity and account for such crucial issues as exposure rates, uptake mechanisms, and cellular transport of SWNTs and their derivatives. These studies formulate the practice of nanomedicine, guide scientific and technological advancement, and have profound impacts on workplace protection and environment control.

**Fig. 7.30.** MTS assay of MCF7 cell absorbance vs. SWNT concentration. The control cell absorbance was measured to be 0.630. Cell absorbance ranges from 0.607 to 0.631 for SWNT concentrations of 0.0125–1 mg mL<sup>-1</sup> [68]. (© American Chemical Society.)

## 7.7

### Cancers and SWNTs

An estimated almost 1.4 million new cases of cancer will be diagnosed in 2005 and over 1500 people will die of the disease per day. Despite intensive research, progress in treatment of the disease has been slow and very few significant advances have been made since President Nixon declared his “War on Cancer” and passage of the National Cancer Act in 1971. Traditional chemotherapy and radiotherapy protocols result in actual cures only infrequently and are often accompanied by serious side effects, some of which are permanent. Since therapy for metastatic cancer requires a method that will destroy cancer cells distant from the primary neoplasm, an effective therapy must involve widespread, but specific tumor cell destruction. There are several causes for the failure of current therapies to cure cancer. While cancer cells are more sensitive than their healthy counterparts to radiation and the drugs used for chemotherapy, the differential between the two is not sufficiently large to allow destruction of all of the cancer cells without damaging the healthy ones. Frequently, even in cases where most of the cancer cells are destroyed, some transformed cells escape detection and survive to establish secondary tumors – sometimes years later. In the process of destroying the tumor, cells of the immune system can be damaged, leading to immunosuppression and eventually tolerance of the tumor. Patients can suffer permanent damage, resulting in neuropathies and arthropathies. A dose that will destroy the tumor, yet not severely damage the host is difficult to determine; and in many cases, it may be impossible to obtain. In addition, cells surviving an initial attack will be stimulated to mutate,

resulting in a more aggressive phenotype. Current evidence indicates that metastatic tumor cells have several mutations. Usually, at least one of these involves a gene coding for DNA repair. This facilitates further mutation and allows the cells to evolve mechanisms for evading destruction. The aim of our current research is to overcome these complications by using nanotubes to target tumor cells with greater specificity so that physical, chemical and genetic therapies can selectively destroy tumor cells, allowing more effective killing without damaging sensitive healthy tissue.

As previously described, the work of Dai et al. [106] represents the first major step toward the direct application of SWNTs for cancer therapy. Here, cells were killed by laser irradiation of engulfed SWNTs, raising the temperature to 70 °C. Internalization of the SWNTs was stimulated by starving the cells for folate and conjugation of the SWNTs with folic acid. While the studies were performed in a somewhat artificial system *in vitro*, modifications of the technique could make this approach a valuable contribution to the anti-tumor armamentarium. The value of hyperthermia as an anti-cancer therapy has long been recognized and current studies indicate that it can lead to significant improvement in response when combined with radiation or chemotherapy. In these studies only temperatures in the range 41–43 °C are required. Van der Heijden et al. [116] found that raising the temperature to only 43 °C was synergistic with four different drugs for the killing of four different human bladder transitional carcinoma cell lines. Raaphorst and Yang [117] found that a temperature of only 41 °C sensitized human cells to killing with cisplatin. The mechanism of enhanced killing involved inhibition of DNA repair, and increased intracellular drug concentrations [118]. In a recent study of sixty eight patients with advanced cervical cancer, Westermann et al. [119] achieved complete remission in 90% of the patients by combining hyperthermia with both radiation and chemotherapy. After 538 days, 74% of the patients remained alive without signs of recurrence. Here the temperature was raised to 41 °C. Hence only moderate heating by laser irradiation of intracellular SWNTs could enhance tumor destruction. The synergistic interaction of hyperthermia and chemotherapy could be utilized if SWNT drug delivery vehicles were also to serve as infrared targets for heating.

Another use of SWNTs for enhancing radiation therapy has been suggested by Yinghuai et al. [120], who have successfully attached C(2)B(10) carborane cages to SWNTs. These could be used to increase concentrations of boron in tumor cells relative to blood and other organs, resulting in sensitization of the tumors for neutron capture therapy.

An obvious method for targeting SWNTs to tumor cells is to attach antibodies specific for the tumor cell surface. Cancer therapy with monoclonal antibodies alone has had minimal success; the best results having been found with trastuzumab (Herceptin) for treatment of her2/nu positive breast cancers [121] and with antibodies against CD20 for non-Hodgkin's lymphoma (Rituxan, Zevalin, Bexxar [122]). While the coupling of monoclonals with radioisotopes or toxins (e.g., ricin) is also being explored, a problem with these approaches is that the antibodies are usually produced in mice, causing them to be recognized as foreign by the

immune system of the patient and destroyed. Conjugating antibodies to SWNTs could extend their lifetimes while targeting the SWNTs to the site of the primary tumor and to metastatic sites. Binding of a toxin to the nanotube or laser heating would then increase the effectiveness of killing. Anti-angiogenesis therapies are also being explored. While these produced promising results during early development, at present they have had limited effectiveness clinically. Recent data indicate the anionic phospholipids, particularly phosphatidylserine, become exposed on the external surface of the vascular endothelial cells in tumors. An antibody produced against these phospholipids localizes in the tumor vasculature and slows the growth of tumors in mice [123]. This effect can be enhanced by pretreatment with docetaxel [124]. Conjugation of this type of antibody to SWNTs would serve to target the SWNTs to the tumor. In this case, blood supply to the tumor would be inhibited by the antibody while additional destruction of the tumor vasculature and the surrounding tissue could be done with laser heating.

The possible uses of SWNTs as delivery vehicles for genes or siRNAs are too numerous to be reviewed here. Transfection of the tumor suppressor gene p53 should be attempted, since this is the most commonly mutated tumor suppressor gene in human cancers. Mutated forms of p53 appear in almost 50% of some tumor types. Both transfection of the p53 gene and transfection of siRNA against the apoptosis inhibitor bcl-2 should drive tumor to self-destruction. Transfection of siRNA the p-glycoprotein coded for by the multidrug resistance gene MDR1 would restore sensitivity of resistant cancer cells to chemotherapeutic drugs. It is possible to attach multiple moieties to SWNTs because of their structure. This will allow almost limitless possibilities for combinations of targeting ligands and inducers of apoptosis or necrosis.

## 7.8 Summary

Iijima could not possibly have imagined, in 1991 [125], the subsequent flurry of enchanting scientific endeavors surrounding CNTs whose impact seems to have increasingly touched every corner of our life. Perhaps no other nanostructure or nanomaterial invented so far has attracted this grand level of attention and fervent study. Much remains to be done to offer high sensitivity and localized treatment for cancers and diseases with functionalized and thus intelligent nanostructures and nanomaterials. The realization of this dream demands joint efforts by researchers in the fields of materials science, physical science, and life science, as nature never intends to favor the description of any specific discipline. It is to our best hope that, after reading this chapter, you may start to envision shuttling biomolecules and drug loads through fluidic cell membranes, reporting complex pathogenic pathways, sensing the pH, ionic strength, and temperature of nano-scale bioenvironment, detecting, treating, and preventing cancers and diseases, all with this synthetic wonder material called CNT.

# Nanotubes, Nanowires, Nanocantilevers and Nanorods in Cancer Treatment and Diagnosis

*Kiyotaka Shiba*

### 8.1

#### Introduction

The elimination of cancer-related suffering and death remains an unachieved goal of modern medicine, biology, pharmaceutical science and medical engineering. For this fervent wish to become a reality, what is needed is continued progress, and even ground-breaking innovation, in both the diagnosis of cancer and its treatment. Nanotechnologies have come into the spotlight because of their potential for use as novel diagnostic tools that enable detection of primary cancers at their earliest stages, and in new therapeutic protocols that effectively and selectively exterminate malignant cells. The present chapter introduces the current status of efforts to develop nanomaterials for cancer diagnosis and therapy, mainly by focusing on nonspherical (non-particulate) nanomaterials such as nanotubes, nanowires and nanorods. Because various nanomaterials have been discovered since the first observation of carbon nanotubes, the physicochemical properties of carbonaceous as well as non-carbonaceous nanomaterials are introduced first (Section 8.2). Subsequent sections present potential applications of these molecules in cancer diagnosis (Section 8.3) and treatment (Section 8.4). Progress in the development of spherical nanoparticles for these purposes is reviewed in other chapters of this volume.

### 8.2

#### Nanotubes, Nanowires and Nanorods

Nanotubes, nanowires, nanorods, nanotubules, nanoribbons, nanobelts, nano-onion, nanocapsule, graphite cones, nanopolyhedrons and bamboo tubes, among others, are the names that have been given to various, mostly one-dimensional, nanomaterials. Some of them are composed of graphitic tubes (carbon nanomaterials), but others consist of noncarbonic elements. Some are covalently linked molecules, while others are noncovalently linked assemblages of macromolecules.

**Fig. 8.1.** Electron micrograph of a single-wall carbon nanotube. (From Ref. [4], with permission.)

This section an overviews the properties of these nonspherical nanomaterials, giving a clue as to their potentially unparalleled utility in some applications.

### 8.2.1

#### Carbon Nanotubes

The discovery of multi-wall carbon nanotubes (MWNTs) by Iijima in 1991 [1] stands as the first of a cascade of brilliant discoveries of various nanomaterials [2, 3]. In 1993, the single-wall carbon nanotube (SWNT), which can be regarded as the simplest form of MWNT, was discovered by Iijima's and other groups [4, 5]. A SWNT is made up of a single layer of graphite molecules rolled up into a hollow cylinder (Fig. 8.1). Though the diameters of these tubes typically range from 1.0 to 1.5 nm [4], nanotubes with diameters of as little as 0.43 nm have been reported [6–8]. MWNTs are tubes composed of two or more concentric cylinders (Fig. 8.2). Those consisting of only two cylinders are often referred to as double-wall carbon nanotubes [9]. Carbon nanotubes are synthesized by (a) laser ablation [10], (b) high-pressure CO conversion (HiPCO) [11], or (c) an

**Fig. 8.2.** Electron micrographs of multi-wall carbon nanotubes. (From Ref. [1], with permission.)

arc-discharge technique [12], and their structures can be dramatically influenced by the conditions under which they are produced, including the metal catalyst used, the temperature, the atmosphere etc. Thus, by applying the appropriate conditions, various SWNT and MWNT derivatives can be obtained, including the nano-onion [13], nanocapsule [14, 15], nanopolyhedron [16], bamboo tube [17], graphite cone [18] and nanohorn [19].

Attractive properties of carbon nanotubes include their high electrical and thermal conductivity, their great tensile strength and their very high elastic modulus [20]. In particular, the electrical properties of nanotubes have received a great deal of attention in nanodevice research. SWNTs can be metallic or semiconducting, depending upon their diameter and chiral angle [21–23], which means that they can act as a molecular wire [24, 25] or as a transistor [26–28]. Indeed, a logic circuit composed of SWNT field-effect transistors (FETs) has been developed [29], and the bottom-up fabrication of such nanoscale block units is expected to break the size limitation that current lithographic technology is encountering.

The electrical conductance [30–33] and capacitance [34], the optical properties [35] and the stiffness [36] of nanotubes have all been shown to be altered by surface adsorption of various molecules. In addition, by integrating the sensing abilities of nanotubes into logic circuits, nanoscale biosensors could be designed that simultaneously quantitate different biomolecules (e.g., mRNAs, proteins and metabolic products) and then give a cue for action (e.g., drug release or signal generation) based on programmed logic. The advent of such devices should revolutionize cancer diagnosis and treatment (Section 8.3.1).

The strength and stiffness of SWNT or MWNTs [37] have also been explored with the aim of developing novel materials, such as carbon nanotube paper [38, 39], film [40, 41], fibers [42], gel [43], nanotube–collagen composite [44], and nanotube–polyurethane composites [45]. One possible use of these materials is as a scaffold for cell growth [46–49], which may indirectly affect cancer treatment as well as regenerative medicine.

### 8.2.2

#### **Noncarbon Nanotubes**

Graphite-like layered structures can also be formed from elements other than carbon, and an array of noncarbon nanotubes have been fabricated from boron nitride (BN) [50, 51], nickel chloride ( $\text{NiCl}_2$ ), niobium disulfide ( $\text{NbS}_2$ ) [52] and molybdenum disulfide ( $\text{MoS}_2$ ) [53], and even a multielement (boron nitride and carbon) coaxial nanotube [54] has been synthesized. Applications that take advantage of the unique properties of these materials are currently being explored.

### 8.2.3

#### **Single-wall Carbon Nanohorns**

Single-wall nanohorns (SWNHs) were discovered in 1999 and are thus relatively new members of the carbon nanomaterial family [19]. They are spherical struc-

**Fig. 8.3.** Electron micrograph of single-wall carbon nanohorns. (Courtesy of Professor S. Iijima and Dr. M. Yudasaka.)

tures with diameters of 80–100 nm, but their constituent parts are graphene nanotubes – i.e., they are spherical aggregates of carbon nanotubes (Fig. 8.3). The constitutive tubes have closed ends with cone-shaped caps (horns) and have diameters of 2–3 nm, which is larger than the typical SWNT. SWNHs have extensive surface areas and multitudes of horn interstices, which enable large numbers of guest molecules to be adsorbed. In addition, as with carbon nanotubes [55, 56], oxidation or acid treatment can be used to create nano-windows in the walls of SWNHs, through which small molecules (e.g.,  $N_2$ , Ar,  $C_{60}$  etc.) can infiltrate their interior space. Furthermore, the size of the pores can be controlled by appropriately controlling the treatment conditions, enabling the preparation of a series of oxidized SWNHs (oxSWNHs) having distinct molecular sieving effects. Oxidation also introduces functional oxygen groups (e.g., carboxyl and quinone groups) at the pore-edges of oxSWNHs, to which various chemical compounds [e.g., biotin and poly(ethylene glycol)] can be coupled to functionalize the surfaces.

In contrast to the synthesis of other carbon nanomaterials, the synthesis of SWNHs (laser ablation of graphite) does not require a metal catalyst. This enables production of extremely pure preparations with no potential for toxicity from contaminating metals. These unique properties are particularly noteworthy because they suggest the feasibility of using SWNHs as carriers in drug delivery systems (see Section 8.4.1).

#### 8.2.4

#### **Nanorods and Nanowires**

Whereas nanotubes are hollow cylinders composed of rolled-up single molecular layers, nanorods and nanowires are not hollow. One way to form these structures is to use capillary action to fill the interior space of carbon nanotubes, e.g., with

lead [57] or bismuth [55]. Arc discharge in the presence of metals has also been used to fill carbon nanotubes with Y [58], Mn [59], Gd [60], T, Cr, Fe, Cp, Ni, Cu, Zn, Mo, Pd, Sn Ta, W, Dy or Yb [61]. In addition, reacting carbon nanotubes with volatile metal or nonmetal complexes produces carbide (TiC, NbC, Fe<sub>3</sub>C, SiC and BC) nanorods [62]. Similarly, reacting Ga<sub>2</sub>O vapor with NH<sub>3</sub> gas in the presence of carbon nanotubes yields GaN nanorods [63], while analogous reactions have been used to synthesize Si<sub>3</sub>N<sub>4</sub> nanorods [63] and oriented silicon carbide nanowires [64].

Various other approaches to the fabrication of nanorods (nanowires) that do not require nanotubes have also been developed, yielding GaN nanorods [65, 66], silicon nanowires (SiNW) [67, 68] and indium phosphate nanowires [69]. The nanorods obtained were either single crystal [62, 63, 65–67, 70], polycrystalline [62] or amorphous [62], depending upon the method and materials used [62].

### 8.2.5

#### Self-assembled Nanotubes

Self-assembly from smaller molecular blocks is an alternative approach to synthesizing nanotubular structures. Formation of such structures from lipid molecules was first reported some time ago [71, 72], and has recently been garnering attention as a tool for microfabrication [73–75]. Peptides represent another set of molecules that can be assembled into tubular structures [76, 77]. In contrast to lipid tubes, peptide tubes are nanometer scale structures, the diameters of which can be fine tuned through appropriate design [78]. What is more, casting ionic metal into a peptide nanotube fabricated from dipeptide building blocks has been used to form metal nanowires with diameters of only 20 nm [79] (Fig. 8.4). Block copolymers are also versatile for fabricating various types of microstructures, including tubes [80, 81], vesicles [82] and toroidal structures [83], among others.

Lipid, peptide and polymer self-assemblages, along with natural proteinous assemblages, are generally highly biocompatible, so their utility as nano-carriers of drugs, antigens and genes is currently being investigated. They also have been used as templates for inorganic wires fabricated through deposition of various inorganic nanocrystals upon them [84–92].

**Fig. 8.4.** Silver nanowires were formed by the reduction of silver ions within the peptide nanotubes, followed by enzymatic degradation of the peptide mold. (From Ref. [79], with permission.)

### 8.3 Cancer Diagnosis

The recent and rapid progress in genomic medicine has required innovative solutions for high-throughput and parallel identification and/or quantification of large numbers of biomolecules, including mRNA, proteins and metabolites [93, 94]. Microarray technology combined with fluorescence detection would be one of the most popular tools for such high-throughput genomic analysis [95–97]; however, that methodology does not yet have sufficient sensitivity or usability. But by using nanomaterials, a new type of ultrasensitive high-density sensor array could be fabricated. Although such next-generation nanosensors are still in an early phase of development, some elemental technologies have already been shown to work.

#### 8.3.1 Carbon Nanotube-based Detection System

As described in Section 8.2.1, the physicochemical properties of carbon nanotubes can be changed by adsorption of molecules onto their surfaces. The nanotube sensor was first demonstrated as a FET-based gas sensor, in which the electrical resistance of a semiconducting SWNT was altered by exposure to electron-withdrawing  $\text{NO}_2$  or  $\text{O}_2$  or to electron-donating  $\text{NH}_3$  molecules [30, 31, 98]. Since then, SWNT-based FETs have been exploited as biosensors through functionalization of the tube surfaces using various biomolecules. For instance, when the surface was modified with biotin, the electronic properties of the resultant biotin–SWNT were altered upon addition of streptavidin (a protein that strongly binds to biotin) [99]. Similarly, when glucose oxidase was immobilized on the surface of SWNTs, the resultant sensor showed increased conductance upon addition of 0.1 M glucose (a substrate of glucose oxidase), probably reflecting a conformational change in the enzyme [100] (Fig. 8.5). Finally, human U1A RNA splicing factor is an antigen in autoimmune diseases such as systemic lupus erythematosus, and detection of autoantibodies against this protein is a diagnostic criterion for the disease. When U1A protein was immobilized on the surface of SWNTs, the binding of a monoclonal anti-U1A antibody at concentrations of less than 1 nM was detected as an electric signal [33], making this construct suitable for development of an ultrasensitive and label-free diagnostic system.

**Fig. 8.5.** Enzyme-coated carbon nanotubes as biosensors. Two electrodes connect a semiconducting SWNT with glucose oxidase immobilized on its surfaces. (From Ref. [100], with permission.)

**Fig. 8.6.** Carbon nanotube nanoelectrode array. MWNT arrays were grown on Ni spots defined by UV lithography. (From Ref. [104], with permission.)

RNA, DNA and peptide molecules that bind to specific target substances are termed aptamers [101–103]. They are artificially created using *in vitro* evolution systems in the order-made manner, and a myriad of aptamers have already been generated against a wide variety of biomacromolecules and inorganic substances. Such aptamers can be used to functionalize the surface of nanotubes to prepare sensors for target substances. For instance, when a DNA aptamer against thrombin [102] was immobilized on the surfaces of SWNTs, the aptamer–SWNT FETs worked as a thrombin sensor. In addition, because aptamers are generally much smaller than antibodies, they could be used to fabricate sensors that are both cheaper and more space-efficient than those fabricated from antibodies.

Another type of ultrasensitive DNA/RNA sensor that has been proposed is one in which nanoelectrode arrays composed of MWNTs having one tip modified with oligonucleotides with specifically designed sequences are fabricated on a SiO<sub>2</sub> matrix [104] (Fig. 8.6). The hybridization of sub-attomole amounts of single strand DNAs could then be detected as a electronic signal using the Ru(bpy)<sub>3</sub><sup>2+</sup>-mediated guanine oxidation method [105]. Such arrays of nanotubes should be easy to construct on silicon tips, thereby providing the opportunity to develop multiplexed detection systems [104].

### 8.3.2

#### **Non-carbon Nanotube-based Detection Systems**

Though carbon nanotubes are highly promising materials with which to construct nanosensors, they also have some limitations. For instance, existing methods of synthesis produce mixtures of metallic and semiconducting SWNTs, necessitating their efficient separation before defined nanosensors can be constructed. This

makes noncarbonaceous tubes or wires attractive, as most of them require no separation step. For instance, silicon nanowires (SiNWs, Section 8.2.4) [67, 68] are always semiconducting, and their surfaces are easily modified. When the surfaces of boron-doped SiNWs are modified with 3-aminopropyltriethoxysilane (APTES) and connected to source and drain electrodes, the nanowires function as pH-sensing FETs [106]. Similarly, biotin- and calmodulin-immobilized SiNWs function, respectively, as anti-biotin antibodies and  $\text{Ca}^{2+}$  FET sensors. A SiNW-based ultrasensitive DNA sensor has also been developed by functionalizing the surfaces of SiNWs with a PNA (peptide nucleic acid) that recognizes the gene for the cystic fibrosis transmembrane receptor [107]. Here, the conductance of the nanowire increased upon PNA–DNA hybridization. Thus, highly sensitive, real-time nanosensors can be fabricated using SiNW [106].

In addition to SiNW, metal oxide nanowires are also attractive candidates for the fabrication of nanosensors. For instance,  $\text{In}_2\text{O}_3$  NWs with immobilized anti-PSA (prostate-specific antigen) antibodies on their surfaces showed enhanced conductivity upon exposure to PSA [108]. Interestingly, a similar SWNT-based sensor showed suppressed conductivity upon exposure to PSA, enabling complementary detection of PSA antigen with these two devices [108].

### 8.3.3

#### Microcantilevers

Whereas nanotube- or nanowire-based sensors transduce biomolecular recognition into changes in electrical conductance [30, 31] and capacitance [34] or changes in optical properties [35], microcantilevers transduce that recognition into the nanomechanical bending of a cantilever, which can be measured *in situ* using optical beam detection [109–111]. Microcantilevers are generally made of silicon nitride that is coated on one side with a thin film of gold (Fig. 8.7). They can be constructed using low-cost semiconductor microfabrication processes, thus offering an ideal platform for high-throughput molecular analysis. For instance, a cantilever on which anti-PSA antibody was immobilized could detect free PSA at a concentration of  $0.2 \text{ ng mL}^{-1}$  against a background of human serum albumin and plasminogen at concentrations of  $1 \text{ mg mL}^{-1}$ . Thus, this technique could compete with

**Fig. 8.7.** Scanning electron micrograph of a section of silicon nanocantilever. (From Ref. [110], with permission.)

ELISA-based diagnoses. Notably, however, although the movement of these cantilevers is on a nanometer scale, a typical microcantilever is 200  $\mu\text{m}$  long, 0.5  $\mu\text{m}$  thick and 20  $\mu\text{m}$  wide, making it difficult to prepare dense arrays of such sensors.

### 8.3.4

#### Nano-tag made of Nanorods

Arraying addressable sensors on a miniaturized tip is one approach to constructing a multiplexed detection system. Other approaches include the simultaneous labeling of several biomolecules with distinctive molecular barcodes, which could be produced with the necessary diversity using nanorods [112, 113]. Sequential electrochemical deposition enables construction of combinatorial striping patterns using gold and silver nanorods, which then could be detected and read using light microscopy (Fig. 8.8). Theoretically, 4160 signatures could be generated from 13-segment, 6.5- $\mu\text{m}$ -long barcodes.

## 8.4

### Cancer Treatment

While nanotube-based diagnosis systems are still at their early stages of development, nanotube-based approaches to cancer treatment are at the experimental

Fig. 8.8. Synthesis of multimetal barcodes. (From Ref. [112], with permission.)

stage. By focusing on drug delivery and imaging systems, several ongoing efforts to make the most of the potential of nanotubes in this area will be introduced.

#### 8.4.1

##### **Carriers for Drug Delivery Systems**

Although synthetic polymers, lipids and peptides are attracting much attention from those involved in the development of drug delivery systems, new classes of materials constructed from carbon nanotubes may also be suitable for drug, protein and gene delivery. Early observations have shown that fluorescently labeled nanotubes are automatically taken up by cells [114]. This internalization of SWNTs, e.g., by HL60 and Jurkat cells, appears to be mediated by endocytosis, leading to accumulation of SWNTs in the cytoplasm [115]. Moreover, when SWNTs are covalently modified with a peptide from the foot-and-mouth disease virus, they elicit a humoral immune response in mice [116]. Likewise, nanotube-based systems also have been shown to mediate gene delivery in similar fashion [117–119]. In addition to genes and DNA, unmethylated CpG motif [120], which is known to confer nonspecific protection against various intracellular pathogens and siRNAs [121] (small RNAs that interfere with the expression of a target gene), has been linked to SWNTs that were then used to deliver the motif into mammalian cells.

SWNHs (Section 8.2.3) are unique among nanomaterials because their constituent parts clearly belong to the nanotube-family, but their overall structure is spherical (Fig. 8.3). The diameters of these spheres, about 80–100 nm, suggests they could show enhanced permeation and retention (EPR) effects [122, 123] and thus could accumulate within solid tumors showing neovascularity. Furthermore, as the synthesis of SWNHs does not require a metal catalyst [124], extremely pure preparations with no contaminating metals can be obtained [125], which would seem to make SWNHs an excellent candidate to be a carrier in a drug delivery system. Indeed, it already has been shown that oxidized SWNHs can adsorb dexamethasone to approximately  $200 \text{ mg mL}^{-1}$  and then slowly release the drug in saline buffer [126]. In addition, peptide aptamers [127] could be used to functionalize the surface of SWNHs and prepare composite materials having multifunctionality [128].

#### 8.4.2

##### **Imaging Agents**

New imaging agents that utilize nanomaterials have also been developed, and one using spherical nanoparticles has already shown good results. For example, dextran-coated ultrasmall superparamagnetic iron oxide (USPIO) nanoparticles have been used to image lymph nodes containing micrometastases in patients with prostate cancer [129]. The development of nanotube-based imaging agents is still at a primitive stage, but the intrinsic near-infrared (NIR) fluorescence of SWNTs [130–132] is an attractive property, as tissue and biological fluids are transparent to NIR light [133], perhaps making it possible to use SWNTs as a new class of bioprobe [134, 135] (Fig. 8.9).

**Fig. 8.9.** Fluorescence image of cell-engulfed SWNT between 1125 and 1600 nm with excitation at 660 nm. (From Ref. [134], with permission.)

Multifunctional molecules that can be used for both diagnosis and treatment should be the ultimate objective of nano-medical material development [136]. For instance, spherical multimodal composites composed of gold-coated nanoparticles containing a dielectric silicon core coated with PEG and a cancer-targeting ligand, Her2, have already been developed. Through illumination with NIR, this composite material has been successfully used to reveal microscopic tumors in breast, and then, by increasing the power of the NIR beam (820 nm), the particle's temperature was increased enough to induce irreversible heat damage to the carcinoma cells [137]. Recently, a similar multifunctional agent was constructed from SWNTs [135]. In that case, SWNTs were functionalized with a folate moiety known to target tumor-associated antigen [138], and were selectively taken up by cells expressing folate receptor. Cells that internalized the SWNT were killed by irradiation with NIR [135].

## 8.5

### Conclusions

Carbon nanotubes and related structures (e.g., nanowires and nanorods) are a recent discovery, and it will take time before materials and protocols that are clinically applicable for the diagnosis and treatment of cancer are developed. Nevertheless, these materials obviously have unique properties, which should soon lead to the development of radically new nanodevices.

Although not introduced in this chapter, a family of nanotubes is currently being investigated with the aim of making new devices that could indirectly influence

cancer diagnosis and cancer therapy. These include probe tips for atomic-force microscopy (AFM) [139–141], ion channel blockers [142], and microcantilevers for medical catheter applications [36], among others.

Finally, careful attention needs to be paid to the potential toxicity of nanomaterials. So far, studies of their toxicity have produced conflicting results [143–148]. Clearly, much additional study of the metabolic pathway taken by nanomaterials in the body [149] and their potential toxicity will need to be carried out before their clinical use becomes practical.

## 9 Multifunctional Nanotubes and Nanowires for Cancer Diagnosis and Therapy

*Sang Bok Lee and Sang Jun Son*

### 9.1 Introduction

Nanomaterials have been one of the most widely studied and attractive subjects for the last decade in the field of biomedical and biotechnological applications, such as MRI contrasting agent [1], DNA transfection [2], biosensors [3], and drug delivery [4]. These nanoparticles are particularly interesting because many of their properties, such as electronic and optical properties, are quite different from those of bulk material. These new properties have provided new opportunities to develop ideal diagnostic/therapeutic systems and to overcome existing biological barriers such as that only very small amounts of monoclonal antibodies can find their targets *in vivo* system [5]. For example, liposomes, the simplest biologically friendly form of nanoparticles, are being used to increase drug concentration at tumor sites; their doxorubicin-embedded complex was approved by the FDA 10 years ago for the treatment of Kaposi's sarcoma, and now they are used in treating breast cancer [6]. While liposomes deal mainly with sizes, not with unique physical properties, for their application, inorganic nanoparticles, such as gold nanoparticles [7], gold nanoshells [8], and quantum dots [9], use the unique electronic and optical properties of nanoscale materials. They are now in commercial use and development as diagnostic and therapeutic tools. All of these nanoparticles can be filled with anti-cancer drugs and detection agents for the targeted gene therapy and early stage cancer diagnosis [10].

Typically, spherical nanoparticles have been used for most nanobiotechnological applications because they are easy to make. However, spherical nanoparticles still need to be improved in terms of controlling particle sizes, surface functionalization, and environmental compatibility due to their structural limitations when multifunctionality is required, especially on their surfaces. The spherical nanoparticle is not an ideal platform for multifunctional nanomaterials because it has a single surface, so that every surface modification for the multifunctionality takes place at the same surface, which can lead to malfunction or interruption between multifunctional components. Tubular nanoparticles have become highly attractive for multifunctional purposes due to their structural attributes, such as distinctive

inner and outer surfaces, over conventional spherical nanoparticles. Inner voids can be used for capturing, concentrating, and releasing species ranging in size from large proteins to small molecules because tube dimensions can be easily controlled by template synthesis. Distinctive outer surfaces can be differentially functionalized with environmentally friendly and/or probe molecules to a specific target. These differentially functionalized, or multifunctionalized, nanotubes have enormous potential in biomedical application, including therapeutic tools [11], drug delivery [12], bioseparations, and biocatalysis [13, 14], and have provided a model system to study wetting and diffusion problems in nanoscale containers [15]. In addition to these nanotubes, nanowires or nanorods have also been highlighted with respect to multifunctionality for biotechnological application [16, 17]. Although nanotubes and nanowires offer huge opportunities and might prove to be useful in bio-nanotechnology – most likely cancer technology, such as early detection and targeted drug delivery for cancer tumors – there are as yet few example applications of diagnostic and therapeutic tools. From this viewpoint, the present chapter includes (a) the most recent success story of magnetic nanoparticles, (b) carbon nanotubes, (c) nanotubes and nanowires composed of artificial peptides, and (d) template-synthesized nanotubes, such as silica and magnetic nanotubes, for the various biomedical applications.

## 9.2

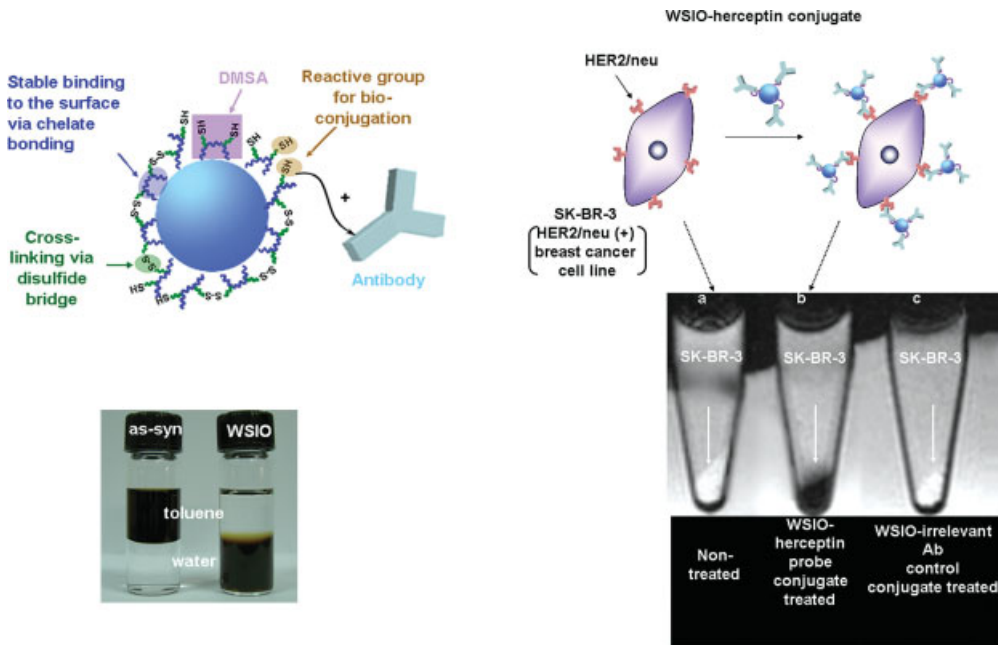

### Advanced Technologies in Magnetic Nanoparticles for Biomedical Applications

Magnetic particles have been extensively studied in the field of biomedical and biotechnological applications, including drug delivery, biosensors, chemical and biochemical separation and concentration of trace amount of specific targets, such as bacteria or leukocytes, enzyme encapsulation, and contrast enhancement in magnetic resonance imaging (MRI) [18–20]. Practically, magnetic nanoparticles are ideal candidate materials for the early detection of cancer and targeted drug delivery due to their natural MRI capability, together with the ability to modify the particle surface with targeting moieties [21]. In addition, new synthetic methods have been recently reported to improve control over particle sizes up to 1-nm scale for mass production [22–24].

#### 9.2.1

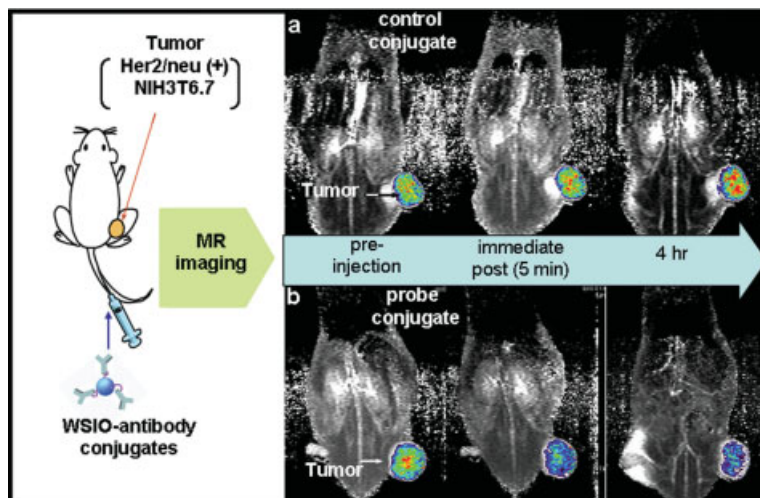

##### MRI and Therapeutic Application of Magnetic Nanoparticles

Recently, a team of Korean scientists have reported that magnetic nanoparticles can be successfully used for cancer diagnosis both *in vitro* and *in vivo* [23, 25, 26]. Magnetic nanoparticles can play a key role in magnetic resonance (MR) diagnosis of early state cancer, which requires sensitive and selective detection techniques because of their strong enhancement in MR signal. In addition, nano-scale size is favorable for more specific and active targeting toward cancer cells due to the leaky and small porous structure of such cells. The team, directed by Jinwoo Cheon, re-

**Fig. 9.1.** Schematic illustration of 2,3-dimercaptosuccinic acid (DMSA)-coated water-soluble  $\text{Fe}_3\text{O}_4$  iron oxide (WSIO) nanocrystals and their solubility test (left-hand side) and *in vitro* cancer diagnosis assisted by WSIO–Herceptin probe conjugate (right-hand side). (From Ref. [26].)

ported that 9 nm water-soluble  $\text{Fe}_3\text{O}_4$  iron oxide (WSIO) nanoparticles are ideal material for cancer diagnosis. Magnetic  $\text{Fe}_3\text{O}_4$  nanoparticles were synthesized through thermal decomposition of  $\text{Fe}(\text{acac})_3$  (acac = acetylacetonate) in a hot organic solvent and their surface was covered with 2,3-dimercaptosuccinic acid (DMSA). The carboxylic group of DMSA ligand is coordinated to the metal surface and disulfide crosslinkage between the ligands stabilizes the ligand shell. This ligand increases the solubility in water, and remaining free thiol groups can be used to attach target-specific antibodies (Fig. 9.1). In this report, the DMSA ligand shell was conjugated with the cancer-targeting antibody Herceptin, which has specific binding properties against a HER2/new receptor overexpressed from breast cancer cells. For *in vitro* study, they examined the binding specificity by treating WSIO–Herceptin probe to a breast cancer cell line, SK-BR-3, and performing an MRI measurement. There was significant darkening of the MR image of the cell line treated with WSIO–Herceptin, while no noticeable difference was observed between the nontreated and WSIO-irrelevant antibody control conjugate-treated cells. The capability of WSIO with multifunctionality for *in vivo* use was further tested with a set of nude mouse implanted at their proximal thigh region with NIH3T6.7 cell lines overexpressed with HER2/neu cancer markers.

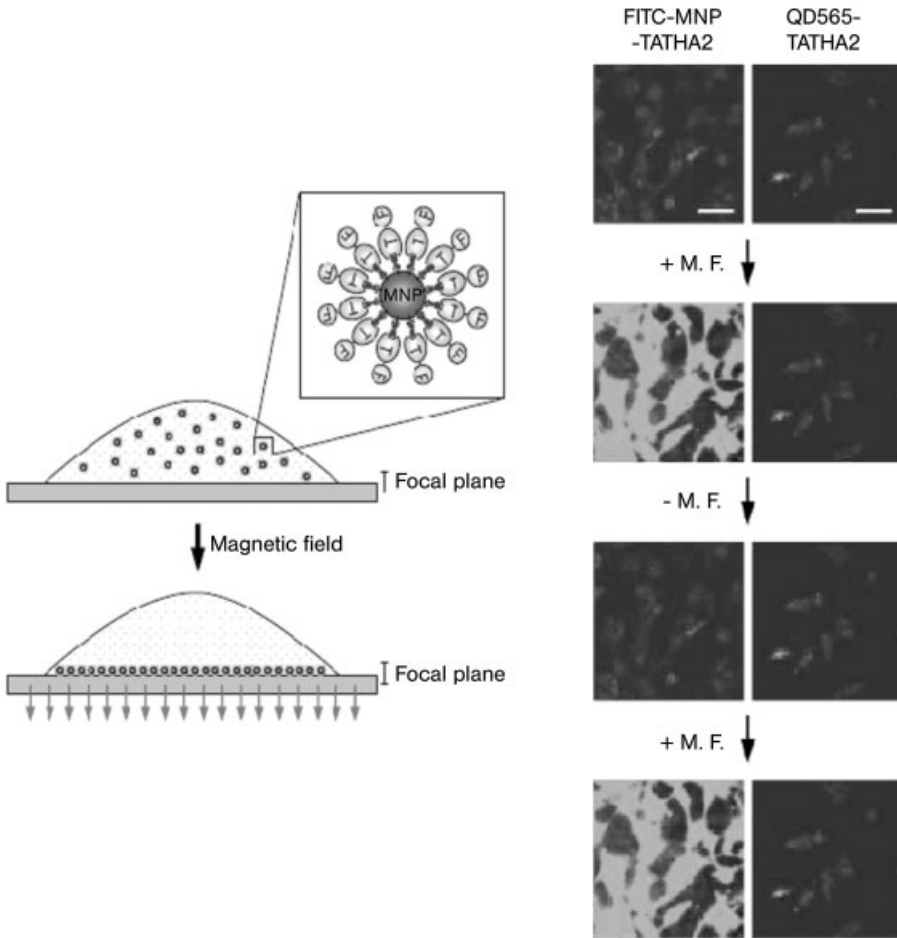

**Fig. 9.2.** *In vivo* MRI of cancer-targeting events of WSIO-irrelevant antibody conjugate (a) and WSIO-Herceptin probe conjugates (b). (From Ref. [25].)

Figure 9.2 shows *in vivo* MRI of cancer-targeting events of WSIO-antibody conjugates. Color maps of T2-weighted MR images of cancer cell implanted (NIH3T6.7) mice at different temporal points (preinjection, immediate post, 4 h) after the intravenous injection of WSIO-irrelevant antibody control conjugates (a) and WSIO-Herceptin probe conjugates (b) reveals that WSIO-Herceptin conjugates induce an immediate color change in the color-mapped MR signal at the tumor site within 5 min. This implies that the WSIO-Herceptin probe conjugates successfully reach and bind to the target cancer cells at the proximal thigh. In the control experiment with WSIO-irrelevant antibody conjugates, however, no change was observed, confirming minimal nonspecific binding to the tumor site.

### 9.2.2

#### Biomedical Diagnostic Application of Magnetic Nanoparticles

Another interesting application of magnetic nanoparticles (MNPs) was reported in *Science* in 2005 by Kim's group [27]. They developed a technology called magnetism-based interaction capture (MAGIC) for the detection of molecular interactions in live cells. Combined with confocal microscopy, which has a very narrow focal plane, the induced movement of superparamagnetic nanoparticles was adapted to detect the molecular interaction of interest or to identify molecular targets. As seen in Fig. 9.3, after internalization of MNPs coated with target-specific probes into live cells, application of a magnetic field can induce concentration of MNPs and associated target proteins at the focal plane, and the translocation of the fluorescent signal can be used to determine whether binding events occur in-

**Fig. 9.3.** Schematic of magnetism-base interaction capture (MAGIC) (left-hand side) and fluorescence microscope images showing translocation of MNPs coated with FITC and TAT-HA2 inside cells by the magnetic field (right-hand side). (From Ref. [27].)

side cells between probe molecule and target proteins. In this study, streptavidin-conjugated MNPs were used as generic reagent for the attachment of biotinylated molecules to the nanoprobe, and efficient intracellular uptake of nanoparticles was mediated by transducible fusogenic TAT-HA2 peptide, which has a high density of cationic residues and thus causes an electrostatic interaction with the negatively charged cell surface. To visualize and track the distribution of MNPs within cells, MNPs coated with fluorescein isothiocyanate (FITC) and TAT-HA2 were prepared; when a magnetic field was applied, specific translocation of MNPs was observed inside cells. Furthermore, this translocation was reversible; the MNPs rapidly dif-

fused away upon removal of the magnetic field and were redirected when it was reapplied. The authors tested whether the MAGIC principle could be used to detect a specific intracellular target for Asp-Glu-Val-Asp (DEVD), an apoptosis inhibitor known to bind caspase-3. After MNPs modified with DEVD and TAT-HA2 were incubated with HeLa cells transfected with caspase-3 fused to red fluorescent protein (mRFP), the red signal translocated in the direction of the magnetic field. As a systematic target identification (ID) experiment for a bioactive small molecule, a normalized EGFP-tagged cDNA library was expressed in HeLa cells by retroviral transduction, and MNPs coated with FK506 were introduced into these cells to identify the receptors for an immunosuppressant, FK506. They identified 19 positive clones that exhibited specific translocation of EGFP in the direction of the magnetic field, and several known FK506-binding proteins and proteins of unknown function were found in these clones. This MAGIC principle can also be used to probe intercellular signaling processes, such as signal-induced phosphorylation and interaction of the NF- $\kappa$ B/I $\kappa$ B.

Enzymes, when immobilized on magnetic nanoparticles (MNPs), can be easily separated from the reaction medium, stored, and reused with consistent results [28]. This system offers a relatively simple technique for separating and reusing enzymes over a longer period than that for both free enzymes alone and enzymes immobilized by physisorption. The most significant advantage of enzyme immobilization on magnetic nanoparticles is their long-term stability, such as reported by Gross's group using *Candida rugosa* lipase (E.C.3.1.1.3) immobilized on  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> magnetic nanoparticles. Lipases are frequently employed enzymes as they are commonly used for the synthesis of enantio-enriched monomers and macromers and for polymerization reactions [29]. MNPs (20 nm) were prepared by sonication of Fe(CO) in decalin and the subsequent annealing of amorphous Fe<sub>2</sub>O<sub>3</sub> nanoparticles. Acetylated thiophene on MNPs was reacted directly with the enzyme. The enzymatic activity of the immobilized lipase was determined by following the ester cleavage of 4-nitrophenyl butyrate. The activity of *Candida rugosa* lipase immobilized on MNPs turned out to be lower than that for the free enzyme, but constant activity over one month was seen in the case of lipase immobilized on MNPs.

Using bifunctional MNPs, Xu's group reported an instant and sensitive detection method for pathogens at ultralow concentration [30]. Compared with magnetic microbeads used in biological separation, MNPs promise high performance because of their large surface/volume ratios and easy entry into cells. For fast pathogen detection, FePt nanoparticles modified with vancomycin, a broad spectrum antibiotic, were prepared as a system that combines two kinds of interactions: magnetic dipole interactions that aggregate the MNPs under an applied magnetic field and specific multi-ligand-receptor interactions. Figure 9.4 shows a schematic illustration for the capture of bacteria by vancomycin-conjugated magnetic nanoparticles. Vancomycin was used to detect pathogens because it can bind to the terminal peptide, D-Ala-D-Ala, on the cell wall of a Gram-positive bacterium via hydrogen bonds. After mixing the solution of MNPs modified with vancomycin with a solution of bacterium, a point magnet was used to capture the "magnetized" bacteria and aggregates were analyzed using a microscopic method. The optical and SEM results

**Fig. 9.4.** Illustration of the capture of bacteria by vancomycin-conjugated magnetic nanoparticles (A), via a plausible multivalent interaction, and the corresponding control experiment (B). (From Ref. [30].)

show that MNPs modified with vancomycin selectively bind to most Gram-positive bacteria and vancomycin-resistant enterococci (VRE).

### 9.3

#### Carbon Nanotubes

Since Iijima discovered the first carbon nanotubes, using the arc discharge method, in 1991 [31], many nanoparticle-based catalytic methods have been developed and have contributed to the improvement in quality and size control of carbon nanotubes [32, 33]. Typically, carbon nanotubes are one to tens of nanometers in diameter and one to hundreds of micrometers long. Although interest in the application of carbon nanotubes has focused mainly on microelectronic devices [34–38], tremendous public concern has pressurized research into their effect on human health. Scientists have begun this bio-related research with the immobilization of biomolecules on carbon nanotube surfaces [39–42].

##### 9.3.1

#### Carbon Nanotubes for Targeted Cancer Cell Death

Hongjie Dai's group have reported that single-wall carbon nanotubes (SWNTs) can be a good multifunctional biological transporter and near-infrared agent for drug

**Fig. 9.5.** NIR absorbance of SWNT at 808 nm vs. SWNT concentrations (left-hand side) and schematic of Cy3-DNA-functionalized SWNT (right-hand side). (From Ref. [43].)

delivery and cancer therapy [43]. SWNTs prepared from high-pressure CO conversion (Hipco) [44] have strong optical absorbance in the near-infrared (NIR) spectral window to which biological systems are highly transparent [45] and this property can be used for optical stimulation of nanotubes inside living cells to release their cargoes such as DNA and drug molecules or destroy cancer cell selectively. Figure 9.5 shows NIR absorbance of SWNT at 808 nm vs. SWNT concentrations; the molar extinction coefficient of the solubilized SWNTs (molecular mass  $\approx 170$  kDa, length  $\approx 150$  nm, diameter  $\approx 1.2$  nm) measured at  $\lambda = 808$  nm in the NIR was  $\epsilon \approx 7.9 \times 10^6 \text{ M}^{-1} \text{ cm}^{-1}$ . The high absorbance of SWNTs in the NIR originates from electronic transitions between the first or second van Hove singularities of the nanotubes. This work exploited the high optical absorbance of SWNTs in the 700–1100 nm NIR window transparent to biological systems at a single wavelength by using an 808-nm laser for *in vitro* radiation [46]. For the DNA transfection experiment, Hipco SWNTs were conjugated with Cy3-DNA by noncovalent adsorption and incubated with HeLa cells at 37 °C.

As seen in Fig. 9.6, the green color in confocal fluorescence image was observed in the cytoplasm region of HeLa, which implies that DNA–SWNT conjugates were internalized inside the cells, but not the nucleus, with nanotubes as the transporter. Upon irradiating the HeLa cells with NIR after DNA–SWNT uptake, colocalization of fluorescence of Cy3-DNA in the cell nucleus was detected, indicating the release of DNA cargoes from SWNT transporters and nuclear translocation after the laser pulses. Conversely, experiments carried out at 4 °C found no uptake of Cy3-DNA–SWNT conjugates inside cells, suggesting an energy-dependent endocytosis mechanism [47] for the uptake observed at 37 °C. For selective cancer cell destruction *in vitro*, SWNTs were noncovalently functionalized with phospholipids that had a poly(ethylene glycol) (PEG) moiety and folic acid (FA) terminal group and then in-

**Fig. 9.6.** Confocal fluorescence images of HeLa cells showing transporting DNA inside living cells by SWNTs: (a) After incubation with Cy3-DNA-SWNT (green); (b) after nucleus staining of HeLa cells by DRAQ5 (red); and (c) after incubation within a Cy3-DNA-SWNT at the low temperature of 4 °C and nucleus staining. (From Ref. [43].)

cubated with folate receptor (FR)-overexpressed HeLa cell and normal cells, respectively. FRs are common tumor markers expressed at high levels on the surfaces of various cancer cells and facilitate cellular internalization of folate-containing species by receptor-mediated endocytosis. After NIR irradiation, extensive cell death for the FR-overexpressed HeLa cells was evidenced by drastic cell morphology changes, whereas the normal cells remained intact. The selective destruction of FR-overexpressed cells was a result of selective binding of FA-functionalized SWNTs and FRs on FR-overexpressed cell surfaces and receptor-mediated endocytosis. This shows that SWNTs are molecular transporters or carriers with very high optical absorbance in the NIR regime where biological systems are transparent. Compared to Au nanoshells employed by Halas, West, and coworkers [48], the SWNTs can be the better NIR absorbing material for cancer cell destruction as lower laser power and shorter radiation times are needed.

### 9.3.2

#### Carbon Nanotubes for Detection of Cancer Cell

Carbon nanotubes have been integrated into a biosensor for the detection of prostate cancer by Chongwu Zhou's group [49]. Figure 9.7 shows, schematically, a device where an active channel made up of nanowires and nanotubes bridges the source/drain electrodes, and the silicon substrate can be used as a gate. They used n-type  $\text{In}_2\text{O}_3$  nanowires (NW) and p-type carbon nanotubes for the complementary detection of prostate specific antigen (PSA), a known oncological marker for the presence of prostate cancer. To detect PSA, they modified the outer surface of NW or SWNT with anti-PSA monoclonal antibody (PSA-AB), a specific ligand for PSA protein. As shown in Fig. 9.7(b), the surface of  $\text{In}_2\text{O}_3$  NW was functionalized with 3-phosphonopropionic acid, which has a COOH group at one end that was used to immobilize PSA-AB by forming amide bonds. The SWNT surface was first functionalized with 1-purenbutanoic acid succinimidyl ester and then treated with the PSA-AB solution (Fig. 9.7c). To investigate the chemical gating effect of PSA on the

**Fig. 9.7.** (a) Schematic of a nanosensor. (b) Reaction scheme for the modification of In<sub>2</sub>O<sub>3</sub> NW. (c) Reaction scheme for the modification of SWNT. (From Ref. [49].)

devices, they incubated devices consisting of both individual NWs and individual semiconducting SWNTs in a PBS-buffered solution containing PSA for 15 h. The electrical properties of the devices, including both current–voltage ( $I$ - $V_{ds}$ ) and current–gate voltage ( $I$ - $V_g$ ) characteristics, were then measured in air before and after the PSA incubation. In this experiment, the authors consistently observed enhanced conductance for NW devices and reduced conductance for SWNT devices after PSA incubation. This complementary response in conductance arises because In<sub>2</sub>O<sub>3</sub> NWs are n-type and SWNTs are p-type semiconductors. As a result, a chemical gating effect of PSA introduces carriers into In<sub>2</sub>O<sub>3</sub> NWs, while the PSA binding decreases the carrier concentration in nanotubes, thus reducing conductance. Furthermore, the authors performed real-time PSA detection and succeeded in detecting PSA with a sensitivity of 5 ng mL<sup>-1</sup>, a level used for the clinical diagnosis of prostate cancer [50].

### 9.3.3

#### Carbon Nanotubes for Targeted Delivery

As new vectors for the delivery of therapeutic molecules, carbon nanotubes (CNTs) have attracted increasing attention due to the ease of translocation across cell membranes and lower toxicity [51, 52]. The use of functionalized carbon nanotubes (f-CNTs) for drug delivery of small molecules and an alternative strategy for the introduction of two different and orthogonal functionalizations to CNTs have been investigated by the group of Alberto Bianco [53]. The orthogonal methodol-

**Fig. 9.8.** Scheme for two different orthogonal CNT modifications. (a) Neat  $(\text{COCl})_2$ ; Pht- $\text{N}(\text{CH}_2\text{CH}_2\text{O})_2\text{CH}_2\text{CH}_2\text{NH}_2$ , dry THF, reflux; (b) Boc- $\text{NH}(\text{CH}_2\text{CH}_2\text{O})_2\text{CH}_2\text{CH}_2\text{NHCH}_2\text{COOH}/$

$(\text{CH}_2\text{O})_n$ , DMF, 125 $^\circ\text{C}$ ; (c) hydrated  $\text{NH}_2\text{NH}_2$ , EtOH, reflux; (d) FTIC, DMF; (e) HCl 4 m in dioxane; (f) Fmoc-AmB, HOBT/EDCHHCl/DIPEA, DMF; 25% piperidine in DMF. (From Ref. [53].)

ogy allows the selection and control of the attachment of active molecules to side-walls and tips of the CNTs. Oxidized MWNTs were activated as the acid chlorides and treated with diaminetriethylene glycol (mono-protected as phthalimide) (Fig. 9.8). The Boc-protected amine group was then introduced to the sidewalls of the MWNTs through 1,3-dipolar cycloaddition. The phthalimide group is particularly useful because it is stable to harsh acidic conditions and orthogonal to the Boc group. Thus FITC and amphotericin B (AmB) can be attached to the tips and side-

walls, respectively, of the CNTs. Fluorescein and AmB were chosen for tracking the uptake of material and as an antibiotic moiety, the active molecule, respectively. AmB is the most effective antibiotic, but is highly toxic to mammalian cells, originating from the formation of aggregates as a result of its lower solubility in water [54]. From the Human Jurkat lymphoma T cell viability test with either FITC-AmB-modified MWNTs (FITC-AmB-MWNTs) or AmB as control, the authors observed the conjugation of AmB to CNTs remarkably reduced the toxic effects. In addition, maximum fluorescence was observed after only 1 h of incubation, indicating rapid cell uptake of FITC-AmB-MWNTs. Most conjugates were found in cytoplasm and around the nuclear membrane. They excluded endocytosis for the mechanism of cell membrane penetration because  $\text{NaN}_3$  did not show remarkable influence on the penetration capacity of MWNT; instead, they proposed a spontaneous mechanism: MWNTs behave like nanoneedles and pass through the cell membrane without causing cell death [55]. They supposed the ability of CNTs to internalize AmB rapidly into the cytoplasm of Jurkat cells reduces the possibility of disruption of the cell membrane structure, thus reducing toxicity. They proved that covalent attachment of AmB to the nanotubes not only prevents the aggregation phenomena that the drug typically displays in solution but also that it has little effect on the antifungal activity.

## 9.4

### Nanotubes and Nanowires Composed of Artificial Peptides

#### 9.4.1

##### Peptide Nanotubes

In 2001, Ghadiri and coworkers reported peptide nanotubes [56–58] that have a new class of antibacterial activities on Gram-positive and/or Gram-negative bacteria [59]. This strategy is based on the self-assembly of ring-shaped cyclic peptide subunits that consist of six or eight alternating D- and L-amino acids. Hydrogen bonding between unit cyclic peptides allows well-defined tubular structures having a uniform internal diameter, which is adjustable by changing the number of amino acid residues in the ring; upon adsorption onto lipid membrane of bacteria, the cyclic peptides can stack to form hollow tubular structures that are open-ended, resulting in an increase in membrane permeability, collapse of transmembrane ion potential, and rapid cell death. Figure 9.9 shows the  $\beta$ -sheet-like, hydrogen-bonded tubular architecture of the self-assembled, eight-residue cyclic D,L- $\alpha$ -peptide, and the modes of membrane permeation accessible to peptide nanotubes. Self-assembly of an eight-residue cyclic D,L- $\alpha$ -peptide subunit is directed by intersubunit backbone-backbone hydrogen bonding to give  $\beta$ -sheet-like, tubular supramolecular structures that are open and hollow. Cyclic D,L- $\alpha$ -peptide nanotubes can display sequence-dependent modes of membrane permeation: intramolecular pore, barrel stave, and carpet-like (cyclic peptides are depicted as ring structures). Peptide nanotubes operating through the carpet-like mode of action could have a greater potential for

**Fig. 9.9.** Chemical structure of the cyclic D,L- $\alpha$ -peptides and schematic representation of the mode of interaction of the tube caps in forming heterometric transmembrane channels. (From Ref. [56].)

membrane discrimination because of their polyvalent display of surface-exposed hydrophilic side chains for potential interactions with various membrane constituents. For antibacterial activity test, a series of six- and eight-residue amphiphilic cyclic D,L- $\alpha$ -peptides was treated against *Escherichia coli* and methicillin-resistant *S. aureus* (MRSA), and each peptide was designed to bear at least one basic residue to enhance its target specificity towards negatively charged bacterial membranes. *In vitro* activity tests revealed that single amino-acid substitution changed membrane selectivity and activity. In addition, the high efficacy observed against lethal MRSA infections in mice indicates that this new class of abiotic structure, the cyclic peptide, and its quick bactericidal action may contribute to limit temporal acquirement of drug-resistant bacteria.

#### 9.4.2

##### Peptide-Amphiphile Nanofibers

Peptide-amphiphile (PA) nanofibers have been prepared by Stupp's group using self-assembly [60]. A PA is composed of several peptide residues, which can be customized through the peptide sequence for specific purposes, and an alkyl tail with 16 carbon atoms that pack in the center of the micelle, leaving the peptide segments exposed to the aqueous environment. Figure 9.10(A) shows the chemical structure of one example of PAs used in experiments. Here, the PA consists of five key structural features. Region 1 is a long alkyl tail that conveys hydrophobic character to the molecule and, when combined with the peptide region, makes the molecule amphiphilic. Region 2 is composed of four consecutive cysteine residues that when oxidized may form disulfide bonds to polymerize the self-assembled structure. Region 3 is a flexible linker region of three glycine residues to provide the hydrophilic head group flexibility from the more rigid crosslinked region. Re-

**Fig. 9.10.** (A) Chemical structure of the peptide amphiphiles (PA). (B) Molecular model of PA. (C) Schematic showing the self-assembly of PA. (From Ref. [60].)

gions 4 and 5 are variable regions and can be modified for specific functionalities. These PAs self-assemble at acidic pH into cylindrical fibers ~6–8 nm in diameter and interior cysteine groups are crosslinked through disulfide bonds to yield pH-stable nanofibers. Stupp and colleagues have shown many useful applications for these PA nanofibers, with various functional molecules coupled to the peptide residues of PA for specific applications. For example, 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) was conjugated to PA to yield PA nanofibers for the magnetic resonance imaging (MRI) [61]. When the Gd(III) ion is chelated to the DOTA, Gd(III) is detoxified and the complex acts as a strong MR agent. A peptide nucleic acid/PA conjugate (PNA-PA) has been prepared to develop isolation tools for the poly A-containing mRNAs and biotin has been incorporated into PA for the high densities of binding sites on their surface [62, 63]. Carbon nanotubes were successfully encapsulated into PA nanofiber without degradation of their structural, electronic, and optical properties [64]. The most interesting application is as a cell differentiator. The authors showed that PA nanofiber composed of the pentapeptide epitope isoleucine-lysine-valine-alanine-valine (IKVAV), which was known to promote neurite sprouting and direct neurite growth, can be used to direct the differentiation of neural progenitor cells largely into neurons while suppressing astrocyte differentiation [65]. Once neural progenitor cells are encapsulated within a three-dimensional network of PA nanofiber it is possible to present to cells the neurite-promoting laminin epitope, which is the peptide element of the PA, at nearly van der Waals density. As a result, the nanofibers can achieve amplification of bioactive epitope presentation to cells.

## 9.5

### Template-synthesized Nanotubes and Nanorods

Carbon nanotubes, self-assembled lipid tubes, and peptide nanotubes have been successfully used in some biomedical applications; however, it is difficult to control their tube diameter or length and some nanotubes such as the lipid tubes must be coated with ceramic or metal to make them rugged enough for biomedical use [66]. Since Martin and coworkers have pioneered a technology, called template synthesis, for preparing *monodisperse* nanotubes of nearly any size and composed of nearly any material, tubular structures have become highly attractive for multifunctional nanoparticles [67]. The template method is a general approach for preparing nanomaterials that involves the synthesis or deposition of the desired material within the cylindrical and monodisperse pores of a nanopore membrane or other solid surface [68]. Fig. 9.11 shows an alumina template that has a cylindrical nanopore with monodisperse diameters and lengths. Porous alumina template can be obtained by well-established electrochemical anodization on aluminum plate. These pore dimensions can be typically controlled, ranging from 5 to a few hundred nanometers in diameter and from tens of nanometers to hundreds of micrometers in length. Depending on the membrane and synthetic method used, such as chemical or electrochemical deposition of desired material, solid

**Fig. 9.11.** Field emission scanning electron micrograph (FESEM) of a home-made alumina template (60-nm in diameter). Top (left-hand side) and cross sectional (right-hand side) images. (Unpublished data prepared by the authors.)

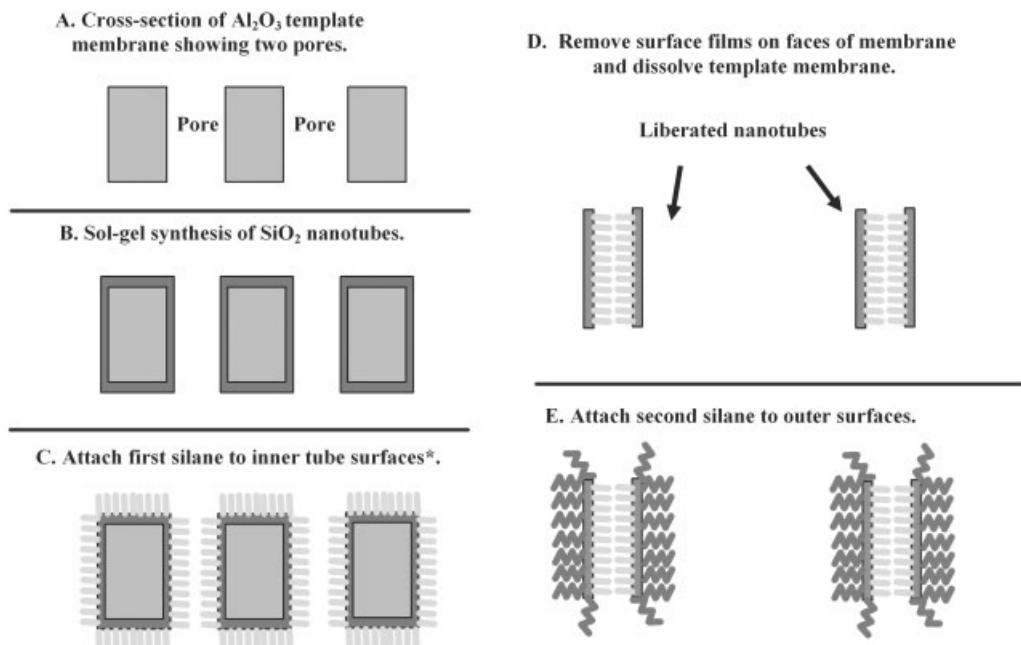

nanowires or hollow nanotubes can be produced. This method has been used to prepare nanowires and nanotubes composed of many types of material, including metals, polymers, semiconductors and carbons. In addition, the template method can be used to prepare composite nanostructures, including concentric tubular composites.

Several unique properties make these nanotubes potential candidate for biotechnological applications. First, their inner voids can be filled with large amounts of interesting materials, such as fluorophores for high optical signal, drug molecules to deliver, magnetic materials for *in vivo* imaging. Second, the distinct outer surfaces can be easily modified with biomolecules. Finally, these nanotubes can be made out of nearly any material. This technology offers tremendous flexibility in making nanotubes with a desired biological property such as biocompatibility or biodegradability [69].

### 9.5.1

#### Differential Functionalization of Nanotube

As another beautiful example of template synthesis, Martin's group recently reported a very important technology, so-called *differential functionalization* between the inner and outer surfaces of nanotubes based on a silica nanotube [13]. They used silica nanotubes for proof-of-concept experiments because they are easy to make, readily suspend in aqueous solution, and because silica surfaces can be easily modified using simple silane chemistry with commercially available reagents. The silica walls of nanotubes are completely transparent for UV/Vis light in the range 200–800 nm, allowing it to pass through to the inner materials. Silica nanotubes were synthesized within the pores of nanopore alumina template membranes using a sol-gel method [70]. The authors have developed the following simple procedure for applying different functional groups to the inner versus outer surfaces of these nanotubes (Fig. 9.12). Before being liberated from the template membrane, the inner surface of a nanotube is modified with the first silane. The

**Fig. 9.12.** Schematic of the differential modification procedure. \* Membrane surfaces also. (From Ref. [13].)

outer surfaces of nanotubes are not modified because they are in contact with the membrane template. The template is then dissolved to liberate the nanotubes, affording free outer surfaces that are then modified with a second silane.

To demonstrate this differential functionalization, two sets of nanotubes were prepared: (a) with the green fluorescent silane *N*-(triethoxysilylpropyl)dansylamide attached to inner surfaces and the hydrophobic octadecylsilane (C18) to the outer surfaces and (b) with the blue fluorescent silane triethoxysilylpropylquinineurethane on the inner surfaces and the bare native (hydrophilic) outer surface. Each of these nanotubes were added to a vial containing water and the immiscible organic solvent cyclohexane. The solvents were then mixed and allowed to separate. The green nanotubes with hydrophobic outer surfaces partition into the (upper) cyclohexane phase (Fig. 9.13A), while blue fluorescence is seen only from the aqueous phase with the hydrophilic nanotubes (Fig. 9.11B). When both sets of nanotubes are added to the solvent mixture in the same vial, tubes with the C18 outer surface chemistry partition into cyclohexane and those with the silica outer surface chemistry partition into water (Fig. 9.11C).

### 9.5.2

#### Selective Extraction of Drug Molecules

Antibody-functionalized nanotubes can be used to extract selectively one enantiomer from a racemic mixture. Fab fragments of antibody produced against the drug 4-[3-(4-fluorophenyl)-2-hydroxy-1-[1,2,4]-triazol-1-yl-propyl]benzotrile (FTB,

**Fig. 9.13.** Vials containing cyclohexane (upper) and water (lower) under UV light excitation after addition of 10 mg of nanotubes with (A) dansylamide on inner and C18 on outer surfaces and (B) quinineurethane on inner and no silane on outer surfaces; (C) 10 mg of both A and B nanotubes; 200-nm diameter nanotubes were used. (From Ref. [13].)

Fig. 9.14) [71] were immobilized on both inner and outer surfaces of silica nanotubes by attaching an aldehyde silane to both surfaces of free-standing silica nanotubes liberated from membrane template; the aldehyde group of this silane reacts with free amino groups on the Fab fragment of antibody via Schiff base chemistry. After racemic mixtures of the SR and RS enantiomers of FTB were incubated with Fab-functionalized nanotubes, the tubes were then collected by filtration, and the amounts of two enantiomers in the filtrate solution were measured by a chiral HPLC method. Figure 9.14 shows chromatograms both before (chromatogram I)

**Fig. 9.14.** Chiral HPLC chromatograms for racemic mixtures of FTB before (I) and after (II, III) extraction with  $18 \text{ mg mL}^{-1}$  of 200-nm Fab-containing nanotubes. (From Ref. [13].)

and after (chromatogram II) exposure of a solution that contained 20  $\mu\text{M}$  of both enantiomers to the Fab-functionalized nanotubes. They found that 75% of the RS enantiomer and none of the SR enantiomer were removed by the nanotubes and that all of the RS enantiomer was removed (chromatogram III) when the concentration of the racemic mixture was dropped to 10  $\mu\text{M}$ . A control experiment with bare silica nanotubes containing no Fab fragment showed negligible extraction of both enantiomers from a 20  $\mu\text{M}$  solution.

Silica nanotubes containing Fab on only the inner surface were prepared by differential functionalization. While nanotubes are still embedded within the pores of template membrane, aminopropyltrimethoxysilane was used to functionalize the inside of the nanotubes with an amine group. After dissolution of the template, the resultant nanotubes were treated with glutaraldehyde, a well-known Schiff base crosslinker, and Fab fragments were immobilized inside the nanotubes through another imine bond between the primary amine of the Fab antibody and the remaining aldehyde group of glutaraldehyde. When a racemic mixture of the drug was incubated with these interior-only Fab-modified nanotubes, 80% of the RS (and none of the SR) enantiomer was extracted, corresponding to almost half the amount extracted by nanotubes with Fab on both their inner and outer surfaces.

#### Silica Nanotube Carrier for DNA Transfection

The use of silica nanotubes as a biomolecule carrier, such as a DNA transporter, has been explored by Wu and coworkers [72]. They used the template synthesis method to fabricate silica nanotubes (SNT) that can transport DNA molecules to cells. First, silica nanotubes were prepared inside the pores of 200-nm diameter commercial alumina membrane using a sol-gel process involving tetraethyl orthosilicate. The inner silica layer was then modified with 3-aminopropyltriethoxysilane (APTS) to generate the polycationic surface required to hold CdSe/ZnS core-shell quantum dots (QDs) or DNAs through the electrostatic forces. Figure 9.15 shows, briefly, the preparation of fluorescent silica nanotubes and their use for

**Fig. 9.15.** Schematic illustration of a fluorescent silica nanotube and its application in gene delivery. (From Ref. [72].)

**Fig. 9.16.** Fluorescence microscopy image of COS-7 cells incubated with green QD-silica nanotube after nucleus staining (red) with propidium iodide. (From Ref. [72].)

gene delivery. Before the gene delivery experiment, cultured mammalian cells such as monkey kidney COS-7 cells were treated with green fluorescent silica nanotubes (gfSNTs) to test the cell membrane permeability of silica nanotubes. They found, by confocal microscopy, that the gfSNT entered about 60–70% of the cells by endocytosis and were mostly localized in the cytoplasm (Fig. 9.16). Cytotox-

**Fig. 9.17.** (A) Bright-field image of COS-7 cells incubated with DNA/silica nanotube complex. Fluorescence image of the same cells (B) showing GFP expression and (C) incubated with GFP-DAN and red-fluorescent silica nanotube. (From Ref. [72].)

icity tests on nanotubes in the cells, using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay, revealed that approximately 80% of the cells were still viable after treatment with gfsNT, indicating that silica nanotubes are not especially toxic under the experimental conditions. For a gene delivery experiment, plasmid DNA was inserted into the nanotube to form a DNA/SNT complex, and the complex was added to COS-7 cells. Cells treated with the DNA/SNT complex showed cytoplasmic GFP expression (Figure 9.17), whereas cells treated with free DNA or red fsNT as a control experiment did not. Although the efficiency of SNT-mediated DNA transfection (ca. 10–20%) is less than that of conventional calcium phosphate (ca. 60–70%), the advantage of this strategy is that SNTs can carry other biomolecules such as RNA or proteins.

#### 9.5.4

#### DNA Nanotubes

Unlike the previous DNA-functionalized nanotubes [73, 74], Martin's group have reported DNA nanotubes composed entirely, or predominately, of DNA itself, based on the template synthesis method and DNA hybridization [75]. First, a template membrane was treated with Mallouk's alternating  $\alpha,\omega$ -diorganophosphonate ( $\alpha,\omega$ -DOP) Zr(IV) to form the outer skin of a DNA nanotube, which guides the growth of a DNA layer [76]. As seen in Fig. 9.18, DNA layers were integrated subsequently into the nanotube from the ( $\alpha,\omega$ -DOP) Zr(IV) skin with the alternating hybridization of the two 15-base segments up to five layers. The nanotubes were then liberated by dissolution of the template in a solution of diluted phosphoric acid and 2 M NaCl at 0 °C and collected by centrifugation. A TEM image shows liberated five-layer DNA nanotubes and shorter nanotubes than the alumina template, which is 36  $\mu\text{m}$  thick, indicating that the tubes were broken during membrane dissolution and centrifugation. Because these DNA nanotubes are made of

**Fig. 9.19.** Thermal decomposition curves for (A) nanotubes composed of the DNAs in Fig. 9.18. Number of DNA layers: (i) 2, (ii) 3, (iii) 5. Nanotubes were embedded within the pores of the template. Inset: five-layer tubes liberated from the template. (B) Five-layer nanotubes composed of hybridized 8 (i), 12 (ii) and 15 (iii) base duplexes. (From Ref. [75].)

double-stranded DNA (dsDNA), they can be heated above the melting point at which dsDNA releases the dehybridized ssDNA chains from the tube, which means this strategy can be used to transport DNA. Consequently, DNA release from the DNA-nanotube-containing alumina membranes into buffer solution was investigated, by UV absorbance (260 nm), upon heating from 23 to 85 °C. Figure 9.19 shows that there was, initially, no DNA in solution because the nanotubes were sequestered within the pores of template; however, above the melting temperature, the release of ssDNA was detected. The same DNA release experiment carried out for nanotubes liberated from the template membrane gave analogous data. This result shows that a new family of layer-by-layer template-synthesized DNA nanotubes can be used for DNA transport and that their release can be controlled by melting the DNA duplexes.

#### 9.5.5

#### Nanobarcodes for Multiplexing Diagnosis

In 2001, Keating and Natan's group exploited metallic nanobarcodes that have alternating metal stripes in a nanorod shape for bioanalysis [16]. Multiplexing and miniaturization is big issues in cancer diagnosis, and in any other bioanalysis. To develop innovative devices that can measure ever-increasing numbers of species from smaller and smaller samples volumes, microarray [77] and encoded microbeads [78], or nanoparticles with distinctive fluorescent signatures [79] have been investigated. Microarrays can encode large numbers of analysis based on position, but slow diffusion of analytes to the surface is an intrinsic problem of planar microarray and the range of analyte concentrations that may be detected at the same time is limited. Although an array of beads in solution, such as microbeads or

Fig. 9.20. Schematic of the synthesis of nanobarcodes. (From Ref. [16].)

nanoparticles, may circumvent the shortcomings of planar microarrays for assay, the number of previously reported bead-based assays that can be performed simultaneously is limited by the number of spectrally distinguishable fluorophores. However, metallic barcodes enable a wide variety of bioanalytical measurements because many thousands of uniquely identifiable particles can be prepared and then used in fluorescence- and mass spectrometry-based assays. Such nanobarcodes have been manufactured electrochemically in the pores of alumina or polycarbonate using the template synthesis method (Fig. 9.20). Striped, cylindrical metal nanoparticles were optically characterized by the pattern of differential reflectivity of adjacent stripes. For example, a metallic nanobarcode composed of Au, Ag, Ni, Pd, and Pt shows different patterns of optical reflectivity, corresponding to their own identity, with respect to the wavelength of illumination light (Fig. 9.21). Figure 9.22 shows that barcoded rods can be used as supports for bioassays, and the selective detection of DNA hybridization on single optically encoded particles was successfully demonstrated for an important first step towards multiplexed hybridization assays. The authors adapted DNA hybridization and immunoassays for use on barcodes. A 24-mer analyte DNA binds to a 12-mer capture DNA immobilized on the surface of a nanobarcode and is later detected by addition of a 12-mer probe DNA that is complementary to the remaining 12 nucleotides and carries a fluores-

cent tag. Each particle can be seen in both the fluorescence (i) and reflectivity (ii) images. In a control experiment, in which the analyte is omitted, a very low fluorescence background is observed (iii) and particles are visible only in the reflectivity image (iv).

### 9.5.6

#### Magnetic Nanotubes

Magnetic nanoparticles have been intensively studied for various biomedical applications, such as early detection of cancer and targeted drug delivery, due to their unique magnetic field-assisted properties like magnetic resonance imaging (MRI) and controlled movement in a magnetic field. Therefore, by combining the attractive magnetic properties with a tubular structure, magnetic nanotubes (MNTs) can be an ideal candidate for multifunctional nanomaterials in biomedical applications, such as targeted drug delivery and MRI. In 2005 Lee's group reported another interesting nanotube based on the template synthesis method [12]. They showed that MNTs can provide another type of useful tool for biomedical and biotechnological applications, including magnetic-field-assisted bioseparation, biointeraction, drug delivery and MRI. Inner voids of MNTs can be used for capturing, concentrating, and releasing species ranging in size from large proteins to small molecules because the tube dimensions can be easily controlled by template synthesis. Distinctive outer surfaces can be differentially functionalized with environmentally friendly and/or probe molecules for a specific target. The group described the synthesis of MNTs and their uses for magnetic-field-assisted chemical and biochemical separations, immunobinding, and drug delivery.

##### 9.5.6.1 Synthesis and Characterization of Magnetic Nanotubes

Silica nanotubes have been synthesized with a layer of magnetite ( $\text{Fe}_3\text{O}_4$ ) nanoparticles on the inner surface of the nanotube using porous alumina film as template (60 and 200 nm pore diameter). To form the layer of magnetite nanoparticles, the silica-nanotube alumina film was dip-coated with a 4:1 mixture solution of  $\text{FeCl}_3$  (1 M) and  $\text{FeCl}_2$  (2 M), dried in an Ar stream, and immersed in  $\text{NH}_4\text{OH}$  [80]. For the differential functionalization of MNTs, the inner nanotube surface was treated with octadecyltriethoxysilane (C18) while MNTs were still embedded in the pores of alumina template. Free-standing MNTs were obtained after polishing both sides of the template film mechanically and dissolving the alumina template in a 0.1 M NaOH solution. After the template was dissolved completely, MNTs were collected by filtration. Transmission electron microscopy (TEM) images of MNTs (Fig. 9.23) show clearly the magnetite layers on the inner surface of the nanotubes; bare silica nanotubes have smooth tubular wall surfaces. Room-temperature magnetization curves of MNTs obtained by superconducting quantum interference device (SQUID) showed that both 60- and 200-nm diameter MNTs exhibit superparamagnetic characteristics and their saturation magnetizations are 2.7 and 2.9  $\text{emu g}^{-1}$ , respectively. Energy dispersive X-ray (EDX) analysis revealed that these magnetic nanotubes consist mainly of Fe and Si.

**Fig. 9.23.** Transmission electron micrographs (TEM) of (A, B) 200 and (C, D) 60-nm diameter silica nanotubes without magnetite (A, C) and magnetic nanotubes (MNTs) with magnetite (B, D). (E) Room temperature magnetization curves of MNTs. (From Ref. [12].)

#### 9.5.6.2 Magnetic Field-assisted Chemical Separation and Biointeraction

In an exemplary chemical extraction and separation experiment, MNTs ( $\sim 10^9$ ) functionalized inside with C18 were added to a solution of 1.1'-dioctadecyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate ( $\text{DiIC}_{18}$ , 38  $\mu\text{M}$ ) in water/methanol (9:1 v/v, 1 mL). The mixture was then shaken and allowed to stand for 10 min so that the dye molecules could enter the MNTs by the strong hydrophobic interaction. These nanotubes are completely suspendible in aqueous phases (even in pure water) due to their outer hydrophilic silica surfaces. A strong magnet was then used to separate the nanotubes, and thus the  $\text{DiIC}_{18}$  molecules, from the solution. Figure 9.24 show that magnetic separation turns an initially red solution, containing the red dye ( $\text{DiIC}_{18}$ ), almost transparent and clear. UV/Vis spectroscopy and fluorescence microscopy studies were further performed to show that more than 95% of the  $\text{DiIC}_{18}$  was removed from solution and the hydrophobic dye was extracted inside the MNTs. As a control experiment, when MNTs without an inner C18 layer were incubated with  $\text{DiIC}_{18}$ , no detectable change was observed. The above results tell us that these MNTs can be used for the extraction, separation, release, and analysis of trace amounts of extremely hydrophobic toxic chemicals, such as polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs), in water [81].

MNTs with human IgG inside were prepared and added to a mixed solution (2 mL, pink color) of fluorescein-labeled anti-bovine IgG [green, 0.71  $\mu\text{M}$  in 0.1  $\text{M}$  phosphate-buffered saline (PBS), pH 7.4] and Cy3-labeled anti-human IgG (red, 0.67  $\mu\text{M}$ ) to show a magnetic bioseparation using antigen–antibody interaction. BSA-derivatized MNTs (BSA-MNTs) were prepared as well to show a nonspecific

**Fig. 9.24.** A vial containing C-18 modified MNTs before (A) and after (B) magnetic separation for 2 min. (C) A solution containing green FITC-labeled anti-bovine IgG and red Cy3-labeled anti-human IgG after magnetic separation with BSA-MNTs (left) and human IgG-MNTs (right). (D) Fluorescence spectra for measuring the amount of remaining red Cy3-labeled anti-human IgG in solution. (From Ref. [12].)

biointeraction. The outer surfaces of all the MNTs were functionalized with poly(ethylene glycol) (PEG) silane to prevent nonspecific adsorptions on silica surfaces. After magnetic separation, the solution changes from the original pink to greenish blue only when MNTs with human IgG inside are added, while the solution with BSA-MNTs remains pink. This means that red Cy3-labeled anti-human IgG was separated specifically from the solution by human IgG-MNTs. Fluorescence spectra show that 84% of the Cy3-labeled anti-human IgG was separated by human IgG-MNTs but only 9% by BSA-MNTs.

Very interestingly, the magnetic properties of MNTs can be used to facilitate and enhance biointeractions between the outer surfaces of MNTs and a specific target surface. As a potential application, the drug delivery efficiency might be greatly improved by magnetic field-assisted biointeraction when the MNTs carry the drug inside and have probe molecules, such as antibody, on the outer surfaces. In a proof-of-concept experiment, onto a anti-rabbit IgG-modified glass slide, 60-nm diameter MNTs with FITC-modified inner surfaces and rabbit IgG-modified outer surfaces were added and incubated for 10 min both with and without a magnetic field applied to the bottom of the glass slide. After washing the unbound nanotubes, the number of bound nanotubes were counted at five different regions of fluorescence microscopy images (Fig. 9.25) and then averaged. A ca. 4.2-fold binding enhancement was observed for the antigen–antibody interactions in the presence of a magnetic field, showing that the efficiency of antigen–antibody interactions can be controlled spatially by means of an external magnetic field.

#### 9.5.6.3 Drug Uptake and Controlled Release

MNTs functionalized on their inner surface with an aminosilane (aminopropyltriethoxysilane, APTS) have been prepared for drug delivery experiments. The MNTs were treated with APTS while still embedded inside the template, which was then dissolved, and the nanotubes were collected by filtration. 5-Fluorouracil (5-FU), 4-nitrophenol, and ibuprofen were then loaded in an organic solvent, such as etha-

**Fig. 9.25.** Fluorescence microscope images of bound FITC-MNTs-Rabbit IgG (60 nm in diameter, 3  $\mu\text{m}$ ) following incubation with anti-rabbit IgG-modified glass with and without the application of a magnetic field under the glass substrate. (From Ref. [12].)

nol or hexane, as model drug molecules into the pores of MNTs functionalized with APTS to study the effect of charged hydrogen bonding interactions between the drug and the inner pore surfaces on loading and release. To remove the drug molecules bound onto the outer surface of MNTs, and weakly bound drugs, drug-loaded MNTs were washed with PBS (1 mL) and filtered quickly twice, and redispersed in pH 7.4 PBS and incubated at room temperature on a rocking platform. After separation of MNTs from solution using either a strong NdFeB magnet or centrifugation, the amount of released drug was determined by UV/Vis spectroscopy by monitoring changes in absorbance at 264 nm (ibuprofen), 400 nm (4-nitrophenol), and 266 nm (5-FU). The percentage release of loaded drug was estimated by measuring the absorbance of drug-released solution after 5 days. UV/Vis spectrophotometry showed that the number of molecules loaded per nanotube was  $\sim 10^7$  for ibuprofen,  $\sim 10^6$  for 4-nitrophenol, and  $\sim 10^7$  for 5-FU. The value for ibuprofen is about twice the monolayer coverage of the MNT inner surface area. Figure 9.26 shows the drug release rate: <10% of ibuprofen was released in 1 h and 80% was released after 24 h. For 5-FU and 4-nitrophenol, however, more than 90% was released in 1 h. Although several factors have to be considered, such as hydrogen bonding, hydrophobic interaction, and solubility, the ionic interaction between

Fig. 9.26. *In vitro* release of ibuprofen, 4-nitrophenol (4-NO<sub>2</sub>-Ph), and 5-fluorouracil (5-FU) from MNTs (60 nm diameter, 250 nm long), and the pK<sub>a</sub> of each drug. (From Ref. [12].)

the inner surface of MNTs and drug molecule is a plausible explanation for this tendency. At pH 7.4, ibuprofen (pK<sub>a</sub> 4.8) is fully ionized so that Coulomb interaction between negatively-charged ibuprofen and protonated aminopropyl groups on the interior of MNTs contributes considerably to retardation of drug release. With 4-nitrophenol (pK<sub>a</sub> 7.2) and 5-FU (pK<sub>a</sub> 8.1), however, the contribution of Coulomb interactions is moderate (4-nitrophenol) or almost negligible (5-FU) because the degree of ionization is less than that of ibuprofen. These results show that the hollow tubular structure of magnetic particles is one of the most promising candidates for various applications, including chemical and biochemical separations and drug delivery, and MNTs with drug-friendly interiors and target-specific exteriors may open up a new field of materials for multifunctional targeted drug delivery.

## 9.6

### Conclusion

We believe that nanotubes or nanowires – with inner chemistry that can be utilized – can be attractive alternatives to spherical nanoparticles – which utilize a single surface – for biomedical and biotechnological applications. Tubular nanoparticles provide more options than spherical ones, especially when multifunctionality is needed because nanotubes have distinctive inner and outer surfaces that can be modified and utilized differentially, enabling them to be equipped with the right function at the right position. The fabrication of nanotubes has been greatly improved by the template synthesis, which affords monodisperse nanotubes with controllable dimensional parameters, such as diameter, length, and wall thickness, together with the differential functionalization technique. However, since the field of

nanotubes and nanowires is still in the early stages of biotechnological applications, much fundamental research is needed to solve challenging problems before commercialization of the technology. For example, although nanotubes can accommodate drugs or biomolecules in their inner space, only their inner surface, and not the whole inner volume, is used in chemical bonds or interactions with chemicals. As Martin mentioned in his review [68], capped nanotubes for which the cap can block the nanotube pore and fall off reversibly according to a chemical or biochemical signal might be one way to overcome such biotechnological problems.

As shown in magnetic particles used for early-stage cancer diagnosis [26] and magnetism-based interaction capture (MAGIC) [27], or peptide nanotubes used for a new class of antibacterial agent [59], combining the properties of a nanomaterial with an existing technology, such as magnetic resonance (MR) imaging, optical or electronic methods, enables us to exploit a novel concept that can not be attained with the conventional technology. Therefore, by combining properties originating from a tubular structure with existing well-understood technology, nanotubes can open up new opportunities to develop a new class of therapeutic and diagnostic tools and to resolve existing biotechnological problems.

### 10.1 Introduction

Traditionally, cancer has been considered as a genetic disease; but functionally, it is the altered protein networks and signaling pathways that drive cancer growth, cell survival, tumor invasion, and distant metastasis [1]. Although high-throughput genomic profiling has offered information regarding genomic signature pattern associated with sub-classification of tumor types, these techniques suffer a severe limitation in monitoring the changes in protein levels, which are the actual molecules of action within the cell. In contrast, proteins as the ultimate effectors of gene function directly participate in biological processes to govern cellular growth, differentiation and survival. The change in protein expression patterns in a given disease state should reflect the pathologic processes taking place within the cells. Many studies have shown that the differentially expressed levels of proteins are associated with cancer progression [2, 3]. Protein biomarkers are becoming increasingly important in cancer diagnosis. According to the FDA, biomarkers can be defined as endogenous molecules that are a measurable indicator specifically associated with a particular disease or disease state and are able to differentiate the different physiological states of an individual. More precisely, different types of markers can be used for early detection of disease, for monitoring effects of therapy, for detecting disease recurrence, and for prognosis. Table 10.1 shows a few examples of characteristics of FDA-approved serum tumor markers [4–14]. Although there are only a few types of cancer that can be identified by a single tumor-specific serum marker [15], their expression levels may correlate the progression of cancer with different detection sensitivity and specificity. For example, prostate-specific antigen (PSA) [14, 16] is a specific marker and can be routinely used for screening high-risk population. In contrast, the change in expression pattern of some markers are clinically associated with multi types of cancer (Table 10.1).

In the post-genome era, in particular, proteomics opens up new horizons because it promises to accelerate the discovery of new protein disease marker. The completion of the human genome project has catalyzed advances in proteomics to

investigate cellular function at the protein level. Particularly, increasingly sophisticated techniques have been rapidly developed for discovering disease biomarkers via large-scale differential profiling [17, 18]. The recognition that every disease induces a specific pattern of change in proteomic microenvironments has important clinical implications for the early detection and progression of disease [19, 20]. Tumors also induce dramatic changes in surrounding stroma, cell–cell contact and angiogenesis. During the changes, plasma, urine, and saliva are readily available samples whose protein content reflects the environment encountered by the blood during its journey through tissues and the circulatory system [21]. Ideally, standard biological sources, such as the above-mentioned body fluids, could be used for identifying biomarkers. A rapid, simple, accurate and inexpensive detection of the relevant marker should be available, together with a measurable and standard baseline as a reference point for diagnosis. However, body fluid-derived proteomes are complex, with a wide range in protein abundance that imposes extreme analytical difficulties for medical studies or clinical diagnoses. Thus, with the advent of a growing number of candidate protein biomarkers for disease diagnosis, it is expected that the number and value of molecular diagnostics, prognosis, and treatment monitoring using protein markers will increase. The development of sensitive techniques with great potential to monitor disease onset is urgently needed for the next phase of cancer diagnosis and monitoring.

This chapter overviews a recently developed technique – nanoprobe-based affinity mass spectrometry (NBAMS) – for the characterization of serum protein markers. Section 10.2 summarizes the fabrication of different types of metal nanoparticle and applications in biology and medical science. The principle of mass spectrometry, the detection method in NBAMS, will be described in Section 10.3. Section 10.4 describes the design, workflow, and performance of NBAMS; the advantages of nanoscale probes such as rapid kinetics, specific detection, and high sensitivity are addressed. Section 10.5 reviews the application of NBAMS technology for selected protein pattern analysis in human plasma/blood. Finally, using NBAMS as a multiplexed immunoassay is demonstrated in Section 10.6 for screening of normal individual and cancer patients.

## 10.2

### Fabrication and Biomedical Applications of Nanoparticles

#### 10.2.1

##### Fabrications and Properties of Nanoparticles

Biomolecule-conjugated nanoparticles (NPs) have been demonstrated to have promising applications in bioanalysis. Among NPs, colloidal gold has attracted the attention of scientists for many years [22, 23]. In general, the synthesis of colloidal gold involves the use of different reducing agents with an aqueous solution of tetrachloroauric acid ( $\text{HAuCl}_4$ ). By controlling the formation of nuclei and the

Tab. 10.1. Characteristics of some approved serum tumor markers [4, 5].

Protein name	Biochemical properties	Molecular weight (kDa)	Primary clinical applications	Upper limit of healthy adults	Other related cancer type	Other related conditions
Alpha-fetoprotein (AFP)	Oncofetal protein, glycoprotein	70	Hepatocellular carcinoma (HCC) and germ-cell (nonseminoma) tumor monitoring and diagnosing	10 ng mL <sup>-1</sup>		Pregnancy, hepatitis, and cirrhosis
CA 15-3	Mucin identified by monoclonal antibodies	300–450	Breast [6, 7] cancer monitoring	25 U mL <sup>-1</sup>	Colorectal, liver, lung, ovarian [8, 9], pancreatic cancer	Benign breast, liver disease
CA 19-9	Blood group antigen identified by monoclonal antibodies, glycoprotein complex	200–1000	Colorectal [10] and pancreatic cancer monitoring	37 U mL <sup>-1</sup>	Breast, gastric, hepatobiliary, hepatocellular, and ovarian [8] cancer	Pancreatitis and benign gastrointestinal diseases
CA 72-4	Glycoprotein identified by monoclonal antibodies	48	Gastrointestinal and ovarian cancer monitoring	6 U mL <sup>-1</sup>	Lung and ovarian [8, 9] cancer	Benign gastrointestinal disease

CA 125	Mucin identified by monoclonal antibodies	200	Endometrial and ovarian [8, 9, 11] cancer monitoring	35 U mL <sup>-1</sup>	Breast, cervical, colorectal, gastrointestinal, lung, pancreatic cancer	Follicular phase of menstrual cycle, early pregnancy, cirrhosis, hepatitis, endometriosis, pericarditis
Carcinoembryonic antigen (CEA)	Oncofetal antigen, a family of related cell-surface glycoproteins	150–300	Colorectal [10], lung, and breast [6, 7] cancer monitoring	3 ng mL <sup>-1</sup> (5 ng mL <sup>-1</sup> for smokers)	Gastric, pancreatic, ovarian [8], uterine cancer	Benign breast disease, cirrhosis, pulmonary emphysema, rectal polyp, ulcerative colitis
Human chorionic gonadotrophin (hCG), hCG b-subunit (hCGb)	Hormone, glycoprotein consisting of 2 non-covalently bound subunits (a and b)	36 (hCG)	Trophoblastic and testis cancer monitoring	5 U L <sup>-1</sup> for men and pre-menopausal women; 10 U L <sup>-1</sup> for post-menopausal women	Breast, gastrointestinal, lung and ovarian cancer	Pregnancy, hydatidiform moles, cirrhosis, duodenal ulcer, and inflammatory bowel disease
Prostate specific antigen (PSA)	Enzyme, glycoprotein serine protease, total PSA (tPSA) in blood consisting of 2 major forms: PSA-ACT (a1-antitrypsin complex & free PSA (fPSA))	28	Prostate [12–14] cancer monitoring and diagnosing	tPSA: 2.5–6.5 ng mL <sup>-1</sup> (by age); fPSA/tPSA = 0.25		Benign prostate hyperplasia

amount of gold for shell growth, i.e., the conditions of reduction, NPs of variant size could be prepared. For example, small size particles can be formed by using strong reducing agents such as sodium borohydride and white phosphorus [24–29]. Depending on the reduction conditions, gold nanoparticles (AuNPs) can be synthesized in the size range 0.82–150 nm [30, 31]. Under inert gas conditions, thiol ligands can be assembled on the surface of AuNP by forming the covalent Au–S bond. Besides Au–S formation, the surface of AuNP can also be modified by charge–charge absorption to attach proteins under suitable pH. Antibody-conjugated AuNPs fabricated by charge–charge absorption have been applied in specific cell and tissue labeling that can be visualized under electronic transmission microscopy (TEM) [27]. NPs can also be increased in size by silver enhancement so as to be observed under optical microscopy [32]. In addition, BIA core can be applied to detect the AuNP because the surface plasma resonance (SPR) absorption peaks of gold colloids display in the visible range, 510–550 nm [33]. The aggregation of AuNPs induces a redshift in the SPR peak, which has been applied in many bioassay [34], including DNA–DNA hybridization [35], carbohydrate–protein interactions [36], and carbohydrate–carbohydrate interactions [37]. Recently, gold colloids have been further explored as affinity probes and used with mass spectrometry in biomaterial analysis [38–40].

Besides AuNPs, magnetic nanoparticles (MNPs) have also attracted great attention due to their unique magnetic properties [41–43]. Quantum size effects and the large surface area to volume ratio of MNPs significantly change their magnetic properties and superparamagnetic characteristics [44]. The magnetic properties of iron oxide MNP depend on the particle size [45, 46]. Small particles (<15 nm) show superparamagnetic character, while large particles are ferromagnetic. MNPs of different sizes can be synthesized by changing the reaction parameters, such as the reaction time, temperature, and the concentrations of reagents and stabilizing surfactants. Because of their special properties, MNPs have been utilized in many applications, such as specific cell targeting, virus separation [47], drug delivery [48, 49], magnetic resonance imaging (MRI) [50, 51], and hyperthermia in cancer therapy [52].

MNPs can be fabricated in aqueous or organic solvent conditions. In the aqueous solvent method [53], MNPs are prepared by stirring the mixture of  $\text{FeCl}_2$ ,  $\text{FeCl}_3$  and  $\text{NH}_4\text{OH}$  (pH adjusting solution) in an ice bath under air. Introduction of air bubbles using a pipette into the mixed solution results in the oxidation of  $\text{Fe}^{2+}$  ions to  $\text{Fe}^{3+}$ , to give  $\text{Fe}_3\text{O}_4$  MNPs. Iron oxide NPs synthesized under organic conditions are better dispersed [54]. In this method, an iron oleic acid metal complex is prepared by the thermal decomposition of pentacarbonyl-iron in the presence of oleic acid at 100 °C. Then, iron oxide NPs are generated by ageing the iron complex at 300 °C. The size distribution of monodisperse NPs synthesized under these conditions ranges from 4 to 20 nm. When the ratio between pentacarbonyl-iron and oleic acid is changed from 1:2 to 1:3, the particle size is tuned from 7 to 11 nm.

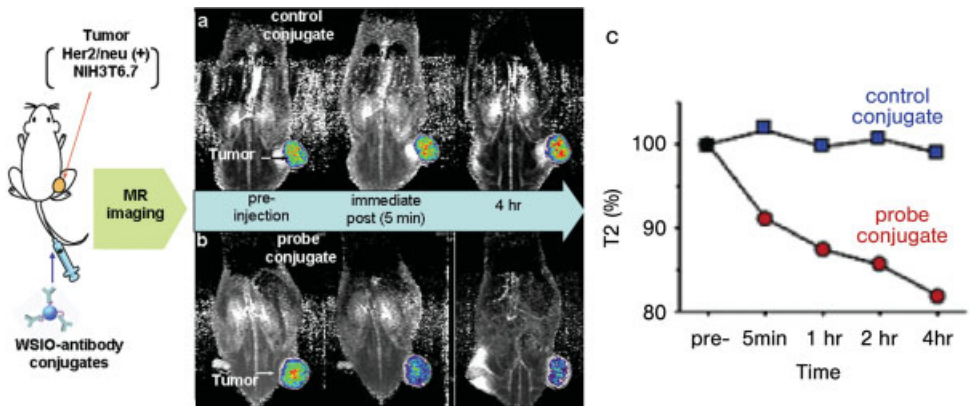

In addition to iron oxide MNPs, many alloy MNPs have been synthesized recently. For example, FePt NPs are effective NPs that are easily modified with thiol ligands [55]. The FePt was synthesized by dissolving platinum acetylacetonate and

**Fig. 10.1.** The Her-2/neu expressing cell was pre-labeled with biotinylated antibody and then selectively bound to streptavidin-conjugated SPIO NP, which acted as contrast agent in  $T_2$ -weighted MR imaging. (From Ref. [65].)

hexadecane-1,2-diol in dioctyl ether under inert gas and then heating the resulting solution to  $100\text{ }^\circ\text{C}$ . Oleic acid, oleyl amine, and  $\text{Fe}(\text{CO})_5$  were then added to the reaction mixture, followed by heating at  $300\text{ }^\circ\text{C}$  for 30 min. After cooling the reaction mixture, ethanol was added to precipitate the FePt NPs.

**Fig. 10.2.** *In vivo* MR detection of cancer-targeting event of WSIO-antibody conjugates (a and b). Color maps of  $T_2$ -weighted MR images of cancer cell implanted (NIH3T6.7) mice at different temporal points (preinjection, immediate post, 4 h) after the intravenous injection of WSIO-irrelevant antibody control conjugates (a) and WSIO-Herceptin probe

conjugates (b). Whereas no difference is seen in the color-mapped MRI for the control conjugate (a), an immediate (5 min) color change to blue at the tumor site is evident with the probe conjugate (b). (c)  $T_2$  versus time after the injection of WSIO-antibody conjugates in (a) and (b) samples. (From Ref. [66].)

Semiconductor quantum dots (QDs) are another type of important NPs developed to have many bio-applications, such as medical diagnosis, *in vivo* cell imaging, and molecular recognition [56]. Not only their good size distribution and uniform shape but also the unique quantum properties makes QDs excellent fluorescent tags. The optical properties of QDs are determined by their sizes. As the particle size decreases, the spacing between two energy levels increases and the wavelength of fluorescence becomes shorter. QDs are synthesized by using semiconductor materials, such as cadmium sulfide, cadmium selenide, cadmium telluride [57], or gallium arsenide [58], under organic or aqueous conditions. QDs with a uniform-size distribution are usually synthesized in organic solvent at high temperature. Trioctylphosphine oxide (TOPO) was first heated followed immediately by injecting the metal precursor (dimethyl cadmium and selenium powder in tributylphosphine) using a syringe. CdSe NPs were then nucleated and the resulting solution became colored. The size of NPs can be modulated by changing the amount of metal precursor and reaction time. QDs so-prepared are hydrophobic due to the surface surfactant layer, TOPO.

CdSe NP, one of the most commonly used semiconductor NPs, possesses useful optical properties, including photo-stability, a wide-range excitation, and no red tail in the emission spectrum. Its quantum yield can be increased by coating with a higher band-gap material such as ZnS to form core-shell QDs [59]. Based on these special fluorescent properties, QDs serve as a convenient and effective dye carrier to be monitored either *in vitro* or *in vivo*. Recently, DNA encapsulated QD is used as a nanosensor to capture target DNA and the binding signal is amplified by fluorescent resonant energy transfer (FRET) through an external fluorescent tag [60]. Interestingly, various color-coded QDs have been applied in the real-time detection of biomolecule and virus in a microfluidic device [61]. QDs also act as a strong tracing marker in *in vivo* cell imaging, which facilitates monitoring of the biomolecule distribution [62].

### 10.2.2

#### **Metal Nanoparticles in Cancer Diagnosis**

Sensitive immunoassay methods are being continuously developed and used in clinical diagnostics to measure specific markers with extremely low concentrations in highly complex biofluids or to detect the premalignant and malignant lesions in early stages. Advances in nanotechnology have facilitated the development of novel ultrasensitive assays for cancer diagnosis in more efficient and economic ways. This section reviews a few iron oxide and gold nanoparticles to illustrate the applications of metal nanoparticles in cancer diagnosis. More information is given in recent reviews [43, 63, 64].

Her-2/neu tyrosine kinase receptor is a 185 kDa protein expressed in approximately 25% of breast cancer cell surface and is an important target in staging and treating breast cancer. Artemov's laboratory [65] have used a two-step labeling protocol to label the Her-2/neu receptor on a breast cancer cell line (AU-565). As shown in Fig. 10.1, the receptors on cancer cells were first prelabeled with biotiny-

lated humanized mAb (Herceptin, anti Her-2/neu antibody), and then streptavidin superparamagnetic iron oxide microbeads (SPIO-MBs) used as  $T_2$  weighted MR contrast agent were selectively bound to the prelabeled receptors. Because the large sizes of SPIO-MBs significantly restricted their delivery and diffusion into cell by passive endocytosis or active transporter system, the particles could remain on the cell surface, facilitating MR imaging. Labeling extracellular receptors is an important advantage for the *in vivo* application of this method because of the lower probability of modulating cell physiology.

A similar approach with the use of nanometer-size magnetic nanoparticles (MNPs) has also been demonstrated *in vivo* for diagnosis of cancer. Cheon and workers [66] have coated Herceptin on 9-nm  $Fe_3O_4$  to give 28 nm sized water-soluble magnetic iron oxide (WSIO)–Herceptin probes. These probes were injected into mice with an implanted fibroblast cell line, NIH3T6.7, which possessed over-expressed Her-2/neu cancer markers. Figure 10.2 showed the  $T_2$ -weighted MR images obtained at the different temporal points after the intravenous tail injection. No change in the color-mapped MR signal (Fig. 10.2a) and  $T_2$  values (Fig. 10.2c) at the tumor site was observed in the control experiment. In contrast, an immediate color change to blue, at the tumor site, became evident within 5 min of the injection of probes. Cheon's results successfully demonstrated the application of antibody-conjugated MNPs for *in vivo* MR diagnosis of human cancer cells implanted in live mice. Notably, the  $T_2$ -weighted MR signal intensity was dependent on the size of WSIO. When the MNPs increased in size, the MR signal intensity decreased [67].

Nanoparticles can also be combined with ELISA assay to develop a more sensitive and efficient assay. Cui and coworkers [68] have fabricated  $Fe_3O_4/Au$  nanoparticles (GoldMag NPs) with core–shell structure and demonstrated that antibody immobilization efficiency on GoldMag NPs (nanometer scale) was higher than that on Dynal bead (micrometer scale). The anti-HBV (hepatitis B virus) antibody-conjugated GoldMag (anti-HBV GoldMag) was used to detect HBV antigen in blood by ELISA type assay. As shown in Fig. 10.3, the anti-HBV GoldMag NPs were incubated with HBV positive serum first. After a washing step, the HRP (horseradish peroxidase) labeled antibody and its substrate were added into the antibody–nanoparticle complex. By applying an external magnetic field for separation, the liquid phase was measured by UV/Vis spectroscopy. The absorbance at 280 nm showed a 12-fold difference between positive serum and negative serum for HBV antibody.

Beside MNPs, AuNPs alone can also be used as contrast reagents for vital optical imaging of precancers and cancers based on their abilities to resonantly scatter visible and near-infrared light. Richards-Kortum and coworkers [69] used bioconjugates of gold nanoparticles (12 nm in diameter) with monoclonal antibodies against epidermal growth factor receptor (EGFR), a transmembrane glycoprotein that is highly overexpressed in epithelial cancers, for molecular specific optical imaging. Because the aggregation of AuNP increased in scattering cross-section per particle, this property produced a large optical contrast between isolated AuNPs and assemblies of AuNPs, and made it suitable for vital optical imaging. Light scat-

**Fig. 10.3.** Schematic of immunoassay using GoldMag NPs for HBV antigen detection. The GoldMag NPs coupled with anti-HBV antibody can capture the HBV antigen by immuno-

reaction, be isolated from liquid by a magnet, and detected by UV/Vis spectrometry after adding HRP-labeled anti-HBV antibody and HRP substrate. (From Ref. [68].)

tering from the labeled cells was very strong and could be easily observed using low-magnification optics and an inexpensive light source such as a laser pointer. Richards-Kortum's laboratory has applied anti-EGFR AuNPs to the top of engineered tissue constructs and utilized PVP to help AuNP penetrate the tissue layer and reach the cervical cancer cell layer. Transmittance and reflectance images of engineered tissue constructs labeled with anti-EGFR AuNPs (Fig. 10.4) clearly show the distribution of EGFR expression in living neoplastic cervical tissue. The advantage of using AuNP as contrast reagent is that, as many markers are not uniquely expressed in disease cells but are over- or under-expressed, the scattering from closely spaced aggregates associated with overexpression can magnify the signal difference owing to moderate levels of overexpression.

PSA is an important serum marker for the diagnosis and monitoring of prostate cancer. Mirkin and coworkers have developed an ultrasensitive method for detecting PSA using barcode assay [70]. This assay relied on using two particles: a magnetic microparticle for capture target protein and DNA-labeled AuNP for signal amplification. Monoclonal anti-PSA antibody coated magnetic microparticle probes were used to specifically bind target PSA from bio-mediate. The AuNP probes functionalized with hybridized barcode DNA strands and polyclonal antibodies to PSA were used to label microparticle probes through antigen-antibody interaction. Magnetic separation of the complexed probes and PSA was followed by dehybridization of the dsDNA on the AuNP probe to release barcode DNA. Because the AuNP probe carried many DNAs per protein binding event, the binding signal was amplified and PSA could be detected at 30 attomolar concentration. The barcode assay was six orders of magnitude more sensitive than the clinically used ELISA assay for PSA. The same laboratory further discovered that an even more sensitive assay was developed by replacing the AuNPs with polystyrene microparticles, which were loaded with more barcode DNAs to provide a better amplification effect (Fig. 10.5) [71].

**Fig. 10.4.** Transmittance (A, C, and E) and reflectance (B and D) images of engineered tissue constructs labeled with anti-EGFR/gold conjugated. The tissue constructs consist of densely packed multiple layers of cervical cancer (SiHa) cells. The contrast agents were added on top of the tissue phantoms in 10% PVP solution in PBS (A and B) or in pure PBS (C and D). After incubation for ~30 min at room temperature, the phantoms were transversely sectioned with a Krumdieck tissue

slicer, and the sections were imaged using a Zeiss Leica inverted laser scanning confocal microscope with a  $\times 10$  (A–D) objective. A small spot on a tissue construct was imaged using a  $\times 40$  oil immersion objective to show high density of the epithelial cell in the phantom. Reflectance images were obtained with 647 nm excitation. Arrows show the surfaces exposed to the contrast agents. Scale bars are  $\sim 200 \mu\text{m}$  (A–D) and  $\sim 20 \mu\text{m}$  (E). (From Ref. [69].)

## 10.3

## Principles of Mass Spectrometry

Mass spectrometry is a technique that measures the mass-to-charge ratio ( $m/z$ ) of molecules. There are three basic components, ion source, mass analyzer and ion detector, in a typical mass spectrometer. Gaseous ions are formed with sample molecules in the ion source and then introduced into the mass analyzer for separation according to their different  $m/z$ . Finally, the ions that pass through the mass analyzer are detected by the ion detector and the molecular weight of the analyte can be derived. For the analysis of target protein, mass spectrometry has become the choice of tool for protein characterization. Over the last decade, mass spectrometry has not only advanced technologically but has also greatly expanded in applications to unknown protein identification, post-translational modification and protein quantitation in biological and biomedical research.

## 10.3.1

## Matrix-assisted Laser Desorption/Ionization Time-of-flight Mass Spectrometry

Among various types of mass spectrometers, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) has become one of the popular tools for protein detection [72, 73]. As shown in Fig. 10.6, the first step involves mixing and co-crystallizing of the sample and excess molar of “matrix” compounds, which are low molecular weight weak organic acids that strongly absorb UV radiation. Even though the exact mechanism of desorption/ionization is not clear, it is generally considered that the matrix absorbs photoenergy from the laser pulse, resulting in energy transfer and desorption/ionization of matrix and

**Fig. 10.6.** Schematic of matrix-assisted laser desorption/ionization time-of-flight mass spectrometer (MALDI-TOF MS). Analyte ions are generated by irradiation of laser in the

MALDI ion source and accelerated into the drift region of TOF mass analyzer. The  $m/z$  of the ions are determined according to their arrival time at the detector.

sample molecules from the condensed phase into gaseous phase. Singly and/or doubly charged sample ions are, therefore, formed during this process. The pulsed nature of MALDI is often coupled with analysis with a time-of-flight (TOF) mass analyzer. Ions generated in the MALDI ion source are accelerated electrically into the drift region, a long, straight and electric field-free tube, and drift to the detector at the opposite end. Because ions with different mass are given the same kinetic energy in the ionization region, the lighter and heavier ions will reach the detector at different times. The  $m/z$  of an ion can be calculated according to the time, distance of flight and the accelerating voltage.

Furthermore, the introduction of peptide mass fingerprints (PMFs) has had a significant impact on unknown protein identification [74]. Based on the properties of the specific enzymatic-hydrolysis of protein and MALDI-TOF MS, protein can be identified simply and rapidly. The protein of interest, which is in many cases purified by gel electrophoresis, is enzymatically or chemically cleaved into a specific set of peptides, and the peptide mixture is analyzed by MALDI-TOF MS. The resulting PMF spectrum is subsequently compared with “virtual” fingerprints obtained by theoretical cleavage of protein sequences stored in databases in a search to identify of possible candidate proteins [75]. Due to its high sensitivity, tolerance to impurities, high speed, and the ability to provide molecule weight information on intact molecule, MALDI-TOF MS has become one of the primary techniques for protein/peptide profiling and protein identification.

### 10.3.2

#### **Affinity Mass Spectrometry**

Recently, surface-enhanced laser desorption/ionization (SELDI) has evolved rapidly as a new frontier for biomarker discovery and clinical diagnoses based on proteomic pattern analysis [76, 77]. The major difference between SELDI and MALDI is the use of a protein chip array that is composed of a chromatographic surface to retain proteins of interest. SELDI shows diverse applications due its flexibility for surface modification. Despite its advantages of high sensitivity and high throughput, however, the pattern recognition platform, unfortunately, suffers from laboratory-to-laboratory variance due to differences in sample preparation, handling, and analysis software. Many complications may result from suppression effects, a wide dynamic range of protein concentration during simultaneous detection of many proteins in sample.

As an alternative to the above approaches, MALDI-TOF MS can be combined with a biologically active probe to rapidly and specifically target, separate, and pre-concentrate proteins of interest. This targeted approach, named affinity mass spectrometry, can accelerate research for class-specific proteins or biomarkers. Several analytical affinity capture techniques have been developed for affinity mass spectrometry. The research group of Hutchens and Yip was one of first to demonstrate MS-based affinity capture by immobilization of “bait” DNA on agarose beads for direct MALDI-TOF MS analysis of targeted proteins from complex biofluids [78]. The concept was further tailored by Nelson and coworkers to develop a mass spec-

trometric immunoassay (MSIA) [79]. They used affinity pipette tips (MSIA tips) to selectively retrieve proteins from biological fluids, demonstrating high-throughput quantitative protein analysis as well as screening of heterogeneous glycan structures in plasma proteins [80–82]. Furthermore, ligands and antibodies can also be immobilized or captured on the surface of gold and organic polymer film as probes [83–85]. Other variations of the biologically active probe for affinity mass spectrometry include the assay of direct desorption/ionization on silicon [86, 87] and self-assembled monolayers [88]. Despite the rapid evolution of efficient chip-based or microbead-based assays for biomedical research, protein chip technologies face some technical challenges such as the special requirement of immobilization chemistry and instruments and denaturing/alternating the native bait proteins caused by the chip/bead surface properties.

In recent years, nanomaterials have begun to serve as biologically active probes in affinity mass spectrometry and show great potential for application in various biology systems. Chen et al. have used gold nanoparticles immobilized on magnetic particles (Au@magnetic particles) and carbon nanotubes (CNTs) to probe proteins and peptides [38, 89]. Magnetic NPs that conjugated with antibodies were also used to probe pathogenic bacteria by Chen's group [90]. Chang et al. used high-affinity diamond NPs to extract and preconcentrate proteins from diluted solution and human serum [91]. In addition, Harrison et al. have introduced the C18 functionalized silica NP and aptamer conjugated MNPs as probes [92].

When affinity molecules are coupled to such NPs, they can function as sensitive biosensors that show superior separation capabilities compared with microbeads [93, 94]. There are more advantages of using NPs as ligand carriers [95]. First, there are simple and facile means of anchoring molecules to the nanoscale surface to form versatile and covalently stable conjugates with the capability of specifically interacting with targeted biomolecules. Second, the large surface area-to-volume ratio and the globular shape of an NP allow multivalent and three-dimensional interactions between ligands and receptors without hindrance. Finally, compared with conventional microarray methods using planar solid supports, functionalized NPs can be used as “water-soluble” probes in biological assays in solution. In principle, these “suspension arrays” should improve assay homogeneity and reduce assay time. In our recent report, sugar-conjugated gold NPs were demonstrated as an affinity probe for efficient separation and enrichment of target protein, and then protein identification and epitope mapping in carbohydrate–lectin recognition [40].

#### 10.4

##### **Nanoprobe-based Affinity Mass Spectrometry (NBAMS)**

During the past few years, we have focused on developing a versatile, sensitive analytical platform based on surface-engineered NPs and mass spectrometry analysis [96, 97]. The principle of nanoprobe-based affinity mass spectrometry (NBAMS) is to use MNPs as an affinity probe to effectively extract and enrich target protein for direct MALDI-TOF MS detection. The probe, derived from antibody-conjugated

MNPs, was designed for protein profiling in human plasma. Three serum proteins with different concentrations, C-reactive protein (CRP), serum amyloid A (SAA), and serum amyloid P component (SAP), have been selected as target proteins to demonstrate the general applicability of the method. Both CRP [98, 99] and SAA [100] are exquisitely sensitive systemic markers of acute phase response and present about  $1 \text{ mg L}^{-1}$  and  $3 \text{ mg L}^{-1}$  in the blood of healthy human, respectively. Overexpression of SAA was also found to be associated with gastric cancer in a recent report [101]. SAP is a biomarker related to Alzheimer's disease and type 2 diabetes [102], with a concentration about  $40 \text{ mg L}^{-1}$  in blood of healthy humans [82, 103].

#### 10.4.1

##### Preparation of Nanoprobes and Workflow

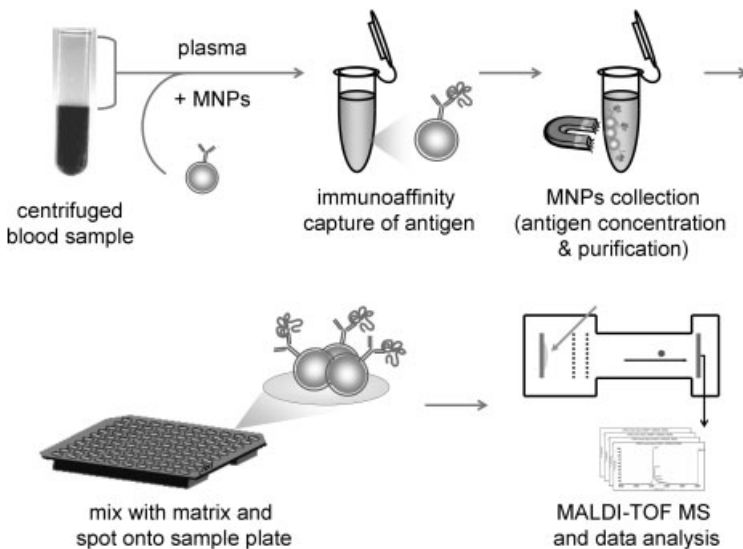

Figure 10.7 illustrates the synthesis of antibody-conjugated iron oxide NPs. The iron oxide ( $\text{Fe}_3\text{O}_4$ ) NPs (MNP 1) were obtained by co-precipitation of  $\text{FeCl}_2$  and

**Fig. 10.7.** Preparation and characterization of MEG-protected antibody-conjugated MNPs. (From Ref. [97].)

$\text{FeCl}_3$  under basic conditions and then dispersed in acidic solution [104]. The particle surface was transformed into an amino functionality by the sol-gel process using tetraethyl orthosilicate (TEOS) followed by addition of 3-aminopropyltrimethoxysilane (APS) to give **MNP 2**, which contains amine terminal groups [105]. Transmission electron microscopy (TEM) revealed that the diameter of **MNP 1** is in the range of 5–15 nm while the average diameter of the iron oxide core of **MNP 2** was 50 nm with a relatively narrow size distribution (Fig. 10.7). Enlargement of the metal core is due to the aggregation of iron oxide during silanization, and the silica shell is visible as a faint circle outside the core. For antibody conjugating, **MNP 2** was treated with a crosslinker, bis(*N*-hydroxysuccinimide ester) (DSS), to crosslink the aminosilane MNPs with antibody [106]. To avoid non-specific binding on the surface of antibody-conjugated MNPs, the resulting MNPs were protected by a blocking reagent, i.e., terminal aminated methoxy-ethylene glycol (MEG). The final products, MEG-protected antibody-conjugated MNPs, were washed and ready to use for NBAMS.

Figure 10.8 shows the workflow of NBAMS. Phosphate-buffered saline (PBS, pH 7.4) diluted plasma sample is incubated with antibody-conjugated MNPs at room temperature. After immunoaffinity capture of antigens, the antigen-captured MNPs are collected by a magnet, and the unbound, non-antigenic components were subsequently removed by a series of washes, abrogating the need for purification and desalting. For subsequent MS analysis, the MNPs were directly mixed with MALDI matrix and directly spotted onto the sample plate for MALDI-TOF MS measurement.

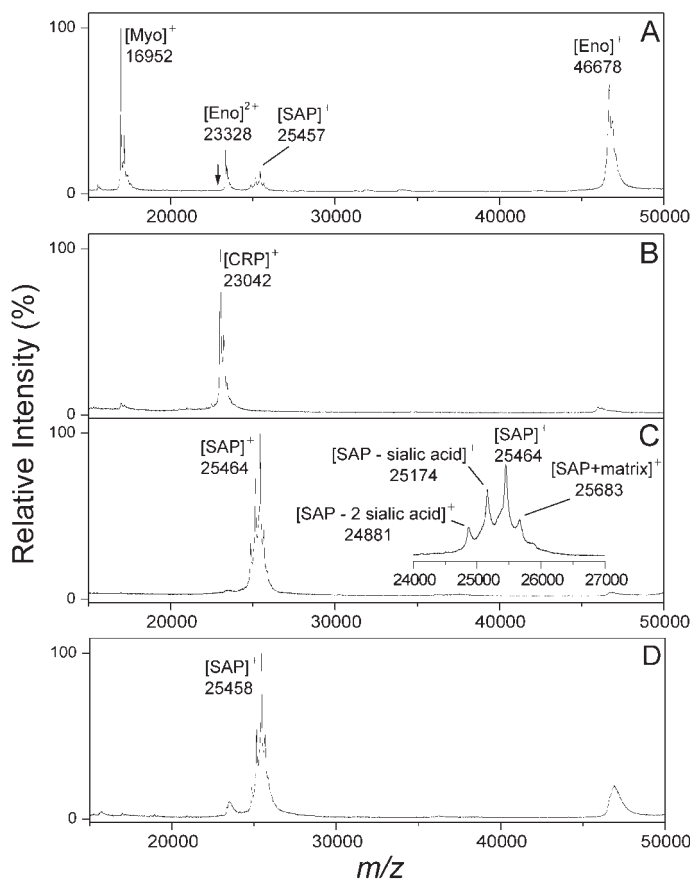

**Fig. 10.8.** Workflow of nanoprobe-based affinity mass spectrometry (NBAMS). The target antigen is specifically extracted from plasma sample by antibody-conjugated MNPs.

After separation by magnet, the isolated, antigen-captured MNPs are directly spotted onto a sample plate and analyzed by MALDI-TOF MS.

## 10.4.2

## Proof-of-principle Experiment

The feasibility of the NBAMS strategy was first evaluated with a protein mixture composed of antigenic proteins (SAP, 20% molar fraction and CRP, 3% molar fraction) and two other “nonantigenic” proteins, myoglobin (Myo, 15%) and enolase (Eno, 62%). The abundance of the targeted antigenic proteins was purposely reduced in mixture to test the extraction efficiency of the targeted protein. As shown in Fig. 10.9(A), the MALDI-TOF mass spectrum of the protein mixture displayed the complexity of the mixture, in which one of the targeted antigens, CRP, was not ob-

**Fig. 10.9.** MALDI-TOF mass spectra of a protein mixture before (A) and after using (B) anti-CRP-conjugated MNPs, (C) anti-SAP-conjugated MNPs, and (D) anti-SAP-encapsulated AuNPs to extract a specific protein. The protein solution (60  $\mu$ L) was composed of 0.5  $\mu$ M myoglobin (Myo), 0.1  $\mu$ M

C-reactive protein (CRP), 0.67  $\mu$ M serum amyloid P component (SAP), and 2.1  $\mu$ M enolase (Eno). The arrow in (A) indicates the theoretical  $m/z$  of CRP. The inset of (C) shows detailed protein expression profiles of wild-type, monosialo-, and asialo-SAP. (From Ref. [96].)

served due to its low abundance (3% molar fraction) and the ion suppression effect [107]. Suppression effects are commonly observed in MALDI-TOF MS due to the presence of salts, buffer, or other more abundant species in complex biological media [108]. The suppression effect can result in reduced signal intensity or even the disappearance of the signal of targeted analyte. Figure 10.9(B) revealed the specificity of the NBAMS methodology, where CRP was extracted and detected with an excellent signal-to-noise ratio of 822. No background peak between  $m/z$  5000 and 50 000 was observed in control experiments before the addition of the protein mixture, showing no “chemical noise” arising from the antibody-conjugated MNPs. The absence of other abundant proteins excluded nonspecific binding arising from electrostatic attraction or hydrogen bonding. The use of nanoprobe-based immunoassay overcomes the suppression effect because the salt and abundant non-antigenic proteins are removed and targeted proteins are selectively concentrated on the MNPs. The strong peak of target protein in mass spectrum without background demonstrates the advantages of nanoprobe-based affinity extraction in providing simultaneous protein isolation, enrichment, and sample desalting without the necessity of additional purification steps.

Mass spectrometric detection is also ideal for characterizing post-translational modifications that cannot be predicted from genomic information. The MALDI-TOF mass spectrum in Fig. 10.9(C) showed a cluster of peaks corresponding to several SAP variants from the affinity extraction using anti-SAP-conjugated MNPs. The expanded view shows that the mass spectrum is dominated by the mass of  $25464 \pm 4$  Da, which is consistent with the theoretical value of 25462 Da, as calculated from the known sequence [109]. Accompanying the major peak were two peaks at 25174 and 24881 Da, corresponding to mass shifts of 290 and 583 Da, respectively. Within experimental uncertainty, the shifts can be attributed to the loss of one or two sialic acid residues (mass of each residue: 291 Da) [82].

In addition to MNPs, surface-engineering gold nanoparticles (AuNPs) can also be an affinity probe [40]. The test of AuNP for immunoreaction was performed with 13-nm AuNPs. Antibody-encapsulated AuNPs were prepared as follows. The pH of a gold colloid was adjusted to 8.5 with 0.1 M  $K_2CO_3$ , followed by addition of antibody in the solution. The reaction was performed on ice for 60 min and the antibody-encapsulated AuNP was separated by centrifugation. The anti-SAP encapsulated AuNPs were incubated with the same protein pool (Fig. 10.9A). After immunoaffinity extraction, the pellet of AuNP containing targeted antigen was subsequently analyzed by MALDI-TOF MS. Figure 10.9(D) shows the extracted SAP from the mixture; however, signal from the enolase was also observed due to the “unoccupied sites” on AuNP. After further modification with bovine serum albumin on the AuNP surface, the co-extraction of enolase can be diminished (data not shown).

In general, antibody–antigen interactions are strong, with dissociation constants ( $K_d$ ) ranging from  $10^{-7}$  to  $10^{-11}$  M. Most antibody–antigen complexes can be dissociated at extreme pH (i.e.,  $pH < 2$  or  $pH > 12$ ). Direct MALDI-TOF MS analysis is performed where particles are placed directly on the MALDI sample plate with addition of matrix. The pH of matrix (SA) solutions is typically less than 2 and thus may serve to elute the antigen bound to the antibody-conjugated MNPs. The direct

MALDI-TOF MS approach provides rapid and sensitive analysis of affinity-bound analyte, avoiding the potential risk of sample loss. In the linear mode of MALDI-TOF MS, the mass resolution did not deteriorate when the antigen-bound MNPs were deposited on the MALDI probe. Similarly, a mass accuracy of 0.02% could be routinely obtained by external calibration, comparable to the mass accuracy of conventional MALDI-TOF MS detection. Thus, the “direct” analysis of nanoscale particles does not diminish the performance of the MALDI-TOF MS.

To confirm the identity of the captured protein, the MNPs pellet was directly subjected to *in situ* digestion with trypsin and analyzed by MALDI-TOF MS. A database search of the peptide mass fingerprinting map with the MS-Fit program (<http://us.expasy.org/uniprot/P02743>) unambiguously matched to serum amyloid P component precursor (Swiss-Prot P02743, see Fig. 10.10). The unique advantage of on-probe protein identification provides potential applications of functionalized MNPs in discovering unknown class-specific proteins.

Theory (m/z)	Experiment (m/z)	Peptide sequence	Missed cleavages	Theory (m/z)	Experiment (m/z)	Peptide sequence	Missed cleavages

**Fig. 10.10.** Assignment of observed peptides from *in situ* trypsin-digestion of antigen-captured MNPs and their corresponding sequences matched to serum amyloid P component precursor (SAP, P02743 in the SwissProt sequence database). The sequence coverage is 58%. (From Ref. [97].)

**Fig. 10.11.** Effect of incubation time on antibody–antigen recognition using antibody-conjugated MNPs. To investigate the time course of antibody–antigen recognition on MNPs, 1  $\mu$ L of supernatant was sampled from a 60- $\mu$ L reaction after different incubation times. The MNPs were conjugated with anti-

SAP (filled squares with solid line) and anti-CRP (filled circles with dashed line). After incubation (3–60 min), the quantities of the antigen remaining in the supernatant were detected by MALDI-TOF MS, and the peak intensities were plotted as a function of incubation time. (From Ref. [96].)

#### 10.4.3

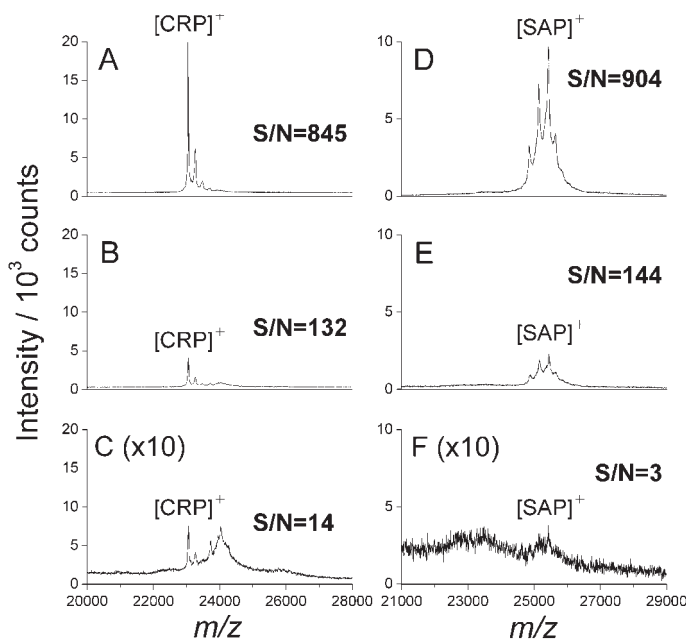

#### Kinetic Study of the Nanoscale Immunoreaction

In traditional immunoassays, the incubation of antibody and antigen is often the rate-limiting step (e.g., 30 min to overnight for conventional ELISA) [110, 111]. The high density of surface antibody should, in principle, speed up antibody–antigen interaction. Figure 10.11 shows the required incubation time of NBAMS approach. The peak intensities, corresponding to unbound antigen (SAP) in solution, decreased dramatically as a function of incubation time over 10 min, at which time free SAP was barely detectable (signal-to-noise ratio was  $<3$ ). Significantly, the binding of CRP was almost completed in an even shorter incubation time ( $<3$  min). Unlike conventional immunoassays such as ELISA, for which the overall process usually requires at least 4 h, the nanoscale immunoassay can be shortened to within 15–20 min. In addition to high antibody density on MNPs, the rapid immunoreaction may be attributed to the water-soluble MNPs; the “suspension arrays” improves the assay homogeneity and reduces sample handling time. The NBAMS approach directly detected specific antibody-captured antigens by MALDI-TOF MS without using a secondary antibody or a reporter reaction. Thus, this rapid and sensitive approach may be amenable to clinical applications such as high-throughput or population screening.

#### 10.4.4

#### Detection Limit and Concentration Effect of Nanoprobe-based Immunoassay

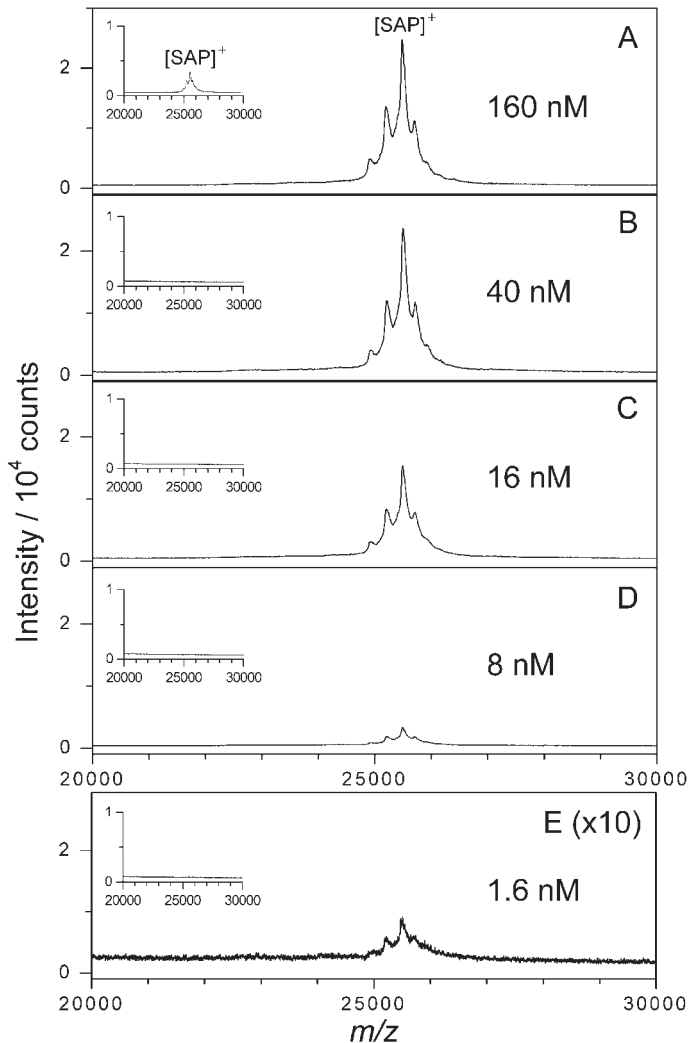

The NBAMS assay also reveals high detection sensitivity. Figure 10.12(A–C) shows that the CRP signals decrease progressively with decreasing concentration, ranging

**Fig. 10.12.** Mass spectra of CRP extracted from 60  $\mu\text{L}$  of protein solution of (A) 145, (B) 29, and (C) 6 nM, using anti-CRP-conjugated MNPs; and spectra of SAP extracted from (D) 1.9  $\mu\text{M}$ , (E) 15 nM, (F) 0.6 nM, using anti-SAP-conjugated MNPs. (From Ref. [96].)

from 145 to 6 nM, and the current assay detection limit for CRP is 6 nM (Fig. 10.12C). Similarly, Fig. 10.12(D–F) shows the mass spectra of SAP extracted from a series of dilutions of 60  $\mu\text{L}$  PBS, ranging from 1.9  $\mu\text{M}$  to 0.6 nM. Strong peak intensities were observed in all spectra except that for the 0.6 nM solution (signal-to-noise ratio of 3). The better detection limit of SAP compared with CRP may be attributed to the different amounts of antibody on MNPs (the rate of anti-SAP to anti-CRP was 1.4). Theoretically, the assay sensitivity of the NBAMS approach depends on the MALDI-TOF MS detection limit and the efficiency of affinity extraction. Assuming full recovery of all the SAP present in the 60  $\mu\text{L}$  of diluted solution (0.6 nM in Fig. 10.12F), the absolute detection limit is estimated to be 36 fmol, which is comparable to the detection limit by direct deposition of SAP onto the MALDI probe (data not shown). Notably, SAP and CRP levels in sera from healthy individuals were about 1.6  $\mu\text{M}$  and 40 nM, respectively [112, 113]. Considering current progress in the detection limit, the nanoscale immunoassay is capable, with reasonable enrichment, of detecting plasma proteins at the subnanomolar level (0.6 nM).

Another advantage of the nanoprobe-based immunoassay is the ability to preconcentrate the antigen from diluted medium to a small volume of MNPs. The concentration effect was demonstrated with a series of solutions with different SAP concentration (8–160 nM). Figure 10.13 shows the MALDI-TOF mass spectra of ex-

**Fig. 10.13.** Mass spectra of SAP extracted from diluted solution using anti-SAP-conjugated MNPs: (A) 160 nM SAP, 50  $\mu\text{L}$ ; (B) 40 nM, 200  $\mu\text{L}$ ; (C) 16 nM, 500  $\mu\text{L}$ ; (D) 8 nM, 1000  $\mu\text{L}$ ; (E) 1.6 nM, 1000  $\mu\text{L}$ . The inset of each panel shows the mass spectrum of solution prior to extraction. (From Ref. [96].)

tracted SAP after preconcentration using anti-SAP-conjugated MNPs. By contrast, the SAP peak was barely discernible (or not detected) when the diluted samples were analyzed by conventional MALDI-TOF MS, as shown in the inset of each panel. Similarly, Fig. 10.13(E) shows that as low as 1.6 nM SAP in a 1000  $\mu\text{L}$  solution was detectable with a signal-to-noise ratio of 13, and this concentration was

comparable to the detection limit of SAP extracted by MNPs (Fig. 10.12F). All the results demonstrate the MNPs are effective probes that provide simultaneous protein cleaning and concentrating for analyte with very low concentration.

## 10.5

### Human Plasma and Whole Blood Analysis by Nanoprobe-based Affinity Mass Spectrometry

#### 10.5.1

##### Selected Protein Profiling from Human Plasma

Human plasma proteome is the most attractive biological medium containing secreted disease-related markers, holding promise in both disease diagnosis and therapeutic aspects [21]. However, it is a very complex mixture of proteins having a wide and dynamic range of abundance of more than  $10^{12}$ . Indeed, 22 high-abundance proteins constitute 99% of the protein content in plasma, with the remaining 1% that are of great interest as potential biomarkers [114]. In the NBAMS immunoassay, specificity is one of the key components to analyze the low-abundance proteins. The NBAMS platform has been applied to human plasma to investigate whether the approach can directly detect low-level proteins in plasma. Before immunoaffinity extraction, no protein profile could be obtained from the crude plasma in healthy individual due to the interference of salt and other plasma components (Fig. 10.14A). After a 200-fold dilution of the plasma sample to reduce the salt concentration, the protein profile in Fig. 10.14(B) shows the commonly observed abundant plasma proteins, including human serum albumin (HSA), apolipoprotein A-I (Apo A-I), hemoglobin  $\alpha$ -chain (Hb-A), hemoglobin  $\beta$ -chain (Hb-B), and transthyretin (TTR). After immunoaffinity extraction, SAP was detected with concomitant depletion of other proteins of higher concentration (Fig. 10.14C). Similarly, Fig. 10.14(D) shows an apparent peak for CRP, even though the level of this protein is 40-fold lower than that of SAP in healthy individuals. Although the analysis showed minor peaks due to nonspecific binding of other high-abundance plasma proteins, they did not interfere with the unambiguous identification of CRP and SAP by mass spectrometry.

#### 10.5.2

##### Comparison of Nanoscale and Microscale Immunoassay

To compare the advantages of magnetic nano-size particles with those of magnetic microbeads (MMP), commercially aminated magnetic microbeads (DYNAL BIOTECH, 2.8  $\mu\text{m}$ ) were conjugated with anti-SAP antibody to obtain anti-SAP MMP by the same modification process used for MNP. With an equal amount of antibody on the particle surface, the signal intensity and signal-to-noise ratio were dramatically reduced in the mass spectrum of MMP compared with MNP experiments. These results indicate that MNPs afford better affinity extraction of the tar-

**Fig. 10.14.** Comparison of immunoaffinity extraction performance between antibody-conjugated MNPs and magnetic microbeads. Mass spectra showed human plasma (A) without dilution; (B) with 200-fold dilution. High-abundance proteins were so dominant that the signals from SAP or CRP were buried

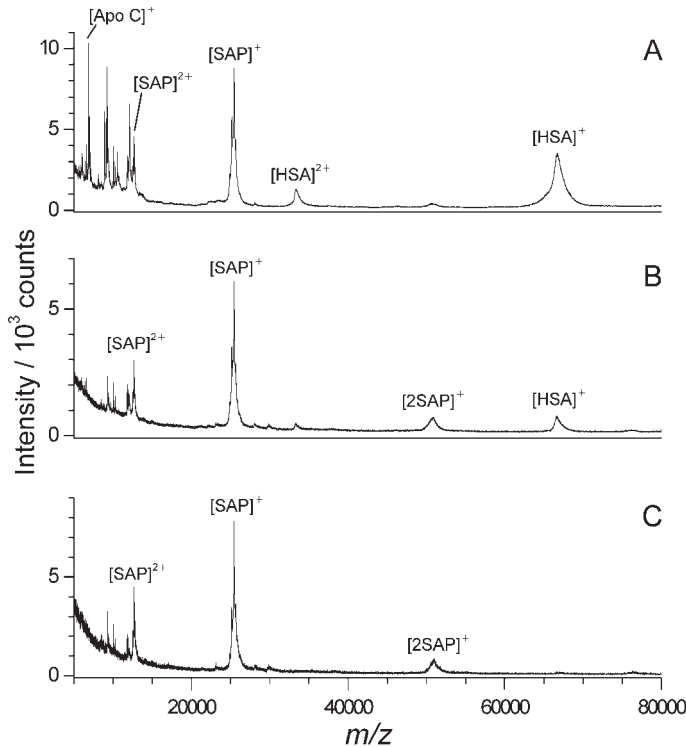

in the spectrum. Representative mass spectra of (C) for SAP and (D) for CRP were obtained after extraction using antibody-conjugated MNPs. Spectra for antibody-conjugated microbeads are shown in (E) for SAP and (F) for CRP. (From Ref. [96].)

get protein, thereby improving the detection. The superior efficiency of MNP could be attributed to its large surface area-to-volume ratio, good reaction homogeneity and fast reaction kinetics in suspension array. Additionally, the mass spectrum of affinity extraction with MNPs preserved good spectral resolution and peak profiles without apparent peak broadening and mass shift.

### 10.5.3

#### Suppression of Nonspecific Binding on Magnetic Nanoparticles

Antibody-conjugated MNPs could effectively enhance the target protein signal for MALDI-TOF MS detection. However, nonspecific binding from other non-antigenic protein on the surface of MNPs interferes with the sensitivity and accuracy of MALDI-TOF MS detection. As shown in Fig. 10.15(A), HSA is the major abundant protein present in human plasma and was coextracted by antibody-conjugated MNPs. To avoid nonspecific binding, bovine serum albumin (BSA) was first tested

**Fig. 10.15.** Mass spectra of nanoscale immunoaffinity extraction of plasma SAP from a 1- $\mu$ L plasma sample with anti-SAP MNPs (A) without blocking, (B) with BSA blocking and (C) with 40 mM MEG blocking. (From Ref. [97].)

**Fig. 10.16.** Concentration effect of MEG on suppression of non-specific binding; the maximum value of target/HSA ratio is normalized as 1.0. (From Ref. [97].)

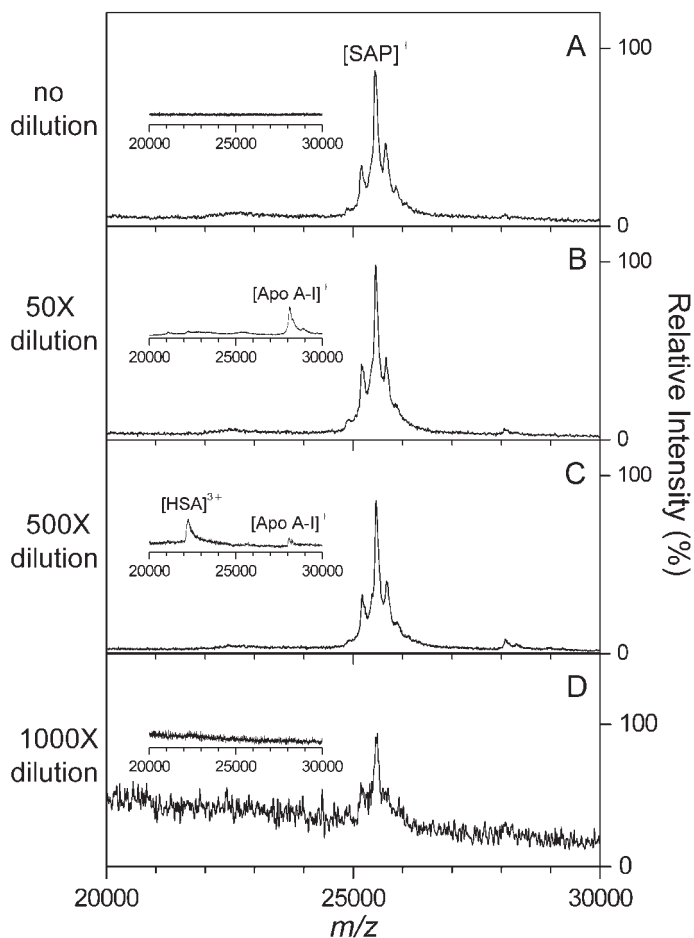

as a blocking agent to protect the anti-SAP MNPs. However, BSA did not yield good suppression of the HSA peak. Recently, Huang and Zheng [115] have reported that the short molecule, ethylene glycol, is biocompatible material with good resistance to nonspecific binding with biological molecules. The short terminal aminated methoxy-ethylene glycol (MEG) linker was tested as the surface blocking spacer to suppress the serious nonspecific binding effect. Indeed, MEG-protected antibody-conjugated MNPs can significantly reduce non-specific binding during the affinity separation of protein biomarkers in human plasma.

By modulating the MEG coupling concentration, the inhibition of nonspecific binding was found to be concentration-dependent (10–100 mM). In Fig. 10.16, three different protein markers, including SAP, CRP, SAA, could be obviously enhanced with the least nonspecific interference from the MEG coupling concentration between 20 and 40 mM. Notably, the amount of antibody on the MNP surface was not affected by the incubation time and the concentration of MEG. Based on above results, moderate surface blocking plays a key role in the enhanced detection specificity of the NBAMS approach.

#### 10.5.4

##### Enrichment of Target Antigen in Human Plasma

The major advantage of NBAMS methodology is the simultaneous selection and preconcentration of targeted protein onto the MNPs, even in a complex biological medium. The concentration effect of NBAMS in human plasma was evaluated with equal amounts of plasma (1  $\mu$ L from each subject) diluted 50-, 500-, and

**Fig. 10.17.** Mass spectra of SAP extracted from human plasma (1  $\mu$ L), undiluted (A), and diluted 50-fold (B), 500-fold (C), or 1000-fold (D), using anti-SAP-conjugated MNPs extraction. Inset of each panel shows the mass spectrum of solution before extraction. (From Ref. [96].)

1000-fold in PBS and analyzed using the nanoprobe-based immunoassay. Figure 10.17 shows the MALDI-TOF mass spectra of plasma SAP extracted from each diluted sample. Incubation of the diluted plasma samples with the antibody-conjugated MNPs resulted in antigen selection and concentration, as demonstrated by the similar mass spectra profiles up to 500-fold dilution (Fig. 10.17C). In the 1000-fold diluted sample (1.8 nM SAP), however, the captured antigen showed significantly lower intensity in the mass spectrum (Fig. 10.17D). This decreased recovery may arise from the incomplete collection of the MNPs from the curved wall of the microcentrifuge tube during the washing steps. Despite the decreased

recovery at 1000-fold dilution, the detection sensitivity in human plasma (estimated to be 1.8 nM) was comparable to the performance of NBAMS in a protein standard (SAP, 0.6 nM in Fig. 10.12F), demonstrating that the nanoscale immunoassay is refractory to the presence of highly abundant nonantigenic proteins, salts, and buffers in plasma. All these results display the general applicability of NBAMS methodology, namely, that concentrations with a 1000-fold difference can be detected successfully. By the good concentration effect, 1  $\mu$ L of plasma is sufficient to unambiguously identify an antigen of interest.

In the NBAMS immunoassay, the rate-limiting step of the total procedure for diseased-related protein analysis by NBAMS is the separation of plasma from blood (30–60 min). To speed up the analysis, the NBAMS approach was performed in a blood sample without prior centrifugation. Figure 10.18(A) shows the profile of the major proteins in human blood, containing Hb-A, Hb-B and HSA. After treatment with anti-SAP- and anti-CRP-conjugated MNPs sequentially, the extracted SAP and CRP was shown in Fig. 10.18(B, C, respectively). Although the highly abundant Hb-A, Hb-B and HSA were coextracted, CRP and SAP were unambiguously identified through mass spectrometric detection within 20 min without interference from the highly abundant contaminants. This demonstrates the feasibility of the NBAMS approach in blood sample analysis and holds promise in speeding up clinical applications.

#### 10.5.5

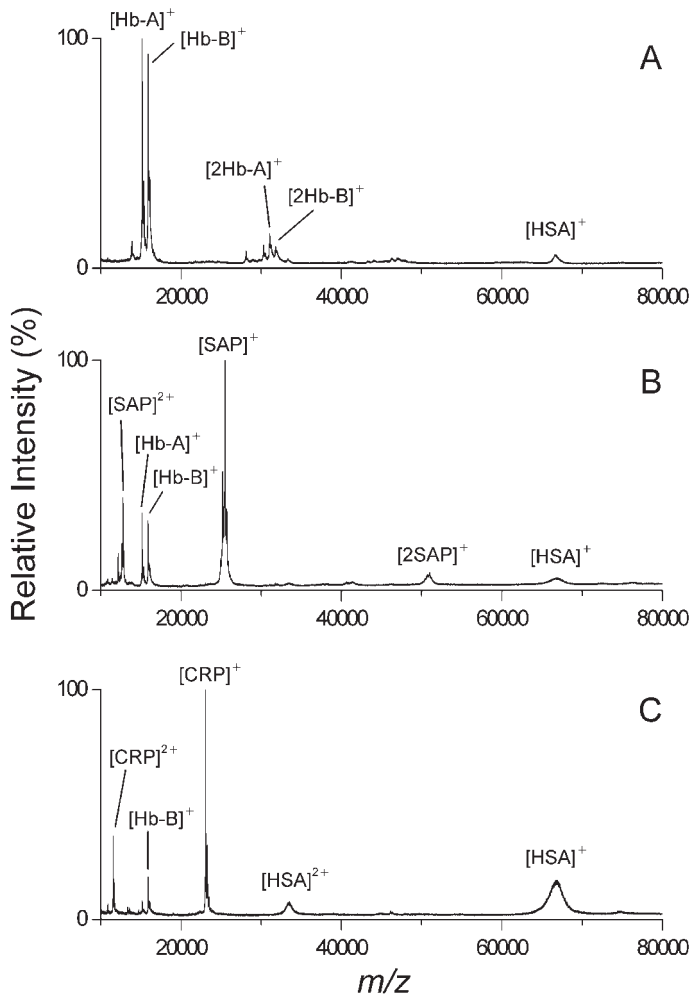

##### **Plasma Protein Profiling in Normal Individuals and in Patients**

The NBAMS approach has been performed with authentic clinical samples plasma (20  $\mu$ L) from six healthy individuals and four patients with gastric cancer [97]. All sample preparation, washing and on-nanoprobe analysis were performed in parallel batches. CRP and SAP were detected successfully in all the healthy individuals, despite the fact that the levels of a few of them were below the detection limit of ELISA ( $<0.159$  mg L<sup>-1</sup>) [101]. The results in Fig. 10.19 illustrate the measured intensities for CRP and SAP, showing significant upregulation and down-regulation in expression levels, respectively. These observed differences in protein levels are consistent with the literature [116, 117] and the ion intensity measured by the nanoprobe-based assay correlated with the concentration measured by ELISA [101], suggesting that the NBAMS approach shows promise for quantitative protein profiling. Analysis with more clinical samples is required for further evaluation on quantitation accuracy.

#### 10.6

##### **Multiplex Assay**

Because of the complex natures of disease, diagnosis using single protein assay often results in insufficient detection specificity. To improve detection specificity and sensitivity to determine disease onset, the utility of multivariant protein

**Fig. 10.18.** Mass spectra of a human blood sample (20  $\mu$ L) from a patient with stroke before (A) and after using (B) anti-SAP-conjugated MNPs or (C) anti-CRP-conjugated MNPs extraction.

markers as disease signature present an evolving direction in diagnosis. Developing multiplexed assays that can simultaneously screen multiple protein biomarkers is a rapidly expanding trend in characterizing disease states [118]. For example, Lokshin et al. [119] have developed new profiling technology, LabMAP, which combines the principle of a sandwich immunoassay with fluorescent-bead-based technology to detect tumor markers and cytokines in serum samples. The sensitivity, around 80–90% specificity, of discriminating early-stage ovarian cancer from

**Fig. 10.19.** Screening of SAP and CRP in human plasma from healthy individuals and patients with gastric cancer using nanoprobe-based affinity mass spectrometry. The mass

spectrum of CRP ( $m/z$  23 kDa) and SAP ( $m/z$  25 kDa) show significant upregulation and down-regulation, respectively. (From Ref. [97].)

healthy controls was increased from 70 to 80% by using CA 125 alone to 90–100% by using the combination of five markers. In addition to the fluorescence-based immunoassay, Wilson has reported antibody-immobilized electrodes as electrochemical immunosensors. Quantitation can be performed simultaneously for two tumor markers, CEA and AFP, in standard protein solution [120]. Lieber's group have developed an antibody-labeled silicon-nanowire sensor array for multiplex electrical detection of PSA, PSA-ACT complex, CEA, and mucin-1. This technology allowed highly selective and sensitive detection of  $0.9 \text{ pg mL}^{-1}$  of PSA in undiluted serum samples [121].

#### 10.6.1

##### Workflow of Multiplexed Assay

In past work, the NBAMS technology has also been successfully demonstrated as a multiplexed immunoassay [97]. Three model proteins, SAA, SAP, and CRP, were still selected as target antigens. Figure 10.20 shows the multiplex immunoassay workflow. Plasma is diluted by PBS, mixed with a mixture of anti-SAA-, anti-CRP-, and anti-SAP-MNPs, and incubated at room temperature. In the same way as described previously, MNPs are isolated, washed, and subjected to MALDI-TOF MS analysis after immunoaffinity capture of antigens. This immunoextraction and subsequent analysis can be completed in 1 h.

**Fig. 10.20.** Workflow of multiplexed immunoassay. For simultaneous analysis of multiple antigens, various antibody-conjugated MNPs are mixed in the appropriate ratio, and incubated with plasma sample. After separation by magnet, the isolated, antigen-captured MNPs are directly spotted onto a sample plate and analyzed by MALDI-TOF MS.

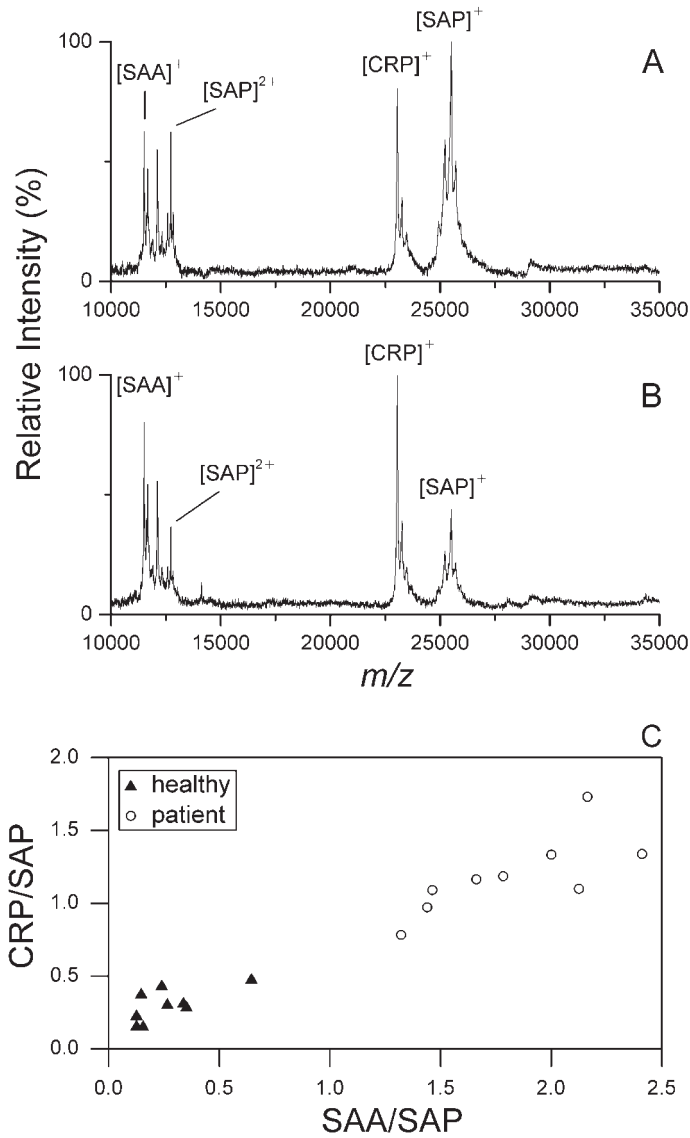

### 10.6.2

#### Screening for Patient and Healthy Individuals

A total of 18 samples, including nine normal controls and nine gastric cancer patients, have been analyzed by the NBAMS multiplexed immunoassay. Figure 10.21 shows representative results of the multiplex assay for SAA, SAP, and CRP from human plasma. Obvious differences can be observed in the protein profile between the two spectra obtained from healthy control (Fig. 10.21A) and gastric cancer patients (Fig. 10.21B). The measured intensities for both SAA and CRP are considerably higher in the gastric cancer patient sample than in the healthy individual. The relative SAA and CRP intensities are consistent with the concentration measured by ELISA (data not shown), and suggest that our immunoassay shows promise for quantitative protein profiling.

The normal and gastric cancer groups can be differentiated with a scatterplot of relative SAA and CRP intensities (Fig. 10.21C). Obviously, the data distribution falls into two clusters in the diagram. A “virtual diagnosis pattern” of the SAA/SAP and CRP/SAP ratio provides a group separation. The low relative SAA and CRP abundances were observed in plasma from the healthy group, whereas higher ratios were observed for gastric cancer cases. The distribution is consistent with the groups of normal and gastric cancer.

It has been increasingly recognized that multivariate parameters characterize disease states better than a single protein assay. By using a mixture of MNPs conjugated with different antibodies, the NBAMS technology demonstrated the capability of simultaneous multiplex protein profiling in complex mixtures like human plasma. Furthermore, this assay provides the speed, high sensitivity, and detection specificity required by disease diagnosis and monitoring. This preliminary data showed the promise for application of rapid screening targeted protein profile for disease diagnosis and monitoring. However, the potential implementation of NBAMS awaits further considerations. Generally, the diagnosis specificity not only depends on the detection specificity but also on statistical specificity of the protein marker. In terms of accuracy and reproducibility of analysis, more samples

**Fig. 10.21.** Representative protein profiles of human plasma from (A) healthy control (from Ref. [97]) and (B) gastric cancer patient obtained by multiplexed immunoassay. (C) Scatter-plot of relative SAA and CRP intensities shows a differentiation between normal and gastric cancer groups.

are required for further evaluation. Further study for quantitative profiling is currently on-going.

## 10.7

### Future Outlook

Surface-conjugated nanoparticles have been shown to act as specific affinity nanoprobes for the multiplexed detection of target proteins in human plasma. Such nanoprobes are envisaged to become excellent tools for the separation and enrichment of low-abundant protein biomarkers. Analysis by MALDI-TOF MS provides unambiguous identification of target antigen. In combination with the ongoing quantitative analysis of plasma protein profiling, this nanoprobe-based immunoassay holds great potential for the early diagnosis of disease, inflammatory events, and eventually cancers. From proof-of-concept experiments to widespread use, as always, the quantification sensitivity, specificity, and reproducibility have to be further evaluated with a large set of clinical specimens. For large-scale analysis, advances in instrumentation will become imperative for the automation of sample preparation, nanoprobe detection, and data analysis. The specificity, speed, and flexibility of the nanoprobe-based affinity assay can easily be adapted for the detection of other class-specific proteins in biological research, clinical proteomics and diagnostics.

# Nanotechnological Approaches to Cancer Diagnosis: Imaging and Quantification of Pericellular Proteolytic Activity

Thomas Ludwig

### 11.1

#### Introduction

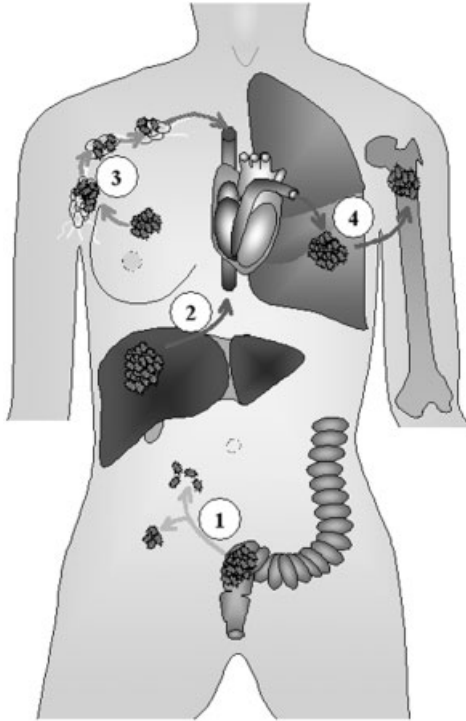

Most cancer related deaths are not caused by the growth of a tumor in its primary location. Metastasis with subsequent local tissue invasion accounts for more than 90% of all lethal outcomes in cancer (reviewed in Refs. [1, 2]). Despite great efforts to improve our understanding of the metastatic cascade (Figs. 11.1 and 11.2) and the accumulation of detailed knowledge about single aspects of this process, comparably little has resulted in patient benefits so far (reviewed in Ref. [3]).

This chapter outlines reasons for this dilemma by analyzing the challenges that result from local, nanoscale processes for *in vitro* and *in vivo* diagnostics. It combines, for the first time, a thorough review of the biological basis of proteolytic activity as the prototype of a highly regulated and spatially restricted process in cancer with a critical analysis of conventional state of the art methods and how the application of nanotechnology creates unique opportunities to further both our understanding and treatment of malignancies.

The mechanisms that confine and concentrate protease activity in the pericellular microenvironment of cancer cells are prerequisites of tumor cell invasion and key factors in the regulation of tumor microecology. This chapter starts with a detailed description of these mechanisms with a special emphasis on the technical problems related to them and how this is connected to the obvious gaps in our knowledge regarding their regulation.

With a reference to the biological background, the next section of the chapter provides the reader with information about the principles and disadvantages of conventional state of the art methods applied in this field. The current imperfections of most methods offer unique opportunities for innovative nanotechnological approaches. As one recent example, atomic-force microscopy is presented as a technique for the nanoscale imaging and quantification of proteolytic activity in the pericellular microenvironment of cancer cells *in vitro*.

In general, techniques that enable real-time, high resolution imaging or precise quantification of local proteolytic activity *in vitro* and *in vivo* remain major chal-

**Fig. 11.1.** Metastasis: The formation of metastasis is a complex and highly dynamic process. It is characterized by the spreading of tumor cells through vessels (2 and 4), lymphatic ducts (3) or cavities (1) to form

new colonies away from their origin. It is undoubtedly a topic of high clinical relevance as it accounts for over 90% of all lethal outcomes in cancer.

lenges. These methods will play an important role in cancer diagnosis, the understanding of basic principles in metastasis, the identification of new therapeutical and targets and, hence drug design in the near future.

The immediate need for these methods has been demonstrated by the results from clinical protease inhibitor trials. Although extensive preclinical data supported the inhibition of protease activity as a promising strategy for cancer therapy, clinical trials with various protease inhibitors, i.e., matrix metalloproteinase-inhibitors (MMPi), did not bring the expected breakthrough in cancer treatment [4, 5] (reviewed in Refs. [6–9]). It might be too early to abandon the concept of protease inhibition in cancer therapy in general, as the design of these clinical trials must be considered. MMPi had to compete, for example, against cytotoxic drugs in late-stage cancer patients. More recent insights into protease function in cancer development and angiogenesis indicate that protease inhibition is unlikely to provide considerable patient benefits in this setting, since proteases are crucial for

**Fig. 11.2.** Cancer cell invasion. Metastasis depends essentially on the ability of cancer cells to invade intact tissue structures (2), and to overcome physiological barriers such as basement membranes upon intra- (3) and extravasation (4). In skin cancer, as depicted here, the breach of the epidermal basement membrane (1) by cancer cells is a defining step with far reaching consequences in terms

of treatment and prognosis of the patient. The upper layer of the skin is free of lymph and blood vessels. No metastasis can be found until the basement membrane has been crossed by the cancer cells. Patients can therefore be healed by total excision of the tumor and no further treatment such as chemotherapy is necessary at this stage.

establishing new metastasis and may not be necessary to maintain them. Animal studies support this position as MMPI treatment was most effective in early stages of cancer [10]. It seems therefore reasonable to initiate new trials that employ protease inhibition early in cancer treatment or in addition to established treatments like surgery and radiation.

Nonetheless, the principle drawback in the clinical application and evaluation of protease inhibitors is the significant gap in our understanding of the complex regulation mechanisms of local proteolytic activity due to methodological obstacles. In addition, there is a serious lack of reliable techniques and parameters to assess protease inhibitor effectiveness *in vivo*. None of the patient trials proved so far that the administered drug dose was sufficient to target local proteolytic activity *in situ*. Surrogate markers, such as serum gelatinase activity, have proven unreliable for tumor screening purposes and were, therefore, inappropriate for monitoring substance response. These results from clinical trials illustrate the necessity to develop

functional methods to test drug efficacy by the quantification of local proteolytic activity.

## 11.2

### Quantification of Local Proteolytic Activity – an Objective

Cancer metastasis is a complex, highly dynamic multistep process that includes:

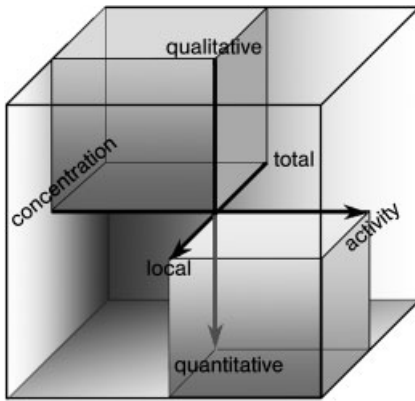

- Cell detachment from the primary tumor mass,
- migration within and intrusion into surrounding tissue structures and ECM,
- degradation of physiological barriers such as endothelial basement membranes,
- penetration into the vascular lumen (intravasation),
- distribution by the blood stream and survival in the circulation,
- adhesion to distant endothelia and extravasation.

and, finally, establishment of a colony in a new environment distant from the cancer cells origin (Figs. 11.1 and 11.2) [11] (reviewed in Refs. [12–14]). The expression of proteases and the development of proteolytic activity is a prerequisite for tumor cells to achieve these aims. Regardless of their diverse etiology, the function of proteases in tumor cell spreading constitutes a final common pathway of all invasive malignancies. In agreement, high concentrations and activities of proteases have been found more often in and around cancers than in normal, benign or pre-malignant tissues.

Most proteases are produced as inactive proenzymes that undergo proteolytic cleavage for their activation. Once activated, their activity is modified by several cellular mechanisms and biochemical factors such as protein trafficking and endogenous inhibitors. The excessive post-translational modification of protease activity is responsible for the critical difference between the concentration of proteases and their activity. This limits the application of many conventional methods, which cannot reliably distinguish between the active or inactive protease.

Proteolytic activity in cancer cell invasion is a very local phenomenon. Although a protease can be widely expressed throughout a tumor, it may, for example, only be active at the leading edge in a small subset of cells at the tumor–stroma interface. Specific mechanisms localize and concentrate protease activity in the pericellular microenvironment of cells. This spatial restriction challenges the maximum achievable resolution of common *in situ* imaging techniques and *in vitro* diagnostics. Until now, no method has proven sensitive enough to employ proteolytic activity in cancer for serum diagnostics and screening purposes.

General considerations can be applied to evaluate the quality of diagnostic tools (reviewed in Ref. [15]). For example, numerous methods and assays have been described for the investigation of enzymatic activity *in vitro* as well as *in vivo*. Despite their heterogeneity in terms of strategy and aims, they can be grouped considering aspects of their primarily targeted parameters. These are qualitative or quantitative evaluation of the local, or total, concentration or activity of one or several enzymes

**Fig. 11.3.** Evaluation parameters of assay methods. Several criteria can be applied to assess diagnostic tools such as protease assays. Most proteases are secreted as inactive proenzymes, and enzymatic activity is additionally regulated by endogenous inhibitors. Proteolytic activity is usually restricted to the pericellular microenvironment of cancer and stromal cells, and may only be present in a small fraction of a sample. Assays detecting protease concentrations (top left-hand side box, at the back) give, therefore, only indirect clues to functionally relevant local proteolytic activity (bottom right-hand side box, at the front). Usually, several complementary methods have to be employed

in combination to understand results in the context of proteolytic orchestration. As an example, western blot analysis of cell lysates can determine the overall concentration of a single protease at a time, but is usually not capable of determining the active fraction of this enzyme. The presence of a broad variety of proteases and inhibitors, in the same spot or separate compartments, gives rise to a complex interplay that cannot be assessed by this method. *In situ* zymography is able to localize proteolytic activity, but it must be considered that the activity observed with a specific substrate may not be of particular functional relevance for the investigated microenvironment.

(Fig. 11.3). The usefulness of an assay depends as much on its sensitivity and specificity as it does on its compatibility for a particular question and application. In most cases, a combination of complementary techniques is required to get an oversight of the functional relevance of a result.

As an example, the most valuable functional information is usually derived from the quantitative evaluation of local enzymatic activity (lower, right-hand box in Fig. 11.3); it is also important to get additional information about the spatial distribution and overall concentration, i.e., of a protease in a specimen (upper, left-hand box in Fig. 11.3). The functional context is derived from the knowledge of the quantitative relationship between concentration and activity and the total to local ratio. Hence, the aim must be to develop dynamic high-resolution imaging techniques or methods that enable precise quantification of local activities *in vivo*.

Investigation of the function of proteases and their utilization for diagnostic purposes in cancer faces two major obstacles – post-translational regulation and spatial restriction.

## 11.2.1

**Regulation of Protease Activity**

Protease activity is tightly regulated at the:

- transcriptional,
- translational and
- post-translational level.

The transcription of MMPs (matrix metalloproteinases) can, for example, be up- or down-regulated by various stimuli such as extracellular matrix proteins, phorbol esters and cell stress [16–19] (reviewed in Refs. [20, 21]). It has been demonstrated for MMP-9 that expression can be increased post-transcriptionally through an enhancement of translational efficiency [22].

Most methodological problems are related to the post-translational regulation of proteases, due to the crucial difference between *concentration* and *activity* (Fig. 11.3).

The activity of proteases is post-translationally regulated by diverse, principle mechanisms:

- Secretion
- activation
- inactivation
- endogenous protease inhibitors
- glycosylation
- oligomerization and
- protein trafficking.

11.2.1.1 **Secretion**

Secretion of most proteases seems to be constitutive, which means that they are secreted once they were synthesized. Strong indicators suggest that, at least in inflammatory cells, MMPs can be stored in vesicles and secreted upon stimulation [23]. Although described for cancer cells, aspects of the regulation of this rapid response to environmental stimuli remain vague [24].

11.2.1.2 **Activation**

As most proteases are secreted as latent enzymes, their activation becomes a critical control point. Extracellular activation of proteases can be initiated by other already active proteolytic enzymes. This is usually obtained by the removal of a peptide that helps to maintain latency. For instance, MMPs are activated by a mechanism generally known as the “cysteine switch” [25, 26]. This model suggests that a cysteine coordinates the active-site zinc atom in the latent enzyme. All identified modes of MMP activation lead to a dissociation of this cysteine residue, which is accompanied by exposure of the active site.

Few proteases – among them MMP-11, MMP-13, and MT-MMPs (membrane type-MMPs) – are activated intracellularly, which makes these proteases important

pacemakers of proteolytic cascades by subsequent activation of other proteases [27–30]. The molecular basis of this intracellular activation is the presence of a specific motif between the propeptide and catalytic domain of these proteases that is recognized by proprotein convertases that process secretory precursor proteins in the trans-Golgi network.

### 11.2.1.3 Inactivation

Proteases can be inactivated by proteolysis, protease inhibitors and removal from the extracellular space or plasma membrane. Although similar in principle, the proteolytic processing of proteases leading to their inactivation is far less understood than the proteolytic processing leading to their activation.

In addition to their irreversible inactivation, limited proteolysis of MMPs can also modify their distribution, substrate specificity and ability to be inhibited. Cleavage of a sequence close to the transmembrane domain of MT-MMPs can generate, for example, soluble subspecies of these proteases [31–34]. Although these shed proteases are catalytically active and may now act as soluble proteases, they have lost most of their invasion promoting activity and effects on cell function [35, 36]. Obviously, protease action must occur in the immediate cellular surrounding to contribute significantly to the regulation of the pericellular microenvironment.

MT-1MMP cannot only undergo autocatalytic shedding. Overexpression can lead, furthermore, to an autocatalytic inactivation that results in a truncated membrane-bound remnant that has lost its catalytic domain [31, 37, 38]. Autocatalytic inactivation could serve as a self-limiting mechanism to down-regulate excessive proteolytic activity. The proteolytic processing of many proteases varies, depending on the prevalence of the activity of other proteases.

Summarizing, the presence and interaction of many different representatives of proteases from distinct families, that have

1. different substrate affinities, concentrations and actual states of activity, that are
2. in addition capable of rapidly activating and inactivating themselves and each other and
3. coexist in a tiny space of only several  $\text{nm}^3$  with
4. a no less complex and dynamic mixture of substrates (Fig. 11.7 below)

leads to a complex and fragile balanced composite that determines the functional relevant net proteolytic activity for this micro-compartment.

### 11.2.1.4 Endogenous Protease Inhibitors

Protease activity is modified on the post-translational level by various endogenous inhibitors. For example, the activity of MMPs is tightly regulated by tissue inhibitors of metalloproteases (TIMPs). To date, four structurally related TIMPs have been identified. The upregulation of TIMPs has been shown to attenuate the invasive behavior of several tumors, whereas reduction in TIMP-levels by means of antisense RNA can confer tumorigenicity to non-invasive cells [39].

TIMPs are clearly multifunctional proteins [40, 41]. TIMP-1 was isolated from fibroblasts and initially characterized to inhibit collagenase activity [42]. Soon after its discovery, TIMP-1 turned out to be identical to a known growth factor that was described to have erythroid-potentiating activity in previous studies [43]. Besides their MMP-inhibiting properties and erythroid-stimulating activity, other growth promoting activities of TIMPs have been reported [44].

Paradoxically, the presence of endogenous protease inhibitors can be of significant importance for the activation of some proteases. TIMP-2 was shown to be required for efficient proMMP-2 activation by MT1-MMP both *in vivo* and *in vitro* [37, 45, 46].

Besides being inhibited by TIMPs, MMP activity is regulated by the recently identified membrane-bound MMP-inhibitor RECK (reversion-inducing cysteine-rich protein with Kazal motifs) and other abundant inhibitors such as  $\alpha_2$ -macroglobulin [47].

#### 11.2.1.5 Glycosylation

Glycosylation has recently been discovered as an alternative way of protease activity regulation. Data provide evidence that the glycosylation of proteases may regulate their substrate targeting. In MT-1MMP, O-glycosylation seems to determine whether the protease can degrade ECM and activate MMP-2 or can only cleave ECM components [48]. This might have drastic consequences on local proteolytic activity, as MT-1MMP is considered to be one of the key activators of proteolytic cascades.

Technically, this aspect has far reaching consequences. It limits the use of simple indicator probes of proteolytic activity, as subtle but functionally crucial differences in specificity of a protease can easily be overseen.

Glycosylation is not only relevant for the “fine tuning” of proteases. Moreover, it is important for the suppression of tumor cell invasion that is mediated by the membrane-bound inhibitor RECK [49]. N-Glycosylation of RECK acts through multiple mechanisms such as suppressing MMP-9 secretion and inhibiting MMP-2 activation, which appear to be regulated independently by the glycosylation at different sites [49].

#### 11.2.1.6 Oligomerization

Multimeric complexes of membrane-bound proteases facilitate their autocatalytic processing and the activation of other proteases. The homo-oligomerization of MT1-MMP is stimulated by at least three of its domains and takes part in the regulation of its activity and turnover [50–52]. The formation of homo-oligomers of MT1-MMP turns out to be of particular relevance for the activation of proMMP-2 [50–52]. It has been hypothesized that other regulatory proteins may be involved in this by facilitating protease clustering [53].

These findings reveal that the oligomerization of proteases further determines the “functional activity” that a protease can unfold in a given context and demonstrate that the nanoscale surrounding of a single protease can determine its actual function.

### 11.2.1.7 Protein Trafficking

The internalization of membrane-bound proteases provides cells with an effective way to regulate the proteolytic activity on their surface. Most studies regarding this mechanism have been carried out for MT1-MMP. Endocytosis of this prominent protease can be mediated by at least two distinct pathways – clathrin-coated pits and caveolae [54–57]. Caveolae are not only involved in the internalization of MT1-MMP in cancer cells, but are an issue in the regulation of MT1-MMP in endothelial cells as well [55].

The rapid internalization of MT1-MMP via clathrin-coated pits is dynamin mediated and depends on the cytoplasmic tail of the protease [51, 54, 58–60]. Once internalized, MT1-MMP can be recycled to the surface [54, 61]. The rapid trafficking of MT1-MMP has the potential to regulate MMP-2 activation and thus represents an extra path of proteolytic cascade initiation [24]. Interestingly, internalization and dynamic turnover of proteases are necessary to maintain their proper function [62].

Besides internalization, trafficking deep within the cancer cells can participate in the regulation of events on the cell surface. For instance, internalized MT1-MMP can be transported to CD63-positive lysosomes for its degradation [63]. The tetraspanin CD63, a well investigated resident of late endosomal and lysosomal membranes, promotes thereby the internalization, lysosomal targeting and proteolysis of the protease [63].

Despite proliferating knowledge about the trafficking of proteases, it is still ill-defined as to how it affects local proteolytic activity quantitatively. It is, for example, still not known whether specific sub-fractions of proteases, which means active, inactivated or inhibitor complexed proteases, are internalized and how this might be regulated. Conceivably, the internalization route might differ for these subtypes of a protease and could ultimately determine whether a protease is degraded or recycled.

One reason for this gap in our current understanding has been the already mentioned, namely, inherent problems in the nanoscale quantification of complex local processes – here proteolytic activity.

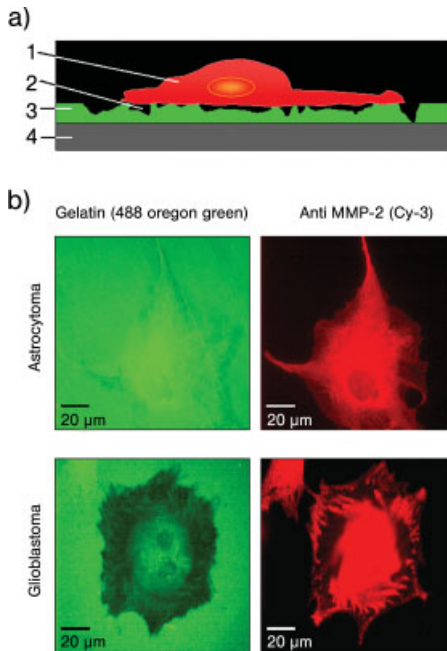

## 11.2.2

### Mechanisms of Confining Proteolytic Activity

An important concept of tumor cell invasion is that cells do not indiscriminately release proteases (Fig. 11.4). Several specific mechanisms that confine and concentrate protease activity in the pericellular microenvironment and cellular sub-domains of tumor cells have been identified (reviewed in Refs. [15, 20, 51, 64–69]).

These mechanisms are prerequisites of tumor cell invasion and key factors in the regulation of tumor microecology and consist of

- Expression of membrane anchored proteases;
- the binding of soluble proteases by membrane-bound receptors;
- local activation of soluble proteases by membrane-associated activators;

**Fig. 11.4.** Detection of local proteolytic activity by fluorescence-labeled gelatin. In cancer cells, proteolytic activity is a locally restricted phenomenon. It can be detected and visualized by surface-bound indicator substrates. (a) Tumor cells (1) were seeded on coverslips (4) coated with fluorescence-labeled gelatin (3). Proteolytic matrix cleavage (2) causes focal loss of fluorescence. (b) Glioblastoma and astrocytoma cells from primary cultures were fixed 48 h after seeding them on fluorescence-labeled gelatin (green). Dark spots in the gelatin coating reflect areas of proteolytic activity. Cells were labeled by indirect immunofluorescence for MMP-2 using Cy3-conjugated secondary antibodies (red).

- the presence of cell surface receptors for protease activating enzymes;
- the regulated localization of receptors and proteases to distinct subcellular domains (i.e., invadopodia);
- specific binding of latent proteases by ECM components;
- induction of proteases expression at the tumor–stroma interface.

#### 11.2.2.1 Membrane-type Matrix Metalloproteinases

The most obvious mediators of cell surface bound proteolytic activity are undoubtedly the transmembrane- and GPI-anchored membrane type (MT) matrix metalloproteinases (MMPs). The first MT-MMP (MT1-MMP) was discovered by Hiroshi Sato and colleagues in 1994, and was thought to act primarily as a membrane-bound activator of the gelatinase MMP-2 [70]. Besides its crucial role in activation of soluble proteases, MT1-MMP itself is now credited for its important contribu-

tion to ECM macromolecule cleavage and its broad-spectrum proteolytic capacities [71].

To date, six MT-MMPs have been identified that are linked to the plasma membrane by a transmembrane domain or a glycosylphosphatidyl inositol (GPI) anchor. The importance of localized proteolytic activity is demonstrated by the observation that expression of either wild-type MT1- or MT2-MMP confers invasiveness to COS-1 cells, whereas the expression of truncated, soluble forms of these transmembrane domain proteases has no invasion promoting effect [36]. Expression of MT1-MMP in cancer cells amplifies their metastatic potential, and constitutively expressing cell lines are generally more invasive than non-expressing cell lines [51, 72, 73].

Besides the pivotal role of MT1-MMP in tumor cell invasion, expression of this protease appears to be of critical importance for a diversity of physiological functions. It is, for example, crucial for the fibrin-invasive activity of endothelial cells during angiogenesis and wound healing [74, 75]. MT1-MMP deficient mice present the most severe phenotype observed in MMP deficient mice so far. Although these mice are born with no grossly abnormal features, the loss of MT1-MMP interferes with normal postnatal development. MT1-MMP deficient mice develop various bone and joint disorders, like dwarfism, osteopenia and arthritis, which suggest a severe impairment of the remodeling of collagen-rich tissues [69, 76].

#### 11.2.2.2 Cell Surface Receptors for Protease Binding

Non-MT-MMPs are bound to the membrane or localized to invadopodia by specific interactions with integrins or other cell surface receptors. For example, MMP-2 is bound by the  $\alpha_v\beta_3$  integrin [77], and CD44 mediates docking of MMP-9 to the plasma membrane [78]. Impressively, CD147 (extracellular matrix metalloproteinase inducer, EMMPRIN) is capable of both induction of MMP expression in stromal cells and subsequent binding of these proteases [79, 80].

Besides MMPs, accumulating evidence indicates the responsibility of serine proteases for the metastatic phenotype of many tumors. The urokinase-type plasminogen activator (uPA) drives the plasmin cascade system, and its expression is elevated in glioblastomas and correlates with malignant progression of astrocytomas [81]. The uPA receptor (uPAR) can tie uPA to the surface of tumor cells. Results indicate that only cell-bound, not soluble, uPA can effectively generate plasmin for the activation of gelatinases (MMP-2 and MMP-9) [82].

#### 11.2.2.3 ECM Binding of Proteases

Physiologically, binding of MMPs to ECM components can prevent loss of the secreted enzyme via diffusion, provide a reservoir of latent enzyme at the target site for rapid activation and might facilitate cellular regulation of local proteolytic activity. Several specific interactions of latent MMPs and ECM proteins on cells or in the extracellular space have been described. For example, heparan sulfate proteoglycans, common components of the ECM, can bind proMMP-7 [83], and

proMMP-9 can form a complex with  $\alpha 1$  and  $\alpha 2$  chains of collagen IV on cells [84, 85].

#### 11.2.2.4 Cellular Microdomains

During cancer cell invasion, membrane-bound proteases are not randomly distributed on the cell's surface. Cancer cells can accumulate proteases in specialized regions such as the leading edge or invadopodia – a term derived from “invasive pseudopodia”. These subcellular domains have proven to be “hotspots” of ECM degradation during cancer cell invasion.

MT1-MMP is concentrated at the lamellipodium through interaction with CD44, which links the protease, furthermore, directly to F-actin [86]. CD44 also recruits MMP-9 to this subcellular localization [87]. At invadopodia, particularly MMP-2, MMP-9 and MT1-MMP can be found. The clustering of active MMP-2 at invadopodia is directly mediated by the  $\alpha_v\beta_3$  integrin [88]. The cytoplasmic tail of MT1-MMP has been identified to regulate its docking to invadopodia and has been suggested to be a prerequisite for the subsequent focal ECM degradation by this protease [89].

Lipid rafts have been discussed in connection with the organization of membrane proteases in cellular microdomains. Interestingly, the aberrant and persistent inclusion into caveolin-enriched lipid rafts limits the tumorigenic function of MT1-MMP in malignant cells [90]. Although cell membranes are certainly not homogeneous mixtures of lipids and proteins, almost all aspects of lipid rafts – their size, composition and turnover – remain controversial (reviewed in Ref. [91]). Despite this, there is a broad consent about their overall biological relevance (reviewed in Ref. [92]). Most aspects of the dispute around the concept of these cellular microdomains are clearly size and resolution related methodical difficulties. Nanotechniques like AFM (atomic-force microscopy) have proven useful for the investigation of lipid rafts in artificial lipid bilayers *in vitro*, but direct investigation in cells is far more difficult [93].

One important function of microdomains in cancer cell invasion could be the partitioning of proteases into distinct cellular localizations, which then serve as platforms for the regulation of local proteolytic activity via protein oligomerization and trafficking. The restriction of proteolytic activity to small subcellular regions can increase the effectiveness and economy of local ECM degradation, but further complicates the detection of these activities.

#### 11.2.2.5 The Tumor–Host Conspiracy

The local host tissue is a constant and active participant during tumor development and metastasis. The extracellular matrix and stromal cells form a complex microenvironment that can limit or even unwillingly facilitate tumor cell invasion (reviewed in Ref. [94]). A striking example of tumor–stroma cooperation is the contribution of matrix-degrading enzymes by the host itself. For example, MMP-11 (stromelysin-3) was discovered in stromal cells of breast carcinomas [95], before its production by tumor cells was described. Most interesting findings originate from studies in MMP knockout mice (Section 11.2.3.3).

Cancer cells can harbor the ability to induce the production of proteases in stromal cells by factors such as EMMPRIN [79, 80, 96]. In agreement with this, expression levels of matrix degrading enzymes are usually strongly elevated at the invasive front of the tumor–stroma interface [97].

### 11.2.3

#### **Local Proteolytic Activity Regulates Complex Cellular Functions**

Proteolytic cleavage of extracellular matrix (ECM) is a potent regulator of many physiological and pathological events [20, 65, 98–100]. It affects fundamental processes such as cell growth, differentiation, apoptosis, and migration. The mechanisms that localize and concentrate protease activity in the pericellular micro-environment of cells are prerequisites for processes like angiogenesis, bone development and inflammation. The role of local proteolytic activity in tumor cell invasion and all these other processes is not restricted to the function of breaking down the ECM by means of a path clearing process [101].

##### **11.2.3.1 Local Proteolytic Activity in Cancer Cell Migration**

To overcome barriers, cells must be able to move actively to their new location. Several direct and indirect effects of proteolytic activity on tumor cell migration can be observed. The ability of cells to migrate on Laminin-5 is positively correlated with the expression of plasma membrane bound MT1-MMP [102]. The same MMP confers the ability to migrate on myelin substrates to transfected 3T3 fibroblasts [103]. Other results indicate that MT1-MMP plays an important role in glioma cell spreading and migration on white matter [103]. For cancer cell migration in 2D systems, there is virtually no need to cleave the ECM as a barrier. Despite this, a synthetic MMP-inhibitor, tissue inhibitor of metalloproteinases-1 and -2, and the COOH-terminal hemopexin-like domain of MMP-2 inhibit the migration of adenocarcinoma cells on gelatin matrix-coated coverslips [104].

The specific extinction of proteins by small interfering RNAs (siRNAs) has been utilized to target the expression of MMP-9 in a Ewing's sarcoma cell line, constitutively expressing this protein [105]. Silencing of MMP-9 resulted in a migratory-adhesive switch, marked by decreased spreading on extracellular matrix coatings and inhibition of migration towards fibronectin [105]. As migratory behavior was unchanged by gelatinase inhibitors, the authors conclude that the migration-promoting activity of proMMP-9 may be independent of its proteolytic activity [105].

##### **11.2.3.2 Local Proteolytic Activity and Cell Signaling**

It has been suggested that all cancers acquire the same capabilities during their development [1]. These include

- limitless replicative potential,
- sustained angiogenesis,
- tissue invasion and metastasis,

- insensitivity to growth inhibiting signals,
- self-sufficiency in growth signals, and
- the ability to evade apoptosis-inducing signals.

All of these aspects seem to be affected by local proteolytic activity, if not entirely dependent upon it, as local proteolysis during tumor cell invasion is not restricted to cleavage of ECM components [20, 65]. Several other molecules have been identified as important targets of tumor cell associated proteases. Among these are chemokines and their receptors, adhesion molecules, clotting factors and protease inhibitors. For example, the association of MMP-7 with CD44v3 regulates heparin-binding epidermal growth factor (HB-EGF) precursor processing [106]. Subsequent HB-EGF binding to its receptor (ErbB4) might regulate other cellular events, such as cell survival [106]. Fas ligand cleavage by the same protease [107] also has a significant effect on tumor cell survival and is implied in protecting tumor cells from chemotherapeutic drug cytotoxicity [108]. Furthermore, most of the ADAM (a disintegrin and metalloproteinase) family of metalloproteinases are membrane bound and involved in cleavage of diverse surface associated molecules, such as TNF- $\alpha$  [109–111].

#### 11.2.3.3 Functional Insights from Matrix-metalloprotease Deficient Mice

Mice, deficient for single MMPs, helped to shed light on functions of these proteases in physiology and disease. The putative central physiological role of several MMPs *in vivo*, which was deduced from their involvement in pathological processes and their abundance during development, proved to be wrong. Many knockout mice, which are the MMP-2 [112], MMP-3 [113], MMP-7 [114], MMP-9 [115], MMP-11 [116], MMP-12 [117] and MMP-20 [118] deficient mice, display no dramatic phenotype (reviewed in Ref. [69]). It must be considered that MMPs have broadly overlapping substrate specificities. Hence, the lack of dramatic phenotypes in these mice probably demonstrates the redundancy of vital mechanisms, rather than their uniqueness.

Obviously, only a few MMPs are indispensable. Given the importance of MT-MMPs for local proteolytic activity and their potential role as triggers of proteolytic cascades, unsurprisingly, MT1-MMP deficient mice bring along the most severe phenotype observed in MMP deficient mice so far. Although these mice are born with no grossly abnormal features, the loss of MT1-MMP is obviously incompatible with normal postnatal development. These mice develop various bone and joint disorders, like dwarfism, osteopenia and arthritis [69, 76].

Despite the absence of lethal phenotypes, mouse models uncovered specific physiological functions of single MMPs. For example, MMP-20 (enamelysin) null mice develop a profound tooth phenotype [118]. MMP-20 is a tooth-specific protease that is only expressed during the early through middle stages of enamel development [118]. Its substrates are enamel specific matrix proteins that are also expressed during this developmental time period [118].

Although MMP deficient mice might not be considered a major breakthrough for proving the overall importance of all MMPs in development, they made a major

contribution to the understanding of host-derived MMPs for tumor cell invasion and metastasis.

MMP-2 and MMP-9 deficient mice develop normally, but in these mice the number of metastatic colonies formed by intravenously injected B16-BL6 melanoma or Lewis lung carcinoma cells is dramatically decreased [112, 119, 120]. MMP-9 knockout mice show a decreased incidence of invasive tumors, but bone marrow transplantation reconstitutes many properties of carcinogenesis in these mice [121].

Mice heterozygous for the ApcMin allele (Min/+) are susceptible to benign intestinal tumors [114]. In this mouse model, MMP-7 ablation by gene targeting and homologous recombination resulted in a reduction of tumor frequency and diameter [114]. Similarly, anthracene derivative induced tumorigenesis is reduced in MMP-11 (stromelysin-3) null mice, and fibroblasts from these mice fail to support metastasis formation by breast cancer cells (MCF-7) upon co-implantation in a nude mice model [116]. Macrophages secrete a selection of proteases, but macrophages lacking MMP-12 (macrophage metalloelastase) from the corresponding null mice are unable to penetrate reconstituted basement membranes *in vitro* and *in vivo* [117].

### 11.3

#### Evaluation of Classical Methods for Quantification of Net Proteolytic Activity

Classic biochemical methods can be employed to investigate the expression of enzymes and their inhibitors on the transcriptional and translational level. Enzyme expression can be quantified in cell and tissue extracts by real-time reverse transcription-polymerase chain reaction (RT-PCR) and northern blot analysis, whereas *in situ* hybridization is useful to localize mRNA expression in tissue sections. ELISA, Western blot, immunocyto- and histochemistry are useful to evaluate the concentration or distribution of any given protein, but it is not possible to deduce enzymatic activity from its mere concentration in a tissue section or extract (Fig. 11.3) (reviewed in Ref. [15]).

As previously stated, most proteases, such as MMPs, are produced as inactive proenzymes and their activity is additionally regulated by natural inhibitors [21]. Most antibodies for immunohistochemistry cannot distinguish between the activated, inactivated or pro-form of a protease [122]. In general, antibodies recognize structural epitopes, not function.

Thus, RT-PCR, *in situ* hybridization and immunological methods may be suitable to localize or quantify the expression and production of proteases and their inhibitors, but do not indicate the resulting matrix degrading activity.

Various chromogenic, fluorogenic and radioactive assays have been developed to detect and quantify protease activity in tissue extracts [123–125]. Additionally, antibodies can recognize neo-epitopes, e.g., on collagens or aggrecan, that are generated by their proteolytic cleavage. Several ELISA assays exploit the formation of these specific neo-epitopes as an indicator for proteolytic activity (“substrate cleav-

age ELISAs”) [126, 127]. The biological function of cryptic fragments and neo-epitopes has been reviewed elsewhere [128, 129].

Gel enzymography – also referred as substrate zymography – [130] and reverse enzymography [42] offer a way to analyze the activities of MMPs and TIMPs in complex biological samples. Enzymography can detect both the proenzyme and the active MMP. In short, zymography involves gel SDS electrophoresis of samples under nonreducing conditions. Protease substrates such as gelatin or casein are incorporated in the gel and retained during electrophoresis. After SDS is removed from the gel by washing, MMPs refold, regain their activity and digest the substrate incorporated in the gel. By staining the gel, usually with Coomassie Blue, proteolytic activity is evident as an unstained band at the corresponding weight of the protease.

One advantage of gel enzymography is the activation of proenzymes after electrophoresis, which enables convenient quantification of the ratio of pro-MMPs to overall activated MMPs. It is, however, impossible to assess net MMP activity *in situ* with this technique, as MMP-TIMP complexes are separated upon electrophoresis.

As a modification of zymography, reverse zymography was developed to detect protease inhibitors such as TIMPs [42]. After electrophoresis and washing, the gel is either incubated in conditioned media, containing soluble proteases, or proteases were added to the gel before polymerization. The activity of protease inhibitors is visualized by Coomassie Blue staining. The result is a dark band, consisting of partially undegraded substrate protected from proteolysis in the presence of the inhibitor.

Summarizing, the above assays can determine net MMP activity, but there are numerous limitations regarding the quantification of the endogenous and local balance of specific matrix degrading activity and inhibition *in situ*. Most assays cannot distinguish between different enzymes, as most ECM-cleaving proteases have broadly overlapping substrates. Preparation of sample extracts precludes, furthermore, the localization of enzyme activity and real-time quantification. Also, tissue homogenization leads to artificial interactions of inhibitors and proteases that were located within different compartments in tissues and cells. Functionally important, high local proteolytic activity that is only present in a small proportion of a tissue section (i.e., tumor–stroma interface) might be underestimated or not be recognized after dilution in the entire tissue extract upon homogenization (Fig. 11.3, total versus local activity).

### 11.3.1

#### **Functional Detection of Local Proteolytic Activity by *In Situ* Zymography**

*In situ* zymography (ISZ) overcomes some of the limitations of conventional zymography and other biochemical assays. It enables both localization and estimation of net MMP activity in tissue sections, and preserves sample histology.

The method has undergone innumerable modifications and adaptations, but the basic principle remains unchanged. In short, ISZ can be seen as an adaptation of zymography to frozen tissue sections. Sections are placed on a surface coated with a protease substrate (e.g. gelatin on microscope slides). After incubation and washing, uncleaved substrate is detected by protein staining of the coating. Proteolytic activity results in unstained spots. The most commonly used techniques today are either photographic emulsion-based or fluorescence-labeled substrate-based ISZ [122, 125]. Photographic emulsion ISZ utilizes the effect of gelatin to release a thiol group containing propeptide upon cleavage. This thiol group induces a structural change in colloidal silver, which results in a change of color. In fluorescence-labeled substrate-based ISZ, thin coatings of fluorescence-labeled substrates indicate proteolytic activity by local loss of fluorescence after proteolytic cleavage.

ISZ has almost exclusively been used for the localization of MMP activities, especially the gelatinases (MMP-2 and MMP-9), although it can be adjusted to virtually any protease group. Most studies that employ ISZ used complementary techniques to provide accurate insights into the function of a specific protease. Several of these studies confirmed that proteolytic activity was not restricted to the tumor cells, but could also be found in the stroma surrounding the tumor [131, 132], stressing once more the regulatory function of tumor–host interaction for invasion and metastasis.

Although ISZ and related techniques can localize even subtle increases of proteolytic activity and enable one to assess the balance between activated proteases and inhibitors, only three to four levels of proteolytic activity can be classified for quantification purposes [131, 133]. It can be concluded that ISZ is a semi-quantitative method for the detection of local proteolytic activity and acts as a complement to, but does not replace, gel zymography and other biochemical assay methods (Fig. 11.3). However, the major disadvantage of ISZ is the restriction of its application to excised specimen after invasive procedures, which greatly limits its application for any screening purpose or early diagnosis of cancer.

### 11.3.2

#### **Tumor Cell Invasion Assays**

The ability of cancer cells to invade the surrounding stromal microenvironment and breach formerly restrictive basement membrane boundaries is a defining step in tumor progression and a hallmark in the development of the metastatic phenotype (reviewed in Ref. [1]). Invasion is a complex, multifactorial event, that requires directed migration and proteolytic activity to degrade extracellular matrix barriers (reviewed in Refs. [134–136]). Diverse *in vitro* assays have been developed to simulate *in vivo* conditions and understand key regulators of this process. Most experimental setups are variations of a modified Boyden chamber assay, introduced in 1987 by Albini and colleagues [137]. The original assay, published by Boyden 1962 for the analysis of leukocyte chemotaxis, is based on a chamber of two medium-filled compartments, separated by a microfilter membrane [138]. In general, cells

migrate from the upper medium compartment through the pores of the filter membrane to the lower medium compartment, which contains chemotactic agents. At the end of the assay the number of cells that have migrated to the lower side of the membrane is determined by fixation and staining of the membrane.

For tumor cell invasion assays, the filter membrane is coated with an ECM preparation – most commonly matrigel – to resemble the basement membrane. NIH 3T3 conditioned media or FCS is usually used as a chemoattractant to stimulate directed migration [139–141].

In all these assays, invasion is not only dependent on local proteolytic activity, but also on matrix composition [142, 143], the ability of the cells to adhere and detach from this matrix [144–146], and the resulting and intrinsic ability of these cells to migrate [147] (reviewed in Refs. [135, 148, 149]).

#### 11.3.2.1 Electrical Resistance Breakdown Assay

In addition to protease substrate based assay systems, local proteolytic activity can be quantified by an innovative, electrophysiological and indicator cell based assay. The electrical resistance breakdown assay offers a complex but stable cell based model system for the dynamic quantification of tumor cell-associated local proteolytic activity, cancer cell invasiveness and the investigation of basic mechanisms in this process. The system can be used for large and even heterogeneous tumor cell populations from primary tumor cultures and cell lines.

Setups, application and the theoretical background of this assay have been described elsewhere in detail [150–155].

### 11.3.3

#### ***In vivo* Detection of Proteolytic Activity**

The early detection of small primary tumors is still the most promising method to improve cancer survival rates and represents the working basis for extensive screening programs of common tumors. Several high-affinity substances targeted against tumor associated markers or angiogenesis have been used to detect solid tumors in animal models and clinical trials. The targeting of tumors by functional imaging with sufficient sensitivity and specificity is a diagnostic challenge. The limiting factor is the tumor-to-background ratio, which results from the lack of specific processes exclusively found in tumors.

There has been a major drive to design biocompatible probes for *in vivo* detection and imaging of cancer cells. The rationale of this approach is based on the specific binding of easily detectable molecules to proteins that are predominantly expressed by tumor cells.

The development of protease activated near-infrared fluorescent (NIRF) probes has been a huge step towards the functional imaging of tumors. The increased and localized proteolytic activity in invading cancer cells is exploited by these small, synthetic substrates. Optically quenched NIRF probes generate a strong NIRF signal after enzymatic cleavage, and have proved capable of detecting and imaging differential protease expression in nude mice *in vivo*. For example, protease

specific NIRF probes were designed to be either activated by cathepsin-B [156] or cathepsin-D [157]. Tissue studies of breast cancer patients link aggressive tumor behavior and high expression levels of these proteases [158, 159].

In principle, NIRF probes seem to have the potential to evolve to a functional method for protease activity monitoring in clinical applications and MMPI trials. The feasibility of this approach has already been demonstrated by direct imaging of MMP-2 activity in response to an MMPI (prinomastat) in a nude mice model [160].

Despite the achievements of NIRF probes in detecting proteolytic activity, small synthetic substrates do not resemble complex protease–ECM interactions. The cleavage of a synthetic substrate by a single protease or protease group does not imply functional relevance of this activity for the heterogeneous ECM micromilieu that surrounds a tumor cell. At present, it is not possible with this technique to relate the detected proteolytic activity to the net ability of living tumor cells to digest specific, local ECM compositions (Fig. 11.7 below) *in situ*.

#### 11.3.4

#### Multiphoton Microscopy and Second-harmonic Generation

Multiphoton microscopy (MPM) has become a preferred fluorescence imaging technique for *in vivo* studies, due to its ability to image processes deep within living tissues and its extremely low out of focal plane excitation. In standard fluorescence microscopy, a single photon causes excitation of a fluorescent dye. Multiphoton microscopy (MPM) is based on the simultaneous absorption of multiple low energy photons to evoke an electronic transition that is equivalent to the absorption of one single high-energy photon. For example, the simultaneous absorption of two red photons (two-photon excited fluorescence) can cause an excitation that is usually caused by a single photon in the range of UV-light. Multiphoton excitation occurs only at the beam focus.

Without using dyes, intrinsic signals of molecules can be utilized for coherent nonlinear photon microscopic techniques, such as second-harmonic generation (SHG) imaging microscopy. Processes like SHG are based on photon scattering rather than photon absorption. With SHG, the first order hyperpolarizability of a sample enables two incident photons of a given wavelength to scatter coherently and produce a photon of half the wavelength (twice the energy). In fluorescence microscopy a proportion of the excitation energy is lost during relaxation of the excited state. Other than this, SHG involves neither excitation of molecules nor absorption of energy. Hence, it shows no photobleaching and theoretically no phototoxicity. SHG does not need exogenous dyes, but is confined to sources that lack a center of symmetry. Higher-ordered structures in biological specimen such as myosin, collagen, and microtubules fulfill this requirement.

MPM and SHG are noninvasive techniques that can be used to image cancer cell induced ECM remodeling, as they permit three-dimensional (3D) reconstruction and investigation of tissues [161], ECM morphology [162], cell metabolism [163] and tumors [164] *in vivo*.

The full theory of SHG and multiphoton microscopy and their application in biological systems are beyond the scope of this chapter, but have been thoroughly reviewed elsewhere [163, 165–169].

### 11.3.5

#### ***In vitro* Detection of Local Proteolytic Activity by Labeled Substrates**

Although detection of proteolytic activity on the subcellular level is not feasible by *in situ* zymography, the thin fluorescence labeled substrate coatings can be utilized to detect and image local proteolytic activity in the microenvironment of cells under tissue culture conditions (Fig. 11.4). The method was developed to detect focal, proteolytic ECM degradation below cells [170], and facilitated functional investigation of the regulation of proteolytic activity at invadopodia. It was used, for example, to demonstrate that invadopodial docking of MT-MMP1 is dependent on its transmembrane and cytoplasmic domain [89]. Overexpression of MT-MMP1 without invadopodial localization failed in these experiments to initiate ECM degradation [89]. A similar experimental setup proved the ability of integrins to direct proteases to sites of invasion, which gave further insights in the connection between integrins, adhesion and proteolysis [171]. Furthermore, fluorescence labeled protease substrates were used to localize local matrix degradation in the microenvironment of melanoma cells in a combined setup of fluorescence microscopy and atomic-force microscopy [172].

Instead of detecting proteolysis by loss of fluorescence, intramolecularly quenched substrates can be used. Cleavage causes an increase of fluorescence emission in these substrates. Results from functional imaging of proteolytic activity in living cells with quenched substrates supported the previously suggested functional importance of intracellular protease activity for matrix degradation [173]. Studies with DQ-collagen IV confirmed that proteolysis of ECM proteins occurs, for example, intracellularly in glioma [174] and breast cancer cells [175]. In addition to the described applications, “quenched substrates” offer crucial advantages for imaging of proteolytic activity within 3D matrix systems [176].

### 11.4

#### **Novel Approaches to Local Proteolytic Activity**

Atomic-force microscopy offers an interesting and novel approach for high-resolution imaging and nanoscale quantification of local proteolytic activity in the microenvironment of live cancer cells [172]. By moving a fine tip across the sample, the AFM detects height changes and produces a 3D image of surface topography (Fig. 11.5). The atomic-force microscope (AFM) was developed by Binnig and coworkers [177], and evolved from the scanning tunneling microscope (STM) [178].

The possibility of scanning native biological samples (i.e., live cells) under physiological conditions – that means in most cases in liquid at 37 °C – opened up a

**Fig. 11.5.** Schematic setup for atomic-force microscopy. AFM utilizes the deflection of a thin silicon nitride spring with a fine probe at its end to reconstruct a 3D topographical map of sample surfaces (here native rat tail tendon in fluid). A laser beam is focused at the end of the triangular spring. Deflection of the spring is registered by a photo detector (hair cross on left-hand side). A feedback loop couples the

photo detector to a piezo tube at the other end of the silicon spring (not shown). The corresponding height is calculated from the physical constants of the piezo-crystal and the voltage that must be applied to it to bring the laser beam back into the center of the photo detector. The AFM tip is moved line wise (horizontal arrow) across the sample to collect  $x$ ,  $y$  and  $z$  data.

whole new perspective for biological, medical and biomaterial research. STM was the first instrument to generate real-space images of surfaces with atomic resolution, but was initially unable to image in fluids or scan non-conducting biological samples [179].

Since that time, AFM has become a rapidly emerging technique in biomedical research (e.g. Fig. 11.6). A wide range of biological samples have been successfully studied under native conditions with the AFM, ranging from proteins incorporated in artificial [180] and native lipid bilayers [181], to whole cells, their mechanical properties, subcellular structures and dynamic changes [151, 182–185].

Nanoscale images of, and structural insights into, the ECM have been obtained by AFM. It was used for example to investigate the interaction of basement membrane macromolecules [186], the surface ultrastructure of collagen fibrils and their association in human cornea and sclera [187], the assembly mechanism of fibrous long spacing collagen [188], the substructure of native, hydrated rat tail tendon ECM [189] and imaging of collagen III polymerization in solution [190]. Among

**Fig. 11.6.** Nanoscale imaging of local proteolytic activity by atomic-force microscopy. The image displays the leading edge of a melanoma cell on a gelatin-coated coverslip (principles shown in Figs. 11.4 and 11.5). By stepwise reduction of the scanned matrix area, the AFM tip is directed to the pericellular microenvironment of the tumor

cell (right) and distant control areas (left). Images of pericellular gelatin (right) illustrate the decrease in size and frequency of larger protein structures compared to intact matrix (arrows in left-hand image). These morphometric alterations can automatically be quantified with the AFM software.

various other applications, AFM was used to examine the structure of single collagen XVI molecules on mica [191].

AFM of normal human skin basement membrane preparations [192] displays the structural diversity of different fibrillar networks and the close meshed, underlying laminin-collagen IV net. Imaging of ECM compositions illustrates the high spatial resolution of the AFM in biological samples (Fig. 11.7).

The ability of the AFM to image ECM-components with high resolution has been exploited in an investigation of protease–substrate interactions *in vitro*. For example, Sun et al. have revealed by AFM the existence of several non-specific

**Fig. 11.7.** 3D reconstruction of AFM images of normal human skin preparations, enriched in basement membranes. The images depict the molecular diversity and complexity of native ECM compositions. (a) Larger scale

magnification; (b) collagen-IV/laminin-V network with typical collagen IV conformations. Arrows: NC-1 domains of collagen IV. (c) Macromolecules such as fibrillin can be identified by their structure.

binding sites for MMP-8 on single type II collagen helices, but only one specific cleavage site for this enzyme [193]. Lin and colleagues demonstrated AFM imaging of real-time proteolysis of single collagen I molecules in fluid [194].

AFM was used alone and in combination with fluorescence microscopy for imaging of local proteolytic activity in the pericellular microenvironment of cancer cells (Figs. 11.2 and 11.4) [172]. Amelanotic melanoma cells were seeded on thin coatings of fluorescence-labeled gelatin or collagen IV (setup comparable to Fig. 11.4). Local loss of fluorescence due to ECM protein cleavage was used for fluorescence microscopic detection of proteolysis and localizing the AFM tip, and served as a positive control. Additional experiments proved that fluorescence microscopy

is not a prerequisite for this approach, as AFM imaging of pericellular matrix is sufficient to detect proteolysis on a subcellular level. As the AFM acquires primarily  $x$ -,  $y$ - and  $z$ -data during scanning, it is very easy to calculate and analyze differences in height and volume of subnanometer structures. AFM depicted significant differences in average height, volume and molecular weight distribution of pericellular matrix proteins between the microenvironment of invasive cancer cells and distant control areas [172]. By treating it as the segment of a sphere, the molecular weight of a protein imaged by AFM can be calculated from the molecular volume of the structure. In these experiments, the AFM registered significant changes in average matrix volume as little as  $0.003 \text{ fl } \mu\text{m}^{-2}$  and decreases in average height of less than 0.5 nm. By focusing on the complex composition of ECM, the possibility of time lapse AFM of primary tumor cell cultures on native human basement membranes is currently being evaluated (Fig. 11.7).

In summary, the AFM can image and quantify nanoscale ECM alterations in the microenvironment of cancer cells. Considering that direct measurement of local proteolytic activity and high-resolution imaging of ECM remodeling have proven difficult, this method is particularly advantageous as it enables nanoscale resolution and functional investigations on the subcellular level.

The advantages of AFM as a rapidly evolving nanotechnique for functional high resolution imaging under physiological conditions are striking, as it can provide functional data in addition to 3D nanoscale images of local phenomena. Current advances in making the AFM a high-resolution tool for simultaneous topography and specific functional recognition imaging of single molecules (“molecular recognition”) like integrins or cellular microdomains such as lipid rafts opens up interesting perspectives [93, 195]. Furthermore, physical parameters such as cell traction, elasticity of membrane compartments and ECM compositions or the binding forces of ligand–receptor complexes can be quantified with nanoscale resolution and integrated in the molecular recognition maps.

## 11.5

### Conclusions and Perspectives

The most devastating process in cancer is metastasis, as it represents the milestone of an irreversible stage of progression that inevitably determines disease prognosis. Regardless of the advancement of therapies for cancer that has already spread, the early diagnosis and removal of the malignancy is still the most promising strategy. The limitations of conventional state of the art methods offer unique opportunities for innovative, nanotechnology based approaches. The development of improved methods that enable real-time high-resolution imaging and quantification of local enzymatic activities will play a major role in the design of new drugs and the understanding of basic principles in tumor cell invasion. These methods themselves harbor the potential to contribute directly to patient benefits due to earlier diagnosis of malignancies and functional monitoring following clinical interventions.

## Acknowledgments

As it is sometimes not possible to cite all relevant articles on a subject, several references have been used as examples to illustrate major principles. I thank Uwe Hansen for the generous supply with various matrix proteins, Sylvia Puttman and Volker Senner for their cooperation and contribution of primary brain tumor cells, and Helga Bertram and Stephan Kusick for their excellent technical assistance in tissue culture and Atomic Force Microscopy. I thank Joerg Hinnerwisch, Mark Lal, Hans Oberleithner, Val Prasad and Michael J. Morton for revising and improving the original manuscript and for interesting discussions. Excerpts of this chapter have been previously published as a review [15]. This work was supported by the Deutsche Forschungsgemeinschaft (LU 854/2-1 and LU 854/3-1) and “Innovative Medizinische Forschung” (LU 110343) of the University of Münster.

## Abbreviations

AFM	Atomic-force microscope
ECM	Extracellular matrix
EMMPRIN	Extracellular matrix metalloproteinase inducer
HSPG	Heparan sulfate proteoglycan
ISZ	<i>In situ</i> zymography
MMP	Matrix metalloproteinase
MT-MMP	Membrane type-matrix metalloproteinase
MMPI	Matrix metalloproteinase inhibitor
MPM	Multi-photon microscopy
NIRF	Near-infrared fluorescence
RECK	Reversion-inducing cysteine-rich protein with Kazal motifs
SHG	Second-harmonic generation
TIMP	Tissue inhibitor of matrix metalloproteinases
uPA	Urokinase-type plasminogen activator

<b>1</b>	<b>Biosensing using Carbon Nanotube Field-effect Transistors</b>	<b>1</b>
	<i>Padmakar D. Kichambare and Alexander Star</i>	
1.1	Overview	1
1.2	Introduction	1
1.3	Carbon Nanotube Field-effect Transistors (NTFETs)	3
1.3.1	Carbon Nanotubes	3
1.3.2	Nanotube Synthesis	4
1.3.3	Fabrication of NTFETs	6
1.4	Sensor Applications of NTFETs	9
1.4.1	Sensitivity of NTFETs to Chemical Environment	9
1.4.2	Bioconjugates of Carbon Nanotubes	12
1.4.3	Protein Detection	14
1.4.4	Detection of Antibody–Antigen Interactions	15
1.4.5	DNA Detection	17
1.4.6	Enzymatic Reactions	19
1.4.7	Glucose Detection	20
1.5	Conclusion and Outlook	21
	References	21
<b>2</b>	<b>Carbon Nanotube-based Sensor</b>	<b>27</b>
	<i>Jian-Shan Ye and Fwu-Shan Sheu</i>	
2.1	Overview	27
2.2	Introduction of Carbon Nanotubes	27
2.3	Growth of Carbon Nanotubes	29
2.4	Methods to Prepare CNTs-based Sensors and Biosensors	29
2.4.1	Individual MWCNTs as Nanoelectrodes	29
2.4.2	Randomly Distributed CNT Electrodes	30
2.4.3	Well-aligned Carbon Nanotube Electrodes	30
2.4.4	Carbon Nanotube Paste Electrodes	31

2.4.5	Screen-printing Carbon Nanotubes	32
2.4.6	Self-assembly of Carbon Nanotubes	33
2.4.7	Carbon Nanotube-packaged Microelectrodes	34
2.5	Application of CNTs-based Electrochemical Sensors and Biosensors	34
2.5.1	Electrochemical and Electrocatalytical Properties of Carbon Nanotubes	34
2.5.2	CNTs-based Electrochemical Biosensors	37
2.6	Functionalization of CNTs	39
2.6.1	Biological Functionalization of CNTs	39
2.6.2	Self-assembly of Surfactant and Lipid Molecules at CNTs	39
2.6.3	Electrochemical Functionalization of CNTs	42
2.6.4	Electrochemical Application of Functionalized CNTs	43
2.6.4.1	Application of Lipid–CNT Nanomaterials in Electrochemical Sensors	43
2.6.4.2	Achieving direct Electron Transfer to Redox Proteins by Functional CNTs	44
2.6.4.3	Biomolecule-functionalized CNTs for Electrochemical Sensors and Biosensors	45
2.7	Conclusions and Future Prospects	48
	Acknowledgments	49

## Preface

As we come closer to the completion of the ten-volume series on *Nanotechnologies for the Life Sciences*, I am reminded of a statement by the great scientist Arthur C Clarke who said: “Any sufficiently advanced technology is indistinguishable from magic.” This statement is particularly true in molecular biosensing based on nanomaterials where the detection limits are ‘magically’ becoming smaller and smaller, even reaching zeptomolar concentrations in addition to opening up possibilities for ultra-sensitive multiplexed detection. Thanks to the development of novel concepts such as bio-bar-code assays, nanomaterials-based companies are revolutionizing the commercialization of molecular diagnostics at breathtaking speeds. Therefore, on behalf of a great team of nano researchers who have been involved in the development of nanomaterials for biosensing and particularly those who have contributed to this specific volume, I am pleased to introduce you the 8<sup>th</sup> volume of the series, *Nanomaterials for Biosensors*. We have come a long way in our journey since the publication of the first volume of the series, *Biofunctionalization of Nanomaterials*, into bringing the existing knowledge base of applications of nanotechnologies in biology, biotechnology and medicine on a single platform. The eighth volume has thirteen chapters covering various aspects of biomolecular sensing using a variety of nanomaterials such as carbon nanotubes, nanowires, nanocantilevers, fullerenes, dendrimers in addition to metallic and quantum dot nanoparticles. The most exciting and unique aspect of the book is that it deals with the utilization of nanomaterials not only for enhancing the capabilities in conventional biosensing platforms, but also brings out newer approaches such as biomimetic and reagent-less biosensing.

The first four chapters of the book are dedicated to various modes of biosensing using carbon-based nanomaterials. The first chapter by Padmakar D. Kichambare and Alexander Star from the University of Pittsburgh, USA, provides an overview of recent advances in biodetection using single-walled carbon nanotube field-effect transistors (NTFETs) focusing primarily on fabrication of NTFET devices and how carbon nanotubes can be effectively integrated into conventional electronics for biosensor applications, for example, antibody–antigen interactions, DNA hybridization, glucose detection and enzymatic reactions. The chapter entitled *Biosensing using Carbon Nanotube Field-effect Transistors* provides a promising outlook for novel sensing applications of carbon nanotubes in living systems as

well as new opportunities for CNT-based bioelectronics. In addition to the utility of CNTs as field effect transistors, they can also be used as material of construction as nanoelectrodes, which can be utilized as electrochemical sensing systems. The second chapter, *Carbon Nanotube-based Sensors*, contributed by Jian-Shan Ye and Fwu-Shan Sheu from the National University of Singapore, brings out the importance of various methods utilized for preparing CNT electrodes and different ways to functionalize them for biosensing applications. Particularly interesting in this chapter is the discussion on mechanistic aspects of electrocatalysis by CNTs. The chapter will be very useful for those who are interested in exploiting the electrochemistry of CNTs in molecular diagnostics. Though CNTs are the most well-studied amongst one-dimensional nanomaterials, there are a considerable number of research investigations into exploiting the potential of other 1D nanomaterials like semiconducting nanowires and cantilevers. The third chapter, therefore, is a comprehensive review on silicon nanowires, conducting polymer nanowires, metal oxide nanowires, and nanocantilevers with reference to carbon nanotubes. The chapter, *Nanotubes, Nanowires, and Nanocantilevers in Biosensor Development*, contributed by Jun Wang, Guodong Liu, and Yuehe Lin from Pacific Northwest National Laboratory in Richland, USA, provides up to date information on the development of 1D-nanomaterial-based biosensors. The fourth and final chapter on carbon nanomaterials for biosensing is *Fullerene-based Electrochemical Detection Methods for Biosensing* presented by Nikos Chaniotakis from the University of Crete, Greece. Fullerenes have not received as much attention as CNTs as suitable materials for biosensing, mainly because their physicochemical characteristics are still not very well understood. However, the chapter provides a complete picture on several possibilities for fullerenes to offer new and powerful tools as electrochemical biosensors especially in signal mediation, protein and enzyme functionalization, and light-induced switching.

Nanomaterials also offer opportunities for ultra-sensitive biomolecular sensing through their local field optical effects, which are several orders of magnitude higher than the corresponding bulk effects. Optically active metallic and quantum dot nanomaterials have opened up avenues for newer techniques such as local surface plasmon resonance (LSPR), surface-enhanced Raman scattering (SERS), surface-enhanced fluorescence (SEF), fluorescence resonance energy transfer (FRET), time-resolved fluorimetry, and others. The next two chapters in the book provide an overview of these technologies. The fifth chapter, *Optical Biosensing Based on Metal and Semiconductor Colloidal Nanocrystals* by R. Comparelli, L. Curri, P. D. Cozzoli, and M. Striccoli from the Italian National Research Council's Institute of Physicochemical Processes of CNR in Bari, focuses in general on metal and quantum dot-based optical biosensing, providing a comparative assessment of recent developments categorized into various novel and/or improved optical techniques with traditional methods. The sixth chapter is exclusively dedicated to optical biosensing by quantum dots. Authors Rumiana Bakalova, Zhivko Zhelev, Hideki Ohba, and Yoshinobu Baba from the AIST-Kyushu National Institute of Advanced Science and Technology in Saga and Nagoya University, both in Japan, present an overview on the current status and future trends of QD-based biosensor develop-

ment. The chapter, *Quantum Dot-based Nanobiohybrids for Fluorescent Detection of Molecular and Cellular Biological Targets*, covers not only the basic principles of design and synthesis of highly fluorescent QDs, but also intricacies of *in vitro* and *in vivo* cellular and deep-tissue imaging.

The utility of gold nanoparticles in optical biosensing is very well known and already finding several commercial applications. However, the application of gold nanomaterials' capability as amperometric sensor is only recently being recognized as very promising and powerful tools in bio-fluid or biomaterial investigations and their associated clinical studies. The seventh chapter, *Detection of Biological Materials by Gold Nano-biosensor-based Electrochemical Methods*, provides a review on gold nanowire arrays and their utility as biosensors in bacterial detection. The authors, Juan Jiang, Manju Basu, Sara Seggerson, Albert Miller, Michael Puglia, and Subhash Basu from the university of Notre Dame in Indiana, USA, provides an in-depth analysis of the application of electrochemical impedance spectroscopy (EIS) in gold nanomaterial-based biosensing and demonstrates the technique's potential in clinical laboratories, environmental monitoring and the food industry to achieve rapid and sensitive detection. Continuing on a similar theme related to electrochemical sensing but utilizing dendrimeric nanomaterials, authors Hak-Sung Kim and Hyun C. Yoon from KAIST at Daejeon, Korea, cover various facets of bioelectrocatalytic enzyme sensors in the eighth chapter. *Dendrimer-based Electrochemical Detection Methods* is a must for readers interested in the fabrication of dendrimer-based biocomposite mono-/multilayers and their biosensing applications.

Each of the last five chapters in the book brings out several fascinating facets of nanomaterial-based biosensing very different from what we have seen so far in the first eight chapters. The author of the ninth chapter, *Coordination Biosensors: Integrated Systems for Ultrasensitive Detection of Biomarkers*, Joanne Yeh from the University of Pittsburgh Medical School, USA, presents altogether a different approach to biosensing, utilizing newer concepts to align the signal transduction centers to enhance the kinetics of reactions leading to improved sensitivity of detection. It has been observed that there is a direct electrochemical and catalytic activity of many proteins at electrodes modified with various nanomaterials such as  $\text{TiO}_2$ ,  $\text{ZrO}_2$ ,  $\text{SiO}_2$ ,  $\text{Fe}_3\text{O}_4$ , metal nanoparticles and carbon nanotubes. In the tenth chapter, the author Genxi Li from Nanjing University in China reviews the literature to demonstrate that nanomaterials can not only provide a friendly platform for the assembly of protein molecules but also enhance the electron-transfer process between protein molecules and the electrode. The chapter entitled *Protein-based Biosensors using Nanomaterials* brings out the advantages of combining proteins and nanomaterials to develop sensitive biosensor elements. Proteins and in general various nano-size structures in the field of life sciences provide testimony to the endless possibilities and elegant applications in our day to day world. Therefore, it is not very surprising that a new branch of science, 'Biomimetics', has roots in a variety of scientific disciplines, and the field of biosensors is not an exception. In the eleventh chapter, authors Raz Jelinek and Sofiya Kulusheva from Ben Gurion University of the Negev in Beer-Sheva, Israel, brings out the utility of concepts and methodologies from the biological world into the laboratory. The

chapter, *Biomimetic Nanosensors*, provides a broader perspective on bio-inspired devices and applications related to nanomaterial-based biosensing.

As the title indicates, the twelfth chapter, *Reagentless Biosensors Based on Nanoparticles*, provides the readers with yet another novel concept in biosensing, where sensing tools are being developed based on perturbation of nanoparticle properties, without the need for reagents, in order to produce unique yet sensitive signals for biomeoclecular sensing. The author, David Benson from Wayne State University in Detroit, USA, provides a strong case for adaptation of reagentless concepts that provide sensors that can be adapted to various detection platforms. The book concludes with its thirteenth chapter, wherein the authors, Shohei Yamamura, Sathuluri Ramachandra Rao, and Eiichi Tamiya from Japan Advanced Institute of Science and Technology at Nomi, Japan, bring us closer to biosensing devices incorporating highly integrated microarray systems that can perform assays at pico- and nano-liter volume level. In this chapter, *Pico/Nanoliter Chamber Array Chips for Single-cell, DNA and Protein Analyses*, the authors discuss three very important topics – novel multiplexed PCR, cell-free protein synthesis, and high-throughput single-cell analysis systems using nanolitre microarray platforms.

Nanotechnology embodies the spirit of interdisciplinary approaches and teams. I am, therefore, very grateful to all the authors who have shared my enthusiasm and vision by contributing high-quality manuscripts keeping in tune with the theme of this volume. It is primarily due to their scholarly contributions that this book comes into existence. I am thankful to my employer, the Center for Advanced Microstructures and Devices (CAMD), for providing me with an opportunity to undertake this enormous project. No words can express the understanding of my family, friends, mentors and most importantly the readers who are now an integral part of my existence and continue to shape my life and I am indebted to them. Finally, Wiley-VCH publishers have done a remarkable job and I am grateful for their support.

## 1

## Biosensing using Carbon Nanotube Field-effect Transistors

*Padmakar D. Kichambare and Alexander Star*

## 1.1

### Overview

This chapter covers recent advances in biodetection using single-walled carbon nanotube field-effect transistors (NTFETs). In particular, we describe fabrication of NTFET devices and their application for electronic detection of biomolecules. A typical NTFET fabrication process consists of combination of chemical vapor deposition (CVD) and complementary metal oxide semiconductor (CMOS) processes. The NTFET devices have electronic properties comparable to traditional metal oxide semiconductor field-effect transistors (MOSFETs) and readily respond to changes in the chemical environment, enabling a direct and reliable pathway for detection of biomolecules with extreme sensitivity and selectivity. We address the challenges in effective integration of carbon nanotubes into conventional electronics for biosensor applications. We also discuss in detail recent applications of NTFETs for label-free electronic detection of antibody–antigen interactions, DNA hybridization, and enzymatic reactions.

## 1.2

### Introduction

The interplay between nanomaterials and biological systems forms an emerging research field of broad importance. In particular, novel biosensors based on nanomaterials have received considerable attention [1–4]. Integration of one-dimensional (1D) nanomaterials, such as nanowires, into electric devices offers substantial advantages for the detection of biological species and has significant advantages over the conventional optical biodetection methods [5]. The first advantage is related to size compatibility: Electronic circuits in which the component parts are comparable in size to biological entities ensure appropriate size compatibility between the detector and the detected biological species. The second advantage to developing nanomaterial based electronic detection is that most biological processes involve electrostatic interactions and charge transfer, which are directly

detected by electronic nanocircuits. Nanowire-based electronic devices, therefore, eventually integrate the biology and electronics into a common platform suitable for electronic control and biological sensing as well as bioelectronically driven nanoassembly [6].

One promising approach for the direct electrical detection of biomolecules uses nanowires configured as field-effect transistors (FETs). FETs readily change their conductance upon binding of charged target biomolecules to their receptor linked to the device surfaces. For example, recent studies by Lieber's group have demonstrated the use of silicon nanowire FETs for detecting proteins [7], DNA hybrids [8], and viruses [9]. This biodetection approach may allow in principle selective detection at a single particle levels [10, 11]. Nanowires hold the possibility of very high sensitivity detection owing to the depletion or accumulation of charge carriers, which are caused by binding of a charged biomolecules at the surface. This surface binding can affect the entire cross-sectional conduction pathway of these nanostructures. For some nanowires, such as hollow carbon nanotubes, every atom is on the surface and exposed to the environment; even small changes in the charge environment can drastically change their electrical properties. Thus, among different nanomaterials, carbon nanotubes have a great potential for biosensing.

Among numerous applications of carbon nanotubes [12–14], carbon nanotube based sensing technology is rapidly emerging into an independent research field. As for any new research field, there is no yet consensus in the literature about the exact sensing mechanism. In this chapter, in addition to selected examples of carbon nanotube based sensors, we address the controversial carbon nanotube sensing mechanism.

To date, sensor applications of carbon nanotubes have been summarized and discussed in several excellent review articles [15–17], which primarily focus on carbon nanotube based electrochemical sensors. This chapter covers only recent advances in biodetection using carbon nanotube field-effect transistors (NTFETs). It is divided into two large sections: NTFET fabrication and their sensor applications. Section 1.3 gives a detailed description of NTFET device structure, its fabrication method and introduces device characteristics. This section also addresses technical challenges in effective integration of carbon nanotubes into CMOS electronics. Section 1.4, which focuses on sensor applications of NTFETs, is divided into several subsections. Before discussing NTFET application for biological detection we describe the effect of environmental conditions on NTFET device characteristics. We give selected examples of NTFET sensitivity for small molecules, mobile ions, and water (relative humidity). The effect of these factors should be well understood before NTFET biodetection is reviewed. We also briefly describe the operation of NTFETs in conducting media, which is particularly important for biosensor applications. Then we briefly summarize interactions of carbon nanotubes with biomolecules (e.g., polysaccharides, DNA and proteins) to set a stage for the subsequent subsections that describe in great details recent applications of NTFETs for label-free electronic detection of proteins, antibody–antigen interactions, DNA hybridization, and enzymatic reactions.

### 1.3

## Carbon Nanotube Field-effect Transistors (NTFETs)

### 1.3.1

#### Carbon Nanotubes

Since their discovery by Iijima over a decade ago [18], interest in carbon nanotubes has grown considerably [19]. Recent advances in the synthesis and purification of carbon nanotubes have turned them into commercially available materials. Subsequently, several experiments have been undertaken to study the physical and electrical properties of carbon nanotubes on the individual and macroscopic scale [20–23]. On the macroscopic scale, spectroscopic and optical absorption measurements have been carried out to test the purity of the carbon nanotubes [24, 25]. For electronic transport measurements it is particularly interesting to perform experiments on isolated, individual carbon nanotubes. The properties of carbon nanotubes depend strongly on physical aspects such as their diameter, length, and presence of residual catalyst [12]. The properties measured from a large quantity of nanotubes could be an average of all nanotubes in the sample, so that the unique characteristics of individual carbon nanotubes could be shadowed. Experiments on individual nanotubes are very challenging due to their small size, which prohibits the application of well-established testing techniques. Moreover, their small size also makes their manipulation rather difficult. Specialized techniques are needed to mount or grow an individual carbon nanotube on the electrode with sub-micron precision.

Carbon nanotubes are hollow cylinders made of sheets of carbon atoms and can be divided into single-walled carbon nanotubes (SWNTs) and multi-walled carbon nanotubes (MWNTs). SWNTs possess a cylindrical nanostructure with a high aspect ratio, formed by rolling up a single graphite sheet into a tube (Fig. 1.1). SWNTs are, typically, a few nanometers in diameter and up to several microns long. MWNTs consist of several layers of graphene cylinders that are concentrically nested like rings of a tree trunk, with an interlayer spacing of  $3.4 \text{ \AA}$  [26]. Because of their unique properties, carbon nanotubes have become a material that has generated substantial interest on nanoelectronic devices and nanosensors [27, 28]. These properties are largely dependent upon physical aspects such as diameter, length, presence of catalyst and chirality. For example, SWNT can be metallic or semiconducting, depending upon the intrinsic band gap and helicity [29]. Semiconducting SWNTs can be used to fabricate FET devices, as demonstrated by Dekker and co-workers [30]. In addition, semiconducting SWNTs exhibit significant conductance changes in response to the physisorption of different gases [24, 31, 32]. Therefore, SWNT-based nanosensors can be fabricated based on FET layout, where the solid-state gate is replaced by adsorbed molecules that modulate the nanotube conductance [33]. Since semiconducting SWNTs have a very high mobility and, because all their atoms are located at the surface, they are the perfect nanomaterial for sensors. These sensors offer several advantages for the detection of biological species. First, carbon nanotubes form the conducting channel in a transistor configura-

**Fig. 1.1.** A seamlessly rolled-up single graphite sheet forms a single-walled carbon nanotube (SWNT). SWNTs are, typically, a few nanometers in diameter and up to several micrometers long. They can be either metallic

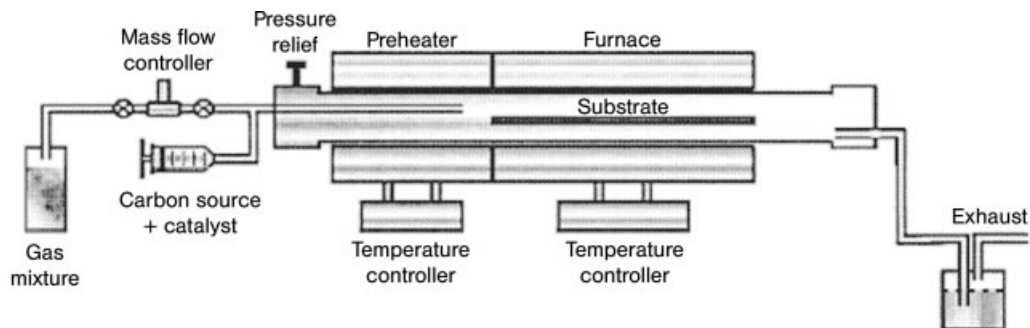

or semiconducting, depending on their helicity and diameter. Semiconducting SWNTs are used for the fabrication of nanotube field-effect transistors (NTFETs). (Adapted with permission from Ref. [4], © Wiley-VCH Verlag).

tion. Second, the nanotubes are typically located on the surface of the supporting substrate and are in direct contact with the environment. This device geometry contrasts with traditional metal oxide semiconductor field-effect transistors (MOSFETs) where the conducting channel is buried in the bulk material in which the depletion layer is formed. Lastly, all of the electrical current flows at the surface of nanotubes. All these remarkable characteristics lead to a FET device configuration that is extremely sensitive to minute variations in the surrounding environment.

### 1.3.2

#### Nanotube Synthesis

Several synthesis methods are used to produce carbon nanotubes [34]. The three most commonly used methods are the arc discharge, laser ablation, and chemical vapor deposition (CVD) techniques. While the arc and laser methods can produce large quantities of carbon nanotubes they lead to resilient contaminants, including pyrolytic and amorphous carbon [35, 36], which are difficult to remove from the sample. Such impurities result in low recovery yield for the carbon nanotube product. However, recent advances in scaling up these methods, as well as development new fabrication methods such as high pressure carbon monoxide (HiPCO), have created commercial supplies of carbon nanotubes with more than 90% purity with competitive prices. In contrast, the less scalable CVD process offers the best chance of obtaining controllable routes for the selective production of carbon nanotubes with defined properties [37]. CVD is catalytically driven, wherein a metal catalyst is used in conjunction with the thermal decomposition of hydrocarbon feedstock gases to produce carbon nanotubes. In most cases, the resultant growth of nanotubes occurs on a fixed substrate within the process. Figure 1.2 illustrates a typical CVD process for the generation of SWNTs. SWNTs are synthesized by the

**Fig. 1.2.** Schematic of a chemical vapor deposition (CVD) reactor that uses a two-zone furnace. Carbon nanotubes grow on the substrate placed inside the quartz tube. (Reprinted with permission from Ref. [34], © 2001, CRC Press).

reaction of a hydrocarbon (e.g.,  $\text{CH}_4$ ) vapor over a dispersed Fe catalyst. The synthesis apparatus consists of a quartz tube reactor inside a combined preheater and furnace set-up. The preheat section is operated at  $\sim 200^\circ\text{C}$ . The catalysts are deposited and then hydrocarbon vapors are carried into the reaction zone of the furnace. An  $\text{Ar}/(10\%)\text{-H}_2$  carrier gas is used that controls the partial pressure inside the quartz tube reactor. Reaction temperatures are typically in the range  $900\text{--}1000^\circ\text{C}$ . The SWNTs grow on the substrates (Fig. 1.3) and form thick mats that are readily harvested. This process produces highly pure SWNTs at a yield approaching 50% conversion of all hydrocarbon feedstock into carbon nanotube product. Similarly, a CVD processes sometimes utilize a feed of hydrocarbon-catalyst liquid for the production of nanotubes, and for this purpose a syringe pump is used to allow the continuous injection of this solution into a preheat section. Various gaseous feed-stocks are used to produce nanotubes, ranging from  $\text{CH}_4$  to  $\text{C}_2\text{H}_2$ . A wide range of transition metals and rare earth promoters have been investigated for the synthesis of SWNTs by CVD. In general, a transition metal is the major component in the catalyst particles used regardless of the catalyst support. The most common metals found to be successful in the growth of SWNTs are Fe, Co, and Ni [38, 39]. However, bimetallic catalysts consisting of Fe/Ni, Co/Ni, or Co/Pt [40] are re-

**Fig. 1.3.** Transmission electron microscopy (TEM) image of an SWNT synthesized by chemical vapor deposition (CVD). (Reprinted with permission from Ref. [37], © 2001, The American Chemical Society).

ported to give the best yield of nanotubes, in addition to some rare earth metals that have also been studied [41].

Despite challenges, the understanding the growth mechanism of SWNTs is crucial for, ultimately, tailoring the production of SWNTs with known lengths, diameters, helical structures and placement of SWNTs at the desired location. Presently, efforts are underway to understand the mechanism of catalytic growth of SWNTs on surfaces and the role of impurities and to increase nanotube yield by varying the substrate, catalyst, and growth conditions [42]. Directional growth of SWNTs has been achieved by electric fields [43, 44], gas flow [45], lattice directions [46], and atomic steps [47].

### 1.3.3

#### Fabrication of NTFETs

To date carbon nanotubes have been used to fabricate various devices, including nanotube-based mechanical devices [48] and field emission devices [13]. This section focuses specifically on fabrication of carbon nanotube field-effect transistors (NTFETs). Figure 1.4(a) shows a schematic drawing of NTFET. A semiconducting carbon nanotube is contacted by source and drain electrodes while the gate elec-

(b) Atomic force microscopy (AFM) image of a typical NTFET device consisting of a single semiconducting

SWNT. (c) Scanning electron microscopy (SEM) image of a typical NTFET device consisting of a random array of carbon nanotubes. (d) Typical NTFET transfer characteristic – dependence of the source-drain conductance ( $G_{SD}$ ) on the gate voltage ( $V_G$ ) – (i) maximum conductance, (ii) modulation, (iii) transconductance, (iv) hysteresis, and (v) threshold voltage.

trode, which is electrically insulated from the nanotube channel, is used to manipulate the nanotube's conductivity. Depending on the particular method of nanotube fabrication, a NTFET can be structured in different ways [49]. However, most publications on nanotube transistors report the use of a degenerately doped Si-substrate with a comparatively thick (100–500 nm) thermally grown oxide layer [30, 50–53]. Silicon substrates are readily available and can be used with both bulk-produced nanotubes and nanotubes grown directly on the Si-substrate by CVD. If doped highly, the Si substrate stays conductive even at low temperatures, making it usable as a so-called back-gate with the  $\text{SiO}_2$  as a stable, if low-k, gate dielectric. Bulk produced nanotubes (laser ablation [54] or HiPCO [55]) are usually purified and deposited onto Si substrates by suspending them in organic solvents (e.g., chloroform, dichloroethane, etc.) and then spin-coating or drop casting on the substrates. In this approach the nanotubes create a random network over the substrate surface. Alignment of the nanotubes is possible, if an AC dielectric field is applied during deposition [56]. Generally, two different configurations of NTFETs, regarding source and drain contacts, are possible. By patterning the contacts before nanotube deposition [30] one can contact nanotubes in bulk, whereas by depositing the contacts onto the nanotubes one contacts only the ends of nanotubes [57], because depositing contact material on top of the nanotube normally destroys the nanotubes underneath the contacts. The second configuration usually guarantees a lower contact resistance than what is achievable in bulk-contacted devices [58]. Room temperature NTFET manufacturing methods, while compatible with CMOS, are limited by ability to disperse effectively carbon nanotubes in the solution and deposit them without further aggregation on device surfaces [59]. Nanotube bundle formation may decrease the semiconducting character of NTFET due to the occasional presence of nanotube bundles containing metallic nanotubes.

For CVD grown carbon nanotubes metal contacts are deposited onto the nanotubes [60, 61], because typical contact materials cannot withstand CVD temperatures, thus making it impossible to grow carbon nanotubes on CMOS structures. Often, the metal contacts are annealed to lower contact resistance [62]. Several studies have tried to optimize the material used for the contacts, including Cr/Au [49] and Pt [30], but only the Cr/Au contacts have been used widely. In this type of contact the chromium layer is a thin (1–3 nm) adhesion layer that facilitates adhesion of the gold to  $\text{SiO}_2$ . An adhesion layer of Ti [63], especially when annealed, allows deposition of smooth films of many metals onto carbon nanotubes because Ti forms titanium carbide at the interface with the nanotube. For this reason, Ti/Au-contacts are another frequently used combination of contact materials. Many publications investigating Schottky barriers between a nanotube and its contacts [61, 64] have employed such contacts. Palladium (Pd) is another material investigated that wets nanotubes well and has been used recently to produce NTFETs with ohmic contacts, i.e., contacts without Schottky barriers [52, 63].

Depending on the number of carbon nanotubes connecting the source and drain electrodes, there are two different device architectures. In the first device architecture, a single nanotube connects the source and drain (Fig. 1.4b). These devices have been used for biosensing with excellent sensitivity. However, there is substan-

tial variation between the different devices that are fabricated and this variation is reflected in the electronic characteristics of individual nanotubes. In addition, the interface between the nanotube and the metallic contact may vary from device to device. Specialized techniques are needed either to mount or grow an individual carbon nanotube at a predetermined location. Placement is difficult and impractical for mass fabrication of NTFETs. For example, although the process of attaching a carbon nanotube strand via arc-discharge or contact method to sharp metal probe is fast, simple and economical it suffers from low yield. Therefore, it is difficult to determine the quality of carbon nanotube strand attached to metal tip unless examined under SEM. When checked under SEM a large percentage of the metal probes have multiple nanotubes attached or clusters of amorphous carbon accompanying the carbon nanotubes [65]. Hence random networks of SWNTs have been explored as an alternative [66].

Nanotube networks take up more space than individual SWNTs, but they are much easier to fabricate and show great promise towards simple mass fabrication of NTFETs. In this second configuration, the devices contain a random array of nanotubes between source and drain electrodes (Fig. 1.4c). In this configuration, current flows along several conducting channels that determine the overall device resistance. The device characteristics depend on the number of nanotubes and density of the nanotube network. It is reported that the conductance drops are associated with junctions formed by crossed semiconducting and metallic nanotubes. Local conductance is more dependent on the number of connections to the specific area; clusters of nanotubes with many paths to the electrode have significantly higher conductance than those parts of the network connected through fewer paths. Areas with low conductance typically only have two to three connections to the network, thus it is likely that these connections are dominated by the presence of highly resistive metallic/semiconducting junctions. When a sufficient back gate voltage is applied to the sample, current flow through the semiconducting tubes is suppressed. Using this technique, differences between metallic and semiconducting SWNT can be distinguished. This type of device configuration, containing a network of conducting nanotube channels, is less sensitive than devices made of single nanotubes. In both types of device configurations, the parameter used for detection is the transfer characteristic – the dependence of either the source-drain current ( $I_{SD}$ ) or conductance ( $G_{SD}$ ) (for a fixed source-drain voltage  $V_{SD}$ ) on the gate voltage ( $V_G$ ) (Fig. 1.4d).

NTFETs can operate as p-type or n-type transistors. The mode of operation can be changed from the pristine p-type to n-type by either adding electron donor molecules (n-doping) or removing adsorbed oxygen by annealing the contacts under vacuum [67]. Polymer-gated NTFETs can also tune their modes of operation: a change in the chemical group of the polymer changes the NTFET from p-type to n-type [68, 69]. Oxygen doping was attributed to the fact that the oxygen interacts with the nanotube–metal junction and causes the p-type characteristic for NTFETs in air by pinning the metal's Fermi level near the nanotube's valance band maximum [33]. However, there is no apparent consensus in the literature about the exact mechanism of chemical sensitivity of NTFETs.

## 1.4

### Sensor Applications of NTFETs

Before discussing NTFET applications for biological detection we first describe the effect of small molecules, relative humidity, and conductive liquid media on NTFET devices characteristics. Effect of these factors should be well understood before NTFET biodetection is reviewed.

#### 1.4.1

#### Sensitivity of NTFETs to Chemical Environment

Generally, the molecular species in the ambient environment have a significant impact on the electrical properties of NTFETs. The conductance of semiconducting SWNTs can be substantially increased or decreased by exposure to  $\text{NO}_2$  or  $\text{NH}_3$  [24]. Exposure to  $\text{NH}_3$  effectively shifts the valance band of the nanotube away from the Fermi level, resulting in hole depletion and reduced conductance. In contrast, on exposure to  $\text{NO}_2$  molecules the conductance of nanotubes increases by three orders of magnitude [70]. Here, exposure of the initially depleted sample to  $\text{NO}_2$  resulted in the nanotube Fermi level shifting closer to the valence band. This caused enriched hole carriers in the nanotube and enhanced sample conductance. These results show that molecular gating effects can shift the Fermi level of semiconducting SWNTs and modulate the resistance of the sample by several orders of magnitude.

The electronic properties of SWNTs are also extremely sensitive to air or oxygen exposure [33]. Isolated semiconducting nanotubes can be converted into apparent metals through room temperature exposure to oxygen. As the surrounding medium was cycled between vacuum and air, a rapid and reversible change in the SWNT resistance occurred in step with the changing environment. Initially, in a pure atmospheric pressure oxygen environment, the thermoelectric power (TEP)  $S$  was positive with a magnitude of nearly  $+20 \text{ mV K}^{-1}$ . This relatively large positive TEP is consistent with that reported for pristine SWNTs near room temperature [71]. As oxygen was gradually removed from the chamber, the TEP changed continuously from positive to negative, with a final equilibrium value of approximately  $-10 \text{ } \mu\text{V K}^{-1}$ . When oxygen was reintroduced into the chamber, the TEP reversed sign and once again became positive. These dramatic 10–15% variations in  $R$  and change in sign of the TEP demonstrate that SWNTs are exceptionally sensitive to oxygen.

In the carbon nanotubes sensors mentioned above, chemical sensing experiments have been conducted with devices in which both nanotubes and nanotube–metal contacts were directly exposed to the environment. The sensing could be dominated by the interaction of molecules with the metal contacts or the contact interfaces. Adsorbed molecules would modify the metal work functions and, thereby, the Schottky barrier [72, 73]. Heinze et al. [64] have assigned the effect of oxygen to the Schottky barrier. Recently, a new device architecture has been studied in which the interface between the metallic contacts and nanotubes is covered by a

**Fig. 1.5.** (a) AFM image of a contact passivated NTFET device covered with poly(ethylene imine). (b)  $I_{SD}-V_G$  dependence for the device in vacuum (center curve), as well as in  $\text{NH}_3$  and  $\text{NO}_2$  gases. (Adapted with permission from Ref. [74], © 2003 American Institute of Physics).

passivation layer, referred to as contact-passivated [74]. In this configuration, with the junction isolated and only the central length of the nanotube channels exposed, the contacts should be isolated from the effect of chemicals. At the same time, the section of the device that is open to the environment can be doped via charge transfer. NTFETs with such configuration have been investigated by measuring sensitivity to  $\text{NH}_3$ ,  $\text{NO}_2$ , and poly(ethylene imine) (Fig. 1.5).

The NTFET devices were fabricated using SWNTs grown by CVD on 200 nm of silicon dioxide on doped silicon from iron nanoparticles as described in Section 1.3.1. These particles were exposed to flowing hydrocarbon to grow carbon nanotubes, and after growth optical lithography was used to pattern electrical leads (35 nm titanium capped with 5 nm gold) on top of the nanotubes. Contact passiva-

tion was achieved by 70 nm silicon monoxide layer. Source and drain electrodes were separated by nearly a micrometer. The dependence of the source-drain current ( $I_{SD}$ ) as function of the gate voltage ( $V_G$ ) was measured from +10 to -10 V using a semiconductor parameter analyzer in air/water/gas mixtures. The low concentrations of gas mixtures could be introduced to the devices by mixing different proportions of air and gases. The contact-passivated devices demonstrated  $\text{NH}_3$  and  $\text{NO}_2$  sensitivity similar to regular NTFETs. Poly(ethylene imine) also produced negative threshold shifts of tens of volts, despite being in contact with only the center region of devices. Thus, the NTFET sensor character was preserved despite isolating Schottky barriers.

Several groups have reported that NTFET fabricated on  $\text{SiO}_2/\text{Si}$  substrates exhibits hysteresis in current versus gate-voltage characteristics and attributed the hysteresis to charge traps in bulk  $\text{SiO}_2$ , oxygen-related defect trap sites near nanotubes, or the traps at the  $\text{SiO}_2/\text{Si}$  interface. It is mentioned that thermally grown  $\text{SiO}_2$  surface consists of Si-OH silanol groups and is hydrated by a network of water molecules that are hydrogen bonded to the silanols. The CVD nanotube growth condition (900 °C) may dehydrate the surface and condense to form Si-O-Si siloxanes. When such a surface is exposed to and stored in ambient air, the surface siloxanes on the substrate react with water and gradually revert to Si-OH, after which the substrate becomes rehydrated. Heating under dry conditions significantly removes water and reduces hysteresis in the transistors.

Kim et al. have reported that the hysteresis in electrical characteristics of NTFETs is due to charge trapping by water molecules around the nanotubes, including  $\text{SiO}_2$  surface-bound water proximal to the nanotubes [75]. They have demonstrated that coating nanotube devices with PMMA can afford nearly hysteresis-free NTFETs [75]. This passivation is attributed to two factors. First, the ester groups of poly(methyl methacrylate) (PMMA) can hydrogen bond with silanol group on  $\text{SiO}_2$ . Baking at 150 °C combined with the polymer-SiO<sub>2</sub> interaction can significantly remove the silanol-bound water. Second, PMMA is hydrophobic and can keep water in the environment from permeating the PMMA and adsorbing on the nanotube in a significant manner.

Bradley et al. have attributed hysteresis in NTFET devices to cation diffusion [76], based on the following experiments. First, NTFET devices that exhibit very small hysteresis were fabricated. Subsequently, these devices were modified by the addition of an electrolyte coating that created mobile ions on the surface of the device and resulted in the large hysteresis. Experiments were also conducted to explore possible mechanisms for cation-induced hysteresis by varying the humidity that changes the hydration layer around the nanotubes, thus leading to the increase of the ionic mobility. The hysteresis has been found to be sensitive to humidity on sub-second time scales, showing promise as a humidity sensor [77].

Sensitivity of NTFETs to charges as well as NTFET operation in conducting liquid media is important for biosensor design where the sensor should operate in physiological buffers with complex mixtures of biomolecules. Figure 1.6 shows a typical transfer characteristic of NTFET measured in air and water using the silicon and water as the gate electrode, respectively. The change in device characteris-

tics upon exposure to a water/gas mixture is reflected in the transfer characteristics. Saline or electrolytes can also gate NTFETs and give high transconductance [62, 78].

#### 1.4.2

#### Bioconjugates of Carbon Nanotubes

Numerous reports demonstrate the ability to chemically functionalize nanotubes for biological applications [79, 80]. Such chemistry is readily transferable to many applications, ranging from sensors [81, 82] to electronic devices [83]. SWNTs are chemically stable and highly hydrophobic. Therefore, they require surface modification to establish effective SWNT–biomolecule interaction.

So far, two methods of exohedral functionalization of SWNTs have been developed – namely covalent and noncovalent. While covalent modifications [84] are often effective at introducing functionality, they impair the desirable mechanical and electronic properties of SWNTs. Noncovalent modifications [85], however, not only improve the solubility of SWNTs in water, but they also constitute non-destructive processes, which preserve the primary structures of the SWNTs, along with their unique mechanical and electronic properties.

Previously, it has been shown that polysaccharides such as starch [86, 82, 83], gum Arabic [84], and the  $\beta$ -1,3-glucans, curdlan and schizophyllan [85], will solubilize SWNTs in water. It has been proposed that at least some of these polymers achieve their goal by wrapping themselves in helical fashion around SWNTs (Fig.

Fig. 1.7. Molecular model of SWNT wrapped in an amylose coil. (Reprinted from Ref. [79], © 2002, The American Chemical Society.)

1.7). Solubilization of the SWNTs with cyclodextrins (CD), which are macrocyclic polysaccharides, has been also investigated [86]. The observed aqueous solubility of SWNTs with  $\gamma$ -CD is unlikely due to encapsulation because the inner cavity dimensions of this CD are far too small to allow it to thread onto even the smallest diameter SWNTs. More recently, however, it has been shown [87] that  $\eta$ -CD, which has 12  $\alpha$ 1,4-linked D-glucopyranose residues and therefore is large enough, does thread onto SWNTs in water, not only solubilizing the NTs but also permitting some partial separations according to their diameters.

Nucleic acids, such as single-stranded DNA, short double-stranded DNA, and some total RNA can also disperse SWNTs in water [88, 89]. Molecular modeling has shown [20] that the non-specific DNA–SWNT interactions in water are from the nucleic acid–base stacking on the nanotube surface, resulting in the hydrophilic sugar–phosphate backbone pointing to the exterior to achieve the solubility in water. The mode of interaction could be helical wrapping or simple surface adsorption. The charge differences among the DNA–SWNT conjugates, which are associated with the negatively charged phosphate groups of DNA and the different electronic properties of SWNTs, have allowed post-production preparation of samples enriched in metallic and semiconducting SWNTs.

Various proteins can also strongly bind to the nanotube exterior surface via non-specific adsorption. Proteins such as streptavidin and HupR crystallize in helical fashion, resulting in ordered arrays of proteins on the nanotube surface [90]. Mechanistically, the non-specific adsorption of proteins onto the nanotube surface may be more complicated than the widely attributed hydrophobic interactions. Quite possibly, the observed substantial protein adsorption is, at least in part, associated with the amino affinity of carbon nanotubes, as was demonstrated recently by monitoring the conductance change in the carbon nanotube [91]. Also, inter-

molecular interactions involving aromatic amino acids, i.e., histidine and tryptophan, in the polypeptide chains of the proteins can contribute to the observed affinity of the peptides to carbon nanotubes [92].

### 1.4.3

#### Protein Detection

Carbon nanotube interactions with proteins have been explored by NTFET devices [91]. In NTFET devices, the ability to measure the electronic properties of the nanotube allowed to query the electronic state of the immobilization substrate. In that work two types of measurements of the device transfer characteristics were performed. In the first measurement, referred to as a substrate-gate transfer characteristic, the current through the drain contact (at fixed source-drain bias) was monitored while a variable gate voltage was applied through a metallic gate buried underneath the SiO<sub>2</sub> substrate. In the second measurement, referred to as liquid-gate transfer characteristics, the device was immersed in a buffer solution and a variable gate voltage was applied through a platinum electrode. The current was passed through the drain contact and a silver reference electrode in the solution. During these measurements, the assembly was shaken gently, using a lab rotator at 3 Hz. The effect of protein adsorption was studied with both measurements. Devices were incubated with streptavidin (40 nm) in 15 mM phosphate buffer at 25 °C. Liquid-gate transfer characteristics were measured continually during the incubations. After 10 h, the devices were rinsed with distilled water and blown dry, and the substrate-gated transfer characteristics of the dried devices were measured.

These results were discussed in terms of a simple model in which adsorbed streptavidin coats the single-walled nanotube (Fig. 1.8). The gradual shift in the threshold voltage is assumed to result from the slow accumulation of a full monolayer of adsorbed protein. This coverage-dependent threshold shift is analogous

**Fig. 1.8.** (a) Size comparison between a carbon nanotube and a streptavidin molecule. (b) Current versus gate voltage for a nanotube device;  $V_{\text{SD}} = 10$  mV. (ii) In phosphate buffer before streptavidin addition. (i) same conditions, to measure the uncertainty in the

threshold voltage. (iii) After 10 h of incubation with streptavidin. Arrows indicate the threshold voltages for the three curves [the arrow for (i) is behind that for (ii)]. (Adapted with permission from Ref. [91], © 2003, The American Chemical Society.)

to the concentration-dependent shift observed when such devices are exposed to aqueous ammonia [93]. The protein adsorbate equilibrates over several hours so that only the full monolayer can be conclusively determined. Such protein monolayers form under various conditions at interfaces that permit protein crystallization, including sidewalls of MWNTs [90, 94]. The results support the proposal that conductance changes are due to charge injection or field effects caused by proteins adsorbed solely along the lengths of the nanotubes.

Protein adsorption on NTFET leads to appreciable changes in the electrical conductance of the devices that can be exploited for label-free detection of biomolecules with a high potential for miniaturization. For example, Dai and coworkers [95] have used a sensor design consisting of an array of four NTFET sensors on SiO<sub>2</sub>/Si chips. Each NTFET consists of multiple SWNTs connected roughly in parallel across two closely spaced bridging metal electrodes. Three types of devices with different surface functional groups were prepared for the investigation of the biosensing: (1) unmodified as-made devices, (2) devices fabricated with mPEG-SH SAMs formed on, and only on, the metal contact electrodes and, lastly, (3) devices with mPEG-SH SAMs on the metal contacts and a Tween 20 coating on the carbon nanotubes. Electrical conductance of these devices upon the addition of various protein molecules was monitored. While device type 1 showed a significant conductance change with protein adsorption, device type 2 with an mPEG-SH SAM on the metal electrodes did not give any conductance change, except in the case of the protein avidin. It was reported that the metal–nanotube interface or contact region is highly susceptible to modulation by adsorbed species [64]. Modulation of metal work function can alter the Schottky barrier of the metal–nanotube interface, thus leading to a significant change in the nature of contacts and, consequently, a change in the conductance of the devices.

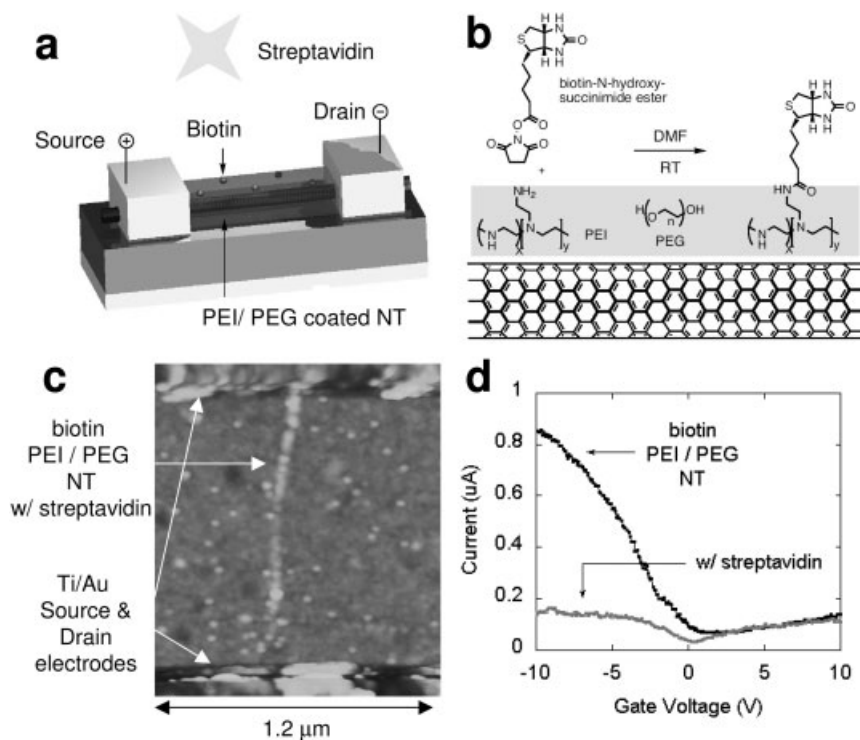

*In situ* detection of a small number of proteins by directly measuring the electron transport properties of a single SWNT has been reported by Nagahara and coworkers [96]. Cytochrome *c* (cytc) adsorption onto individual NTFET has been detected via the changes in the electron transport properties of the transistors. The adsorption of cytc induces a decrease in the conductance of the NTFET devices, corresponding to a few tens of molecules. This experiment was carried out by measuring the conductance versus electrochemical potential of the SWNT with respect to a reference electrode inserted in the solution, and observed a negative shift in the conductance versus potential plot upon protein adsorption. The number of adsorbed proteins has been estimated from this shift.

#### 1.4.4

#### Detection of Antibody–Antigen Interactions

Specific sensitivity can be achieved by employing recognition layers that induce chemical reactions and modify the transfer characteristics. In this two-layer architecture carbon nanotubes function as extremely sensitive transducers while the recognition layer provides chemical selectivity and prevents non-specific binding that is common for complex biological samples.

Following this design, nanotubes have been functionalized to be biocompatible and to be capable of recognizing proteins. This functionalization has involved noncovalent binding between a bifunctional molecule and a nanotube to anchor a bioreceptor molecule with a high degree of control and specificity. Star and co-workers have fabricated [97] NTFET devices sensitive to streptavidin using a biotin-functionalized carbon nanotube bridging two microelectrodes (source and drain, Fig. 1.9a). The SWNT in the NTFET device was coated with a mixture of two polymers, poly(ethyleneimine) and poly(ethylene glycol). The former provided amino groups for the coupling of biotin-*N*-hydroxysuccinimide ester (Fig. 1.9b) and the latter prevented the nonspecific adsorption of proteins on the functionalized carbon nanotube. Figure 1.9(c) shows an AFM image of the device after its exposure to streptavidin labeled with gold nanoparticles (10 nm). Lighter dots represent gold nanoparticles and indicate the presence of streptavidin bound to the

nanoparticles (10 nm in diameter). (d) Source-drain current dependence on gate voltage of the NTFET device based on SWNTs functionalized with biotin in both the absence and presence of streptavidin. (Adapted with permission from Ref. [97], © 2003, The American Chemical Society.)

biotinylated carbon nanotube. The source-drain current dependence on the gate voltage of the NTFET shows a significant change upon the streptavidin binding to the biotin-functionalized carbon nanotube (Fig. 1.9d). The experiments reveal the specific binding of the streptavidin, which occurs only at the biotinylated interface.

The mechanism of the biodetection was explained in terms of the effect of the electron doping of the carbon nanotube channel upon the binding of the charged streptavidin molecules. Dai and coworkers [98] have also analyzed specific antigen–antibody interactions using NTFET devices. In particular, they have studied the affinity binding of 10E3 mAbs antibody (a prototype target of the autoimmune response in patients with systematic lupus erythematosus and mixed connective tissue disease) to human auto antigen U1A.

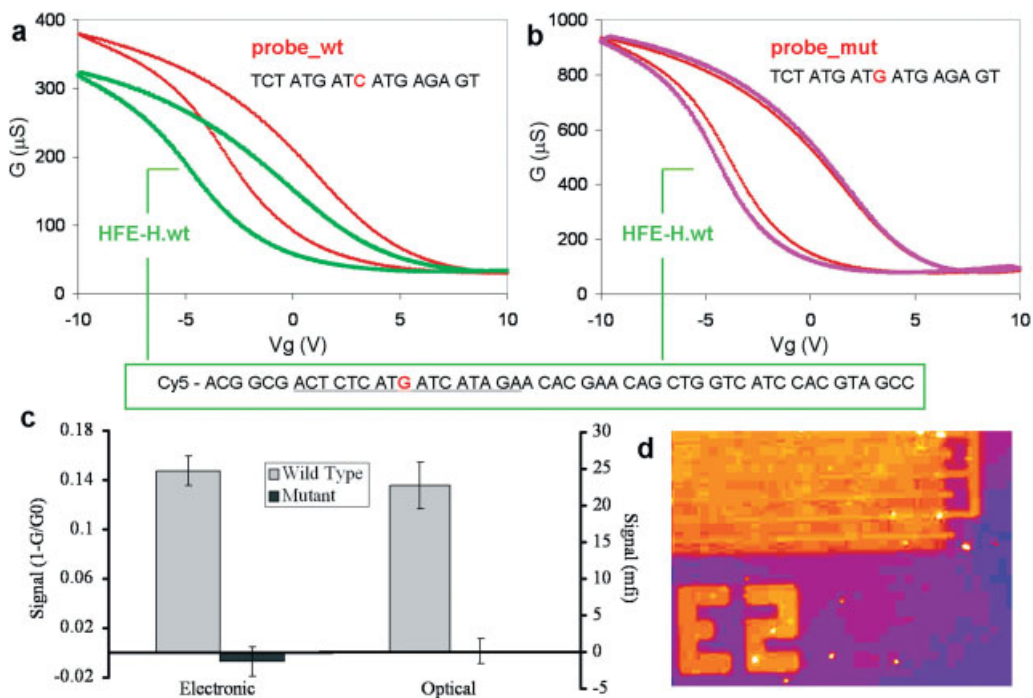

#### 1.4.5

#### DNA Detection

DNA biosensors based on nucleic acid recognition processes are quickly being developed towards the goal of rapid, simple and inexpensive testing of genetic and infectious diseases. To date, there are several reports on the electrochemical detection of DNA hybridization using multi-walled carbon nanotube (MWNT) electrodes [99]. Whereas electrochemical methods rely on the electrochemical behavior of the labels, measurements of the direct electron transfer between SWNTs and DNA molecules paves the way for label-free DNA detection (Fig. 1.10). To illustrate the practical utility of this new nanoelectronic detection method, an allele-specific assay to detect the presence of SNPs using NTFETs has been recently developed [100]. This DNA assay targeted the H63D polymorphism in the human HFE gene, which is associated with hereditary hemochromatosis, a common and easily treated disease of iron metabolism [101, 102].

DNA sensing mechanism using NTFETs has been recently explored by selective attachment of DNA molecules at different device segments. Tang et al. [103] have found that DNA hybridization on gold electrodes rather than on SWNT sidewalls is mainly responsible for NTFET detection due to Schottky barrier modulation. In another approach, DNA hybridization occurs on the surface at the gate of NTFET [104]. As a result, the conductance in SWNTs was changed through the gate insulators. In the work, the 5' end-amino modified peptide nucleic acid (PNA) oligonucleotides were covalently immobilized onto the Au surfaces of the back gate of NTFETs. PNA is a synthetic analog of DNA, in which both the phosphate and the deoxyribose of the DNA backbone are replaced by a polypeptide. PNA mimics the behavior of DNA and hybridizes with complementary DNA or RNA sequences, thus enabling PNA chips to be used in biosensors. The micro-flow chip was fabricated by using poly(dimethylsiloxane) (PDMS) prepolymer. The NTFET nano-sensor array was placed onto the PDMS chip in such a way that the PNA probe-modified Au side was positioned to face the open chamber for the introduction of solutions and the electrical measurements. A PNA probe with the base sequence 5'-NH<sub>2</sub>-ACC ACC ACT TC-3', which was fully complementary to the tumor necro-

responses in SNP detection assays. (d) Fluorescence microscopy image of the NTFET network device, with the electrodes 10 nm apart, after incubation with Cy5-labeled DNA molecules. (Adapted with permission from Ref. [100], © 2006, The National Academy of Sciences of the USA.)

sis factor- $\alpha$  (TNF- $\alpha$ ) gene sequence, was used as a model system. The base sequence for full complementary target DNA was 5'-GGT TTC GAA GTG GTG GTC TTG-3' while the non-complementary DNA oligonucleotide sequence was 5'-CCC TAA GCC CCC AA-3'.

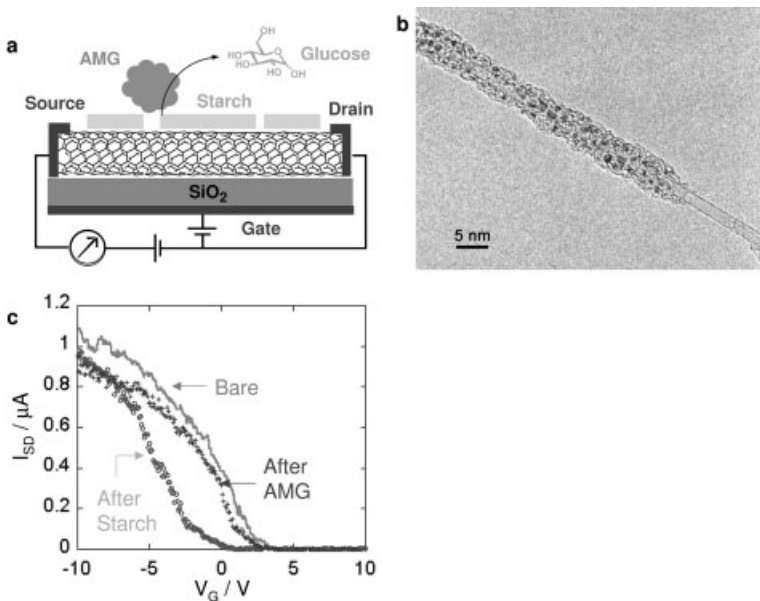

The electrical properties of the NTFET devices were measured at room temperature in air. First, the blank PBS solution was introduced into the PDMS-based micro flow chip, revealing that no substantial change in the source-drain current of NTFET was obtained. The current increased dramatically while monitoring in real time for about 3 h. The increase in conductance for the p-type NTFET device was consistent with an increase in negative surface charge density associated with binding of negatively charged oligonucleotides at the surface. DNA hybridization can be detected by measuring the electrical characteristics of NTFETs, and SWNT based FET can be employed for label-free, direct real time electrical detection of biomolecule binding.

## 1.4.6

**Enzymatic Reactions**

SWNTs can be made water soluble by wrapping in amylose (linear component of starch) [86]. These SWNT solutions are stable for weeks, provided nobody spits on them. Indeed, the addition of saliva, which contains  $\alpha$ -amylase, precipitates the nanotubes as the enzyme breaks amylose down into smaller carbohydrate fragments, finally resulting in the formation of glucose. The enzymatic degradation of starch has been recently monitored electronically using NTFETs [105]. Figure 1.11(a) shows the experimental setup used for this study. NTFET devices display transconductance and source-drain current–voltage characteristics typical of the p-type device behavior. The device characteristics, i.e., the source-drain current  $I_{SD}$  as a function of the gate voltage  $V_G$ , were measured to evaluate the effect of starch deposition and the subsequent enzymatic degradation of the starch layer on the carbon nanotubes.

Starch was deposited onto the FET by soaking the silicon wafer in a 5% aqueous starch solution and the device characteristics were found to be shifted by approxi-

**Fig. 1.11.** (a) NTFET device for electronic monitoring of the enzymatic degradation of starch with amyloglucosidase (AMG) to glucose. mately 2 V toward more negative gate voltages. The direction of the shift equates with electron doping of the nanotube channel by the polysaccharide. Quantitatively similar doping effects have been observed when carbon nanotube FET devices were exposed to  $\text{NH}_3$  gas, amines [106], poly(ethylene imine) (PEI) [107], and proteins [91]. After the enzyme-catalyzed reaction had been performed on the starch-functionalized devices and washed with buffer, the  $I_{\text{SD}}$  vs.  $V_{\text{G}}$  characteristics recovered almost completely to the trace recorded before starch deposition (Fig. 1.11). This indicates that, during the enzyme-catalyzed reaction, nearly all the starch deposited on the surface of the nanotube device is hydrolyzed to glucose which is washed off by the buffer prior to the electronic measurements.

#### 1.4.7

##### Glucose Detection

The diagnosis and management of diabetes mellitus requires a tight monitoring of blood glucose levels. Dekker and coworkers have demonstrated the use of individual semiconducting SWNT as a versatile biosensor [108]. The redox enzyme glucose oxidase ( $\text{GO}_x$ ) that catalyses the oxidation of  $\beta$ -D-glucose ( $\text{C}_6\text{H}_{12}\text{O}_6$ ) to D-glucono-1,5-lactone ( $\text{C}_6\text{H}_{10}\text{O}_6$ ) has been studied. The redox enzymes go through a catalytic reaction cycle where groups in the enzyme temporarily change their charge state and conformational changes occur in the enzyme that can be detected using NTFET devices.

In addition to pH sensitivity,  $\text{GO}_x$ -coated semiconducting SWNTs appeared to be sensitive to glucose, the substrate of  $\text{GO}_x$ . Figure 1.12 exhibits real-time measure-

**Fig. 1.12.** Real time electronic response of the NTFET sensor to glucose, the substrate of glucose oxidase ( $\text{GO}_x$ ). The conductance of a semiconducting SWNT with immobilized  $\text{GO}_x$  is measured as a function of time in 5  $\mu\text{L}$  milli-Q water. The conductance of the  $\text{GO}_x$ -coated SWNT increases upon addition of glucose to the liquid. Inset: (a) the same measurement on

a second device where the conductance was a factor of 10 lower; (b) the same measurement on a semiconducting SWNT without  $\text{GO}_x$ ; no conductance increase is observed in this case. (Reprinted with permission from Ref. [107], © 2003, The American Chemical Society.) (B) Schematic of  $\text{GO}_x$  immobilized on SWNT for electronic glucose detection.

ments where the conductance of a GOx-coated semiconducting SWNT in milli-Q water has been recorded in the liquid (left-hand arrow in each graph in Fig. 1.12). No significant change in conductance was observed as a result of water addition. When 0.1 M glucose in milli-Q water was added to the liquid (right-hand arrow in each graph), however, the conductance of the tube increased by about 10%. A similar 10% conductance change was observed for another device (Fig. 1.12a inset), which had a factor 10 lower conductance. Glucose did not change the conductance of the bare SWNT but did increase the device conductance after GOx was immobilized. Inset (b) of Fig. 1.12 shows such measurement on a bare semiconducting SWNT. These measurements clearly indicate that the GOx activity is responsible for the observed increase in conductance upon glucose addition, thus rendering such nanodevices as feasible enzymatic-activity sensors.

## 1.5

### Conclusion and Outlook

Recent advances in the rapidly developing area of biomolecule detection using carbon nanotube systems have been summarized here. SWNTs appear as structurally defined components for various electronic devices. The semiconductive properties of SWNTs are of special interest as these SWNTs have been applied to fabricate FETs for sensing applications. This area requires further development, particularly related to the fabrication of FETs based on individual SWNTs. The use of carbon nanotubes as nanocircuitry elements is particularly interesting. Biomaterials linked to nanotubes may be used as binding elements for the specific linkage of the nanotube to surface in the form of addressable structures.

Important chemical means to functionalize SWNTs with other electronic materials such as conductive polymers or nanoparticles is anticipated to generate materials of new properties and functions. The localized nanoscale contacts of SWNTs with bio-surfaces will be a major advance in understanding and exploring the new applications. The use of nanodevices to monitor various biologically significant reactions is envisioned. In future, it should be possible to connect the living cells directly to these nanoelectronic devices to measure the electronic responses of living systems. The combination of the unique electronic properties of SWNTs and catalytic features of biological system could provide new opportunities for carbon nanotubes based bioelectronics.

### Carbon Nanotube-based Sensor

*Jian-Shan Ye and Fwu-Shan Sheu*

#### 2.1

##### Overview

Carbon nanotubes (CNTs) possess high electrical conductivity, high chemical stability, and extremely high mechanical strength and modulus. These special properties of both single-walled carbon nanotubes (SWCNTs) and multiwalled carbon nanotubes (MWCNTs) have attracted much attention in electrochemistry. To develop nanostructured macroscopic electrodes, randomly dispersed nanotubes, well-aligned CNTs, CNT paste, screen-printing CNTs, self-assembly of CNT, and CNT-packaged microelectrodes have been used. Furthermore, single and long MWCNTs, after formation, can be used as a nanoelectrode. The resultant nanotube-based electrodes have been used successfully for electroanalytical purposes such as the development of sensors and biosensors. We outline here the unique electrochemical and electrocatalytical properties of CNTs-based sensors/biosensors and discuss novel applications as well as future challenge of CNTs in electrochemical sensors.

Functionalization of CNTs is one of the most active fields in nanotube research, which provides an effective tool to broaden the electrochemical application spectrum of CNTs. In this chapter, we summarize various approaches to functionalize CNTs for the development of novel electrochemical sensors. Particular emphasis is directed to the use of lipid-functionalized CNTs for sensors and biosensors and for the synthesis of photoswitched-functional devices. Functionalization of nanotubes generates a novel, interesting class of nanomaterials, which combines the properties of the nanotubes and the functional moiety, thus offering new opportunities in the development of electrochemical sensors.

#### 2.2

##### Introduction of Carbon Nanotubes

Carbon nanotubes (CNTs) have captured the imagination of researchers worldwide since they were first observed by Iijima in 1991 [1]. With 100× the tensile strength of steel, a thermal conductivity better than all but the purest diamond, and electrical conductivity similar to copper, but with the ability to carry much higher cur-

rents, CNTs are very interesting and promising nanomaterials. Their small dimensions, unique structures, strength, and remarkable physical properties make them a unique material with a wide range of potential applications.

CNTs, consisting of only  $sp^2$  hybridized carbon atoms, are cylindrical nanostructures with a diameter ranging from 1 nm to several nanometers, and a length of tens of micrometers. They are made of graphene sheets wrapped into a hollow cylinder and capped by fullerene-like structures. There are two typical types of nanotubes, SWCNTs and MWCNTs. The latter consist of several to tens of concentric cylinders of these graphitic shells with a layer spacing of 0.3–0.4 nm. MWCNTs tend to have diameters in the range 2–500 nm, depending on the method of synthesis. An MWCNT can be considered as a mesoscale graphite system, whereas a SWCNT is truly a large single molecule. High-resolution transmission electron microscope (HRTEM) results showed that the first observed CNTs by Iijima in 1991 [1] were fullerene-like tubes consisting of coaxial multiple shells. These tubes were MWCNTs. The interlayer spacing is 0.34 nm, which is slightly greater than that of graphite (0.335 nm) due to a combination of tubule curvature and van der Waals force interactions between successive graphene layers.

After two years, it was discovered that the use of transition metals as catalysts afforded CNTs with a single shell or wall only [2]. These nanotubes were SWCNTs. An ideal SWCNT can be viewed as an “extended” fullerene, and consists of a single graphite layer wrapped into one seamless hollow cylinder. Closure of the cylinder is the result of pentagon inclusion in the hexagonal carbon network of the nanotube walls during the growth process. SWCNTs normally have a narrow diameter distribution (with diameter of the order of 1 nm) but tend to assemble in nanotube bundles during the growth process [3]. This corresponds to the theoretically predicted lower limit for stable SWCNT formation based on considerations of the stress energy built into the cylindrical structure of the SWCNT.

There are three types of SWCNTs: “arm-chair” ( $n, m$ ) tubes where  $n = m$ , “zig-zag” ( $n, 0$ ) tubes and chiral (all other tubes with independent  $n$  and  $m$ ) tubes. Theoretical calculations indicate that the electronic properties for a single-walled nanotube will vary as a function of its diameter and helicity [4–6]. A SWCNT may behave as a semiconductor or metal, and a slight change in the chirality can transform a nanotube from a metal to a semiconductor. In general, about one-third of SWCNTs are metallic, characterized with wrapping vectors of  $n - m = 3l$  ( $l = 0, 1, 2, \dots$ ). All other tubes are semiconductors [7, 8].

Carbon–carbon covalent bonds are one of the strongest in nature, and a structure based on a perfect arrangement of these bonds oriented along the axis of nanotubes would produce an exceedingly strong material. Early theoretical work and recent experiments on individual nanotubes have confirmed that nanotubes are one of the stiffest structures ever made [9–11].

CNTs possess high electrical conductivity, high chemical stability, and extremely high mechanical strength and modulus. These special properties of both SWCNTs and MWCNTs have attracted much attention in electrocatalysis [12–17] and as chemical sensors/biosensors [18–24].

The present chapter only covers particular aspects related to CNTs-based electrochemical sensing systems. Different methods of preparing CNT electrodes and the

possible ways to functionalize CNTs are described, with the major part devoted to the use of lipid-functionalized CNTs for sensors and biosensors and for the fabrication of photoswitched-functional devices. Furthermore, the possible mechanism of electrocatalysis by CNTs is discussed.

### 2.3

#### Growth of Carbon Nanotubes

CNTs are generally produced by three main techniques, arc discharge, laser ablation, and chemical vapor deposition (CVD). The arc discharge method, initially used for producing  $C_{60}$  fullerenes, is the most common and perhaps easiest way to produce CNTs, as it is rather simple to undertake [25]. During arc discharge, a vapor is created by an arc discharge between two carbon electrodes with or without catalyst. Nanotubes self-assemble from the resulting carbon vapor. This technique produces a mixture of components and requires the separation of nanotubes from the soot and catalytic metals present in the crude product. In the laser ablation technique [26], a high-power laser beam impinges on a volume of carbon-containing feedstock gas (methane or carbon monoxide). Presently, laser ablation produces a small amount of clean nanotubes, whereas arc discharge methods generally produce large quantities of impure material. CVD is achieved by putting a carbon source in the gas phase and using an energy source, such as plasma or a resistively heated coil, to transfer energy to a gaseous carbon molecule. CVD nanotube synthesis is essentially a two-step process, consisting of a catalyst preparation step followed by the actual synthesis of the nanotube. The catalyst is generally prepared by sputtering a transition metal onto a substrate and then using either chemical etching or thermal annealing to induce catalyst particle nucleation. Thermal annealing results in cluster formation on the substrate, from which the nanotubes will grow. Excellent alignment, as well as positional control on the nanometer scale, can be achieved by using CVD [27, 28].

Even though much progress on CNT growth has been made in the past decade, it is still challenging to produce CNTs with desired properties for specific applications. In particular, new methods are desired that can be directly integrated into device fabrication. With continued effort in the development of growth techniques, it is expected that CNTs with desired properties, quality, and quantity could be obtained for various applications.

### 2.4

#### Methods to Prepare CNTs-based Sensors and Biosensors

##### 2.4.1

##### Individual MWCNTs as Nanoelectrodes

MWCNTs are tiny electrodes made of carbon, metals or semiconducting materials having typical dimensions of 1–100 nm. MWCNTs can be used as a new material for the construction of nanoelectrodes. Campbell et al. have reported the fabrica-

tion and characterization of electrodes constructed from single MWCNTs [29]. To construct a nanoelectrode, single nanotubes were attached to a mechanically cut Pt tip, using Ag epoxy, and subsequently cleaned by immersion in a fresh piranha solution (3:1 concentrated  $\text{H}_2\text{SO}_4$ :30%  $\text{H}_2\text{O}_2$ ). The sigmoidal voltammetric response of these nanotubular electrodes is characteristic of steady-state radial diffusion. The limiting current of uninsulated electrodes scales linearly with the depth of immersion into electrolyte solutions. However, the walls of nanotubular electrodes can be selectively insulated with a thin layer of polyphenol so that electrochemical activity is limited to the tip region. In this case the limiting current is essentially independent of immersion depth. These nanotubular electrodes are robust, can be fabricated in high yield, and are of uniform diameter. Most importantly, their great strength and high length-to-diameter aspect ratio will be particularly valuable for applications such as scanning electrochemical microscopy (SECM) and electrochemical analysis of biological materials.

#### 2.4.2

##### **Randomly Distributed CNT Electrodes**

To prepare CNT electrodes, randomly distributed CNTs can be casted at the surface of the electrode. Before casting, the concentrated solutions of CNTs in sulfuric acid [20], dimethylformamide [30], concentrated nitric acid, or a Nafion/water mixture [31] are prepared. Coated electrodes were are at high temperature (e.g., 200 °C for 3 h) and then readied for use after careful washing. The randomly deposited CNTs are less mechanically stable and have worse electrical contact to the underneath electrodes than the vertically aligned CNTs directly grown on conductive substrates.

#### 2.4.3

##### **Well-aligned Carbon Nanotube Electrodes**

To construct a CNT electrode, SWCNTs are shaped into an electrode by filtering suspension of nanotubes on a membrane filter [32] to form a nanotube sheet. Another method is casting the SWCNT suspension on the surface of solid electrodes such as Pt, Au, or glassy carbon [33–36]. In contrast, to construct a MWCNT electrode, the MWCNTs are usually mixed with bromoform [12], mineral oil [15], or packed into the cavity at the tip of a microelectrode to form a CNT powder microelectrode [36] as discussed above. MWCNT electrodes prepared by these methods may suffer from mechanical instability during detection, thus limiting their practical application. Fortunately, high-density well-aligned CNTs, which are multi-walled and vertically aligned on a large area of substrates (Fig. 2.1), can be readily synthesized [37, 38]. These CNTs aligned on the substrate are very stable and can be used as photoswitched functional devices [39], electrochemical sensors/biosensors [40–44] and supercapacitors [45]. In particular, this well-aligned MWCNT electrode has been successfully used as a novel candidate for non-enzymatic glucose sensors with the resistance to toxicity by chloride ions [46].

#### 2.4.4

##### Carbon Nanotube Paste Electrodes

Carbon paste electrodes (CPEs) belong to a special group of heterogeneous carbon electrodes. To prepare CPEs, carbon paste, i.e., a mixture prepared from carbon (graphite) powder and a suitable liquid binder is packed into a suitably designed electrode body. CNT-based CPEs were first reported by Britto et al. [12]. To study the electrochemical response, nanotubes were initially dispersed in bromoform as a binder material and packed into a glass tube. The resultant electrode had randomly distributed tubes with no control over the alignment of the nanotubes. Subsequently, numerous approaches have enabled the random distribution of nanotubes on electrodes, either by dispersing the tubes with a binder, such as dihexadecyl hydrogen phosphate [47], Nafion [21], or forming the nanotube equivalent of a carbon paste [48, 49] that can be screen printed [50], forming a nanotube/Teflon composite [22].

Due to numerous advantageous properties and characteristics, CPEs are widely used in amperometry, coulometry, and potentiometry. CNTs-based CPEs are easily obtainable at minimal costs and are especially suitable for preparing an electrode materials with desired composition and, hence, with pre-determined properties. Electrodes made in this way are usually intended to be used as highly selective sensors and/or biosensors for both inorganic and organic electrochemistry. The rapid development of new nanomaterials and nanotechnologies has provided many new opportunities for electrochemical application. In particular, the immobilization and adsorption of biomolecules on electrode surfaces is of great importance and interest for biosensor and bioelectronic applications. Recent studies have demonstrated that CNTs can enhance the electrochemical reactivity of biomolecules and promote the electron-transfer reactions of proteins. These properties make CNTs an efficient material for use in a wide range of electrochemical biosensors, ranging from amperometric enzyme electrodes to DNA hybridization biosensors. Rubianes and Rivas have recently described the performance of CNT paste electrodes prepared by dispersion of MWCNTs within mineral oil [48]. The resulting paste electrode shows excellent electrocatalytic activity toward ascorbic acid, uric acid, dopamine,

3,4-dihydroxyphenylacetic acid (dopac) and hydrogen peroxide. These properties permit an important decrease in the overvoltage for the oxidation of ascorbic acid (230 mV), uric acid (160 mV) and hydrogen peroxide (300 mV) as well as a dramatic improvement in the reversibility of the redox behavior of dopamine and dopac, in comparison with classic carbon (graphite) paste electrodes (CPE). The substantial decrease in the overvoltage of the hydrogen peroxide reduction (400 mV) associated with a successful incorporation of glucose oxidase (GOD) into the composite material allows the development of a highly selective and sensitive glucose biosensor, without using any metal, redox mediator, or anti-interference membrane. Such excellent performance of CNTPEs toward hydrogen peroxide, represents a very good alternative for developing other enzymatic biosensors. To determinate homocysteine, Lawrence et al. [51] have provided an effective means by using a CNT paste electrodes. A decrease of ca. 120 mV in the overpotential for the oxidation of homocysteine, compared with a traditional carbon paste electrode, is reported along with greatly enhanced signal-to-noise characteristics. The analytical parameters have been assessed with a linear range from 5 to 200  $\mu\text{M}$ , and a detection limit of 4.6  $\mu\text{M}$ . Furthermore, the generic nature of this increased reactivity of the CNT surface towards thiol moieties has been demonstrated with cysteine, glutathione, and n-acetylcysteine, providing a greatly enhanced electrochemical response compared with the carbon paste electrode. Pedano et al. have reported that CNTs paste electrodes are suitable for adsorptive stripping potentiometric measurements of trace levels of nucleic acids [52]. Compared with that obtained at carbon (graphite) paste electrode (CPE), the guanine oxidation signal is greatly enhanced due to the electroactivity inherent to CNTs. Trace ( $\mu\text{g L}^{-1}$ ) levels of the oligonucleotides and polynucleotides can be readily detected following short accumulation periods, with detection limits of 2.0  $\mu\text{g L}^{-1}$  for a 21-base oligonucleotide and 170  $\mu\text{g L}^{-1}$  for calf thymus dsDNA.

SWCNTs have also been used for the development of CPEs. Ricci et al. have used Prussian blue modified-SWCNTs for successive assembling of paste electrodes [53]. The electrochemical feature of such electrodes has been fully evaluated with cyclic voltammetry (CV) and amperometric experiments. The result showed that Prussian blue-modified CNT paste electrodes have a high sensitivity towards hydrogen peroxide with a detection limit of  $7.4 \times 10^{-6}$  M. The Prussian blue-modified CNT paste electrode also possessed strong stability even at basic pHs (i.e., pH 9 and 10), demonstrating no significant loss of signal after three days continuous work. In addition, the loading in the paste mixture of GOD has brought a sensitive tool for the detection of glucose in a range between 0.1 and 50 mM. More recently, Antiochia et al. have studied the electrocatalytic oxidation of NADH at SWCNT CPEs for use in a redox mediator in solution and dissolved in the paste [54].

#### 2.4.5

#### Screen-printing Carbon Nanotubes

Screen-printing technology is particularly attractive for the production of disposable sensors [50]. Recently, Trojanowicz et al. have successfully prepared CNT-

modified screen-printed electrodes for chemical sensors and biosensors [55]. They found that MWCNTs can be used to modify working graphite ink electrodes of the three-electrode screen-printed sensing stripe. Modification has been made by evaporating on the graphite surface a solution of MWCNT in dimethylformamide. The effect of such treatment on reversibility of the electrode process of the system hexacyanoferrate(II)/(III) has been shown, along with an improvement in sensitivity of detection of the pesticide paraoxon with biosensors containing organophosphorus hydrolase immobilized by adsorption on the nanotube-modified graphite ink electrode. The catalytic sensing of methanol has also been demonstrated with the use of a screen-printed sensor modified with MWCNT and Co(II) salt present in the measuring solution. More recently, Guan et al. have prepared a disposable electrochemical biosensor for glucose monitoring [56]. The sensor was based on MWCNTs immobilized with GOD upon a screen printed carbon electrode. The effect of MWCNTs on the response of amperometric GOD electrodes for glucose was examined. Results obtained, of interest for basic and applied biochemistry, represent a first step in construction of a MWCNT-enzyme electrode biosensor with potential application in the biosensor area.

#### 2.4.6

#### **Self-assembly of Carbon Nanotubes**

Self-assembly is the fundamental principle that generates structural organization on all scales from molecules to galaxies. Self-assembly is also a manufacturing method used to construct things at the nanometer scale. The conjugation of CNT with biomolecules and nanoparticles is an emerging field of research that has important potential applications in bionanotechnology. For example, the metallic/semiconductive properties of CNTs have been exploited to produce functional, technologically relevant devices such as sensors [57]. Electrostatic matching can be used to coat CNTs with layers of oppositely charged polyelectrolytes [58]. By using a similar strategy, Mann and his colleagues [59] have described a layer-by-layer procedure based on programmed biomolecular assembly to produce a multi-component, multi-layered CNT-based conjugate. The conjugate consists of a multi-walled CNT core coated with four functionalized layers that successively comprise protein-encapsulated iron oxide nanoparticles [biotinylated ferritin (bFn)], the tetra-valent biotin-binding protein, streptavidin (SA), 24-base three-stranded biotin-terminated oligonucleotide duplexes, and oligonucleotide coupled Au nanoparticles. They demonstrated that the core/multi-shell architecture can be constructed stepwise by specific recognition processes involving biotin–SA binding or DNA duplexation, and that these interactions can be exploited for reversible assembly/disassembly of the Au nanoparticle layer. A recent study showed that CNTs can be self-assembled at the electrode surface for the development of a sensor and biosensor.

Shimoda et al. have reported the formation of macroscopically ordered CNT membranes on a substrate by self-assembly [60]. To form the ordered SWCNTs, SWCNTs produced by the laser ablation method and purified by reflux and filtra-

tion were chemically etched to short bundles by ultrasonic-assisted oxidation. After removing the acid by filtration, the processed SWCNTs were dispersed in deionized water. A thin film appears on the surface of a soaked glass substrate in the SWCNTs/water dispersion with natural vaporization of water. Transmission electron microscopy measurements show that the SWCNT bundles are uniaxially aligned. The self-assembly of SWCNTs at gold electrodes can also be achieved by thiolation [61]. Recently, effective CNT coating was obtained by self-assembling short SWCNTs at an electrode surface [23, 24]. Such vertically aligned SWCNTs act as molecular wires to allow electrical communication between the underlying electrode and a redox enzyme. Direct electron transfer between the prosthetic group of the enzyme and an electron surface obviates the need for redox mediators and is thus extremely attractive for developing reagentless sensing devices. More recently, Wang and Iqbal have reported that thin films of vertically aligned individual SWCNTs can be deposited on silicon using a CVD process [62]. Oriented SWCNT growth was achieved by employing two methods of catalyst precursor self-assembly followed by ethanol CVD. Using the silicon substrate as the working electrode in an electrochemical cell and the enzyme beta-NAD (nicotinamide adenine dinucleotide) synthetase dissolved in a buffered electrolyte solution, the enzyme was attached at the nanotube ends. This was shown using scanning electron microscopy and cyclic voltammetry. Enzyme immobilization on the 1 to 2 nm diameter tube ends of the individual SWCNTs allows for dense packing of the enzyme and utilization of the electrode as an enzymatic sensor in a biofuel cell configuration.

#### 2.4.7

#### **Carbon Nanotube-packaged Microelectrodes**

Packaged microelectrodes are easy to prepare and have been successfully used to prepare electrodes. To fabricate CNT powder microelectrodes, a 76- $\mu\text{m}$  diameter Pt microelectrode was first chemically etched to form a cavity of 10  $\mu\text{m}$  deep, and the etched tip was then grounded on a flat plate (such as glass slide) with CNTs until the micro cavity was filled with CNTs [63, 64]. In this way, the direct electrochemistry of redox enzymes such as GOD [64], horseradish peroxidase [65], as well as the electrocatalytic detection of nitrite [66], cysteine [67], and hydrazine [63] have been reported.

### 2.5

#### **Application of CNTs-based Electrochemical Sensors and Biosensors**

##### 2.5.1

#### **Electrochemical and Electrocatalytical Properties of Carbon Nanotubes**

CNTs combine, uniquely, high electrical conductivity, high chemical stability, and extremely high mechanical strength. These special properties of both SWCNTs

and MWCNTs have attracted the interest of many researchers in the field of electrochemical sensors. Many advances in producing, modifying, characterizing and integrating CNTs into electrochemical sensing systems have been achieved [68]. CNTs, new materials for electrochemical sensing, can be either used as single probes after formation *in situ*, or even individually, when attached onto a proper transducing surface after synthesis. Both SWCNTs and MWCNTs can be used to modify several electrode surfaces in either vertically oriented “nanotube forests” or even a non-oriented way. They can be also used in sensors after mixing them with a polymer matrix to form CNT composites [69].

To find new electrocatalytic surfaces, a suitable electrode substrate, such as glassy carbon or gold, is modified with a film or layer of CNTs. Several methods have achieved the electroanalysis of different analytes by using CNT modified electrodes. Benefits of low detection limits, increased sensitivity, decreased overpotentials and resistance to surface fouling are found by these CNTs-based electrodes [69].

Electrochemistry implies the transfer of charge from one electrode to another. Due to the curvature of the carbon graphene sheet in nanotubes, the electron clouds change from a uniform distribution around the C–C backbone in graphite to an asymmetric distribution inside and outside the cylindrical sheets of the nanotube [70]. Because the electron clouds are distorted, a rich  $\pi$ -electron conjugation forms outside the tube, therefore making CNTs electrochemically active (Fig. 2.2).

There are numerous reports of CNT-modified electrodes for the detection of different analytes with low detection limits, decreased overpotentials, and resistance to surface fouling. However, the exact reason for the unique catalytic properties of CNTs remains unknown. In this regard, Compton and his colleagues [71, 72] addressed the question as to why CNTs are catalytic and provided definitive evidence for their electrocatalytic properties. They explored the reduction of the one-electron aqueous redox probe ferricyanide at a CNT film-modified basal plane pyrolytic graphite (BPPG) electrode and compared it with a bare BPPG electrode. Peak-to-

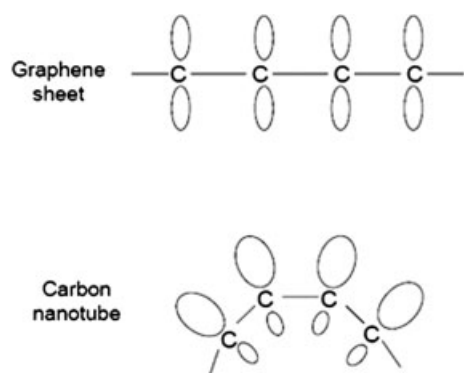

Fig. 2.2. Schematic of the electron distribution along a graphene sheet and around a carbon nanotube (CNT).

peak separations of 58 and 350 mV, respectively, were observed; the peak-to-peak separation is an indication of the heterogeneous charge transfer kinetics, showing that, in this case, CNTs exhibit fast electron transfer [71]. They further compared the electrocatalytic properties of CNTs with an edge plane pyrolytic graphite electrode (EPPG). EPPG electrodes are fabricated by taking a piece of high quality, highly ordered pyrolytic graphite (HOPG) and cutting the desired electrode geometry such that the layers of graphite lie perpendicular to the surface. Conversely, BPPG electrodes are produced by cutting the electrode geometry such that the graphite layers lie parallel to the surface. For voltammetry of ferricyanide at the EPPG electrode, a peak-to-peak separation of 78 mV was observed, suggesting that the electrochemical reaction occurs with a not dissimilar rate constant as at the CNT-modified surface. The slight difference in peak-to-peak separation of the CNTs compared with EPPGs probably reflects the slight impurities at the basal plane in the EPPG electrode. A catalytic response was also seen for the electrochemical oxidation of epinephrine where identical responses were obtained at both the CNT modified electrode and the EPPG; again, slow electrode kinetics was observed at a bare BPPG electrode. Indeed, it has been well documented that the electrode kinetics at EPPG electrodes are at least three times faster than at BPPG electrodes [73], but, seemingly, this was the first comparative approach to provide evidence for electrode kinetic enhancements at CNTs. Edge plane sites/defects are consequently introduced on the electrode surface, resulting in faster electron transfer. This occurs to the point that, after roughening for about a minute, a nearly identical response to that of the EPPG electrode can be observed. This clearly shows that edge plane sites are the dominant sites at which fast electron transfer occurs [74, 75]. The above experiments suggest that edge plane-like sites, which in CNTs occur at the ends and along the tube axis (where graphite sheets terminate at the surface of the tube), are likely to be the reason why nanotubes exhibit fast heterogeneous charge transfer, and explains why they have been widely reported as “electrocatalytic” in the electrochemical literature (Fig. 2.3) [72].

To understand the nature of the electrocatalytic properties and the electrochemical reactivity of CNT, Wang’s group [76] studied the effect of electrochemical pretreatment on CNTs prepared by different processes. They found that anodic pretreatment results in a dramatic improvement in the electrochemical reactivity of ARC-produced CNT, whereas CNTs produced by CVD appear to be resistant to anodic activation. Such a dramatic difference in the pretreatment effect upon ARG and CVD-produced CNTs is illustrated using NADH, ascorbic acid, hydrazine and hydrogen peroxide model redox systems. Differences in the effect of the electrochemical pretreatments are attributed to the anodic preanodization, effectively “breaking” the basal-plane end caps of ARC-CNT, thereby exposing edge plane defects, similar to those already present in the open-end caps of CVD-CNTs. In contrast, Gooding and his colleagues [77] demonstrated the importance of oxygenated species at the ends of CNTs for their favorable electrochemical properties. Definitive evidence is presented for the favorable electrochemical properties of CNT-modified electrodes arising from the ends of SWCNTs due to oxygenated carbon species in general, and carboxylic acid moieties in particular, produced during

**Fig. 2.3.** Schematic representation of the possible variants of CNTs. In both the bamboo and herringbone variations, graphite planes are formed at an angle to the axis of the tube and, therefore, these CNTs have a higher proportion of edge plane sites/defects. (Adapted from Ref. [72] with permission.)

acid purification. Interestingly, large amounts of well-aligned CNTs with open tips have been produced recently by pyrolysis of iron(II) phthalocyanine [78]. The aligned CNTs have an average length of about 10  $\mu\text{m}$  and diameters ranging from 92 to 229 nm. Some of the produced CNTs showed Y-junction structures due to the self-joint growth of two neighboring CNTs. The well-aligned CNTs indicated a bamboo-shaped multiwalled structure and fairly good crystallinity. Availability of the CNTs with open tips will make it possible to further study the electrocatalytic nature of CNTs.

### 2.5.2

#### CNTs-based Electrochemical Biosensors

For use as amperometric enzyme electrodes or DNA hybridization biosensors, CNTs need to be coupled with enzymes or ssDNA probes, respectively. Gooding and his colleagues have successfully self-assembled short SWCNTs to an electrode [24]. The vertically aligned SWCNTs act as molecular wires to allow electrical communication between the underlying electrode and a redox enzyme [23, 24] (Fig. 2.4). Such direct electron transfer between the prosthetic group of the enzyme and an electron surface makes it possible to develop reagentless sensing devices. The direct electron transfer of oxidases and dehydrogenases at CNT-modified electrodes and the dramatic decrease of the overpotential of hydrogen peroxide and NADH indicate great promise for the biosensing of glucose, lactate, cholesterol, amino acids, urate, pyruvate, glutamate, alcohol, hydroxybutyrate, etc. For example, CNT/Nafion/GOD-coated electrodes, coupling the selective reactivity of GOD to glucose with the electrocatalytic detection of hydrogen peroxide and the permselectivity of Nafion, offered a highly selective low-potential (0.05 V vs.  $\text{Ag}|\text{AgCl}$ ) biosensing of glucose [21]. More interestingly, Lin and coworkers [79] reported glucose biosensors based on GOD covalently attached at the free end of vertically-aligned CNTs, which have been grown on a metal-coated silicon substrate. They

**Fig. 2.4.** Nanoforest of vertically aligned CNT-trees acting as molecular wires. (Adapted from Ref. [24] with permission.)

detected the reduction current of hydrogen peroxide, instead of the oxidation current, at a very low potential ( $-0.2$  V vs. saturated calomel electrode). The low-potential reductive detection of the hydrogen peroxide led to a highly selective amperometric monitoring of the glucose substrate, along with linearity up to  $30$  mM, and a detection limit of  $0.08$  mM. Different from GOD, dehydrogenase-based amperometric devices based on the co-immobilization of dehydrogenases and their  $\text{NAD}^+$  cofactor to electrodes for the biosensing of important substrates such as lactate, alcohol or glucose have also been described [69]. Oxidation of the product (i.e., NADH) serves as the anodic signal and regenerates the  $\text{NAD}^+$  cofactor. Therefore, CNT-modified electrodes, offering an accelerated electron transfer of NADH along with minimization of surface fouling associated with the accumulation of NADH oxidation product [20], provide great promise as dehydrogenase-based enzyme electrodes. For example, Wang and Musameh have reported a low-potential stable detection of ethanol based on the co-immobilization of alcohol dehydrogenase and its  $\text{NAD}^+$  cofactor within a CNT/Teflon matrix [80]. Similar advantages are expected for the biosensing of lactate or glucose in connection with lactate or glucose dehydrogenase, respectively [69]. Deo et al. [81] have reported an amperometric biosensor for organophosphorus (OP) pesticides based on a CNT-modified transducer and an organophosphorus hydrolase (OPH) biocatalyst. To prepare the CNT/OPH biosensor, a bilayer approach with the OPH layer atop of the CNT film was used. The CNT layer leads to a greatly improved anodic detection of the enzymatically generated p-nitrophenol product, including higher sensitivity and stability. The biosensor was used to measure as low as  $0.15$   $\mu\text{M}$  paraoxon and  $0.8$   $\mu\text{M}$  methyl

parathion, with sensitivities of 25 and 6 nA  $\mu\text{M}^{-1}$ , respectively. Li et al. have studied a CNT-modified biosensor for monitoring total cholesterol in blood [82]. The sensor consists of a carbon working electrode and a reference electrode screen-printed on a polycarbonate substrate. Cholesterol esterase, cholesterol oxidase, peroxidase, and potassium ferrocyanide were immobilized on the screen-printed carbon electrodes. MWCNTs were added to prompt electron transfer. Experimental results show that the CNT-modified biosensor offers a reliable calibration profile and stable electrochemical properties.

The remarkable electrocatalytic activity of CNTs, together with the ability to modify CNTs for accumulating important biomolecules, make them extremely attractive for a wide range of electrochemical biosensors, ranging from enzyme-based electrochemical biosensors to DNA hybridization biosensors [69]. CNT-based electrochemical biosensors combine the specificity of enzymes with the electrocatalytic ability of nanotubes, and are expected to be extremely useful for clinical diagnostics and environmental monitoring.

### Functionalization of CNTs

#### 2.6.1

##### Biological Functionalization of CNTs

Biological functionalization of CNTs has come to be of significant interest in recent years due to the possibility of developing sensitive and ultrafast detection systems in biomedical sciences and biotechnological application. CNTs functionalized with biological assays could be the key to novel nano-biosensing techniques. Functionalization of CNT surfaces using proteins and antibodies could enable specific interactions and selective binding to target biomolecules with a very low sample size, often approaching a single protein. Alteration of the surface chemistry of their sidewalls can lead to covalent functionalization and, hence, to their potential application in drug delivery and chemical and biochemical sensing applications [83]. The functionalization of CNTs with proteins like streptavidin and biotin with the help of a polymer coating with poly(ethylene glycol) (PEG), and covalent interactions with its amine-terminated variant, has been demonstrated [84]. Since all the atoms in CNTs are surface atoms, binding proteins or antibodies to surfaces can greatly affect their surface states and, thus, their electrical and optical properties. This effect can be exploited as a basis for detecting biological surface reactions in a single protein or antibody attached to CNT surfaces.

#### 2.6.2

##### Self-assembly of Surfactant and Lipid Molecules at CNTs

Surfactant adsorption at interfaces has been widely studied because of its importance in detergents, lubrication, and colloid stabilization [85]. CNTs are insoluble

in organic solvents and in water, which at present considerably restricts their areas of use. To enhance the solubility of CNTs, detergents are mixed and shaken with nanotubes to form stable suspensions [86]. The chemical adsorption of SDS molecules on the surface of the nanotubes creates a distribution of negative charges that prevents their aggregation and induces stable suspensions in water. The SDS molecules can be oriented perpendicularly to the surface of the nanotube, forming a monolayer. The molecular organization of surfactant at the solid–liquid interface can be (a) the hydrophobic part of SDS is adsorbed on the graphite by van der Waals interactions, likely following the carbon network, and (b) the hydrophilic part of the surfactant is oriented toward the aqueous phase, forming half-cylinders on the surface of the graphite plane [87]. Because CNTs are rolled-up graphene sheets, the SDS molecules may form similar half-cylinders on the surface of the tubes, either oriented parallel or perpendicularly to the tube axis.

The self-assembly of lipids at metallic–aqueous interfaces has been well studied. To determine whether lipid molecules could adsorb and self-organize on CNTs, creating stable assemblies, Richard et al. have designed and synthesized new reagents that form lipidic “rings” made up of supramolecular half-cylinders [88]. TEM results indicated the formation of supramolecular assemblies of these molecules on the surface of the nanotubes. To explore the possibility of functionalizing the surface of CNTs in a noncovalent but permanent way with different reagents, the self-assembly of a series of molecules made of a double lipidic chain was further tested. In contrast to the single-chain lipids, no organization was detected by TEM when an aqueous solution ( $1 \text{ mg mL}^{-1}$ ) of the second series of molecules was directly sonicated with 1 mg of MWCNTs. To investigate whether micelles are necessary to form these supramolecular assemblies, the MWCNTs were sonicated in the presence of mixed micelles. TEM observations showed perfectly organized striations on the CNTs. The size of the striations, determined by TEM, varied from 55 to 75 Å, in perfect agreement with the length of the different lipidic chains. These results are also coherent with a half-cylinder arrangement of the double-chain lipids on the surface of the nanotubes. Hence, the formation of micelles appears to be a key step for the formation of supramolecular assemblies on the CNT surface. This process constitutes a simple, versatile protocol for the non-covalent functionalization of nanotubes.

One of the most exciting applications of CNTs is in the exploration of proteins and cells in aqueous solution. Few of these applications have yet been realized, because of the incompatibility of the CNT surface, which is hydrophobic and prone to nonspecific bioadsorption with biological components such as cells and proteins. In addition, the aqueous environment required for biological materials is not suitable for unfunctionalized CNTs [89]. In nature, cells are faced with a similar challenge of resisting nonspecific biomolecule interactions while engaging in specific molecular recognition. These functions can be simultaneously fulfilled by mucin glycoproteins, defined by their dense clusters of O-linked glycans. Zettl and associates [90] have described a biomimetic surface modification of CNTs using glycosylated polymers designed to mimic natural cell-surface mucins. A  $C_{18}$  lipid at one end of a mucin-mimic polymer is introduced to enable surface modification of

CNTs. Lipids self-assemble on the surface of CNTs through hydrophobic interactions in the presence of water [88] and lipid functionalized glycopolymers form ordered arrays on graphite surfaces [91]. The lipid-functionalized mucin-mimic is self-assembled on CNTs in a similar manner as the organization of native mucins in the cell membrane, with the glycosylated polymers projecting into the aqueous medium. CNTs modified with mucin-mimics were soluble in water, resisted non-specific protein binding, and bound specifically to biomolecules through receptor–ligand interactions. This strategy for biomimetic surface engineering provides a means to bridge CNTs and biological systems.

Several successful strategies using covalent or noncovalent chemistry have been applied to functionalize the sidewall of CNTs. Among these, noncovalent methods are attractive as they may preserve the inherent properties of the nanotubes [88, 92]. Supported bilayer lipid membranes (s-BLMs) have attracted increasing interest due to their potential application as electrochemical biosensors, molecular devices, and for investigating the photoinduced electron transfer in biomembranes [93, 94].

Recently, we [39] successfully self-assembled s-BLM on the surface of MWCNTs using Tien's method [94, 95]. The CV responses of BLMs-coated MWCNTs in PBS were studied. At bare MWCNT electrodes, a large background current  $i$  (in the range of  $10^{-5}$  A) was observed. When the MWCNT electrodes were coated with BLMs, the background current was dramatically reduced to the range of  $10^{-9}$  A, indicating a strong insulation effect of the lipids assembled on the surface of the MWCNTs. Since the membrane capacitance ( $C_m$ ) can be obtained from the background current of the CV ( $C_m = i/v$ ), the thickness of lipid membrane  $T_m$  on MWCNTs can be calculated from  $T_m = 2.2\epsilon_0 A/C_m$  ( $\epsilon_0$ : vacuum dielectric permittivity,  $A$ : surface area).  $T_m$  was thus calculated to be about 4.38 nm, which is approximately double the molecular size of phosphatidylcholine – consistent with a bilayer structure of the lipid membrane [94]. The static water contact angles on the surface of MWCNTs were measured to be  $6\text{--}7^\circ$ , indicating a hydrophilic property of the MWCNT surface. The bilayer lipid membrane can thus be formed with the hydrophilic moiety of one lipid layer absorbed on the surface of MWCNTs, and that of another lipid layer faced to the testing PBS solution. This result agrees with that reported by Kanyó et al. [96] but differs from that found by Richard et al. [88]. Kanyó et al. reported that the surface of MWCNTs, without heating treatment, were hydrophilic [96]. In contrast, Richard et al. reported that a monolayer of synthetic lipid was self-assembled at the surface of CNTs, in which the van der Waals interaction between the hydrophobic part of lipid and the carbon network was suggested [88]. The different hydrophilicity reported may come from the different fabrication methods of the CNTs. When MWCNTs were synthesized from the chemical source of ethylenediamine, chemical elemental analysis indicated that 1.8–2.8% nitrogen existed in the MWCNTs used in the present study [37]. Functional groups containing nitrogen on the MWCNT surface may contribute partly to the hydrophilic property on the MWCNTs synthesized and used here. In addition, it is known that the carbon shell (i.e., each carbon shell of the MWCNT) is closed by various functional groups, most frequently by COOH, –OH, and CO groups. For MWCNTs, the outer shell may often contain discontinuous spots of

imperfection. These local vacancies could also be closed by the functional groups mentioned above [96]. Possibilities exist for these functional groups to confer the hydrophilic surface of the MWCNTs.

### 2.6.3

#### Electrochemical Functionalization of CNTs

The electrochemical functionalization of CNTs has opened up new opportunities to fabricate novel nanostructures by improving both their solubility and processibility. Small-diameter (ca. 0.7 nm) SWCNTs are predicted to display enhanced reactivity relative to larger-diameter nanotubes due to increased curvature strain. Bahr et al. have described the derivatization of these small-diameter nanotubes via electrochemical reduction of various aryl diazonium salts [97]. The estimated degree of functionalization is as high as one out of every 20 carbons in the nanotubes bearing a functionalized moiety. The functionalizing moieties can be removed by heating in an argon atmosphere. Nanotubes derivatized with a 4-*tert*-butylbenzene moiety possessed significantly improved solubility in organic solvents. Functionalization of the nanotubes with a molecular system holds strong promise as useful building blocks for the construction of novel hybrids for nano-sensor applications.

Electrochemical functionalization of CNTs is a selective, clean, and nondestructive chemical method. But it meets difficulties in homogeneous electrografting of SWCNTs in large quantities because the reaction is often localized on a very thin film (ca. 2  $\mu\text{m}$ ). To solve this problem, Zhang et al. have utilized a room-temperature ionic liquid (RTIL)-supported three-dimensional network SWCNT electrode [98]. In their work, large quantities of SWCNTs were considerably untangled in RTILs so as to greatly increase the effective area of the electrode. *N*-Succinimidyl acrylate (NSA), as a model monomer, was dissolved in the supporting RTILs and was electrografted onto SWCNTs (SWCNTs-poly-NSA). As an application example, GOD was covalently anchored on the SWCNT-poly-NSA assembly, and the electrocatalytic oxidation of glucose in this assembly was investigated. RTILs have opened a new path in electrochemical functionalization of CNTs. Recently, we studied the effect of electrochemical oxidation in 0.2 M  $\text{HNO}_3$  for MWCNTs [99]. Scanning electron microscope (SEM) and transmission electron microscope (TEM) images reveal that electrochemical oxidation increases the specific area of MWCNTs by cutting off the nanotube tips. Cyclic voltammetry and constant current charging/discharging was used to characterize the behavior of electrochemical double layer capacitors (EDLCs) of the oxidized MWCNTs in 1.0 M  $\text{H}_2\text{SO}_4$ . The specific capacitance of the oxidized-MWCNTs was remarkably improved. Electrochemical oxidation is, hence, an effective way to improve the performance of MWCNT electrodes in EDLC application. More recently, electrochemical nitration of self-assembled SWCNT sheets with  $-\text{NO}_2$  groups was achieved [100]. A SWCNT sheet, used as the working electrode in 6 M aqueous solution of potassium nitrite, was anodically oxidized to form  $-\text{NO}_2$  groups on the SWCNTs. Attenuated-total-reflection Fourier-transform infrared and micro-Raman spectroscopy showed

the presence of chemisorbed  $-\text{NO}_2$  groups, consistent with transmission electron microscope images of the nanotube bundles after functionalization.

#### 2.6.4

### Electrochemical Application of Functionalized CNTs

#### 2.6.4.1 Application of Lipid–CNT Nanomaterials in Electrochemical Sensors

Sensors represent a most plausible and exciting application area for nanobiotechnology, and nanosensors based on CNTs are expected to emerge in the marketplace in significant volumes over the next ten years. Despite tremendous excitement recently generated by experimental breakthroughs that have led to realistic possibilities of using CNTs in electrochemical sensors, further experimental and theoretical research is necessary. The formation of stable lipid–CNT assemblies offers a simple, efficient method for the development of sensors/biosensors. The supramolecular structure of lipid–CNTs may lead to several applications in the field of nanobiotechnology. For example, it could be used for the development of molecular sensors (biosensors) for detecting the body's molecules. To actualize and optimize the full commercial potential of CNT-based electrochemical sensors, efforts must continue to be devoted to integrate the nanotube-arrays with power, miniaturized and easy-to-use electrochemical instruments for bimolecular sensing, genetic analysis, and drug discovery or screening.

The photoelectric effects of bilayer lipid membranes (BLMs) and electron mediator modified BLMs have been extensively studied, on account of their possible applications in understanding the mechanism of natural photosynthesis, in developing artificial photoelectric devices [101], and in mimicking functionalities of natural photosynthetic systems, which are represented by photoactive groups, electron donors and acceptors [102]. Various attempts have been made to realize an artificial photosynthesis and solar-energy conversion system under laboratory conditions. For example, synthetic dyes have been used to dope BLMs and the corresponding photoresponses have been investigated [103].

Recently, we have described the self-assembly of BLM and  $\text{C}_{60}$ -containing BLM at well-aligned MWCNTs for the development of a novel photoswitchable electrochemical device [39]. The lipid membrane at MWCNTs is estimated to be 4.38 nm thick, which is approximately double the molecular size of phosphatidylcholine, indicating that the BLM at the surface of nanotubes has a bilayer structure. Lipid membrane self-assembled at MWCNTs acts as an insulating layer while the incorporated  $\text{C}_{60}$  can mediate the transport of electrons as well as photocurrent across BLM (Fig. 2.5). The membrane resistance of  $\text{C}_{60}$ -BLM/MWCNTs is 369.3  $\Omega$ , which is much smaller than that of BLM/MWCNTs ( $3.238 \times 10^6 \Omega$ ). Furthermore,  $\text{C}_{60}$ -BLM/MWCNTs possess photoelectric properties due to the electron mediation of  $\text{C}_{60}$  in the lipid membrane. The photoelectric conversion properties of MWCNTs, BLM/MWCNTs, and  $\text{C}_{60}$ -BLM/MWCNTs were thus studied using an amperometric technique. At the lipid interface,  $\text{C}_{60}$  transports about 30–40% of electrons, compared with that of pure MWCNTs, from MWCNTs to the redox species in solu-

**Fig. 2.5.** (a) Schematic of BLM/MWCNTs and C<sub>60</sub>-BLM/MWCNTs electrode for photocurrent measurement and electrochemical experiments (BLM = bilayer lipid membrane). tion. The successful self-assembly of BLM and incorporation of C<sub>60</sub> into the BLM at MWCNTs may provide an easy way for construction of new biosensors and bioelectronic materials using BLM/MWCNTs and/or C<sub>60</sub>-BLM/MWCNTs nanocomposites.

#### 2.6.4.2 Achieving direct Electron Transfer to Redox Proteins by Functional CNTs

CNT electrodes have been successfully used to study protein electrochemistry. The novel electrochemical properties and the nanoscale size of CNTs have opened research opportunities in studying hitherto unapproachable phenomena at interfaces and bifaces for redox proteins [23, 24, 104, 105]. The direct electron transfer of proteins such as peroxidases [23, 24, 65], cytochrome *c* [15, 30, 106], myoglobin [107], catalase [108], azurin [15], and GOD [64] have been achieved by the use of CNT electrodes.

Recently, Mao and associates [109] have described the preparation and bioelectrochemical properties of functional nanohybrids through co-assembling of heme-proteins (i.e., horseradish peroxidase, hemoglobin, myoglobin and cytochrome *c*) and surfactants onto CNTs. The prepared protein–surfactant–CNT nanohybrids (Fig. 2.6) possess facilitated interfacial electron transfer of the proteins with en-

**Fig. 2.6.** Cartoons of (A) bioelectrochemically functional unit through co-assembly of protein and surfactant onto a single MWCNT and (B) nanohybrids consisting of single biofunctional nanotubes deposited onto the glassy carbon electrode. (Adapted from Ref. [109] with permission.)

hanced faradic responses. The enhancements are ascribed to the ability of surfactants to facilitate protein electrochemistry and to the improved portion of electroactive proteins assembled, of which the latter assignment is closely associated with the electrochemical and structural properties of the nanotubes, and the three-dimensional (3D) architecture of the CNT film confined on the glassy carbon electrode. It is proposed that the single and/or small bundles of the nanotubes in the CNT film electrode can be rationally functionalized with surfactants to be functional nanoelectrodes capable of facilitating electron transfer of proteins. The 3D confinement of these functional nanowires onto the GC electrode essentially increases the portion of electroactive proteins assembled in the nanohybrids. These properties of the protein–surfactant–CNT nanohybrids, combined with the bioelectrochemical catalytic activity, could make them useful for development of bioelectronic devices and for the investigation of protein electrochemistry at functional interfaces.

#### 2.6.4.3 Biomolecule-functionalized CNTs for Electrochemical Sensors and Biosensors

Biomolecule-functionalized carbon nanomaterials have been of interest in electrochemical areas in both fundamental research and application. The immobilization of molecules, biomolecules or even nanoparticles on SWCNTs has been exploited, motivated by the prospects of using nanotubes as new types of sensor/biosensor materials [110–113]. In contrast, there are few studies on the modification of

MWCNTs [36, 114–117]. The conducting nature of the MWCNTs, together with their outstanding electronic and mechanical properties, make them attractive for potential applications. Hemin (iron protoporphyrin IX) is the active center of the heme-protein family, such as *b*-type cytochromes, peroxidase, myoglobin and hemoglobin. It contains a porphyrin ring, which can be immobilized at the surface of CNTs through noncovalent functionalization by  $\pi$ - $\pi$  interaction [92]. We have successfully constructed a hemin-modified MWCNT electrode [43] and characterized its electrochemical behavior by CV. The electron-transfer coefficient ( $\alpha$ ) was found to be 0.38, with a heterogeneous electron transfer rate ( $k$ ) of  $2.9 \text{ s}^{-1}$  for the adsorbed hemin. The hemin-modified MWCNT electrodes show ideal reversibility in  $5 \text{ mM K}_3[\text{Fe}(\text{CN})_6]$  in the range  $0.02$ – $1.00 \text{ V s}^{-1}$ , indicating fast electron-transfer kinetics. CV of the hemin-modified MWCNT electrode in pH 7.4 phosphate buffer solution (PBS) clearly shows the dioxygen reduction peaks to be close to  $0 \text{ V}$  (vs.  $\text{Ag}|\text{AgCl}$ ). These results are useful in the development of a novel oxygen sensor for working at a relatively low potential. To improve the sensitivity of CNT-based electrochemical sensors toward hydrogen peroxide, we functionalized MWCNTs with iron-phthalocyanines (FePc) [40]. Highly sensitive and selective glucose sensors can be constructed on FePc-MWCNTs electrodes based on the immobilization of GOD on a poly-*o*-aminophenol (POAP)-electropolymerized electrode surface. SEM images indicate that GOD enzymes trapped in POAP film tend to deposit primarily on the curved tips and evenly disperse along the sidewalls. The GOD@POAP/FePc-MWCNTs biosensor we proposed exhibits excellent performance for glucose with a rapid response (less than 8 s), a wide linear range (up to  $4.0 \times 10^{-3} \text{ M}$ ), low detection limits ( $2.0 \times 10^{-7} \text{ M}$  with signal-to-noise of 3), a highly reproducible response (RSD of 2.6%), and long-term stability (120 days). Such characteristics may be attributed to the catalytic activity of FePc-functionalized CNT, permselectivity of POAP film, as well as the large surface area of CNT materials. Aligned CNT electrode arrays have been used to achieve direct electron transfer to enzymes with redox centers close to the surface of the protein [23, 24]. Most of the electrochemistry was dominated by proteins immobilized on the electroactive ends of the nanotubes. Both horseradish peroxidase and myoglobin functionalized CNTs [23] could be used analytically to detect hydrogen peroxide.

CNTs have generated considerable recent interest in bioelectronics and electrochemistry owing to their unique mechanical, electrical, and chemical properties [69, 118]. The electrocatalytic properties of these materials have been exploited as a means of promoting electron-transfer reactions of a wide range of important biomolecules [107, 119]. For example, the greatly enhanced electrochemical reactivity of hydrogen peroxide and NADH at CNT-modified electrodes makes these nanomaterials extremely attractive for numerous oxidase- and dehydrogenase-based amperometric biosensors [20, 21]. The use of CNT molecular wires offers great promise for achieving efficient electron transfer from electrode surfaces to the redox sites of enzymes [105]. Recently, Georgakilas and colleagues have described the magnetic modification of CNTs [120]. It is expected that the magnetic and catalytic properties of CNTs can be exploited for the magnetoswitchable control of electron transfer reactions with functionalized magnetic particles. Pyrene can be non-

covalently attached on the CNT surface. A carboxylic derivative of pyrene is used as an interlinker for the binding of capped magnetic nanoparticles on the CNTs. The increased organophilic character of the capped nanoparticles induces high solubility in organic media for the modified CNTs.

The unique structure and the outstanding electronic properties of CNTs coupled with the specific recognition properties of DNA would indeed make CNT–DNA bioconjugates widely useful in biosensors [121]. To prepare the bioconjugates, CNTs are treated with concentrated oxidizing acids so as to cover their ends and surfaces with oxygen-containing groups such as carboxyl groups and ether groups. The pretreated CNTs are then dispersed in water or organic solvents with the aid of ultrasonic oscillation. Biomolecules can be linked to CNT-modified electrodes with the aid of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) and/or *N*-hydroxysuccinimide (NHS) through the formation of an amide bond between the carboxylic groups on CNTs and the amino groups in biomolecules. Guo et al. have studied the electrochemical characteristics of the immobilization of DNA on the surface of MWCNTs [122, 123]. Both single strand and double strand calf thymus DNA molecules were attached to MWCNT-modified gold electrodes with the aid of EDC and NHS. The results of CV, electrochemical impedance spectroscopy (EIS), and piezoelectric quartz crystal impedance (PQCI) indicate that calf thymus DNA can be immobilized on MWCNTs via a cationic polyelectrolyte. No matter how DNA molecules were immobilized on MWCNTs, they still remained bioactive and could interact with small molecules such as chlorpromazine hydrochloride and ethidium bromide (EB). Recently, SWCNTs functionalized with amino groups have been prepared via chemical modification of carboxyl groups introduced on the CNT surface [124]. Two different approaches (amide and amine-moieties) were used to produce the amino-functionalized nanotubes. The amino-termination allows further chemistry of the functionalized SWCNTs and makes possible covalent bonding to polymers and biological systems such as DNA and carbohydrates. Wang et al. have attached CdS nanoparticles capped with octadecanethiol (ODT) to SWCNTs, which were dispersed in toluene after pretreatment with acetone, through hydrophobic interactions [125]. Then, streptavidin was anchored to CdS-SWCNTs, followed by combination with biotinylated probe DNA. The resultant SWCNTs-DNA bioconjugates were attached to a microplate through “sandwich” hybridization. Target DNA can be detected via determination of cadmium in CdS nanoparticles dissolved by nitric acid at a mercury film GCE by stripping voltammetry. The detection limit is around  $40 \text{ pg mL}^{-1}$ . With selective functionalization of oligonucleotide probes at the open ends of MWCNTs, Meyyappan’s group [121] reported that a nanoelectrode array based on vertically aligned MWCNTs embedded in  $\text{SiO}_2$  can be used for ultrasensitive DNA detection. Characteristic electrochemical behaviors are observed for measuring bulk and surface-immobilized redox species. Sensitivity is dramatically improved by lowering the nanotube density. More recently, they reported a similar approach for the fabrication of nanoelectrode arrays using vertically aligned MWCNTs embedded within a  $\text{SiO}_2$  matrix [126]. CV and pulse voltammetry were employed to characterize the electrochemical properties of the MWCNT array. The unique graphitic structure of the

at the open end of MWCNTs, and the longer red lines represent target molecules hybridized with the probe molecules. The hemisphere represents the diffusion layer of  $\text{Ru}(\text{bpy})_3^{2+}$  mediators. (Adapted from Ref. [126] with permission.)

novel MWCNT nanoelectrodes were compared with model systems such as highly oriented pyrolytic graphite and glassy carbon electrodes. Low-density MWCNT nanoelectrode arrays display independent nanoelectrode behavior, showing diffusion-limited steady-state currents in cyclic voltammetry over a wide range of scan rates. Electroactive species can be detected at concentrations as low as a few nm. In addition, ultrasensitive DNA/RNA sensors have been demonstrated using the low-density MWCNT arrays with selectively functionalized oligonucleotide probes (Fig. 2.7). This platform can be widely used in analytical applications as well as fundamental electrochemical studies. In summary, biomolecule-functionalized CNT electrodes can in the future be used as a new type of miniature DNA affinity biosensors [127].

## 2.7

### Conclusions and Future Prospects

We have addressed recent advances in electrochemistry and electrochemical application of CNTs, particularly of the functionalized CNTs with specific properties. The attractive properties of functionalized CNTs have paved the way for the construction of a wide range of electrochemical sensors/biosensors exhibiting attractive analytical behavior. In particular, functionalization of the CNT surface can result in highly soluble materials, which can be further modified with active molecules, making them compatible with biological systems. Therefore, many applications can be envisaged by using functionalized CNTs. With the creation of bifaces and interfaces at lipid-CNTs nanocomposites, progress in CNT technology may

well lead to better insights into biological and physical chemistry processes. This will make it possible to find compounds more compatible with CNT technology and to facilitate more effective use in electrochemical applications. Highly selective and sensitive molecular sensors based on CNTs are set to become commonplace in the near future.

## Acknowledgments

Part of the work conducted in our laboratory and reviewed in this chapter was supported by the Academic Research Grant of the National University of Singapore R-398-000-024-112, and by the Defense Science & Technology Agency of Singapore R-154-000-243-422, to F.-S. S. We are also grateful to many colleagues who have collaborated with our group over the years, contributing heavily to the development of the CNT electrochemical sensors.

## Nanotubes, Nanowires, and Nanocantilevers in Biosensor Development

*Jun Wang, Guodong Liu, and Yuehe Lin*

### 3.1

#### Introduction

Recent developments in designing and synthesizing conducting one-dimensional (1D) nanostructured materials, including carbon nanotubes (CNTs) and nanowires, etc., have attracted much attention across scientific and engineering disciplines because of their great potential for replacing conventional bulk materials in micro- and nanoelectronic devices [1, 2] and in chemical [3, 4] and biological sensors [4–9]. Various methodologies and technologies have been developed to fabricate 1D conducting nanomaterials [10, 11]. For example, chemical methods, including catalytic vapor deposition (CVD) have been widely used to synthesize CNTs [12, 13] and silicon nanowires [14, 15] on catalytically patterned substrates at desired sites with controlled orientations. Microfabrication [10, 11], soft lithography techniques [10, 11], and electric fields [16], etc. have been employed to fabricate highly oriented 1D nanomaterials. Various electrochemical techniques have been developed to fabricate 1D conducting polymer nanowires [17, 18]. New techniques are being explored to synthesize new 1D nanomaterials.

One-dimensional nanostructured materials as building blocks for biosensors are promising because of their unique electronic, optical, chemical, and mechanical properties, which are intrinsically associated with their low dimensionality and the quantum confinement effect. Therefore, 1D nanomaterials have broad applications in developing various types of biosensors, e.g., electrical [19, 20], optical [21], and mechanical [22] (nanocantilever biosensors). For example, CNTs exhibit excellent electronic properties. They can be used as molecular wires for facilitating electron transfer on the surface [23]. One-dimensional nanomaterials have a high aspect ratio, which makes them exhibit extreme sensitivity and superior response. Owing to their high sensitivity, 1D nanomaterials can be used to construct label-free biosensors. This will be very attractive and avoid exhausting and complicated labeling. With the ever-decreasing sizes of these 1D nanostructures, the “bottom-up” chemical approach is playing an increasingly important role because of its capability to make much smaller features compared to the “top-down” approach. So, combined with bottom-up techniques, 1D nanomaterials are ideal building blocks for

constructing miniature biochips. The detection mechanism with these tiny nanosensors is based on chemical interactions between the surface atoms of 1D nanostructured materials and adsorbed molecules. This interaction will provide a direct electronic readout within a few seconds of electron-donating or -withdrawing molecules adsorbing onto the nanomaterials. A miniature biochip based on 1D nanomaterials will be implanted in the body and will detect multiple biological molecules *in vivo*! In general, these 1D nanomaterials are expected to play an important role in the development of various emerging technologies that will improve the way we live.

Biosensors based on 1D nanomaterials have shown great advantages. However, real applications in biological diagnosis are a long way off. A major challenge remains to fully exploit the 1D nanostructure with one lateral dimension between 1 and 100 nm. For example, 1D nanostructured material-based biosensors need to bind biological recognition molecules onto the device. It is a great challenge to individually address high-density biomolecule nanoarrays. There is also a need for deconvolution of noise from the signals. To analyze proteomic signatures, a major challenge will be to identify signatures from low-concentration molecular species in the presence of an extremely high concentration of non-specific proteins.

As a branch of nanotechnology, 1D nanomaterial-based biosensor development has made great progress. Each year, thousands of articles on nano-related biosensors are published, and many reviews have appeared in different journals [24, 25]. The present chapter introduces reviews on biosensor development based on 1D nanomaterials, CNTs, semiconducting nanowires, and some cantilevers. The chapter is comprehensive – previous reviews on nanomaterials-based biosensor development have focused on one of 1D nanomaterials, e.g., either carbon nanotubes or nanowires. The emphasis here, however, is on CNTs and electrochemical/electronic biosensor developments. Section 3.2 gives a detailed description of carbon nanotubes-based biosensor development, from fabrication of carbon nanotubes, the strategies for construction of carbon nanotube based biosensors to their bioapplications. In the section on the applications of CNTs based biosensors, various detection principles, e.g., electrochemical, electronic, and optical method, and their applications are reviewed in detail. Section 3.3 introduces the method for synthesis of semiconducting nanowires, e.g., silicon nanowires, conducting polymer nanowires and metal oxide nanowires and their applications in DNA and proteins sensing. Section 3.4 simply describes the development for nanocantilever-based biosensors and their application in DNA and protein diagnosis. Each section starts with a brief introduction and then goes into details. Finally, Section 3.5 summarizes the development of 1D nanomaterials based biosensors.

### 3.2

#### Carbon Nanotubes in Biosensor Development

CNTs, rolled graphene sheets, were discovered in 1991 by Iijima [26] following the historical finding of the new fascinating member of the carbon family –

“Buckyball” fullerene (carbon nanocage) and other nanocarbon particles [27]. CNTs have basic  $sp^2$  carbon units that comprise a seamless structure with hexagonal honeycomb lattices, being several nanometers in diameter and up to hundreds of microns long. CNTs can be divided into two major groups, i.e., single-wall CNTs (SWCNTs) and multiwall CNTs (MWCNTs). SWCNTs represent a single graphite sheet rolled flawlessly, demonstrating a tube diameter of 1 to 2 nm, whereas MWCNTs show concentric and closed graphite tubules with diameters ranging from 2 to 50 nm and an interlayer distance approximately 0.34 nm [28]. Typical SWCNTs have an open-ended nanostraw or a capped nanohorn tubular structure. Because of the highly oriented architectures, these novel nanostructures exhibit physicochemical properties different from those of bulk graphite and diamond and thus provide their unique electronic, chemical, thermal, and mechanical properties [29, 30]. Since the early 1990s, CNT science has been one of the fastest growing areas of research in chemistry, physics, materials, and life technologies. The important properties and possible potential applications of CNTs have been reviewed recently [31–35].

The first type of CNT-based sensor was prepared by using MWCNTs mixed with bromoform as a binder packed into a glass capillary. This modified electrode exhibited remarkable improvement with regard to the electrochemical oxidation of dopamine [36]. Since then, work has concentrated on their electrocatalytic performance towards the redox behaviors of biomolecules [37, 38], especially towards the fabrication of effective, prototype deoxyribonucleic acid (DNA) and glucose biosensors [39, 40]. Recent summaries of the preparation conditions, interferences, interfacing, comparison, or analytical promise of the CNT-based sensors can be found in more specific reviews [41–43].

### 3.2.1

#### Preparation and Purification of CNTs

CNTs synthesis has mainly involved three major methods: the carbon arc-discharge method, or electric arc discharge (EAD) [26, 44], the laser vaporization of a graphite electrode or laser ablation (LA) [45], and a chemical method, CVD [11, 12]. EAD uses a direct current arc between carbon electrodes within a noble gas, like argon or helium [26]. In CVD, the CNTs are formed by the decomposition of the gaseous hydrocarbon at 700–900 °C and atmospheric pressure [46]. Materials produced by the EAD and LA protocols are in the forms of porous membranes and powders that require further processing. CNTs can be grown directly on substrates by the CVD process. Among these three techniques, the CVD is the most promising synthesis route for economically producing large quantities of CNTs. This is because the catalyst-involved CVD can use a lower temperature to form CNTs than the other two techniques. In addition, the catalyst can be deposited on a substrate, which allows for ordered synthesis and the formation of novel structures. CNT-based research for sensor applications only gained momentum after these highly oriented, large-scale productions emerged.

MWCNTs were first made by Yacaman et al. [47] followed by others [12, 13, 45]. Their experimental set-up usually consists of a high-temperature oven in which the catalysts are placed onto a highly resistant ceramic or metal plate. The nature and yield of the deposit obtained in the reaction are controlled by varying different parameters, such as the nature of the metals and the supports, the hydrocarbon sources, the gas flows, the reaction temperature, and the reaction time. By selecting the proper conditions, both the physical (e.g., length, shape, diameter) and chemical (e.g., number of defects, graphitization) properties of MWCNTs can be designed in advance. The choice of catalysts is vital in growing a good quality of CNTs and has been a subject for several research groups. Supported Co, Ni, and Fe catalysts were found to be the most active in the CVD growth thus far, although the metals and supports demand different temperature ranges [48, 49].

The first SWCNTs were reported by Iijima and Ichihashi when employing the EAD set-up with a low product yield [50]. This synthesis was significantly improved in 1996 when Dai et al. demonstrated that LA can be an effective way to grow highly uniform tubes that have a greater tendency to form aligned bundles than those prepared using EAD [45]. These ordered CNTs were fabricated by laser vaporization of a carbon target in a furnace at 1100 to 1200 °C, which was a much lower temperature than that was previously thought necessary for nanotube formation. A Co-Ni catalyst assists the growth of the nanotubes, presumably because it prevents the ends from being “capped” during synthesis. In a later work, the same group showed that high quality SWCNTs could be produced by CVD decomposition of methane on supported transition metal oxide catalysts [51]. The experimental set-up was similar to apparatus generally producing multiwalled nanotubes; however, some factors, including the catalyst composition, the support, and the hydrocarbon, were different. Fe<sub>2</sub>O<sub>3</sub> was found to be significantly more efficient in SWCNT production than CoO or NiO. Methane was used instead of the generally applied acetylene or ethylene because of its kinetic stability at high temperatures. Since there is no pyrolytic decomposition, the carbon atoms needed for the growth of nanotubes are produced by a catalytic reaction from the methane on the metal surfaces. The reaction time was dramatically reduced from the usually applied hour(s) to 10 min, and thus it prevents the outer surface of the nanotubes from being coated with amorphous carbon. In the following year, Colomer et al. proved, after viewing the nanotube bundles by transmission electron microscopy, that the best yield of SWCNTs is obtained by using a Fe-Co binary mixture supported by alumina [52]. Other groups have explored the possibility of extending their successful approach for MWCNTs into SWCNTs growth, mainly focusing on CVD [12, 13, 46–49].

High-purity CNTs can be, theoretically, achieved by optimizing the synthetic routes, and this should be viewed as part of the overall performance of the proposed preparation protocol. Nevertheless, the as-synthesized CNT materials unavoidably contain significant amounts of impurities, including amorphous carbon, graphite particles, and metal catalysts. The purification schemes that have been developed usually take advantage of differences in the aspect ratio [53] and oxidation

rate [54] between the nanotubes and the impurities. Zhou et al. proposed a method that can reach final product purity over 95% [55]. The protocol combines hydrogen peroxide reflux with filtration that can effectively remove most of the impurities. Recently, Chiang et al. modified a gas-phase purification technique previously reported by Smalley and others [53] that uses a combination of high-temperature oxidations and repeated extractions with hydrochloric acid. This improved procedure significantly reduces the amount of impurities (catalyst and non-nanotube forms of carbon) within the nanotubes, increasing their stability remarkably. The onset of decomposition of the purified nanotubes (determined by thermal gravimetric analysis in air) is more than 300 °C higher than that of the crude nanotubes. Transmission electron microscopy analysis of the purified nanotubes reveals near complete removal of iron catalyst particles. The iron content of the nanotubes was reduced from 22.7 wt.% in the crude nanotubes to less than 0.02 wt.% in the final product. Nanotubes purified by this method can be readily dispersed in common organic solvents, in particular *N,N*-dimethylformamide, using prolonged ultrasonic treatment. These dispersions can then be used to incorporate single-wall CNTs into polymer films.

### 3.2.2

#### **Construction of CNT-based Biosensors**

Interest in exploring CNTs in biosensor fabrication has grown exponentially since the inception of CNTs in 1991 [26] and the first CNT-based sensor report [36]. Following the preparation and purification of a large quantity of CNTs as discussed above, the immobilization of these sensing layers onto the transducer support is introduced below. Basically, these CNT immobilizations have been based on dispersion, solubilization, adsorption, functionalization, composite entrapment, and other surface anchoring protocols.

##### **3.2.2.1 Dispersion and Stabilization by Oxidative Acids**

The well-ordered, all-carbon hollow CNTs possess unique walls and ends and thus resemble the sensing properties of basal planes of pyrolytic graphite (through their walls) and of edge planes of pyrolytic graphite (through their open ends). This sensing mechanism, in addition to their high surface-to-volume ratio, high chemical and thermal stability, high tensile strength, and elastic nanostructures, has made them excellent candidates for sensor fabrication. However, the spontaneous coagulation and the lack of solubility of CNTs in aqueous media is a major challenge for their application. To prevent coagulation of the as-synthesized CNTs, oxidative acid treatments are usually explored, including refluxing and sonication in a concentrated mixture containing sulfuric acid and nitric acid, as reported by Smalley's group [56]. This procedure, while occasionally generating surface defects and tube shortening, can produce abundant carboxylated sites on the CNT walls and caps. A dark stable aqueous suspension of CNTs can be achieved after removing excess acids. More recently, Mallouk's group have reported that a stable SWCNT aqueous dispersion at concentrations above 0.3% can be obtained as a re-

sult of the hydrogel formation. This follows the treatments by a mixture containing  $\text{H}_2\text{SO}_4 + (\text{NH}_4)_2\text{S}_2\text{O}_8 + \text{P}_2\text{O}_5$  and a subsequent mixture with  $\text{H}_2\text{SO}_4 + \text{KMnO}_4$  [57]. Similar approaches have also been reported for a stable aqueous MWCNT hydrogel formation [58].

### 3.2.2.2 Dispersion by Surfactant Interaction

To preserve the intact CNT nanostructures after dispersion, a noncovalent stabilization/immobilization might be attractive. Simple physical stabilization, such as centrifugation, filtration, distillation, and sonication, in coupling with simple immobilization, including evaporation, casting, or spin coating, can be directly applied for respective sensor fabrications [35, 36]. Nevertheless, the hydrophobicity of the CNT walls, which accounts for vast majority of the tubes, is a major barrier when it comes to dispersing and manipulating the sensor surface and anchoring in a controlled manner.

Considering the relatively hydrophilic caps of CNTs, the noncovalent surfactant- and polymer-assisted aqueous dispersion may offer an alternative to overcome the drawbacks of the simple physical stabilization [59, 60]. The systematic study of the SWCNT dispersion in various surfactants has been reported and tabulated by Sun et al. [41], with the CNT solubilities ranging 10–50 mg mL<sup>-1</sup>.

### 3.2.2.3 Polymer-assisted Solubilization

Because of the pseudo-amphiphilic feature of CNTs, due to their hydrophilic carboxylated ends and hydrophobic sidewalls, various ionic and nonionic polymers, such as poly(*p*-phenylenevinylene) [59], poly{(*m*-phenylenevinylene)-*co*-[2,5-dioctyloxy-(*p*-phenylene)-vinylene]}, [60] or poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide) triblock polymers, have been reported to “wrap” CNT in polymeric chains to facilitate dispersing and to stabilize the nanotubes, without impairing their physical properties [59, 60]. Wang et al. developed a method that directly applied Nafion polymer-assisted CNT dispersion in sensor fabrication [61]. Similar to other polymers used to wrap and solubilize CNTs, Nafion bears a polar side chain and can produce a CNT suspension in phosphate buffer or alcohol solution. Increasing the Nafion content from 0.1 to 5 weight percent (wt.%) results in dramatic enhancement of the solubility of both single-wall and multiwall CNTs (Fig. 3.1). A homogeneous solution of the Nafion/CNT complex is observed in Nafion solution, but no such solubilization is observed in ethanol or phosphate-buffer solutions containing no Nafion. The CNT/Nafion association does not impair the electrocatalytic properties of CNTs with respect to the redox reaction of hydrogen peroxide. The Nafion-induced solubilization of CNT thus permits various applications, including the modification of electrode surfaces for preparing amperometric biosensors, and field-effect transistors [62].

### 3.2.2.4 CNT Adsorption on the Transducer Substrate

Although the dispersion and distribution of CNTs in aqueous media have proved to be challenging, some non-polar organic solvents such as *N,N*-dimethylformamide (DMF) cause less coagulation of the tubes and thus permit a greater extent of dis-

**Fig. 3.1.** Photographs of vials containing  $0.5 \text{ mg mL}^{-1}$  SWCNT (A) and MWCNT (B) in different solutions: phosphate buffer ( $0.05 \text{ M}$ ,  $\text{pH } 7.4$ ) (a), 98% ethanol (b), 10% ethanol in phosphate buffer (c), 0.1% Nafion in phosphate buffer (d), 0.5% Nafion in

phosphate buffer (e), and 5% Nafion in ethanol (f). (C) TEM image of a 0.5% Nafion solution containing MWCNT ( $0.3 \text{ mg mL}^{-1}$ ). (Reprinted with permission from Ref. [61]. © 2003 American Chemical Society.)

persion. This organic solubility offers the possibility for directly coating or spin casting of the CNT organic solution onto the sensor substrate and subsequent solvent evaporation. Re-immersion of these resultant CNT-based sensors into aqueous media showed no loss of operational performance and thus provides proof of strong adsorption on the surface. The first CNT-based sensor by Britto and co-authors was based on nanotubes solubilized in bromoform as a binder material following packing into a glass tube to complete the sensor construction [36]. Presently, many sensors still use this approach because of the ease of fabrication. The most often used substrates are glassy carbon, gold, platinum, carbon fiber, and glass. Lately, a protocol derived to co-incorporate some recognition reagent has been reported [63, 64]. Although these protocols are almost the simplest and most convenient ways to fabricate CNT-based sensors, the non-specific CNT adsorption needs to be addressed to gain greater control over their random distribution if a highly reproducible and stable sensor is demanded.

#### 3.2.2.5 Surface Functionalization of CNTs

Biosensors need specific surface recognition towards targets, and have thus promoted the modification of CNTs. These modifications usually start with the CNTs' sidewalls, ends, and defects, which are rich in nanotube-bound carboxylic groups. The latter are the nondestructive outcome of oxidative acid pretreatment on CNTs. The external-added functional molecules can be as small as simple amino acids or as large as protein macromolecules. Linkages between the nanotubes and the functional components, with or without coupling agents, are based on carboxylate chemistry via amidation and esterification, as well as ionic interaction schemes.

Accordingly, these functionalizations can be covalent or noncovalent bonding in nature.

Liu et al. have used dicyclohexylcarbodiimide (DCC), a coupling reagent which converts the carboxylate ends of the SWCNTs into carbodiimide leaving groups, to react with amines on cysteamine ( $\text{NH}_2\text{CH}_2\text{CH}_2\text{SH}$ ) [65]. The single-walled nanotubes with free thiol terminal groups then covalently attached onto substrate gold surface through a self-assembly process. Although atomic force microscopy (AFM) and transmission electron microscopy (TEM) have revealed different surface morphology of the resultant modified surfaces [66], this functionalization protocol offers control over the spatial distribution, lengths, and other surface patterns of the nanotubes aligned on the substrate by adjusting the assembled amount and time. Gooding and coauthors employed a similar carbodiimide-activated conjugating method in immobilization of microperoxidase (MP-11) onto the perpendicularly aligned nanotubes that were pre-anchored on the cysteamine-modified gold electrode [66]. Other direct bonding or electrostatic complexing approaches include using such as bridging metal ions to connect a polyelectrolyte-modified surface and the carboxylic acid terminated tubes [67] and complexing with an oppositely charged polyelectrolyte [66]. While these approaches provide various patterned nanotubes, a major concern lies in that the aligned tubes have little support and, therefore, the electrodes may lack robustness [67].

To elucidate the covalent, electrostatic, and nonspecific contributions to protein–SWCNT interaction, Davis et al. carried out the experiments of amidation both in the presence and absence of the coupling reagent DCC [69, 70]. They discovered that glucose oxidase is adsorbed along the length of CNTs randomly distributed on a glassy carbon electrode. Though coupling can be controlled, to a degree, through variation of tube oxidative pre-activation chemistry, careful control experiments and observations made by AFM suggest that immobilization is strong, physical, and does not require covalent bonding. Figures 3.2 and 3.3(a) exhibit their proposed protein–nanotube conjugates, which were readily characterized at the molecular level by AFM. Ferrocene monocarboxylic acid behaves as a mediator to promote charge transfer communication between electrode surface and the enzyme molecules. Under such conditions, the glucose signal was  $10\times$  greater than if only glucose oxidase was adsorbed onto the glassy carbon electrode without CNTs (Fig. 3.3b). This approach demonstrated the possible device application; protein attachment appears to occur with retention of the native biological structure. The role of nanotubes in this proposed glucose sensor was to provide (1) the high-aspect ratio electrode to which high capacity glucose oxidase loading was achieved, and thus greater signals were generated from more active enzyme interfacing and (2) provide possible direct electrical communication between a redox-active biomolecule and the delocalized  $\pi$  system of its CNT support [71].

#### 3.2.2.6 Composite Entrapment and CNTs Bulky Electrode Material

The first nanotube composites were prepared by Ajayan and coauthors by mechanically mixing MWCNTs and epoxy resin [72]. Because CNTs themselves could be

**Fig. 3.2.** Schematic representation of the “SWCNT Glucose Biosensor.” Solution-phase D-glucopyranose is turned over by oxidase enzymes immobilized on the nanotubes. This redox process at the enzyme flavin moieties is “communicated” to the nanotube  $\pi$  system through the diffusive mediator ferrocene

monocarboxylic acid. The redox action of the ferrocenes at the nanotube surface ultimately generates a quantifiable catalytic current that is characteristic of substrate detection and turnover. (Reprinted with permission from Ref. [70]. © 2003 Wiley-VCH.)

viewed as an extreme form of conducting polymer, the combination of nanotubes with conventional  $\pi$ -conjugated conducting polymers offers new electronic properties and high surface area capacity. This well suits the integration of substrate and transducer when making biosensors.

Wallace et al. combined MWCNTs and glucose oxidase to be embedded into polypyrrole (Ppy) with 0.1 M NaClO<sub>4</sub> as supporting electrolyte [73]. Such an enzyme electrode retains its stability at 70% after 3 days storage in the dry state at 4 °C. The use of these 3D electrodes offers advantages in that large accessible enzyme loadings can be obtained within an ultrathin layer. The iron-loaded nanotube tips (generated from CNT preparation) also contribute partial catalytic capacity toward H<sub>2</sub>O<sub>2</sub> oxidation. A biosensor based on Ppy/DNA composite covered CNT under-

(lower curves) and presence (upper curves) of the substrate,  $\beta$ -D-glucose. (TMAFM = tapping-mode atomic force microscopy). (Reprinted with permission from Ref. [70]. © 2003 Wiley-VCH.)

layers was recently provided for DNA sensing [74]. By applying an impedance technique to this two-layer-based sensor, the complementary DNA target can be detected down to  $5 \times 10^{-11}$  M.

Sol-gel chemistry involves the hydrolysis and condensation of suitable alkoxy-silane precursors and has been widely employed for the preparation of inorganic materials (monolithic, hybrid, composites, and chromatographic stationary phase) suitable for various applications. Recently, Bachas and coworkers have applied a CNT sol-gel composite as an enzyme-friendly platform to develop biosensors [75]. Using L-amino acid oxidase as a model enzyme, the biosensors were made in aqueous sol-gel processes involving methyltrimethoxysilane, ethyltrimethoxysilane and propyltrimethoxysilane as precursors. Aliquot amounts of MWCNTs and enzyme were added into the sol when the hydrolysis took place. The resultant sensor proved to be stable and retained more than 50% of its response after 1 month of testing. In such an immobilization protocol, the porous  $-\text{Si}-\text{O}-$  sol-gel network

encapsulates biomolecules while the use of CNTs, as the conductive part of the composite, facilitated fast electron transfer rates.

Because of the unique  $sp^2$  hybrid surface structures, CNTs themselves could be viewed as an extreme form of conducting polymer. The CNT bulky material may be applied directly towards sensor construction without binders or other auxiliary components. Wang and co-authors have developed a simple approach for preparing effective CNT-based biosensors from CNT/Teflon composite material by hand-mixing a certain amount of CNTs in the dry-state with granular Teflon to obtain a desired composition of CNT/Teflon [76]. Carbon composites, based on the dispersion of graphite powder within an insulator, offer convenient bulk modification for the preparation of reagentless and renewable biosensors. Wang et al.'s approach relies on CNTs as the sole conductive component rather than as the modifier cast on other electrode surfaces. The bulk of CNT/Teflon composites hence serve as a reservoir for the enzymes. By comparing the sensors' performance against their respective composite compositions, the CNT content of 40–60 wt.% has been suggested. CNT/Teflon composites combine advantages of CNTs and bulk composite electrodes that permit a wide range of applications without the need for a graphite surface. Certain amounts of enzymes (e.g., glucose oxidase and alcohol dehydrogenase) and cofactor (e.g.,  $NAD^+$ ) can be mixed with the CNT/Teflon composite and used as electrode materials, depending upon specific needs. These biosensor interfacing displayed a marked electrocatalytic action toward hydrogen peroxide and  $\beta$ -nicotinamide adenine dinucleotide (NADH) and, hence, this is promising for the development of biosensors for glucose (in connection with oxidase enzymes) and ethanol (in connection with dehydrogenase enzyme), respectively [76]. Similar approaches have been developed for CNT-based sensor fabrication using nanotube–mineral oil paste, reagent-embedded CNT paste, or powders to determine DNA, glucose, cysteine, and other biomolecules.

Composites consisting of CNTs and other nanotubes or nanoparticles were reported recently for enhancing the catalytic capacity of the sensing devices. Luong's group [77] and Yao's group [78] used platinum nanoparticles combining with CNTs to construct a biosensing platform for glucose oxidase. Wang et al. employed semiconductor CdS nanoparticle-tagged CNTs for DNA hybridization detection [79].

#### 3.2.2.7 More Sophisticated Surface Tailoring Based on Combination of Co-adsorption, Integration, Prohibition, Spacing, Linkage, Sandwich, Tagging, and other Anchoring Approaches

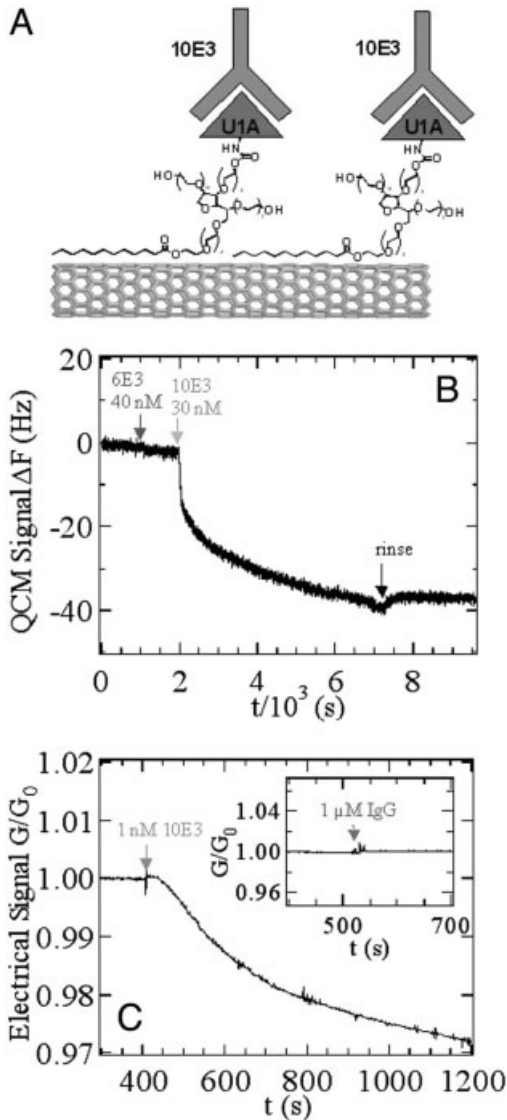

Biosensors involve biomolecules and biorecognition reactions. Their optimal operational performance depends on the maximization of the desired signals while minimizing the side reaction. DNAs, enzymes, antigens, and other biomolecules usually bear charges, depending on the medium pH. CNT biomodifications based on non-specific interaction with DNAs or proteins can be achieved through the sidewall electrostatic interaction, hydrogen bonding, and other mechanisms, as well as the insertion of smaller biomolecules into the tubular channel. The nature of these noncovalent bondings are complicated and were proposed by Dai et al. as

mainly the results of hydrophobic interaction and the  $\pi$ -stacking of the conjugated pyrenyl group of 1-pyrenebutanoic, succinimidyl ester, or coating with some surfactants, such as Triton [80, 81]. More specific binding to functionalize the CNTs can take advantage of covalent bonding, DNA hybridization, coupling agents, and antigen–antibody interactions. Biosensing by these approaches was reported for the CNTs attachment of decorated glucose oxidase [82], thiolated DNA [83], amine-terminated DNA [84], and peptide nucleic acid (PNA) – a DNA mimic [85].

The non-specific adsorption of proteins on nanotubes is not always desirable, especially when tested in real biofluid samples that contain many co-existing proteins. More sophisticated sensors, therefore, need to address issues like target-recognition enhancement, blockage of undesired interference (the co-existing proteins' non-specific adsorption on the nanotube surfaces), long-term storage, etc. Accordingly, CNT surface engineering might be a combination of different tailoring techniques. Dai et al. have presented a typical example [81] (Fig. 3.4). In their approach U1A, a protein involved in the splicing of message ribonucleic acid (mRNA), was covalently linked to Tween-20, a surfactant. The complex was then noncovalently cast onto the single-walled CNT surface. The latter was as-grown on a quartz wafer that was *in situ* monitored by its conductance and frequency response during the sensing measurement.

This CNT modification with the adsorption of biotinylated Tween-20 allowed streptavidin recognition by the specific biotin–streptavidin interaction, but provided resistance toward other protein adsorptions. Under such design, the sensor could detect the binding of 10E3, a specific antibody for recognition of U1A, at concentrations as low as 1 nM (Fig. 3.4), while showing no response toward other existing proteins such as streptavidin, avidin, bovine serum albumin (BSA),  $\alpha$ -glucosidase, staphylococcal protein A (SpA), and immunoglobulin G (IgG) (Fig. 3.4C). The blocking mechanism toward coexisting proteins was proposed as the formation of a nearly uniform layer of surfactant Tween-20 through the favorable hydrophobic interaction on the nanotube surface, with the poly(ethylene glycol) (PEG) segments extending into the aqueous media to provide the observed protein resistance. Noticeably, this protein-resistant assembly may be covalently conjugated to specific antigens to allow sensitive detection of antibodies, or *vice versa* [81]. This proposed real-time immunosensor can thus compare favorably with a standard fluorescence-based assay with immobilized antigens on planar arrays.

Wang et al. have recently developed a CNT-based amplified bioelectronic protocol that uses DNA for linking particles to CNTs [63]. As can be seen in Fig. 3.5(a), the preparation is based on the sandwich hybridization (a) or antigen–antibody (b) binding along with magnetic separation of the analyte-linked magnetic-bead/CNT assembly (A), followed by enzymatic amplification (B), and chronopotentiometric stripping detection of the product at the CNT-modified electrode (C). TEM observations (Fig. 3.5D) indicate that the hybridization event leads to crosslinking of the alkaline phosphatase (ALP)-loaded CNTs and the magnetic beads (with the DNA duplex acting as “glue”). In this new bioaffinity assay, CNTs play a dual amplification role in both the recognition and transduction events, namely as carriers for

numerous enzyme tags and for accumulating the product of the enzymatic reactions. With such an assembly, the extraordinarily low detection limits were reported for DNA and IgG of  $1$  and  $500 \text{ fg mL}^{-1}$ , respectively.

### 3.2.3

#### CNT-based Electrochemical Biosensors

Soluble CNTs have been electrochemically and quantum-chemically characterized for their bulk properties [86]. Results showed that the electronic states are not strongly affected when the nanotubes are functionalized. The electronic properties of CNTs range from metallic to semiconductive, depending on the nanotube's own diameter and chirality. These subtle electronic properties offer various electrochemical features for CNT-based sensors after functionalization of the nanotubes.

##### 3.2.3.1 Direct Electrochemistry of Biomolecules on Carbon Nanotubes

Recently, direct electrochemical communications between redox-active macromolecules and conventional electrode substrates mediated by CNTs have received attention because of their potential to lead a mechanistic study of the structure–function relationship of these biomolecules and their guidance toward biosensor design. Wang et al. reported the direct electrochemistry of cytochrome *c* at electrochemically activated SWCNT-modified electrodes [23]. Gooding et al. and Rusling et al. have used aligned nanotubes to promote the direct electrochemistry of redox-active proteins [66, 67]. These studies demonstrate that direct electro-

chemistry of redox-active biomacromolecules can be improved through the use of CNTs.

In addition to the aforementioned charge transfer promotion, there have been reports on the electrocatalytic behavior of CNTs toward some small biomolecules such as cysteine and hemocysteine [87], ascorbic acid [88], uric acid [89], dopamine [90]. The mechanisms of this surface mediation are not currently well understood, and the terminology of electrocatalysis should be exercised cautiously for different electrode material and media. The promoted electrochemical reactions for hydrogen peroxide, NADH, and quinones enable possible sensing schemes for more than 800 enzymes that involve these substrates, products, coenzymes, and cofactors.

Several hundred enzymatic reactions of  $\text{NAD}^+/\text{NADH}$ -dependent dehydrogenases have NADH as a cofactor. The electrochemical oxidation of NADH has thus been the subject of numerous studies related to the development of amperometric biosensors. Problems inherent to such anodic detection are the large overpotential encountered for NADH oxidation at ordinary electrodes and surface fouling associated with the accumulation of reaction products. CNTs have thus been examined in recent work [91] as the new electrode material to alleviate these problems.

Lin et al. have employed CNTs that had been pretreated with dispersion in concentrated sulfuric acid to cast a glassy carbon electrode [91]. Figure 3.6 shows a typical hydrodynamic voltammogram of  $1 \times 10^{-4}$  M NADH in a physiological medium (0.05 M phosphate solution, pH 7.4). This voltammogram demonstrates an electrocatalytic behavior of the CNT coating towards NADH with varying potentials, as evidenced by the MWCNT-coated electrode (B) responding to NADH over

**Fig. 3.6.** Hydrodynamic voltammograms for  $1 \times 10^{-4}$  M NADH at unmodified (A) and MWCNT-modified (B) GC electrodes. Operating conditions: stirring rate, 500 rpm; electrolyte, phosphate buffer (0.05 M, pH 7.4). (Reprinted with permission from Ref. [91]. © 2002 Elsevier.)

Fig. 3.7. Current–time recordings obtained after increasing the NADH concentration (by  $1 \times 10^{-4}$  M at each step) at unmodified (A) and MWCNT-modified (B) GC electrodes.

Inset: the corresponding calibration curve. Operating conditions: potential, +0.3 V. (Reprinted with permission from Ref. [91]. © 2002 Elsevier.)

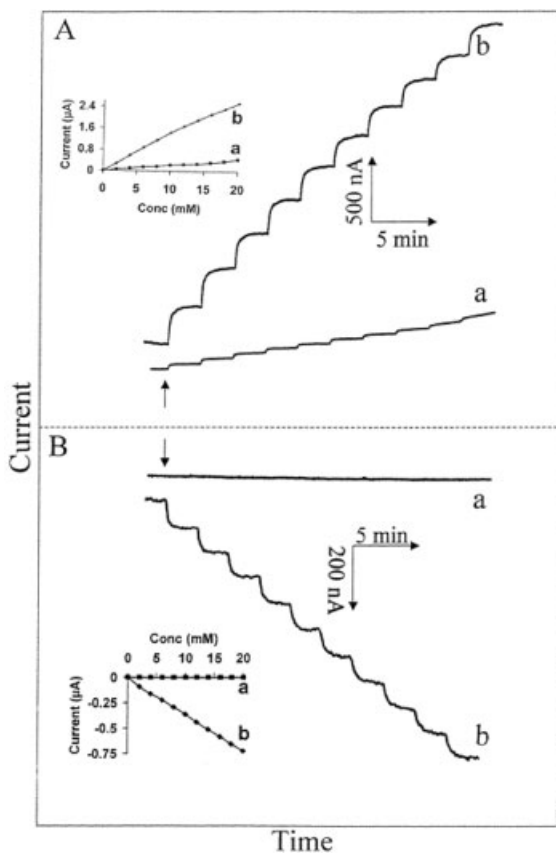

the entire 0.0–1.0 V range, whereas the bare electrode (A) responds only at potentials higher than +0.6 V. The modified electrode yields an approximately three-fold larger NADH peak than does the unmodified electrode. Figure 3.7 shows that successive additions of  $1 \times 10^{-4}$  M NADH result in increasing response detected at the CNT-modified electrode (B) but no response at the unmodified electrode (A) when the detection potential was kept low (i.e., 0.3 V). Evidently, the electrocatalytic action of CNT enables the fast response (i.e., 10 s to reach the steady state) to the change of NADH concentrations at the low-detection potential. The amperometric response of  $5 \times 10^{-3}$  M NADH appears to be very stable; the decay of the signal is less than 10% and 25% after a 60-min period at the MWCNT-modified and SWCNT-modified electrodes, compared with 75% and 53% at the graphite-coated and acid-treated electrodes, respectively. This shows the capability of CNTs to resist the fouling effects and prevent the diminishing of signals in successive cyclic voltammetric detections. The oxygen-rich groups on the CNT surface, introduced during the acid dispersion, are perhaps responsible for such electrocatalytic behavior

for the oxidation of NADH. The resistance to fouling of CNT-based electrodes has yet to be understood.

The CNT-coating offers remarkably decreased overvoltage for the NADH oxidation as well as reducing the surface fouling effects of the electrodes. These characteristics indicate the great promise of CNTs for developing highly sensitive, low potential, and stable amperometric biosensors based on dehydrogenase enzymes.

### 3.2.3.2 Enzyme/CNTs Biosensors

Most reported CNT-based biosensors for glucose thus far involve the enzymatic reaction by glucose oxidase (GOx) [61, 69, 70, 76, 78]. Wang and Musameh have employed CNT/Teflon-based electrodes, which are immobilized with GO<sub>x</sub> enzyme [76]. Figure 3.8 compares the amperometric response to successive additions of 2 mM

**Fig. 3.8.** Current–time recordings for successive 2-mM additions of glucose at graphite/Teflon/GO<sub>x</sub> (a) and the MWCNT/Teflon/GO<sub>x</sub> (b) electrodes measured at +0.6

(A) and +0.1 V (B). Electrode composition, 30:69:1 wt.% carbon/Teflon/GO<sub>x</sub>. (Reprinted with permission from Ref. [76]. © 2003 American Chemical Society.)

glucose at the graphite/Teflon/ $\text{GO}_x$  (a) and the MWCNT/Teflon/ $\text{GO}_x$  (b) electrodes using operating potentials of +0.6 V (A) and +0.1 V (B). The CNT-based bioelectrode offers substantially larger signals, especially at low potential, reflecting the electrocatalytic activity of CNTs. Such low-potential operation of the CNT-based biosensor results in a highly linear response (over the entire 2–20 mM range) and a slower response time ( $\sim 1$  min vs. 25 s at +0.6 V). The glucose biocomposite based on single-wall CNTs results in a more sensitive but slower response than that based on multiwall CNTs. The low-potential detection also leads to high selectivity (i.e., effective discrimination against coexisting electroactive species). Despite the absence of external (permselective) coating, the glucose response at +0.1 V was not affected by adding the common acetaminophen and uric acid interferences at 0.2 mM [76]. A similar addition of ascorbic acid resulted in a large interference, reflecting the accelerated oxidation of this compound at the CNT surface [88].

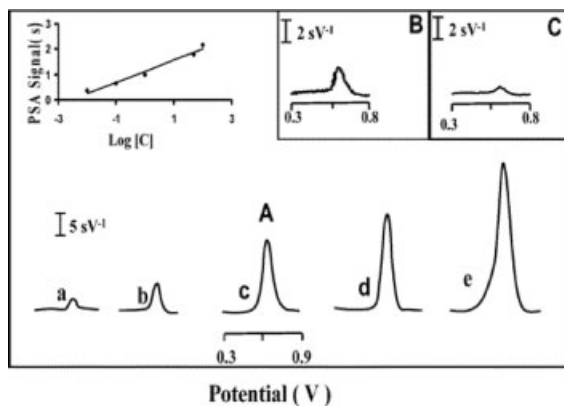

Recently, Sheu et al. have reported the non-enzymatic detection of glucose [92]. This approach uses MWCNTs but needs a strong basic media that may not be compatible with the bioenvironment.

### 3.2.3.3 DNA and Protein Biosensors

Interest in the detection of DNA has grown aggressively because of its importance in the diagnosis and treatment of genetic disease, drug discovery, and anti-bioterrorism efforts. The completion of the Human Genome Project offers an abundance of gene mapping and screening. A hybridization recognition scheme, based on the Watson–Crick base pair principle, is the central point when constructing a DNA sensor. The unique electric, thermal, chemical, mechanical, and 3D spatial properties of CNTs make them a natural choice as transducers for hybridization-based DNA sensors. Different attachment protocols for DNA probes (single strand DNA molecules) onto CNTs were introduced, either by unmodified or surface-confined nanotubes [40, 63, 93].

Wang and coworkers have developed an ultrasensitive DNA biosensor based on a “dual amplification route” by using CNTs both as recognition sites and transducers, namely as carriers for numerous enzyme tags and for accumulating the product of the enzymatic reaction [63]. Figure 3.9 displays typical chronopotentiograms for extremely low target DNA concentrations (0.01 to 100  $\text{pg mL}^{-1}$ ; a–e). Well-defined  $\alpha$ -naphthol signals are observed for these low DNA concentrations in connection with 20-min hybridization. The resulting plot of response vs.  $\log[\text{Target}]$  (shown as inset) is linear and suitable for quantitative work. The favorable response of the 5  $\text{fg mL}^{-1}$  DNA target (B) indicates a remarkably low detection limit of around 1  $\text{fg mL}^{-1}$  (54 aM), i.e., 820 copies or 1.3 zmol in the 25- $\mu\text{L}$  sample. Such a low detection limit compares favorably with the lowest values of 5 zmol (3000 copies) and 25 amol reported for electrical DNA detection. The smaller signal observed in a control experiment for a huge ( $\sim 10^6$ ) excess of a non-complementary oligonucleotide (Fig. 3.9C vs. B) reflects the high selectivity associated with the effective magnetic separation. The amplified electrical signal is coupled to a good reproducibility. Two series of six repetitive measurements of

**Fig. 3.9.** Chronopotentiometric signals for increasing levels of the DNA target: (a) 0.01, (b) 0.1, (c) 1, (d) 50, (e) 100  $\text{pg mL}^{-1}$ . Also shown (inset) is the resulting calibration plot (A), and the response for 5  $\text{fg mL}^{-1}$  target

DNA (B) and 10  $\text{ng mL}^{-1}$  non-complementary (NC) oligonucleotide (C). Sample volume, 25 (B) and 50  $\mu\text{L}$  (C). (Reprinted with permission from Ref. [63]. © 2003 American Chemical Society.)

1  $\text{pg mL}^{-1}$  DNA target or 0.8  $\text{ng mL}^{-1}$  IgG yielded reproducible signals with relative standard deviations of 5.6% and 8.9%, respectively [63].

Noticeably, Wang's "dual amplification" mode for the DNA sensor as above has also been applied to an immunosensor for IgG because of the similarity between DNA hybridization and antigen-antibody interaction. An extremely low detection for IgG was reported, as 500  $\text{fg mL}^{-1}$  [63]. In contrast, DNA, RNA, proteins, and enzymes all bear multiple charges, and their adsorption onto the nanotubes is expected to change their electronic properties. These changes, upon adsorption, can be readily transduced into measurable sensing signals [38, 94]. DNA has already been used as a template to localize CNTs to make new building blocks or alignments in electronics and bioelectronics, such as field-effect transistors (FETs) [95]. These functionalized FETs, coupled with advanced sensor array techniques, can therefore serve as a new direction in CNT-based bioassays [77, 80].

#### 3.2.3.4 Immunosensors

Electrochemical immunosensors based on CNTs have been designed [20]. Vertically aligned arrays of single CNTs called SWCNT forests have been developed for amperometric enzyme-linked immunoassays of proteins by Rusling and coworkers [20]. A prototype amperometric immunosensor was evaluated based on the adsorption of antibodies onto perpendicularly oriented assemblies of SWCNT forests. The forests were self-assembled from oxidatively shortened SWCNTs onto Nafion/iron oxide coated pyrolytic graphite electrodes. Anti-biotin antibodies strongly adsorbed to the SWCNT forests. They found that the detection limit for horseradish peroxidase (HRP) labeled biotin was 2.5  $\text{pmol mL}^{-1}$  (2.5  $\text{nM}$ ) in the presence of a soluble mediator. Unlabeled biotin was detected in a competitive approach with a detection

limit of  $16 \text{ nmol mL}^{-1}$  and a relative standard deviation of 12%. The immunosensor showed low non-specific adsorption of biotin-HRP (approx. 0.1%) when blocked with bovine serum albumin. The biosensor platform is also being developed to accommodate flow-through sensor design with direct electron transfer detection of the enzyme label on a CNT matrix. Traditional electrochemical immunosensors were based on mediated electron transfer. However, efficient direct electron transfer will offer some advantages, such as a simple possibility for a reagentless immunoassay. CNTs exhibit excellent electrical properties, and they are a suitable candidate for developing such a reagentless immunoassay.

#### 3.2.4

##### Flow-injection Analysis

Flow detectors have been widely used in process chemistry and online monitoring. It is the core part for real time, *in situ* analysis and for the integration of separation and detection – “lab-on-a-chip.” Microfabricated fluidic devices, particularly used as sensors for capillary electrophoresis (CE) and liquid chromatography (LC), have gained steadily growing attention in recent years [64]. Wang et al. have presented a CNT-based detector for a conventional as well as a miniaturized CE system [64]. CE combines the advantages of high performance, design flexibility, reagent economy, high throughput, miniaturization, and automation. It demands a detector with high sensitivity, inherent miniaturization (of both the detector and control instrumentation), and compatibility with advanced micromachining technologies, and low cost and power requirements [64]. Conventional detectors are based on gold, platinum, and various forms of carbon. A CNT-based electrode offers an alternative for low potential detection, it imparts enhanced sensitivity, and it leads to long-term stability. In this approach, Wang et al. used a Nafion/CNT-coated screen-printed electrode for end-column amperometric detection. After anodic pretreatment (3 min at +1.5 V in 1 M sulfuric acid), this sensor showed substantial electrocatalytic behavior and resistance to surface fouling toward hydrazine, phenol, tyrosine, purine, and amino acids, when compared with the bare surface. The CNT microchip detector also displayed well-defined concentration dependence.
