<b>1</b>	<b>Biofunctionalization of Fluorescent Nanoparticles</b>	<b>1</b>
	<i>Michael J. Murcia and Christoph A. Naumann</i>	
1.1	Introduction	1
1.2	Fluorescent Nanoparticle Probes	2
1.2.1	Dye-doped Nanoparticles	3
1.2.2	Quantum Dots (QDs)	5
1.2.3	Metal Nanoparticles	7
1.2.4	Hybrid Architectures Involving Fluorescent Nanoprobes	9
1.2.4.1	Metal–Dye	9
1.2.4.2	Dye-doped Silica Shells	9
1.2.4.3	Quantum Dot-containing Microspheres	10
1.3	Bioconjugation of Fluorescent Nanoparticles	11
1.3.1	General Considerations	11
1.3.1.1	Overview	11
1.3.1.2	Common Coupling Reactions	13
1.3.2	Bioconjugation of Polymeric Nanoparticles	13
1.3.2.1	Noncovalent Approaches	13
1.3.2.2	Covalent Approaches	15
1.3.3	Bioconjugation of Quantum Dots	15
1.3.3.1	Noncovalent Approaches	16
1.3.3.2	Covalent Approaches	16
1.3.4	Bioconjugation of Metallic Nanoprobes	16
1.3.4.1	Noncovalent Approaches	17
1.3.4.2	Covalent Approaches	17
1.4	Design of Biocompatible Coatings	17
1.4.1	General Considerations	17
1.4.1.1	Overview	17
1.4.1.2	Colloidal Stability	18
1.4.1.3	Biocompatible Surfaces	19

1.4.1.4	Cytotoxicity	20
1.4.2	Nanoparticle-stabilizing Coatings	21
1.4.3	Low Cytotoxicity Coatings	23
1.5	Applications	23
1.5.1	Biosensing	24
1.5.1.1	Polymeric Sensors	25
1.5.1.2	Quantum Dot Sensors	25
1.5.1.3	Metallic Sensors	26
1.5.2	Fluorescent Nanoparticles as Labels in Biological Imaging	27
1.5.2.1	Dye-doped Nanoparticles	27
1.5.2.2	Quantum Dots	27

## Preface

On behalf of a great team of nano researchers who have been part of this exciting project, I am pleased to introduce to the scientific community a comprehensive ten volume series on *Nanotechnologies for the Life Sciences (NtLS)*, which is going to be a knowledge base of encyclopedic proportions for applications of nanotechnologies in biology, biotechnology and medicine. This is a unique series of books on an important facet of nanotechnology being presented by the nanotechnologists for the nanotechnologists. What you have in your hand is the first volume, *Biofunctionalization of Nanomaterials*, in this exciting series.

The first volume has eleven chapters covering various aspects and techniques for functionalization of different nanomaterials with variety of biomolecules. The book begins with an exciting chapter by *Michael J. Murcia* and *Christoph A. Naumann* from the Indiana University-Purdue University, USA, which provides an overview of developments in *biofunctionalization and biocompatible coating of fluorescent nanoparticles*. There is an explosion of knowledge on carbon nanotubes, long, thin cylinders of carbon, discovered in 1991 by S. Iijima and the focus of their practical applications have been due to their unique physical properties such as optical, electrical, thermal, elastic behavior and so on. However, once it was demonstrated that it is possible to functionalize them with biomolecules, there has been a great interest amongst nanoresearchers to investigate their potential in life sciences. The University of California team of researchers from Riverside, USA, *Elena Bekyarova*, *Robert C. Haddon* and *Vladimir Parpura*, has done a remarkable job in capturing the up-to-date information in their chapter entitled *biofunctionalization of carbon nanotubes*. Metallic and metal oxide nanoparticles are well studied and their extraordinary physical and chemical properties make them useful in variety of applications. Not surprisingly, a great deal of research work was carried out to make them not only biocompatible, but also attach biological molecules in order to extend their applications into the life sciences. Four chapters have been dedicated to capture this information and the authors of these four chapters – 3, 4, 6 and 8 – have done a thorough job in comprehensively providing the information on biofunctionalization aspects of a wide variety of metallic/metal oxide nanoparticles. *Yong Guo* from the Southern Illinois University, Carbondale, USA, dealt with *biofunctionalization of magnetic nanoparticles*. *Ming Zheng* and *Xueying Huang* from DuPont Central Research and Development, USA, described some unique aspects

of *biofunctionalization of gold nanoparticles*. Grit Festag, Uwe Klenz, Thomas Henkel, Andrea Csllki and Wolfgang Fritzsche from the Institute for Physical High Technology, Jena, Germany, in a very unique fashion reviewed several approaches towards *biofunctionalization of metallic nanoparticles* for biosensing. In addition to the completely chemical based approach for biofunctionalization, Raphael Levy and Chris Doty from the University of Liverpool, UK, provided a state-of-the-art review on the use of biomolecules themselves for stabilization of metallic nanomaterials in the chapter entitled *stabilization and biofunctionalization of metallic nanoparticles: the peptide route*.

In addition to metallic nanoparticles, polymeric nanoparticles have been widely investigated for their applications in life sciences primarily in the area of drug delivery. It is again very important for the polymeric nanoparticles to be either biocompatible or biofunctionalized in order to be suitable for life science applications. *Biofunctionalization of phospholipid polymeric nanoparticles* by Junji Watanabe, Jongwon Park, Tornomi Ito, Madoku Takai, and Kazuhiko Ishihara from the University of Tokyo, Japan, provides information, based on their own research experience, on phospholipid polymeric nanoparticles and their biofunctionalization. The chapter *magnetic core conducting polymer shell nanocomposites for DNA attachment and hybridization* contributed by Jean-Paul Lellouche of Bar-Ilan University, Israel, presents an interesting perspective towards biofunctionalization of magnetic core polymer shell nanomaterials. The researchers from the Northeastern University, Boston, USA, – Sushama Kommareddy, Dinesh B. Shenoy and Mansoor M. Amiji – brought out comprehensive information on *gelatin nanoparticles and their biofunctionalization*.

Amongst all the biomolecules, proteins are unique and their conjugation to nanomaterials provides a very broad base for life science researchers. The research group from Clemson University, USA, led by Ya-Ping Sun with Mohammed J. Meziani and Yi Lin brought out an excellent in-depth analysis of various conjugation approaches to bind proteins to variety of nanomaterials in their chapter entitled *conjugation of nanomaterials with proteins*. In this chapter, they provide an overview of current and emerging approaches in the coupling of metal and semiconductor nanostructures with proteins and their assemblies into different architectures followed by approaches to conjugation of carbon nanotubes with proteins and the mechanistic issues involved with nanotube-protein interactions. The chapter entitled *folate-linked lipid based nanoparticles for tumor-targeted gene therapy* by Yoshiyuki Hattori and Yoshie Maitani, Institute of Medicinal Chemistry, Japan, contains a review of literature on folate-linked liposomes and nanoparticles, and show the effectiveness of folate-linked lipid-based nanoparticles as a vector for DNA transfection and for suicide gene therapy to treat human nasopharyngeal and prostate tumors.

I am very grateful to all the authors who have shared my enthusiasm and vision by contributing high quality manuscripts, on time, keeping in tune with the original design and theme of not only this particular volume but also the whole series. You will not be having this book in your hand but for their dedication, perseverance and sacrifice. I am thankful to my employer, the Center for Advanced Micro-

structures and Devices (CAMD), and especially to my superior, Prof. Josef Hormes, Director of CAMD, who has been supporting me in all my creative ventures. Without this backing it would be impossible to make this venture of such magnitude a reality. No words can express the understanding of my wife, Suma, in allowing me to make my office a second home and bearing with my spending innumerable number of hours in front of the computer at home. My little daughter, Saakshi, has been the source of joy and inspiration in bringing forth my intellectual creativity. My families, friends and mentors are integral part of my existence and continue to shape my life and I am indebted to them. While it would be impossible to thank everyone individually in this preface, I must make a special mention of the support from Wiley VCH publishers in general and the publishing editor, Dr. Martin Ottmar, in particular, who has been working closely with me to ensure this project becomes a reality. I am grateful for this support.

I also would like to take this opportunity to provide few glimpses of the rest of the nine volumes in this series. As I write this preface, I am pleased to let you know that the second and the third volumes are in press and will be published shortly after volume one. The second volume, *Biological and Pharmaceutical Nanomaterials*, provides information on variety of nanomaterials from natural sources and also those that are particularly relevant from pharmaceutical stand point of view. As life scientists learn about nanotechnologies, they also need to be familiarized with tools and techniques for characterization and the third volume, *Nanosystem Characterization Tools in the Life Sciences*, brings forth the required information. The rest of the volumes in this series deal in general with sensing, controlled release, devices, engineering, biomimetic approaches that are relevant to life sciences. These volumes are currently under preparation and I hope to present them to you as soon as possible.

As I stop for moment and ponder at the amount of information that the dedicated team of scientists have been compiling for this ten volume series, I can't help but become philosophical. Scientific endeavors by their very nature, while providing answers to several questions, create more and more questions. If one examines the growth of various scientific disciplines one would realize that while we made tremendous progress in scientific achievements, we continue to be puzzled by several unanswered questions in addition to several more new ones popping up every day. In the words of one philosopher, "the measure of our intellectual maturity is our capacity to feel less and less satisfied with our answers to better problems." One could say that the progress in science is directly proportional to the number of unsolved problems. It is pertinent to remember what Einstein said once, "We can't solve problems by using the same kind of thinking we used when we created them." What we need as scientists is lateral thinking. In order for developing lateral thinking one needs to comprehend the existing knowledge and develop the ability to connect seemingly unconnected points in the web of knowledge.

Nanoscience and nanotechnology is beginning to gain respectable place in this web of knowledge that we scientists have been creating. This new scientific discipline is being touted as the greatest revolution in the history of mankind and is

anticipated to positively affect every facet of our existence. It is anticipated to improve quality of our life in leaps and bounds. However, Nanotechnology's greatest gift to mankind, in my view, is its ability to promote lateral thinking amongst not only scientists but all those who are associated with this new approach to problem solving. This is what I would like to call "nano vision or nano thinking". It is the ability to think small while thinking big and to connect small and big at the same time." The followers of "nano thinking", so called "nano thinkers", are growing day by day and their presence is beginning to be felt strongly in the field of life sciences. It is my endeavor to be a catalyst in inculcating this new thinking by providing a multi-pronged base of knowledge in nanotechnologies for the life sciences. The ten volume series *NtLS* is anticipated to be the solid foundation for all those who are interested in applying "nano thinking" in life sciences. I am leaving the book in your hands and take your leave sharing a quotation from one of the greatest thinkers from the United States of America, Oliver Wendell Holmes, who said "Man's mind, once stretched by a new idea, never regains its original dimensions." It is my hope that this book series will help in stretching the limits of thinking in all those who come in contact with it.

Challa S. S. R. Kumar

## Biofunctionalization of Fluorescent Nanoparticles

*Michael J. Murcia and Christoph A. Naumann*

### 1.1 Introduction

The current revolution in life sciences is strongly linked to the availability of sophisticated new experimental tools that enable the manipulation of biomolecules and the study of biological processes at the molecular level using state-of-the-art imaging techniques, such as single molecule imaging. Optical microscopy is fundamental to furthering our understanding of the structural, organizational, and dynamic properties of biological systems because a wide variety of complementary, non-invasive optical techniques exemplified by wide-field microscopy techniques, such as brightfield, darkfield, phase contrast, and DIC exist. Among these optical detection techniques, fluorescence microscopy is particularly important because it facilitates highly sensitive and specific imaging experiments. In addition, more sophisticated imaging approaches such as confocal and near-field imaging provide the opportunity for 3D and sub-diffraction limit imaging, respectively.

Optical microscopy is now sensitive enough to track individual molecules if they are conjugated to appropriate imaging probes. Traditionally, such single molecule probes were  $\mu\text{m}$ -size colloidal particles and single fluorophores [1]. Colloidal probes such as gold or fluorescently labeled polystyrene beads are typically much larger (0.1–1  $\mu\text{m}$ ) than the biomolecule to be studied. However, fluorescent dyes, though smaller, show pronounced photo-instabilities, including blinking (due to fluorescence intensity fluctuations) and photobleaching, thus complicating single molecule tracking experiments and other fluorescence-based long-term studies. From the above description, further progress in the field of optical single molecule imaging obviously depends on the availability of appropriate labels that combine small size and high photostability with the ability to be used in multicolor studies. Fluorescent nanoparticles fulfill these important criteria. To be used in a biological environment, these nanoprobles need to be biofunctionalized appropriately, which remains a significant challenge.

The main focus of this chapter is to provide an overview of recent developments addressing the bioconjugation of fluorescent nanoparticles and their surface modification using biocompatible coatings. Section 1.2 summarizes the different types

of fluorescent nanoparticles, including dye-doped nanoparticles, quantum dots (QDs), metal nanoparticles, and  $\mu\text{m}$ -size hybrids comprising fluorescent nanoprobes. Section 1.3 describes recent developments concerning the conjugation of biomolecules to fluorescent nanoparticles, and compares the different conjugation approaches for nanoparticles consisting of polymeric, semiconductor, or metallic materials. An overview of published design architectures of biocompatible surface coatings as applied to fluorescent nanoparticles is given in Section 1.4. Finally, Section 1.5 lists representative examples of how biofunctionalized nanoprobes can be applied to problems in biosensing, as well as single cell and biological tissue imaging.

## 1.2

### Fluorescent Nanoparticle Probes

Gold nanoparticles that are surface-functionalized with proteins have been used in electron microscopy (EM) applications for quite some time [2]. A prominent example is the specific labeling of tissue by use of antibody-conjugated Au-nanoparticles (10–40 nm diameter) and their imaging by use of transmission electron microscopy (TEM). Such EM studies can achieve the detection of Au-probes with a resolution of less than 10 nm [3]. Though this demonstrates a great sensitivity, EM is limited by its inability to image living biological systems. Optical microscopy may overcome this limitation. For example, colloidal gold of 30–40 nm diameter has been used as an optical imaging label on multiple single molecule tracking experiments at the cellular level [1, and references therein]. Here, colloidal gold is used as a Rayleigh scatterer, for which the scattering  $\propto d^6$  ( $d$  = diameter), thus making tracking experiments with probe diameters of less than 30 nm extremely challenging or even impossible.

Fluorescent nanoparticles are highly attractive imaging probes because, in contrast to scattering probes, their detection is not limited by the Rayleigh scattering condition. As a consequence, fluorescent nanoprobes  $> 1$  nm can be detected if appropriate imaging setups are used. Importantly, at this size range, such nanoprobes do not exceed the size of individual proteins, thus addressing an important condition for high-quality imaging at the molecular level. In addition, single molecule detection is improved because the weak scattering of the probes lowers the optical background and thus enhances the imaging sensitivity. Figure 1.1 illustrates the size range of these probes in comparison with that of other nanoparticles. The most common types of fluorescent nanoparticles, dye-doped nanospheres and luminescent quantum dots (QDs), are described below in more detail, together with some recently introduced hybrid architectures of fluorescent nanoprobe-containing  $\mu\text{m}$ -size particles. Also included is an overview of optically active metal nanoparticles because these probes are highly relevant in single molecule spectroscopy.

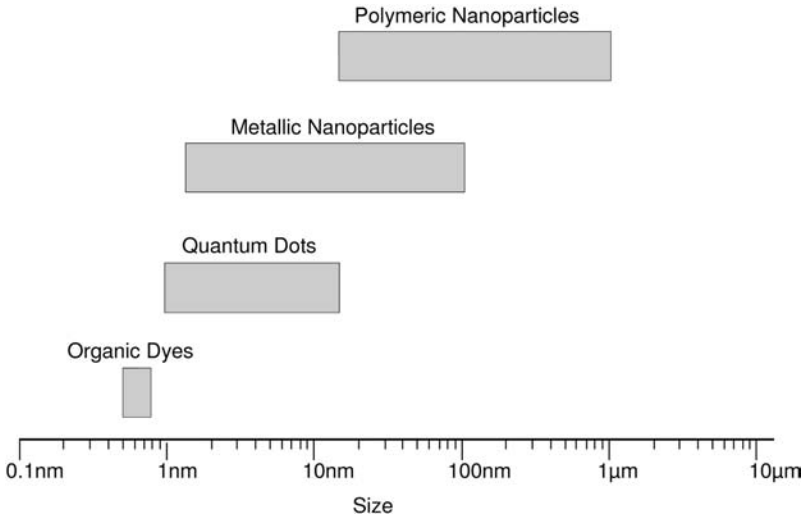

Fig. 1.1. Size ranges of commonly used fluorescent nanoprobes.

### 1.2.1

#### Dye-doped Nanoparticles

Dye-doped nanoparticles are polymer or silica-based particles containing organic or inorganic dyes [4, 5]. Dyes can be attached to the nanoparticle surface or can be embedded inside the particles either noncovalently or covalently. For imaging applications, dye-doped nanoparticles containing embedded dyes are particularly attractive because their photostability can be enhanced due to the better protection of the dyes from oxygen. For example, incorporation of pyrene dyes into polystyrene particles using a normal microemulsion approach led to a 40-fold increase in emission intensity with respect to the pure dye at the identical concentration [6]. Brightness of the fluorescence signal from such imaging probes can be controlled by the number of dye molecules per nanoparticle, with the maximum dye density limited only by self-quenching. Therefore, dye-doped nanoparticles can be quite photostable without showing fluorescence intensity fluctuations (blinking).

Typical polymer-based dye-doped nanoparticles are made of hydrophobic polymers. The hydrophobic dye molecules are kept within such nanoparticles through noncovalent hydrophobic interactions, thus preventing the gradual release and photooxidation of the dyes. Dye-doped polymeric nanoparticles have been applied down to a size of  $\sim 20$  nm [7]. Although they are reasonably photostable, the hydrophobic nature of these probes complicates imaging applications in aqueous environments, which are required for studies on biological systems. Common unwanted phenomena are clustering and non-specific binding. To overcome these problems, the hydrophobic core particles can be surface-functionalized with hydro-

philic coatings such as polymers like poly(ethylene glycol) (PEG), polysaccharides such as dextran, or proteins such as bovine serum albumin (BSA).

Dye-doped silica nanoparticles are attractive imaging probes because their hydrophilic nature reduces the problems of non-specific binding and clustering. Silica shows several additional properties beneficial for optical imaging applications in biological systems, including chemical inertness, transparency, and the ability to act as stabilizers in protecting the embedded dyes from the outside environment [4]. In addition, the surface hydroxyl groups can be chemically modified, allowing for the straightforward surface modification with amines, carboxyls, or thiols. In addition, pH changes do not lead to swelling and porosity changes, and silica particles are less prone to attack from microbes [8]. However, the incorporation of hydrophobic dyes into the hydrophilic silica matrix is challenging, requiring specific modifications of either the dye molecules or the silica. For example, dyes can be modified with a hydrophilic molecule such as dextran or a hydrophobic silica-precursor can be used during nanoparticle synthesis [9]. Dye-doped silica particles were first synthesized using the Stoeber method [10]. However, this method leads to polydispersity and average particle sizes of  $>100$  nm. More recently, these limitations have been overcome by use of a reverse microemulsion method that can create monodisperse dye-doped silica particles down to a size of 15 nm (Fig. 1.2) [11]. Notably, this elegant approach facilitates the size-tuning via adjustment of the microemulsion composition and does not require elevated temperatures and pressures [11, 12]. Silica also has been used to create hollow silica nanospheres filled with dye molecules [13].

Rare-earth-doped  $\text{LaPO}_4$  nanoparticles are another interesting class of nanoprobes that show promising properties for diagnostic and imaging applications [14]. These systems combine small size ( $<10$  nm), high chemical stability, very good quantum yield, and high photostability. Furthermore, they are expected to show low cytotoxicity. Recently, such rare-earth-doped  $\text{LaPO}_4$  nanoparticles were successfully surface-functionalized to allow their subsequent coupling to biomole-

**Fig. 1.2.** Schematic of the reverse microemulsion method for the synthesis of dye-doped silica nanoparticles (adapted from Bagwe et al., 2004) [11]. In this method, nm-sized water droplets, which are stabilized by

surfactant molecules, are formed in a continuous oil phase, thus forming a thermodynamically stable oil–water–surfactant microemulsion.

cules [15]. The nanoparticle surface was first functionalized with aminohexanoic acid and then linked to avidin using EDC coupling.

### 1.2.2

#### Quantum Dots (QDs)

Nanocrystals based on semiconductor materials began attracting the interest of physicists three decades ago because of their interesting quantum properties. These properties are the result of size-dependent band gaps, which cause the color emitted by a semiconductor nanocrystal of a specific composition to be a function of its diameter. Physically, quantum properties (in this case a size-dependent fluorescence emission) are expected to occur if electron–hole pairs (excitons) are confined to dimensions that are smaller than the electron–hole distance (exciton diameter) [16–19]. As a result of this condition, the state of free charge carriers within a nanocrystal is quantized and the spacing of the discrete energy states (emission colors) is linked to the size of the nanoparticle. It is this quantum confinement effect that led to the term “quantum dot”.

Quantum dots can be based on metallic or semiconductor materials. Most widely used are CdSe and CdTe quantum dots because their quantum confinement region spans the entire optical spectrum. More recently, there has been growing interest in quantum dots with near-infrared emission properties, such as CdTe/CdSe, InAs, or PbS (which are of use in animal imaging studies) [20, and references therein]. In addition, several groups have studied silicon nanocrystals [21–23]. Quantum dots also show other fascinating optical properties, including broad absorption and narrow emission bands, which allows a single laser to excite dots of a wide size-range, with each dot emitting its own specific color. This is in contrast to organic-based fluorophores, which are characterized by narrow Stokes shifts (difference between maximum wavelengths of absorption and emission bands). To protect their surface from photobleaching, quantum dots can be passivated by use of a higher-bandgap semiconductor shell or an organic layer [24]. In fact, successfully passivated, quantum dots show dramatically enhanced photostability, enabling their long-term observation in optical experiments [25]. Furthermore, quantum dots can be brighter than their dye counterparts at an equivalent quantum yield [26] because of their notably higher extinction coefficients [20]. Given the above properties, quantum dots bring fascinating possibilities for single molecule cellular imaging studies because they combine small size, broad absorption, narrow size-tunable emission (covering the entire optical spectrum), and excellent photostability. These features outperform traditional fluorescent dyes in many respects.

The traditional approach to synthesizing quantum dots relies on heating specific organic solvents and injection of semiconductor precursors. In a typical preparation [27], Cd(CH<sub>3</sub>)<sub>2</sub> and elemental Se are combined with trioctylphosphine oxide (TOPO), which acts as a solvent and stabilizing agent. This mixture is subjected to high temperature (about 350 °C) for 24 hours at which time the mixture is cooled and Zn(CH<sub>3</sub>)<sub>2</sub> and S(SiMe<sub>3</sub>)<sub>2</sub> added to form a stabilizing ZnS shell. To cre-

ate nanocrystals of a narrow size distribution, an additional size-selective precipitation step needs to be included. Because dialkylmetal compounds are very sensitive to oxygen and water and become pyrophoric upon exposure to air, alternative approaches of quantum dot synthesis have been explored. Consequently, CdSe quantum dots can be formed using CdO, selenium, and hexylphosphonic acid or tetradecylphosphonic acid [28]. This synthesis reduces the reaction times to less than 30 min, but still uses temperatures upwards of 300 °C. In another example, our group has synthesized CdSe/ZnS quantum dots by use of sonochemistry [29]. This low-temperature approach not only produces spherical high-quality quantum dots with quantum yields of up to 70% and emission bands of less than 50 nm (FWHM), but also allows for straightforward control of the synthesis parameters. Figure 1.3 shows the photoluminescence spectra of CdSe core quantum dots and

**Fig. 1.3.** Quantum dots show size-tunable emission properties. The samples represent different sizes of quantum dots, which produce different colors upon UV light. Within the quantum confinement region, an increase in particle sizes produces a redshift in the emission spectrum. Spectra and photograph were obtained from CdSe quantum dots synthesized sonochemically [29].

the colors of these samples upon UV illumination, which are representative of this procedure.

To be of use in biological imaging applications, quantum dots need to be water-soluble. Indeed, synthetic approaches for CdTe [30–32] and CdS [30, 33–38] have utilized aqueous solvent conditions. However, these nanocrystals usually lack the quantum yield and narrow size distribution observed for TOPO-synthesized quantum dots. TOPO-stabilized quantum dots, however, show hydrophobic surface properties. To disperse TOPO-stabilized quantum dots in aqueous solution, several surface modification strategies have been pursued (Fig. 1.4). A common approach is to synthesize quantum dots in TOPO and replace the hydrophobic TOPO layer with bifunctional molecules containing thiol and hydrophilic moieties separated by a molecular spacer (Fig. 1.4: approach I) [39, 40]. The thiol groups bind to the CdSe or ZnS surface, while the hydrophilic moieties radiate from the surface of the corresponding semiconductor. Unfortunately, thiols bind less strongly to ZnS than to Au, which leads to a dynamic equilibrium between bound and unbound thiols. This behavior reduces the long-term water solubility of ZnS-capped quantum dots. To shift the equilibrium towards bound moieties, monothiols have been replaced with molecules containing more than one thiol group (Fig. 1.4: approach II) [41–43]. Another stabilization concept is to enhance binding via surface cross-linking of bound molecules. On the basis of this concept, ZnS-shelled quantum dots have been made water-soluble by adding a silica shell to the nanoparticles by using alkoxysilanes during the polycondensation (Fig. 1.4: approach III) [44–48]. Two types of silanes have been used to stabilize quantum dots in aqueous solution. The first includes silanes whose surface functional groups are positively or negatively charged at neutral pH [48]. The second type includes silanes with poly(ethylene glycol) chains [48, 49]. TOPO-coatings also can be made water-soluble without their replacement by adding amphiphilic molecules such as lipopolymers or amphiphilic diblock copolymers, whose hydrophobic moiety stabilizes the TOPO-coating via hydrophobic forces and whose hydrophilic moiety is exposed to the solvent environment, guaranteeing water-solubility (Fig. 1.4: approach IV). The last approach has the advantage of not exposing the sensitive surface of the quantum dot during a surface exchange step.

### 1.2.3

#### **Metal Nanoparticles**

In contrast to noble metals in bulk, nanoparticulate forms of such materials result in interesting photochemical and electronic properties [50]. Three strategies have been pursued to study the photochemical activity of metal nanoparticles: (a) direct excitation of the metal nanoparticles; (b) indirect excitation of the metal nanoparticles via surface-conjugated dye molecules; and (c) photocatalytic processes in semiconductor–metal nanocomposites [50]. After excitation with UV or visible light, metal nanoparticles show several interesting phenomena, including photoluminescence [51–53], nonlinear optical phenomena [54, 55], and surface-enhanced

**Fig. 1.4.** Schematic representation of four common approaches to hydrophilic surface modification of TOPO-stabilized quantum dots. Approach I: TOPO replacement with a heterofunctional linker consisting of a thiol end group, a spacer, and a hydrophilic end group such as carboxylic acid. II: TOPO replacement with a linker consisting of two thiol groups on one end and a hydrophilic end group on the other end. Approach III: TOPO replacement with a silane forming a stable shell via crosslinking. Approach IV: Stabilization of TOPO layer using amphiphilic molecules such as PEG lipopolymers or amphiphilic diblock copolymers that are held on the surface by hydrophobic interaction with the octyl chains of TOPO.

Raman scattering (SERS) [56–61]. Due to the significant field enhancement, SERS can be used as an extremely sensitive analytical tool, thereby exceeding the sensitivity from luminescence-detecting techniques. For example, biomolecules can be detected with 1000-fold better sensitivity if they are bound to Au nanoparticles [62]. Silver nanoparticles also are useful in this respect. The main experimental challenge in SERS is to keep the surface roughness uniform and reproducible.

There are multiple strategies for synthesizing metal nanoparticles [50]. For example, they can be synthesized using a biphasic reduction approach [63–69]. In this procedure, a noble metal salt such as  $\text{HAuCl}_4$  is dissolved in water and phase-transfer extracted into an organic solvent followed by reduction with  $\text{NaBH}_4$ . Metal nanoparticles also have been synthesized using reverse micelle procedures where the size and size distribution of nanospheres can be controlled by the micelle composition [12, 70–73]. Gold nanoparticles are particularly attractive for studies in a biological environment because they show no surface oxidation and high biocompatibility without any surface modification. In addition, thiol chemistry can be applied to conjugate molecules to the gold surface.

#### 1.2.4

### Hybrid Architectures Involving Fluorescent Nanoprobes

#### 1.2.4.1 Metal–Dye

Another interesting application of metal nanoparticles is their use in combination with conjugated dye molecules (Fig. 1.5). Such hybrid systems are attractive because they can be studied by use of electron microscopy in addition to fluorescence-based techniques such as fluorescence microscopy and spectroscopy. Importantly, if conjugated to biomolecules, metal nanoparticle–dye hybrids can be used as very sensitive biomolecular imaging probes [74, 75]. Interestingly, dye molecules attached to metal nanoparticles can show enhanced emission. For example,  $\text{Py-CH}_2\text{NH}_2$  molecules bound to gold particles show pronounced emission that is much stronger than that for unbound  $\text{Py-CH}_2\text{NH}_2$  in THF [50]. The main disadvantage of this approach is that the surface-exposure of the dyes promotes their photooxidation.

#### 1.2.4.2 Dye-doped Silica Shells

To reduce photooxidation, dyes also can be embedded within the nanoparticle. As illustrated in Fig. 1.5(B), dyes can be incorporated into a nanoparticle-capping silica shell. For example, up to 12 alternating fluorescent and nonfluorescent silica shells have been added to silica core particles, where the shells were doped with six dyes of different emission wavelengths. Dyes of multiple colors have been incorporated previously in silica beads throughout the matrix of the particle [76], but not in an ordered fashion [77]. This multi-shell approach helps to reduce unwanted energy transfer. As a multiplexing probe, the system is not as simple to analyze as a quantum dot-based one. Re-absorption of the fluorescence emission,

**Fig. 1.5.** Common hybrid architectures containing fluorescent nanoprobables include (A) dyes bound to a nanoparticle surface; (B) dyes incorporated into the silica shell of a nanoparticle; (C) fluorescent probes such as quantum dots or dyes incorporated into the core of microparticles; and (D) a multiplexing approach by embedding probes of different colors.

which is related to the identity of the fluorophore, alters the emission intensity. As a result, it is difficult to determine the possible number of spectral combinations in a designed system, and a flow cytometer must be used to identify the number of individual species in the mixture. This shelling approach has also been reported for single dye systems for enhanced fluorescence [10].

#### 1.2.4.3 Quantum Dot-containing Microspheres

An interesting hybrid architecture that has been developed recently is the quantum dot embedded microsphere. Unlike a dye embedded polymeric bead, the quantum dot microbeads utilize the narrow emission of quantum dots combined with their broad absorption characteristics to perform multicolor detection experiments with one excitation wavelength [78–81]. By incorporating up to six different colors of quantum dots and ten intensities of those colors, the quantum dot microbeads can, theoretically, optically “bar code” biomolecules with one million possible spectral signatures. Realistically, the number is likely to be substantially lower due to spectral overlap, fluorescence intensity variations, and signal-to-noise requirements. The multiplexing approach has been tried with organic dyes, but was limited to two colors due to spectral overlapping and the inability to excite more than two or three dyes with the same wavelength [82].

## 1.3 Bioconjugation of Fluorescent Nanoparticles

### 1.3.1 General Considerations

#### 1.3.1.1 Overview

To apply fluorescent nanoparticles to biosensing and biomedical imaging applications, it is crucial to develop strategies towards their biofunctionalization. These include the proper linkage of biomolecules to nanoparticles (bioconjugation) and the design of appropriate biocompatible coatings. This section outlines the different aspects of bioconjugation, and Section 1.4 provides a corresponding discussion of biocompatible coatings.

Bioconjugation can be described as any procedure that links a nanoparticle to a biomolecule under mild conditions [83]. As described above, the synthesis of nanoparticles often does not render them capable of attachment to biomolecules, because their surface-chemical properties are not appropriate. Therefore, nanoparticles frequently must undergo surface transformations to create the chemistry needed for coupling to biomolecules under mild (physiological) conditions. There are a few key requirements for successful bioconjugation reactions [4]. Crucially, the conjugation process must avoid compromising the activity of biomolecules. In addition, the bioconjugation ideally should not hinder the signal of the nanoparticle. Another requirement is the ability to control the number of linkage sites on the nanoparticle surface where biomolecules can bind. This requirement can be quite challenging. In addition, the biomolecule–nanoparticle coupling should be stable and, for crystalline particles, the surface should be covered to avoid free valence states. Finally, the thickness of any nanoparticle shell should remain as small as possible relative to the nanoparticle size.

Figure 1.6 illustrates several possible strategies to bioconjugate nanoparticles. Simple adsorption of biomolecules to the nanoparticle surface via noncovalent forces represents the least demanding approach (Fig. 1.6A). However, in this case, the activity of bound biomolecules may be compromised and the amount of bound biomolecules per nanoparticle is difficult to control. In addition, this bioconjugation approach does not target one protein preferentially. Another concept is based on the physisorption (noncovalent coupling) of biomolecules to molecules (e.g., other biomolecules) acting as mediators between biomolecule and nanoparticle surface (Fig. 1.6B). This design may be advantageous over the first one, because it may help biomolecules to bind in a proper orientation. Figure 1.6(C) is based on the chemical coupling between reactive groups of biomolecules (e.g., thiols and primary amines) and crosslinker molecules. These crosslinkers may bind to the nanoparticle surface via physisorption or chemisorption (covalent coupling). However, there are frequently multiple active sites on the target biomolecule to which the probe can bind, thus preventing controlled binding. Furthermore, uncontrolled

**Fig. 1.6.** Common strategies for the conjugation of biomolecules to nanoparticles include direct physisorption of biomolecules (A), assisted physisorption using pre-bound molecules (B), chemical linkage of biomolecules to crosslinkers either physisorbed or

chemisorbed on the nanoparticle surface (C), direct chemical coupling of biomolecules to nanoparticles (D), and the targeted binding of biotinylated biomolecules to streptavidin-coated nanoparticles via biotin–streptavidin coupling (E).

binding may interfere with the biologically active sites of biomolecules. To overcome this limitation, a ligand (typically an antibody) can be bound to the nanoparticle via the crosslinker. This ligand then facilitates coupling to the biomolecule of interest with high specificity. These crosslinker-based bioconjugation strategies are best executed if appropriate heterobifunctional crosslinkers are used. A large variety of such crosslinker molecules is now commercially available. Alternatively, homobifunctional crosslinkers can be used where one reactive end group is protected. Here, nanoparticle and biomolecule are coupled by binding of the partially protected linker to either nanoparticle or biomolecule and by deprotecting the linker prior to bioconjugation. Unprotected homobifunctional crosslinkers are always problematic because they can induce the clustering of nanoparticles. Figure 1.6(D) shows a facile approach for the chemical coupling of biomolecules to nanoparticles. This approach is particularly useful for attaching oligonucleotides to nanoparticles, e.g., via mercapto groups [84–86]. Still, control over the number of bound biomolecules per nanoparticle remains a challenging endeavor. To achieve such control, a separation step, such as nanoparticle separation using gel electrophoresis, must be added [87]. Another popular approach is to link biotinylated ligands or target biomolecules to streptavidin (or avidin)-functionalized nanoparticles with high specificity (Fig. 1.6E). In this case, the biotin-binding proteins, avidin or streptavidin, act as linker molecules [88, 89].

### 1.3.1.2 Common Coupling Reactions

The bioconjugation of nanoparticles is critically dependent on the availability of effective covalent coupling procedures. Figure 1.7 lists the most common coupling procedures. The reaction between primary amine and carboxylic acid groups is a very popular coupling procedure (Fig. 1.7A). In a first step, a carboxylic acid reacts with 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDAC) and *N*-hydroxysulfosuccinimide (NHS) to form an acyl amino ester that subsequently reacts with the primary amine to create a stable amide bond. This approach also is attractive because preparation of the ligands is less demanding. A widely used approach is based on the reaction between thiol and maleimide groups (Fig. 1.7B). This affords a stable thioether bond, typically with good yield at physiological pH. Most prominently, this reaction can be used to directly link maleimide-functionalized ligands to thio-groups of proteins. If no thiols are available, they can be created by using heterobifunctional crosslinkers with one thiol endgroup or by reducing disulfide bonds within the target protein. The coupling of two thiols to form a disulfide linkage is another straightforward reaction approach (Fig. 1.7C). Unfortunately, the resulting disulfide bond is relatively labile in biological fluids like serum. Another useful reaction scheme is based on the covalent linkage between aldehyde and hydrazide groups to form a hydrazide bond (Fig. 1.7D). Reactive aldehyde groups can be created by oxidation of carbohydrate groups. Obviously, mild oxidation conditions have to be used for the oxidation reaction on relatively unstable molecules like antibodies. Chemical reaction between two primary amines is another approach for bioconjugation applications (Fig. 1.7E). In this case, coupling can be achieved using homobifunctional crosslinkers such as glutaraldehyde [90, 91].

## 1.3.2

### Bioconjugation of Polymeric Nanoparticles

From a bioconjugation perspective, polymeric nanoparticles are attractive because they can be prepared with various different reactive groups on their surface. The obvious benefit is that a comparably broad spectrum of conjugation chemistry approaches can be used, including covalent and noncovalent ones (Fig. 1.6). These different bioconjugation strategies are reviewed below.

#### 1.3.2.1 Noncovalent Approaches

One of the most widely applied approaches in bioconjugating polymeric nanoparticles is simple physisorption of the biomolecules on the particle surface (Fig. 1.6A) [93–97]. Because biomolecule activity is compromised by uncontrolled adsorption, spacer molecules have been introduced (Fig. 1.6B). For example, nanoparticles first coated with Protein A (isolated from the cell wall of *Staphylococcus aureus*), which attaches specifically to the Fc fragment of the IgG antibody, have proper Fab orientation for antibody binding [97]. Unfortunately, such simple adsorption approaches are only of limited use when applied in serum. This is because serum proteins compete with antibodies for adsorption sites [93–95]. Furthermore, *in vivo* experiments have revealed that such simply designed nanoparticles tend to accumulate

in the liver and spleen. Using a similar design strategy, polystyrene nanoparticles have been functionalized with humanized mAb HuEP5C7.g2 [98]. These delivery systems target cells expressing E and P-selectin.

### 1.3.2.2 Covalent Approaches

Obviously, the activity of ligands bound to nanoparticles strongly depends on the stability of the ligand–nanoparticle linkage and the proper orientation of the ligand. To address these needs, ligands have been bound covalently to polymeric nanoparticles using several different conjugation approaches (Fig. 1.6E) [7, 99–102]. For example, an amide linkage strategy was pursued to bind lactose to the poly(vinylamine)-grafted nanoparticles [99]. Such lactose-functionalized carrier systems are useful because they specifically bind to lectin RCA<sub>120</sub>. The same amide-based linkage chemistry was used to bind proteins to dye encoded latex particles [7]. In another approach, transferrin was conjugated to PEG coated poly(cyanoacrylate) nanocrystals, with the transferrin bound to PEG via periodate oxidation [100]. A heterobifunctional linker was used to bind antibodies to BSA-containing nanoparticles [101, 102]. In this case, the crosslinker (glutaraldehyde) was bound to BSA to provide free aldehyde groups, which could then be linked to the primary amines of the antibodies. Another interesting strategy is based on formation of ligand-carrying nanoparticles via polymerization of monomers with bound ligands. Such a strategy has been applied to create nanoparticles with biotin groups, which then allowed for specific linkage to avidin [103, 104]. The grafting of carbohydrates to poly(L-lysine) was also reported [105]. This carrier can bind to carbohydrate-binding proteins on the surface of target cells.

### 1.3.3

#### Bioconjugation of Quantum Dots

Though quantum dots are very small, their surface area is large enough for linking to multiple biomolecules [106]. There are several ways to bind biomolecules to quantum dots. These involve either direct binding to the quantum dot surface or attachment via a stabilizing layer acting as a crosslinker between the ligand and reactive surface of the nanoparticle. In the first case, ligand binding can be achieved covalently or noncovalently. Direct covalent coupling is accomplished commonly by use of thiol coupling chemistry, although a silane-based coupling is needed if quantum dots carry a stabilizing silica shell. Noncovalent ligand-quantum dot coupling, however, is typically pursued using electrostatic or hydrophobic forces. On the basis of these general concepts, several bioconjugation strategies have been pursued. These are discussed below.

**Fig. 1.7.** Commonly used chemical reactions in the bioconjugation of fluorescent nanoparticles. Shown are the coupling chemistries between (A) carboxylic acid and primary amine, (B) thiol and maleimide

groups, (C) two thiols to form a disulfide bond, (D) hydrazide and aldehyde groups, and (E) two primary amines. (Adapted from Nobs et al., 2004 [92].)

### 1.3.3.1 Noncovalent Approaches

An electrostatic coupling approach has been applied to link negatively charged CdTe quantum dots and positively charged enzymes [107]. Electrostatic coupling also was pursued in several applications to bind positively charged protein domains (pentahistidine segment) to oppositely charged alkyl-COOH-capped quantum dots [31, 42, 88, 108–112]. An alternative electrostatic-based coupling strategy has been used to bind nanocrystals coated with trimethoxysilylpropyl-urea and acetate groups with high affinity in the cell nucleus [44]. Here the binding of the silanized nanocrystal surface is controlled with an anionic silane reagent. Negatively charged quantum dots have also been electrostatically bound to positively charged Maltose Binding Protein [113]. Quite often, adsorbed proteins show a stabilizing effect on the quantum dot surface, thereby improving the optical properties of the probes. For example, a two-fold increase in fluorescence was observed after adsorption of 10–15 Maltose-Binding Protein Pentahistidine (MBP-5HIS) to the quantum dot surface [114].

### 1.3.3.2 Covalent Approaches

A relatively straightforward covalent bioconjugation approach is based on the replacement of thiol acids present on the quantum dot surface with thiolated biomolecules. This strategy has been used to attach oligonucleotides, DNA [41, 84] and bovine serum albumin (BSA) [86] to quantum dots. Proteins also have been conjugated to quantum dots by reacting carboxylic acid groups on the nanoparticle surface with amine groups of the proteins [115]. A similar strategy was used to covalently attach IgG and streptavidin to quantum dots. The IgG system was applied as a cancer marker, whereas the streptavidin system was utilized for labeling actin, microtubules and the cell nucleus [116].

In another application, antibodies have been bound to quantum dots via sulfo-NHS crosslinking [117]. In a different approach, reactive biotin was covalently linked to either surface sulfhydryl or amine functionalities, thus allowing for the biotinylation of the quantum dot surface and the subsequent binding to streptavidin [44]. A biotin–streptavidin coupling approach was chosen, for example, to bind quantum dots to fibroblasts [44]. In this case, the nanocrystals were functionalized with biotinamidocaproic acid 3-sulfo-*N*-hydroxysuccinimide ester and then allowed to bind to fibroblasts previously incubated with phalloidin–biotin and streptavidin. A combination of covalent and noncovalent coupling strategies was pursued by conjugating quantum dots stabilized with amphiphilic PEG lipids to DNA. Here, the DNA coupling was achieved by replacing  $\frac{1}{2}$  of the PEG-PE phospholipids with amino PEG-PE. Thiol modified DNA was then covalently coupled to the amines on the surface of the quantum dot [118].

### 1.3.4

#### Bioconjugation of Metallic Nanoprobes

Most conjugation concepts described for the linkage of ligands to quantum dots can also be applied to metal nanoparticles, such as Au or Ag nanoprobes. Again,

surface modification is accomplished using thiol-coupling chemistry. The binding of biomolecules to these nanoparticles can be covalent or noncovalent. With respect to biofunctionalization, gold nanospheres are particularly attractive because gold shows excellent biocompatibility properties, and does not require additional surface chemical modification prior to bioconjugation. In addition, gold nanoparticles can be made with very narrow size distribution. This is advantageous if accurate control of the number of bound biomolecules per nanoparticle is required.

#### 1.3.4.1 Noncovalent Approaches

One option for bioconjugation is the direct attachment of a biomolecule to the metallic nanoparticle surface. Short peptide chains such as tiopronin [119] and the tripeptide glutathione [120] have been conjugated directly to a gold surface. Globular proteins have also been directly conjugated. Miziani et al. conjugated globular proteins directly to the surface of silver sulfide nanoparticles [121]. In another application, gold nanoparticles were coated with BSA via electrostatic interactions under mild conditions [122]. Due to the bioinertness of gold, biomolecules directly bound on the gold surface can retain their activity, as shown, for example, for redox enzymes [123] and cytochrome c [124]. Biotin–streptavidin coupling concepts have also been used. For example, disulfide-modified biotin was conjugated to gold nanoparticles and subsequently reacted with streptavidin [125].

#### 1.3.4.2 Covalent Approaches

Direct coupling of biomolecules to the surface of metal nanoparticles represents a very facile bioconjugation strategy. Among the different metals, this conjugation strategy is best suited for gold because of its excellent bioinertness. For example, thiol-modified DNA has been conjugated directly to gold particles [74, 126–128]. Direct thiol coupling was also pursued to conjugate SH modified PEG to gold-shelled silica nanoparticles [129]. Covalent bioconjugation to the nanoparticle can also be mediated by heterobifunctional crosslinker molecules. One example is the surface modification of iron oxide nanoparticles with a trifluoroethylester-terminal poly(ethylene glycol) (PEG) silane and the subsequent coupling of biomolecules via their terminal amine or carboxyl groups [130].

## 1.4

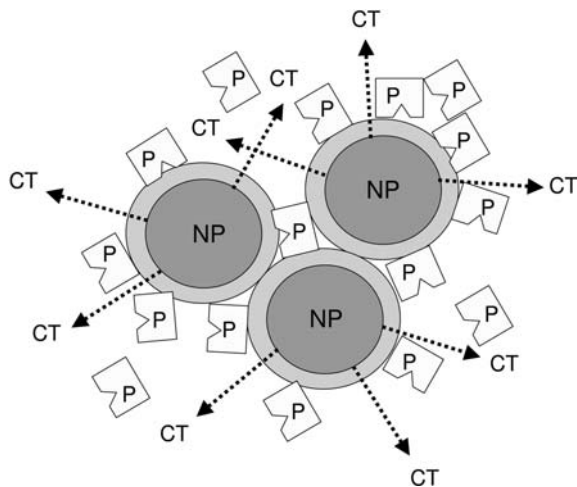

### Design of Biocompatible Coatings

#### 1.4.1

##### General Considerations

##### 1.4.1.1 Overview

Though multiple bioconjugation strategies have been worked out, the routine application of fluorescent nanoparticles in biomedical imaging remains challenging. This is largely because not only appropriate conjugation between biomolecules to nanoparticles is required but other important criteria concerning biocompatibility

**Fig. 1.8.** Potential problems compromising the biocompatibility of fluorescent nanoparticles, including nanoparticle (NP) clustering, non-specific adsorption of proteins (P), and release of cytotoxic ions (CT).

have to be fulfilled. These criteria include (a) prevention of nanoparticle aggregation in a biological environment, (b) effective suppression of non-specific adsorption of biomolecules at the nanoparticle surface or their accumulation close to the surface, and (c) low cytotoxicity (Fig. 1.8). To address these criteria, nanoparticles need to be capped with protective coatings that show passivating surface properties. Notably, the first criterion, good colloidal stability, does not guarantee the biocompatibility of nanoparticles as, firstly, ions and proteins may be accumulated on or near the nanoparticle surface, thus varying the complex molecular composition nearby. Secondly, especially with heavy metal-containing quantum dots (e.g., CdSe, CdTe), individual nanoparticles may remain cytotoxic if the coating does not protect the biological environment from released heavy metals ions.

#### 1.4.1.2 Colloidal Stability

The dispersion stability of nanoparticles is well-described by the Derjaguin–Landau–Verwey–Overbeek (DLVO) theory, which predicts that such stability is determined by the balance between attractive van der Waals and repulsive electrostatic forces. As a result, nanoparticles are expected to remain stable (show no particle aggregation) if the strength of the repulsive electrostatic force exceeds that of the attractive van der Waals (vdW) force. In other words, nanoparticles show no aggregation if they contain a sufficient density of surface charges. Indeed, particles with charged surface properties do not aggregate in ion-free solutions. At the same time, this balance can clearly be shifted in favor of vdW forces if the charges on the particle surface are screened by counter ions in the solution. This is an important aspect to consider during chemical surface modification, because such

**Fig. 1.9.** Fluorescence correlation spectroscopy autocorrelation curves of ZnS-capped CdSe quantum dots surface-functionalized with carboxylic acid in Millipore water (dark curve) and 10 mM MES buffer (lighter curve). The notably higher diffusion time obtained for the buffer-based system indicates nanoparticle clustering.

modifications may result in surface charge neutralization, thereby compromising dispersion stability. More importantly, nanoparticles with charged surfaces tend to become unstable (show aggregation) in a biological environment. Figure 1.9 shows the loss of colloidal stability due to charge screening. Here comparative fluorescence correlation spectroscopy (FCS) autocorrelation curves from our laboratory are presented for CdSe/ZnS quantum dots with negatively charged carboxylic acid surface groups in Millipore water and in 10 mM MES buffer. As illustrated, the nanoparticles in MES buffer show notably higher diffusion times, indicating their increasing aggregation. If quantum dots are surface-functionalized with a layer of hydrophilic polymers such as poly(ethylene glycol) (PEG), colloidal stability can be achieved even in the presence of ions in solution. Such particle stabilization via polymer coatings is attributed to the flexibility of polymer chains and their repulsive “entropic spring” effect during particle–particle interaction. Currently, the concept of stabilization of nanoparticles due to the addition of polymeric coatings is widely accepted. Indeed, several experimental results seem to support the concept [131, 132]. Peptides adsorbed to the quantum dot surface can also have a similar stabilizing effect [133]. Conversely, it has been theoretically predicted that homopolymers, if end-grafted to nanoparticles in good solvents, may lead to nanoparticle attraction [134].

#### 1.4.1.3 Biocompatible Surfaces

To make fluorescent nanoparticles ‘bioinert’, their surfaces need to be designed so as to prevent the non-specific adsorption of all relevant molecules in the biological medium. It is challenging to improve the design of surface coatings to a level of sophistication that fulfills this requirement. Fortunately, promising strategies for

the creation of bioinert surfaces are known from biomaterials research in the biomedical engineering community. As a result, our understanding about the host response of living tissue with respect to biomaterials has improved significantly and numerous sophisticated biomaterials have been developed [135]. A key aspect for the creation of colloidal solids with sufficient stealth properties in a cellular environment is the understanding of protein adsorption. Like surfactants, proteins have a high tendency to adsorb at interfaces. Interactions between proteins and surfaces are primarily noncovalent and include electrostatic, hydrophobic, and hydrogen-bonding interactions [136]. The different interactions result from the “surface inhomogeneity” of proteins, which typically are characterized by surface patches that may be charged, neutral, hydrophilic, or hydrophobic in character [137]. Consequently, surface properties of biomaterials affect the mechanism, rate, and extent of protein adsorption. Protein adsorption can be suppressed most efficiently on biomaterials whose surfaces are neutral, hydrophilic, and highly dynamic [138]. A paradigm of a protein-resistant surface is a solid substrate surface-functionalized with grafted PEG chains [139]. This is so because PEG is electrically neutral, thus minimizing electrostatic interactions, and highly hydrophilic, thus minimizing hydrophobic interactions. As the PEG chains are highly dynamic in an aqueous environment, the formation of strong hydrogen-bonding between protein and polymer is effectively suppressed. Besides those enthalpic effects, the high dynamics of the PEG chains results in a high entropy, which is also unfavorable for protein adsorption. It has been generally assumed that the surface resistance of PEG functionalized substrates is a result of the steric repulsion grafted PEG chains show for adsorbing proteins [138, 140, 141]. However, this assumption is valid only if the grafted PEG chains are of very high molecular weight and show large enough grafting densities to form polymer brushes [142]. Interestingly, Prime and Whitesides found that protein adsorption is prevented effectively even if the PEG chains have only two ethylene oxide segments, thus indicating that surface coverage is the most important parameter to prevent protein adsorption [143, 144]. In the same context, Single-chain Mean Field Theory (SCMF) calculations and experimental studies showed that protein adsorption on hydrophobic surfaces is prevented because PEG chains bind to the hydrophobic substrate, thereby blocking possible protein binding sites [145]. A later SCMF study by Szleifer and co-workers found that polymers with a low substrate affinity are more effective for kinetic control, whereas those with a higher affinity lead to a lower equilibrium concentration of adsorbed proteins [146]. Obviously, protein adsorption on substrates surface grafted with synthetic polymers is dependent on both the steric hindrance effect of the grafted polymer layer and the affinity of the underlying substrate for proteins and other molecules.

#### 1.4.1.4 Cytotoxicity

Several potential processes lead to cytotoxicity. One source of nanoparticle-induced cytotoxicity, rather independent of particle composition, occurs if nanoparticles adsorb to cell surfaces [147, 148] or if they get ingested by cells [149, 150]. The cytotoxicity of CdSe/ZnS quantum dots is suggested to be due mostly to their inter-

action with cells [151]. Another source of nanoparticle-induced cytotoxicity occurs when the nanoparticle is composed of toxic materials that can be gradually released. A prominent example concerning fluorescent nanoparticles is the gradual release of heavy metal ions such as  $\text{Cd}^{2+}$  from CdSe or CdSe/ZnS quantum dots [152, 153]. Heavy metal ions are cytotoxic and often show several pathways of cytotoxicity. Indeed,  $\text{Cd}^{2+}$  may induce hepatotoxicity, immunotoxicity, and nephrotoxicity; apoptosis being a critical part of each toxicity type [154]. Studies concerning Cd-induced hepatotoxicity show, for example, the relevance of direct and indirect cytotoxic pathways [155]. The direct pathway is caused by  $\text{Cd}^{2+}$  binding to sulfhydryl groups on key mitochondrial molecules, thus damaging the mitochondria. The indirect pathway, though, is assumed to occur via activation of Kupffer cells. However, not all metals show such pronounced cytotoxicity. For example, gold nanoparticles have good biocompatibility properties [156]. From the above information, nanoparticles only show very low cytotoxicity if all potential sources of cytotoxicity are prevented efficiently.

#### 1.4.2

#### Nanoparticle-stabilizing Coatings

To enhance the biocompatibility of nanoparticles, one popular strategy has been to cap the nanoparticles with polymeric coatings of high biocompatibility. In particular, poly(ethylene glycol) (PEG) has been applied as a coating material because of its excellent biocompatibility properties. Originally studied on flat macroscopic surfaces for biomaterials applications, PEG coatings have been widely applied to sub-micron sized delivery systems and imaging probes [48, 49, 116, 118, 131, 157, 158]. Delivery systems coated with PEG have notably longer circulation times in the blood, thus exceeding traditional non-nanoparticle-based delivery methods for the prolonged delivery of drugs, diagnostics, genes, and vaccines [159–162]. Based on the success of PEG coatings in drug delivery systems, similar coating strategies have been applied to the design of biocompatible coatings of nm-size imaging probes in biological and biomedical imaging. A facile approach for adding a PEG layer to the quantum dot surface is via physisorption of amphiphilic molecules [116, 118]. Here one interesting strategy has been to use PEG-containing lipopolymers, which result in excellent colloidal stability in *Xenopus* embryo cells over several days [118]. In an alternative amphiphilic passivation approach, block copolymers have been utilized to enable colloidal stability of quantum dots [116, 163, 164].

Chemically coupled PEG coatings have even greater stability. Wuelfing et al. reported the surface functionalization of gold nanoparticles using  $\text{CH}_3\text{O-PEG-SH}$  [131]. Covalent PEG coatings were also used to increase the colloidal stability of CdSe [49], CdS, [158] and  $\text{SiO}_2$ -capped CdS [48] quantum dots. However, in these cases, the PEG coatings lack reactive surface groups, thus preventing the further immobilization of ligands on the PEG layer. To overcome this limitation, nanoparticles need to be surface-functionalized via mixtures of mono-functional PEGs and other linker molecules [48] or via heterobifunctional PEG-linkers. Heterobifunc-

**Fig. 1.10.** Design of nanoparticles with stabilizing, biocompatible coatings, including (A) adsorption of amphiphilic molecules such as amphiphilic diblock copolymers; (B) chemical coupling of hydrophilic polymeric systems; and (C) linkage of spacer molecules with hydrophilic surface groups.

tional PEG-linkers can be synthesized via monoprotected symmetric PEG linkers, such as monoprotected diamines derived from tetraethylene glycol [165–167]. Another strategy for the synthesis of heterobifunctional PEG linkers is based on the ring-opening polymerization of ethylene oxide using a metal alkoxide initiator [168–171]. For example,  $\alpha$ -acetal-PEG-SH has been synthesized using this strategy [172]. Here the facile modification of the acetal group into a reactive aldehyde allowed the immobilization of ligand molecules on the surface of PEGylated gold particles [173]. Meanwhile, various heterobifunctional PEG linkers are also commercially available. Figure 1.10 shows the design of a biocompatible surface coating where a few linkers support the targeted immobilization of ligand molecules. Such a design can be accomplished by using a mixture of homofunctional and heterobifunctional PEGs. An excess of homofunctional PEG molecules, which have no reactive surface groups after surface coating, suppresses the non-specific binding of proteins, whereas the heterobifunctional linkers facilitate the targeted coupling to ligands. Notably, however, a PEG layer does not prevent cytotoxic side reactions due to the leaching of toxic heavy metal ions from quantum dots. In those cases, an additional protective layer preventing the egress of harmful ions is essential [153].

PEG-based coatings are not the only biocompatible polymeric coatings. For example, poly(acrylic acid) has been used to stabilize luminescent silicon nanoparticles [174]. Because this anionic polyelectrolyte has a high density of carboxylic acid moieties, the immobilization of amine-containing molecules is straightforward. A similar concept has been applied to conjugate CdS quantum dots with aminodextran [175]. Dendrimers have also been used as stabilizing coating material [176]. Quantum dots have been embedded into larger polymeric spheres via a facile procedure using block copolymers [163, 177], and CdSe-ZnS quantum dots have been incorporated into glyconanospheres via electrostatic coupling with carboxymethyl-dextran and polylysine [178]. Several other procedures have afforded gold glyconanospheres [173, 179, 180]. Quantum dots capped with specific peptide coatings have recently been shown to be quite promising biocompatible imaging

probes that can be designed for targeted labeling of biomolecules [20, and references therein].

### 1.4.3

#### Low Cytotoxicity Coatings

As stated before, successful application of fluorescent nanoparticles in a biological environment requires not only high dispersion stability and the suppression of non-specific biomolecule adsorption, but also should show low cytotoxicity. This topic is particularly important for applications involving quantum dots where toxic heavy metal ions can be released [152]. If properly passivated, quantum dots seem to show no significant cytotoxicity. For example, a study on *Xenopus* embryos did not reveal significant cytotoxicity after injection of  $2 \times 10^9$  and  $5 \times 10^9$  CdSe/ZnS quantum dots per cell [118].

Several strategies have been pursued to suppress this oxidation process. One approach is simply to passivate the quantum dot surface with binding ligands [181]. Importantly, such a passivation not only lowers the cytotoxicity of nano-probes, but also enhances their quantum yields. Quantum dots can be further passivated by adding a protecting semiconductor shell. Such coatings also significantly lower the cytotoxicity of CdSe quantum dots, but do not completely eliminate the problem [152]. Surface silanization is another promising approach to suppressing surface oxidation [44, 46, 182–184]. The stability of the coating is provided by crosslinks within the siloxane shell. Importantly, such shells are quite stable in a biological environment [46]. Furthermore, CdSe/ZnS quantum dots with a protective shell of crosslinked silica significantly reduce the release of  $\text{Cd}^{2+}$ , thus lowering the cytotoxicity of fluorescent nanoparticles [153]. Interestingly, the addition of a bovine serum albumin (BSA) layer further reduced the cytotoxicity of CdSe/ZnS quantum dots [152]. The BSA, added to the mercaptoacetic acid-functionalized quantum dot surface using EDC coupling, may act as a diffusion barrier for  $\text{O}_2$  molecules.

Based on the above discussion, the appropriate biofunctionalization of nanoparticles clearly must address the features of colloidal stability, bioinertness, specificity with respect to target biomolecules, and low cytotoxicity. Figure 1.11 shows a biofunctionalization architecture where these crucial features are considered in its design.

## 1.5

### Applications

Our growing ability to synthesize and surface-functionalize nanoparticles has provided new opportunities in bioanalytical and biological imaging applications. Metallic nanoparticles have been used primarily in bioanalytical projects. Nanoparticle-based imaging applications, however, rely more on dye-doped polymeric nanoparticles and quantum dots due to their excellent fluorescence proper-

**Fig. 1.11.** Schematic of an appropriately biofunctionalized quantum dot. The inner coating protects from surface oxidation whereas the outer coating guarantees dispersion stability and biocompatibility. Immobilized ligands mediate the specific binding to biomolecules.

ties and photostability. While dye-doped systems have been used initially in such imaging applications, quantum dots have recently increasingly become the nanoparticle systems of choice. It is fair to say that further progress in bioanalytical and imaging applications is strongly linked to the availability of novel biofunctionalized nanoparticles of improved designs. Though developing rapidly, this highly interdisciplinary field is still in its infancy. The rapidly growing number of publications over the last decade reflect its relevance.

Though this chapter focuses primarily on the relevant *concepts* of biofunctionalization, this section describes recent *applications* using biofunctionalized fluorescent nanoparticles. We do not claim to review all published applications where such particles have been used because this is clearly beyond the scope of the chapter. Instead, the intent is to provide a representative overview of recent nanoparticle-related applications in the fields of diagnostics and live cell and *in vivo* imaging.

### 1.5.1

#### Biosensing

Fluorescent nanoparticles are highly promising probes for bioanalytical applications. In particular, their use in the field of biosensors is attractive because fluorescence-based techniques are extremely sensitive and nanoparticle probes show high photostability, thus allowing for long-term observations.

### 1.5.1.1 Polymeric Sensors

Bioanalytical applications based on polymeric nanoparticles are now well established. In one application, the combination of two silica precursors, tetraethyl-orthosilicate and phenyltriethoxysilane, was used to synthesize organic dye-doped silica nanoparticles. The nanoparticles were coated with avidin to determine biotinylated bovine serum albumin. In addition, a glutamate sensor was designed by immobilizing glutamate dehydrogenase on the nanoparticle surfaces [185]. In another application, a BODIPY-doped polymeric nanoparticle was designed for the detection of  $\text{Cu}^{2+}$ . Here the metal-chelating receptor, cyclam, was covalently bound to the surface of the nanoparticle. In the presence of  $\text{Cu}^{2+}$  the fluorescence emission of the BODIPY is quenched by the overlapping adsorption band of the metal-chelator complex [186]. Fluorescent polymeric nanoparticles have also been used for the intracellular monitoring of key biological components. Using three different nanoparticle fabrication technologies, sensors based on polyacrylamide, cross-linked decyl methacrylate, and silica-based sol-gel have been characterized in aqueous solution and intracellular surroundings. Each matrix can be combined with specific “free dyes”, ionophores, or enzymes to produce sensors selective for the biological component of interest. These nano-optodes are termed PEBBLEs (probes encapsulated by biol. localized embedding). Spherical sensors less than 600 nm in diam. (and reducible to below 100 nm) have been made from all three matrices. Acrylamide-based sensors have been used to monitor intracellular pH and calcium (with proven selectivity over  $\text{Mg}^{2+}$ ). Decyl methacrylate has been successfully applied to intracellular potassium monitoring with probes 1000× more selective for potassium than sodium. Such a sol-gel-based approach has also proven useful for monitoring intracellular oxygen at physiologically interesting concentrations. PEBBLEs, with a wide range of both simple and complex sensing schemes, provide a unique tool for minimally invasive intracellular monitoring, with many significant advantages over free dyes as well as over fiber-optic sensors [187–189].

### 1.5.1.2 Quantum Dot Sensors

The great potential of quantum dots for sensing applications has been demonstrated in several instances. In one application, quantum dots have been utilized as maltose sensors [114]. Here quantum dots were surface-functionalized with a maltose-binding protein (MBP) containing  $\beta$ -cyclodextrin-QSY-9 attached to the binding site to quench the quantum dot emission. The sensor concept is that maltose displaces the  $\beta$ -cyclodextrin-QSY-9, thus inducing quantum dot emission. Another reported quantum dot-based maltose sensor using MBP acts as a double FRET sensor [114]. Here the quantum dot emission excites Cy3 that is adsorbed on the surface of the MBP. The Cy3 emission then excites the  $\beta$ -cyclodextrin-Cy3.5 whose emission is observed. Once maltose is introduced to the sensor, the Cy3 emission is no longer quenched by the Cy3.5, because the  $\beta$ -cyclodextrin-Cy3.5 has been displaced by maltose [114].

Quantum dots also show great promise in immunoassays. For example, an immunoassay has been performed by binding an antibody covalently to a glass chip,

followed by binding of the antigen. The antigen was then detected with the addition of antibody labeled quantum dots, which bound selectively to the captured antigen [190]. In another application, Tran et al. prepared quantum dot conjugates with the immunoglobulin G (IgG) binding domain of streptococcal protein G (PG) appended with a basic leucine zipper attachment domain (PG-zb). They also demonstrated that the quantum dot/PG conjugates retain their ability to bind IgG antibodies, and that a specific antibody coupled to quantum dots via the PG functional domain efficiently binds its antigen. Preliminary results indicated that electrostatically self-assembled quantum dot/PG-zb/IgG bioconjugates can be used in fluoro-immunoassays [191]. Quantum dot–antibody conjugates were again successfully used in fluoro-immunoassays to detect both a protein toxin (staphylococcal enterotoxin B) and a small molecule (2,4,6-trinitrotoluene) [108]. Goldman et al. described a conjugation strategy employing an engineered molecular adaptor protein, attached to the quantum dots via electrostatic/hydrophobic self-assembly, to link quantum dots with antibodies. Quantum dots can also be used as sensors for sugars; a quantum dot FRET application using adsorbed MBP has been mentioned [114].

Powerful sensor concepts can also be designed using the multiplexing capability of quantum dots. This results from the broad excitation and narrow, size-dependent emission bands of quantum dots. This concept has been used, for example, to embed quantum dots of six different colors and ten intensities per color in nanoparticles composed of styrene, divinylbenzene, and acrylic acid. This combination can, theoretically, code one million nucleic acids or protein sequences [80]. In another application, a high-throughput assay has been developed for the parallel detection of antibodies using quantum dot microbeads. In this case, a custom designed microfluidic chip with multiple micro-wells was utilized for capturing of microbeads, antibody injection into each micro-well, QD injection, and fluorescence detection [192]. These beads could be identified with a standard flow cytometer at a rate of 1000 beads  $s^{-1}$  [193].

#### 1.5.1.3 Metallic Sensors

Gold nanoparticles (2.5 nm) have been used to recognize and detect specific DNA sequences and single-base mutations. Detection is based on fluorescently tagged, thiol modified oligonucleotides bound to the surface of the gold nanoparticle. Upon self-assembly, the fluorophores arch toward the gold surface, quenching the fluorescence. Upon binding the appropriate target sequence, the oligonucleotide undergoes a conformational change, moving it away from the gold nanoparticle surface, and restoring the fluorescence [194]. Another interesting approach to ultrasensitive detection of DNA hybridization is based on Au nanoparticle-amplified surface plasmon resonance (SPR). Interestingly, even without further optimization, the sensitivity of this technique begins to approach that of traditional fluorescence-based methods for DNA hybridization and oligonucleotide detection [62]. Gold nanoparticles have also been used in the detection of glucose and glucose oxidase. The growth of the Au nanoparticles requires  $H_2O_2$  and converts it into  $O_2$ . In the presence of glucose oxidase and glucose,  $O_2$  is converted into

H<sub>2</sub>O<sub>2</sub>, allowing the Au nanoparticles to grow, thus giving a shift in absorbance over time [195]. Finally, Ag has also been employed for surface plasmon-based nanosensors concerning the detection of Alzheimer's disease. Autopsied brain samples of humans with Alzheimer's disease show elevated levels of amyloid-derived diffusible ligands (ADDLs), which suggest that a definitive chemical diagnosis of Alzheimer's could be achieved with a sensitive method to detect ADDL or anti-ADDL antibodies. The  $\lambda_{\max}$  of silver nanoparticles conjugated with anti-ADDL was monitored before and after the incubation with ADDL. The resulting  $\Delta\lambda_{\max}$  indicated that it is possible to monitor the interaction between ADDL and anti-ADDL using Ag nanoparticles. While undergoing a promising initial trial, the practicality of the system as a sensor is limited because its specificity becomes low at nM concentrations of anti-ADDLs [196].

## 1.5.2

### Fluorescent Nanoparticles as Labels in Biological Imaging

#### 1.5.2.1 Dye-doped Nanoparticles

Though very small, fluorescent dyes are only of limited applicability in biological imaging because of their poor photostability and limited brightness. To improve the photostability, initially, dye-doped nanoparticles have been used as photostable imaging probes. For example, 20 nm dye-doped latex nanoparticles have been linked to DNA-binding proteins (restriction enzyme EcoR1) to probe specific sequences on stretched DNA [7]. In addition, ruthenium bipyridyl-doped silica nanoparticles can be used to stain and image leukemia cells [4]. More recently, Ru(bpy)-doped silica nanoparticles have been applied successfully in several fluorescent imaging applications, including immunocytochemistry, immunohistochemistry, and DNA and protein microarrays [197]. Here the nanoparticles were surface-functionalized with avidin, thus allowing straightforward coupling to biotinylated antibodies. In one case, avidin-capped, dye-doped silica nanoparticles were conjugated with biotinylated mouse anti-hIgM to stain human peripheral blood mononuclear cells. In another case, these photostable nanoprobe were coupled to biotinylated goat anti-ChAT antibodies to label choline acetyltransferase to image mouse brain tissue. Interestingly, these dye-doped silica nanoparticles are not outperformed by quantum dots with respect to photostability.

#### 1.5.2.2 Quantum Dots

Among the different types of fluorescent nanoparticles, quantum dots seem to show the greatest promise as labels in biological imaging applications. Since their introduction as labels in cellular imaging in 1998 [44, 115], multiple reports have shown the strengths of these nanoprobe for tagging and imaging applications in biological systems. This strength is based on the impressive photostability of quantum dots and on their broad excitation and narrow size-dependent emission properties. Most importantly, the high photostability guarantees the observation of biomolecules over longer time periods. Dubertret et al. have reported a very elegant example of such a long-term observation of biological processes [118]. Here, quan-

tum dots with biocompatible coatings were injected into *Xenopus* embryos and their movement into different cells during tadpole development was monitored over several days.

Quantum dot multi-color imaging in cells is another fascinating imaging approach. For example, quantum dots biofunctionalized with streptavidin and IgG have been used to label the breast cancer marker Her2 on fixed and live cancer cells, to tag actin and microtubules, and to stain nuclear antigens inside the nucleus [116]. Quantum dots have also been shown to be useful in studying ATP driven biological processes. The *in vitro* sliding of quantum dot labeled actin filaments was observed over periods of 10–12 s [198]. The chaperonin proteins GroEL (from *Escherichia coli*) and T.th ('T.th cpn', from *Thermus thermophilus* HB8) typically encapsulate denatured proteins within a cavity and release them in the presence of ATP. This encapsulation and release technique was used to give quantum dots high thermal and chemical stability in various aqueous mediums, while also allowing the controlled release of quantum dots [199].

Quantum dot labels are particularly advantageous over traditional organic dyes in single-molecule tracking applications because dye-based tracking experiments are limited by very short observation times [200, 201]. Quantum dot-based single molecule tracking in biological systems represents a fascinating emerging research area. The first results indicate great promise. Dahan et al. have successfully tracked individual quantum dot-tagged glycine receptors in the neuronal membrane of live cells and analyzed the diffusion properties [202]. Furthermore, this technique allowed them to observe the entry of individual glycine receptors into the synapse, which was confirmed by electron microscopy experiments. The ability to detect quantum dots not only optically but also by electron microscopy is clearly a very powerful feature. Another recent single-molecule application was related to the monitoring of quantum dot-labeled epidermal growth factor. In this case, a new transport process was discovered [203].

Fluorescent nanoparticles have also been applied in animal imaging experiments; again, quantum dots seem to show great promise. Proper biocompatible surface coating is essential for long-term stability of the probes in a biological environment [204]. In another application, quantum dots have been targeted *in vivo* via peptides immobilized on the quantum dot surface [205]. Here, several types of peptides were used to label different regions of the mice tissue. Thus, quantum dots with lung-targeting peptides were shown to accumulate in the lungs of mice whereas other peptides targeted quantum dots to blood or lymphatic vessels in tumors. Targeted quantum dot transport in live animals was recently reported in mice [164]. In this case, PEG-coated nanoprobe were used that carried conjugated antibodies directed against prostate-specific membrane antigens. A clear boost in animal imaging should be expected from the recent development of quantum dots with emission bands in the near-infrared (NIR) because this wavelength range offers an optical window for tissue imaging. Indeed, NIR quantum dots have been applied successfully to conduct imaging experiments on rat and porcine tissue [206, 207]. In one case, rat coronary vasculature was studied. In the other case, porcine sentinel lymph nodes were imaged. Interestingly, when injected interdermally

on the thigh of a 35 kg pig, doctors could visualize the nearby sentinel lymph nodes within 3–4 min and use the infrared signal as a guide during surgery. Despite the relatively low power NIR excitation used ( $5 \text{ mW cm}^{-2}$ ) the sentinel lymph nodes were observed as deep as 1 cm below the skin surface.

# Biofunctionalization of Carbon Nanotubes

*Elena Bekyarova, Robert C. Haddon, and Vladimir Parpura*

### 2.1

#### Introduction

The decade long history of carbon nanotubes (CNTs) has been largely devoted to investigation of their growth mechanism and physical and chemical properties. This has led to sustained progress in the synthesis of materials of higher purity, to chemically functionalized CNTs with specifically tailored properties, and to the development of technologies for the processing and assembly of CNTs into functional structures and devices. Recent research on the chemical interactions between biological molecules and CNTs has led to the assembly of functional hybrid (CNT-biomolecule) structures for nanoelectronics, scaffolds for cell and tissue growth, and high-performance biosensors. While much remains to be accomplished, this fascinating nanomaterial clearly offers great potential for the development of revolutionary hybrid structures and devices, and work in this field has propelled CNTs to a point that their entry into the realm of nanobiotechnology and nanomedicine is now a reality [1].

In this chapter, we overview the currently available methods for biofunctionalization of CNTs and some of their applications in biology and nanotechnology. We briefly discuss the structure, properties, and most common methods for synthesis of CNTs, focusing on current progress in patterned growth and purification of CNTs. We summarize the achievements in chemical modification of CNTs that are related to the solubilization of CNTs in water, since the dispersion and stabilization of CNTs in aqueous media is a key step in developing biological applications. We present various schemes for noncovalent and covalent modifications of CNTs with biological molecules. Additionally, we review the applicability of the modified CNTs in the assembly of electronic devices, for biosensing, and as scaffolds or substrates for neuronal growth.

**Fig. 2.1.** Transmission electron microscopy images of (a) multi-walled carbon nanotubes, (b) single-walled carbon nanotubes, (c) double-walled carbon nanotubes, and (d) a bundle of single-walled carbon nanotubes. (TEM micrographs in (b)–(d) [112] are reproduced by permission of the American Chemical Society Publications.)

## 2.2

### Carbon Nanotubes – Types, Structures and Properties

CNTs can be classified according to the number of concentric graphene cylinders that constitute their structure (Fig. 2.1). Multi-walled CNTs (MWNTs) consist of several concentric graphene cylinders with their ends individually capped with hemispheres of fullerene molecules. Typically, their outer diameter ranges from 2 to 100 nm, while their inner diameter is about 1–3 nm. The MWNTs are from 1 to several hundred  $\mu\text{m}$  long. Double-walled CNTs (DWNs) are composed of two concentric graphene cylinders, and represent an intermediate structure between MWNTs and single-walled CNTs (SWNTs), the later consisting of a single graphene cylinder. Although the smallest SWNTs reported have a diameter of 0.4 nm [2, 3], which corresponds to a hemispherical fragment of the  $\text{C}_{20}$  dodecahedron, SWNTs are usually produced with a random distribution of diameters (0.7–2 nm) and exist in hexagonally close-packed bundles held together by van der Waals forces.

Based on their hexagonal lattice structure, SWNTs are classified as armchair, zigzag and chiral (Fig. 2.2). The wrapping angle of the graphene sheet determines the electronic properties of SWNTs [4–6]. All armchair nanotubes are conductive (metallic), while the zigzag and chiral nanotubes can be either metallic or semiconducting. Most currently available synthetic methods produce SWNTs with a random distribution of metallic and semiconducting nanotubes in a ratio of 1:2. Because CNTs are either metallic or semiconducting, they provide the necessary building blocks for molecular electronics. In addition, they are ballistic conductors with high effective mobility and can sustain very high current densities. A rope of SWNTs has a room temperature conductivity in the range  $10\,000\text{--}30\,000\text{ S cm}^{-1}$  [7]. These properties provide a unique opportunity to develop miniature advanced

**Fig. 2.2.** (a) Two-dimensional graphene sheet. A carbon nanotube is formed by rolling up the graphene sheet and superimposing the two ends OA of the chiral vector ( $C_h$ ). The chiral vector is defined as  $C_h = na_1 + ma_2$ , where  $a_1$  and  $a_2$  are unit vectors in the two-dimensional hexagonal lattice, and  $n$  and  $m$  are integers. The pair of integers  $(n, m)$  and the chiral angle ( $\theta$  – the angle between  $C_h$  and  $a_1$ ) define the nanotube type: armchair ( $n = m$ ,  $\theta = 30^\circ$ ), zigzag ( $n$  or  $m = 0$ ,  $\theta = 0^\circ$ ) and chiral ( $\theta$  between  $0$  and  $30^\circ$ ). The diagram is constructed for a  $(5, 2)$  carbon nanotube.  $T$  is the basic translation vector for the tubule and the unit cell of this tubule is defined by  $OABB'$ . (b) Schematic models for the three types of SWNTs. (Courtesy of Riichiro Saito, Tohoku University, Japan.)

sensors [8] for rapid, label-free electronic detection of different biological materials (Section 2.5.2). With a Young's modulus of  $\sim 1$  TPa [9, 10], CNTs also have exceptional mechanical strength – a useful feature for tissue scaffolds and engineering.

### 2.3 Synthesis of Carbon Nanotubes

The most widely used techniques for synthesis of CNTs are electric arc discharge, laser ablation, chemical vapor deposition (CVD) and high-pressure carbon monoxide disproportionation (HiPco) [11]. The first two methods involve the vaporization of carbon in an inert atmosphere, whereas CVD and HiPco are based on catalytic decomposition of hydrocarbons. The synthesis of CNTs has advanced to the point that patterns of aligned MWNTs or SWNTs can be engineered. Such patterned growth is of interest in tissue engineering [12]. CNT-based scaffolds have some advantages over bio-degradable synthetic polymers currently used in tissue engineering as they possess the structural integrity and high mechanical stability to support developing tissue and to withstand *in vivo* forces [12].

SWNTs can be aligned by applying an electric field during CVD growth of the nanotubes [13–15], and vertically aligned arrays of MWNTs (Fig. 2.3) are routinely produced in standard CVD experiments [16–19]. Network architectures have been produced by the reassembly of dense CNT arrays using the capillary forces induced

by the evaporation of liquids from the CNT films or mats (Fig. 2.3) [12, 19]. In this process, the nanotubes collapse to cellular structures due to the induced surface tension; the resulting periodic architectures might find applications as scaffolds for tissue engineering. Indeed, similar structures composed of MWNTs (Fig. 2.4) have been used to support the cellular adhesion and growth of mouse fibroblasts [12].

While patterned films and mats that are attractive for cell growth, biosensors, and bioelectronics all require relatively small amounts of material, applications may be envisaged in which bulk quantities of CNTs are necessary. Although bulk production is a necessary step, the purity of the CNT material is an essential prerequisite for further progress. MWNTs of high purity can be readily synthesized. However, SWNTs typically contain a substantial fraction of carbonaceous impurities together with the metal that is used as a catalyst in the synthesis. Quality control in SWNT manufacturing is a major issue, and the absence of widely accepted and established methods for quality assessment has raised questions regarding the purity of commercially available CNT materials [20]. Certainly, high purity material is required if SWNTs are to play an important role in biotechnology. Although quality control is virtually nonexistent in the CNT industry, analytical tools for reliable evaluation of the quality of SWNT materials exist, and efforts to establish standards in the field may help to reform current CNT industrial practices. Solution phase near-infrared (NIR) spectroscopy [21–24], Raman spectroscopy [25, 26], thermogravimetric analysis [25, 27], and combinations of these analytical methods [28] have been used to evaluate SWNT purity. At this point, NIR spectroscopy has been established as the simplest, fastest, most efficient and unambiguous technique for the quantitative assessment of the carbonaceous purity of SWNTs [29], while thermogravimetric analysis can reliably estimate the metal content based on the residue remaining after pyrolysis of the carbon content of the sample.

The quality of CNTs can be improved by progress in the synthesis or purification techniques, and significant achievements in both areas have been reported. Recently, very high purity, metal-free SWNTs (carbonaceous purity of 99.98%) have been synthesized [30]. The purification processes are based on a combination of several steps, which usually include gas or vapor-phase oxidation, wet chemical oxidation, centrifugation, filtration or chromatography (see Refs. [31–35] and references therein).

## 2.4

### Approaches to Aqueous Solubilization of Carbon Nanotubes

#### 2.4.1

##### Chemical Modifications

As-prepared SWNTs self-assemble in hexagonally packed bundles, in which the nanotubes are held together by van der Waals forces. The strength of these attractive forces makes the exfoliation of individual CNTs from the bundle and their stabilization in solution difficult. An additional complication arises from the chemical inertness of the CNTs due to the absence of functional groups in their graphitic structure, making their dissolution in a solvent a complex issue. Consequently, chemical functionalization has been used as a valuable route to the solubilization and exfoliation of individual CNTs from the bundles.

One of the most widely used chemical approaches to introduce functionalities onto CNTs involves treatment with strong oxidizing agents such as nitric and sulfuric acids. These strong acids preferentially disrupt the aromatic ring structure at the caps of CNTs and lead to the introduction of carboxylic acid groups at the open ends [21, 31, 34, 36, 37]; this functionality can undergo further reactions to produce a large family of tailored materials. Numerous amidation and esterification reactions of oxidized SWNTs have been reported [36, 38]. Typically, carboxylic acid functionalized SWNTs (SWNT-COOH) are treated with thionyl chloride ( $\text{SOCl}_2$ ) to form the acyl chloride intermediate (SWNT-COCl) [31], which is then reacted with an amino derivative. This approach has been used to covalently attach octadecylamine to the open ends of the SWNTs, affording SWNT-CONH(CH<sub>2</sub>)<sub>17</sub>CH<sub>3</sub>, a form of the carbon nanotubes that proved to be soluble in various organic solvents (Fig. 2.5) [21]. This approach has proved to be applicable to various functionalities. However, the solubilization of CNTs in aqueous solutions – a prerequisite for use in many biological applications – is a more challenging task because of the hydrophobic nature of CNTs. Although stable aqueous solutions of SWNTs have been obtained by ultrasonication in a mixture of sulfuric acid and hydrogen peroxide [39], the more common methods of dispersing CNTs in aqueous solutions involve: (a) coating CNTs with surfactants, (b) functionalization of CNTs with water-soluble polymers, and (c) interaction of CNTs with biological molecules. These methods are detailed below.

#### 2.4.2

##### Use of Water-compatible Surfactants

Surfactant-induced dispersion of CNTs depends on the presence of hydrophilic and hydrophobic regions in the surfactant molecule. Adsorption of the surfactant on the side walls of the nanotubes occurs through the hydrophobic tail of the surfactant molecule, which can adopt a wide range of orientations with respect to the tube, leaving the hydrophilic moiety oriented towards the aqueous phase. This can induce stable dispersions of surfactant-coated SWNTs in water. SWNTs were

**Fig. 2.5.** (a) A solution of SWNTs chemically functionalized with octadecylamine [21] by the general functionalization scheme illustrated in (b).

successfully dispersed in water with various surfactants [40–42]. This surfactant detached tubes from the bundles during vigorous sonication and stabilized individual SWNTs in solution [41]. Since the individual nanotube encased in a close-packed SDS micelle had a lower specific gravity than SDS-coated bundles, centrifugation led to their separation. This made it possible to use spectroscopy to study individual SWNTs, which displayed a bright photoluminescence in the NIR [41]. Since then, surfactant-assisted dispersion of nanotubes has been widely used by several research groups for fundamental studies of the electronic properties of individual SWNTs, as these properties give rise to distinctive features in the optical spectra [43–47].

Various anionic, nonionic, and cationic surfactants have been studied for their ability to disperse SWNTs in water [46]. Typically, a solution of a specific surfactant concentration is mixed with the nanotubes using high shear homogenization, followed by ultrasonication, and ultracentrifugation.

Among ionic surfactants, sodium dodecylbenzene sulfonate (SDBS) and SDS are the most efficient dispersing agents. For nonionic systems, surfactants with higher molecular weight suspend higher amounts of SWNT material [46].

### 2.4.3

#### Functionalization with Water-soluble Polymers

The covalent attachment of water-soluble polymers is an efficient approach to the dispersion of CNTs in water. By applying the functionalization scheme of Fig. 2.5, poly-*m*-aminobenzene sulfonic acid (PABS) [48, 49] and polyethylene glycol (PEG) [49] have been covalently linked to SWNTs to form water-soluble nanotube-graft copolymers (Fig. 2.6) [48, 49]. Several other types of functionalized SWNTs bearing water-soluble moieties have been synthesized (Scheme 2.1), including the attachment of water-soluble linear polymers, such as monoamine-terminated polyethylene oxide (PEO) [50], diamine terminated polyethylene glycol (PEG<sub>1500N</sub>) [51],

Fig. 2.6. SEM images of (a) SWNT-PABS and (b) SWNT-PEG [49].

poly(propionylethylenimine-*co*-ethylenimine) (PPEI-EI) [51], poly(vinyl alcohol) (PVA) [51], and glucosamine (GA) [52] to CNTs. Since these functionalized nanotubes have high solubility in water ( $8\text{--}89\text{ mg mL}^{-1}$ ) [51], this is clearly an efficient route for the aqueous dissolution of carbon nanotubes.

#### 2.4.4

#### Interaction and Functionalization with Biological Molecules

Interactions of CNTs with biological molecules, such as lipids, DNA and proteins, efficiently disperse the CNTs in water. Noncovalent modification is the preferred method if the electronic characteristics of the nanotubes need to be preserved. Co-

**Scheme 2.1.** Structures of SWNTs functionalized with polymers: PABS – poly(*m*-aminobenzenesulfonic acid), PEG – poly(ethylene glycol), GA – glucosamine, PPEI-EI – poly(propionylethylenimine-*co*-ethylenimine), PEO – poly(ethylene oxide) and PVA – poly(vinyl alcohol).

valent chemistry, which takes place via modifications of the CNT side walls, disturbs the extended  $\pi$ -network, leading to a localization of electrons at the defect sites that are generated at the point of attachment. However, covalent chemistry at the ends of the SWNTs retains the SWNT electronic properties and provides a robust linkage to the biological molecule, although with some variability in the endogenous properties and functions of these molecules.

#### 2.4.4.1 Noncovalent Biofunctionalization

Various lipids and proteins, including enzymes, peptides and nucleic acids, adsorb strongly to CNTs [53–59]. These interactions between CNTs and biological molecules provide a more efficient means to solubilize the nanotubes in water than the use of surfactants and polymers. In a similar manner to surfactants, amphiphilic biological molecules, which possess hydrophobic and hydrophilic moieties, solubilize CNTs in aqueous media. For example, MWNTs form stable dispersions in water upon interaction with specific lipid derivatives composed of a lipidic chain of 12 and 18 carbon atoms and a polar head group [56]. Single-chain lipidic reagents self-organize on the nanotube walls, forming supramolecular assemblies. Similar highly ordered heterogeneous structures have been found upon adsorption of other biological molecules. For example, HupR, a DNA binding protein from the nitrogen-regulatory protein subfamily, and streptavidin interacted strongly with MWNT to form highly ordered helical structures, but the exact solubility in water was not reported [53]. However, an efficient protocol for dispersion of CNTs

in water using a specifically designed amphiphilic  $\alpha$ -helical peptide, which functioned by wrapping individual CNTs, has been reported and this led to a stable dispersion of CNTs at a concentration of  $0.7 \text{ mg mL}^{-1}$  [60].

Single-stranded DNA (ssDNA) interacts strongly with CNTs to form stable CNT-DNA hybrids, which efficiently disperse CNTs in aqueous solution [57, 61]. A concentration of CNTs of  $0.2\text{--}0.4 \text{ mg mL}^{-1}$  was readily achieved upon dispersion with DNA, and it was possible to further concentrate the CNTs solution to  $4 \text{ mg mL}^{-1}$  [61]. It has been suggested that this highly efficient mechanism for dispersion of individual SWNTs in solution involves  $\pi$ -stacking interactions between the nanotube walls and the DNA bases, resulting in helical wrapping of the nanotubes. In addition, the hydrophilic interactions between the sugar-phosphate groups in the backbone of DNA and surrounding water molecules render the hybrid structure soluble in water. The phosphate groups on the SWNT-DNA hybrid provide a negative charge density on the surface of the CNT, enabling the debundling and dispersion of individual SWNTs [57, 61, 62]. The wrapping of the nanotubes with ssDNA was found to be sequence dependent, and the interaction between certain DNA sequences and individual SWNTs allowed ion-exchange chromatography separation based on the electronic characteristics of SWNTs. The separation procedure takes advantage of the different electrostatic charges on the hybrid macromolecules, which are composed of metallic and semiconducting SWNTs [57, 61]. Since the separation of metallic and semiconducting SWNTs is the most important obstacle to the application of carbon nanotubes in nanoelectronics, this DNA-assisted separation demonstrates the power of hybrid CNT-biological molecules for solving problems in nanotechnology.

A combination of surfactants and polymers has also been used for noncovalent attachment of proteins to CNTs, in which the successive adsorption of surfactants (Triton X-100 or Triton X-405) and biotin-functionalized polymer (PEG) provides an interface for binding with streptavidin [63].

Biomolecules can be attached to noncovalently functionalized CNTs. In this approach 1-pyrenebutanoic acid succinimidyl ester (1-PBA) is irreversibly adsorbed on the hydrophobic graphene surface of the CNTs via  $\pi$ -stacking interactions [64]. The protein is then covalently attached to the succinimidyl functionality of 1-PBA through a nucleophilic substitution reaction by an amine group of the protein (Fig. 2.7). This approach for immobilization of proteins onto CNTs has been utilized in development of biosensors based on glucose oxidase-functionalized SWNTs (Section 2.5.2) [55].

An important question that arises is whether the immobilized biological molecules retain their biological activity. Studies regarding this issue are limited. In one study on the structure and functions of proteins adsorbed on SWNTs, it was shown that the proteins undergo conformational changes upon interaction with the carbon walls [59]. The authors used enzymes as highly sensitive probes of the protein functions and found that, depending on the nature of the protein, SWNTs can differentially affect the biological activity of the adsorbed proteins; soybean peroxidase retained 30% of its native activity, while  $\alpha$ -chymotrypsin retained only 1% of its native activity, and was denatured when attached to SWNTs [59].

**Fig. 2.7.** 1-Pyrenebutanoic acid succinimidyl ester (1-PBA), adsorbed on the side-wall of a SWNT via  $\pi$ -stacking, has been used to immobilize protein due to interactions with the protein's amino groups. (Modified from Ref. [64].)

#### 2.4.4.2 Covalent Biofunctionalization

Carbodiimide chemistry can be readily applied to covalently link CNTs to various biological molecules. Carbodiimide activates the carboxylic acid groups, which are easily introduced into the CNTs by the oxidative treatments discussed earlier, and it facilitates their reaction with the amino groups present in the biological molecules. Carbodiimide coupling agents commonly utilized for these reactions are the water-soluble derivatives 1-ethyl-3-(3-dimethylaminopropyl)-*t*-carbodiimide (EDC) (Scheme 2.2, paths a, b) and *N,N'*-dicyclohexylcarbodiimide (DCC) (Scheme 2.2, path c), which are often used with dimethylformamide (DMF) as a solvent. *N*-Hydroxysuccinimide (NHS), which reacts with the carboxylic groups to form an active intermediate ester, is often used to assist amide bond formation in the presence of EDC (Scheme 2.2, path b). These general reactions have been utilized to functionalize CNTs with proteins [65] and amine-terminated DNA [66, 67].

Alternatively, CNTs can be chemically modified by introducing amine moieties [68], which can be further reacted with the biological molecules (Scheme 2.3). In the first step, the carboxylic acid groups of the SWNTs, introduced by oxidation with nitric acid, are reacted with thionyl chloride to form an acyl chloride intermediate, which is then crosslinked with ethylenediamine to produce amine-terminated SWNTs (SWNT-NH<sub>2</sub>). These SWNT-NH<sub>2</sub> have been used for covalent attachment of DNA [68]. This was achieved by introducing maleimide groups to SWNT-NH<sub>2</sub>

by crosslinking with succinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC) and further reacted with thiol-terminated DNA [68]. The resulting DNA-CNT hybridized selectively with complementary DNA sequences, while showing little interaction with non-complementary DNA sequences, indicating that the procedure preserves DNA specificity.

In addition to the chemistry that occurs at the oxidized open ends of CNTs, the side walls undergo 1,3-cycloaddition reactions (Scheme 2.4) [69, 70], and both SWNTs and MWNTs have been covalently linked to *N*-protected amino acids by this technique, which can be used to prepare water-soluble CNTs [70]. In such functionalization schemes the amino acid is condensed with paraformaldehyde in

the presence of CNTs dispersed in DMF (Scheme 2.4; 1); the protecting group, *N*-tetrabutoxycarbonyl (Boc), in the derivative (Scheme 2.4; 2) is cleaved by reaction with HCl. The resulting amino acid functionalized CNTs (Scheme 2.4; 3) have a remarkable solubility in water ( $20\text{ mg mL}^{-1}$ ). Additionally, amino acid functionalized CNTs can be reacted easily with *N*-terminal protected amino acid (Fmoc-Gly-OH) via a coupling reaction activated with *N*-hydroxybenzotriazole (HOBT) and diisopropylcarbodiimide (DIC) (Scheme 2.4; 4).

## 2.5

### Applications of Biofunctionalized Carbon Nanotubes

#### 2.5.1

##### Assembly of Electronic Devices

Biofunctionalization of CNTs can potentially facilitate the use of these materials in functional structures and for the bottom-up design of nanodevices if it is possible to make use of the powerful self-assembly properties of natural substances. Because CNTs are promising building blocks for molecular electronics, the nanofabrication of electronic devices utilizing CNTs based on the self-assembly principles of biology has been attempted. For example, the bottom-up fabrication of field-effect transistors (FETs) based on individual SWNTs has been attempted by using DNA-mediated self-assembly and homologous genetic recombination [71]. A long

**Fig. 2.8.** DNA-templated deposition of SWNT between gold electrodes. (a) DNA-bearing gold electrodes immersed in a solution of oligonucleotide-functionalized SWNT. (b) Bridging the two electrodes with a SWNT by hybridization between the complementary strands [72]. (Reproduced by permission of Elsevier.)

DNA molecule was used as a scaffold onto which streptavidin-functionalized SWNTs were assembled, utilizing primary antibodies against RecA, a protein from *Escherichia coli*, and biotinylated secondary antibodies. This allowed a controlled localization of a semiconducting SWNT at a desired address on the DNA scaffold molecule. Electrical contact to the nanotubes may be obtained by metallization of the scaffold DNA molecule. Because the nanotubes are usually a mixture of metallic and semiconducting constituents, the fabrication of devices with reproducible characteristics represents a challenge, although the emerging methods for separating CNTs based on their electronic properties will assist this endeavor [57, 61]. However, the approach involves a complex multi-step process, and thus would lead to a low production yield of devices.

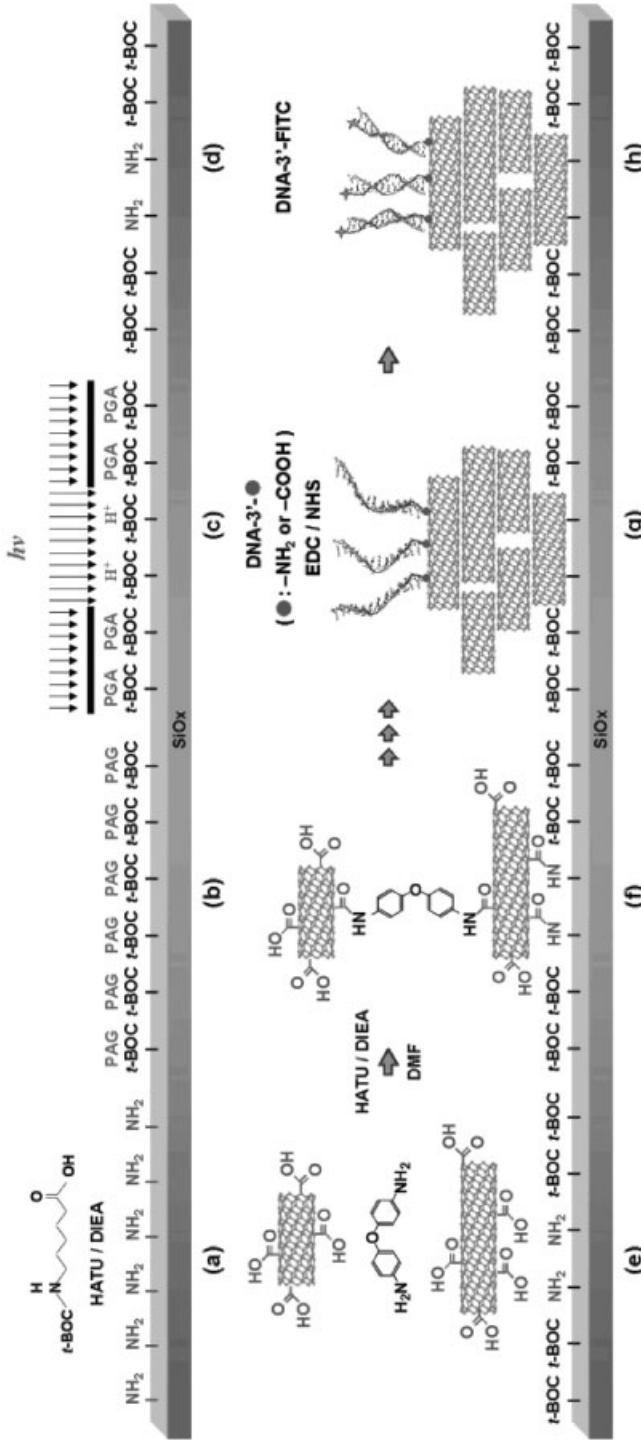

A suggested alternative approach for fabrication of an FET, with a reduced number of reaction steps, could enable the production of devices in high yield. This approach utilized the hybridization between short complementary DNA sequences located on metal contacts and SWNTs (Fig. 2.8) [72]. The thiol-terminated oligonucleotides were deposited on gold contacts, and the devices were immersed in a solution of SWNTs functionalized with complementary oligonucleotides. This allowed the hybridization of the complementary oligonucleotides, with one strand on the electrodes and the other attached to the SWNTs; the success of this operation led to the placement of individual SWNTs or small bundles between the electrodes, with efficient electrical contacts to the SWNTs at both electrodes in about 12% of the devices [72]. Those devices that exhibited efficient electrical contacts had stable electrical characteristics over hundreds of measurements. Indeed, this technique was also implemented to assemble SWNT-FET devices [73]. Although both approaches described above are far from a general technology, they highlight the potential use of biofunctionalized CNTs and self-assembly approach for bottom-up construction of CNT-based electronics.

**Scheme 2.5.** Schematic of procedures for DNA directed self-assembling of multiple carbon nanotubes and gold nanoparticles [75]. (Reproduced by permission of the American Chemical Society Publications.)

Controlled assembly of multifunctional SWNT structures is of interest for development of devices for biosensing. The functionalization of CNTs with biological molecules facilitates the formation of such functional structures and it also increases their versatility. Nanoparticle–CNT structures have been prepared using a DNA-directed self-assembly [74, 75]. In one approach DNA-graft gold nanoparticles have been attached to SWNTs grafted with complementary DNA chains, using the carboxylic group of the SWNT-COOH and amine-terminated DNA [75]. This approach has been used to assemble CNTs into various multicomponent structures, containing interconnected MWNTs and SWNTs, (Scheme 2.5) [75], and multifunctional structures could be obtained by varying the base sequence and the number of complementary DNA chains grafted to the gold nanoparticle.

Besides the assembly of functionalized CNTs (above), it is possible to functionalize pre-formed films of CNTs and prepare CNT film-based devices. Such preparations are readily achieved by spraying [8] or filtration [76, 77]. Additionally, the versatile chemistry at the open ends of the CNTs forming the film [36, 37] affords the opportunity to interconnect the nanotubes and to form patterned multi-layered SWNT films [78, 79]. Thus, carboxylic acid terminated CNTs have been interconnected using 4,4'-oxydianiline as a linker molecule [78]. The functionalized CNTs can be stacked on aminated glass substrates, which allows a diverse patterning of the CNT films and the introduction of various functional groups for further conjugation with biological molecules [78]. For example, DNA oligonucleotides have been attached, using carbodiimide chemistry (Scheme 2.2), to pre-patterned CNT multilayer films to give interfaces that exhibit a high sensitivity in subsequent hybridization (Scheme 2.6) [78]. Although their performance is inferior to individual

CNT devices, film-based devices made of CNTs provide convenient manufacture and have led to a powerful sensor platform [8]. Since this approach can lead to patterning at a specific location on a substrate, it could advance the development of sensors requiring site specificity.

SWNTs functionalized with poly-L-lysine (PLL) have been reported to assemble in functional structures, which have been used as a platform for electrodes with enhanced biosensing properties [80]. Assembly was achieved by reacting carboxylic acid bearing SWNTs with some of the amino groups of PLL (Scheme 2.7). The unreacted amino groups were available for subsequent attachment of the SWNT-PLL graft copolymer to the carboxylic acid bearing gold electrodes and also for conjugation to horseradish peroxidase. Attachment of this enzyme led to the construction of electrodes for amplified sensing of hydrogen peroxide [80]. Indeed, various enzymes could be attached using this method to the PLL-functionalized CNTs for the development of sensor devices. Because PLL is a permissive substrate for cellular adhesion and growth, this methodology could be exploited for development of composite substrates that would serve a dual role; they would support cellular growth and also serve as sensors.

### 2.5.2

#### **Biosensing**

Among the potential usage of CNTs in biology and medicine, the development of advanced biosensor devices has emerged as the most promising short-term application. CNTs offer a unique combination of quasi-1D structure and excellent electronic properties, which can dramatically improve the miniaturization prospects for electronic biosensor devices. Additionally, CNTs offer new opportunities for rapid, sensitive and label-free detection of biological agents, with the selectivity of detection provided by biofunctionalization of the CNTs. Furthermore, the nanotubes can clearly serve both as the transducer and as the platform where the bio-recognition event occurs. Taken together, these prospects make CNTs one of the most promising materials for advanced biosensors.

Several groups have already demonstrated the use of SWNTs in biosensors [55, 81–92]. Research on CNT-based biosensors is currently focused on exploiting two major fundamental approaches: the development of CNT electrodes for the electrochemical detection of biological agents and fabrication of transistor devices for electronic detection of binding events.

Electronic detection of biological species is very attractive because it offers a fast and direct, label-free detection, while sampling data in real time. Additionally, it does not require preparation steps and multiple reagents, making the use of these sensors quite simple. Electronic detection is possible because a semiconducting SWNT exhibits a significant conductance change in response to interaction with gas molecules, which can change the electron density on the nanotube [93, 94]. Similar electronic changes in the behavior of SWNTs have been found upon interaction with small biological molecules and proteins [55, 89, 95, 96]. The *in situ* electronic detection of proteins using CNTs has proved to be very sensitive. Adsorp-

**Fig. 2.9.** Schematic of a nanotube field-effect transistor (FET). The nanotube (SWNT) is functionalized with biotin using a polymeric functional layer, which coats the nanotubes. (Modified from Ref. [89]; by permission of the American Chemical Society Publications.)

tion of cytochrome *c*, a redox catalyst in the respiratory chain of mitochondria, on an individual SWNT in a transistor configuration induced a sufficient decrease in the conductance of the device to allow the detection of a few tens of molecules [96].

An FET composed of an individual pristine SWNT (Fig. 2.9) has been shown to change its resistance upon exposure to proteins [89]. For example, adsorption of streptavidin on the SWNT shifted the transconductance towards negative gate voltages with little change in the current. Taking into account that the nanotubes before the adsorption exhibited p-type electronic behavior, presumably due to doping from environmental oxygen [94], these changes indicate an electron transfer from the streptavidin molecule to the nanotube. This hybrid, streptavidin-SWNT has been shown to be sensitive to the presence of biotin, which specifically binds to streptavidin, resulting in a decrease of the current. Because the interaction between streptavidin and SWNTs is non-specific it is necessary to impart selectivity to the device and to prevent non-specific interactions; this can be accomplished by coating the SWNTs with hydrophilic polymers, PEG and polyethyleneimine (PEI), containing biotin. The polymer coated/biotin functionalized SWNTs devices are very sensitive in the detection of streptavidin – down to as few as 10 protein molecules [89].

Although the mechanism of chemical sensing exhibited by SWNTs has not been unambiguously identified, as discussed above it seems probable that the resistance change in the devices originates from doping of the CNTs as a result of charge-transfer processes that are associated with interactions between the SWNTs and the analyte [8]. In some cases the conductance change originates from electronic effects occurring at the metal–nanotube contacts during adsorption [97].

In addition to direct sensing with SWNTs, biologically functionalized SWNTs also show promise as sensors. For example, glucose oxidase (GO) has been covalently attached to a semiconducting SWNT and used as the conducting channel in an FET [55]; the attached GO retained its enzymatic activity and imparted sensitiv-

ity to the nanotubes towards glucose. Importantly, the increase in conductance measured with such devices in the presence of glucose was rapid, which has implications for real time studies of enzymatic activity at molecular level. The GO-coated SWNT devices were very sensitive to pH, whereas the conductance of pristine SWNT was pH independent in the range 4–5.5; after modification of the nanotube with GO, a strong increase in conductance with decreasing pH was observed [55]. On changing the pH from 4 to 5.5, the effective gate voltage changed by 20 mV, which corresponded to a 30  $\mu\text{S}$  change in the conductance of the nanotube. These measurements show that it is possible to detect the doping induced by the binding of about 50 protein molecules to a  $\sim 600$  nm long semiconducting SWNT.

Several research groups have explored the electrochemical detection of biological molecules with electrodes consisting of CNTs in their pristine or modified forms; details of the achievements in electrochemical biosensing using CNTs have been outlined in a recent review [98]. Since their introduction into electrochemistry, CNT electrodes have demonstrated an enhanced sensitivity compared with conventional carbon electrodes. For example, detection of transmitter dopamine exhibited characteristic cyclic voltammograms at conventional electrodes such as glassy carbon and pyrolytic carbon fibers, as well as at CNT electrodes [81]. However, the conventional electrodes suffered from poor reversibility, while CNT electrodes exhibited excellent reversibility and were also very sensitive in the analysis of goat brain tissue. This illustrates the potential to use CNT electrodes for *in vivo* and *in vitro* neurotransmitter investigations involving dopamine, and possibly with other oxidizable transmitters. Similarly, the ultrasensitivity of CNT electrodes in electrochemical detection of proteins and DNA has been reported [91]. Covalent coupling of the alkaline phosphatase (ALP) enzyme to CNTs has led to the highest sensitivity (detection limit 1  $\text{pg L}^{-1}$ ) reported thus far for electrical detection of DNA. This CNT-ALP-linked assay can be modified for antigen detection by using specific antibody–antigen recognition, which could provide a fast, simple solution for molecular diagnosis in pathologies where molecular markers exist, such as DNA or protein.

Ultrasensitive DNA detection has been also achieved with a nanoelectrode array composed of aligned MWNTs embedded in silicon dioxide. The nanoelectrodes have been fabricated by a bottom-up approach, which resulted in precisely positioned and well-aligned MWNTs embedded in the silicon dioxide matrix. This configuration provided structural integrity to the electrodes and allowed the sensitivity of the array to be tailored by controlling the nanotube density [83]. The sensitivity was increased dramatically upon lowering the nanotube density in the array, allowing for the detection of less than a few attomoles of oligonucleotide.

A similar approach has been used to develop a MWNT-based nanoelectrode array for selective detection of glucose [85]. Nanotubes in the array were embedded in an epoxy matrix. The exposed nanotube tips were functionalized with glucose oxidase using carbodiimide chemistry. The devices showed a linear response to glucose up to a concentration of about 30 mM with the detection limit down to 0.08 mM, achieving a much wider range than necessary for sampling glucose in human blood and urine.

Alternative approaches for the development of glucose biosensors involve conducting polymer coated CNT arrays [86, 87]. In this approach GO was incorporated into a layer of conducting polymer, such as polypyrrole [87] or polyaniline [86], which coated aligned nanotubes. The amperometric response from these aligned nanotube–polymer nanowires was much higher than that of conventional electrodes using conducting polymers.

An additional advantage of CNT-based biosensors is the possibility of the favorable improvement of screen-printed graphite sensors by their modification with CNTs [92]. MWNTs have been used for modification of working graphite ink electrodes; the nanotubes were deposited on the graphite surface by evaporation of a solution of MWNTs in DMF, and the electrodes were further modified by adsorption of organophosphorus hydrolase, which allowed detection of the pesticide paraxon with greater sensitivity than for previous detection methods [92].

Atomic force microscopy (AFM) is a CNTs biosensing application that also impacts structural biology; due to their high aspect ratio, strength and chemical versatility, CNTs can be used to improve upon standard AFM tips in several ways. The most obvious is to enhance the image resolution as the tip size is significantly reduced when SWNTs are utilized. Standard commercial silicon-based tips have radial curvatures of about 5–10 nm, while SWNT AFM tips with a diameter in the range of 1–3 nm have already been fabricated [99, 100]. The improved resolution of the CNT tips has been demonstrated clearly in an AFM study of isolated proteins at room temperature in which a MWNT tip reproducibly resolved the distinct Y-shape of an isolated immunoglobulin G (IgG) [101], while previous images obtained with conventional tips yielded only a heart-shaped structure. Similarly, SWNT tips were used for high-resolution imaging of isolated DNA molecules [102]. This method has been implemented for determination of haplotypes on UGT1A7 [101], a gene suggested to be a cancer risk factor. Using SWNTs as a tip gives a resolution of approximately 10 bases, which enables direct reading of DNA sequences, and the utilization of SWNT tips in haplotyping clearly could be applied to the understanding and diagnosis of genetic diseases.

AFM probes with functionalized SWNTs as tips have been proposed as the ideal high-resolution probe for mapping chemical domains by using chemical force microscopy [103]. SWNT tips are extremely sensitive to surface polarity, pH and many other chemical characteristics of the sample, as demonstrated by tapping mode AFM studies using a tip of CNTs with terminal carboxylic groups [104], where it was possible to chemically map the patterned substrate containing areas of methyl and carboxylic groups (Fig. 2.10). The ability of AFM tips to detect biological molecules has also been demonstrated, and biotin-modified SWNT AFM tips have been used to study biotin interaction with streptavidin immobilized on a mica surface [104]. This method offers the opportunity to detect the spatio-temporal location of a specific molecule; in this approach the temporal resolution would be limited by the scanning speed and biosensor properties, while the spatial resolution would be limited by the diameter of the nanotube. For example, nanotubes capable of sensing glucose [105, 106] or neurotransmitters could be used to scan for the uptake and release of these compounds from specific cells under various stimuli.

**Fig. 2.10.** (a) Schematic of a SWNT tip with attached carboxylic acid groups. (b)–(d) Chemical mapping with functionalized SWNT tip. (b) Schematic of a patterned substrate consisting of a self-assembled monolayer (SAM) region terminated with methyl groups and surrounded by carboxylic acid-terminated

SAM. (c) Tapping mode phase image of the patterned SAM in (b) imaged with a carboxylic acid-terminated SWNT tip, and (d) phase image of a similar substrate imaged with a C<sub>6</sub>H<sub>5</sub>-terminated SWNT tip. (Courtesy of Charles M. Lieber, Harvard University, USA.)

### 2.5.3

#### Substrates for Neuronal Growth

The first use of CNTs in contact with living cells made use of carbon nanotubes as a substrate for neuronal growth [107]. In this work, cultured hippocampal neurons were grown on MWNTs deposited on PEI-coated coverslips. Scanning electron microscopy was used to visualize the morphological parameters of neuronal growth. The neuronal bodies adhered to the surface of the MWNTs, showing outgrowth of neurites that elaborated into many small branches. The neurons remained alive on the MWNTs for at least 11 days.

**Fig. 2.11.** (A) SEM image of a neuron grown on as-prepared MWNTs (AP-MWNTs). (b) Fluorescence image showing a live neuron on AP-MWNTs, which accumulated the vital stain, calcein. Arrow indicates a growth cone. Scale bar, 20  $\mu\text{m}$ . (c) Drawing summarizing the

effects of MWNT charges and (d) the effects of graft copolymer SWNT-PEI on growth cones, neurite outgrowth and branching. PEI, polyethyleneimine. (Modified from Refs. [108, 109].)

More recently, this work was extended by characterizing the morphological features of live neurons labeled with the fluorescent dye calcein, and visualized with a fluorescence microscope (Fig. 2.11) [108]. Neuronal growth was systematically controlled by modified MWNTs, prepared by covalently conjugating CNTs with functionalities designed to carry negative, neutral or positive charges at physiological extracellular pH. By using these CNTs as the scaffold for neuronal growth, it was found that the neurons grown on positively charged MWNTs showed more numerous growth cones, longer neurite outgrowth and more successful neurite branching than neurons grown on negatively charged CNTs (Fig. 2.11). Thus, by varying the electrostatic charge on the MWNTs it was possible to manipulate the growth pattern of the neurons. Similarly, neuronal growth was also modulated by using a SWNT-PEI graft copolymer as a scaffold or substrate for cultured neurons [109]. SWNT-PEI promoted neurite outgrowth and branching; neurons grown on SWNT-PEI showed more extensive neurite branching than neurons grown on as-prepared (AP-) MWNT, but having quantitatively similar neurite branching to those of neurons grown on PEI. The number of their growth cones was comparable to those on neurons grown on AP-MWNTs; the neurite lengths were intermediate and fell between those of neurons grown on AP-MWNTs and PEI (Fig. 2.11). Where PEI was combined with SWNTs, the positive charge on the PEI was reduced, perhaps by  $\sim 20\%$ , in proportion to the SWNT loading in the copolymer. The surface charge

reduction could be the basis for the effect of the copolymer on neuronal growth characteristics. Besides giving new information on the sensitivity of neuron growth parameters to substrate quality and charge, the data gathered may provide the basis for the development of materials where the ratio of SWNT/PEI in the copolymer could control neurite outgrowth and branching.

Taken together these studies demonstrate that CNTs can be used as a scaffold or substrate for neuronal growth and that modifications of CNTs, including graft copolymers with PEI, can be employed to modulate the arborization of neuronal processes and their outgrowth. This suggests that it may become possible to employ suitably functionalized CNTs as neural prostheses in neurite regeneration.

## 2.6

### Concluding Remarks

It is apparent from the body of work detailed in this chapter that there is already an impressive array of currently available methods for biofunctionalization of CNTs and of CNT applications in biology and nanotechnology. As a result of their unique properties and the sophistication of the chemistries available for their modification, CNTs have immense potential in biotechnology and biomedicine that are only now starting to be realized – although their toxicity remains a concern [110, 111]. Presently, CNTs are mainly under investigation in research laboratories, but if there is widespread commercialization of CNTs, the exposure of the general populace to this material must not occur without adequate testing. At this point there is no indication that CNTs will be any more hazardous than other forms of carbon, and their enormous potential in nanomedicine mandates the continued investigation of this unique nanomaterial from the biological standpoint.

### Acknowledgments

We thank Erik Malarkey for his comments on an earlier version of this manuscript. The authors' work is supported by the National Institute of Mental Health (MH 069791) and by DOD/DARPA/DMEA under Award No. DMEA90-02-2-0216. V.P. is an Institute for Complex Adaptive Matter Senior Fellow.

## Biofunctionalization of Magnetic Nanoparticles

Yong Gao

### 3.1

#### Introduction

Advances in information storage technologies since the 1950s have led to tremendous progress in the preparation of magnetic particles of nanometer dimensions with defined properties [1, 2]. Since then, magnetic nanoparticles have found applications in biomedicine [3]. Magnetic particles with a grain size down to the nanometer scales have been used for *in vitro* cell/protein bio-separation, and chem-/bio-syntheses of pharmaceutical drug molecules. They have also been employed for *in vivo* magnetic drug targeting, magnetic resonance imaging (MRI) and magnetic hyperthermia tumor therapy [4–12]. More recently, due to rapid advances in nanotechnology, novel synthetic routes for fabricating magnetic nanoparticles with the ability to rigorously control the microstructures of magnetic nanoparticles, for example, coating, crystallinity and size uniformity, have been reported [13–38]. The development of these new types of magnetic nanomaterials has led to renewed research efforts on the functionalization of magnetic nanoparticles for their expanded biomedical applications.

*In vitro* and *in vivo* applications of magnetic nanoparticles in biomedicine are due to numerous beneficial factors associated with the unique nanometer-scale magnetic and physiological properties of magnetic nanospheres. Below a critical size, magnetic nanoparticles become single-domain and exhibit phenomena that differ from those of micrometer-sized counterparts, such as superparamagnetism, quantum tunneling of the magnetization, and unusually large coercivities, [1, 39–41]. Superparamagnetic iron oxide nanoparticles have been used as MRI contrast agents because of their very large magnetic moments – typically three orders of magnitude greater than those of other paramagnetic materials [4–6]. In addition to endowing them with unique magnetic properties, the small dimensions of magnetic nanoparticles, which range from several nanometers to hundreds of nanometers, typically smaller than those of proteins, cells and viruses, allow magnetic nanoparticles to have “close” contacts with a biological entity of interest. Thereby, magnetic nanoparticles can be utilized as a support for immobilization of bioactive molecules for bio-separation and bio-labeling applications since these nano-

particular supports present minimal steric hindrance to the surface-loaded proteins and cells. Magnetic nanoparticles also have advantages over their micrometer counterparts in *in vivo* bioapplications due to their small sizes. For example, *in vivo* applications of magnetic particles usually prefer a particle dimension below 20 nm for high tissue penetration [42]. The small sizes can also help magnetic nanoparticles evade hepatic clearance from the bloodstream by the mononuclear phagocyte system (MPS). This will increase the plasma half-life of nanoparticles and, thus, increase the probability of attaining the desired target inside the body with magnetic nanoclusters [43].

A core/shell structure is usually required in many biomedical applications of magnetic nanoparticles. Such nanoclusters have an inorganic core, e.g., iron oxide, surrounded by an outer layer of shell wall that consists of long-chain organic ligands or inorganic/organic polymers. For many biomedical applications, the inorganic cores need to be superparamagnetic. For instance, the Food and Drug Administration (FDA) approved iron oxide MRI contrast agents have a superparamagnetic nano-core coated with dextran polymers. Superparamagnetism is also preferred for bio-separation and bio-labeling applications of magnetic nanoparticles. This is because (1) superparamagnetic cores will respond to an external magnetic field, but retain no magnetic properties once the field is removed [7]. The lack of magnetic remanence will allow magnetic materials to be repeatedly dispersed and concentrated in solution without forming magnetized clusters; and (2) superparamagnetic materials have large magnetic moments, permitting the use of low-field magnets for efficiently concentrating nanoparticles. Recently, progress has been made on the synthesis of monodisperse and structurally well defined iron oxide and other types of magnetic nanoparticles [13–33]. These new materials can be employed for constructing the interior cores of the core/shell magnetic nanoparticles – potentially endowing them with improved magnetic properties. Hyeon has recently reviewed developments in the chemical synthesis of magnetic nanoparticles [44].

The shell wall of core/shell magnetic nanoparticles is of particular importance to the bioapplications, stability and magnetic properties of nanoparticulate complexes. Due to anisotropic dipolar attraction, nanoparticles tend to aggregate into large clusters that cause the loss of specific properties associated with single-domain nanostructures. Consequently, long-chain organic ligands or a layer of polymers are usually introduced to coat the inorganic cores to prevent core aggregations. In addition to improving the stability of nanoparticles, the shells also determine the solubility of nanocomplexes in aqueous buffer media and provide a platform for the functionalization of nanoclusters. Bio-active molecules, e.g., antibodies and proteins, can be immobilized onto the surface of shell walls and interact with a biological entity in surrounding solutions. However, as the size of nanoparticles decreases, the influence of surface interactions upon the magnetic properties of magnetic nanoparticles becomes more significant due to the increased volume fraction of surface atoms. The symmetry is reduced for the chemical surroundings of magnetic metal cations at the surface due to the incomplete coordination sphere. As a consequence, the magnetic properties of the nanoparticle surfaces

usually differ from those in the body of the nanoparticle, and surface effects could become increasingly important to the overall magnetic properties of magnetic nanoparticle as its size decreases [45–50].

The present chapter focuses on recent developments in the synthesis and biofunctionalization of core/shell magnetic nanoparticles as well as their applications in biological and medical sciences. Although widely used in bio-separation applications, micrometer-sized magnetic particles are outside the scope of this review. This chapter is divided into three sections: functionalization of magnetic nanoparticles for (a) *in vitro* protein/cell separation (Section 3.2); (b) *in vitro* biochemical/chemical synthesis of therapeutic drugs and their intermediates (Section 3.3); and (c) *in vivo* bio-imaging, drug targeting and tumor hyperthermia treatments (Section 3.4), which includes some recent work on molecular imaging and gene therapy using functionalized magnetic nanoparticles. Although most reported molecular imaging and gene therapy experiments were carried out under *in vitro* environments, the ultimate goal in these two areas is to develop novel techniques using magnetic nanoclusters for *in situ* cellular visualization and gene therapy in living animals. Therefore, functionalization of magnetic nanoparticles for cellular imaging and gene therapy is listed under the *in vivo* applications of magnetic nanoparticles.

## 3.2

### Functionalization of Magnetic Nanoparticles for *In Vitro* Protein/Cell Separation

The synthesis of core/shell magnetic nanoclusters and the attachment of bio-active ligands to the surface of the outer shells are key to bioapplications of magnetic nanoparticles. Several strategies have been developed recently for coating magnetic cores. The most common method is to use long-chain organic ligands to wrap up the inorganic cores. Hydrophobic interactions between ligands from neighboring nanoparticles will prevent adjacent inorganic cores agglomerating into a larger cluster. However, biological applications usually require magnetic nanoparticles to have good solubility in aqueous media. Hydrophobic long-chain alkanes will lower the solubility of magnetic nanoparticles in aqueous buffers. To solve this problem, our group has investigated the employment of charged bipyridinium carboxylic acids for coating iron oxide cores to make these nanoparticles water-soluble (Fig. 3.1) [51]. The positive charges on the surface of nanoparticles not only stabilize nanoparticles, by repelling neighboring clusters from forming aggregation, but also improve the solubility of nanoparticles in aqueous media. This is particularly important with biotin-functionalized maghemite nanoparticles since biotin is practically insoluble in distilled water. Both biotin and bipyridinium ligands were anchored to the surface of inorganic cores, having an average dimension of about 13 nm due to interactions between carboxyl groups and iron oxide. Such biotin-functionalized maghemite nanocomposites have been utilized for affinity isolation of fluorescein-labeled protein avidin.

A similar strategy using a bidentate enediol dopamine as a stable anchor of mag-

**Fig. 3.1.** Structure of magnetite nanoparticles coated with biotin and bipyridinium carboxylic acids. (Adapted from Fan et al. [51].)

netite nanoparticles for protein separation has been reported by Xu (Fig. 3.2A) [52]. Two types of superparamagnetic nanoparticles were synthesized and tested as supports for immobilization of nitrilotriacetic acid: one has a cobalt core with a  $\text{Fe}_2\text{O}_3$  shell, and the other has a  $\text{SmCo}_{5.2}$  core surrounded by an  $\text{Fe}_2\text{O}_3$  shell. Dopamine was anchored to magnetic nanoparticles via interactions between its bidentate enediol functional group and surface iron oxide. Nitrilotriacetic acid was linked to dopamine through a long tether. Upon chelation to  $\text{Ni}^{2+}$ , dopamine-functionalized magnetic nanoparticles separated histidine-tagged proteins from a cell lysate with high efficiency and capacity. Histidine-tagged proteins were segregated from the solution due to interactions between a histidine tag and  $\text{Ni}^{2+}$  complexed with nitrilotriacetic acid. The separation process was readily achieved by applying an external small magnet. A similar bidentate enediol functional group, C-undecylcalix[4]resorcinaren, has also been reported for coating cobalt magnetic nanoparticles that self-assemble into bracelet-like rings [53].

Interactions between a sulfur group and FePt have been utilized to immobilize nitrilotriacetic acid for the separation of histidine-tagged proteins from a cell lysate

**Fig. 3.2.** Structures of magnetic nanocomposites using dopamine (A) and sulfur (B) to anchor nitrilotriacetic acid for separating histidine-tagged proteins. (Adapted from Xu [52, 54].)

(Fig. 3.2B) [54]. Many other functional groups, such as  $-OH$ ,  $-SH$  and  $-NH_2$ , have also been tested for their interactions with metals and metal oxides as capping agents of magnetic metal and metal oxide cores. For instance, the amino groups of vancomycin have been employed for immobilizing the antibiotic to the surface of FePt nanoparticles [55]. Such complexes could capture and detect vancomycin-resistant enterococci and other Gram-positive bacteria at concentrations of  $10^1$  cfu mL $^{-1}$  within an hour. Additional examples of using amino groups for the functionalization of magnetic nanoparticles have also been reported [56, 57]. A similar nanocomposite of IgG and magnetite has also been employed by Chen's group as an effective affinity probe to concentrate target bacteria selectively [58]. IgG was immobilized onto the surface of a magnetite core via an ester bond. Other than antibodies, DNA/RNA-functionalized magnetic nanoparticles have also been used for the isolation and extraction of DNA/RNA targets [59]. The surfaces of these nanoparticles were usually coated with molecular beacon DNA probes for specific recognition of DNA/RNA targets in solution.

The  $-OH$ ,  $-SH$  and  $-NH_2$  functional groups are usually introduced through a surface exchange reaction with pre-synthesized magnetic nanoparticles coated with a different functional group [31, 60, 61], or by co-precipitation of an aqueous solution of metal ion salts such as  $Fe^{2+}/Fe^{3+}$  in the presence of these organic capping groups [42]. For example, iron oxide nanoparticles coated with  $\alpha$ -cyclodextrin (CD) were obtained by a surface exchange reaction from iron oxide nanoparticles protected by oleate [62].  $\alpha$ -CD was added to the surface of nanoparticles by vigorously stirring, at room temperature, mixtures of hexane suspensions of iron oxide nanoparticles coated with oleate and an equal volume of  $\alpha$ -CD aqueous solution. Oleate-stabilized nanoparticles were transferred from organic into aqueous phase by surface modification using  $\alpha$ -CD. CD molecules have  $-OH$  groups that can bind to the surface of iron oxide cores.

An interesting way of capping magnetic iron oxide cores is to use phospholipids to form nanometer-sized magnetoliposomes. An example [63] of such phospholipid-coated magnetite nanoparticles, employing 1,2-myristoyl-*sn*-glycerol-3-phosphoglycerol, sodium salt and 1,2-dimyristoyl-*sn*-glycerol-3-phosphocholine, had an iron oxide core dimension of 8 nm and a phospholipids/surfactant shell of 4 nm. These particles were effective ion exchange media for the recovery and separation of proteins from protein mixtures. These nanocomposites demonstrated high adsorptive capacities of proteins and exhibited none of the diffusion resistances offered by conventional porous ion exchange media.

Due to strong interactions with metal oxide, organosilane groups have also been explored for anchoring bioactive molecules onto the surface of iron oxide nanocores. Zhang has reported a novel approach using bifunctional trifluoroethyl ester polyethylene glycol (PEG) silane for the functionalization of iron oxide nanoparticles (Fig. 3.3) [64]. Folate acid, a widely used targeting agent for cancer therapies [65], was attached to the outer terminus of the PEG chain to demonstrate the effectiveness of bio-active ligand immobilization by this strategy. Silylation of magnetite is key to the functionalization of magnetic nanoparticles in this route. Introduction of PEG molecules as a linker will potentially benefit *in vivo* applications of these

**Fig. 3.3.** Structure of magnetite nanoparticles coated with PEG and folic acid. (Adapted from Kohler et al. [64].)

nanoparticles since PEG molecules are nonimmunogenic, nonantigenic and protein resistant and can increase particulate circulation time in the blood. Willner has used the silylation of magnetic metal oxide surfaces for the immobilization of redox functions to magnetite particles. Such complexes were used in constructing a magneto-switchable bioelectrocatalysis sensor [66].

Sol-gel approaches have been examined for coating magnetic metal oxide cores to form a core/shell structure having an inorganic metal oxide core wrapped with a layer of silica [67–76]. Two different strategies have been investigated to generate silica coatings on the surface of iron oxide particles. The first method relies on the well-known Stöber process [77], in which silica is formed *in situ* through the hydrolysis and condensation of a sol-gel precursor. For example, Xia has reported the use of tetraethyl orthosilicate (TEOS) for coating mixed-crystalline iron oxide nanoparticles (water-soluble ferrofluid) [74]. Because the iron oxide surface has a strong affinity towards silica, no primer was required to promote the deposition and adhesion of silica, allowing magnetic nanoparticles directly coated with amorphous silica to be formed via the hydrolysis of TEOS. A second sol-gel approach is based on a microemulsion strategy, in which micelles or inverse micelles are used to confine and control the coating of silica on core nanoparticles. The microemulsion approach can control the thickness of the silica shell wall coating so that the stability and solubility of the formed magnetic nanoparticles in aqueous media can, presumably, be tuned for different bio-applications. An example is discussed

in Section 3.3 (Fig. 3.7 below) [75]. Core/shell magnetite/silica nanoparticles were synthesized by a microemulsion approach and functionalized with protein  $\beta$ -lactamase to promote hydrolysis.

Natural polymers and their derivatives have been widely utilized for coating magnetic metal and metal oxide nanocore surfaces. In particular, natural biopolymers such as dextrans, proteins/peptides and PEG are usually the materials of choice for the synthesis of core/shell magnetic nanoparticles designated for *in vivo* applications. This is because such natural polymers are inexpensive and are known to be nonimmunogenic and nonantigenic in the body. Natural polymers are usually anchored onto the surfaces of magnetic metal oxide cores through carboxylate groups on their side chains. Section 3.4 includes detailed discussions and examples of using these natural polymer-functionalized magnetic nanoparticles for *in vivo* applications.

Tremendous research efforts have focused on the employment of synthetic polymers for coating the surfaces of magnetic inorganic cores to generate core/shell magnetic nanoparticles. For example, layer-by-layer deposition of charged polymers onto the surfaces of magnetic inorganic cores in sequence has been reported [78]. Although progress has been made, the layer-by-layer assembly strategy has yet to become the method of choice for coating very small, sub-20 nm magnetic nanoparticle cores because of the curvature of nanoparticle surfaces and the mechanical strength of the polymeric chains. Unfortunately, magnetic nanoparticles with an overall dimension below 20 nm are usually preferred for some *in vivo* applications due to their high tissue penetration capability and long blood circulation time [42, 43]. Here we focus on two alternative strategies that can potentially be utilized and expanded for synthesizing magnetic nanoparticles of various sizes and shapes.

The first approach is to utilize surface-initiated polymerization to grow polymer chains on the surface of inorganic cores. Free radical initiators are first immobilized onto the surfaces of metal and metal oxide cores followed by polymer growth outwards to give rise to a radius structure. Among many polymerization routes, living free radical polymerization, especially atom transfer radical polymerization (ATRP), has become the method of choice for the surface-initiated polymerization synthesis of core/shell magnetic nanoparticles (Fig. 3.4) [79]. ATRP is a versatile technique that offers several advantages over other polymerization routes, including control over molecular weight and molecular weight distribution for the synthesis of well-defined and complex macromolecular architectures of magnetic nanoparticles [80]. For example, by manipulating reaction time and the concentration of polymerizable ligands in solution one can control the shell wall polymer molecular weight and, thus, the thickness of the polymeric shell wall of core/shell magnetic nanoparticles. ATRP also allows the polymers to be end-functionalized or block copolymerized upon the addition of other monomers. Not only does this feature offer tailorability of the polymer coating with various compositions and functionalities, but also provides the platform for functionalization of the polymeric shell wall with bio-active functional groups. As a consequence, extensive research has been carried out by many groups using ATRP for the synthesis of core/shell polymer magnetic nanoparticles [79, 81, 82]. Our group has examined

**Fig. 3.4.** Surface-initiated ATRP synthesis of polymeric core/shell nanoparticles using divinylbenzene (DVB) as a crosslinking agent. (Reproduced by permission of the American Chemical Society.)

recently an ATRP method for the preparation of core/shell maghemite/polystyrene nanocrystals (Fig. 3.4) [79]. Our inorganic cores have an average size of about 11 nm while the thickness of the crosslinked polystyrene shells were maintained to only about 4.7 nm (Fig. 3.5). However, further work is needed to adapt ATRP techniques for the synthesis of hydrophilic and water-soluble magnetic nanoparticles for biomedical applications. A recent paper from Armes [83] on the synthesis of hydrophilic polymer-grafted ultrafine inorganic oxide particles suggested that such water-soluble polymeric magnetic nanoparticles can potentially be achieved through a different ATRP method.

**Fig. 3.5.** TEM micrograph of 10% DVB-crosslinked  $\text{Fe}_2\text{O}_3$ /polystyrene core/shell nanoparticles on a lacey carbon film coated copper grid (300 mesh) consisting of woven-

mesh-like holes. The polystyrene shells are visible at the edge of a hole. Dark spots on the carbon film are  $\text{Fe}_2\text{O}_3$  cores. (Reproduced by permission of the American Chemical Society.)

A second, extensively researched, approach to synthesizing polymeric core/shell magnetic nanoparticles is to use pre-formed synthetic polymers as a matrix to confine and control the formation of magnetic cores. For example, core/shell magnetic nanoparticles have been produced by chemical co-precipitation of iron salts in an aqueous solution of the poly(ethylene oxide) (PEO)/poly(propylene oxide) (PPO)–poly(acrylic acid) (PAA) graft copolymers [84]. After magnetite nucleation begins, carboxylic acid groups on the PAA backbone bind to the particle surface, limiting the magnetic core growth. The bifunctional polymer shell is formed from the hydrophilic PEO and hydrophobic PPO side chains in the graft copolymer. These nanoparticles are stable and soluble in organic solutions. Similar magnetite nanoparticles coated with long poly(vinyl-*N*-alkylpyridinium) chains have also been synthesized by this strategy [85]. Alkylated polyethylenamines made these materials highly bactericidal toward both Gram-positive and Gram-negative pathogenic bacteria. Other types of polymers such as poly(vinylpyrrolidone) [86, 87], polylactide [88], poly(isopropylacrylamide) [89], polyacrylate [90], poly(methacrylate) [91], poly(vinyl alcohol) [92] and polysiloxane block copolymers [93] have also been reported as matrices for the synthesis of core/shell magnetic nanoparticles.

### 3.3

#### **Functionalization of Magnetic Nanoparticles for Biochemical/Chemical Synthesis of Therapeutic Drugs and Their Intermediates**

Catalysts are widely used in pharmaceutical and chemical industries in producing therapeutical drug molecules and their intermediates. Catalysts such as biocatalysts (enzymes) and metal catalysts (homogeneous and heterogeneous catalysts) can promote organic and biological reactions that are otherwise too slow for industrial standards. Recycling and reuse of industrial catalysts is particularly important for cutting industrial operation costs and minimizing environmental pollutions, especially when expensive and toxic heavy metals are used [94].

Recently, efforts have been directed towards the use of magnetic nanoparticles as supports for immobilization of biocatalysts [75, 95, 96]. Core/shell magnetic nanoparticles are usually covalently attached with biocatalyst enzymes on their shell surfaces. Due to the small sizes of particles, nanoparticle-immobilized proteins are usually soluble in aqueous buffers, which differs from other supports such as polystyrene beads, in which proteins are usually suspended in solution. The magnetic, usually superparamagnetic cores will allow these biofunctionalized particles to be magnetically concentrated with the assistance of an external magnetic field. This could allow immobilized enzymes to be used repeatedly or continuously in various reactors. Enzymes can be easily separated from soluble reaction products and unreacted substrates, thus simplifying work-up and preventing protein contamination of the final products. This will also simplify the control of microbial contamination in immobilized proteins.

*Candida rugosa* lipase (E.C.3.1.1.3) has been immobilized on maghemite nanoparticles with an average size of about  $20 \pm 10$  nm (Fig. 3.6) [95]. A carboxylate

**Fig. 3.6.** Representative structure of magnetic nanoparticles immobilized with *Candida rugosa* lipase. (Adapted from Dayal [95].)

group was used to anchor a 2-thiophene thiolate linker and the enzyme was chemically bonded to the nanoparticle surface through a C=N bond using glutaraldehyde. The amount of immobilized enzyme was determined by standard BCA protein assays of the original lipase solution, the supernatants and washing solutions after immobilization, respectively. The presence of protein on the surface of nanoparticles was also confirmed by AFM measurements of a small amount of the enzyme-functionalized magnetic nanoparticles on a thin layer of glue deposited on a steel disk. Enzymatic activity of the immobilized lipase was determined by following the ester cleavage of *p*-nitrophenol butyrate aqueous solution with UV spectroscopy. The enzymatic activity for *Candida rugosa* lipase immobilized on maghemite nanoparticles was lower than that of the free enzymes, but the loss in activity on nanoparticles was significantly lower than that reported for enzyme immobilized on micrometer-sized polymeric beads using physisorption. The most significant advantage of the nanoparticle-immobilized enzyme is its long-term stability. The hybrid enzyme–nanoparticle composites showed only a ~2% decrease in activity over 14 days due to desorption or denaturation. This long-term stability illustrates the advantages of attaching enzymes chemically to the nanoparticles.

A similar investigation was also reported recently using magnetic nanoparticles for immobilization of  $\beta$ -lactamase I (Fig. 3.7) [75]. Here, a layer of silica coating was placed on the surface of an iron oxide core. TEM images determined the average size inorganic core to be about 9.1 nm, with a silica shell of about 3.5 nm.  $\beta$ -Lactamase I was immobilized onto the surface through glutaraldehyde and C=N bonds. An assay evaluation, using a UV spectrometer, of active  $\beta$ -lactamase I on nanoparticle composites was carried out at room temperature using phenoxymethylpenicillin as the substrate in a buffer. The nanoparticle-immobilized enzyme showed an activity of about 53.76% of that of the free enzyme in solution. However, a kinetic study has shown that the  $K_M$  of the immobilized enzyme matches well that of the parent free enzyme. This suggests that nanoparticle-immobilized enzymes do not suffer from the mass-transfer problems frequently encountered with insoluble supports used for immobilizing enzymes.

**Fig. 3.7.** Immobilization of enzyme  $\beta$ -lactamase I to core/shell iron oxide/silica nanoparticles. (Adapted from Gao [75].)

Other than biocatalysts, metal catalysts, especially homogeneous metal catalysts, have also been immobilized onto the surfaces of core/shell magnetic nanoparticles. Due to their small sizes, the solubility of magnetic nanoparticles in organic media can be tuned by controlling the structure of organic and polymer coatings of nanoparticles. Such soluble supports could be magnetically concentrated and isolated from reaction media by applying an external magnetic field. Magnetic nanoparticles are an ideal soluble support, providing a unique solution to the problem of recycling homogeneous catalysts in pharmaceutical and chemical industries. The reader is referred to two recent papers in this emerging field [97, 98].

### 3.4

#### **Functionalization of Magnetic Nanoparticles for *In Vivo* Bio-imaging, Drug Targeting and Tumor Hyperthermia Treatments**

Magnetic nanoparticles have been explored extensively as contrast agents for *in vivo* magnetic resonance imaging (MRI), magnetic guides for drug targeting and mediators for magnetic hyperthermia treatments of a large variety of diseases. With proper coatings, superparamagnetic nanoparticles can interact with an external magnetic field and deliver radiotherapeutic and chemotherapeutic agents to a target area – minimizing the cytotoxicity of tumor therapeutic agents to healthy body compartments. This is important in the treatment and diagnosis of certain types of cancers due to, for example, their lack of specific tumor markers and the presence of the blood–brain barrier (BBB). A further medical use of magnetic nanoparticles is to utilize superparamagnetic nanoclusters as MRI contrast agents for cancer diagnosis and detection. A third major *in vivo* application of magnetic nanoparticles is magnetic hyperthermia therapy. Magnetic nanoparticles can be made to resonantly respond to a time-varying magnetic field, with advantageous results related to the transfer of energy from the exciting field to the nanoparticles. This is utilized to make magnetic nanoparticles heat up, which leads to their use as hyperthermia mediators, delivering toxic amounts of thermal energy to targeted tumor cells.

Typical magnetic nanoparticles used in *in vivo* studies consist of a magnetic core surrounded by a biocompatible polymeric coating. Iron oxide particles such as magnetite or its oxidized form maghemite are by far the most commonly employed for *in vivo* applications. Highly magnetic materials such as cobalt and nickel are toxic and susceptible to oxidation and hence are often overlooked for *in vivo* biomedical applications. Iron oxide nanoparticles are physiologically well tolerated. For example, dextran-magnetite has no measurable toxicity index LD<sub>50</sub> [99–101]. This is partially because the body is designed to process excess iron. In the human body iron is stored primarily in the core of the iron storage protein ferritin. Iron contained in endosomes and lysosomes is metabolized into elemental iron and oxygen by hydrolytic enzymes, where the iron joins normal body stores [101]. Iron homeostasis is well controlled by adsorption, excretion and storage. As a consequence, iron from iron nanoparticles in the body can be processed and iron oxide

can be tolerated by the body. However, notably, iron has a rather limited bioavailability, and in some situations it can also be toxic to cells [102].

*In vivo* applications require that these magnetic nanoparticles have a long-circulating time in the body in order to reach the target sites [43] before being eliminated from the blood circulation through clearance by the mononuclear phagocyte system (MPS) [103]. The MPS, also known as the reticuloendothelial system, is defined as the cell family consisting of bone marrow progenitors, blood monocytes and tissue macrophages such as Kupffer cells in the liver. These macrophages are widely distributed and strategically placed in many tissues of the body to recognize and clear senescent cells, invading microorganisms and particles [104]. The first step of the clearance mechanism is the opsonization process. Opsonins, circulating plasma proteins, adsorb themselves spontaneously onto the surface of an invading entity. Particles of different surface characteristics, size and morphology attract different arrays of opsonins, which can interact with the specialized plasma membrane receptors on monocytes and macrophages [105]. Then, endocytosis/phagocytosis of the particles by the circulating monocytes or the fixed macrophages leads to the elimination of particles from circulation.

Previous studies of liposomes and polymeric nanoparticle systems have shown that, among many surface factors, the size, surface charge density and hydrophilicity/hydrophobicity have a profound effect on opsonization [43]. Therefore, significant efforts have been directed at exploring various biocompatible coating materials to increase plasma half-life as long as possible in order to increase the probability of reaching the desired targets in the body [106]. Neutral and hydrophilic natural and synthetic polymers have become the materials of choice. For example, dextrans have been frequently used for coating iron oxide nanocrystals [43]. Other biological macromolecules such as heparin and polysaccharides that complement regular proteins have also been investigated [107, 108]. Among synthetic polymers, poloxamers, poloxamines and their block-copolymers increase their circulation time [109, 110], and can potentially be utilized for coating iron oxide nanoparticle cores for this purpose. An alternative approach is to covalently anchor PEG macromolecules onto the nanoparticle surfaces. PEG is an effective polymer for suppressing the protein adsorption-opsonization process [65]. Immobilization of PEG to drug carrier surface is well known in liposome drug delivery where PEG macromolecules are conjugated to the surfaces of liposomes to improve their circulation lifetime, bioavailability and decrease their immunogenicity [111]. Recent successes using this PEG strategy in a quantum dots biodistribution study [112] has offered the possibility of extending this method to other nanomaterials, including iron oxide nanoparticles.

#### 3.4.1

##### MR Imaging

Superparamagnetic nanoparticles represent a class of MRI contrast agents that are usually referred to as  $T_2$  (transversal relaxation time) or  $T_2^*$  contrast agents [113] as opposed to  $T_1$  (longitudinal relaxation time) agents such as paramagnetic gado-

linium chelates [114]. MRI is based on the NMR (nuclear magnetic resonance) signal of protons from water in tissues and organs through the combined effects of a strong static magnetic field ( $B_0$ ) and a transverse radiofrequency field (rf field) [115]. After rf excitation, hydrogen nuclei attempt to return to their ground states through two independent relaxation processes: (1) longitudinal relaxation, which is also called  $T_1$ -recovery or “spin–lattice” relaxation; hydrogen atoms release the previously absorbed energy to the surrounding tissue (lattice) in their attempt to re-align with  $B_0$ . (2) Transverse relaxation, also called  $T_2$  decay or “spin–spin” relaxation, which is due to the exchange of energy between spinning hydrogens in tissues. MR images of biological tissues are constructed from relaxation data collected by a computer applying a two-dimensional Fourier transformation to give the amplitudes of NMR signals [116–118]. While, in many clinical situations, the intrinsic differences in relaxivity ( $1/T$ ) between tissues are small, exogenous contrast agents can be utilized to improve greatly the diagnostic value of MRI for a better delineation of tissues [100]. Gadolinium complexes are the most commonly used  $T_1$  contrast agents while superparamagnetic iron oxide nanoparticles are FDA-approved  $T_2$  agents.

Depending on their size, colloidal iron oxide nanoparticles of magnetite ( $\text{Fe}_3\text{O}_4$ ) to maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ) are often called SPIO (superparamagnetic iron oxide) with a particle size typically larger than 50 nm, and USPIO (ultra-small superparamagnetic nanoparticles), with a dimension  $< 50$  nm [6, 119]. Hydrophilic polymers such as heparin [107], dextran [120], chitosan [121], starch [122], DNA [123], and cyclodextrin [124] have been employed for coating the iron oxide cores. These water-soluble macromolecules are employed to stabilize nanoclusters by preventing aggregation of their inorganic cores and reduce opsonization process. However, the structure of surface coating materials greatly influences the magnetic properties of magnetic nanoparticles [45–50]. Adoption of different polymers for coating iron oxide cores could significantly alter MR relaxation properties of the overall nanoparticle contrast agents [124].

Due to their size, SPIOs usually can be cleared out of the blood circulation and accumulated in MPS organs very quickly, especially in liver and spleen [113, 125]. For example, about 80% of the injected SPIO doses were found in liver and 5–10% in the spleen with a plasma half-life of less than 10 min [4]. As a consequence, SPIOs can decrease the liver and spleen signals within several minutes after i.v. administration, and this type of agent is usually used for liver and spleen imaging [126–129]. USPIOs, however, are smaller than SPIOs. They usually have longer plasma life, higher than 2 hours, and therefore remain in the blood long enough to act as blood-pool agents for MR angiography [113]. Also because of their small sizes, USPIOs can leak into the interstitium, where they can be accumulated in the lymph nodes and thereby used for imaging lymphatic systems [130–135].

Progress has been made on the functionalization of core/shell magnetic nanoparticles for tissue/organ-specific *in vivo* imaging. Antibodies such as human polyclonal IgG and L6 antibodies have been physically adsorbed or covalently attached to iron oxide nanoparticles [136–138]. Investigations in rodents revealed that

antibodies led to a high concentration of magnetic nanoparticles at specific sites. Recently, Moore has reported using a peptide [139] for the functionalization of iron oxide nanoparticles for tissue-specific *in vivo* imaging. The synthetic peptide EPPT1(YCAREPPTRTFAYWG) – a short fragment of the CDR3 V<sub>h</sub> region of a monoclonal antibody ASM2 – was covalently linked to the surface of aminated crosslinked superparamagnetic iron oxide nanocomplexes (CLIO-NH<sub>2</sub>). CLIO-NH<sub>2</sub> consists of a core of superparamagnetic iron oxide and a crosslinked coating of dextran with amino groups [140, 141]. EPPT1 peptide has significant affinity towards under-glycosylated mucin-1 antigen (uMUC-1), which is overexpressed on many cancer cell lines. A Cy5.5 dye was also immobilized onto the surface of CLIO-NH<sub>2</sub> as a near-infrared fluorescence optical probe. *In vivo* MRI and near-infrared-imaging experiments on tumor-bearing mice showed specific accumulation of the probe in uMUC-1-positive tumors and no signal in control tumors. The high specific concentration of magnetic nanoparticles at the target sites was due to the presence of EPPT1 peptide on the surface of dextran–iron oxide nanoparticles. Similar experiments using folate-labeled magnetic nanoparticles for *in vivo* imaging of tumors with overexpressed folate receptors have also been reported recently [142].

Cellular imaging has long attracted a great deal of research interest [143]. Studies using unfunctionalized iron oxide nanoparticles for labeling various types of cell lines such as leukocytes, lymphocytes and monocytes for MR imaging of cells have been reported [124, 144–146]. If a cell can be sufficiently loaded with magnetic materials, then MRI can be adopted for use in cell tracking with a resolution of 20–25  $\mu\text{m}$  or higher, approaching the size of single cells [6]. However, cellular uptake of dextran-coated iron oxide nanoparticles was low. Improvements are still needed to increase the cellular uptake of magnetic nanoparticles. Recently, progress has been made towards this goal for high-efficiency internal labeling of large numbers of cells. Iron oxide nanoparticles with a HIV-1 tat peptide fragment attached at the outer surface of their dextran coating (CLIO-NH<sub>2</sub>) increase the cellular uptake of nanoparticles over 100-fold into lymphocytes when compared to untagged particles [147, 148]. HIV-1 tat peptide carries a transmembrane and a nuclear localization signal within its sequence and is, therefore, capable of translocating exogenous nanoparticles into cells [149]. Folic acid has also been immobilized onto iron oxide nanoparticles for targeting the folate receptor-bearing cells [150, 151]. Folate-mediation internalized folate-labeled nanoparticles and increased the cellular uptake of iron oxide nanoparticles that were used as contrast agents for cellular imaging. Iron oxide nanoparticles functionalized with the C<sub>2</sub> domain of synaptotagmin I [152] and dendrimers [153] have also been synthesized and utilized for MRI studies of cells. A further goal in this area is to exploit the use of MRI techniques to image transgene expression. Research in this area has focused on depicting the activity of endocytotic receptors for cellular uptake of functionalized iron oxide nanoparticles [154, 155]. A growing number of cell biologists, molecular biologists and experts in MRI are working together to develop techniques for the *in situ* visualization of gene expression in living animals [143].

## 3.4.2

**Targeted Drug Delivery**

Magnetic drug targeting has attracted a great deal of attention. This approach is an alternative to antibody-directed drug targeting, offering additional advantages for the treatment and diagnosis of certain types of cancers due to, for example, their lack of specific tumor markers and presence of the BBB [156]. *In vivo* experiments of magnetic drug targeting have usually been performed in rodents [157], but investigations using swine [158] and rabbits [159] have also been reported. Generally, iron oxide cores are coated with silica, and polymers such as PVA and dextran. The first clinical trials in humans with a magnetic drug targeting were reported by Lübke et al. [160, 161]. They used a ferrofluid (size about 100 nm) coated with starch polymers and anionic phosphate groups for loading the drug epirubicin. The shell phosphate group forms strong anionic interactions with the positively charged amino sugars of epirubicin. During infusion and for 45 min afterwards, a magnetic field was applied about less than 0.5 cm from the tumor site. It took about only 30 min in half of the patients before the ferrofluids could be successfully directed to the tumors. Similar investigations using liposomes containing magnetic nanoparticles and drugs have also been reported [162]. Magnetic drug targeting has been employed to deliver cytotoxic drugs to brain tumors, which are difficult to treat due to the BBB. Pulfer and Gallo demonstrated that particles as large as 1–2  $\mu\text{m}$  could be concentrated at the site of intracerebral rat glioma-2 tumors [156].

Despite early success, magnetic drug targeting still needs to be improved to make it more effective. Limitations [161] include (1) difficulties in scaling up from small rodent models to humans or large animals due to the requirement of much stronger external magnetic fields; (2) the possibility of embolization of the blood vessels in the target region due to accumulation of the magnetic carriers; and (3) difficulties in controlling the release of drug molecules from carriers and the molecular uptake of these therapeutic agents by tumor cells.

Some of the aforementioned limitations can be overcome if magnetic nanoparticle carriers are utilized for delivering radiotherapeutic agents for tumor radiotherapy. In contrast to chemotherapeutic drugs, radioisotopes can be delivered close to the tumor sites and exert their cytotoxicity over a defined, radioisotope-dependent distance – the chelated metals do not need to be released from the carriers so that they can bind to or enter the cells to be cytotoxic. The effectiveness of this technique has been confirmed by several investigations using yttrium-90 [163] and rhenium-188 [164] in both animal and cell culture studies.

Arbab et al. have recently demonstrated the possibility of using iron oxide nanoparticles for delivering mesenchymal stem cells (MSCs) to a targeted area in an animal model by applying an external magnet [165]. MSCs were labeled with iron oxide nanoparticles and the resulting magnetic cell complexes were intravenously injected into two groups of rats with or without a magnet placed over the livers. Experiments showed that the external magnets influenced the movement of labeled MSCs as higher iron concentration and increased labeled cell numbers

were detected in rat livers with external magnets. These results demonstrated that cells could be retained in the region of interest inside the body using magnetic forces, and magnetic drug targeting can be utilized for *in vivo* delivery of stem cells or genetically altered cells to the target sites.

A further area of interest in the use of targeted magnetic nanoparticles is in the field of gene therapy. One of the impediments to successful gene therapy is the inefficient delivery of genes because of low transfection efficiencies. This can be addressed by using a viral vector carrying the therapeutic gene loaded on magnetic carrier surface. An external magnetic field was applied to allow the viral vector a longer period of time in contact with the tissues, thereby increasing the efficiency of gene transfection and expression [166–168]. Research in this area has recently attracted a great deal of interest – a review article is listed here [169] for interested readers.

### 3.4.3

#### **Magnetic Hyperthermia**

Magnetic hyperthermia is a promising form of cancer therapy aside from the well-known methods of surgery, chemotherapy and radiotherapy [170, 171]. Magnetic nanoparticles are used as mediators for magnetic hyperthermia. In broad terms, magnetic hyperthermia involves dispersing magnetic particles through the targeted tissue, and then applying an AC magnetic field of sufficient strength and frequency to cause the particle to heat. This heat conducts into the immediately surrounding diseased tissue. Hyperthermia treatment of cancers is based on observations that some cancer cells are more sensitive to temperatures in excess of 41 °C than their normal healthy counterparts. Two kinds of heat treatment are currently distinguished: mild hyperthermia is performed between 41 and 46 °C to stimulate the immune response for non-specific immunotherapy of cancers, and thermoablation between 46 and 56 °C for thermal destruction of tumors by direct cell necrosis, coagulation or carbonization [170, 171].

Generally, two types of magnetic nanoparticles have been used for magnetic hyperthermia, via two different mechanisms: (a) heating of ferromagnetic nanoparticles when exposed to a time varying magnetic field, which is essentially due to hysteresis losses and Brownian relaxation losses of the particles; and (b) Brown and Néel heating mechanisms that contribute to the heating of superparamagnetic nanoparticles. The heating power of the particles is quantified as the specific absorption rate (SAR) and describes the energy amount converted into heat per time and mass. Superparamagnetic nanoparticles usually give higher SAR than ferromagnetic nanoparticles because the hysteresis loop of ferromagnetic nanoparticles can rarely be fully used because of physiological and technical restrictions on the external field amplitude [4]. Consequently, dispersions of superparamagnetic nanoparticles appear to be the most promising since they are used as ferrofluids. This technique is termed magnetic fluid hyperthermia (MFH) [170]. However, ferromagnetic nanoparticles remain potentially useful due to their Curie tempera-

ture – providing one of the more powerful methods for controlling the maximal temperature *in vivo*.

Maghemite nanoparticles encapsulated in polymer matrix beads have been tested successfully for the treatment of macroscopic liver tumors [172, 173], which were introduced through the arterial embolization method, taking advantage of the fact that liver tumors take their blood supply from the hepatic arterial system. Such beads appear to be safe and well-tolerated as there was no significant hepatic clearance 28 days after injection [174]. Under inductive applicator conditions of 53 kHz and  $30 \text{ kA}^{-1}$ , an intratumoral temperature of  $48 \text{ }^\circ\text{C}$  was reached after 5 min. Smaller magnetic nanoparticles have also been investigated for magnetic hyperthermia. Magnetite nanoparticles from ferrofluids coated with dextran can be taken up by carcinoma cells. However, cellular uptake of these dextran-iron oxide nanoparticles was low. To solve this problem, magnetic nanoparticles were coated with aminosilane groups; *in vitro* cellular uptake of such nanoparticles in glioblastoma cells was found to be  $1000\times$  higher than for their dextran-magnetite counterparts [175]. To further improve mediator uptake by cancer cells for better intracellular hyperthermia treatment efficacy, monoclonal IgG antibody was immobilized onto the surface of PEG-coated magnetite nanoparticles [176]. These particles exhibited an improved *in vitro* specificity for cancer cells and, thus, higher cellular uptake by tumor cells than non-functionalized PEG-magnetite nanoparticles. Similar investigations using various antibodies and their fragments for labeling magnetoliposomes have also been tested for improving the cellular uptake of magnetic liposomes during hyperthermia experiments [177–179]. *In vivo* experiments were performed by injecting these magnetic liposomes into the tumor-harboring mice. Most of the mediators accumulated in the tumor tissue while the rest were distributed in liver and spleen. After these mice were exposed to an AC magnetic field, the temperature of the tumor tissue increased and the growth of tumor usually ceased over a period of time [177–179]. However, few studies have been reported on the administration of mediators through i.v. injections. Functionalization of magnetic nanoparticles for *in vivo* hyperthermia is still in its early stages. Collaboration between materials scientists and hyperthermia experts is needed to further develop this promising therapy.

### 3.5

#### Conclusions

This chapter has summarized recent advances in the synthesis of functional biomolecule–magnetic nanoparticle hybrid systems. The uses of such biofunctionalized nanoparticles for *in vitro* protein/cell isolation and immobilization of biocatalysts for drug synthesis as well as *in vivo* applications such as drug targeting, MR imaging and hyperthermia therapies have been discussed. Nanometer-sized magnetic particles have many advantages over their micrometer counterparts in biomedical applications due to the unique physical, chemical and physiological properties associated with their small dimensions. A combination of the unusual

properties of nanomaterials and biomaterials provides a unique opportunity for physicists, chemists, biologists, material scientists and experts from many other fields to mold this new area of nanobiotechnology. Based on recent advances in the field, exciting new science and novel systems can be anticipated from such an interdisciplinary effort.

## 4

# Biofunctionalization of Gold Nanoparticles

*Ming Zheng and Xueying Huang*

### 4.1

#### Introduction

Gold (Au) as a precious material was first extracted in the 5<sup>th</sup> millennium BC [1]. The “soluble” gold, which we now call colloid gold, was developed around the 5<sup>th</sup> or 4<sup>th</sup> century BC [1]. Even though several scientists studied the formation and synthesis of colloid Au, such as using phosphorous in CS<sub>2</sub> to reduce chloroaurate (AuCl<sub>4</sub><sup>-</sup>) [2], colloid Au did not gain wide attention or became a subject of broad interest in the scientific community until very recently, especially in the last decade. The interest in such tiny Au particles partially arises from the commercial and industrial needs for new, advanced materials. These particles are nanometer size materials with unique optic, electronic, and magnetic properties. Macromolecular biological molecules, also in the nanometer size range, possess functionalities that enable recognition and self-assembly. The integration of nanoparticles and biological molecules is very attractive and has gained tremendous attention from academics and industry, because such a combination could create new materials for electronics and optics, and lead to new applications in genomics, proteomics, and biomedical and bioanalytical areas [3–8]. To be integrated with biological molecules or be used in biological systems, Au nanoparticles (NPs) have to be soluble in aqueous solution. This chapter, therefore, is mainly focused on the synthesis of water-soluble Au NPs, their surface functionality and modification, and biological applications. Section 4.2 reviews two general synthetic routes for obtaining monolayer-protected Au nanoparticles. Examples of programmable assembly of these particles using biomolecules, i.e. DNA and proteins, are covered in Section 4.3. The problem of nonspecific binding between nanoparticles and biomolecules is discussed in Section 4.5. Finally, Section 4.6 reviews biological and biomedical applications of Au nanoparticles.

### 4.2

#### General Synthetic Routes

Generally, Au nanoparticles are synthesized by reduction of aurate salts, usually chloroaurate (AuCl<sub>4</sub><sup>-</sup>) with reducing agents, such as sodium borohydride (NaBH<sub>4</sub>),

thiocyanate, phosphorus, citrate, ascorbic acid, and even ethyl alcohol [9]. The synthesized Au NPs have particle sizes ranging from sub-nanometer, e.g. 0.8 to 80 nm with their color changing from yellow-orange to red-purple to blue-green. The size of Au NPs determines their unique optical and electronic properties. Au NPs synthesized by the reduction of aurate salts are composed of an internal core of pure Au that is surrounded by a surface layer of adsorbed  $\text{AuCl}_2^-$  ions [9]. These negatively charged surfaces prevent Au NPs aggregating. However, these Au NPs are very sensitive to their environmental factors such as pH, temperature, electrolytes, and solvent. For these Au NPs to be utilized, a key issue is their surface chemistry and functionalization that determine their stability, functionality and applications. To solve this issue, various ligand-protected Au NPs have been synthesized recently, mainly by direct synthesis and ligand exchange reaction.

#### 4.2.1

##### Direct Synthesis of Ligand-protected Au NPs

In the past three decades, two major classes of ligand-protected Au NPs have been developed. The first is phosphine-protected Au NPs, which were originally reported by McPartlin et al. in 1969 [10] and then modified by Cariati et al. in 1971 [11]. Synthesis was achieved through reduction by  $\text{NaBH}_4$  of either an aurate salt, such as  $\text{HAuCl}_4$  in the presence of triarylphosphine in a two-phase system of toluene and water, or  $\text{Au(L)X}$  (here L is triarylphosphine and X is an anion, such as  $\text{I}^-$ ,  $\text{SCN}^-$ , or  $\text{CN}^-$ ) in an organic solvent such as ethanol. As Au–P bonding is very weak the phosphine ligand could be easily replaced by other ligands. Apart from being used as the starting materials for other functionalized Au NPs, phosphine ligand-protected Au NPs have very limited use. The second class is thiol- or amine-ended ligand-protected Au NPs, first developed by Brust et al. in 1994 [12]. In their initial report, Brust et al. synthesized toluene-stable dodecanethiol-protected Au NP by using  $\text{NaBH}_4$  to reduce  $\text{HAuCl}_4$  in a two-phase system with tetraoctylammonium bromide as the phase-transfer, [Fig. 4.1(route a)]. Subsequently, they developed a one-phase synthesis by using methanol as the reaction solvent [13] [Fig. 4.1(route b)]. These Au NPs are mainly organic-soluble. Since

Fig. 4.1. Au NPs synthesized through a two-phase route (a) and a one-phase route (b).

Fig. 4.2. Schematic structures of tetra(ethylene glycol) and thioalkylated oligo(ethylene glycol) protected Au NPs.

1998, this synthetic strategy has been extended, initially by Schaaff et al. [14] and Murray et al. [15] and then by many other researchers, to the synthesis of various water-soluble Au NPs. Compared with phosphine ligand-protected Au NPs, thio-protected Au NPs have a much more stable Au-S bond, giving the nanoparticles higher stability and wider utility.

A few authors have proposed a mechanism for the formation of the thiol monolayer on protected Au NP [12, 16, 17]. As shown in Eqs. (1) and (2), the electron-rich thiol group (HS-) in R-SH reacts with AuCl<sub>4</sub><sup>-</sup> to form a polymer intermediate. The polymer is then reduced by BH<sub>4</sub><sup>-</sup> to form the nanoparticle.

Although the synthetic methods developed by Brust et al. and Murray et al. provide guidelines for preparing ligand-protected Au NPs, the details for NP formation, such as solvent selection, control of nucleation and aggregation, are still not well understood. There is still an element of art in the synthesis of a new ligand-protected Au NP. Among various reaction conditions to be optimized, solvent selection for the synthesis is especially important. This is demonstrated by the synthesis of tetra(ethylene glycol) protected Au NP (Au-EG<sub>4</sub>) (Fig. 4.2). Foos et al. first reported the synthesis of short ethylene oxide chain protected gold nanoparticles by ligand exchange reaction [18]. The procedure involved synthesis of hexanethiol (C6) protected gold nanoparticles followed by two steps of replacing C6 with ethylene glycol thiol molecules. Direct synthesis of ethylene glycol protected nanoparticle was, unsuccessfully, also attempted by Foos et al. using published methods. Bartz et al. synthesized Au-EG<sub>4</sub> NP directly in aqueous phase with a very low molar ratio of reducing agent (NaBH<sub>4</sub>) and tetrachloroauric acid, resulting in partial reduction [19]. With increasing amount of NaBH<sub>4</sub>, the reaction increased aggregation. The yield was very low. We also synthesized Au-EG<sub>n</sub> (n = 2-4) using methanol as the solvent. The reagents HAuCl<sub>4</sub> and EG<sub>n</sub>-SH, for example, were dissolved in a mixture of methanol and acetic acid; a freshly prepared NaBH<sub>4</sub> solution in methanol was then added with rapid stirring. Au-EG<sub>4</sub> nanoparticles formed as soon as the NaBH<sub>4</sub> methanol solution was added. After purifying and drying, the nanoparticle is readily redissolved in water to form a clear red/purple solution. However, the yield is very low (>10%). No precipitation was ob-

served in the reaction mixture, meaning that the reduction reaction of  $\text{HAuCl}_4$  was not complete. The mechanism of partial reduction in methanol was not investigated. After many trials, we established a direct synthesis of ethylene glycol  $[\text{HS}-(\text{CH}_2\text{CH}_2\text{O})_n-\text{CH}_3, n = 2-4]$  protected gold nanoparticles in a mixed solvent of methanol and water by utilizing the  $\text{NaBH}_4$  reduction method, with much improved yield [20, 21]. The key for this synthesis is the control of water content in the reaction mixture. A water content of 9–18% (v/v) is the optimum for the formation of stable, water-soluble nanoparticles. Instead of  $\text{Au-EG}_4$ , Brust et al. successfully synthesized a thioalkylated oligo(ethylene glycol) ligand-protected Au NP by using a mixed solvent of 2-propanol and methanol (Fig. 4.2) [22].

Even though the solvent effect on the synthesis of water-soluble nanoparticles was not systematically investigated in our original work, the polarity and solubility of the ligand are relevant to solvent selection for the synthesis. The solubility of Au NPs is determined by the capping ligand. Capping ligands for preparing water-soluble Au NPs can be classified into three categories: cationic, anionic, and neutral based on the charge on the molecules. In view of synthetic conditions for preparing Au NPs, we divide the capping ligands into different categories: strongly ionic, weakly ionic, and neutral. Here we briefly review solvent selection in each category of Au NP synthesis. Such a review should be beneficial as a reference for synthesizing new ligand-protected Au NPs.

#### 4.2.1.1 Strongly Ionic Ligand-protected Au NPs

For strongly ionic ligands, including strong cationic and strong anionic, water as the single solvent is sufficient for synthesizing water-soluble nanoparticles. Examples include the synthesis of gold nanoparticles capped with coenzyme A [23], *N,N*-trimethyl(undecylmercapto)ammonium [24], 5-mercapto-2-benzimidazole sulfonic acid sodium salt [25], and the zwitterionic ligand cysteine [26].

#### 4.2.1.2 Weakly Ionic Ligand-protected Au NPs

For weakly ionic ligands, a mixture of water and a water-miscible organic solvent, such as methanol, is usually used for the synthesis. Examples include the synthesis of gold nanoparticles protected with tiopronin [14], glutathione (GSH) [15], and mercaptosuccinic acid [27, 28]. In the synthesis of tiopronin-protected gold nanoparticles, using water as the only solvent leads to a water-insoluble product [14]. For the synthesis of GSH protected gold nanoparticle, a 2:3 water-methanol medium is used to prevent uncontrolled reduction reaction [15]. Presumably, the ratio of water to organic solvent in the mixed solvent system is related to the structure and polarity of the ligand. When a weak anionic ligand is highly polar and water soluble, water as the sole solvent could be sufficient for the synthesis of NPs. Examples include synthesis of Au NPs protected with meso-2,3-dimercaptosuccinic acid [29], and L-cysteine [30].

#### 4.2.1.3 Au NPs Protected with Neutral Ligands

A mixed solvent of water and a water-miscible organic, such as methanol or ethanol, is usually a good start to synthesize neutral ligand protected Au NPs. Neutral

ligands for coating nanoparticles include ethylene glycol small molecules, as described above, and poly(ethylene glycol) (PEG) molecules. With increasing units of ethylene glycol from 2 to 4 to 70 [31], or aldehyde derivatized PEG ( $M_n = 3090$ ) [32], the solvent used in the synthesis of nanoparticles changes from a mixture of water and methanol to simply water. Sugar molecules and oligosaccharides are another important type of water-soluble ligand. Glyco-Au NPs have been synthesized in a mixed solvent of water and methanol [33–37]. Apparently, the solubility of the ligand molecules plays a major role in choosing the right solvent for the synthesis. Although the mechanistic reasons for this correlation are not clear, this summary should nevertheless provide a useful guidance for the synthesis of new types of water-soluble Au NPs.

#### 4.2.2

#### Ligand Exchange Reaction

Au-X ( $X = P, S, \text{ or } N$ ) is quite labile. This unique character can be utilized to synthesize versatile surface functionality. One of the earliest examples, demonstrated by Schmid et al., replaced the triarylphosphine ligand on Au NP with a sulfonated triarylphosphine ligand [38]. Murray et al. pioneered the thiol ligand exchange reaction [39], a general route for the preparation of ligand-protected Au NPs. Since then, ligand exchange or  $S_N2$  reactions have been widely used for preparing nanoparticles protected with either a homogeneous monolayer or a heterogeneous monolayer (also called mixed monolayer). Mixed monolayer protected Au NPs are especially important because they are used most in applications in electrochemistry [40, 41], conductivity [42, 43], fluorescence [44, 45], biological bindings [46, 47], and coatings [48]. Synthetically, the ligand replacement reaction has both advantages and disadvantages compared with direct synthesis. Versatility is its biggest advantage. By using ligand replacement reaction, various different mixed monolayer protected Au NPs can be synthesized that do not heavily depend on the nature of the ligands and the reaction conditions. However, the ligand replacement reaction certainly has several disadvantages. First, unlike direct synthesis, it is a multi-step process. Secondly, for the preparation of mixed monolayer protected Au NPs, it is difficult to control the number of ligands on a nanoparticle. The composition of the mixed monolayer is essential and directly responsible for the surface properties and interactions with the target molecules.

#### 4.3

#### Preparative-scale Synthesis and Solution-phase Characterization of DNA-directed Nanoparticle Assemblies

In the previous section, we reviewed synthetic strategies for preparing ligand-protected Au NPs. These materials serve as building blocks for the assembly of higher order nanoparticle structures that could be used for applications as well as for fundamental studies. One assembly strategy involves using DNA molecules.

DNA has the unique self-assembly capability, i.e. hybridization. In addition, DNA is very hydrophilic and negatively charged. Unless the nanoparticles are positively charged, there is not much nonspecific binding between DNA and nanoparticles. Those two unique features have allowed many successful routes for the controlled assembly of nanoparticles using DNA functionalized Au NPs. These include nanoparticle assemblies through either specific hybridization of a single strand DNA attached on the nanoparticle [49, 50] or by electrostatic interaction of positively charged nanoparticles with DNA molecules [51, 52]. In addition, Niemeyer et al. have prepared nanoscale networks and aggregates using biotinylated DNA and streptavidin [53, 54]. DNA functionalized nanoparticles have been used successfully for DNA detection and as biosensors [55, 56].

Bio-based assembly of nano-scale materials into higher order structures is an active area of research. Previous studies by Alivisatos et al. [50, 57] and Mirkin et al. [49, 58] have demonstrated the power of using DNA hybridization to assemble nanoparticles into higher order structures. Work from Alivisatos et al. in particular has demonstrated the possibility of using DNA-directed assembly to make small-scale finite nanoparticle complexes that resemble artificial molecules. These structures may serve as model systems for studying nano-scale phenomena, and have potential applications in nanoelectronic circuits, optoelectronics and biosensors. One critical issue that needs to be addressed is the scale of the synthesis of these nanoparticle-based artificial molecules. Also lacking is the direct solution characterization of such assemblies, so that structure–function relationships can be established for these artificial molecules. We describe here our methods for solving the scaling-up problem, and the solution characterization of some simple nanoparticle assemblies we have made.

For this study, we first developed ligand-protected Au NPs with high stability and relatively uniform-size distributions. Following known synthetic routes, we have made glutathione and tiopronin [*N*-(2-mercaptopropionyl)glycine] monolayer-protected Au NPs [14, 59]. However, these particles, as synthesized, still have a size distribution that is too broad for our subsequent assembly studies. We have, thus, developed a non-solvent precipitation method as a very efficient way to fractionate particles of different sizes to obtain highly monodispersed nanoparticles [60]. By adding increasing amounts of either methanol or ethanol, particles of larger to smaller sizes are precipitated out of solution. After centrifugation, particles of a particular size can be selected for further assembly. A typical example for fractionation of Au-Tp NPs is given here. Au-Tp NPs (0.3 g) were dissolved in 50 mL of a 100 mM sodium chloride solution. The first fraction of the nanoparticles was precipitated out by adding methanol to the nanoparticle solution to a final content of 10% by volume. Nanoparticles were collected by centrifugation at 4000 rpm for 1 min in a Sorvall® RT7 PLUS centrifuge (Kendro Laboratory Products, Newtown, CT). More methanol was then added to the supernatant to a final content of 20% by volume and the precipitated nanoparticles were collected as described above, as the second fraction, which was used for the following experiments.

To label nanoparticles with single-stranded DNA (ssDNA), we chose the ligand

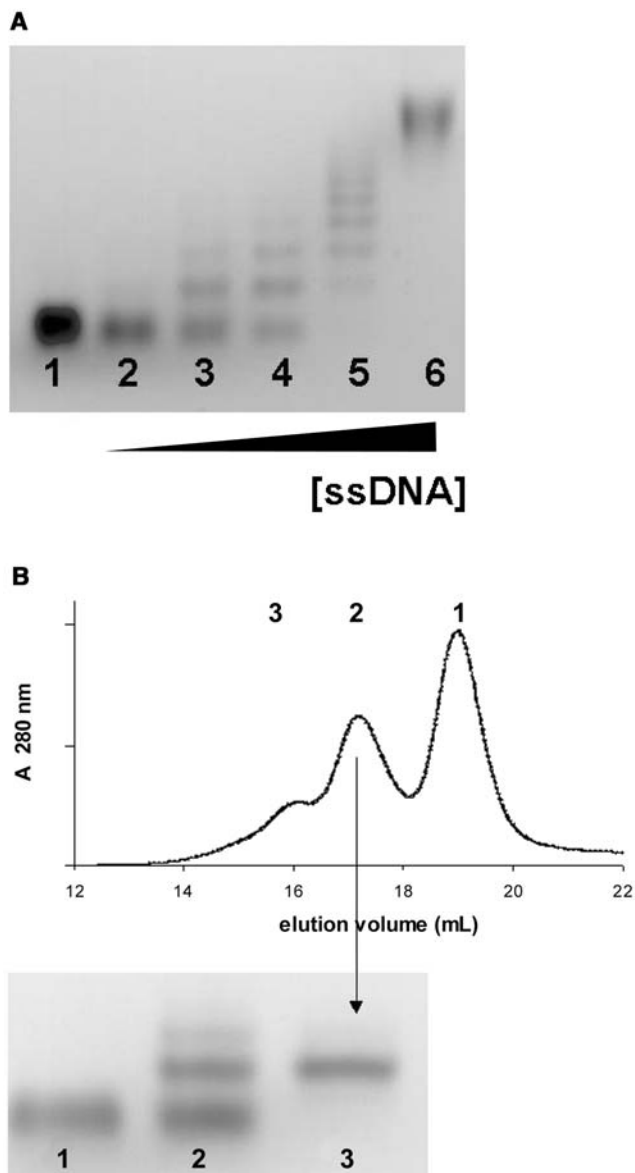

**Tab. 4.1.** Stoichiometry for attaching ssDNA to Au NPs by using ligand replacement reaction (volume unit =  $\mu\text{L}$ ).

	<i>Rxn 1</i>	<i>Rxn 2</i>	<i>Rxn 3</i>	<i>Rxn 4</i>	<i>Rxn 5</i>	<i>Rxn 6</i>
Au-Tp (60 $\mu\text{M}$ )	3	3	3	3	3	3
SsDNA (40 $\mu\text{M}$ )	0	1	2	4	8	1.6 (400 $\mu\text{M}$ )
NaCl (1 M)	1.5	1.5	1.5	1.5	1.5	1.5
H <sub>2</sub> O	10.5	9.5	8.5	6.5	2.5	8.9
Total ( $\mu\text{L}$ )	15	15	15	15	15	15

replacement reaction described in Section 4.2. A typical example is as follows. Single-stranded DNA (ssDNA) oligo nucleotides were purchased from Integrated DNA Technologies, Inc. (Coralville, IA), with 5' C6 SH modification. Materials were used as-received without further treatment. For this example, a ssDNA with sequence AAA AAA GCG TGG GCG TGG GCG TGG GCG TGG GCG was used. The gold particles had a concentration of 60  $\mu\text{M}$  in H<sub>2</sub>O. To determine the optimal ratio of Au-Tp vs. ssDNA for labeling reaction, a titration experiment was set up by mixing appropriate amounts of Au-Tp, ssDNA, NaCl, and H<sub>2</sub>O (Table 4.1). Each reaction was carried out in a 1.5 mL volume test tube. The reaction mixture was incubated at 60 °C for 15 min and allowed to slowly cool to room temperature over 30 min. Products were analyzed by gel electrophoresis using a 4% agarose/Tris-Borate-EDTA (TBE) gel (BioWhittaker, Rockland, ME). The gel was immersed in 1X TBE running buffer (89 mM Tris, 89 mM boric acid, 2 mM EDTA, pH 8.3), and electrophoresis was carried out at a constant voltage of 90 V for 80 min in an Horizon 58 gel box (Life Technologies, Rockville, MD). The gel image (Fig. 4.3A) was recorded using a HP ScanJet 6300C scanner (Agilent Technologies, Wilmington, DE). Lanes 1–6 correspond to reactions 1–6, respectively, in Table 4.1.

This experiment showed that Au particles with different numbers of ssDNAs labels can be clearly resolved by a 4% agarose gel (Fig. 4.3A). As the ratio of ssDNA vs. Au-Tp increases, more ssDNAs can be found on a particle. Thus, the stoichiometry of ssDNA and Au-Tp can be used to control the average number of ssDNAs on the surface of Au particles.

Due to the narrow size distribution of our nanoparticles, we were able to use liquid chromatography to obtain Au particles with an exact number of ssDNAs attached. After the labeling reaction, we separated reaction mixture with a size exclusion gel filtration column. A typical example of the separation of Au NPs with different numbers of single-stranded DNAs is given here. Here, the labeling reaction was performed as follows: 400  $\mu\text{M}$  ssDNA (986-ZF) (8  $\mu\text{L}$ ) and 1 M NaCl (12  $\mu\text{L}$ ) were added to 100  $\mu\text{L}$  of Au-Tp (60  $\mu\text{M}$ ). The reaction mixture was incubated at 60 °C for 15 min and allowed to slowly cool to room temperature over 30 min. This mixture was then injected into a Superdex 200 gel filtration column (Amersham Biosciences, Piscataway, NJ) mounted on a BioCAD/SPRINT HPLC system (PerSeptive Biosystems, Framingham, MA), and eluted with 0.05 NaCl/0.15 M NaHPO<sub>4</sub> buffer (pH 7) at 0.5 mL min<sup>-1</sup>. The elution profile is shown in

**Fig. 4.3.** (A) Gel electrophoresis (4% agarose gel) of gold nanoparticles reacted with increasing amounts of ssDNA molecules (Table 4.1). (B) Gel filtration separation and subsequent gel electrophoresis of gold nanoparticles labeled with different numbers of ssDNA molecules. A Superdex 200 gel filtration column (Amersham Biosciences, Piscataway, NJ) mounted on a BioCAD/SPRINT HPLC

system (PerSeptive Biosystems, Framingham, MA) was used. Elution was performed with 0.05 M NaCl/0.15 M NaHPO<sub>4</sub> buffer (pH 7) at 0.5 mL min<sup>-1</sup>. Peaks 1–3 correspond to nanoparticles labeled with 0, 1 and 2 ssDNA, respectively. The gel image compares Au-Tp (lane 1), Au-Tp/ssDNA reaction mix (lane 2), and the column fraction corresponding to peak 2 (lane 3).

**Fig. 4.4.** (A) Gel filtration separation of a hybridization reaction of ssDNA-labeled gold particles, with conditions similar to those described in Fig. 4.3. (B) Gel electrophoresis of the separated fractions from (A).

Fig. 4.3(B). Peaks 1–3 correspond to nanoparticles labeled with 0–2 ssDNA, respectively. The gel image at the bottom of Fig. 4.3(B) compares Au-Tp (lane 1), Au-Tp/ssDNA reaction mix (lane 2), and the column fraction corresponding to peak 2 (lane 3). The gel mobility of the peak 2 fraction is consistent with the material being a one-particle/one-ssDNA species. By following the above procedure, we have labeled Au particles with two different ssDNA sequences that are complementary. The hybridization reaction was then carried out by mixing these two types of particles. The hybridization mixture was separated again by size exclusion gel filtration. A typical elution profile is shown in Fig. 4.4(A). In addition to the major product eluted in peak 2, side-products represented by peaks 1 and 3 are noticeable. These arise from impurities in the starting materials, which contain a small fraction of particles with 0, 2 and more ssDNA attached. Figure 4.4(B) shows a gel image, comparing the Au-Tp/ssDNA reaction mix (lane 1), the hybridization reaction mix (lane 2), and the column fraction corresponding to peak 2 in Fig. 4.4(A) (lane 3). The gel mobility of the peak 2 fraction is consistent with it being a dimer species. This material was analyzed by transmission electron microscopy (TEM) [Fig. 4.5(A)]. Quantitatively, over 90% of the purified species is dimeric Au NPs. Figure 4.5(B) provides an enlarged view of some dimer structures.

The synthetic procedure we have developed could be used to construct more complex structures. As a demonstration, we have synthesized a triatomic structure

Fig. 4.5. TEM images of gold nanoparticle dimer structures prepared according to Fig. 4.4.

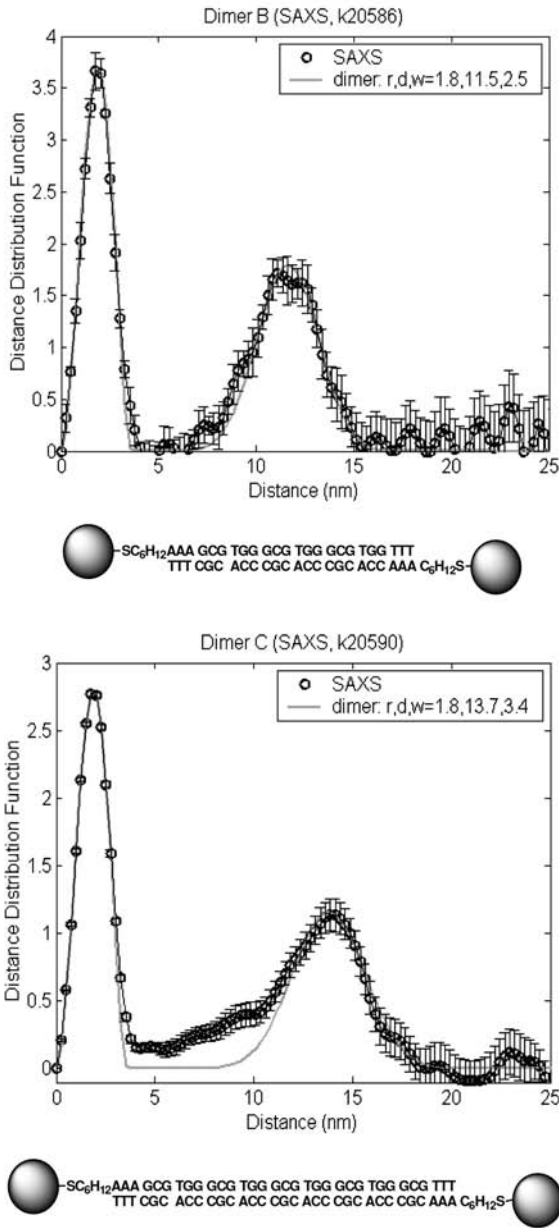

involving hybridization of three ssDNAs, each of which contain two segments that are complementary to part of the other two sequences (Fig. 4.6). Using the ligand exchange reaction and size exclusion separation techniques described above, we first obtained Au particles labeled with each of the three ssDNAs (lane 2 in Fig. 4.6). Hybridization between two types of Au particles labeled with two different ssDNA yielded a two-particle assembly (lane 3 of Fig. 4.6). The complete trimer structure (lane 4) was obtained by mixing the purified two-particle assembly with third-type ssDNA labeled Au particles. TEM images of the purified final hybridization mixture confirmed formation of the designed product.

Large-scale preparation has allowed us to measure directly solution structures of nanoparticle assemblies by small angle X-ray scattering (SAXS). Previous studies of nanoparticle assemblies have relied on TEM, which has the advantage of requiring small samples. However, TEM is performed under vacuum conditions and the projection nature of the TEM image prevents a direct measure of the geometric parameters of particle assemblies. Large-scale synthesis allows us for the first time to use solution methods to measure directly the geometry of nanoparticle assemblies we have made. SAXS spectroscopy proved to be ideal for our Au nanoparticle complexes, because of the large electron density on Au particles. We have measured two dimer structures of different bond lengths (Fig. 4.7). Dimer A was constructed with a 24 base pair long dsDNA with a C6 spacer on each side. Dimer B was similarly constructed with a 33 base pair long DNA. The measured Au–Au separation is 11.5 and 13.7 nm for dimers A and B, respectively. In both cases, the monomer diameter, as measured by the position of the first peak, is 3.6 nm. Assuming

**Fig. 4.6.** Gel electrophoresis and TEM image of gold particle trimer structures prepared by the DNA hybridization process. Lane 1 is from a DNA labeling reaction mixture. Lanes 2-4 are monomeric, dimeric and trimeric Au particle complexes, respectively.

the C6 spacer is 1 nm long and the diameter of Au particles is 3.6 nm, then from the measured length of either dimer one obtains  $0.246 \text{ nm bp}^{-1}$  (dimer A) or  $0.245 \text{ nm bp}^{-1}$  (dimer B). However, C6 might be flexible, and the estimated 1 nm might be a source of error. Thus, the base-separation parameter was also calculated by the length difference between the two dimers: the length difference of 2.2 nm between two dimers can be attributed to the 9 base pair difference. This gives  $0.244 \text{ nm bp}^{-1}$ , which is consistent with the previous estimation. Table 4.2 lists the derived structure parameters. To our surprise, the particle-particle separations in these dimer structures are consistent with the A- instead of the B-form DNA structure (the latter is expected under normal physiological conditions).

**Fig. 4.7.** SAXS measurements of two gold particle dimer structures linked with different lengths of DNA. In the two data plots, open circles are the experimental data, and the solid lines are simulations using the parameters shown.

Tab. 4.2. Geometrical parameters of two Au particle dimers obtained by SAXS measurement.

In summary, we have established a simple yet effective way to make large quantities of nanoparticle-based diatomic and triatomic artificial molecules. Monodispersed Au-Tp NPs are obtained through direct synthesis, followed by fractionation using an alcohol precipitation procedure. Au-Tp particles with one DNA oligonucleotide molecule per particle are obtained in large quantity by size exclusion chromatography. From these particles, simple diatomic and triatomic artificial molecules are self-assembled through DNA hybridization reactions. Relatively large quantities of pure diatomic and triatomic structure are obtained after fractionation and purification by size exclusion chromatography, allowing for the first time characterization of these structures in solution. SAXS data revealed that double-stranded DNA bridging two gold nanoparticles adopts, unexpectedly, the A-type conformation, illustrating the dramatic effect of environmental conditions on DNA structures.

#### 4.4

#### Bifunctional Proteins for Programmable Assembly of Nanoparticles

DNA hybridization is only one of many possible ways to assemble nanoparticles. We have explored the possibility of using DNA as a template to define spatial locations for the assembly of nanoparticles. As one such way of using DNA, we sought to create a protein that has bifunctionality: it would bind with high affinity and specificity to DNA as well as nanoparticles. Our approach is to create a fusion protein composed of a DNA binding domain and a nanoparticle binding domain (Fig. 4.8).

There are many proteins that recognize a specific sequence of DNA. Transcription factors involved in gene regulation possess such a property. We decided to use the class of DNA binding proteins called Zn fingers, owing to their high binding affinity and specificity, and because many such proteins are available. Comparison of the human genome sequence with a few other sequenced mammalian species showed that the Zn finger domain is the most frequently observed protein domain in mammalian cells [61, 62]. One can even evolve Zn finger proteins to bind DNA sequences of one's choice. A well-characterized Zn-finger protein Zif268 [63, 64] was chosen here for demonstration. For the nanoparticle binding domain, we chose well-characterized ligand binding protein domains to bind to

Fig. 4.8. Design of bifunctional proteins to assemble nanoparticles onto DNA.

nanoparticles that are surface coated with the cognate ligands. The GST (glutathione S-transferase)-GSH (glutathione) pair was chosen for demonstration (Fig. 4.8). We constructed the bifunctional protein following conventional molecular biology protocol, overexpressed it in *E. coli* cells, and purified the protein using GST affinity purification.

We performed a set of protein functional assays to demonstrate that, indeed, the designed protein has bifunctional binding capabilities. The Zif268 DNA binding site was defined by sequence 5'-GCGTGGGCG-3'. When the purified protein was incubated with a DNA construct that contains multiple Zif268 binding sites, we observed a clear band shift in a gel electrophoresis assay, indicating that the purified GST-Zif268 fusion protein binds to the target DNA sequence. Similarly, we showed that the protein binds to GSH-modified Au NPs (Fig. 4.9).

Fig. 4.9. Gel electrophoresis analysis of protein binding to Au-GSH particles.

**Fig. 4.10.** Gel electrophoresis analysis of GST-Zif268 and DNA binding to Au-GSH particles. (A) Is a direct gel image, whereas (B) is the gel image under UV illumination.

Evidence for the bifunctional binding activity was provided by an experiment shown in Fig. 4.10(A) and 10(B). This is a gel shift assay on the purified GST-Zif268 protein binding to both Au-GSH nanoparticles and DNA. Figure 4.10(A) is a direct gel image, whereas Fig. 4.10(B) is the gel image under UV illumination, indicating where the DNA band is located. As can be seen in Fig. 4.10, addition of a piece of DNA that contains protein recognition sequence caused the protein-particle complex to migrate at a different speed, and DNA co-migrated with Au particles. These results indicate that the bifunctional protein can indeed direct particles onto DNA. However, we also noticed a problem in this system that limits the efficiency of assembly by the bifunctional protein: the positively charged Zif268 has a tendency to nonspecifically bind to the negatively charged Au-GSH nanoparticles. Effectively, the Au-GSH particles compete with the DNA for the Zif268 binding site, and reduce the efficiency of the intended assembly. Such a problem triggered us to look into the general issue of nonspecific binding, which will be discussed in detail in the next section.

#### 4.5

#### Strategies for Eliminating Nonspecific Interactions and Enabling Specific Binding with Biomolecules

It is very attractive to integrate nanoparticles with biological molecules such as DNA, and proteins to create new materials for potential new applications in

electronics, optics, genomics, proteomics, and biomedical and bioanalytical areas. However, for proteins, nonspecific binding could be a serious issue. Proteins are much more complicated than DNA. They can be either hydrophobic or hydrophilic, with either positive or negative charge, making it extremely challenging to avoid nonspecific binding with nanoparticles. To fully utilize the potential of protein–nanoparticle hybrids, we synthesized ethylene glycol monolayer protected gold nanoparticles that are very stable in aqueous media and have complete resistance to nonspecific bindings with proteins, DNA and RNA [20]. However, these biologically inert nanoparticles do not provide functionality. To allow specific interactions or bindings with biological entities, a specific binding functionality has to be introduced onto the nanoparticles. For this purpose, we designed nanoparticles protected with a mixed monolayer of an ethylene glycol molecule and a ligand. The ethylene glycol short chains with well-defined lengths function as a shielding component to minimize nonspecific interaction between nanoparticles and biological molecules, whereas the ligand acts as a capture agent to engage biological molecules specifically. To demonstrate this method, we prepared a Au NP protected with a mixed monolayer of tri(ethylene glycol) and glutathione [ $\text{Au}-(\text{S}-\text{EG}_3)_n\text{GSH}$ ] by adding a reducing agent ( $\text{NaBH}_4$ ) to a mixture of  $\text{HAuCl}_4$ ,  $\text{EG}_3-\text{SH}$ ,  $\text{GSH}$ , methanol and acetic acid in a one-step direct synthesis (Fig. 4.11). We discovered

**Fig. 4.11.** Reaction scheme for making  $(\text{EG}_3-\text{S}-)/\text{GSH}$  mixed monolayer protected nanoparticles.

that in a one-step direct synthesis the water content in the reaction mixture was critical for synthesizing Au NPs in high yield. The optimum water concentration is 9–18%. This method also applies to the synthesis of other Au NPs protected with a mixed monolayer in which ethylene glycol is the major component. The synthesis utilized the optimum condition such that water for dissolving  $\text{NaBH}_4$  was added into the mixture of reagents to a final concentration of 12.5% (v/v). Under this condition, the reaction went well and no precipitation was seen. The yield was about 40%. The purified nanoparticles were very stable in pure water as well as concentrated electrolyte solutions, such as 1.0 M aqueous NaCl. These nanoparticles did not degrade after one-year storage in water.

In such a mixed monolayer protected Au NP system, GSH as a ligand molecule enables specific binding to a target. However, GSH might also contribute to the nonspecific binding. Thus, quantitative control of the ligand number or percentage is crucial to achieve specific interaction. The feeding ratio of  $\text{EG}_3\text{-SH}$  and GSH is easily controlled in the direct synthesis approach, but the essential information is the relative amount of  $\text{EG}_3\text{-S-}$  and GSH on the nanoparticle surface, which is directly responsible for the surface properties and interactions with the target molecules. To control the relative amount of the shielding component ( $\text{EG}_3\text{-S-}$ ) and the capture component (SGH), we envisage two approaches. The first is to study the relative reactivities of  $\text{EG}_3\text{-SH}$  and GSH by synthesizing a series of Au NPs with controlled feeding molar ratios of the shielding and capture components, followed analysis of the surface composition. The measured surface composition can be plotted against the feeding ratio to determine the relative reactivity of the shielding and capture components, which could be used to control the surface composition. For example, we have used  $^1\text{H}$  NMR spectroscopy as an analytical tool for measuring the surface composition of  $\text{EG}_3\text{-S-}$ /tiopronin on Au NPs and determined that the  $\text{EG}_3\text{-SH}$  is three times more reactive than tiopronin [59]. However, in many cases of mixed monolayer protected Au NPs, it is not easy to determine an accurate surface composition. In addition, NMR analysis is very tedious and needs sophisticated equipment.

For most applications, accurate understanding of the surface composition might not be necessary. The correlation of the feeding ratio of  $\text{EG}_3\text{-SH}$  and the ligand with the nanoparticle binding performance should be sufficient information to design the synthesis of nanoparticle with only specific interactions. Based on this consideration, we developed the second approach by using gel electrophoresis analysis to identify a critical feeding ratio for the nanoparticle to avoid nonspecific interactions and in the meantime to provide maximum binding to a specific target. We used  $\text{Au}(-\text{S}-\text{EG}_3)_n\text{GSH}$  as an example. With a constant ratio of  $\text{HAuCl}_4$  and capping agents ( $\text{EG}_3\text{-SH}$  and GSH) at 2.0, a series of nanoparticles were synthesized with the feeding ratio of  $[\text{EG}_3\text{-SH}]/[\text{GSH}]$  at 1, 4, 14, and 19, respectively.  $\text{Au}(-\text{S}-\text{EG}_3)_{4\text{fr}}\text{GSH}$  represents the nanoparticle synthesized when the feeding ratio of  $[\text{EG}_3\text{-SH}]/[\text{GSH}] = 4$ . The charge density of  $\text{Au}(-\text{S}-\text{EG}_3)_{n\text{fr}}\text{GSH}$  nanoparticles representing the surface density of GSH was characterized qualitatively with their migration speed in the gel electrophoresis [Fig. 4.12(a)]. Lane 1 is  $\text{Au}(-\text{S}-\text{EG}_3)_{1\text{fr}}\text{GSH}$  nanoparticles with an  $\text{EG}_3\text{-SH}/\text{GSH}$  feeding ratio of 1:1.

**Fig. 4.12.** (a) Gel electrophoresis image illustrating the migration of  $(EG_3-S-)/GSH$  mixed monolayer protected nanoparticles as a function of feeding ratio of  $[EG_3-S-]/[GSH]$ . A 4% agarose gel was used and run at 90 V for 40 min. Lanes 1–4 are  $Au(-S-EG_3)_{nfr}GSH$  with  $n = 1, 4, 14,$  and  $19,$  respectively. Lane 5 is the pure  $Au-S-EG_3$  nanoparticle. In all cases,  $10 \mu L$  of Au particles at concentration of  $50 \mu M$  were loaded onto the gel. (b) Gel electrophoresis image of the nanoparticles from Fig. 4.12(a) bonded with lysozyme. A 1% agarose gel was used and run at 90 V for 20

min. Lanes 1, 3 and 5 are  $Au(-S-EG_3)_{nfr}GSH$  with  $n = 1, 4,$  and  $14,$  respectively. Lanes 2, 4, and 6 are the mixture of lysozyme and  $Au(-S-EG_3)_{nfr}GSH$  with  $n = 1, 4,$  and  $14,$  respectively. Protein binding reactions were carried out by mixing  $7 \mu L$  of  $50 \mu M$  Au nanoparticles with  $7 \mu L$  of  $1 mg mL^{-1}$  lysozyme solution for 10 min incubation time at room temperature. (Reprinted with the permission from Ref. [59], M. Zheng, X. Huang, *J. Am. Chem. Soc.* **2004**, 126, 12047–12054. © 2004 American Chemical Society.)

Lanes 2–5 are the same amount of  $Au(-S-EG_3)_{nfr}GSH$  nanoparticles with  $n = 4, 14, 19,$  and pure  $Au-S-EG_3,$  respectively. The migration speed of  $Au(-S-EG_3)_{nfr}GSH$  nanoparticles decreased with decreasing percentage of GSH on the nanoparticle surface. In the mixed monolayer of  $(EG_3-S-)/GSH$  protected gold nanoparticles, the major contribution for nonspecific binding is from the electrostatic interaction introduced by GSH molecules. Therefore, a positively charged protein lysozyme is a very good indicator for testing the nonspecific binding. Binding results for  $Au(-S-EG_3)_nGSH$  nanoparticles are shown in Fig. 4.12(b). Lanes 1, 3, and 5 are  $Au(-S-EG_3)_{nfr}GSH$  nanoparticles with  $n = 1, 4,$  and  $14,$  respectively. Lanes 2, 4, and 6 are the same amount of  $Au(-S-EG_3)_{nfr}GSH$  nanoparticles with  $n = 1, 4,$  and  $14,$  respectively, mixed with lysozyme. When the molar feeding percentage of GSH is less than 20%,  $(EG_3-S-)/GSH$  mixed monolayer protected nanoparticles have negligible binding with lysozyme. In this example, the ratio of  $(EG_3-S-)/GSH$  on the nanoparticle surface was not measured and is unknown.

The GSH molecule on the  $Au(-S-EG_3)_nGSH$  particle is a natural substrate for the enzyme glutathione-S-transferase (GST). The GST–GSH binding pair thus provides an opportunity to demonstrate the specific binding between nanoparticles

**Fig. 4.13.** Schematic of specific binding of GST protein to  $\text{Au}(-\text{S}-\text{EG}_3)_n\text{GSH}$  particles.

and proteins under more common biological conditions (Fig. 4.13). From the nonspecific binding tests for  $\text{Au}(-\text{S}-\text{EG}_3)_{n\text{fr}}\text{GSH}$  (Fig. 4.12) we saw negligible binding with lysozyme when the nanoparticle  $[\text{EG}_3-\text{SH}]/[\text{GSH}]$  feeding ratio is at 4. Nanoparticles with feeding ratios of 9 and 14 were chosen for specific interaction with GST protein. Figure 4.14 demonstrates that neither  $\text{Au}(-\text{S}-\text{EG}_3)_{9\text{fr}}\text{GSH}$  nor  $\text{Au}(-\text{S}-\text{EG}_3)_{14\text{fr}}\text{GSH}$  bound to lysozyme (lanes 2 and 5, respectively), while both particles migrated faster (lanes 3 and 6) after incubation with GST protein, indicating their specific interaction with GST. The faster migration of the  $\text{Au}(-\text{S}-\text{EG}_3)_{n\text{fr}}\text{GSH}/\text{GST}$  complex is, presumably, due to the negative charge of the GST protein (pI 6.2) in the pH 8 gel running buffer (TBE).

In summary, gel electrophoresis of the nanoparticles has been used to identify the optimum feeding ratio of a capture ligand and  $\text{EG}_3-\text{SH}$  at which the nanoparticle enables maximum specific binding with a biological target without the interference of nonspecific interactions. This approach could be easily applied to other nanoparticles protected with a mixed monolayer of an ethylene glycol molecule and a ligand.

**Fig. 4.14.** Gel electrophoresis image illustrating specific binding of  $\text{Au}(-\text{S}-\text{EG}_3)_{n\text{fr}}\text{GSH}$  ( $n = 9$  and  $14$ ) with GST protein. A 0.8% agarose gel was used and run at 90 V for 20 min. Gold particles were suspended in  $\text{H}_2\text{O}$  with a concentration of  $\sim 50 \mu\text{M}$ . Lane 1 is  $10 \mu\text{L}$  of  $\text{Au}(-\text{S}-\text{EG}_3)_{9\text{fr}}\text{GSH}$ ; lanes 2 and 3 are the same amount of Au

particles incubated with  $1 \mu\text{L}$  of lysozyme ( $10 \text{ mg mL}^{-1}$  in water) and  $5 \mu\text{L}$  of GST ( $0.5 \text{ mg mL}^{-1}$  in water), respectively. Lanes 4–6 are identical to lanes 1–3, except that  $\text{Au}(-\text{S}-\text{EG}_3)_{14\text{fr}}\text{GSH}$  was used. (Reprinted with the permission from Ref. [59], M. Zheng, X. Huang, *J. Am. Chem. Soc.* **2004**, 126, 12047–12054. © 2004 American Chemical Society.)

## 4.6

### Biological Applications

Water-soluble Au NPs have numerous applications in biology, medicine, catalysis, electronics, and optics. Here, we briefly review current efforts towards biological applications, which can be divided into subjects relating to nucleic acids, proteins, and cells and viruses.

#### 4.6.1

##### Nucleic Acids

Mirkin et al. first demonstrated the Au NP color change from red to blue when two complementary strands of DNA on two different Au NPs hybridize to form a NP aggregate [49]. Mirkin et al. further discovered that the Au NP aggregate could be converted back into individual Au NPs by heating the NP aggregate to dehybridize DNA, and that this was a reversible process in solution [65]. When a multilayer of Au NPs was formed on a glass substrate by hybridization of DNA attached on the NPs, a sharp response of plasma resonance intensity to temperature was observed [66]. Based on these fundamental discoveries, Reichert et al. developed a chip-based optical detection of DNA through hybridization of the surface-immobilized capture probe oligonucleotide and the target probe attached on Au NPs [67]. Storhoff et al. developed an easy “spot-and-read” colorimetric detection method for highly sensitive DNA detection [68]. Mirkin et al., furthermore, developed a multiplexed detection of DNA targets in a microchip format with the detection limit as low as 20 femtomolar [56]. Such a high detection sensitivity was achieved by applying a thin Ag coating to the surface of DNA hybridized Au NPs and then using surface-enhanced Raman spectroscopy (SERS) as the detection tool. By developing a magnetically-induced solid-state electrochemical detection method instead of SERS, Wang et al. achieved a DNA detection limit at the level of  $\sim 1.2$  fmol [69]. Another DNA detection method utilizes the ability of Au NP to quench fluorescence, which happens when a Au NP (2–3 nm) is in relatively close contact with a fluorophore (1–2 nm range), due to non-radioactive energy transfer from the excited fluorophore to Au NP [70]. This method employs a single stranded DNA with one end attached to an Au NP and the other end to a fluorophore to form a constrained loop DNA structure. When the DNA molecule on the Au NP hybridizes with a target ssDNA, the probe DNA loop on the Au NP opens and the fluorophore lights up. Based on this method, researchers have developed single-mismatch detection for oligonucleotides [70, 71]. Using DNA hybridization, Au NPs have also been assembled on the surface of carbon nanotubes [72].

#### 4.6.2

##### Proteins

Unlike DNA, which is very hydrophilic and negatively charged, proteins are much more complicated. They can be either hydrophobic or hydrophilic, with either pos-

itive or negative charge. In addition, nonspecific binding can be a serious issue. Unsurprisingly, therefore, applications of Au NPs with proteins have been far less developed than with DNA. However, several published papers deal with the interactions between nanoparticles and proteins, and applications in protein detection [73, 74], enzyme inhibition [75, 76], biosensor [77–79], nano-domain structure control [80, 81], and control of the nonspecific interaction of nanoparticles with proteins [59]. The interaction between Au NPs and proteins has been studied extensively. Examples include controlling the orientation of cytochrome *c* on Au NPs [82] and maintaining the enzymatic activity of fungal protease on Au NPs [83]. For protein detection, Thanh et al. [74] used antigen-coated Au NPs to detect antibodies by measuring the Au NP plasmon resonance shift induced by the aggregation of Au NPs. The detection limit could reach  $1 \mu\text{g mL}^{-1}$ . Mirkin et al. [77] used DNA hybridization to attach antigens to Au NPs and to then detect antibodies by a colorimetric scanner with a detection limit of  $\sim 20 \text{ nM}$ . This group also capped oligonucleotide-Raman dye conjugated molecules on Au NPs, attached antigens through hybridization, and then detected antibodies by using SERS [78]. Mirkin's methods are suited for the detection of multiple proteins. In a different approach, Willner et al. [79] developed an amplified optical detection of thrombin by using the binding between aptamer attached Au NPs and adsorbed thrombin on aptamer functionalized surface (detection limit at  $2 \text{ nM}$ ). In the area of enzyme inhibition, Rotello et al. have developed anionically functionalized, amphiphilic Au NPs to efficiently inhibit chymotrypsin through electrostatic interaction [75, 76]. They further demonstrated that Au NPs functionalized with alkanethiol-tetra(ethylene glycol) acetic acid bind to chymotrypsin, and the enzyme on the Au NP surface retains its activity and exhibits pronounced substrate chemoselectivity [84]. To build controlled Au NP structured materials, functionalized double stranded DNA has been used as a template to assemble protein attached Au NPs through the interaction between biotin bound on DNA and streptavidin on Au NP [80]. Enzymes, such as bacterial DNA methyltransferases could be used to manipulate the structure of DNA molecules linked with Au NPs, thus resulting in control of the distance between Au NPs [81]. In a biosensor application, Lu et al. demonstrated a colorimetric lead biosensor by using DNAzyme-directed assembly of Au NPs [85, 86]. The unique features of this method are its high speed ( $\sim 10 \text{ min}$ ) and high sensitivity ( $\sim 100 \text{ nM}$  for  $\text{Pb}^{+2}$ ).

#### 4.6.3

#### Cells and Virus

Functionalized Au NPs have many attractive properties. They are nanometer in size, and may have various functional ligands on the surface. These special properties provide them with many possible modes of interaction with biological cells, such as specific binding to the cell membrane and penetration through the membrane to interact with biological molecules inside a cell or virus. For example, carbohydrate-functionalized Au NPs have been developed to explore their multivalent interactions with cell membrane surfaces, such as lectins [87]. These studies

could have potential applications in lectin detection, control of cell fertilization, proliferation, viral infection, and inflammatory response. Dragnea et al. incorporated citrate-protected Au NPs inside brome mosaic virus and used them as a spectroscopic marker that could open up new opportunities for *in vivo* monitoring of viral capsid transitions [88].

# Biofunctionalization of Phospholipid Polymer Nanoparticles

*Junji Watanabe, Jongwon Park, Tomomi Ito, Madoka Takai, and Kazuhiko Ishihara*

### 5.1

#### Introduction

Recently, our interest in biomaterials has shifted to nanobiomaterials, which is integrated with nanofabrication. Nano-scaled fabrication is based on molecular assemblies such as micelles, self-assembled monolayers, and supramolecular compounds [1–8]. Also, many kinds of nano-scaled devices, such as bio-chips and nanoparticles, have been proposed and designed [9–17]. Nano-scaled chemistry and nanofabrication focus on chemical reactions and sensing. The most fascinating phenomena, chemical reactions, are created in a nano-scaled world, but are never carried out on an ordinary scale. In these nano-scaled devices, the bio-interface property is the dominant factor in providing excellent performance. To enhance biofunctionalization it is most important for the nano-scaled device to suppress non-specific protein adsorption since the surface is exposed to many biological components; blood, serum, and cells. Few researchers have understood the importance of materials in the design of biointerfaces and bioconjugations on the nanoscale [18–21]. This chapter summarizes newly engineered materials using bioinspired phospholipid polymer chemistry for biofunctionalization, with particular focus on phospholipid polymer nanoparticles for molecular diagnosis. Phospholipid polymers are available in numerous situations for specific biomaterials [22–25], and could function as a molecular machine [26–28]. Ishihara et al. proposed a fundamental concept for the synthesis of phospholipid polymers in the early 1990s [29, 30]. Now, we easily purchase many kinds of products containing phospholipid polymer – cosmetics, eye care products, textile goods, and fine chemicals for advanced bioreactions – which were designed through collaborations between Professor Ishihara and industrial companies. This is typical process and development – from laboratory materials to commercial products. The developed phospholipid polymer synthesis has been recognized world-wide, and much work has been reported subsequently (see Ref. [31] for an excellent review). Further research into nanofabrication may well provide us with a better “quality of life” –

perhaps especially when the design of biomaterials is based on phospholipid polymers.

## 5.2

### **Nanofabrication for Biomedical Applications**

Nanoparticles are a good substrate for bioconjugation. They have (a) a relatively high specific surface area, (b) good dispersivity in aqueous media, and (c) can be combined with nano-processed bio-chips. These characteristics can be used in a wide variety of applications, e.g. medical diagnosis, drug delivery carriers for targeting, micro-total analysis systems, and biosensors [32–35]. The most important factor in improving the nanoparticles is the enhancement of specificity to the target biomolecule such as antigen, substrate, and DNA (i.e. selectivity), and the suppression of non-specific interactions (sensitivity). Thus, bioinspired phospholipid polymers are key materials in the research on and development of nanoparticles.

#### 5.2.1

##### **Nano-scaled Processing**

Nanoparticles are a promising architecture for analyzing chemical species and providing a dynamic response. Many kinds of nanoparticles with unique structures have been prepared; Mori et al. have reported hybrid nanoparticles composed of a polymer shell with a silica core [36–38]. The polymer shell was carefully designed by the use of atom transfer radical polymerization, forming a hyperbranched structure. The nanoparticles showed reversible pH-induced complexations in a polyelectrolyte. Nanoparticles based on silica can be designed with unique structures, for easy dissolution by hydrogen fluoride. Kamata et al. have fabricated a core-shell spherical colloid with a hollow interior [39]. The hollow colloid provides a small container, in which a gold particle was trapped. The colloid particle, with its movable core, resembles a bell. The nanoparticles reported above could not be applied as advanced biomedical materials in their present form. However, suitable preparative techniques for biofunctionalization should soon be available.

Vertegel et al. have examined the size effect on the stabilization of immobilized enzyme by using silica nanoparticles (particle size 4–100 nm) [40]. Their report is impressive and important in terms of expressing biofunctions effectively. For enzyme immobilization, stronger protein–particle interactions exist on larger nanoparticles, resulting in multipoint immobilizations. The immobilized enzymes show less enzymatic activity. Akashi et al. have synthesized directly core-corona nanoparticles (one-pot preparation), which consist of a hydrophobic core and hydrophilic corona, by using water-soluble macromonomers [41, 42]. The key item is the water-soluble macromonomer; a typical example was reported using a methacrylate monomer containing a methoxy-terminated poly(ethylene glycol) side chain. The water-soluble segment was enriched spontaneously at the interface between the hydrophobic core and water, thus stabilizing the interfacial energy. The

preparative conditions are easily changeable to prepare many kinds of nanoparticles with core-corona morphology. Recently, lectin-conjugated nanoparticles have been prepared for the purpose of detecting the HIV virus [42]. From human serum, the virus is easily captured, and the nanoparticles formed in a precipitation. Caldwell et al. evaluated surface coverage by the immobilization of biomolecules; in particular, oligonucleotides were attached to polystyrene-based nanoparticles [43]. A number of the attached oligonucleotides were evaluated using the sedimentation field flow fractionation technique (a type of chromatography). This characterization technique is a powerful tool for estimating surface conditions: a number of functional groups, active linkage for bioconjugation, immobilized proteins, and binding target molecules in each step.

### 5.2.2

#### Key Materials for Nanofabrication

We have proposed recently the assembly of phospholipids polar group on nanoparticles. Nanoparticles are generally unstable as colloid particles in aqueous media. A hydrophilic moiety and ionic groups are incorporated onto the surface to prepare the interface. One unusual interface is the cell membrane, which is composed of phospholipid molecules, glycoproteins, and channel-forming proteins. It provides not only division between the cytoplasm and the outer environment but also allows communication via antenna molecules and channels. Ishihara et al. have designed and synthesized a novel functional monomer with a phospholipid polar group, 2-methacryloyloxyethyl phosphorylcholine (MPC, Fig. 5.1), in order to fabricate the cell membrane structure as a biointerface [29–31]. MPC (methacrylate derivative) easily polymerized with any kind of acrylate and methacrylate monomers by conventional radical, living radical, and atom transfer radical polymerizations [44–47]. Finely designed polymers with phospholipid polar groups were easily prepared by these polymerization techniques. The phospholipid polymer could form the cell membrane-like interface using coating, polymer blending, and polymer graft techniques [48–53]. A typical phospholipid polymer is copolymerized with *n*-butyl methacrylate (BMA); the phospholipid polymer-coated surface is illustrated in Fig. 5.2. The phospholipid polymer provided a very bio-inert interface; in particular, a non-specific interactive biointerface was obtained on diverse materials, and many biomedical devices have been developed using phospholipid polymer technology [22–25]. The stability of the phospholipid polymer-modified enzyme was also significantly prolonged in comparison with the native enzyme [26–28]. Furthermore,

Fig. 5.1. Chemical structure of 2-methacryloyloxyethyl phosphorylcholine (MPC).

Fig. 5.2. Schematic illustration of bioinert properties on phospholipid polymer surfaces by poly(MPC-co-BMA).

the phospholipid polymer spontaneously formed nano-structured aggregations, indicating amphiphilic and surfactant-like properties [54]. Employment of a polymer-based biomimetic surface is a promising approach to prepare nano-scaled devices for biofunctionalization.

### 5.3

#### Design of Bioconjugate Nanoparticles

Bioconjugate nanoparticles have contributed to the development of advanced biomedical research. Nano-scaled materials are both available and very interesting. The most favorable characteristics of the nanoparticles are their ability to form fine, stable dispersions in aqueous media, the ease in which immobilized biomolecules can be located, and their relatively large surface area.

##### 5.3.1

#### Bioconjugate Phospholipid Polymer

The phospholipid polymer was designed for bioconjugation with biomolecules such as proteins, peptides, and DNA. We have synthesized a functional monomer – a *p*-nitrophenyloxycarbonyl poly(oxyethylene) methacrylate (MEONP) – having an active ester linkage for bioconjugation [55]. MPC, MEONP, *n*-butyl methacrylate (BMA) were copolymerized to prepare the bioconjugate phospholipid polymer (PMBN, Fig. 5.3) by a conventional radical polymerization technique with 2,2'-azobisisobutyronitrile as an initiator. This polymer serves two functions – suppression of non-specific adsorption from the human body and the connection of biomolecules via an active ester group. Table 5.1 shows typical synthetic results. Two kinds of the phospholipid polymers were prepared with regards to solubility in water. The MPC unit is highly hydrophilic, so the solubility was changeable by MPC unit composition. Below 30 mol% of MPC unit, the phospholipid polymer could not dissolve in water but did so in ethanol. The water-insoluble polymer provided a stable biointerface for capillary electrophoresis [56]. A bioconjugate phospholipid polymer having 40 mol% of MPC could easily dissolve in water; 2 mol% of active ester groups were incorporated.

##### 5.3.2

#### Solution Properties by Fluorescence Probe

The fluorescence probe sodium 1-anilinoanthracene-8-sulfonate (ANS) is used as an indicator for the estimation of polarity in hydrophobic environments, showing a maximum fluorescence at 515 nm ( $\lambda_{EM}$ ) in water and 475 nm ( $\lambda_{EM}$ ) in *n*-butyl alcohol [excitation at 370 nm ( $\lambda_{EX}$ )]. The maximum fluorescence wavelength depended on various environmental conditions. For example, it is possible to estimate micro-environment factors such as change in higher-ordered conformation in proteins. Generally, amphiphilic polymers spontaneously aggregate in an aqueous media.

**Fig. 5.3.** Chemical structure of active ester monomer (MEONP) formed using *p*-nitrophenyl chloroformate (a) and the bioconjugate phospholipid polymer (PMBN) (b) derived from the copolymerization of MPC, BMA and MEONP. The average number of oxyethylene units was 4.5.

We evaluated the change in the maximum fluorescence wavelength by ANS. Figure 5.4 indicates that the maximum wavelength shifted upon increasing the polymer concentration. Above 0.1 mg mL<sup>-1</sup> of polymer, the wavelength was below 480 nm, indicating that the ANS molecule is trapped in lower polarity. The change in maximum wavelength showed that the phospholipid polymer spontaneously formed aggregates, indicating that it could form hydrophobic domains in a water

environment. Therefore, phase-separated organic solvent containing polymer as core materials of the nanoparticles was stably dispersed in the phospholipid polymer aqueous solution as an emulsion, and the interface on the emulsion covered with the phospholipid polymer was then prepared. The ANS test confirmed that the phospholipid polymer aggregated in water above a concentration of  $0.1 \text{ mg mL}^{-1}$ , and could therefore be employed as an emulsifier and a surface modifier for nanoparticles.

### 5.3.3

#### Bioconjugate Nanoparticles

Bioconjugate nanoparticles have been prepared by solvent evaporation methods for the systematic design of core materials – polystyrene (PS) as a conventional polymer and poly(L-lactic acid) (PLA) as a biodegradable polymer. According to the molecular design of the bioconjugate phospholipid polymer, the hydrophobic chains, *n*-butyl groups, were considered to penetrate on the surface of nanoparticles. The phospholipid polar groups and active ester groups, which formed domains, were concentrated at the nanoparticle surface to stabilize the interface, and the *p*-nitrophenyl ester groups can freely conjugate with biomolecules (Fig. 5.5). In this section, we examine whether the characteristics of nanoparticles would alter by changing the core materials. As core polymer materials, PLA and PS were used to prepare PMBN/PLA or PMBN/PS nanoparticles by a solvent evaporation technique in aqueous medium [55, 57, 58]. In this process, the PMBN was utilized as an emulsifier, and the polymer concentration regulated the average diameter of the nanoparticles. The diameter decreased with increasing initial concentration of PMBN. Typical preparative concentrations of PMBN, PLA, and PS were 1.0, 10

Fig. 5.5. Schematic illustration of bioconjugate phospholipid polymer nanoparticles.

and  $10 \text{ mg mL}^{-1}$ , respectively. The surface of the nanoparticles was characterized by X-ray photoelectron spectroscopy (XPS), surface  $\zeta$ -potential, dynamic light scattering (DLS), scanning electron microscopy (SEM), and determination of active ester groups.

#### 5.3.4

##### Surface Elemental Analysis by X-ray Photoelectron Spectroscopy

Surface analysis of the PMBN/PLA nanoparticles was carried out with XPS to estimate the phospholipid polar groups on the surface. Figure 5.6 shows the XPS spectra of  $\text{C}_{1s}$ ,  $\text{O}_{1s}$ ,  $\text{N}_{1s}$ , and  $\text{P}_{2p}$  on the surface of the PMBN nanoparticles. From the XPS analysis,  $\text{O}-\text{C}-\text{O}$  and  $\text{C}=\text{O}$  peaks from the phospholipid polymer were observed at 287.0 and 289.0 eV, respectively. Furthermore, a small broad peak attributed to an aromatic group based on the *p*-nitrophenyl ester group was also observed at 291.5 eV. Additionally,  $\text{N}_{1s}$  and  $\text{P}_{2p}$  peaks attributed to choline methyl (403.0 eV) and phosphate ester (134.0 eV) were observed. Moreover, the PMBN/PS nanoparticle was also characterized (Fig. 5.6). These results strongly indicated that the interface on the PMBN/PLA and PMBN/PS nanoparticles was covered with phospholipid polar groups and *p*-nitrophenyl ester groups.

#### 5.3.5

##### Surface $\zeta$ -Potential on Nanoparticles

As an alternative characterization, surface  $\zeta$ -potential was measured to estimate the coverage of the bioconjugate phospholipid polymer. The phospholipid polar group contains a quaternary choline methyl group (cation) and a phosphate ester group (anion). Their ions form an intramolecular ion pair; therefore, their charge is neutralized [59]. If the nanoparticles were covered with phospholipid polymers, the  $\zeta$ -potential on the surface would be roughly 0 mV. That is why the  $\zeta$ -potential was

Fig. 5.6. X-ray photoelectron spectra of PMBN/PLA nanoparticles (a) and PMBN/PS nanoparticles (b).

measured for the phospholipid polymer coverage. The  $\zeta$ -potential of the PMBN/PLA and PMBN/PS nanoparticles were  $-2.1 \pm 3$  mV and  $-2.3 \pm 2$  mV, respectively. The obtained  $\zeta$ -potential is almost the same ratio and roughly 0 mV, as we expected. Farokhzad et al. reported a bioconjugate polymer nanoparticle composed

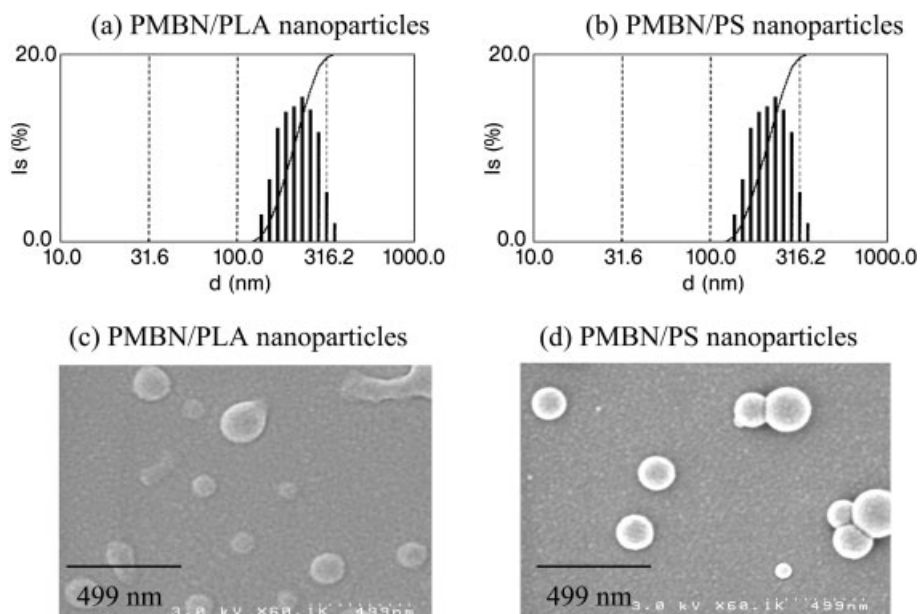

of aptamers for targeting drug delivery to prostate cancer cells. The polymer used was PLA-*block*-poly(ethylene glycol) (PEG) with a terminal carboxylic group (PLA-PEG-COOH) [60]. According to the report, the  $\zeta$ -potential of the PLA-PEG-COOH was  $-50 \pm 3$  mV, and of the PLA bare particle was  $-24 \pm 5$  mV. This indicates that the surface potential was significantly shifted to a more negative charge than the unmodified PLA nanoparticles, as a result of surface modification. Veronesi et al. reported that vanilloid (VR1) receptors on the cell membrane were activated by membrane depolarization, which is induced by charged polystyrene nanoparticles [61]. The acid-sensitive ionic channels could be activated by the electrostatic charge carried on chemically modified particles: neutral polystyrene nanoparticles (particle size: 750 nm), negative polystyrene nanoparticles (having carboxyl groups) (particle size: 860 nm), and positive polystyrene nanoparticles (having diamino groups) (particle size: 850 nm). The  $\zeta$ -potential of each nanoparticle was  $-55$  (neutral),  $-88$  (carboxyl), and  $-23$  (diamino) mV, respectively. From their reports, the nanoparticles showed a negative charge to maintain stability by electrostatic repulsion. For nanoparticles covered with the phospholipid polymer, the surface charge was nearly neutral, because it formed intramolecular ion pairs in phosphorylcholine groups. From the  $\zeta$ -potential results, the phosphorylcholine groups were assembled on the nanoparticles.

### 5.3.6

#### **Particle Size by Dynamic Light Scattering and Morphology by Scanning Electron Microscope**

The particle size and size distribution of phospholipid polymer nanoparticles have been determined by dynamic light scattering measurements (DLS). The concentration of PMBN/PLA and PMBN/PS nanoparticles was  $2.5 \text{ mg mL}^{-1}$ . The size distribution of the nanoparticles is shown in Fig. 5.7. The particle size of PMBN/PLA was  $270 \pm 100$  nm, and that of PMBN/PS was  $320 \pm 100$  nm. It is considered that these two particles have almost the same diameter with monodispersity. The miscibility between the phospholipid polymer and core polymer materials was slightly different; the PLA core is a little superior to the PS core material. Monodispersed nanoparticles were easily, and in large quantities, prepared by an emulsion technique.

The particle size of the phospholipid polymer nanoparticles was observed using a scanning electron microscope (SEM). Figure 5.7 shows SEM pictures of the nanoparticles. From this result, the size of the PMBN/PLA and PMBN/PS nanoparticle were seen to be approximately similar, showing good agreement with the DLS measurement. Particle morphology was quite good, with a spherical form. Generally, the nanoparticle was utilized up to  $100 \text{ } \mu\text{g mL}^{-1}$ . Bioreactions were carried out in a 96-well multiplate, providing a maximum volume of  $300 \text{ } \mu\text{L}$ . To prepare nanoparticles in large quantities (mg scale), several kinds of bioreaction and biofunctionalizations can be fully designed at a laboratory level. With our emulsion technique, preparative conditions can easily be scaled-up, and the nanoparticles can then be produced on an industrial scale.

**Fig. 5.7.** Size distribution by dynamic light scattering of PMBN/PLA (a) and PMBN/PS (b) nanoparticles, and scanning electron microscope pictures of PMBN/PLA (c) and PMBN/PS (d) nanoparticles.

### 5.3.7

#### Determination of Active Ester Groups on Nanoparticles

Biomolecules can be quite easily immobilized on phospholipid polymer nanoparticles. A protein-bound amino group could, for example, couple to the ester groups on the polymer under physiological conditions, producing *p*-nitrophenol as a leaving group (Fig. 5.8). The bioconjugate reaction is accelerated under weak alkaline conditions. The conversion is easily estimated by the released *p*-nitrophenol. To quantify the active ester groups on the phospholipid polymer nanoparticles, NaOH aqueous solution ( $0.1 \text{ mol L}^{-1}$ ) was added to each suspension of PMBN/PLA and PMBN/PS for complete hydrolysis of the active ester groups. The released *p*-nitrophenol was detected by UV measurement at 400 nm. The molar extinction coefficient of the *p*-nitrophenol was calculated as  $\epsilon_{400} = 1.8 \times 10^4 \text{ L mol}^{-1} \text{ cm}^{-1}$ . Figure 5.9 shows the change in UV spectra of PMBN/PLA nanoparticles after and before hydrolysis. From this result, the active ester groups on the PMBN/PLA nanoparticles were estimated as  $1.0 \times 10^{-9} \text{ mol (mg-nanoparticle)}^{-1}$ . Thus, an active ester group exists on the PMBN/PLA nanoparticles, and the amount of such groups on PMBN/PS nanoparticles was roughly the same as on PMBN/PLA nanoparticles. The *p*-nitrophenyl ester groups, which could connect with the amino

**Fig. 5.9.** UV spectra of *p*-nitrophenol (abs. 400 nm) before (dashed line) and after (solid line) hydrolysis of PMBN/PLA or PMBN/PS nanoparticles in 0.1 M NaOH aqueous solution.

groups on the proteins, were at the surface of the nanoparticles. Therefore, the interface of the PMBN/PLA and PMBN/PS nanoparticles was covered with active ester groups as well as phospholipid polar groups.

## 5.4

### Biofunction on Nanoparticles

One biofunctional enzyme reaction has been evaluated on phospholipid polymer nanoparticles. In addition, a sequential enzymatic reaction has also been designed. The most favorable characteristic is the local concentration of enzyme on the nanoparticles. An increase in this local concentration is effective for valuable and rare biomolecules.

#### 5.4.1

##### Design of Sequential Enzymatic Reaction

We have recently proposed a novel signal amplified diagnosis system using a sequential enzymatic reaction on nanoparticles. The nanoparticles are composed of a phospholipid polymer with active ester groups and polystyrene core. The amplified signal was evaluated by using choline oxidase and peroxidase, which were co-immobilized onto the nanoparticles. The choline oxidase reacts with choline chloride, producing hydrogen peroxide that is used as a substrate in the next enzymatic reaction by peroxidase. In this sequential reaction, the amount of tetramethylbenzidine is evaluated by change in absorbance, for the single enzymatic reaction (peroxidase) and/or sequential enzymatic reaction (choline oxidase and peroxidase) (see below for more details).

Fig. 5.10. Scheme of sequential enzymatic reactions via degradation product.

#### 5.4.2

#### Amplified Signal on Nanoparticles

The active ester group on the nanoparticles is labile to the primary amino group, affording a carbamate linkage for bioconjugation. We have already estimated the conversion of the active ester linkage; 40% of the active ester linkage was converted by a reaction with proteins [58]. Two kinds of enzymes, choline oxidase and peroxidase, were co-immobilized onto the surface, and the sequential enzymatic reaction was then evaluated. The combination of the enzymes displayed communication via the degradation product (hydrogen peroxide) (Fig. 5.10). As a substrate, choline chloride (Cho), tetramethylbenzidine (TMBZ), and hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) were used. The Cho was oxidized by the choline oxidase, and H<sub>2</sub>O<sub>2</sub> was newly produced as a degradation product. The produced H<sub>2</sub>O<sub>2</sub> was used for the next enzymatic reaction; the oxidation of TMBZ by peroxidase. The H<sub>2</sub>O<sub>2</sub>, which was originally added to the media, could also be used as substrate.

Two kinds of protocol regarding the enzymatic reaction were examined: (a) TMBZ and H<sub>2</sub>O<sub>2</sub> were added to the suspension and (b) Cho was added to the suspension with TMBZ and H<sub>2</sub>O<sub>2</sub> (TMBZ/Cho). With protocol (a), only the enzymatic activity of the peroxidase was evaluated. However, newly produced H<sub>2</sub>O<sub>2</sub> would enhance the sequential enzymatic reaction [protocol (b)]. The result of the enzymatic reaction was evaluated by the change in absorbance at 450 nm (Fig. 5.11). Enzymatic reaction on the nanoparticles was significantly greater than that of a simple enzyme solution, when TMBZ was added as the substrate. The total amount of enzymes in the enzyme solution was larger than that of the immobilized enzyme on the nanoparticles, because the concentration of the enzymes in the solution was the same as the feed concentration for the preparation of the enzyme-immobilized nanoparticles. Taking the total amount of the enzyme concentration into account, choline oxidase and peroxidase were considered to be locally concentrated on the particle surface in comparison with the solution.

Fig. 5.11. Characterization of enzymatic reaction by changing substrate addition.

The sequential enzymatic reaction was also compared. The change in absorbance increased with addition of TMBZ/Cho, which was twice as large as that of the addition of only TMBZ. The increased enzymatic activity was considered to be based on choline oxidase, and the produced  $H_2O_2$  was effectively free to move to its binding site at the substrate. Initially, sufficient  $H_2O_2$  was added to the media to promote the enzymatic reaction; therefore, the increased enzymatic reaction was caused by  $H_2O_2$  newly produced by choline oxidase. With nanoparticles, the enzymes, choline oxidase and peroxidase, were closely immobilized onto the nanoparticles; therefore, the diffusion pathway of the produced  $H_2O_2$  was significantly shorter than that in solution. Thus, the produced  $H_2O_2$  was differed from the originally added  $H_2O_2$ , which needed a long pathway to react with the peroxidase. Conversely, no significant difference in the enzyme solution was observed between the single reaction (TMBZ) and the sequential reaction (TMBZ/Cho). This indicated that the reaction with peroxidase proceeded through a single reaction, even if Cho was added to the media.

## 5.5

### Application for Molecular Diagnosis

Recently, molecular diagnosis using bioconjugate nanoparticles has focused on the biomedical field. The obtained S/N ratio (signal/noise) generally decreased due to non-specific protein adsorption under physiological conditions. In this section we introduce a hyper-sensitive C-reactive protein detection system using the phospholipid polymer nanoparticles.

#### 5.5.1

##### Example of C-reactive Protein Detection Using Nanoparticles

The C-reactive protein (CRP) is synthesized by the liver in response to interleukin-6 and is well known as one of the classical acute-phase reactants and as a marker of

inflammation. For some time, the measurement of CRP concentration has been used as a clinical bio-marker for monitoring autoimmune diseases and infectious processes, such as rheumatoid arthritis. It has recently been suggested that a marker of inflammation, along with serum cholesterol, are critical components in the development and progression of atherosclerosis [62, 63]. However, the prospect of using CRP as a predictor of future vascular risks faced a large obstacle because existing conventional assay methods were neither sensitive enough to detect very low-levels of CRP in serum nor concerned about problems of non-specific protein adsorption and denaturation of conjugated biomolecules [64, 65]. Among conventional analytical methods, immunoassay, which uses the specific affinity of antigen-antibody, has been considered as a useful technique for clinical analyses and medical diagnostics [66]. Major progress in the use of immunoassay principles occurred with the development of several fundamental techniques [67]. Among several methods, immunoagglutination using colloidal particles has been widely used because of its rapid, simple, and inexpensive properties [68, 69]. There have been many innovations in diagnostics since microsphere agglutination was first used in medical diagnosis as agglutination-based tests in the late 1950s [70]. Although various types of colloidal particles (e.g., latex, gold, sol, and polymeric particles) have been introduced to immobilize the biorecognition element (e.g., antibody, DNA, etc.) for immunoagglutination, the latex particle, prepared by emulsion polymerizations, has been widely used in the diagnostics of various infections and to detect biomarkers or some chemical compounds in biological fluids [71]. However, several problems need to be addressed to produce a sensitive and reliable immunoassay. For example, for medical diagnostics such as CRP detection, latex particles suffered from non-specific binding, which originated from plasma proteins in serum, because of its highly hydrophobic surface. Also, the immobilized biomolecule became denatured and inactivated when it was physically adsorbed on the latex particle surface despite several advantages of immunoagglutination. These findings reduced the sensitivity, and thus the reliability, of the diagnostics. To address these challenges, we prepared novel nanoparticles as immunoagglutination substrates based on our phospholipid polymer that had already solved existing problems.

The nanoparticles were prepared by the solvent evaporation technique under the systematic design of PMBN/PLA. According to the molecular design of PMBN, the PMBN chains, particularly *n*-butyl group, were considered to miscibly interpenetrate on the surface of PLA particle. The MPC domains were arranged at the surface owing to hydrophilicity, and then the *p*-nitrophenyl ester groups, which can be conjugated with biomolecules, were also freely arranged toward the outside. Mono-dispersion of the PMBN/PLA ( $d = 205 \pm 43$  nm) measured by DLS was confirmed by field emission scanning electron microscopy (FE-SEM) [Fig. 5.12(a)]. Additionally, the  $\zeta$ -potential of PMBN/PLA ( $-5.6$  mV by electrophoresis light scattering measurement) indicated a slightly negatively charged surface. Biocomponents, including the plasma proteins, commonly have a slightly negative charge. Therefore, PMBN/PLA with a large negative  $\zeta$ -potential must suffer from non-specific protein binding when it is used as an immunosensing tool. MPC-PNP was ex-

**Fig. 5.12.** SEM observations of anti-CRP antibody-immobilized PMBN/PLA nanoparticles: magnified view (a), normal view (b) and agglutination by antigen (c).

pected to show biocompatibility against non-specific binding of the plasma proteins with a slightly negatively charged surface, caused by arrangement of phosphorylcholine groups that were regarded as important to reduce protein adsorption, on PMBN/PLA.

PMBN/PLA can bind with biomolecules such as antibodies because it has *p*-nitrophenyl ester groups on its surface. Through a condensation reaction between amino groups of the antibody and *p*-nitrophenyl ester groups, the anti-CRP monoclonal antibody was immobilized on the MPC-PNP. For optimization, a fluorescent probe (Alexa Fluor 488, Molecular Probes, USA) labeled anti-CRP antibody was used to determine accurately the amount of antibody on PMBN/PLA. The immobilized amount of antibody was measured directly and calculated from the fluorescence intensity after immobilization. On the basis of experimental results,  $100 \mu\text{g mL}^{-1}$  of anti-CRP antibody was regarded as the optimal concentration for immobilization on PMBN/PLA. The remaining *p*-nitrophenyl ester groups

on the surface were thoroughly blocked by 20 mM glycine. The  $\zeta$ -potential of the PMBN/PLA ( $-25.3$  mV) was further decreased after antibody immobilization because the antibody has a negative charge.

After preparation of the anti-CRP antibody immobilized PMBN/PLA, it was applied to detect serum-free CRP by the immunoagglutination method. Figure 5.12 also indicates FE-SEM photographs of the immunoagglutination at an initial state (b) and after aggregation (c). The immunoagglutination of PMBN/PLA was clearly successfully achieved by specific antigen–antibody binding. Following the confirmation of immunoagglutination, the dependency for serum-free CRP concentration was investigated with the anti-CRP antibody immobilized PMBN/PLA and commercially available polystyrene nanoparticles. The increase in optical density was investigated to evaluate the degree of immunoagglutination when agglutination occurred among particles. To avoid interference of light absorbance into antibody molecules, the optical density was measured at 570 nm when immunoagglutination was thoroughly performed for 90 min at 37 °C.

Figure 5.13 shows the calibration curves for serum-free CRP by PMBN/PLA and polystyrene nanoparticles. For PMBN/PLA, the calibration curve clearly had a linear correlation for serum-free CRP concentrations (from 0.01 to 10 mg dL<sup>-1</sup>); polystyrene nanoparticles, however, had a limited linearity (from 0.1 to 10 mg dL<sup>-1</sup>). The difference between the two calibration curves might be related to the resistance of protein adsorption on the surface of particles. With polystyrene nanoparticles, it could be that antigen–antibody binding did not occur and, instead, non-specific adsorption of CRP took place that affected the detection results. Overall, for polystyrene nanoparticles it was difficult to detect CRP at low concentrations although non-specific adsorption could be ignored at high concentrations because of the high response from antigen–antibody binding. Conversely, low concentrations

Fig. 5.13. Standard calibration curve for serum-free CRP obtained from the change in optical density at 570 nm when the immunoagglutination among anti-CRP antibody conjugated PMBN/PLA nanoparticles ( $\square$ ) and conventional polystyrene nanoparticles ( $\circ$ ) was completed following each serum-free CRP injected.

**Fig. 5.14.** Consideration of the regulating effect of non-specific binding from plasma proteins in human serum by comparing the calibration curves for serum-free CRP and CRP in serum; PMBN/PLA nanoparticles (□) and conventional polystyrene nanoparticles (○).

of CRP could be detected by PMBN/PLA because there were no problems with non-specific binding of CRP. From successfully obtained calibration curves, CRP detection was investigated with CRP in serum; the previous calibration curves in Fig. 5.13 were considered as standard calibration curves for CRP.

### 5.5.2

#### High-performance Diagnosis in Serum

Figure 5.14 indicates the change in optical density of serum-containing particles with CRP concentrations in serum. These were compared with standard calibration curves to consider non-specific binding from plasma proteins in serum. Adsorption of plasma proteins, such as BSA and  $\gamma$ -globulin, in serum on the particles might induce the agglutination of particles, and this non-specific agglutination would be a major problem for reliable CRP detection. As shown in Fig. 5.14, polystyrene nanoparticles gave a quite different standard curve because non-specific agglutination occurred, resulting in plasma protein adsorption. This phenomenon could also be explained by particle preparation parameters such as ionic strength and hydrophobicity. However, the calibration curve was almost identical when PMBN/PLA was used to detect the CRP in serum. Thus, non-specific binding of plasma proteins rarely occurred on the MPC-PNP, and highly sensitive and reliable CRP diagnostics could be obtained. Normally, the detection limit for CRP was below  $0.06 \text{ mg dL}^{-1}$  for medical diagnostics. Furthermore, with infants, much lower detection limits are required to detect CRP. The MPC-PNP fully satisfied the requirement for CRP detection.

To determine their thermal stability, anti-CRP antibody immobilized PMBN/PLA

**Fig. 5.15.** Remaining immunologic activities of conjugated anti-CRP antibody on PMBN/PLA nanoparticles and conventional polystyrene NP; the calibration curves for serum-free CRP were obtained after 2 h storage 55 °C; PMBN/PLA nanoparticles (□) and conventional polystyrene nanoparticles (○).

and polystyrene nanoparticles were stored at 55 °C for 2 h, and were then used to detect serum-free CRP under the same conditions as for the determination of the standard calibration curves. Figure 5.15 shows the calibration curve for serum-free CRP obtained after this treatment. From the figure, the calibration curve of the PMBN/PLA was almost the same as the standard curve. However, the polystyrene nanoparticles gave a very different curve, indicating that anti-CRP antibody immobilized on polystyrene nanoparticles was denatured by the high temperature treatment and almost lost its selectivity for CRP. However, for PMBN/PLA, the immobilized antibody was clearly not influenced by the increase in temperature.

The resistance of protein adsorption and suppression of antibody denaturation on PMBN/PLA might be related to the hydration state of the phosphorylcholine groups. The following concept is generally accepted when considering protein adsorption on a polymer substrate [72]. Water molecules bind to the hydrophobic part of the polymer through van der Waals forces. These bound water molecules cause protein adsorption by hydrophobic interaction. When a protein molecule is adsorbed on a polymer surface, the water molecules between proteins and the polymer need to be replaced. This phenomenon induces a much stronger interaction with a change in the denaturation of the proteins. If the water at the surface is in a similar state to bulk water, the protein does not need to release bound water molecules even if the protein molecules are in contact with the surface. Under the hypothesis concerning the effect of water states, our group has previously analyzed the water state of hydrated MPC polymers, and recognized that the water state on the MPC polymer surface is naturally maintained [73, 74]. For PMBN/PLA, this hypothesis can also be used to explain several experimental results because its sur-

face was successfully covered with MPC units. Furthermore, as additional proof of the hypothesis, the colloidal stability of the PMBN/PLA was also explained. Generally, colloidal stability can be achieved in two ways: (a) the particles can be given an electric charge (either positive or negative) and if all have the same charge they will repel one another more or less strongly when they approach; (b) the particles can be coated with an adsorbed layer of some material (say a polymer), which itself prevents their close approach. Although the PMBN/PLA did not correspond to either situation it has good colloidal stability – as indicated in the FE-SEM picture for initial colloidal states [Fig. 5.12(a)]. On the basis of our hypothesis, it was strongly solvated with water molecules, and polar groups like bound water molecules resist coagulation among the PMBN/PLA nanoparticles.

## 5.6

### Conclusions

Nanofabrication is a promising technique that opens up a new scientific field, integrating biochemistry, bioscience, material science, polymer chemistry, and nano-scaled processing. Under the nano-scale environment, surface properties (biointerface) are dominant factors and, thereby, regulate biofunctions. In particular, non-specific protein adsorption is a typical phenomenon in nanofabrication. A series of phospholipid polymers are good candidates for nanofabrication involving biofunctionalization.

## 6 Bifunctionalization of Metallic Nanoparticles and Microarrays for Biomolecular Detection

*Grit Festag, Uwe Klenz, Thomas Henkel, Andrea Csáki, and  
Wolfgang Fritzsche*

### 6.1 Introduction

Characterization of molecular interactions represents a core technology for today's biomedical research. The specific binding of bioactive compounds to certain pathogens, the discovery of novel pathways in the cell, or the early detection of low numbers of disease-related molecules are examples of the wide application of biomolecular detection. With the ongoing elucidation of the molecular bases for life processes, a further demand for testing the presence and, eventually, the quantity of molecules of interest is expected. One interesting development is the field of point-of-care (POC) diagnostics that describes the application of biomolecular detection outside the dedicated laboratory and near the patient, such as in the medical practice. Other applications with similar technical requirements are, for example, the testing for toxic organisms in food processing factories or the detection of pathogens in air conditioning systems. This set of applications requires a highly robust technology, both regarding a minimized maintenance and stability against users not trained as laboratory personnel. It includes a signal that is easily transformed into results, without the need for user input or extended processing. The decentralized character of this approach asks for cost-efficiency of detection equipment that has to be provided in large quantity. The resulting need for miniaturization is matched by the general development towards minimal sample liquid volume. Although sample holders with several thousands of detection sites have been described already for gene expression chips, typical analytical questions for POC diagnostics will be limited to a handful of parallel tests. Moreover, the highly-developed fluorescence readers needed for the readout of expression chips are hardly suitable for POC applications due to their high costs and complicated detection setup.

What measurement principles are best suited for this novel field in bioanalytics? The demonstration of DNA-conjugated metal nanoparticles [1, 2] was the starting point for a novel family of detection techniques based on these particles. These particles allowed for various elegant detection schemes with sensitivities comparable or even better than for fluorescence-based assays. Surprisingly, the – in comparison

to fluorescent dyes – large mass of the particles does not interfere with the specificity of the binding of the conjugated molecules. In certain applications they even enhance the specificity compared with fluorescence assays [3].

This chapter describes the application of biofunctionalized nanoparticles for biomolecular detections. The first section describes application aspects, including typical assay formats, array fabrication, and the numerous detection schemes established. The most important types of nanoparticles (regarding their composition) are introduced in Section 6.2.1. The following section describes the synthesis of metal particles. Particle biofunctionalization represents the key step for an integration of the nanoparticles into biological assays. The various bioconjugation approaches regarding gold nanoparticles are introduced in Section 6.2.3.1 for DNA and Section 6.2.3.2 for proteins. Other metal nanoparticles follow in Section 6.2.3.3. Section 6.2.4 gives the outlook for further applications of bioconjugated particles.

Although biofunctionalized particles are important for assays, substrates modified with capture molecules are often required to realize chip-based detection with its potential for miniaturization as well as parallelization. Such substrates usually exhibit self-assembled monolayers to bind the capture molecules (Section 6.3.1.1). For a typical system, optimization, regarding blocking of undesired unspecific interactions, is required (Section 6.3.1.2). Beside molecular layers, nanoporous gels provide another interesting option for efficient binding of capture molecules (Section 6.3.2). This chapter concludes with an outlook (Section 6.4) that forecasts future developments.

### 6.1.1

#### **Applications**

Nanotechnologies extend the limits of molecular diagnostics to the nanoscale and offer a broad spectrum of potential applications in molecular diagnostics, as summarized by Jain [4]. Beside technologies such as nanowires or nanopores, we will focus on nanoparticle technologies using, especially, gold nanoparticles as labels for biomolecule probes.

A typical assay in biomolecular detection probes the presence of target molecules by using capture molecules that are complementary to the targets. These capture molecules bind the target, and this binding is detected using labels that are either attached to the targets (e.g. by PCR in the case of DNA or RNA) or added by another binding molecule in a kind of sandwich assay (Fig. 6.1). Capture probes attached to solid substrates are easily incubated and washed. Moreover, by using separate binding spots for various capture probes, the assay can be multiplexed with only minimal sample volume requirement.

### 6.1.2

#### **Array Fabrication**

The need for analytical methods that can deal with many probes, and, ideally, analyze all of them together, led to the development of so-called microarrays or bio-

**Fig. 6.1.** Microarray-based, sequence-specific DNA detection with gold nanoparticle labels. (A) Solid substrate, functionalized for binding of capture probes. (B) Covalent attachment of capture-oligonucleotides. (C)–(E) For the direct detection scheme, the target probes have to be labeled prior to hybridization. (C) Hybridization of DNA target strands labeled with gold nanoparticles or (D) biotin molecules. (E) Labeling of the biotin-tagged targets with streptavidin-modified nanoparticles. (F) In the indirect approach (sandwich), the unlabeled target strands are hybridized to the capture strands first, (G) followed by an additional hybridization with labeled DNA probes.

chips, which enable massive parallel mining of biological data, multiplexing, and automation in a miniaturized format [5]. The particular strength of array analysis results from the highly redundant measurement of many parallel biomolecular hybridization or recognition events, which leads to an extraordinary level of assay validation [6, 7].

DNA microarrays can be fabricated by two strategies. In the first approach, the on-chip (*in situ*) synthesis of capture oligonucleotides at defined places provides high yields of capture probes that are consistent over the surface of the support. It permits combinatorial strategies for the fabrication of large oligonucleotide arrays. In the second strategy, an off-line approach in which pre-synthesized oligonucleotides have been deposited onto the substrate (*ex situ*), available in most biology laboratories, enables assessment of the capture probes before they are attached to the surface. Deposition is also the method of choice for long sequences as PCR products. When many arrays are needed with the same probes, deposition may be more economical than *in situ* synthesis.

### 6.1.3

#### Detection Methods

Different applications of metal nanoparticles for biomolecular detection are favored by their multi-purpose possibility of signal development.

The most common characterization techniques of metal nanoparticles are high-resolution transmission electron microscopy (HRTEM) as well as scanning tunneling microscopy (STM), atomic force microscopy (AFM), small-angle X-ray scattering, and X-ray diffraction [8]. For paralleled assays in microarray format, electrical/electrochemical and optical methods are preferred, such as optical absorbance as well as optical scattering, surface plasmon resonance (SPR) imaging, and surface-enhanced Raman spectroscopy (SERS).

##### 6.1.3.1 Optical Absorbance

Imaging the optical absorbance of surface-bound particles is probably the simplest method for analyzing nanoparticle-labeled DNA at surfaces. The extinction coefficient of metal nanoparticles can exceed those of organic dyes by many orders of magnitude, which has been explained by the collective resonance of conduction electrons in the metal (surface plasmon resonance, SPR, [9–11]). An important enabling step for DNA labeling by nanoparticles was the development of a method in 1996 that allowed the direct oligonucleotide modification of gold nanoparticles [1, 2]. This enabled a simple optical characterization by monitoring a color change during hybridization events of two complementary DNA–nanoparticle complexes in solution. Solutions of gold nanoparticle aggregates with interparticle distances larger than the average particle size appear red. But when biomolecular recognition events lead to significantly decreased interparticle spacings the solution turns blue, which is detectable in a spectral shift. The dependency on interparticle spacing was also used in colorimetric, heterogeneous biomolecule detection schemes on thin-layer chromatography plates [12]. By using solid supports the color differentiation was enhanced; this is attributable to increased aggregation of the pre-organized DNA-linked nanoparticles upon drying the solution on the support, which also prevented samples (heated above the DNA dissociation temperature) from re-hybridizing. Thus, a permanent record of the test could be obtained. Furthermore, gold nanoparticle-labeled probes exhibited characteristic, exceptionally sharp “melting transitions” compared with those of fluorophore-labeled targets, which allows the discrimination of even small DNA sequence defects. By aligning the oligonucleotides in a “tail-to-tail” [13] rather than “head-to-tail” fashion on the nanoparticles the sensitivity could be further improved, and it was even possible to distinguish target sequences with single nucleotide polymorphisms from the fully complementary target. The altered melting profiles yielded a selectivity that was over three times higher than that observed for fluorophore-labeled targets [3]. The absorbance signal of the surface-bound gold nanoparticles could be further amplified by autocatalytic deposition of silver metal [14]. Such silver enhancement leads to a growth of the gold nanoparticles (Fig. 6.2) and makes the nanoparticle-based assays readable by simple flatbed scanners. The sensitivity of this scanomet-

**Fig. 6.2.** Metal enhancement of gold nanoparticles by a stepwise electroless deposition of silver. Atomic force microscopy (AFM) images and their corresponding section analyses show the growth of single 30 nm-sized gold nanoparticles after 0, 2 and 10 min enhancement time, as examples. For orientation, selected particles are marked by

arrows through the experiments. (A) Slowly growing particles by a homemade silver acetate/hydroquinone silver enhancement solution (average height of 31, 38 and 48 nm, respectively). (B) Fast growing particles by means of a commercial silver enhancement kit (Silver Enhancement Solution™, British Biocell) (31, 130, and 442 nm, respectively).

ric array detection exceeds that of analogous fluorophore systems by two orders of magnitude (50 fM vs. 5 pM, respectively) [3].

Microstructured biochips were introduced in this field to monitor the binding of nanoparticle-labeled target DNA to arrayed capture DNA probes by both reflected and transmitted light [15]. Moreover, the authors found that the intensity of reflected light directly relates to the number of bound particles and to the concentration of hybridizable targets in solution.

Beside the large extinction coefficient there is a just as huge scattering coefficient that enables extremely sensitive imaging and quantification of nanoparticle-tagged biomolecules by scattered light. This was shown for selenium nanoparticle-antibody conjugates that – bound to biotinylated target DNA – could be imaged by

scattering light in an evanescent field [16]. The use of an internally reflecting waveguide allows for measurement of real-time binding or melting of a light-scattering label of a DNA array.

As well as for the optical absorbance, the spectrum and intensity strongly depends on the size, shape, and material composition of the nanoparticles. Thus, the use of different-sized gold nanoparticles as scattering labels results in different colors of scattered light, e.g. green-scattering 50 nm and orange-scattering 100 nm particles [17].

Li and Rothberg introduced a completely different approach by designing – in combination with gold nanoparticles – a novel fluorescent assay for DNA hybridization based on the electrostatic properties of DNA without the need for probe or surface modification [18]. The fluorescence of single-stranded dye-tagged DNA was efficiently quenched when the DNA probes had bound to gold nanoparticles, whereas double stranded DNA refused to adsorb to the particles (Section 6.2.3.1). Hence, these hybridization events could be measured indirectly as fluorescence signals.

#### 6.1.3.2 SPR Imaging

In the past decade, SPR methods have contributed significantly to the sensing and quantification of biomolecule interactions; four emerging application areas have been identified: food analysis, proteomics, immunogenicity, and drug discovery [19]. SPR biosensors enable the measurement of analyte binding to immobilized biomolecules without using labels. The first SPR biosensor, introduced by Biocore AB in 1990, can detect protein–protein interactions and, moreover, was combined with miniaturized flow systems for efficient sample delivery to the sensor surface. Since it was possible to reproducibly self-assemble gold nanoparticles from solution onto glass surfaces – functionalized with amine or thiol groups – new SPR biosensors were developed that enable label-free optical detection in a chip-based format [20]. In a typical SPR spectroscopy setup a laser beam is aimed at the back of a substrate. Although even subtle changes in the refractive index at the surface of the substrate result in changes of its resonant reflection angle, nanoparticles bound to the sensed analytes increase the shifts in deflection angles, leading to a considerably elevated detection sensitivity [21].

#### 6.1.3.3 Raman Scattering

The enhancement of optical signals by metal nanoparticles is also exploited at detection by Raman scattering [22, 23]. Especially, silver and gold nanoparticles are extremely effective at enhancing the scattering signal from adsorbed, Raman-active molecules. Thus, it was possible to detect different DNA target molecules by the use of DNA probes simultaneously labeled with both Raman-active ligands and nanoparticles by Raman spectroscopy [24]. The microarray format included capture DNA strands immobilized on a chip and, thereafter, incubated with target probes. Gold nanoparticles modified with Cy3-labeled, alkylthiol-capped oligonucleotides were used to monitor the presence of specific target DNA strands.

Initially, the nanoparticle probes were not visible to the naked eye, and no Raman signal was detectable. The authors assumed a lack of electromagnetic-field enhancement for the nanoparticles due to the large nanoparticle spacings compared with closely spaced gold nanoparticles that were shown to give a surface-enhanced Raman scattering (SERS) enhancement [25]. But, in contrast to the undeveloped particles, silver enhancement of the bound DNA-nanoparticle probes resulted in the growth of an Ag layer around each Cy3-labeled nanoparticle probe, thereby leading to large Raman scattering enhancements with an unoptimized detection limit of 20 fM target concentration.

#### 6.1.3.4 Electrical Detection

In addition to these versatile optical detection schemes metal nanoparticles offer the possibility for an electrical readout. Owing to their conductivity, it seems self-evident to use them as a conductive bridge between two electrical leads. This can be used in DNA detection schemes by immobilizing capture oligonucleotides in a gap between two electrodes and a subsequent labeling with gold nanoparticles. Möller et al. were able to hybridize complementary, gold-nanoparticle-tagged oligonucleotides to the surface-bound capture DNA between two microstructured electrodes [26]. An additional silver enhancement step makes the bound nanoparticles grow and come into contact, thereby bridging the gap. The resulting drop of resistance was measured by an integrated measurement system consisting of a 'DNA chip reader' with an embedded PC [27] (Fig. 6.3). The microstructured chip had 42 1  $\mu\text{m}$ -wide electrode gaps, each independently accessible and simultaneously read out. The system is transportable, autonomously working and therefore also suitable for readout outside the laboratory. It could detect 5  $\mu\text{M}$  of target DNA concentration. Park et al. have described a similar resistive system with which they could detect target DNA down to 500 fM as well as single-nucleotide polymorphisms with a selectivity of up to  $10^5:1$  without a thermal-stringency wash [28].

By depositing biofunctionalized nanoparticles on electrode arrays Campas et al. were recently able to measure the hybridization efficiency by amperometry [29]. They achieved significant differences in current density between complementary and mutated oligonucleotide sequences. Similarly, electrodeposition of enzyme-modified colloidal gold on electrodes provided a proof-of-principle concept for enzymatic multisensors.

#### 6.1.3.5 Electrochemical Detection

Other approaches used colloidal gold labels in novel, sensitive electrochemical sensors [30]. After oxidative gold metal dissolution under acidic conditions the resulting aqueous metal ions were detected by anodic stripping voltammetry (ASV). Dequaire et al. used disposable carbon-based electrodes and evaluated the method for a noncompetitive heterogeneous immunoassay of an immunoglobulin G with a detection limit of 3  $\mu\text{M}$  [30]. In addition, ASV has been assigned to an electrochemical DNA detection method [31]. The combination of sensitive gold(III) determination at screen-printed microband electrodes with the large number of gold(III) ions released from each gold particle allowed detection of as low as 5  $\mu\text{M}$  amplified

**Fig. 6.3.** Electrical detection of gold nanoparticle-labeled DNA. DNA strands ('captures') that bind the molecules of interest ('targets') are immobilized between microstructured electrode gaps on a chip. If any complementary target DNA is present, the target molecules, labeled with gold nanoparticles, will bind and form the starting point of subsequent metal enhancement steps. The resulting metal layer is detected by a

significant drop in electrical resistivity between the electrodes. (A) Gold electrodes 10  $\mu\text{m}$  wide were used to create gaps. (B) The zoom visualizes the details of one of the 1  $\mu\text{m}$  gaps on the silicon oxide substrate. (C) Overview showing the half-inch chip. (D) DNA chip socket of the paralleled readout system. (E) The portable DNA chip reader. (Modified after Ref. [27].)

DNA fragment. Both an advanced magnetic processing technique and a deposition of gold onto the immobilized gold labels increased the sensitivity of the system by forcing DNA duplex isolation and increasing the number of gold atoms for the oxidation, respectively [32]. The use of different nanoparticles (PbS, CdS, ZnS) with different redox potentials enabled Wang et al. to establish a multilabel system, where every nanoparticle species encodes a different DNA sequence and can be selectively identified by ASV [33]. Using voltammetry makes the integration of a higher number of probes on one substrate problematic. Although Ozsoz et al. did not address the question of microarray formats, their use of differential pulse voltammetry would be appropriate for direct simultaneous detection of many nanoparticle probes at arrayed microelectrodes [34].

#### 6.1.3.6 Gravimetric

Beside their advantageous optical and electrical properties, metal nanoparticles have a high specific mass that can be exploited in detection schemes based on gravimetric principles, as has been shown for both quartz-crystal-microbalances (QCMs) and oscillating microcantilevers. Extremely small mass changes at the oscillating surface cause characteristic changes in the frequency of nanomechanical resonator detectors.

Okahata et al. even reported binding kinetics of a protein to double stranded DNA immobilized on a QCM [35]. Metallic nanoparticles also enhance the sensitivity of gravimetric DNA sensors, up to a picomolar range, when using them as DNA labels [36]. A further increase, up to femtomolar sensitivities, was obtained either by hybridizing a second layer of nanoparticles to the first one [37] or by additional gold deposition on the nanoparticle labels [38].

Conversely, cantilever-based optical deflection assays were able to discriminate DNA single-nucleotide mismatches even without the need for external labeling. In these approaches the microcantilevers were functionalized with capture molecules. A subsequent biomolecule recognition reaction could be detected due to the induced deflection of the cantilever [39]. While hybridization of complementary target oligonucleotides resulted in net positive deflection, targets containing one or two internal mismatches caused net negative deflection. According to Thundat and colleagues, this cantilever approach can be adapted to high-throughput array formats providing distinct positive/negative signals for an easy interpretation of DNA hybridization. Moreover, Gimzewski and co-workers extended these oligonucleotide hybridization assays on individual cantilevers to cantilevers in an array [40]. The differential deflection of the cantilevers provided true molecular recognition signals despite the nonspecific responses of individual cantilevers. Beside the detection of oligonucleotide hybridization, the general applicability to biomolecular processes was demonstrated by monitoring molecular recognition between proteins as well.

## 6.2

### **Nanoparticles and their Biofunctionalization**

Colloidal nanoparticles differ from bulk material due to their large surface-to-volume ratio. Since inorganic nanoparticles show interesting – strongly size-dependent – optical, electrical, magnetic, and/or electrochemical properties, they offer many opportunities in biological applications. Some of these will be described subsequently. Reference [41] reviews the different physical characteristics of metal nanoparticles and their implementation in assays.

The intense optical absorption of metal colloids is due to the collective electronic (or plasmon) resonance and is defined by the nanoparticle material, size, and geometry. Consequently, not only the size but also their shape plays an important role.

## 6.2.1

### Types of Nanoparticles used for Biomolecular Detection

#### 6.2.1.1 Metal Nanoparticles

Metal nanoparticles are dispersions of a solid phase in a liquid phase, mostly as metal colloids with dimensions of nm to  $\mu\text{m}$  (Au [42], Ag [43], [44], Pt [45], Pa [46], Cu, Fe, and Hg [47]). The most important metal particles are gold and silver sols synthesized from metal salts. Gold particles are composed of a starting atom surrounded by a defined quantity of gold-atoms, magic numbers corresponding to the formula  $[10n^2 + 2]$  [8, 48], where  $n$  is the number of layers in the particle. The minimum size of these colloid particles is 13 atoms. Such particles are close to icosahedrons or dodecahedrons [49], approximating to spheres with increasing diameter.

#### 6.2.1.2 Core/Shell Particles

Metal core/shell nanoparticles also have interesting optical properties. Heterogenic bimetallic nanoparticles exhibit two plasmon resonances, appropriate to the electronic bands of the pure elements (of both the core and the shell metal phases) [49]. The optical properties of such nanoparticles are explained by the Mie theory for cladded particles [50, 51]. Compared with heterogeneous species, homogenous bimetallic nanoparticles, synthesized, for example, by alloying under laser irradiation, exhibit only one surface plasmon peak, which lies between the absorption bands of the pure metals [49]. Bimetallic (mostly heterogeneous) nanoparticles also play an important role in biomolecular detection when Raman-active ligands are used [24].

Furthermore, pure metal nanoparticles have some disadvantages concerning their chemical stability or when used in different solvents. To prevent particle coalescence, colloids can be coated with a dielectric shell, e.g. a silica shell. Liz-Marzán et al. have used silane coupling agents as surface primers to make the particle surface vitreophilic, followed by self-assembly of a hydrated silica monolayer [43]. Thus, the resulting silica surface enables the same bioconjugation strategies as for silica nanoparticles. This has been summarized recently by Drake et al. [52].

After surface modification the inert metal core/dielectric shell nanoparticles could be transferred into practically any solvent. The thickness of the optically transparent silica layer could be determined in a controlled way. Varying the silica shell thickness and the refractive index of the surrounding solvent allowed control over the dispersions' optical properties. For example, the intensity of the plasmon bands of such nanoparticles depends on the shell thickness. With increasing silica shell thickness, up to a defined size, the intensity of the plasmon band increased and, simultaneously, the absorption peak shifted to longer wavelengths (redshift) due to the increased local refractive index around the particles. However, above the defined layer thickness of 80 nm scattering becomes significant, resulting in a strong increase in absorbance at shorter wavelengths (blue-shift), which is similar to the properties of gold-free silica particles. The same results were caused by (bio-)polymeric adsorption onto the metal particle surface. The polymeric shell

also changed the geometric and dielectric parameters of the particles [53]. Moreover, the dependence of variations in extinction and light scattering spectra on the gold core diameter, the shell refractive index and thickness could adequately be described by the dipole approximation of the Mie theory.

Another type of nanoparticle composite consists of a metal shell encapsulating a dielectric core [54]. The optical properties of such monodisperse silica nanoparticles (so-called Stöber particles [55]) can be influenced by covering the particles with a thin, uniform metallic shell. Keeping the size of the dielectric core constant, the optical absorption shift is relatively sensitive to the shell thickness. Assuming a constant core/shell size ratio it depends on the absolute size whether the particles absorb or scatter light [56]. Implementation of such nanoshells in living tissue and application of near-infrared light can photothermally destroy the labeled cells [57].

#### 6.2.1.3 **Magnetic Nanoparticles**

Magnetic nanoparticles are mostly compounds with iron oxides ( $\text{Fe}_3\text{O}_4$ /magnetite and  $\gamma\text{-Fe}_2\text{O}_3$ /maghemite) and are, therefore, not pure metal particles. However, they are mentioned here because they are also powerful, versatile nanoscaled tools in biology and medicine. There are two types of magnetic particles: (1) so-called magnetic beads containing nm-sized iron oxide particles surrounded by a polymer-silica matrix and (2) pure metal oxide particles in the nm-range (real nanoparticles, strictly speaking). Suspensions of small ferrimagnetic single-domain iron oxide particles are called ferrofluids and can be used for medical applications if biocompatible. Functionalization of these magnetic beads or nanoparticles, respectively, enables the binding of protein or DNA and, therefore, their application in biomolecular detection and their potential use in medical diagnostics and therapies, e.g. in thermal tumor treatment (magnetic hyperthermia [58]) where only biocompatible magnetic nanoparticles are usable. For many diagnostic applications both magnetic beads and nanoparticles are usable. Thus, they are employed as contrast agents in magnetic resonance imaging (MRI) as well as in detecting biomolecular binding events by means of magnetic sensors. Magneto-resistive detection methods exploit the fact that an applied magnetic field, e.g. due to magnetic particles attached to the sensor, causes a shift in electric resistivity [59–62]. Additionally, the magnetic separation of biomolecules attached to magnetic beads is a standard laboratory method. Thus, Ho et al. employed antibody-presenting magnetic nanoparticles as effective affinity probes for selectively concentrating traces of target bacteria from sample solutions [63].

#### 6.2.1.4 **Quantum Dots**

Quantum dots are nanocrystals of cadmium chalcogenides (CdS, CdSe, CdTe), in the range of 200–10 000 atoms, that exhibit strongly size-dependent optical and electrical properties [64]. Irradiated with low-energy light of a broad, continuous excitation spectrum, semiconductor nanocrystals have a narrow, tunable emission spectrum, and, moreover, they are photochemically stable and therefore complementary, and in some cases perhaps even superior, to conventional fluorophores [65]. But, dependent on their size, the photoluminescence signal can consist of

the entire spectrum of visible light. This enables the excitation of different sizes of quantum dots at the same time and makes them suitable as luminescent probes for labeling of biological systems [4, 66, 67].

### 6.2.2

#### **Synthesis of Gold (Silver) Nanoparticles**

The method used most for the synthesis of gold (as well as other metal) nanoparticles is the reduction of metal salts by different reducing agents (organic acids [68], substituted ammonias [68, 69], formaldehyde [70], hydrogen peroxide, phosphorus [71], gases, protecting agents [72, 73], and electrical fields [74]. Gold colloids are mostly synthesized by the reduction of gold(III) salts, and, among these, the citrate reduction of  $\text{HAuCl}_4$  is the most common procedure [68], where sodium citrate acts both as a nucleating and reducing agent [47]. Initially, the citrate is oxidized to acetone dicarboxylic acid [49]. In the following step, gold ions become atoms by forming an intermediate complex and, thereafter, nucleation islands. The smallest island is composed of 13 gold atoms [75]. Further metal ions are reduced on the surface of such nucleation centers to give larger particles. The particle size (12–147 nm) is determined by the quantity of citrate ions [76]. The resulting polycrystalline, nearly spherical particles are polydispersed, showing a relatively uniform shape and homogeneous size distribution (standard deviations of 10–15%, depending on the particle diameter).

The stability of the citrate-reduced colloids is determined by the concentration of salt ions in the solution. A dielectric shell of charged ions keeps the particles apart, therefore stabilizing the solution against aggregation. Small changes in reaction conditions can make this shell partially unprotected, resulting in an irreversible coagulation of the colloid solution. By using different ligands during or after the synthesis the particles can be sterically stabilized (Section 6.2.3).

Another approach to synthesizing metal (gold) nanoparticles is the Brust–Schiffrin method, involving the phase transfer of a tetrachloroaurate complex from aqueous to organic solution, followed by reduction with sodium borohydride in the presence of a thiol-stabilizing ligand [72, 73, 77]. The resulting particles are smaller (1–3.5 nm) and more monodispersed than the citrate colloids.

Size control of gold nanoparticles by the use of different stabilizing agents depends on the ligand type and its properties [78]. For alkane thiol ligands the molar ratio of aurate to thiol influences the average particle size [79]. By using a multivalent alkane thiol stabilizer Yonezawa et al. obtained smaller, more monodisperse gold nanoparticles than with conventional monoalkanethiols, thereby enabling systematic size control with atomic precision [80].

### 6.2.3

#### **Biofunctionalization**

Colloidal metal particles can be modified either during or after particle synthesis. Similar to the formation of self-assembled monolayers (SAMs) on planar surfaces

(Section 6.3.1.1) the post-synthetic coupling of biomolecules to the particle surface occurs in various steps. First, the biomolecules bind through electrostatic interactions by displacing the surrounding citrate ions. Thereafter, a chemical bond between the ligand and the particle follows, e.g. a thiol-gold coupling.

#### 6.2.3.1 **Modification of Gold Nanoparticles with Oligonucleotides/DNA**

Oligonucleotides can be attached to metal nanoparticles in different ways. Since the resulting DNA-nanoparticle conjugates differ in oligonucleotide surface densities, the availability for hybridization to targets, and in the tendency to nonspecifically bind to surfaces, the attachment chemistry impacts significantly on their use in heterogeneous detection schemes [81]. Bioconjugate chemistry has been studied most intensively for gold nanoparticles. As they provide the simplest, most stable conjugation chemistry for oligonucleotides, we will focus on the biofunctionalization of colloidal gold (Fig. 6.4).

**Thiol, Di-, Trisulfide** Nuzzo et al. have shown that gold surfaces can be easily functionalized by free thiols and disulfides [82, 83]. Their adsorption studies of methanethiol and dimethyl disulfide showed a strong binding of both adsorbates to gold surfaces, with the bonding of disulfide being greatly favored, probably due to dissociation of the disulfide bond to give a stable surface thiolate. However, these oligonucleotide-gold conjugates lose activity as hybridization probes when soaked in solutions containing thiols, which displace the derivatized oligonucleotide from the gold surface. To overcome this drawback Letsinger et al. described a new steroid-cyclic disulfide anchoring group for binding oligonucleotides to gold surfaces [84]. The resulting nanoparticle conjugates kept their hybridization activity and were much more resistant to attack by a thiol than conventional gold conjugates that contain alkyl mono-thiol or acyclic disulfide linkers. The same authors subsequently reported that oligonucleotides connected to gold through three sulfur groups were even more stable than these dithiane conjugates, stabilizing gold particles even larger than 30 nm in diameter [85].

Gold nanoparticles are usually linked to oligonucleotides by a thiol at the 5' or 3' end of the oligonucleotide, leaving the nucleotides unobstructed for hybridization to their complements. However, dependent on oligonucleotide content, length, and coverage, DNA tends to adsorb nonspecifically to gold surfaces through the nucleotides, inhibiting hybridization [86, 87]. To prevent DNA surface adsorption, mixed monolayers of the thiol-derivatized probe and a spacer-thiol have been explored. On planar surfaces, mercaptohexanol (MCH) can orient the DNA perpendicularly and facilitate hybridization by displacing the non-covalent and nonspecific adsorption of thiolated DNA [88–90]. Park et al. considered MCH concentration and reaction time as a key to controlling the conformation changes of oligonucleotides attached to gold nanoparticles [91]. With increasing MCH concentration (1  $\mu\text{M}$ –1 mM) the electrophoresis mobility of the Au-DNA conjugates slightly decreased towards those of gold nanoparticles without DNA attached, but stabilized by BPS [bis(*p*-sulfonatophenyl)phenylphosphine dihydrate, dipotassium salt]. This result points to a stepwise loss of surface-bound oligonucleotides, which suggests that

**Fig. 6.4.** Scheme of the covalent attachment of oligonucleotides to gold nanoparticles by different linker groups: (A) alkyl-thiol, (B) multiple-thiol anchor, (C) steroid disulfide, (D) amine/succinimide, and (E) maleimide.

**Fig. 6.5.** Formation of oligonucleotide layers on gold nanoparticle surfaces. The conformation depends on the DNA molecule density on the surface. (A) At very low surface coverage, no steric interactions occur between strands on the surface. (B) For higher molecule densities, collisions will occur between the ends of neighboring oligonucleotides, restricting the possible strand orientations and forcing the DNA strands to “stand up”. (C) As surface coverage increases, the oligonucleotides approach their theoretical limit of a densely packed monolayer of “standing up” DNA strands. (Modified after Ref. [92].)

reaction with concentrated MCH displaces the DNA molecules from the nanoparticle surface. Changes in effective size ( $D_{\text{eff}}$ ) of the Au-DNA conjugates were quantified by the Ferguson plot method. The obtained drop in  $D_{\text{eff}}$  confirmed the loss of surface-bound oligonucleotides with higher MCH concentrations ( $>0.1$  mM). However, MCH led to an increased hybridization capacity, presumably due to better availability of the oligonucleotides to base pairing. In addition, Rant et al. characterized the conformation of oligonucleotide layers on Au surfaces by fluorescence investigation [92] (Fig. 6.5).

Although thiols and mercaptoalkyl residues can be incorporated into DNA simply by adding the suitable phosphoramidite modifier through solid-phase DNA synthesis [93], thiol- or disulfide-modified DNA is commercially available.

**Other Coupling Strategies (Phosphine, Maleimide, Amine/Succinimide, Lysine)** In 1969, McPartlin et al. were the first to describe very small gold clusters that were passivated by organic groups (phosphines). This undecagold contains a gold core of 11 atoms, with the gold atoms on the surface attached covalently to phosphine groups [94]. By altering the organic groups the clusters were made water soluble [95] and derivatized to link to proteins [96–98]. Larger gold clusters were subsequently developed, showing better visibility at high magnification by transmission electron microscopy (TEM) and increased enhancement with silver [98]. These 1.4 nm-sized gold nanoparticles ( $\text{Au}_{55}$ ) are commercially available bearing a single activated functional group (Nanogold<sup>TM</sup>, Nanoprobes Inc.). They have been reacted with proteins or appropriately modified oligonucleotides to form 1:1 nanoparticle:biomolecule conjugates. Using a maleimide group or an *N*-hydroxysuccinimide, the gold clusters can react specifically with thiols or amino groups, respectively [100]. Thus,  $\text{Au}_{55}$  clusters passivated with a phosphine ligand shell, which is functionalized with a single reactive maleimide group, were used to prepare DNA–gold conjugates from disulfide-modified and thiolated oligonucleotides [101, 102].

As well as thiolated oligonucleotides, Ozsoz et al. used amino-modified oligonucleotide probes to covalently attach to gold nanoparticles bearing carboxy-groups [34]. After modifying the gold colloids with L-cysteine, standard activation methods

converted the carboxylic acids into succinimide esters, which allow the formation of a peptide bond with amino-modified DNA.

DNA–nanoparticle conjugates are also an interesting alternative “bottom-up” fabrication technology to produce nanowires using long DNA molecules as templates. Due to the relatively poor intrinsic electric conductivity of DNA, metallization is required and can be achieved by nanoparticles. An *ex situ* approach uses the electrostatic interaction between positively charged particles and the negatively charged DNA phosphate backbone to attach lysine-capped gold colloidal particles to DNA double-helices [103, 104]. However, Harnack et al. discovered that negatively charged tris(hydroxymethyl)phosphine (THP)-capped gold nanoparticles also bind densely to DNA [105]. Although the binding mechanisms of THP-gold nanoparticles to DNA, and the factors controlling the binding efficiency, were still unclear, the authors expected hydrogen-bonding interactions to be important since each THP ligand provides three hydroxyl groups that can serve as either OH donors or O acceptors. Cooperative, THP-gold conjugates preferably adsorb to hydrophilic areas such as DNA molecules.

Supporting these observations, but in contrast to conventional wisdom, Li and Rothberg also showed that single stranded DNA (ss-DNA) adsorbed on negatively charged gold nanoparticles whereas double stranded oligonucleotides (ds-DNA) did not [106]. They attributed these different electrostatic propensities to the flexible structure of ss-DNA. Single strands can uncoil sufficiently to expose their bases so that attractive Van der Waals forces cause sticking to the gold. However, the duplex structure of ds-DNA does not permit the uncoiling needed to expose the bases. Hence, repulsion between the negatively charged phosphate backbone and the adsorbed citrate ions dominates so that ds-DNA will not adsorb. Moreover, they demonstrated that the adsorption rate of ss-DNA to gold nanoparticles is length and temperature dependent [107] and, additionally, can effectively stabilize the gold colloid against salt-induced aggregation. Exploiting these observations, they designed a simple, fast colorimetric hybridization assay that does not require functionalization of the gold, the probe or the target DNA, but was able to easily detect single base mismatches.

### 6.2.3.2 Modification of Gold Nanoparticles with Proteins

Proteins bind to gold colloids for three main reasons: sulfur bonding (cysteine and methionine), charge (lysine), and hydrophobic attraction (tryptophan) (Fig. 6.6). Generally, this conjugation is irreversible, but long-term storage at high pH or in a buffer containing surfactant may cause some proteins to dissociate.

Initially, the coupling of gold nanoparticles to proteins was used to visualize cellular structures by electron microscopy because of the high electric densities [108], as shown for antibodies and lectin [109, 110]. More recently, Ho et al. reported a method for fabricating biofunctionalized nanoparticles by attaching human immunoglobulin (IgG) on their surfaces through either electrostatic or covalent binding [63]. By selective binding of these IgG-presenting gold nanoparticles to bacterial cell walls they were able to study the interactions between IgG and pathogens by transmission electron microscopy.

**Fig. 6.6.** Schematic summary of functionalization approaches of proteins to gold nanoparticles. Proteins bind to the particle surface by (A) sulfur bonding, (B)

charge interactions, and/or (C) hydrophobic attractions (white: hydrophilic, black: hydrophobic regions), dependent on the amino acids exposed to the particle surface.

The first nanoparticle labeling of genomic nucleic acids was applied using the biotin/streptavidin biorecognition reaction [111].

Studying the association of proteins onto gold particles at various protein concentrations yield typical saturation curves [14]. The number of bound molecules depends on the molar concentration of the protein free in solution, the number of possible adsorption sites and inversely correlates with the equilibrium constant for dissociation of protein from particles. The applicability of Scatchard analysis to the formation of protein–gold complexes indicates a finite number of adsorption sites, leading to saturation, which is best explained by assuming a monomolecular shell of protein around the particles.

In the past, colloidal gold–protein complexes were used extensively in immunocytochemistry as secondary reagents for the localization of antigens. Horisberger et al. examined the adsorption of protein A onto 11.2 nm-sized gold nanoparticles, regarding the process and extent of the adsorption, the optimal conditions of preparation, and the stability of such gold–protein complexes [112]. The adsorption isotherm was independent of pH at low protein coverage. However, in the presence of a large excess of protein A, the highest coverage was obtained at pH 5.1, the isoelectric point of the protein. Furthermore, the extent of protein association onto gold particles also varied with the different protein coverage and decreased with increasing coverage. The obtained complexes were stable under storage at low but not at high protein coverage (up to 12 and 26 molecules adsorbed per particle, respectively). Beside use in immunoassays by coupling antibodies to colloidal gold, the streptavidin–biotin system [113] offers further possible applications (for a review see Ref. [114]). The tetravalent protein streptavidin can bind the small biomolecule biotin with high sensitivity and affinity. Thus, streptavidin-functionalized nanoparticles can be coupled easily to other molecules modified by biotin. By attaching biotinylated oligonucleotides to streptavidin-functionalized particles, DNA–nanoparticle conjugates have been formed [115], enlarging the recognition capacity of streptavidin by a highly specific binding site for the complementary DNA sequence. This offers the opportunity to detect DNA–DNA hybridization events

by gold nanoparticles. Furthermore, Niemeyer and Ceyhan have described a DNA-directed functionalization of colloidal gold with protein [116]. Thereby, oligonucleotide-modified gold nanoparticles were coupled to complementary DNA–streptavidin conjugates, which also have been functionalized with biotinylated antibodies. The bioactivity of the resulting protein–gold conjugates was proved in an immunoassay.

Recently, Levy et al. have demonstrated a general approach to the synthesis of extremely stable gold nanoparticles using a pentapeptide ligand [117]. Based on protein folding considerations, the basic design principle aimed at a ligand that can readily attach to the surface of the gold particle and form a well-packed passivation layer with a hydrophilic terminus. The resulting pentapeptide thiol capping ligand was able to convert citrate-stabilized gold nanoparticles into stable, water-soluble nanoparticles with chemical properties comparable to those of proteins. The stability of different particle preparations conferred by ligands of various peptide sequences has been evaluated by exposing the particles to increasing salt concentrations until precipitation occurred. This stability depended on the ligand length, hydrophobicity, and charge.

In contrast to bioconjugation after nanoparticle synthesis, direct conjugation methods eliminate the need for intermediate stabilizing agents or dense passivation that minimizes the free surface area for interactions with the desired adsorbates and often tends to aggregation with even mild processing. Burt et al. were able to produce water-soluble gold nanoparticles less than 2 nm in diameter directly conjugated to bovine serum albumin (BSA) protein without application of high temperature or high pressure. They obtained a near-quantitative yield of well-dispersed, protein-conjugated gold nanoparticles that remain stable indefinitely in solution under ambient conditions [118].

#### 6.2.3.3 Biofunctionalization of other Metal Nanoparticles

Oligonucleotides have been less successfully attached to nanoparticles made from materials other than gold (such as Ag, Cu, Pd, Pt), probably because of the weaker bond energies between sulfur and the other metals. Thiols possibly bound to these surfaces are readily displaced by oxidants or other competing ligands (including the DNA bases). A thin gold shell grown around metal cores of different materials and shapes can improve biomolecule attachment, retaining the characteristics of the core material, as shown for core-shell Ag/Au nanoparticles by Mirkin's group [115].

#### 6.2.4

#### Biological Applications of Gold Nanoparticles

Due to their binding specificity as well as their large variety of functional groups, biomolecules (nucleic acids, proteins) are able to offer new opportunities for the functionalization of nanoparticles. Furthermore, efforts have been made to combine the intrinsic opportunities of proteins, e.g. optical, catalytic, mechanical or switchable properties, with the specific features of nanoparticles.

Gold nanoparticle-oligonucleotide-conjugates are of great interest since complementary DNA base pairing makes them specifically addressable. This can be used for biomolecular detection schemes as well as for organizing supramolecular nanostructures. It also offers versatile applications in the field of biosensors, disease diagnosis, gene expression, and molecular nanotechnology [8]. There are two pioneering strategies for the functionalization of gold nanoparticles with oligonucleotides. In 1996, Mirkin et al. used short DNA molecules as a linker between 13 nm-sized particles, resulting in macroscopic assemblies. The DNA attached to the gold nanoparticles remained accessible to hybridization with complementary DNA in a sequence-specific but reversible manner [1]. Conversely, DNA can be used as a template to bind small gold nanoparticles on a single oligonucleotide strand [2]. Furthermore, there are other strategies for forming supramolecular aggregates, e.g. semi-synthetic conjugates by self-assembly of nucleic acids, inorganic nanoparticles, and proteins such as streptavidin [119].

### 6.3

#### Substrates and their Biofunctionalization

Oligonucleotides and other biomolecules cannot be coupled directly to the surface silanol groups of silicon oxide or glass substrates. Therefore, the surface must be functionalized with a group that can be used either to initiate oligonucleotide synthesis or to which the pre-synthesized capture oligonucleotides can be attached. In principle, there are two means of obtaining substrates that can bind biomolecular capture probes: (1) nearly monomolecular thin films and (2) nanoporous gels (Fig. 6.7). The first method provides binding sites two-dimensionally, whereas the latter ones form 3D arrangements. The advantage of impermeable, monomolecular binding layers over nanoporous membranes/gels is that there is no need for diffusion into pores, i.e. capture and target molecules can access the probes immediately. This enhances the rate of capture probe immobilization as well as hybridization/binding rates, especially for extended molecules and/or labels that would be influenced by steric hindrance. However, 3D nanoporous gels yield a

**Fig. 6.7.** Strategies of substrate biofunctionalization: (A) functional planar interfaces and (B) microscaled reaction volumes (nanoporous hydrogels). Inset: nanoparticle-labeled oligonucleotide strands immobilized in the gel.

largely enhanced surface area and, therefore, a higher capacity for binding of capture and target probes, leading to enhanced signal levels.

### 6.3.1

#### Molecular Thin Films

##### 6.3.1.1 Self-assembly Monolayers

Adsorption of organic thin-films enables the biofunctionalization of planar surfaces. Typical approaches are either Langmuir–Blodgett (LB) techniques or a spontaneous organization of molecules into stable, well-defined structures (self-assembly). Self-assembled monolayers (SAMs) are widely used, highly ordered monomolecular films that spontaneously form on surfaces by chemisorption. These 2D monolayers consist of oriented molecules containing a head group that is reactive towards the surface. The alkyl chain usually influences the physico-chemical properties and stabilizes the SAM by intermolecular interactions, whereas the tail groups define the binding properties of the layer to further possible ligands. Compared with the similar LB films, in SAMs the ligand covalently binds to the surface, resulting in a very strong bonding. Several systems give SAMs, e.g. organosulfur compounds on metal surfaces or carboxy groups on metal oxides [120, 121].

Exposure of gold surfaces to alkane-thiol solutions leads to the self-assembly of these molecules. The resulting organic ultrathin film can be monitored by surface plasmon resonance spectroscopy (SPRS). Peterlinz and Georgiadis introduced a novel two-color SPR method, with which they obtained both film thickness and film dielectric constant and studied the chain length- and concentration-dependent kinetics of film formation in different solvents. Self-assembly in ethanol consists of three distinct kinetics steps, whereas the formation in heptane can be described with a single-step Langmuir adsorption model [122]. In ethanol, the results were most consistent with a film formation mechanism involving adsorption of both chemisorbed and physisorbed molecules. Expanding their SPRS studies the authors examined the formation kinetics for a two-component monolayer film containing thiol-modified single strand DNA (ssDNA including a hexamethylene linker) as well as mercaptohexanol [123]. After adsorbing HS-C6-ssDNA, exposure to an aqueous solution of mercaptohexanol results in a very rapid mercaptohexanol adsorption followed by a slow desorption of HS-C6-ssDNA. The final coverage of thiol-tethered DNA with mercaptohexanol diluent was estimated as  $5.2 \times 10^{12}$  HS-C6-ssDNA  $\text{cm}^{-2}$ . This corresponds to coverage densities described elsewhere [124–126]. Coverage versus time data calculated from the two-color SPR best fitted those of a model that accounts for adsorption, desorption, and diffusion (ADD) of the adsorbate, although this model predicts a saturation coverage of  $1 \times 10^{14}$  molecules  $\text{cm}^{-2}$ . The adsorption and hybridization kinetics of surface-bound thiolated ssDNA hybridized to fully complementary ssDNA were remarkably similar for these two different interfacial binding processes. The occurrence of sequence-specific hybridization was confirmed by SPRS melting studies. The amount of surface-immobilized duplexes differed only slightly from that for the same du-

plexes in free solution. A hybridization coverage of about one-third of that for the adsorption accounts for a loss of some adsorbed HS-C<sub>6</sub>-ssDNA during rinsing and mercaptohexanol-mediated desorption as well as for the hybridization efficiency.

The effect of DNA length and the presence of a thiol anchoring group on the assembly of oligonucleotides at gold surfaces was investigated by Steel et al. [127]. The thiol-anchoring group strongly enhanced oligonucleotide immobilization. Adsorbed thiol-ssDNA oligonucleotides shorter than 24 bases tended to organize in an end-tethered configuration, for which the surface coverage is largely independent of oligonucleotide length. However, for strands longer than 24 bases, the surface coverage starts to decrease considerably with probe length, presumably corresponding to a less ordered arrangement of DNA chains. Furthermore, Shchepinov et al. investigated the influence of steric factors on the hybridization of nucleic acids to oligonucleotide arrays [128]. They used spacer molecules to reduce steric interference of the support on the hybridization behavior of immobilized oligonucleotides. The optimal spacer length was determined to be at least 40 atoms, resulting in up to a 150-fold increased hybridization yields. Beyond this, steric hindrance can also be a problem if the surface-bound oligonucleotides are too close to each other. The highest hybridization yields were given for surfaces containing about 50% of the maximum oligonucleotide concentration. A further important factor influencing the hybridization efficiency is the base composition of the reacting oligonucleotides, owing to the lower stability of A:T versus G:C pairs. Southern et al. described the mechanism of duplex formation as a process that starts with the formation of a transient nucleation complex from the interaction of very few base pairs [129]. Mismatches close to the centre of an oligonucleotide have a strongly destabilizing effect on the duplex, whereas mismatches at the end are less destabilizing and thus more difficult to discriminate.

However, organosilicon derivatives on silicon oxide and glass are the most important for biological applications – and therefore we will focus on these.

Since all the standard surface modifications require silanol groups, the absolute number and relative distribution of surface hydroxyl (silanol) groups is important [130]. By varying the concentration of silanol groups it is possible to substantially change the properties of such a surface. Zhuravlev has studied the surface concentration of hydroxyl groups (silanol number  $\alpha_{\text{OH}}$ ) for a large variety of amorphous silicas [131]. By using the deuterio-exchange method with mass spectrometric analysis he estimated a silanol number of about 5.0 OH groups per nm<sup>-2</sup> (corresponding to  $5 \times 10^{14}$  cm<sup>-2</sup>), independent of the origin and structural characteristics of the fully hydroxylated surfaces, and considered the value as a physicochemical constant. However, preliminary vacuum treatment within the range from 200 to 1100 °C significantly decreased the concentration of hydroxyl groups ( $\alpha_{\text{OH}} < 0.15$ ), pointing to strong dehydroxylation of the surface.

Furthermore, the coating morphology, including silane layer thickness, density, and the orientation of the surface molecules, strongly depends on the amount of water the solvent contains [130]. Once the surface offers functional groups for subsequent biomolecule coupling, there are different strategies for covalent attachment of DNA (or proteins) to glass surfaces to build microarrays, as described in Ref. [132]. To enable molecular interactions with other biomolecules (e.g. hybrid-

**Fig. 6.8.** Surface modification with silanes for DNA attachment. (A) Direct binding of amino-modified DNA by epoxy-groups of 3-glycidoxypropyltrimethoxysilane (GOPS). (B) Amino-attachment chemistry of 3-

aminopropyltriethoxysilane (APTES). The binding of amino-modified oligonucleotides works indirectly by the bifunctional crosslinker 1,4-phenylenediisothiocyanate (PDC) [135].

ization) the immobilized capture probes should be fixed at their extremities. Therefore amino- or carboxy-modified DNA molecules are normally used, requiring adequate functionalized substrate surfaces. Consolandi et al. have described two robust procedures for oligonucleotide microarray preparation, including glass functionalization with appropriate silanes (Fig. 6.8), a coating step using polymers, and a surface activation step to allow for the attachment of amino-modified oligonucleotides [133]. These chemical platforms showed an overall high loading capacity and availability to hybridization against targets, a good uniformity, resistance to consecutive probing/stripping cycles, and the possibility of performing enzymatic reactions.

Recently, Martin-Palma et al. have presented a novel biofunctionalization technique for the deposition of amine groups on different surfaces [134]. The proposed activation method induced amino-group fixation on the surface of materials ranging from semiconductors to metals and insulating materials. The reactivity of the functionalized surfaces could be determined by using a fluorescent reagent that specifically reacts with amine groups.

### 6.3.1.2 Optimization of Gold Nanoparticle-based Microarrays for DNA Detection

However, substrate modification with silanes (as a prerequisite for capture DNA binding) often leads to inhomogeneous surfaces and/or non-specific binding of the labeled DNA. For that reason, Fritzsche and co-workers examined different cleaning strategies as a prerequisite for substrate functionalization, characterizing

two different surface modification methods with silanes so as to provide functional groups for covalent attachment of amino-modified DNA [135]. To reduce non-specific binding of gold-tagged DNA molecules, different blocking strategies were examined, especially those for nanoparticle labeling. The two examined silanes differed in their DNA binding homogeneity, maximum signal intensities, and sensitivity. Non-specific gold binding could be blocked by treatment in 3% bovine serum albumin (BSA). Another approach to characterizing surface modification methods by silanes employed atomic force microscopy (AFM) [136]. After silanization of the silicon oxide substrate, parts of the surface were covered by an elastomeric mask and then treated with oxygen plasma, leading to damage of the silane layer. AFM characterization of the surface (Fig. 6.9) revealed a height difference of  $\sim 1.8$  nm, which can be attributed to the thickness of the silane layer.

### 6.3.2

#### Nanoporous Gels

As well as glass or silicon surfaces, organic polymers offer another interesting option for the immobilization of nanoparticles. A higher loading capacity can be obtained by using thick layers consisting of a 3D network.

**Fig. 6.9.** DNA immobilization using APTES surfaces. A step in an APTES surface to measure the layer thickness was fabricated as follows: (A) parts of the silanized surface were covered by an elastomeric mask and thereby protected against damage by subsequent

oxygen plasma. (B) The resulting step of about 1.8 nm is visible in the scanning force micrograph and represents the height of the silane layer. (Modified after Ref. [136] with permission of Oxford University Press.)

Since the first introduction of solid-phase synthesis on an organic polymer support (2% crosslinked polystyrene [137]), new biomaterials with polyethylene backbone structures have been developed. These materials are characterized by improved hydrophilic/hydrophobic properties as well as a good biocompatibility. Another important feature of these polymers is the resistance to standard solvents and their good swelling properties [138].

In addition to other applications the polymers can be used as beads for combinatorial synthesis resins such as Tentagel™ [139, 140], polyethylene glycol–polystyrol (PEG-PS) [139] and polyethylene glycol–polyacrylamide copolymers (PEGA) [141]. Furthermore, polymers suitable for solid-phase synthesis have been micropatterned by spinning-on the pure monomers without functionalization, followed by light-induced polymerization [142]. More recently, Amirgoulova et al. described polymer coatings based on PEG for the study of immobilized biomolecules [143]. The crosslinked, star-polymer derived surfaces not only allowed reversible protein unfolding and refolding but also interacted negligibly with the immobilized proteins.

While preparing the polymer, bacteria cells [144] as well as proteins [145, 146] can be enclosed for different microfluidic reactors and for biochemical reactions, respectively. Although in these processes the enzymes and cells were non-covalently bound at the matrix of the polymer, they were restrained/prevented sterically from leaving the gel.

Bieber and co-workers were able to immobilize *Salmonella* antibodies in a 3D polymer network based on acrylamide derivatives and polyethylene linkers [147]. To extend this strategy the applied polyethylene glycol diacrylates and bisacrylated bis-diamino polyethylene glycols ( $M_r = 4000, 6000, \text{ and } 8000$ ) were functionalized by using hydroxy acrylate. Thus it was possible to bind biomolecules covalently instead of simply enclosing them in the polymer. Additionally, both the network structure (e.g. width of the meshes) and the functionality of the synthesized polymer could be adapted by an adjustable crosslinking reaction and the specific loading with functional groups, respectively. The resulting loading capacity of these spaces of biorecognition reactions were up to  $1000\times$  higher than those of plain 2D surfaces.

Before their immobilization by covalent binding in the nanoporous gel the biomolecules should be tested for their ability to penetrate coats of different hydrogels. A simple possibility is to use gel electrophoresis primarily employed for the separation and purification of DNA and proteins [148] (Fig. 6.10).

The investigated gels were loaded with a protein standard mixture and treated with sodium dodecyl sulfate (SDS), which binds to the amide groups in the protein. Thus, the protein becomes negatively charged, in dependency of the length of its amino acid chain. Application of an electric field forces the molecules through the gel with different electrophoretic mobility due to their different electric charge, which is proportional to the size of the molecule. Higher polymer concentrations and smaller monomers yield a 3D network with tighter meshes. Larger molecules are, therefore, unable to penetrate into the gel.

In addition to the immobilization of biomolecules on functionalized surfaces,  $10\ \mu\text{m}$ -thin coats of functionalized spots of polyethylene glycol-based polymers

**Fig. 6.10.** (A) Electrophoresis is a rapid method for separating biomolecules according to their charge and molecular size/weight. When exposed to an electric field, biomolecules in the electrophoresis gel move towards one of the electrodes in a manner that depends on the molecule's charge and molecular size and on the size of the gel pores/meshes. Thereby, sodium dodecyl sulfate (SDS) gel electrophoresis is a rapid qualifying and quantifying method for proteins that can be separated only by their molecular weights. SDS binds to hydrophobic domains of proteins, masking their individual charge differences. SDS-protein complexes have a negative charge and can be size-separated since the resulting charge of the complex is proportional to the molecular weight of the protein. During separation, SDS-protein complexes are attracted to the anode and

separated by enforcement through the porous gel structure, which allows small proteins to move very fast, whereas larger molecules show a significant decelerated mobility. (B) This principle can be utilized to characterize the pore size of nanoporous gels. A mixture of proteins of known size and mass (116.0, 66.2, 45.0, 35.0, 25.0, 18.0, and 14.4 kDa) was driven by an applied electric field into two different gels. A standard 12% polyacryl amide gel (A) leads to certain mobility and a complete separation of the mixture. (C) Under similar conditions regarding voltage and time, a 12% poly (bisacryl polyethylenglycol<sub>4000</sub>) gel shows significantly different results: The proteins move much more slowly, and fewer bands are observed. This is because molecules above a certain threshold size become stuck in the gel, resulting in a band consisting of the remaining larger molecules.

(0.5–2 mm in diameter) have been prepared on glass substrates. These functionalized arrays are easy to use and suitable for commercial spotting systems. After activation of the glass supports and their modification with acrylsilane the monomer solution, containing a photo-initiator, was coated. To generate the spots ultraviolet radiation was applied through a mask, leading to polymerization at the exposed areas. At the non-exposed areas, unreacted monomer solution was rinsed off after polymerization had finished. Thereby, the loading of the hydrogel is influenced by the ratio of the different functional groups in the monomer solution. In subsequent steps the prepared hydroxy-functionalized spots were transformed into carboxylic acids and active esters, which can react with amino-modified, fluorescence-labeled DNA. Finally, the oligonucleotides are bound covalently at the polymer matrix and are then qualitatively and quantitatively detectable by the fluorescent group (Fig. 6.11).

**Fig. 6.11.** Binding of fluorescence-labeled DNA molecules in a nanoporous hydrogel demonstrated by fluorescence microscopy. The gels were prepared with different hydroxy acrylate concentrations, (a) 0, (b) 1 and (c) 10 mM, leading to different concentrations

of hydroxy groups in the gel network and, therefore, different binding capacity of the biomolecule/DNA loading. The area-related loading capacity of these reaction spaces is up to 1000× higher than for plain 2D surfaces.

#### 6.4 Outlook

The detection and characterization of bioactive molecules represents a field of great importance for various aspects of our daily life, such as health management, food quality control, forensic, or environmental protection. Further development aims to increase the sensitivity and specificity of the assays; other important parameters are the robustness of the methods and their mobility to enable measurements outside dedicated laboratories and at the point of application. Thin molecular layers on solid substrates with nanometer dimensions are a key component of promising approaches in this field. Further developments aim for even simpler read-out schemes (as demonstrated by metal nanoparticle-based assays), label-free assays, and handheld instrumentation to realize visions such as point-of-care diagnostics.

# Conjugation of Nanomaterials with Proteins

*Mohammed J. Meziani, Yi Lin, and Ya-Ping Sun*

### 7.1

#### Introduction

The coupling of biomolecular entities and materials at the nanoscale has the potential to revolutionize many fields of science and technology, potentially having a significant impact on current biomedical technologies, nanoelectronics, and related areas [1–9]. Because nanoparticles and biomolecules typically have the same nanometer length scale, they are natural companions in hybrid systems. The availability of various nanostructures, such as semiconductor and metal particles and carbon nanotubes, with controlled properties at the nanoscale makes them extremely attractive candidates for use in biotechnological systems. These nanostructures possess strongly size-dependent optical, electrical, magnetic, and electrochemical properties [1–9]. In addition, simple modifications of these nanostructures, e.g. to their surface layer for enhanced aqueous solubility, biocompatibility or biorecognition, make them better suited for integration.

In the early stages, nucleic acids were preferentially investigated in the functionalization of nanostructures because they are more readily available by synthetic chemical means and more adaptable than proteins [10, 11]. Recently, significant progress has been made in extending the adaptability of nanostructures with proteins [1, 2, 12–22]. Proteins are involved in almost all biological processes and are employed in a wide range of forms because of their excellent functional specificity. Protein-based nanostructures are expected to offer some additional advantages and play a key role in the development of multifunctional materials and devices for biotechnological applications [1, 2, 12–22]. For example, nanostructures provide numerous complementary systems with a wide range of free energies of association. Also, methods for working with these systems are known from standard procedures in biochemistry and molecular immunology. Indeed, protein recognition chemistry has been widely applied in diagnostic testing. Future investigations are predicted to focus on the generation of altered protein building blocks for the self-assembly of novel biological reaction compartments using today's powerful techniques of molecular biology. Mutagenesis and protein engineering will allow the design of recombinant proteins that have optimized recognition capabilities for

the assembly of distinctively shaped superstructures and have appropriate amino acid residues for the effective nucleation of organic and inorganic nanomaterials [1].

The conjugation of nanomaterials with proteins is a very broad field, especially in the light of recent advances in the development of various nanomaterials. In this chapter, we focus on nanomaterials based on nanoscale semiconductors and metals and on carbon nanotubes. Other significant classes of nanomaterials not covered here include polymeric nanoparticles and related nanostructures [23–27], fullerenes and derivatives [28–33] etc., which are by no means less important. Despite our interest in these other classes [34–39], it is probably better to cover them elsewhere. In the present chapter, we first provide an overview of current and emerging approaches in the coupling of metal and semiconductor nanostructures with proteins and their assemblies in different architectures. We then report recent achievements in the use of supercritical fluid processing technology as an alternative process. We also highlight recent successes in the conjugation of carbon nanotubes with proteins and the mechanistic issues involved with nanotube–protein interactions. Finally, we briefly summarize the challenges and perspectives in this interdisciplinary field.

## 7.2

### Coupling of Inorganic Nanoparticles with Proteins

#### 7.2.1

##### Chemical Functionalization Methods

Wet-chemical preparation of conjugated nanoparticles involves mixing a protein with modified nanoparticles in solution. The modification of nanoparticles prior to mixing is usually by chemical functionalization with a linker. Here, the linker serves three functions: (1) it converts the hydrophobic nanoparticles into hydrophilic species to enable them to be transferred into aqueous solution, (2) to stabilize the nanoparticles to avoid their uncontrolled particle growth or agglomeration and (3) it has to recognize the protein (Fig. 7.1). The linker has to be chosen carefully for every nanoparticle material. The functional coupling groups in proteins are either available in the native form or incorporated by chemical means or by genetic engineering.

Figure 7.1 shows examples of chemical interactions used for the coupling of nanoparticles with protein molecules. Coupling to the particle surface is frequently performed through citrate, thiol, and phosphane groups [1, 2]. With a labile capping layer, such as citrate, proteins can be linked directly with a metal particle by exchange reactions with stronger binding ligand. This method has been applied in the coating of colloidal gold with thiol-containing proteins, such as immunoglobulins (IgG) and serum albumins, which have cysteine residues that are accessible for heterogeneous interphase coupling [40, 41]. Gold and silver nanoparticles stabilized by citrate ligand have been functionalized with IgG molecules at a high pH,

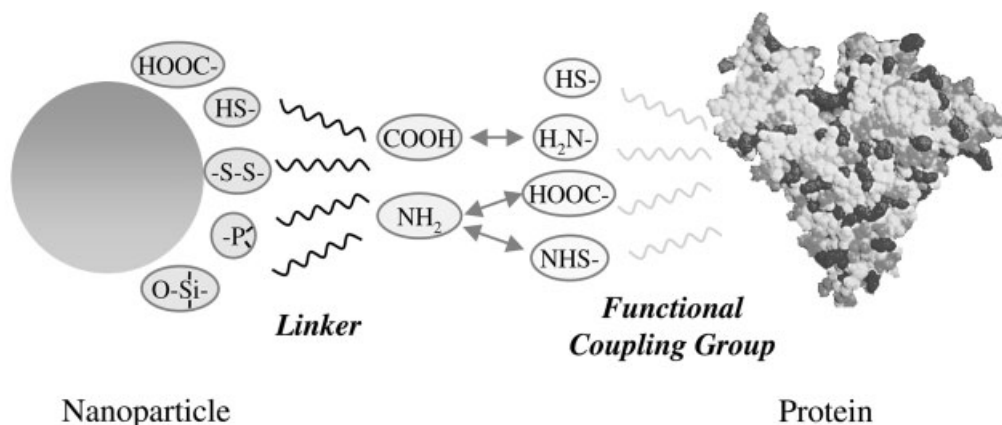

Fig. 7.1. Schematic representation of functional groups used to couple nanoparticles with protein species.

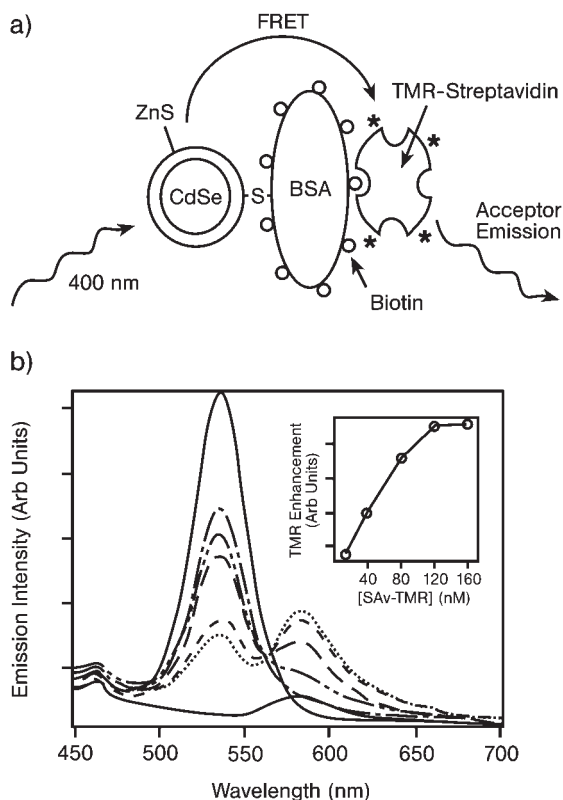

slightly above the isoelectric point of the citrate ligand [40]. Coupling was carried out by an effective binding between the negatively charged citrate groups of the colloids and the positively charged amino acid side chains of the protein. Other kinds of proteins were similarly coupled through electrostatic interactions [42–47], e.g., the directed adsorption of heme-containing redox enzymes at citrate-stabilized silver nanoparticles [42–44]. In a different approach, nanoparticles were also coupled to proteins by using linkers based on thiols or disulfides and phosphane ligands, which possess terminal carboxy, amino, and maleimide groups [48, 49]. Here the coupling is achieved by means of carbodiimide-mediated esterification and amidation or reaction with thiol groups. This strategy was routinely used for histological purposes by coupling proteins with well-defined 0.8 nm undecagold nanoclusters stabilized with arylphosphanes [48]. Cyclic disulfide linkers for coupling showed a better affinity to nanoparticles, and these conjugates are more stable towards ligand exchange than those prepared with a single thiol group or acyclic disulfide units. The high stability is probably a result of attaching the ligands to the nanoparticles through two sulfur atoms. These disulfide linkers have been used in generating gold nanoparticle–oligonucleotide conjugates as probes for recognizing specific sequences in DNA segments and as building blocks for assembling novel structures and materials [50].

The above-mentioned ligands have also been exploited to impart biocompatibility and bioactive functionalities to semiconductor nanoparticles through surface modification with biomolecules [10, 11, 16, 51–58]. There has been significant progress in the understanding of specificity and binding capabilities of proteins toward nanoscale semiconductor particles. [10, 11, 16, 51–64]. Globular protein bovine serum albumin (BSA) has been one of the widely used proteins. For example, BSA was used to form a bioconjugate with luminescent CdTe, CdS and CdSe nanoparticles, often referred to as quantum dots (QDs) [56, 61]. Such QDs are character-

ized by broad excitation and size-tunable photoluminescence spectra with narrow emission bandwidths that span the visible spectrum, allowing simultaneous excitation of several particle sizes at a single wavelength. They also have exceptional photochemical stability and relatively high quantum yields when used as luminescent probes in biological labeling [17–22]. Mamedova et al. [56] generated bioconjugates of BSA protein with cysteine-capped 2 nm-sized CdTe nanoparticles by using glutaric dialdehyde as a crosslinking agent. Such conjugation was reported to increase the luminescence intensities of the CdTe nanoparticles, which was attributed to the possible presence of resonance energy transfer from the tryptophan moieties in BSA to the CdTe nanoparticles. In a different study by Willard et al. [61] CdSe-ZnS core/shell particles of  $\sim 3$  nm were coated by chemisorption to biotinylated BSA, which was specifically attached to tetramethylrhodamine-labeled streptavidin (Sav-TMR) (Fig. 7.2). In this conjugate, the TMR fluorescence caused by fluorescence resonance energy transfer (FRET) from the QD donors to the TMR acceptors was enhanced. In separate work, the same CdSe-ZnS core/shell nanoparticles, stabilized by dihydrolipoic acid ligands, were also coated with a recombinant variant of maltose-binding protein (MBP) containing a pentahistidine segment at its C-terminus and a single Cy3 fluorophore covalently attached to a distinct cysteine residue [62]. The binding sites of the approximately 10 MBP molecules per QD were occupied by  $\beta$ -cyclodextrin-Cy3.5 ( $\beta$ -CD-Cy3.5) conjugates. Also within these defined conjugates, the protein-bound Cy3 served as a bridging acceptor/donor for energy transfer from the QD to the maltose-displaceable  $\beta$ -CD-Cy3.5.

In many other cases, however, a simple thiol bond to the particle surface was not sufficient to accomplish a permanent linkage. Instead, an equilibrium is established, with dynamic ligand exchange. To avoid this, a shell of silica is often grown on the particle by means of a sol-gel technique, and the linkage groups pointing outward are added as functionalized alkoxysilanes during the polycondensation process [17]. Recently, thiolated DNA has been linked to the surface of silanized CdSe/ZnS particles through a heterofunctional linker. On an ideally shaped surface, the number of linkage groups should be adjustable, and inert functional groups that determine the solubility and the surface potential of the particles should be added. The linkage groups of the ligands should adhere to the crystallite surface as much as possible, and the ligands should be covalently linked together to avoid exchange completely.

Two fascinating examples of coupling biomolecules with inorganic nanoparticles have been reported recently. One, by Ishii et al. [58], used a wrapping approach to encapsulate 2–4 nm-sized CdS particles within chaperonin proteins. The chaperonin proteins GroEL and *T.th* encapsulate denatured proteins inside a cylindrical cavity. After refolding, the encapsulated proteins are released by the action of ATP, which induces a conformational change in the chaperonin's cavity. These proteins are characterized by a cylindrical cavity with a diameter of 4.5 nm and a wall thickness of 4.6 nm. For complexation, a solution of 2–4 nm-sized CdS particles in dimethylformamide was mixed with an aqueous solution of the chaperonin proteins in Tris-HCl buffer. The characteristic photoluminescence of the CdS particles within the chaperonin-CdS nanoparticle complex lasted for an unusually

**Fig. 7.2.** (a) Scheme of a FRET system assembled by chemisorption of thiol-modified biotinylated BSA to CdSe (QD) and subsequent coupling of TMR-STV. (b) Fluorescence emission spectra from solutions containing  $\sim 15$  nM QD-bBSA and 0 (—), 16 (— — —), 40 (— — — —), 80 (— — — — —), 120 (— — — — — —), and 160 nM (— — — — — — — —)

SA/TMR. The lower solid curve is from a 160 nM SA/TMR control. An excitation wavelength of 400 nm was used for all samples. Inset: enhanced TMR fluorescence intensity at 585 nm from QD-bBSA/SA/TMR solutions as a function of SA/TMR concentration. (From Ref. [61].)

long time (more than 400 days) in the presence of GroEL complexes; in the absence of GroEL, photoluminescence disappeared within 2 hours. The second example, reported by Willner and et al. [64], consisted of nanowiring redox enzymes with gold nanoparticles to enhance the routing of electrons from the enzymes to electrodes. An “electrical nanoplug” was obtained by assembling an Au nanoparticles (1.4 nm)–glucose oxidase (GOx) conjugate at the macroscopic Au electrode. The bridge between the macroscopic electrode and the gold nanoparticles consisted of dithiol spacer units. Investigation of the catalytic properties of the assembly by cyclic voltammetry revealed that glucose oxidation occurred with a unimolecular electron-transfer seven times higher than the electron-transfer rate constant of native GOx with  $O_2$ .

While the use of surface-modified nanoparticles has been a typical route in preparing conjugates, the linker and chemical functionalization for the modification are added complications to an already sophisticated conjugate system. However, despite some obvious advantages, direct conjugation of biological species to inorganic nanoparticles has not been a common practice. This is probably a result of the generally incompatible experimental conditions required for biological species and for the formation and stabilization of nanoparticles. Some recent examples of direct coupling are highlighted below.

### 7.2.2

#### **Protein-assisted Assemblies of Inorganic Nanoparticles**

Self-assembly processes represent the state-of-the-art for organizing nanoscale objects into periodically ordered macroscopic materials. While this biomimetic process is not new, scientists have only recently begun to realize its potential for the artificial control of matter. This interesting class of nanomaterials provides exceptional potential for a wide variety of applications, including photonic and memory devices, two-dimensional (2D) arrays of magnetic nanoparticles [65–70]. Methods developed to produce these bulk-like hierarchical structures include biomimetic methods and amphiphile and colloidal templating, among others. In this section, we review only those approaches related to the use of proteins as crosslinkers, or as templates (assemblies and systems), in the organization and patterning of inorganic nanoparticles into two- and three-dimensional functional structures.

##### **7.2.2.1 Crosslinking Route through Protein Recognition**

Protein molecules can serve as crosslinkers because of their tremendous recognition capabilities. Their coupling to nanoparticles has generally been performed in three ways (Fig. 7.3): (a) nanoparticles are functionalized with individual recognition groups that are complementary; (b) particle-bound recognition groups are bridged through a bispecific linker molecule; and (c) a bispecific linker that directly recognizes the surfaces of the nanoparticles is used.

One protein system with highly specific recognition properties consists of antibodies and antigens, which are excellent candidate molecules for the programmed assembly of a wide range of nanoparticles in solution. Shenton et al. [40] first reported a strategy based on the surface attachment of either IgE or IgG antibodies followed by interparticle conjugation of gold and silver in the presence of bivalent antigens with appropriate double-headed functionalities (Fig. 7.3). The resulting structures were in the form of macroscopic filaments that consisted of a network of spatially separated Au and Ag nanoparticles. Similarly, streptavidin (STV)–biotin binding has been used to assemble nanocrystals in solution or onto a substrate. The STV–biotin interaction is considered the strongest ligand–receptor interaction currently known [12, 13]. Another great advantage of STV is its extreme chemical and thermal stability. Connolly and Fitzmaurice [13] used this approach to functionalize gold nanocrystals by chemisorption of a disulfide biotin analogue (DSBA), and then crosslinked by multi-site binding on subsequent addition of the

**Fig. 7.3.** (a) Scheme showing the approaches based on protein recognition systems for the assembly of nanoparticles in solution. (b) Example of TEM images showing colloidal Au/anti-dinitrophenyl DNP antibody conjugate before (left) and after (right) addition of DNP-DNP double-headed antigen. Scale bars 150 and 60 nm, respectively. (From Ref. [40].)

protein, streptavidin. The applicability of the STV–biotin system for generating supramolecular aggregates is also enhanced by the availability of various biotin analogues [71, 72] and recombinant STV mutants [73–77].

Today, with the power of biotechnological innovations, it is also possible to generate new proteins that can specifically recognize and grow inorganic “building blocks” (Fig. 7.4). This is a promising approach for selecting peptides that can recognize specific inorganic crystals and crystallographic orientations of nonbiological origin, including InP, GaAs, and Si [52], and can control II–VI (ZnS, CdS, CdSe, ZnSe, and PbS) semiconductor nanocrystal size, crystal structure, shape, and optical properties.

To identify the appropriate compatibilities and combinations of biological–inorganic materials, a combinatorial library of genetically engineered M13 bacteriophage was used to rapidly select peptides that could not only recognize but also control the growth of specific inorganic materials (Fig. 7.4). The phage display library is based on a combinatorial library of random peptides of a given length (e.g., 7 or 12 mers) that are fused to the pIII minor coat protein of the filamentous coliphage M13. Five copies of the fused random pIII coat protein are located on one end of the phage particle and account for 10–16 nm of the particle. Belcher and co-workers [52] used phage display to select peptide sequences with binding specificity for III–V semiconductor materials based on pIII minor coat protein expression. Brown [78] used repeating polypeptides displayed on the surface of the

bacterium *Escherichia coli* to bind selectively to metal particles. Selected viral-bound pIII peptides can also be used to nucleate II–VI materials for which they were selected [79]. Highly ordered composite material from genetically engineered M13 bacteriophage and ZnS nanocrystals has been generated by using a liquid crystal system (Fig. 7.4) [80–82]. The nucleating peptides have also been expressed in higher copy number along the protein VIII (pVIII) major protein coat of the virus, facilitating the organization of II–VI nanocrystals into highly ordered nanowires [83]. Recently, a virus-based scaffold produced through the self-assembly motifs employed by the M13 bacteriophage was used as a template for the synthesis of single-crystal ZnS, CdS, and freestanding chemically ordered CoPt and FePt nanowires, with the means of modifying substrate specificity through standard biological methods [84].

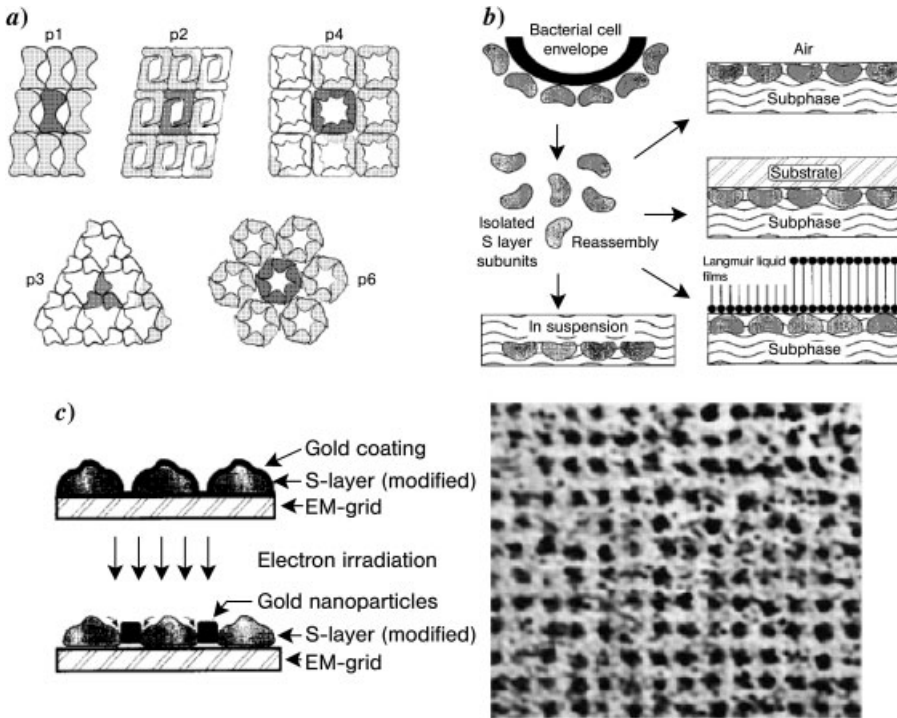

### 7.2.2.2 Template-directed Approach

An alternative approach to establish nanoparticle organization in supramolecular architectures involves the *in situ* formation of nanoparticles within preformed biological or biomimetic templates; in particular, those based on regular 2D lattices of bacterial cell surface proteins and hollow biomolecular compartments such as virus particles.

Crystalline bacterial cell surface layers (S-layers) are one of the most common outermost cell envelope components of a broad spectrum of bacteria and archaea. These S-layers are monomolecular arrays composed of a single protein or glycoprotein species and represent the simplest biological membranes developed during evolution. S-layer lattices exhibit either oblique, square or hexagonal lattice symmetry with unit cell dimensions in the range of 3–30 nm, and they are generally

5–10 nm thick and show pores of identical size (diameter, 2–8 nm) and morphology. The availability of these regular pores within the 2D protein crystal S-layers has allowed controlled nucleation of inorganic nanoparticles into ordered arrays (Fig. 7.5) [85].

Recently, it was demonstrated that S-layer proteins recrystallized on solid supports, or S-layer self-assembly products deposited on such supports, may be used to induce the formation of CdS particles [86] or gold nanoparticles [87, 88]. Inorganic superlattices of CdS with either oblique or square lattice symmetries were prepared by exposing self-assembled S-layer lattices to CdCl<sub>2</sub> solutions followed by slow reaction with H<sub>2</sub>S. Precipitation of the inorganic phase was confined to the pores of the S-layers, with the result that CdS superlattices with prescribed symmetries were prepared. In a similar procedure, a square superlattice of uniform 4 to 5 nm-size gold particles with a 12.8 nm repeat distance was generated [87]. In this procedure, a square S-layer lattice chemically modified with thiol groups was exposed to tetrachloroauric(III) acid and then electronically irradiated through TEM.

The shape of the gold particles resembled the morphology of the pore region of the square S-layer lattice. Electron-diffraction patterns revealed that the gold nanoparticles failed to form a perfect lattice. These experiments were repeated with a broad range of metal salts, such as  $\text{PdCl}_2$ ,  $\text{NiSO}_4$ ,  $\text{KPtCl}_6$ ,  $\text{Pb}(\text{NO}_3)_2$ , and  $\text{K}_3\text{Fe}(\text{CN})_6$  [89]. In general, the inner cavities of the protein layer serve as localized reservoirs of cations that are reduced *in situ* to metal clusters under the electron beam. These experiments clearly demonstrated that nanocrystal superlattices can be induced by S-layers as templates with a broad range of particle sizes (5–15 nm in diameter), interparticle spacings (up to 30 nm), and lattice symmetries (oblique, square or hexagonal).

Other processes dealing with the hollow protein compartments have also yielded fascinating results in the generation and assembly of nanoparticles (Fig. 7.6). For instance, the ferritin-like protein of the bacteria *Listeria innocua* [90] and the cowpea chlorotic mottle virus (CCMV) [91] furnished a suitable constrained reaction environment for the synthesis of monodisperse inorganic nanoparticles since they have hollow spherical supramolecular structures with internal cavity diameters of 5 and 18–24 nm, respectively. In both systems, the interior surfaces have regions of high charge density, which act as sites for synthetic mineral nucleation. Iron oxide particles of about 5 and 27 nm, respectively, were generated through incubation of these protein templates with iron(II) solutions at controlled pH and temperature followed by oxidation [90, 91]. The organization of these bioinorganic nanoparticles into network structures was also explored, e.g., through the coupling of biotin recognition groups to the ferritin and then conjugation in solution with streptavidin [14]. In other work, iron oxide nanoparticles of about 8 nm were also synthesized within the cavity of lumazine synthase protein [92].

Similarly, wild-type and recombinant tobacco mosaic virus (TMV) hollow cylinders have been used as templates to generate inorganic-organic nanotube composites by means of template mineralization [93–96]. The highly polar exterior surface of TMV has been used for surface mineralization of iron oxyhydroxides, CdS, PbS, and silica [95]. These materials form a thin coating over the virus nanorod, affording inorganic nanofibrils 20–30 nm in diameter and as long as 1  $\mu\text{m}$ . Dujardin et al. [96] recently used TMV as a template for the alignment and controlled deposition of Pt, Au, and Ag nanoparticles. By varying the deposition conditions, they demonstrated that one can either specifically decorate the external surface with metallic nanoparticles via the chemical reduction of  $[\text{PtCl}_6]_2^-$  or  $[\text{AuCl}_4]_2^-$  or obtain constrained growth of Ag nanoparticles within the 4 nm internal channel present in the virus through the photochemical reduction of Ag salts. In principle, as suggested by these investigators, 1D arrays of a wide range of quantum dots should become accessible by engineering and templated mineralization of the internal and external surfaces of TMV tubules. Microtubules prepared by polymerization of the protein tubulin have also been utilized as templates for the synthesis of inorganic nanomaterials [97].

The above examples demonstrate that sophisticated nanostructured architectures can be designed when protein molecules and nanoparticles are combined. Future

development in this field will benefit from the rapid advances being made in chemistry and protein technology. However, there is still a great demand for alternative methods to resolve typical problems that arise in the biofunctionalization of inorganic nanoparticles. In particular, harsh reaction conditions often lead to the degradation and inactivation of sensitive biological compounds, and to the formation of unstable bioconjugates because of ligand-exchange reactions that occur at the colloid surface. Among other limitations associated with these processes are excessive solvent use, disposal and trace residues, and multi-step operations.

## 7.2.3

**Supercritical Fluid Methods**

Supercritical fluid (SCF) technology in nanomaterial preparation and processing is one alternative method in the biofunctionalization of inorganic nanoparticles that shows great promise in addressing many of the challenges highlighted above. SCFs are solvents operating above their critical temperature and pressure. Among the most important properties of SCFs are their low and tunable densities, which can be easily varied from gas-like to liquid-like via a simple change in pressure at constant temperature. Numerous investigations have been conducted on SCFs [98–103]. Results have demonstrated their unique advantages as alternative media for both chemical reactions and materials processing. Example applications and related advantages are their use as environmentally benign solvents [98], the ability to selectively tune chemical reactions or processes [104–110], enhancement of reaction rates due to the low viscosities or high diffusivities in the fluids [109–110], the ability to solvate or precipitate solutes selectively [111], and the production of fine particles and fibers via rapidly expanding SCF solutions [112, 113].

Among the most widely investigated techniques for the processing of fine particles are SAS (Supercritical Anti-Solvent) [114–117] and RESS (Rapid Expansion of Supercritical Solutions) [118–123]. These techniques have comprehensively reviewed [102, 103]. Briefly, in RESS the solute is dissolved in a SCF, and then the solution is rapidly expanded through a small nozzle or orifice into a region of lower pressure [114, 118, 124, 125]. The rapid reduction in pressure (and thus, density) results in rapid precipitation of the solute. Experimentally, the supercritical solution can be generated either by heating and pressurizing a solution from room temperature or by continuously extracting the solute using an extraction column [125]. The RESS process is driven by a decrease in pressure, which can propagate at up to the speed of sound in the expansion nozzle. Because solubilities in SCFs can be up to a million times higher than those under ideal gas conditions, rapid expansion from supercritical pressure to ambient pressure results in extremely high supersaturation (and, consequently, homogeneous nucleation of the solute), leading to narrow size distributions in the products. Cosolvents, such as methanol or acetone, can be mixed with carbon dioxide (CO<sub>2</sub>) to increase the solvating power in RESS.

Because some compounds in commonly used SCFs have low solubility, the SAS process was developed. In SAS precipitation, one or more solutes immiscible with SCF are dissolved in a conventional solvent that is miscible with SCF. The solution is then “mixed” with the SCF to precipitate the solute particles. This can be achieved by introducing the SCF into a batch of solution in a chamber or by spraying solution through a nozzle into an SCF-filled chamber. A variation of this process is to mix solution and SCF continuously in a co-current or a counter-current fashion. Other minor variations of this mode of operation of antisolvent process are the bases for several techniques now in use, including Precipitation with Compressed Antisolvent (PCA), Solution Enhanced-dispersion by Supercritical fluids (SEDS), and Aerosol Supercritical Extraction System (ASES) [126–128]. All these

processes have been used to produce micron and submicron particles from various materials, including inorganics (metal, semiconductor), polymers, proteins, and other small organic molecules such as drugs [102, 103]. For example, several pharmaceutical compounds, such as lovastatin, stigmaterol, salicylic acid and theophylline, have been processed via RESS into micron- and sub-micron-sized particles [102]. Several reports have also considered using the RESS process for the direct formulation of drug:polymer systems by a co-precipitation strategy. The SAS process also produced micron-sized particles of proteins such as insulin, lysozyme and trypsin. Adding a polymer to the system as a carrier may furnish active protein-loaded microparticles.

Results from these experiments and others suggest that these processes generally produce micron- or submicron-sized particles [113, 129–132]. For nano-sized particles, Sun and co-workers [102, 103] made a simple but significant modification to the traditional RESS by using a liquid solvent or solution at the receiving end of the supercritical solution expansion, or the Rapid Expansion of a Supercritical Solution into a Liquid SOLvent (RESOLV). The RESOLV process produces exclusively nanoparticles from various materials [59, 60, 102, 103, 133–140]. For example, cadmium sulfide (CdS) nanoparticles of  $\sim 3$  nm in average diameter have been prepared using RESOLV by rapidly expanding a supercritical ammonia solution of  $\text{Cd}(\text{NO}_3)_2$  into a room-temperature aqueous or ethanol solution of  $\text{Na}_2\text{S}$  [133]. The nanoparticles so-produced could be prevented from aggregating by the presence of a polymeric or other protection agent in the receiving solution [133]. The same RESOLV process with a similar reaction scheme has been applied to the production of many other metal and semiconductor nanoparticles. These nanoparticles are all small, on average less than 10 nm in diameter, and are protected to form stable suspensions [59, 60, 102, 103, 133–138]. As recognized by Sun and co-workers [59, 60, 138], a unique feature of the RESOLV process for nanoparticle production is that it requires no nanoscale templating agents for nanoparticle formation because the templating effect is provided by the supercritical fluid rapid expansion process, thus offering a clean way to directly couple nanoparticles with biological species. For example, Sun and co-workers have demonstrated recently that the metal and semiconductor nanoparticles coated directly with natural protein species could be prepared in the RESOLV process [59, 60, 138]. Figure 7.7 shows a typical RESOLV apparatus for preparing protein-conjugated nanoparticles.

#### 7.2.3.1 BSA-conjugated Silver Nanoparticles

An example use of RESOLV in the direct conjugation of nanoparticles with proteins is the coupling of nanoscale Ag with bovine serum albumin (BSA) [138]. Typically, a methanol solution of  $\text{AgNO}_3$  was added to the syringe pump, followed by evaporation of the solvent methanol. The syringe pump was then filled with liquid ammonia. When pumped through the heating unit, the ammonia solution of  $\text{AgNO}_3$  was heated and equilibrated at  $160^\circ\text{C}$  before reaching the expansion nozzle. The supercritical solution was rapidly expanded via a  $50\ \mu\text{m}$  fused silica capillary nozzle into a room-temperature aqueous solution of  $\text{N}_2\text{H}_4$  or  $\text{NaBH}_4$ . The system pressure was kept constant during the rapid expansion. BSA protein was in

Fig. 7.7. Experimental setup for preparing protein-conjugated Ag<sub>2</sub>S nanoparticles via RESOLV [60].

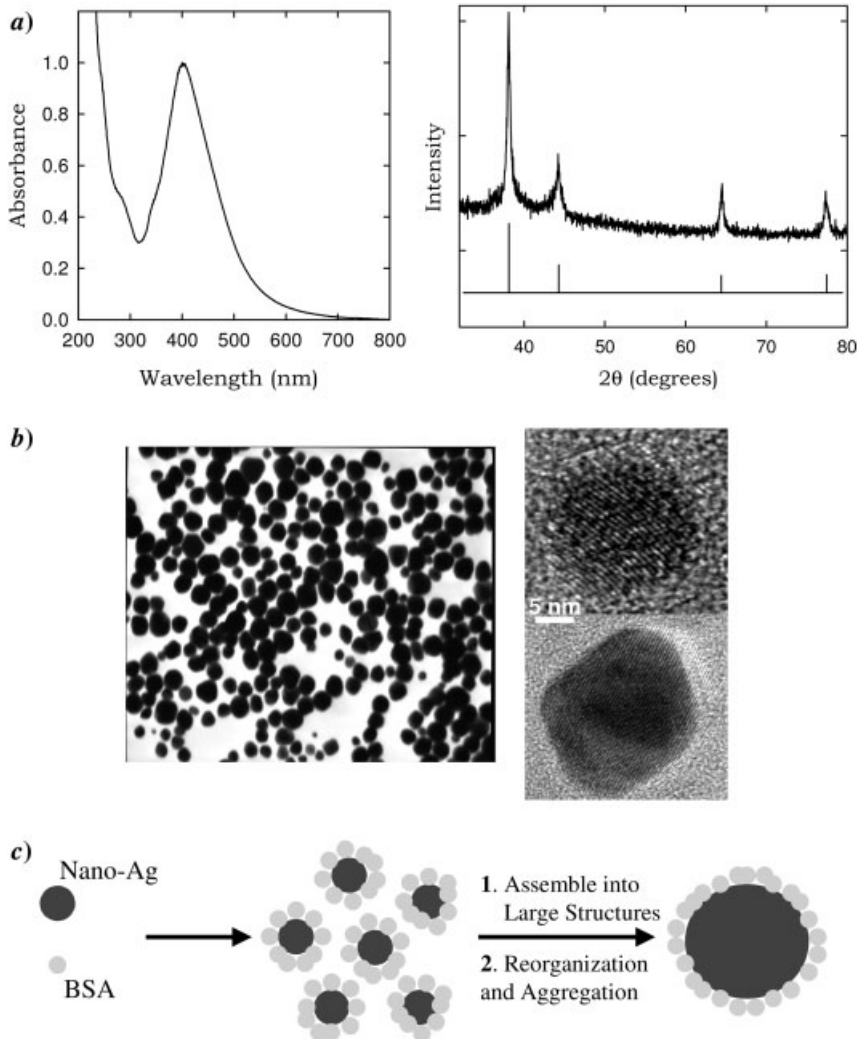

the aqueous receiving solution for direct conjugation with the Ag nanoparticles as they form in the rapid expansion process.

The BSA-conjugated Ag nanoparticles form a stable aqueous suspension that resembles a homogeneous solution. As shown in Fig. 7.8(a), the surface plasmon absorption band ( $\sim 420$  nm) of the Ag nanoparticles broadens upon protein conjugation, reflecting changes in nanoparticle surface properties due to interactions with the protein species. X-Ray powder diffraction analyses of the solid-state samples (Fig. 7.8a) confirmed the expected presence of nanoscale Ag (fcc) particles. Figure 7.8(b) shows the low and high-resolution TEM images of BSA-protected Ag nanoparticles with hydrazine reductions. The average particle size and size distribution standard deviation are 43 and 10 nm, respectively. These nanoparticles appear to be polycrystalline with multiple misaligned lattice fringes, suggesting that the BSA-protected Ag nanoparticles are probably agglomerated smaller nanoparticles. Gel electrophoresis, used to analyze the conformation of BSA protein conjugated to Ag nanoparticles, showed two bands corresponding to BSA monomer and dimer that were much weaker in the nanoparticle sample than in the blank BSA sample; most of the nanoparticle sample becomes stationary, appearing at the gel onset. These low mobility species are probably BSA-protected Ag nanoparticles.

The assembly of smaller Ag nanoparticles produced initially in RESOLV with chemical reduction is likely driven by protein aggregation to form larger, but relatively well-organized, structures of Ag nanoparticles (Fig. 7.8c).

### 7.2.3.2 BSA-conjugated Semiconductor Nanoparticles

BSA-conjugated Ag<sub>2</sub>S and CdS nanoparticles have also been prepared via the RESOLV procedure [59, 60]. Similar experimental parameters were used to produce Ag<sub>2</sub>S and luminescent CdS nanoparticles. Here, a supercritical ammonia solution of AgNO<sub>3</sub> or Cd(NO<sub>3</sub>)<sub>2</sub> was used in the rapid expansion and a room-temperature aqueous solution of Na<sub>2</sub>S (10 mg mL<sup>-1</sup>) was at the receiving end. After rapid ex-

**Fig. 7.8.** (a) UV/Vis absorption spectrum (left) and X-ray powder diffraction pattern (right) of the BSA-conjugated Ag nanoparticles prepared via RESOLV. (b) TEM images of BSA-conjugated Ag nanoparticles. (c) Scheme illustrating the assembly of smaller protein-conjugated Ag nanoparticles into larger and organized structures, driven by protein aggregation. (From Ref. [138].)

pansion was complete, the ambient suspension of nanoparticles was transferred to membrane tubing with large pore sizes for dialysis to remove free BSA and other salts and reagents.

BSA-conjugated  $\text{Ag}_2\text{S}$  nanoparticles thus produced in RESOLV form a yellowish suspension without precipitation under ambient conditions. The UV/Vis absorption spectrum of the nanoparticle suspension is a structureless curve with gradu-

**Fig. 7.9.** TEM images of BSA-conjugated  $\text{Ag}_2\text{S}$  nanoparticles prepared via RESOLV and then dialysis. (From Ref. [60].)

ally increasing absorbance towards shorter wavelengths, indicating that these nanoparticles are quantum confined. According to TEM analyses (Fig. 7.9), the BSA-conjugated  $\text{Ag}_2\text{S}$  nanoparticles are well-dispersed, mostly single crystals, with an average particle size of 6.3 nm and a size distribution standard deviation of 1.6 nm.

Atomic force microscopy (AFM) results (Fig. 7.10) provide strong evidence for well-dispersed  $\text{Ag}_2\text{S}$  nanoparticles uniformly coated with BSA in a core/shell-like

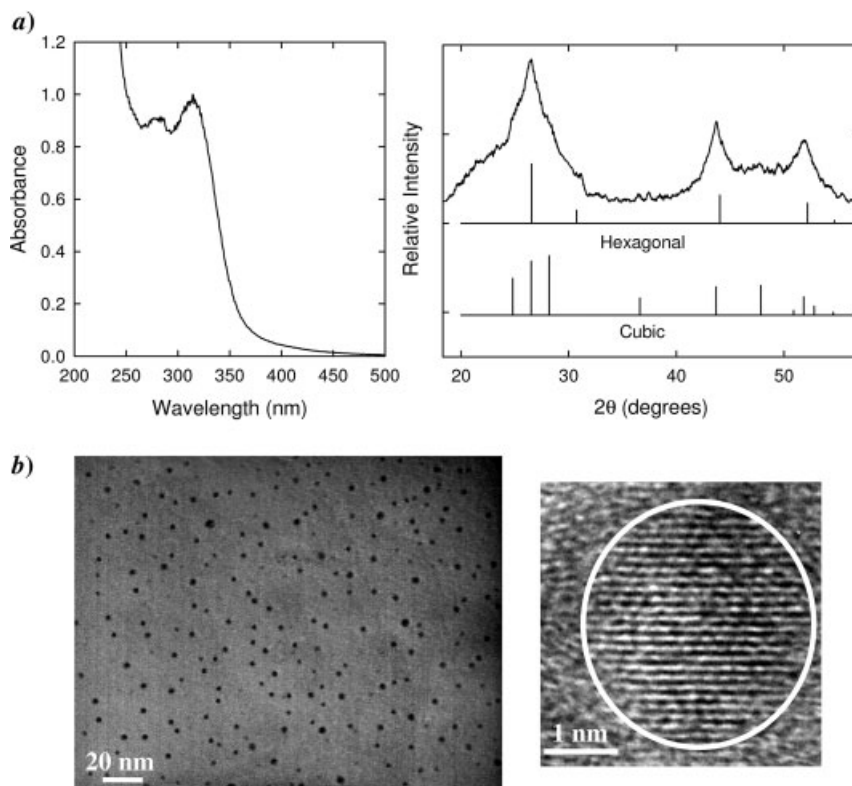

**Fig. 7.10.** Height (left) and phase (right) images from the AFM analysis of BSA-conjugated  $\text{Ag}_2\text{S}$  nanoparticles prepared via RESOLV and then dialysis. (From Ref. [60].)

arrangement, with overall circular features of 20–30 nm (the larger apparent particle size is due to the tip convolution effect [141]).

Similarly, a yellowish homogeneous suspension of BSA-conjugated CdS nanoparticles was obtained after dialysis. Apparently, interactions between BSA protein species and CdS nanoparticles are relatively strong to sustain the conjugation [59]. The UV/Vis absorption spectrum of the suspension exhibits a well-defined peak at 320 nm (Fig. 7.11a), indicating that the BSA-conjugated CdS nanoparticles are around 2–3 nm in diameter [142]. According to powder X-ray diffraction analysis, the nanoparticle sample is probably a mixture of cubic and hexagonal CdS. TEM results (Fig. 7.11b) show that the CdS nanoparticles are mostly single crystals with an average particle size of 2.9 nm and a size distribution standard deviation of 0.7 nm.

BSA protein species conjugated to the CdS nanoparticle surface have been visualized via AFM imaging (Fig. 7.12a). These images are dominated by circular features of around 20 nm in size, which are consistent with well-dispersed individual CdS nanoparticles that are each coated with BSA protein species in a core/shell-like arrangement [59]. The presence of BSA on the CdS nanoparticle surface is also made evident by the well-known affinity of the conjugate to the surface of nanoscale gold (Fig. 7.12b) [16, 143].

BSA-conjugated CdS nanoparticles produced via RESOLV have interesting luminescence properties (Fig. 7.13). The luminescence spectrum has a relatively narrow bandwidth close to the absorption onset with no surface defect emissions at long wavelengths. This is primarily the exciton emission associated with band-gap excitation [142]. The observed luminescence quantum yield is high, ~20% with

**Fig. 7.11.** (a) UV/Vis absorption spectrum (left) and X-ray powder diffraction pattern (right) of the BSA-conjugated CdS nanoparticles. (b) TEM images of the BSA-conjugated CdS nanoparticles. (From Ref. [59].)

reference to the fluorescence standard 9,10-diphenylanthracene, which is also consistent with substantial contributions from exciton emission [142]. The rapid expansion of supercritical ammonia solution may have a special passivation effect on the nanoparticle surface [133], suppressing the surface defect luminescence and enhancing the exciton emission from the CdS nanoparticle [133, 142, 144]. Conversely, the broad emission seen for CdS nanoparticles generated by other methods, such as those encapsulated in the micelles of sodium dioctyl sulfosuccinate (AOT) [145], is due primarily to energy trapping states associated with surface defects [142, 144, 145].

BSA protein species conjugated to the  $\text{Ag}_2\text{S}$  and CdS nanoparticles through the RESOLV process remain intact, according to the modified Lowry assay for total protein analysis [146–148]. BSA conjugation serves the dual purposes of stabilizing these nanoparticles to prevent agglomeration in aqueous suspension and introducing biocompatible functionalities into these nanoparticles for further biological interactions or couplings (e.g., antibody attachment).

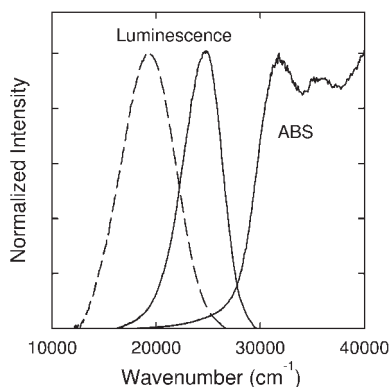

**Fig. 7.12.** (a) Height (left) and phase (right) images from the AFM analysis of BSA-conjugated CdS nanoparticles. (b) Scanning TEM (Z-contrast mode) image for the coating of colloidal gold by BSA-conjugated CdS nanoparticles. (From Ref. [59].)

Mechanistically, the relatively strong interactions between BSA and these semiconductor nanoparticles (strong enough to remain stable in dialysis) are worth noting. BSA protein contains 60 amino moieties in lysine residues, 26 arginine moieties in guanidino side chains, and also 17 disulfide bonds with one free thiol in cysteine residues [149]. These functionalities are probably responsible for the conjugation to these nanoparticles through thiolate linkages and/or weak covalent bonds with alkylamines [150–152].

### 7.2.3.3 Assembly and Disassembly of Nanoparticles through Protein Isomeric Conversion

Protein-conjugated semiconductor nanoparticles produced through the supercritical fluid processing method RESOLV can also be organized into supramolecular architectures by simply using isomeric conformations of proteins. For example,

**Fig. 7.13.** Luminescence spectrum of BSA-conjugated CdS nanoparticles in a stable aqueous suspension (—) compared with that of the similarly sized CdS nanoparticles prepared and encapsulated in AOT micelles (---). (From Ref. [59].)

Meziani et al. [60] have demonstrated the possibility of assembling and disassembling BSA-conjugated  $\text{Ag}_2\text{S}$  and CdS nanoparticles by adjusting solution pH. Under high pH conditions ( $\text{pH} \sim 12$ ), BSA is expected to be in the aged form, in which the protein drastically expands and forms soluble aggregates through intermolecular disulfide exchanges [60]. Aggregation is reflected by the clustering of these nanoparticles, as observed in AFM images of the  $\text{Ag}_2\text{S}$  sample (Fig. 7.14). In these clusters, individual  $\text{Ag}_2\text{S}$  nanoparticles are still separated by protein species and protected from agglomeration into larger  $\text{Ag}_2\text{S}$  nanoparticles. At neutral

**Fig. 7.14.** AFM height (left) and phase (right) images of BSA-conjugated  $\text{Ag}_2\text{S}$  nanoparticles at high  $\text{pH} \sim 12$ . (From Ref. [60].)

**Fig. 7.15.** Scheme illustrating the assembly and disassembly of BSA-conjugated semiconductor nanoparticles due to changes in BSA conformations at different solution pHs. (From Ref. [60].)

pH, the BSA protein coating the well-dispersed  $\text{Ag}_2\text{S}$  nanoparticles (Fig. 7.10) is predominantly in the native form. This pH-dependent assembly and disassembly of BSA-conjugated  $\text{Ag}_2\text{S}$  nanoparticles, driven by the isomeric conversion of the protein, is qualitatively reversible [60]. In the isomeric conversion, BSA protein is relatively unharmed at high pH and, for the most part, can return to its native configuration, thus making it possible to maintain the reversibility (Fig. 7.15).

In summary, the supercritical fluid processing method RESOLV can be used effectively as an alternative and unique way of producing clean, active protein-conjugated nanoparticles. Since the nanoparticle formation involves no templating agents in an aqueous environment, the method can enable direct conjugation of nanoparticles to proteins. These protein-conjugated nanoparticles are stable (without agglomeration and precipitation) in an aqueous suspension, and the protein species associated with the nanoparticles remain intact, and are amenable to further biofunctionalizations. The produced semiconductor nanoparticles, such as CdS, can have strongly luminescent features, which are particularly valuable in biosensor-related applications.

### 7.3

#### Coupling of Carbon Nanotubes and Proteins

Among various large-aspect-ratio nanomaterials, carbon nanotubes possess unique and rich physical and chemical properties because of the one-dimensional structural arrangement of a chemically versatile element [153–156]. Conceptually, carbon nanotubes may be formed by rolling graphene sheets into tubular structures – single-walled carbon nanotubes (SWNTs) from a single graphene layer and multiple-walled carbon nanotubes (MWNTs) from multiple layers [153]. The chiral vector for rolling-up ( $\mathbf{C}_h = n\mathbf{a}_1 + m\mathbf{a}_2$ ), often referred as the chiral index ( $n, m$ ), uniquely defines the diameter ( $d$ ) and the chiral angle ( $\theta$ ) of the SWNT (Fig.

Fig. 7.16. Conceptual formation of carbon nanotubes by rolling up a graphene sheet.

7.16) [Eqs. (1) and (2), where  $a_{c-c}$  ( $\sim 0.142$  nm) is the nearest neighbor C–C distance].

$$d = \frac{\sqrt{3}a_{c-c}}{\pi} \sqrt{n^2 + nm + m^2} \quad (1)$$

$$\theta = \tan^{-1}[\sqrt{3}m/(2n + m)] \quad (2)$$

The chiral index also directly determines the electronic structure of the nanotube: metallic when  $(n - m)/3$  is integer (“semi-metallic” if  $n \neq m$ ) and otherwise semiconducting [154].

Biological applications of carbon nanotubes through their integration with bioactive molecules in particular have been investigated both in solution phase and in solid state [157–163]. For solution-phase applications, such as substance delivery [163–168], pathogen detection [169, 170], and other biomedical applications, the nanotubes should be dispersible or soluble in physiological environments. Thus, the aqueous solubilization of carbon nanotubes is essential [158, 159, 161–163], and has benefited enormously from recent developments in the chemical functionalization of nanotubes [171–175]. Examples of solid-state bioapplications of carbon nanotubes include scaffolds for cell growth [162, 176–178], biosensors and biocatalytic electrochemical devices [157, 160, 179], electromechanical devices [180], sharp scanning microscopy probes [181], etc.

Protein–carbon nanotube conjugates were among the earliest and most popular topics in multidisciplinary research efforts on the bioapplications of nanotubes. These conjugates may be formed either non-specifically or specifically (see below). Examples in various related applications are also reviewed below.

## 7.3.1

**Non-specific Adsorption**

Like other nanomaterials, carbon nanotubes have a high surface area, but with a surface of quantum-confined conjugated carbon networks. However, it was the nanometer-sized hollow interior of these tubular species that drew most initial attention, stimulating the imagination that they could be used as carriers to encapsulate and deliver bioactive species to selected targets [182–185]. As supportive evidence, some enzymes encapsulated in MWNTs seemed to retain their biocatalytic properties [183]. However, the encapsulate-and-deliver idea is still a matter of theory since there has been no report of the controlled release of these encapsulated species from nanotubes at any targeted site. Furthermore, problems with such encapsulation are far from resolved.

The early experiments on encapsulating proteins into nanotubes revealed that proteins were adsorbed on the MWNT exterior surface [185]. This phenomenon became widely known when Balavoine et al. [186] found that streptavidin and HupR readily adsorbed onto the MWNT surface, with the adsorbed proteins sometimes even forming helical array structures along the nanotube sidewall. Although the reproducibility for the ordered arrays was poor, these results suggested strongly that there are indeed competent noncovalent and non-specific interactions between carbon nanotubes and protein species.

Despite efforts to ensure the specific conjugation of carbon nanotubes and proteins (Section 7.3.2), several groups realized that non-specific interactions between these two entities are almost inevitable. Dai and co-workers [179, 187] reported that streptavidin, avidin, BSA,  $\alpha$ -glucosidase, and staphylococcal A are adsorbable to SWNTs. Similarly, Azamian et al. [188] found that proteins with different isoelectric points, such as cytochrome *c* ( $pI \sim 10.8$ ) and ferritin ( $pI \sim 4.6$ ), exhibit similar affinity toward SWNTs (Fig. 7.17).

Since ferritin contains an iron core, Lin et al. [189] used it as a model protein to study protein–nanotube interactions in aqueous media via TEM. It was qualitatively but unambiguously demonstrated that non-specific interactions between ferritin and SWNTs were so significant that the nanotubes were solubilized in water as a result. In agreement with reports by Azamian et al. [188], the ferritin–nanotube conjugation via such non-specific interactions was quite similar to that in the presence of special reagents for covalent coupling during reaction. Despite the visual similarity, the non-specific conjugates were much less stable than covalent ones (Section 7.3.2) [189].

**Fig. 7.17.** AFM image of a cytochrome *c*–SWNT conjugate from non-specific adsorption. Scale bar = 90 nm. (From Ref. [188].)

**Fig. 7.18.** Enzymatic activity retained as a function of surface coverage of enzymes on SWNTs: adsorbed SBP (▲) and adsorbed CT (●). Each point represents an average of a minimum of three separate experiments, with

some points showing errors smaller than the symbol. Specific activities above half-maximal coverage could not be obtained because of leaching of the adsorbed enzyme during activity measurement. (From Ref. [191].)

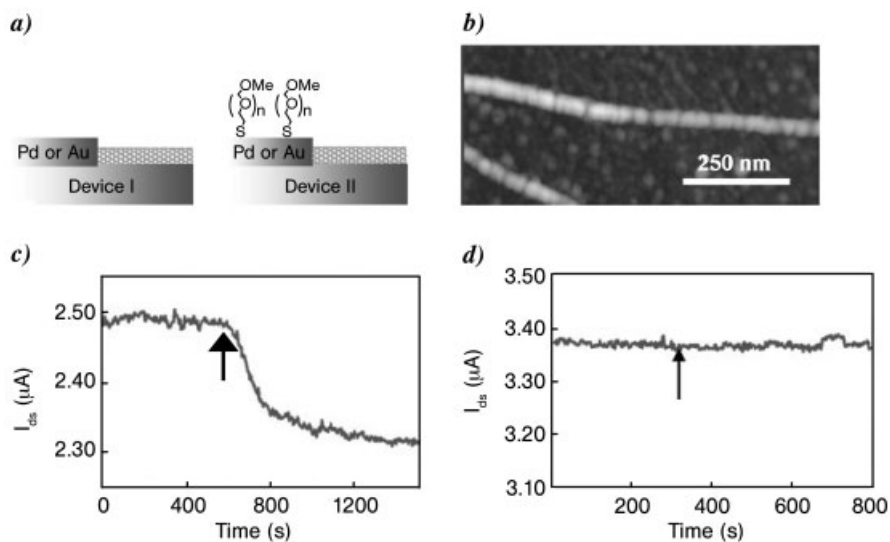

Rege et al. [190] reported enhanced retention of the enzymatic activity of  $\alpha$ -chymotrypsin (CT) embedded in polymer–SWNT composite films compared with those without nanotube fillers. They speculated that this could be a consequence of enzyme–nanotube hydrophobic interactions that slowed the leaching of enzymes from the films. However, other reported results contradict this conclusion. As recently reported by Karajanagi et al. [191], CT almost completely lost its enzymatic activity upon non-specific conjugation with SWNTs (Fig. 7.18), possibly due to its structure unfolding. These authors showed by AFM that the tertiary structures of CT molecules, upon adsorption onto SWNTs, changed significantly from those in solution phase. However, another enzyme, soybean peroxidase (SBP), retained its structure when adsorbed, which is consistent with the observed retention of a reasonable fraction of activity. Also consistent are quantitative FT-IR investigations, which demonstrated much more significant secondary structural changes of CT than SBP in both  $\alpha$ -helix and  $\beta$ -sheet contents upon the enzyme–nanotube conjugation [191].

Microscopy techniques are widely used to visualize both aqueous soluble protein–nanotube conjugates and those on substrates. For the latter, other instrumental techniques are also used to obtain additional information. For example, quartz crystal microbalance (QCM) has been used to trace the protein adsorption event on a SWNT film that was evenly formed on a gold-coated QCM quartz crystal substrate [179]. The signal change marked the adsorption events on the film and scaled with the concentration of the protein solution for adsorption. The results obtained for adsorptions of various proteins on SWNTs are in reasonable agreement with microscopy observations. However, protein adsorption on the substrates could interfere in such evaluations unless the substrates are fully covered by a monolayer of nanotubes.

Protein adsorption on carbon nanotubes can also be detected electrochemically. In particular, solid-state field-effect transistor (FET) devices from semiconducting SWNTs have been envisioned for use as biosensors [160, 179, 192]. In principle, some small perturbation on the electronic structure of the semiconducting SWNT from the adsorption of even a trace amount of guest molecules may induce a detectable electrical response in the device characteristics [192–195]. Metallic SWNTs, however, are much less sensitive to changes in chemical environments. For example, the adsorption of cytochrome *c* ( $pI \sim 10.8$ ) in a buffer solution onto a SWNT FET device was detected by measuring the device conductance change [196]. Consistent with microscopy results, the change in conductance was quantified to be from the adsorption of  $\sim 20$  protein molecules per  $\mu\text{m}$  length of a semiconducting SWNT under the given experimental conditions. In fact, the detection limit of such FET devices is of the order of 100 pM of cytochrome *c*.

A consistent observation by different groups is that the conductance of the nanotubes decreases upon protein adsorption, regardless of the charge of the proteins at physiological pH. This is obviously not solely due to the electrostatic gating effect from charge injection from protein molecules to the p-type semiconducting SWNT [179, 196, 197]. Besteman et al. [197] proposed that such a conductance decrease (as a function of the liquid-gate voltage) could originate from the nanotube capacitance change upon the adsorption event, during which ion proximity to the nanotube is limited. However, vigorous debates continue on whether the device response is from the non-specific adsorption of proteins on nanotubes at all [198]. It has been argued that the adsorption of proteins with rather small charge ( $pI \sim 5\text{--}7$ ) at the electrode–nanotube contacts contributes more to the detected conductance change than that along the nanotube sidewall [198]. Poly(ethylene glycol) (PEG) is a well-known protein-resistant material that is often used to protect surfaces from protein adsorption [199, 200]. By selectively applying a PEG layer onto the metal electrodes, these researchers showed that there was no detectable electronic response of the nanotube FET device to the adsorption events at protein concentrations of 100 nM [198] (Fig. 7.19). There was an exception, avidin, which is highly positively charged at neutral pH ( $pI \sim 10\text{--}11$ ). This protein was capable of inducing a response even when the electrodes were protected, although the signals were much weaker than those from non-protected devices. As expected, when the nanotube surface was also protected via protein-resistant species, no device response could be detected with any of the proteins investigated.

Whatever the sensing mechanism might be in the FET devices upon protein–nanotube conjugation, the evidence is already overwhelming for non-specific adsorption of proteins onto carbon nanotubes. The mechanism for such conjugation, however, is complicated and subject to further investigation. The nanotube surface has been widely considered as being hydrophobic [201]. Thus, it has been suggested intuitively that the hydrophobic interactions between nanotubes and certain protein structural units play a significant role in the observed adsorption. For example, Karajanagi et al. [191] attributed the differences in changes in the structures and enzymatic activities of two enzymes (SBP and CT, *vide supra*) upon their adsorption on SWNTs to hydrophobic interactions. For SBP, there is a hydrophobic

**Fig. 7.19.** (a) Configuration sketches of SWNT FET devices type I (unprotected Pd/Au electrodes) and type II (electrodes coated with a PEG self-assembled monolayer). (b) AFM image of a SWNT type II device after exposure to human chorionic gonadotropin (hCG). (c) Electrical data of type I device during exposure to hCG. (d) Electrical data of type II device during exposure to hCG. (From Ref. [198].)

“pocket” with 19 amino acid residues on the surface, distant from the enzymatic active sites in its tertiary structure, which may help the enzyme to retain a significant fraction of its activity. Conversely, CT does not contain a large hydrophobic cluster, which was speculated to be the cause for the loss of activity upon its adsorption onto SWNTs with significant secondary and tertiary structural changes [191]. Also consistent with the hydrophobic interaction scheme is the finding that the amphiphilicity of the large peptide species favors their binding with nanotubes in aqueous solution, similar to the surfactant effects [202]. Dieckmann and co-workers [203, 204] took advantage of a similar concept and designed an amphiphilic peptide with an  $\alpha$ -helix secondary structure for the noncovalent aqueous solubilization of SWNTs (Fig. 7.20). However, one example is clearly inconsistent with the hydrophobic scheme. Fibrinogen, a well-known soluble plasma glycoprotein that is affinitive to many hydrophobic surfaces, was found to be inert to SWNTs. This might be due to the protein’s large size (molecular weight  $\sim 340$  kDa) [187].

Among other possible mechanisms for non-specific protein–nanotube conjugation are electrostatic interactions and hydrogen bonding, especially when carbon nanotubes are pre-treated with oxidative acids. After such treatment, the nanotube surface usually becomes defective, with many oxygen-containing groups, such as carboxylic acids, hydroxyls, ketones, etc., at the defect sites [205–207]. These organic groups make electrostatic interactions and hydrogen bonding between nanotubes and certain surface residues of proteins quite plausible. Electrostatic interactions obviously do not dominate as several groups have shown that SWNTs are

**Fig. 7.20.** Design of  $\alpha$ -helix peptide (top) and a model sketch of the peptide-SWNT conjugate by noncovalent interaction (bottom). (From Ref. [203].)

attractive to both positively and negatively charged protein species in aqueous solutions [188] and at device level [179, 198] at physiological pH.

The increasing evidence for amino-affinity of semiconducting SWNT surfaces [194, 208–210] might also help to explain the above phenomenon, since most proteins under consideration contain lysine and/or arginine units that provide primary amino groups. For example, previous studies show that there is  $\sim 0.04$  electron donation to a semiconducting SWNT per adsorbed amine [211]. From such a unit quantity of charge transfer, Bradley et al. [212] estimated that a significant portion of the threshold shift of the gate voltage in a nanotube FET device upon streptavidin adsorption is due to charge transfer from amino groups to the semi-

conducting SWNT. However, they also suspected that other residues, such as tryptophan and tyrosine, may play a secondary role in the charge transfer because they contain aromatic structures. Indeed, investigations conducted with a peptide library have found that the tryptophan residue, in particular, was affinitive towards the SWNT surface [202].

### 7.3.2

#### Specific Conjugation and Biorecognition

Specific conjugation of proteins and carbon nanotubes is opposite to non-specific conjugation. In the former, selected chemical reagents are used with known chemistry to link proteins to nanotubes in a more controllable fashion. Protein surface amino groups from residues, such as lysine, are widely involved in some of these specific conjugations. For example, nanotube-bound carboxylic acids, often generated from oxidative acid treatments, can be coupled with protein amines to form amide linkages (Scheme 7.1), which was extrapolated from chemistry developed previously for functionalizing carbon nanotubes with other polymeric and oligomeric molecules [171–175, 181, 213]. Various types of proteins, such as BSA, ferritin, and cytochrome *c*, have been conjugated to carbon nanotubes via this route [188, 189, 214, 215]. The reactions were often carried out in the presence of carbodiimide reagents, such as 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDAC), which are specific for the formation of amide linkages by converting carboxylic acids into more reactive intermediates toward coupling with amines. The carbodiimide-nanotube reaction has been referred to as the activation step and is sometimes assisted by sonication [213]. Many proteins also contain carboxylic acids, which may compete with those from nanotubes in the amidation reactions, resulting in possible protein self-aggregation. Thus, the activation step is better carried out in the absence of proteins so that excess carbodiimide molecules can be removed before the conjugation reaction. The addition of *N*-hydroxysuccinimide (NHS) after carbodiimide activation may further enhance the stability of the reactive intermediate, and thus be beneficial to the yields of the covalent protein–nanotube conjugates [215]. This and similar strategies have been used to functionalize carbon nanotubes with other biomolecules (such as nucleic acids and their analogs [216, 217]) under physiologically benign conditions.

Amide linkages between proteins and carbon nanotubes have also been reported to be formed in room-temperature ester-to-amide transformation reactions in aqueous solution (Scheme 7.1) – an even milder approach [218]. In the reaction, a water-soluble nanotube sample with ester-attached oligomeric PEG functionalities was placed in small-pore-size dialysis tubing with a protein (e.g. BSA). Although the PEG functionalities on the nanotubes might have resisted approaching proteins in aqueous solution, the final protein–nanotube conjugation obtained this way was in fact quite similar to that obtained by carbodiimide-activated coupling reactions [214]. The driving force for such a mild transformation, which overcomes the initial protein-resistivity of nanotube-bound PEG groups, likely comes from both the thermodynamic stability of the amide linkages (compared with ester

Scheme 7.1

Scheme 7.2

ones) and the *in situ* removal of relatively small PEG molecules via dialysis. In addition, hardly any NMR signals from PEG moieties could be detected from the conjugates after the reaction, indicating the effectiveness of the method.

Covalent functionalization seems to facilitate the aqueous solubilization of SWNTs, resulting in enhanced yields of solubilized nanotubes compared with non-specific interactions under similar conditions [189]. Aqueous-soluble covalent protein–nanotube conjugates are also much more stable than non-specific conjugates. For example, as discussed in Section 7.3.1, water-soluble covalent ferritin–SWNT conjugates are much more stable in solution when subjected to long-period standing or vigorous dialysis conditions than non-specific ones. After dialysis, although there seemed to be some protein loss in the covalent conjugates, the protein–nanotube association was still much more pronounced than that in non-specific conjugates similarly dialyzed [189]. Probably, the non-specific adsorption contributes significantly to the initial approaching of proteins toward nanotubes during covalent conjugation. The formation of amide linkages then “locks” the proteins on the nanotube surface defect sites where carbodiimide-activated intermediates are present (Scheme 7.2) [159, 189].

Covalent water-soluble protein–nanotube conjugates have found some applications in bacterial detection. Elkin et al. [169] adsorbed anti-*Escherichia coli* polyclonal antibodies onto BSA-functionalized SWNTs in physiological solutions. The nanotube-bound antibodies efficiently captured *E. coli* O157:H7 in solution, which was demonstrated by both SEM (Fig. 7.21) and confocal microscopy. Because of the high surface area and one-dimensional flexible structure of SWNTs, such multiplicity antibody displays might be of enhanced pathogen detection sensitivity and could also potentially be used for decontamination of bacterial cells in complex matrices.

Another form of interaction of carbon nanotubes with cells is the translocation of nanotubes through the cell membranes – internalization. In a recent example, SWNTs were functionalized with biotin using a similar carbodiimide coupling

**Fig. 7.21.** (a) AFM image of a covalent BSA-SWNT conjugate sample. (b) and (c) SEM images showing the strong interactions of immuno-SWNTs (SWNT-BSA-antibody goat anti-*Escherichia coli* O157 conjugate) with pathogenic *E. coli* O157:H7 cells. (From Ref. [169].)

method, and then conjugated to streptavidin via selective biotin–streptavidin interactions [167]. While streptavidin proteins cannot enter cells by themselves, the water-soluble SWNT–biotin–streptavidin conjugates were able to internalize into many types of cells, such as human promyelocytic leukemia (HL60), Chinese hamster ovary, and 3T3 fibroblast cells (Fig. 7.22). Streptavidin alone did not show appreciable cytotoxicity to HL60 cells. However, the cytotoxicity of SWNT–biotin–streptavidin conjugates toward the same cell line was dose-dependent, which is consistent with protein internalization via nanotube carriers. SWNT–biotin–streptavidin internalization is probably accomplished through endocytosis, which could be blocked at 4 °C. Co-localization of SWNTs and endosomes formed during such endocytosis is direct evidence for internalization.

SWNTs functionalized by a peptide that mimics the function of  $G_s$  protein were able not only to penetrate human and murine fibroblast and keratinocytes cells membranes but also to translocate into the cell nucleus [161, 165]. The nanotube functionalization was covalent, but based on 1,3-dipolar addition of azomethine ylides onto the nanotube sidewalls [161, 164]. The functional group end-capped with amine was then modified with peptide sequences to obtain peptide–SWNT conjugates. Murine 3T3 fibroblast cells were still largely viable when the soluble

**Fig. 7.22.** Confocal images of HL60 cells after incubation in solutions of (a) a fluorescein-labeled SWNT sample; (b) a mixture of SWNT-biotin-fluoresceinated streptavidin conjugate (green) and the red endocytosis marker FM 4-64 at 37 °C (image showing fluorescence in the green region only); (c) same as (b) but with additional red fluorescence shown due to FM 4-64 stained endosomes; (d) same as (c) after incubation at 4 °C. (From Ref. [167].)

functionalized SWNT concentration was as high as 5  $\mu\text{M}$ , but the nanotube solution quickly became toxic to these cells upon increasing the concentration by only twice as much. The uptake mechanism, however, is not due to endocytosis, since the internalization is temperature independent (the same at both 4 and 37 °C) [165]. Nevertheless, there are several other reports on the cell internalization of both non-functionalized carbon nanotubes and those functionalized with other bioactive species (such as nucleic acids) [166, 219, 220]. These reports discuss the cytotoxicity of carbon nanotubes [219] and their potential in bioimaging (via nanotube near-IR fluorescence) [220] and drug, vaccine, and gene delivery systems [164–168].

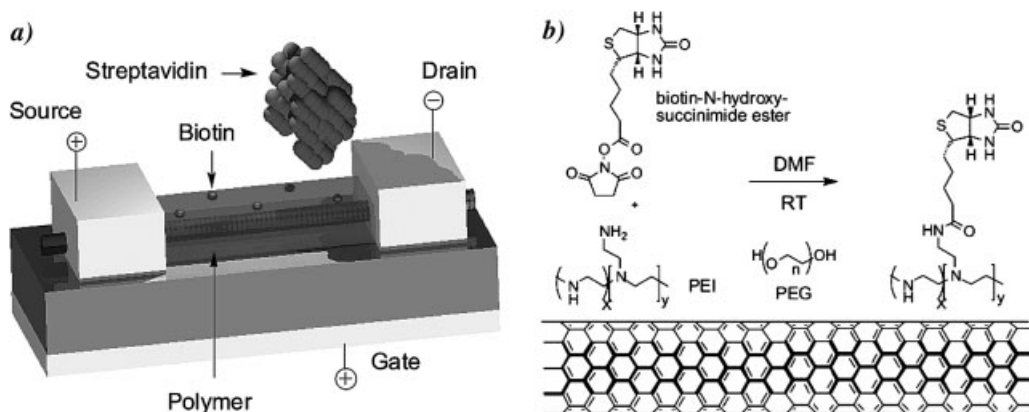

In addition to direct covalent methods, specific protein–nanotube conjugation can also be achieved through the use of a bifunctional molecule, with one end attaching to the protein and the other end to the nanotube. Chen et al. [221] reported

the use of 1-pyrenebutanoic acid succinimidyl ester as a linker for indirect protein–SWNT conjugation. The pyrene moieties of the bifunctional molecules are proposed to interact noncovalently with the nanotube surface via “ $\pi$ – $\pi$ ” stacking, while the succinimides react with pendant amino groups on the protein to form amide linkages. This method was successfully applied to SWNTs at device level [197]. However, the necessity of using this linker molecule has never been seriously determined, especially considering the competitive non-specific interaction bindings from proteins themselves. In Chen et al.’s original control experiment [221], it was claimed that no binding was found between ferritin and SWNTs grown on a TEM grid without the presence of the linker molecule. This contradicts later observations by other workers, who consistently found that ferritins are actually very affinitive to SWNTs, even in aqueous solution [188, 189].

Although considered to be specific conjugation modes, neither direct covalent functionalization nor the usage of pyrene-succinimide bifunctional molecule could provide the selectivity for carbon nanotubes to bind one protein but repel another. One general prerequisite to obtaining such selectivity or biorecognition is efficient elimination of non-specific adsorption. Thus, the application of a protein-resistant layer (such as PEG) on the nanotubes prior to protein conjugation is essential. Shim et al. [187] first demonstrated such a possibility by adsorbing surfactant Triton X-100 and then PEG to SWNTs on silica surface. They proposed that the hydrophobic part of Triton molecule adsorbs onto SWNTs, while its hydrophilic tail facilitates subsequent adsorption of PEG, which alone hardly interacts with the nanotube surface. SWNT devices protected this way were resistant to streptavidin and other protein molecules. With biotin modification on adsorbed PEG, however, streptavidin efficiently coated the nanotube surface, which still repelled other proteins [187]. The well-known biotin–streptavidin interaction obviously accounts for such observed selectivity or biorecognition.

Although each Triton molecule contains an oligomeric ethylene glycol chain as its hydrophilic tail, a simple Triton coating is not sufficient to prevent non-specific adsorption of proteins on nanotubes [187]. Some other surfactants, such as Tween-20, which has dendritic PEG tails, protect the nanotubes much better, even without additional PEG adsorption. Such surfactant coating is quite useful for SWNTs on substrates in devices [179], but not so impressive in aqueous solutions [188]. In a report by Erlanger et al. [222], an anti-fullerene IgG monoclonal antibody was claimed to be specifically conjugated to SWNTs in the presence of Tween-20 in an aqueous environment. Although this antibody is known to be specific to fullerene C<sub>60</sub>, the observed binding might simply be another example of non-specific adsorption. Further evidence is definitely required to prove whether the anti-fullerene antibody is truly selective toward SWNTs.

Nevertheless, biorecognition sites can be created similarly at the PEG end of Tween-20 surfactant molecules. For example, with biotin attachment to the dendritic PEG tails of Tween-20 prior to its adsorption on SWNT FET devices, no protein except streptavidin could be conjugated [179]. In another report, PEG was co-adsorbed onto SWNT devices with another functional polymer, polyethylene

**Fig. 7.23.** (a) Schematic diagram illustrating a biotinylated SWNT-FET for streptavidin recognition. (b) Biotinylation of PEI on the nanotube surface, with co-adsorbed PEG. (From Ref. [223].)

imine (PEI), instead of surfactant molecules [223]. The pendant primary amine groups on PEI were available for subsequent biotin derivatization and, thus, streptavidin recognition (Fig. 7.23).

The protein-resistivity of PEG-coated SWNTs on substrates may be interfered with by the same PEG coating on substrates themselves [Fig. 7.24(a, b)]. The availability of highly water-soluble SWNTs with PEG functionalities [224, 225] provides an excellent opportunity to demonstrate unambiguously the protein-resistant function of the PEG layer on the nanotubes in aqueous solution. As Lin et al. [189] reported, PEG-functionalized SWNTs can totally repel ferritins in aqueous solution. As shown in the TEM image (Fig. 7.24c), ferritins surround the nanotubes, but obviously at a distance, which is due to the PEG functionalities. Other water-soluble SWNTs, such as those functionalized by poly(propionyl ethylenimine-co-ethylenimine) (PPEI-EI) [213, 226] or poly(vinyl alcohol) (PVA) [227], similarly repel proteins in aqueous solution [189]. The protein-resistance coupled with the water-solubility of these functionalized SWNTs could be important in their biomedical applications. Data from other PEG-containing materials suggest that such protein-resistant nanotubes may have reduced cytotoxicity and increased retention time in the circulatory system [228]. All of these hypotheses, however, remain to be verified.

In addition to the well-known biotin–streptavidin interaction, biorecognition may also be achieved through other biologically known supramolecular pairwise selective interactions, such as the antibody–antigen interaction, carbohydrate–lectin interaction, and others. For this purpose, the indirect but selective attachment of different types of proteins to carbon nanotubes can be achieved via initial nanotube functionalization with the corresponding counterpart species. For in-

**Fig. 7.24.** (a) AFM image showing the non-specific binding of streptavidin on SWNTs as-grown on substrate. (b) AFM image showing that the non-specific binding was largely prevented by coating SWNTs with surfactant

Triton X-100 followed by PEG. (From Ref. [187].) (c) TEM image showing that the non-specific binding of ferritin species to water-soluble SWNTs was completely prevented by the covalent PEG functionalities on SWNTs.

stance, an antigen named U1A was attached to Tween-20 molecules and adsorbed onto a SWNT FET device, which was then only responsive to the U1A's antibody counterpart, 10E3 [179]. SWNTs were also co-functionalized in a carbodiimide-activated reaction with an antibody and an enzyme, alkaline phosphatase (ALP), with the latter serving as the electrochemical tag [229]. Such conjugates have been used in combination with immunological magnetic beads for ultrasensitive immunosensing or antigen detection. The antigen was attached in a sandwich-like configuration to nanotube-bound and magnetic-bead-bound antibodies. The captured antigens were then separated magnetically. The electrochemical detection signals were enhanced by comparing multiple copies of enzymatic species on the nanotube surface to single enzyme tags. DNA sensing was achieved via a similar strategy, with selectivity coming from the complementary DNA sequence hybridization instead of antibody–antigen interactions [229].

A natural  $\beta$ -1,3-glucan, schizophyllan (SPG), was found to be able to noncovalently wrap around and solubilize SWNTs in water [230]. Using SPG with lactoside appendages, the carbohydrate-functionalized SWNTs can be conjugated to *Ricinus communis* agglutinin, a lactoside-specific lectin that is inert to other carbohydrates

such as  $\alpha$ -mannose and some other monosaccharides. In another example taking advantage of carbohydrate–lectin specific interactions,  $\beta$ -D-galactose-functionalized SWNTs could be crosslinked by a galactoside-specific lectin from the peanut *Arachis hypogaea*, forming interconnected networks [231].

Very recently, noncovalent functionalization of SWNTs by a mucin-mimic with  $\alpha$ -N-acetylgalactosamine ( $\alpha$ -GalNAc) moieties has been reported [232]. These sugar moieties could be recognized by *Helix pomatia* agglutinin (HPA),  $\alpha$ -GalNAc's specific counterpart (Fig. 7.25). When HPA was plugged with free GalNAc, no binding occurred between the deactivated agglutinin and the  $\alpha$ -mucin mimic-SWNT conjugate. Specificity was further demonstrated by a noncovalent conjugate sample of SWNTs with a similar mucin mimic but bearing sugar moieties of  $\beta$ -configuration. Again, no binding was found between HPA and the  $\beta$ -mucin mimic-SWNT conjugate.

In a similar strategy, Gu et al. [170] reported recently multivalent carbohydrate display on SWNTs for the detection of *E. coli* O157:H7, which took advantage of the selective interactions of the nanotube-bound sugar moieties ( $\beta$ -D-galactose) with the periplasmic galactose-binding proteins on the pathogen surface. The pathogen cells could be agglutinated by the  $\beta$ -D-galactose-functionalized SWNTs, while inert to those functionalized by either  $\alpha$ -D-mannose or BSA protein [170].

Reconstitution of flavoenzymes was also used for enzyme–nanotube conjugation for the purpose of subsequent electronic sensing of a catalytic event via nanotube conductor arrays. As reported by Patolsky et al. [233], the glucose oxidase (GOx) cofactor, flavin adenine dinucleotide (FAD), was first functionalized covalently onto the SWNT array, which was formed by self-assembly on an Au substrate as the electrode. With the protection of SWNTs with PEG, apo-GOx proteins were then immobilized onto the SWNTs via apoenzyme-FAD reconstitution. The conversion of glucose into gluconic acid by the redox enzyme was found to be efficiently transferred to the Au electrode and was highly dependent upon the lengths of the nanotubes, which apparently serve as the pathway for electron transfer [233].

Since these supramolecular but selective interactions are well-known in biology, scientists in the bio-nano field are more inclined to use these interactions to conjugate proteins and nanomaterials, including carbon nanotubes, for biologically and biomedically significant purposes. Proteins conjugated this way probably retain their bioactive structures and functions. However, when proteins are conjugated to carbon nanotubes via other covalent or noncovalent pathways, their secondary and other advanced structures are largely unknown because of their close proximity to the nanotubes. This should be investigated, especially in the light of a recent valuable attempt by Karajanagi et al. [191] on the advanced structures of two enzymes (SBP vs. CT) upon adsorption on SWNTs. From that work, it seems that the secondary and tertiary structures of proteins could easily be affected when adsorbed onto carbon nanotubes. However, the structural and biofunctional alterations to each protein induced in the conjugation events will need to be carefully evaluated on a case-by-case basis before mechanistic details of the interactions

Fig. 7.25. Specific binding of HPA to  $\alpha$ -mucin mimic-coated nanotubes: (a) specific binding of HPA to the surface of  $\alpha$ -mucin mimic-SWNTs; (b) lack of binding of HPA to  $\beta$ -mucin mimic-SWNTs; and (c) inhibition of HPA binding by soluble GalNAc. (From Ref. [232].)

and any potential regulations for the changes in protein structures and biological functions are understood.

#### 7.4

#### Conclusions and Perspectives

As described in this chapter, exciting progress has been made over the past few years in the coupling and assembly of proteins and nanostructured materials (metal, semiconductor and nanotubes). A typical route for preparing these conjugates involves mixing proteins with chemically modified nanomaterials. Protein molecules can also act as crosslinkers or as templates to build nanometer-sized supramolecular structures by self-assembly. The field continues to grow and contribute to new interdisciplinary areas concerned with the synthesis, self-assembly, and processing of organized matter. Despite the progress made, this field is still in its infancy, with many challenges ahead. For example, there is still great demand for alternative and selective coupling methods that allow the preparation of stable, clean, and stoichiometrically well-defined bioconjugate nanomaterials. In this regard, an interesting recent development is the use of supercritical fluid processing, wherein a protein can be attached directly to inorganic nanoparticles in an effective and clean fashion. Other areas where there is much to be learnt are the surface interaction and the interface between nanomaterials and proteins and the control of shape and physico-chemical properties of proteins by means of genetic engineering and bioconjugate chemistry.

Among the enormous challenges are how to design well-ordered structures and how to adapt them efficiently in the macroscopic world. Here, the electrostatic and topographic properties of biological macromolecules, such as bacterial superstructures and hollow protein compartments, still must be understood. Research effort on the discovery, selection and development of peptides from combinatorial peptide and protein libraries will also benefit this field. It will allow the production of even more suitable biological structures, since they can provide recombinant protein units that have optimized recognition capabilities for inorganic materials and their assemblies in distinctively shaped superstructures.

Further future investigations should also address the issues of the applications of these bioconjugate materials. Interdisciplinary research in this field has great potential for discovering and producing advanced materials, which can then lead to novel devices for sensing, signal transduction, catalysis, and new biocompatible materials and interfaces desired for biomedical sciences and tissue engineering.

# Stabilization and Functionalization of Metallic Nanoparticles: the Peptide Route

*Raphaël Lévy and R. Christopher Doty*

### 8.1

#### Introduction

Gold and silver nanoparticles have attracted a great deal of recent attention due to their potential use in a numerous applications such as biosensing, bottom-up assembly of nanodevices, and catalysis. The advantages of these particles include easy, non-toxic synthesis and chemical modification protocols, and outstanding optical properties that enable single-particle detection with no blinking or bleaching. Many of these applications depend crucially on the stabilization and functionalization of metal nanoparticles with adequate capping ligands.

This chapter begins with a discussion of aqueous synthesis protocols for different shapes and sizes of gold and silver nanoparticles, and various strategies to transfer nanoparticles synthesized in organic solvents into water. As the nanoparticle size increases, the dominant optical characteristic changes from fluorescence to absorbance to scattering. For each regime there is an optical technique capable of achieving single-particle detection. The role of Au nanoparticles in DNA sensing is discussed along with the use of DNA and proteins to assemble Au nanoparticles into discrete structures. Long-range ordering of Au nanoparticles on two-dimensional (2D) protein crystal templates is presented as an alternative assembly method. The chapter continues with a description of stabilization and functionalization of metallic nanoparticles using peptides. The concept of a peptide toolbox for bionanotechnology containing capping ligands, recognition and self-assembly motifs is introduced. The interaction of amino acids, peptides and proteins with gold and silver is briefly reviewed. Rational and combinatorial designs of peptides provide capping ligands to convert nanoparticles into protein-like materials. A major advantage of the peptide route is that stabilization and functionalization are achieved in a single step. A wide variety of functions can be easily transferred to the nanoparticles using peptides with extensions. Furthermore, their protein-like properties open up new possibilities to purify and handle nanoparticles and prepare conjugates with a defined number of recognition groups per particle. Finally, some remarkable properties of peptides that have not yet been used in the context of nanoparticles are presented.

## 8.2

### Metallic Nanoparticles – An Overview

#### 8.2.1

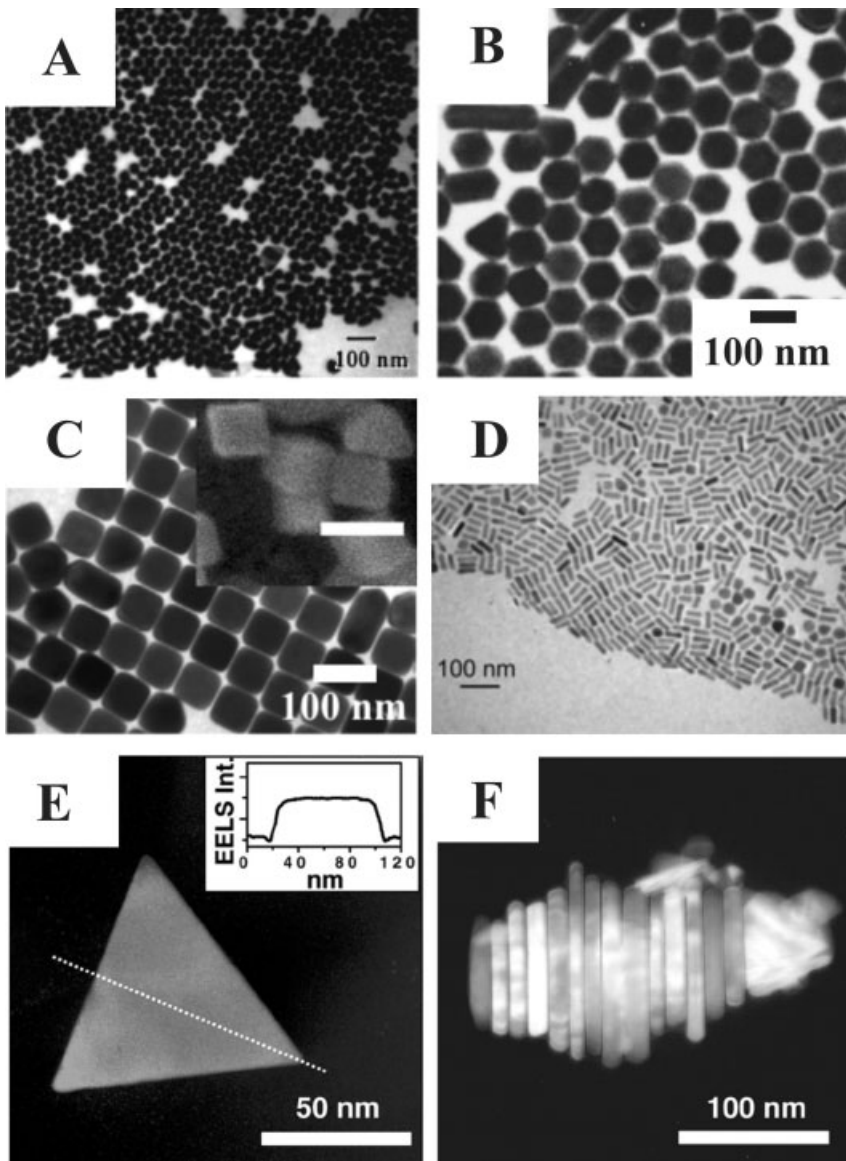

##### Metallic Nanoparticles – Preparation

While fluorescence from semiconductor nanocrystals ranging from the UV to the near-IR is best achieved with particles less than 10 nm in diameter, sizes easily obtained by syntheses in organic solvents, metal nanocrystals need to be greater than 30 or 40 nm in diameter to take advantage of their light-scattering properties. This is too large for synthesis in organic solvents, but an aqueous synthesis utilizing sodium citrate as both reducing agent and electrostatic stabilizer can produce Au nanocrystals between 10 and 150 nm in diameter [1]. For reproducible, quantitative results, nanocrystals need to be monodisperse in both size and shape. Unfortunately, the citrate-reduction synthesis gives highly polydisperse results for nanocrystals greater than ca. 30 nm in diameter. Recent work using 12 nm citrate-stabilized Au nanocrystals as seeds for the growth of larger nanocrystals has allowed the synthesis of monodisperse, spherical nanocrystals, with diameters between 30 and 110 nm, and monodisperse, ellipsoidal nanorods of similar size [2, 3] (Fig. 8.1A).

Gold nanoparticles in the shape of rods, rectangles, cubes, triangles, hexagons, and branched structures can be synthesized in very high yield by varying the ratios of an interdependent mixture of small Au nanoparticle seeds, cetyltrimethylammonium bromide (CTAB),  $\text{HAuCl}_4$ ,  $\text{AgNO}_3$ , and ascorbic acid [4–6] (Fig. 8.1B–D). For some shapes, especially rods, the presence of  $\text{Ag}^+$  was essential for their synthesis in high yield. The precise role of the Ag ions is unknown, but it is believed that an interaction with the Br ions of CTAB affects either the surface of the Au nanoparticle or the shape of the CTAB template.

Although tremendous advances have been made in the synthesis of large, water-soluble Au nanocrystals, the same cannot be said for Ag nanocrystals. Silver oxidizes much more readily than Au, and the larger van der Waal's attraction between Ag spheres compared with Au spheres reduces the effectiveness of electrostatic repulsion as a method of stabilization. Thus far, this problem has been solved by depositing Au around the Ag nanocrystal, much like the seeded growth syntheses mentioned above, to reduce oxidation of the Ag surface. In monolayer and bilayer quantities, this does not affect the absorption or light-scattering properties of the original Ag core [7].

Silver nanoparticles have also been synthesized as rods, wires, and triangular prisms – the first two shapes by a very similar procedure to that used to obtain Au nanorods [8]. Silver nanoparticle seeds (4 nm diameter) were added to a growth solution containing  $\text{AgNO}_3$ , CTAB, and ascorbic acid. The pH was then increased with NaOH to enable the ascorbic acid to reduce the Ag ions. The ratio of nanoparticle seeds to Ag ions and the pH are key factors in determining whether rods or wires are produced. Nanorods can be synthesized reproducibly with aspect ratios between 2.5 and 15 for widths of 10 to 15 nm. Nanowires of similar width and up

to 4 mm long have been produced. The many spherical Ag nanoparticles produced along with the nanorods and nanowires must be removed by centrifugation. Triangular prisms have been synthesized in very high yield by the photoinduced conversion of spherical Ag nanoparticles [9]. A solution containing 8 nm citrate-stabilized Ag nanoparticles and a particle stabilizing agent were irradiated with a 40 W fluorescent light for 3 days. The spherical nanoparticles were gradually converted into nanoprisms with an edge length of 100 nm [Fig. 8.1(E) and 8.1(F)].

In addition to synthesis in aqueous solutions, nanoparticles can be synthesized in organic solvents and transferred into the aqueous phase via ligand-exchange. Solubilization via ligand-exchange requires displacement of the hydrophobic molecule attached to the nanoparticle surface by a hydrophilic one, usually a carboxylic acid-terminated molecule [10, 11]. A particularly good example of this technique is the use of a thioalkylated monohydroxy tetraethylene glycol (PEG-OH) to transfer tetraoctylammonium bromide-stabilized Au nanoparticles from toluene to water [12]. These 5 to 8 nm particles displayed excellent stability between pH 0 and 14 and in 3.5 M NaCl. They also did not aggregate in the presence of proteins. The particles' extraordinary stability is due to the bifunctional nature of the PEG-OH capping ligand. The alkanethiol end forms a strong bond with the Au surface and a tight hydrophobic shell around the particle while the ethylene glycol end imparts water solubility and presents an uncharged surface to the aqueous environment. Gold nanoparticles have also been synthesized in the presence of PEG-OH [12]. These particles had diameters between 2 and 4 nm and displayed the same excellent stability as the larger nanoparticles produced by ligand-exchange. The efficiency of ligand exchange depends upon the relative bond strengths between the two molecules and the nanoparticle surface, and usually requires a large excess of the hydrophilic molecule in solution during the ligand exchange. Unfortunately, this requirement precludes direct attachment of some biological molecules that are not available, or are prohibitively expensive, in such large quantities, e.g. many peptides and proteins.

Another approach to making nanocrystals water-soluble is to encapsulate them in a layer of silica/siloxane via a surface silanization procedure [13, 14]. In subsequent crosslinking reactions, charged molecules can be incorporated into the shell to provide electrostatic stabilization to the water-soluble nanocrystals, or long-chained, hydrophilic molecules, such as polyethylene glycol, can be used to provide steric stabilization. The resulting silica shell has exposed amino, mercapto, and phosphate groups that can be used to further functionalize the nanocrystal surface. While the silica-encapsulated nanocrystals are very stable and do not aggregate in aqueous solution, gradual decomposition of the silica layer eventually leads to nanocrystal precipitation and limits the length of time they can be left in water.

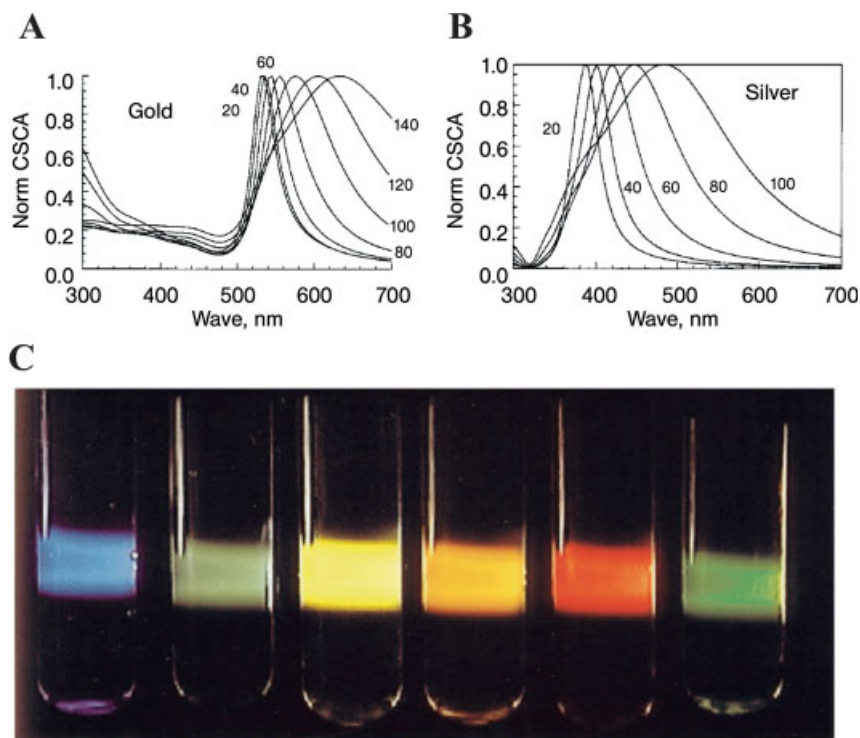

### 8.2.2

#### **Metallic Nanoparticles – Optical Properties**

Almost every application of metallic nanoparticles takes advantage of their ability to strongly absorb and scatter light. This is because they possess a distinctive opti-

cal property known as surface plasmon resonance, which is effectively due to the collective oscillation of free electrons. For Ag and Au nanocrystals the wavelength at which this occurs is in the vicinity of 400 and 500 nm, respectively, and is a function of the nanocrystal size and composition, the molecules attached to the surface of the nanocrystal, and the surrounding medium. Many biological applications of metal nanocrystals will rely on their light scattering properties because scattered light can be detected thousands of times more sensitively than transmitted light [15, 16]. A solution of nanocrystals will scatter an incident beam of monochromatic light without changing its frequency, but when illuminated with an incident beam of white light, the wavelength at which the scattered light is a maximum is a function of particle size, shape, and composition (Fig. 8.2A and 8.2B). Through a combination of Ag and Au nanocrystals of different sizes, one can view scattered light of every color in the visible light spectrum (Fig. 8.2C). The particle size dependence of the wavelength of scattered light was predicted by Mie using classical electromagnetic theory [1, 17]. In the Rayleigh limit ( $R < \lambda/20$ , where  $R$  is the radius of the nanocrystal and  $\lambda$  is the wavelength of incident light) the wavelength of scattered light remains unchanged, while the intensity increases as  $R^6$ . For nanocrystals outside the Rayleigh limit, an increase in particle size broadens the scattering spectrum and shifts it to longer wavelengths. In general, the maximum intensity of light scattered from an Ag nanocrystal is at least  $10\times$  that of an Au nanocrystal of the same size, and the spectral shifts with regard to particle size are more pronounced. The scattering spectra are also affected by the refractive index of the medium containing the nanocrystals. Increasing the refractive index increases the intensity of scattered light and shifts it to longer wavelengths. The intensity of scattered light for Au nanocrystals is enhanced by an increase in the medium refractive index more so than Ag, but the spectra of Ag shift more than those of Au [15]. These effects are important experimentally, because raising the refractive index of the medium increases the signal-to-noise ratio of a particular measurement, by both increasing the scattering from the metal nanocrystals and decreasing the background scattering from dielectric materials. Light scattering from metal nanocrystals cannot be quenched, and the nanocrystals do not degrade under optical excitation like many molecular fluorophores, permitting time-dependent studies. In fact, the scattered light intensity of a 60 nm diameter Au nanocrystal is approximately equivalent to the fluorescent light intensity of 270 000 fluorescein molecules [15]. This allows the detection of a single particle using a simple optical microscope in dark-field mode. The main drawback of this detection strategy is the background scattering from the biological sample and from defects in microscope slides. This background cannot be removed by an emission filter in an experiment where the illumination and detection have to be at the same wavelength, but, as mentioned above, refractive index matching can be effective. To ensure that the detected light comes from a metallic particle, more sophisticated instrumentation is needed in which the scattered light is analyzed using a spectrometer coupled to the microscope or a tunable filter to recognize the characteristic scattering spectrum of the metallic nanoparticles.

While light absorption and scattering are practical detection methods for large

**Fig. 8.2.** Normalized scattering cross-sections as a function of wavelength for (A) gold and (B) silver nanoparticles of various sizes. (C) Light scattering from aqueous solutions of (from left to right) 40 nm Au nanoparticles; 40, 78, 118, and 140 nm Au nanoparticles; and fluorescein illuminated by a single beam of white light. metal nanoparticles, small (diameter  $< 5$  nm) nanoparticles can be detected by light emission. Previous work has shown blue, red, and near-IR emission from water-soluble Au nanoparticles [18, 19]. The exact mechanism is unknown, but it is thought that relaxation of excited conduction electrons into sp- and d-band holes, intraband and interband, respectively, combined with surface effects from the ligand shell can explain the different light emission peaks. Although these nanoparticles show a million-fold enhancement in fluorescence quantum yield compared with bulk gold, the quantum yields ( $10^{-3}$ – $10^{-5}$ ) are still much lower than for organic fluorophores and semiconductor quantum dots. Recent work on nanodots, however, has further increased the quantum yield of Au one hundred-fold [20, 21]. An eight-atom cluster of Au stabilized by a poly(amidoamine) (PAMAM) dendrimer emits blue light ( $\lambda_{\text{max}} = 450$  nm) with a quantum yield of  $41 \pm 5\%$  [20]. Additional work on 5-, 13-, 23-, and 31-atom clusters extended the emission into the UV and the near-IR (Fig. 8.3), with a quantum yield of 70% for the five-atom, UV-emitting cluster [21]. The quantum yield decreases to 10% as the emission energy decreases from the UV to the near-IR, as a result of increased competition

Fig. 8.3. Photoluminescence excitation (dashed lines) and emission (solid lines) spectra for Au nanodots with cluster sizes of 5, 8, 13, and 31 atoms. The emission spectra redshift as cluster size increases. (Reprinted with permission from [21]. Copyright (2004) by American Physical Society (APS).)

from nonradiative pathways. The emission energy scales with the number of atoms, as predicted by a jellium model, indicating that the fluorescence is “proto-plasmonic” and arises from intraband transitions of the free electrons. The clusters are stable over long periods in water, can be stored as dry powders, and, unlike semiconductor quantum dots, their synthesis is easy and non-toxic. Their discrete excitation spectra, however, excludes their use in the single-excitation, multiplexed bioassays for which semiconductor quantum dots show so much promise. However, it does allow them to function as energy transfer pairs and long lifetime fluorescent labels for *in vivo* imaging.

In addition to Au nanodots, Dickson and co-workers have also produced fluorescent Ag nanodots [22, 23]. Silver ions were photoreduced in the presence of PAMAM dendrimers to produce two- to eight-atom clusters [22]. Single nanodot fluorescence was detected at between 530 and 650 nm. Photoluminescence beyond 600 nm was also seen from Ag nanodots formed by the chemical reduction of Ag ions in the presence of oligonucleotides [23]. Mass spectral analysis showed that the cluster size was between one and four Ag atoms. Chemical shifts in the NMR spectra of the cytosine bases suggest that base-specific interactions may play an important role in nanodot formation and that oligonucleotides with specific sequences may be able to control cluster stoichiometry. Unlike the Au nanodots discussed above, the photoluminescence of different-sized Ag nanodots can be excited by a single source, making them available for applications that require a degree of multiplexing.

Particles that are too small to be detected by light scattering and too big to fluoresce with any efficiency can be detected using a recently developed photothermal

technique [24]. Called photothermal interference contrast, it relies on the increase in temperature around a metal nanoparticle when it absorbs laser light at the same frequency as its plasmon resonance. Changes in the temperature-dependent local index of refraction can be detected optically using a second laser beam. One benefit of this technique is that it does not detect non-absorbing scatterers. For instance, 10 and 80 nm Au particles were mixed with 300 nm latex spheres and spin-coated onto a substrate. As shown in Fig. 8.4(A), the 80 nm Au particles and 300 nm latex spheres were detected using differential interference contrast. Using the photothermal technique, only the 80 and 10 nm Au nanoparticles were detected (Fig. 8.4B and 8.4C). Nanoparticles as small as 2.5 nm have been optically detected using the photothermal detection system [24]. Another benefit of this technique is that organic and biological samples have a negligible photothermal background. This was shown in the visualization of individual 10 nm Au particles attached to membrane proteins of COS7 cells. By tilting the sample, 3D images of the Au nanoparticles were obtained [25]. Because absorption is used, there is no photobleaching, blinking, or saturation of the metal nanoparticles. One concern with this technique is that the temperature rise around the nanoparticles could interfere with the function of live biological samples. For a 10 nm particle, the temperature increase on the surface of the particle is estimated to be 15 K. This can be lowered by changing the laser power and the location of the laser beams in relation to the particles.

### 8.2.3

#### **Metallic Nanoparticles – Applications**

The uniformity of citrate-stabilized Au nanocrystals, the ease with which the citrate molecules can be displaced from the Au surface, and the unique optical properties of both individual and aggregated clusters of Au nanocrystals are all critical to successful utilization in biological applications. An area of early success was the attachment of thiol-terminated DNA oligonucleotides to Au nanocrystals, in which complementary strands of DNA were used to assemble both dimers and trimers and large, aggregated structures of nanocrystals [26, 27]. The nucleotide-induced aggregation caused a red to blue color change in the aqueous nanocrystal solution. This aggregation is reversible upon heating the solution above the melting temperature of the DNA [28]. In this way the absorbance of Au nanocrystals is used to detect DNA hybridization [29, 30]. A more solid-state approach to the detection of DNA hybridization is to immobilize a strand of DNA on a substrate and flow a solution of nanocrystals containing the complementary strand of DNA over the substrate [31, 32] (Fig. 8.5). The attachment of nanocrystals on the surface can be detected by light scattering. This technique offers greater sensitivity and can detect DNA in the femtomolar concentration range [31, 33].

Complementary strands of DNA can be attached to nanocrystals of different size, shape, and/or composition. In this way, large nanocrystals can be surrounded by small ones [34], metal nanocrystals can be surrounded by semiconductor ones [35], and vice-versa [36]. The challenge with this technique is to control the degree of nanocrystal ordering (Fig. 8.6). Ideally, one would form dimers, trimers, and

**Fig. 8.4.** (A) Differential interference contrast image of 10 and 80 nm Au particles with 300 nm latex particles. Only the 80 nm Au and 300 nm latex particles can be detected. (B) Photothermal image at low heating laser

power shows the 80 nm Au particles but not the 300 nm latex particles. (C) Increasing the laser power brings the 10 nm Au particles into view. (Reprinted with permission from [24]. Copyright (2002) by AAAS.)

**Fig. 8.5.** Two different types of three component sandwich assays for oligonucleotide detection. (A) A two-color detection method taking advantage of the light scattering properties of different sized Au nanoparticles. (B) An extremely sensitive

detection method in which silver atoms are reduced onto 13 nm Au particles to amplify the signal for detection by a flatbed scanner. (A) reprinted with permission from [32]. Copyright (2001) by ACS. (B) reprinted with permission from [31]. Copyright (2000) by AAAS.

other well-defined structures, such as monolayers and multilayers [37]. However, this requires precise control of the number of DNA molecules attached to the nanocrystal surface, and it is not currently possible to generate a solution of nanocrystals with only, and exactly, one (or two, or three, etc.) DNA molecule per nanocrystal. In a given solution there is a statistical distribution of desired capping ligands per nanocrystal. The challenge then is to separate the nanocrystals with one oligonucleotide from those with two, three, four, etc., which at present has only been consistently achieved by gel electrophoresis [36, 38, 39]. To achieve maximum resolution the nanocrystals should be size-monodisperse and homogeneous in charge, and the DNA molecules should have a mobility similar to that of the nanocrystals so that the attachment of only one or two oligonucleotides has a significant effect on the overall mobility through the gel. Besides being time-consuming and relatively inefficient, the pore size of the gel presents a serious limitation to the size of nanocrystals that can be separated.

In addition to using nanoparticles to detect biological molecules, biological mol-

**Fig. 8.6.** TEM images of dimers and trimers of 5 and 10 nm Au nanoparticles linked by DNA. A schematic of the particular DNA-based assembly method is shown to the left of the TEM images. (Reprinted with permission from Ref. [37].)

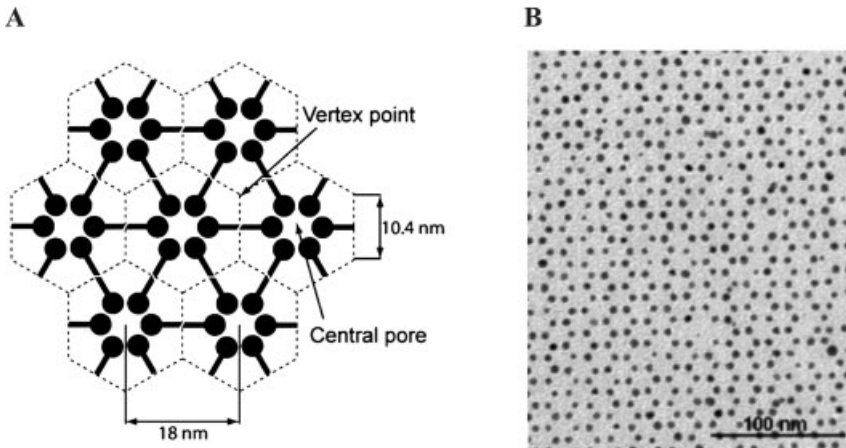

ecules can be used to self-assemble nanoparticles into patterns that are not otherwise thermodynamically or kinetically favorable. As discussed in the previous section, DNA has been used to assemble dimers, trimers and much larger aggregated structures. Another potentially powerful, high-yield method for creating dimers, trimers, or chains of nanoparticles involves the use of solid-phase reactions on PS

Wang or HMPA-PEGA resins and Fmoc protecting groups [40]. This technique takes advantage of the low-density packing of functional groups, in this case lysine, on the resins. Thus, a 2.2 nm Au nanoparticle with a ligand shell consisting of equal parts octanethiolate and mercaptoundecanoic acid will react with only one lysine. Protection of the remaining carboxyl groups in the ligand shell with methylamine followed by cleavage of the resin bead leaves a single carboxylic acid on the nanoparticle available for further functionalization. Monofunctionalization was tested by dimerizing nanoparticles with ethylenediamine. The overall efficiency of this process is extremely low, however; only 3% and 15% of the nanoparticles remained after cleavage of the PS Wang and HMPA-PEGA resins, respectively. Of those remaining particles, around 60% formed dimers, with some forming higher-order clusters. To form chains of nanoparticles using this method, the efficiency needs to be much higher, but it is nonetheless a powerful method for monofunctionalizing nanoparticles.

A single biotinylated dextran molecule has been conjugated to 15 nm Au particles through careful consideration of the molecular weight of the aminodextran molecules and the surface area of the nanoparticles [41]. A 2000 kDa aminodextran was functionalized with pyridyldithio propionate to create the disulfide bonds, and biofunctionality was imparted by conjugation with biotin. The benefit of this technique is the stability imparted to the nanoparticle by coating it with one molecule capable of forming hundreds of thiol bonds rather than with hundreds of individual thiol-containing molecules. As proof of this the particles were run through a typical polymerase chain reaction protocol without loss of biological activity. This technique can be expanded beyond biotin to include haptens, antibodies, and oligonucleotides. The number and type of functional molecules per dextran can be altered as required for use in sensitive bioassays or programmed self-assembly.

In addition to the well-known biotin–streptavidin system, antibodies and antigens can be used to link nanoparticles together. Mann and co-workers have shown that Au nanoparticles stabilized by IgE and IgG antibodies assemble into 3D networks in the presence of bivalent antigens [42]. Macroscopic filaments with aspect ratios greater than 100 precipitated from solution when the conformational freedom of the bivalent hetero-antigen was increased by doubling the size of the spacer between its functional ends. They were also able to form bimetallic aggregates by mixing IgE-stabilized Au nanoparticles and IgG-stabilized Ag nanoparticles with a bivalent hetero-antigen. The feasibility of aggregation-based immunoassays has been demonstrated by Thanh and Rosenzweig [43]. At a comparable sensitivity to ELISA, the concentration of anti-protein A in serum samples was determined by following the aggregation of protein-A coated Au nanoparticles with a UV/Visible spectrophotometer.

Thus far, the aggregation-based techniques intended for the long-range assembly of ordered nanoparticle structures have resulted in large, disordered 3D clusters. A template-based method for precise positioning of nanoparticles using S-layer proteins is an interesting alternative [44, 45]. S-layer proteins are found on the surface of prokaryotic (e.g., bacteria) cells and can self-assemble into 2D structures on solid supports. Interestingly, for nanotechnology, the symmetry and lattice constants of

**Fig. 8.7.** (A) Schematic representation of the hexagonal ordering of S-layer proteins. Protein monomers arrange to form a central pore 2 nm in diameter and 18 nm apart. Vertex points are 10.4 nm apart. (B) TEM image of 5 nm citrate-stabilized Au nanoparticles on the

the self-assembled structure can be tailored, and the protein units contain identical central pores with diameters that can range between 2 and 6 nm. An S-layer protein investigated recently for long-range ordering of nanoparticles has hexagonal symmetry, a central pore size of 2 nm, and a lattice constant of 18 nm (Fig. 8.7A). Mann and co-workers found that negatively charged citrate-stabilized Au nanoparticles with a diameter of 5 nm formed long-range, ordered assemblies with hexagonal symmetry and a center-to-center distance of 18 nm [44]. The same was true of a solution of 10 nm citrate-stabilized Au particles, except that the particles that bound to the S-layer template were 8.0 nm. They also found that the 5 nm particles bound preferentially to the 9.7 nm particles when a solution containing a mixture of the two was placed on the protein template. Particles larger than the lattice constant of the template only bound randomly to the structure, as did smaller Au nanoparticles with a positive surface charge. While Mann and co-workers were unable to determine if the nanoparticles were located in the central pore of the S-layer protein units, Bergkvist et al. showed that the nanoparticles were in fact located at the vertex point of three protein units [45]. The center-to-center distance of 18 nm was maintained by nanoparticle adsorption to every other vertex point. Adding 25 mM NaCl during nanoparticle adsorption resulted in the occupation of every vertex point and a center-to-center distance of 10 nm [Fig. 8.7(B)]. Nanoparticle adsorption to the protein template is a result of electrostatic interactions between the negatively charged Au nanoparticles and positively charged residues of the S-layer protein, while interparticle separation is controlled by electrostatic repulsions between Au nanoparticles.

Metal nanoparticles could also be used as scaffolds for the self-assembly of

enzymes and receptors. Still in its infancy, several proof of principle experiments have been published, mainly by the groups of Rotello and Scrimin [46]. The mobility of thiols on gold surfaces and the possibility to easily make mixed self-assembled monolayers presenting various chemical moieties are key ingredients in these studies. An early example demonstrated that flavin binding sites could be imprinted in a gold nanoparticle supported monolayer containing both hydrogen bonding and aromatic stacking elements [47]. More recently, dipeptide-functionalized nanoparticles with esterase-like activity have been prepared [48]. Confinement of the catalytic units in the monolayer drives a 300-fold enhancement of activity compared with the dispersed monomeric dipeptide, demonstrating the crucial role of cooperativity in these systems.

### 8.3

#### Stabilization and Functionalization of Metallic Nanoparticles – The Peptide Route

##### 8.3.1

##### Peptides, Proteins and Nanoscale Science

Peptides are short sequences of amino acids linked by peptide bonds. When a sequence is longer than 30  $\alpha$ -amino acids, the molecule is generally called a protein or a polypeptide if it is a synthetic polymer. Proteins are biopolymers composed of the 20 natural  $\alpha$ -amino acids. Essential components of life, they fulfill the roles of elastic material, enzymes, motors, signal transducers etc. Protein function arises from precisely defined folding of the polymer chain into a 3D structure. Whereas elaborate tasks are generally assumed by large proteins or complexes of proteins (3–100 nm), short sequences composed of less than ten  $\alpha$ -amino acids are used by living organisms as highly specific recognition sequences (e.g., cellular localization sequences, enzyme substrate and ligand–receptor recognition sequences).

Understanding the relationship between the amino acid sequence of a protein and its structure is a major and fundamental field of research known as the folding problem. It has wide implications for drug development and discovery. One of the tests of this understanding is the ability to design from first principles unnatural sequences that fold according to predictions. This has been successfully achieved at the level of secondary structures (e.g. helix and beta-sheet) [49–51], while the *de novo* design of catalytic proteins is an emerging field (e.g., Kaplan and colleagues have reported the design of an O<sub>2</sub>-dependent phenol oxidase whose structure, sequence, and activity have been designed from first principles [52]).

One of the challenges of nanotechnology is to create nanostructures capable of handling complex tasks. In the nanometer range, proteins are fairly clearly the most advanced devices known. Furthermore, molecular biology offers powerful tools to modify, adapt, purify and manipulate these natural devices. Therefore, two complementary approaches have been taken. The first seeks to modify existing proteins or viruses [53, 54] to solve technological problem on the nanoscale [55],

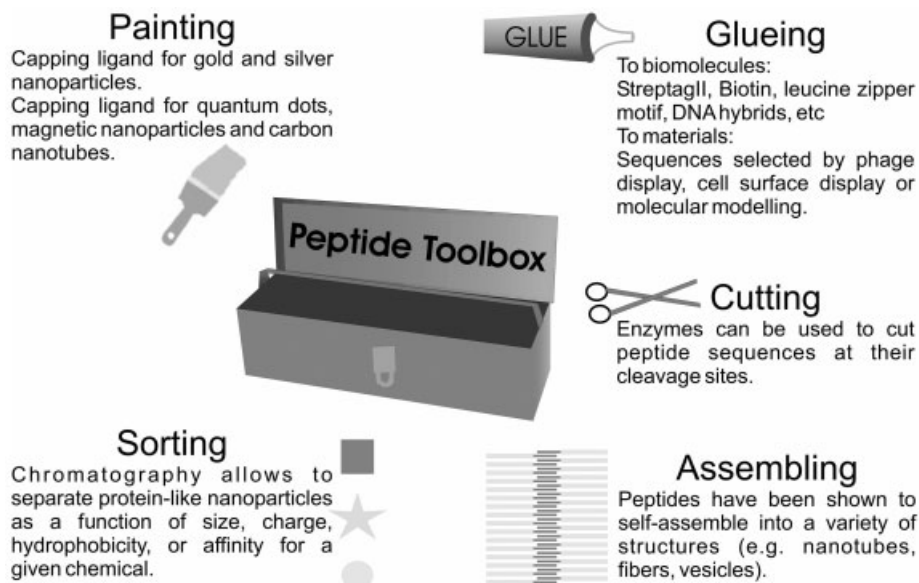

Fig. 8.8. Peptide toolbox for bionanotechnology.

whereas the second seeks to confer protein-like properties to artificial nanomaterials having useful physical properties (e.g., metallic nanoparticles, quantum dots and carbon nanotubes). In the following, we focus on protein-like metallic nanoparticles obtained using peptides as capping ligands.

### 8.3.2

#### Peptide Toolbox for Bionanotechnology

Peptides are a large family of commercially available molecules. The concept of a *peptide toolbox* is emerging from recent work. As illustrated in Fig. 8.8, this toolbox contains sequences that can achieve various tasks. Peptides can be used as a capping ligand to control the surface properties of nanomaterials. They offer various affinity pairs as well as binding motifs to synthetic materials. Enzymes can be used to cleave or modify peptide sequences at precisely defined sites. Most powerful biochemistry tools are intrinsically parts of the peptide toolbox and are readily available to handle and modify peptide-capped materials. This includes various chromatography techniques that allow nanomaterials to be separated on the basis of size, charge, hydrophobicity and affinity as well as various well-established bioconjugation reagents. Designed peptides can self-assemble into extended structures from micelles, fibers, and nanotubes to vesicles and hydrogels. The toolbox has only been superficially explored in the context of nanoparticles and their assemblies. Most importantly, peptide-capped nanoparticles may offer a path for

integrating various properties into well-defined complex materials. Examples will be given to show that peptide properties can be readily transferred to metallic nanoparticles by using peptides as capping ligands.

### 8.3.3

#### **Peptides as Capping Ligands**

##### **8.3.3.1 Interactions of Amino Acids with Noble Metals**

To our knowledge, no systematic study of amino acid interactions with gold is available. However, thiols and amine groups are known to interact strongly with gold. For example, alkanethiol, mercapto- and amino-dextrans have been used as capping ligands for gold nanoparticles [56, 57]. Therefore, as expected, cysteine (thiol on its side chain) and lysine (primary amine on its side chain) do bind to gold nanoparticles [58].

Sastry and co-workers have published several studies on amino acid interactions with metallic nanoparticles (Ref. [59] gives a more complete review). Cysteine, [60] lysine [61] and tryptophan [62] were used as a capping ligand for silver or gold nanoparticles. Lysine-capped nanoparticles disperse in acidic aqueous solution, while aggregation attributed to hydrogen bonding occurs at neutral and basic pH [61]. In addition, water-dispersible gold nanoparticles have been synthesized by the spontaneous reduction of aqueous chloroaurate ions by tryptophan [62]. The same group has used isothermal titration calorimetry to characterize the pH-dependant binding of lysine and aspartic acid to gold nanoparticles [63]. Xu and colleagues have shown that lysine-capped nanoparticles can be assembled into suprastructures through peptide bond formation in the presence of a condensation agent [EDC, ethyl-3-(dimethylaminopropyl)carbodiimide] [64]. Modulation of the lysine to gold ratio allows the assembly of linear chains of nanoparticles [65]. Aggregation of nanoparticles has been seen upon addition of thiol-containing amino acids and peptides [66, 67].

Lysine residues on proteins play an important role in their adsorption onto gold. Xie and colleagues have characterized in detail the use of peptide–bovine serum albumin (BSA) conjugates as capping ligand for gold nanoparticles (BSA contains 59 lysines, of which up to 35 are thought to reside on its surface) [68]. BSA can also be used during the synthesis of gold nanoparticles, resulting in water-soluble sub-2 nm particles [69].

##### **8.3.3.2 Peptides as Reducing Agent and Template in Metallic Nanoparticle Synthesis**

Peptides were first used in noble metal nanoparticle synthesis in the seminal work of Schaaff and colleagues in 1998, where the tripeptide glutathione GSH was used to obtain 1.5 nm gold clusters encapsulated in a peptide layer. Synthesis involved the decomposition of polymeric Au(I)SG compounds [70]. Inspired by biological mechanisms for the reduction and mineralization of noble metals, Slocik and colleagues have used a histidine-rich peptide to mediate the formation of various metal, metal oxide and metal sulfide clusters [71, 72]. They have also shown that, in some cases, antibodies can recognize the peptide sequence immobilized on the

particle surface. Djalali and colleagues reported that the same histidine-rich peptide immobilized on a heptane dicarboxylate nanowire template was able to control the nucleation and growth of monodisperse highly packed gold nanoclusters [73, 74]. This approach has been extended to the synthesis of continuous platinum nanowires using a slightly different peptide sequence [75]. Two-dimensional arrays of a self-assembled protein complex, chaperonin, have been used for the constrained synthesis of Ni-Pd and Co-Pd nanoparticles [76]. The sub-unit proteins were genetically engineered to expose a large number of histidines inside the solvent-accessible pore of the chaperonin and, hence, promote the binding of metal ions. Sequences selected by phage-display technology for their affinity to metallic surfaces have been used in silver and cobalt nanoparticle synthesis [77]. In an even more elaborate study, the same group has immobilized a silver-binding peptide in the inner cavity of the self-assembled cage protein ferritin [78]. Controlled growth of a silver nanocrystal within the cavity was observed in the presence of silver nitrate. This approach might be extended to other materials using other peptide templates.

### 8.3.3.3 Rational Design of a Peptide Capping Ligands for Gold Nanoparticles: CALNN

Based on protein folding considerations, we have recently designed a pentapeptide ligand, CALNN, that converts citrate-stabilized gold nanoparticles into extremely stable protein-like gold nanoparticles [79]. Soluble proteins are usually folded in such a way that their hydrophobic groups are located in the interior of the macromolecule, while charged and hydrophilic groups are exposed to water. The pentapeptide CALNN (Chart 8.1) was designed to mimic this architecture. The thiol group in the side chain of the N-terminal cysteine (C) can bind covalently to the gold surface. Alanine (A) and leucine (L) in positions 2 and 3 possess hydrophobic side chains and were chosen to promote the self-assembly of the peptide. Asparagine (N) in positions 4 and 5 is an uncharged, but hydrophilic amino acid due to the amide group on the side chain, and the C-terminal asparagine in position 5 bears a negative charge due to the terminal carboxylic group.

This design proved to be extremely successful at providing peptide-capped particles that are stable over a wide range of pH and ionic strength (up to 1 M NaCl for 13 nm gold nanoparticles at pH 7 and up to 4 M NaCl for 4 nm gold nanoparticles). Importantly, CALNN-capped nanoparticles can be manipulated like a robust protein, e.g., they can be freeze-dried and resuspended in water, purified by size-exclusion and ion-exchange chromatography.

Chart 8.1. CALNN structure.

#### 8.3.3.4 Combinatorial Exploration of Peptides as Capping Ligands: the CALNN Family

CALNN is one of 3 200 000 possible sequences of five natural amino acids, and the remarkable stability that it imparts to gold nanoparticles encouraged us to further investigate its structural basis. Thus, exactly like mutagenesis is used to identify the active domain of proteins, we studied the effect of systematic variations of peptide sequence on stability to achieve a better understanding of peptide capping ligands [79]. The variation criteria were the peptide length, N-terminal amino acid (first amino acid), which when cysteine is likely to be the anchor, the peptide core (second and third amino acids), and the peptide carboxyl terminus (fourth and fifth amino acids). A subset of these peptides induced immediate aggregation of the nanoparticle solution. A common feature of peptides in this subset was the presence of two groups having a strong affinity for gold (cysteine, lysine and arginine) at the two ends of the sequence. A striking example is NNLAC, the reverse sequence from CALNN that has the N-terminus amino group at the distal end from the cysteine and induces immediate aggregation, whereas CALNN is an excellent capping ligand. This exemplifies how subtle changes in peptide sequences can have a dramatic effect on performance as capping ligand.

The effect of the remaining peptides on the electrolyte-induced aggregation of gold nanoparticles was then systematically studied. Quantitative analysis of the experimental data corroborates the initial design criteria, establishing the need for a cysteine as an anchor to the gold nanoparticle, a clear correlation between peptide length and stability, and the need for interaction between adjacent peptide chains through hydrophobic interactions or hydrogen bonding. The balance between peptide charge and cohesive interaction also plays a major role.

#### 8.3.3.5 Peptide-capped Silver Nanoparticles

Despite having superior light absorption and scattering properties, silver nanoparticles have not had the same impact as gold nanoparticles in applications that require work in aqueous environments. This is due primarily to a tendency to oxidize that leads to a complete loss of particle stability, most notably in acidic environments. Also, a higher van der Waals' interaction results in particle aggregation at lower ionic strengths than for Au nanoparticles – a problem for biological applications that take place in buffered saline solutions. All of these issues have been overcome through the use of the pentapeptide CALNN [80]. Addition of peptide to relatively unstable 15 nm citrate-stabilized Ag particles results in peptide-stabilized Ag nanoparticles that are stable between pH 4 and 12 and in 1 M solutions of NaCl. Peptide-stabilized Ag nanoparticles 8 nm in diameter can also be synthesized using a modified two-phase arrested precipitation method. These nanoparticles are also stable over a wide pH range (6–12) and in 1 M NaCl solutions.

#### 8.3.3.6 Peptides as Capping Ligands for Fluorescent and Magnetic Nanoparticles

Similar approaches have been used successfully for the stabilization and functionalization of other types of nanomaterials. Weiss' group has used synthetic phytochelatin-related peptides as an organic coat on the surface of colloidal CdSe/

ZnS semiconductor nanocrystals [81]. The peptides are designed to bind to the nanocrystals through a C-terminal adhesive domain composed of multiple repeats of cysteine pairs flanked by hydrophobic 3-cyclohexylalanines. This adhesive domain is followed by a flexible hydrophilic linker domain to which various bio-affinity tags can be attached, resulting in water-soluble, monodisperse peptide-coated nanoparticles with high colloidal stability and ensemble photophysical properties similar to those of the original, TOPO-coated nanocrystals. PEG-modified peptides were used to improve the accessibility of bio-affinity tags (e.g., biotin). In a recent review focused on quantum dots in biology, the same authors discuss the possibilities offered by a *peptide toolkit* to control surface and photophysical properties [82]. These include switching the emission by using a quencher linked to the nanocrystal through an enzyme-cleavable peptide sequence.

Belcher and colleagues have reported phage display-selected peptides as a template to grow FePt magnetic nanoparticles [83]. The particles obtained are ferromagnetic at room temperature, possessing coercivities up to 1000 Oe and may have some applications in high-density memory devices. Fernig and colleagues have reported the first synthesis of peptide-capped water-soluble cobalt nanoparticles [84]. The peptides facilitated the formation of nanoparticles and partly protected the nanoparticles from oxidation.

#### 8.3.4

#### Peptide Extensions to Introduce Functionalities

The introduction of specific recognition groups at the surface of gold nanoparticles is an important prerequisite for their use in bioanalytical assays. Peptides having extensions can be used to introduce functions on the nanoparticles surface. Using a peptide mixture containing a matrix peptide (e.g., CALNN) and one or more functional peptides (e.g., CALNN-XXX where XXX is or bears the functional group), particles having a wide range of functions can be prepared. In contrast to most previously reported approaches, the stabilization and the functionalization of particles in this system are independent, but, crucially, both are achieved preparatively in the same step. Therefore, the number of recognition functions present on each particle can be easily controlled and reduced to a single or very few moieties without compromising the stability of the particles [85]. Recently, particles presenting various chemical groups have been successfully prepared by this approach. These include peptide sequences consisting of natural amino acids as well as artificial amino acids and hybrid sequences consisting of amino acids and oligonucleotides.

##### 8.3.4.1 Biotin and Strep-tag II

Nanoparticles functionalized with biotin and with a peptide analogue of biotin (Strep-tag II: WSHHPQFEK) [86] have been obtained using a peptide mixture containing, on a molar basis, 90% CALNN and 10% CALNNGK(biotin)G or CALNNGGWSHHPQFEK [79]. The nanoparticles were purified from excess peptides by size-exclusion chromatography and immobilized on a nitrocellulose mem-

brane. Streptactin-peroxidase was then used to detect the presence of biotin and of its peptide analogue on the membrane (Fig. 8.9). The results demonstrate the presence of functional groups as well as the absence of non-specific binding to the CALNN-capped nanoparticles by streptactin-peroxidase.

#### 8.3.4.2 Peptide-DNA Hybrids

Gold nanoparticles stabilized by thiol-modified oligonucleotides have been used for the programmed self-assembly of nanostructures and for oligonucleotide detection. Wang and colleagues have shown that a peptide-DNA hybrid molecule, i.e., CALNN-DNA, provides a simple route to DNA functionalized particles. Moreover, the ratio of CALNN-DNA to CALNN in the preparation mixture directly controls the amount of DNA available on the nanoparticle surface. The particles retain the stability of the peptide-capped particles. Importantly, this work extends the peptide toolbox to DNA-based assays and DNA-based nanostructured materials. Thus, it is possible to prepare, in a one-pot synthesis, particles functionalized with DNA(s) and other recognition motifs (e.g., peptide recognition motif to inorganic materials). As proof of principle, particles bearing both DNA and biotin extensions have been prepared and detected in a microarray format (Fig. 8.10) [85].

#### 8.3.4.3 His-tag and Nickel Nitrilotriacetic Acid (Ni-NTA)

Immobilized metal affinity chromatography (IMAC) is extensively used in biological research to purify engineered proteins having a histidine tag (generally composed of six consecutive histidines) [87, 88]. Nitrilotriacetic acid immobilized on a gel chelates nickel ions that interact specifically with the histidine tag. The relevant proteins are then eluted from the column using a competitor (imidazole) or a pH

**Fig. 8.10.** Binding of bifunctional peptide-capped particles labeled both with biotin and DNA on microarrays. (A) Scheme of the bifunctional particles. (B) Dark field imaging of the protein microarray after binding of the particles and silver enhancing. (C) Dark field imaging of the DNA microarray after binding of the particles and silver enhancing. (Adapted from [85] with permission.)

change. A large variety of derived protocols based on this interaction have been developed, e.g., Ni-NTA magnetic beads and nanoparticles [89] for the separation of histidine tagged proteins, Ni-NTA gold clusters for their localization using electron microscopy [90] and Ni-NTA lipids for the 2D crystallization of histidine-tagged proteins [91].

Peptides having a histidine tag extension and peptides having a NTA extension could be obtained by standard peptide synthesis and coupling protocols. This will provide new tools to detect and follow histidine-tagged proteins. More importantly, as described in Section 8.3.5.2, it allows an unprecedented control of quantitative labeling through affinity chromatography and opens a new route to multistep synthesis of nanostructures.

### 8.3.5

#### Chromatography of Peptide-capped Nanoparticles

Protein chromatography techniques offer routes to separation based on size, charge, hydrophobicity and affinity. Chromatography media have been optimized to avoid unspecific interactions in the context of protein purification and, thus, are compatible with peptide-capped nanomaterials. This provides a range of protocols to obtain extremely well-defined and pure nanoparticles. Examples of size-exclusion and affinity chromatography are presented below to illustrate the possibilities these techniques offer. Ionic and hydrophobic exchange chromatographies have also been used in purifying peptide-capped nanoparticles.

### 8.3.5.1 Size-exclusion Chromatography

Size-exclusion chromatography on Sephadex G25 provides a rapid means of separating peptide-capped gold nanoparticles from small reagents, including free peptide resulting from the preparation [79]. This process can be scaled up easily for preparative and production purposes. By using a gel with a higher fractionation range, particles of different sizes can be separated (Fig. 8.11).

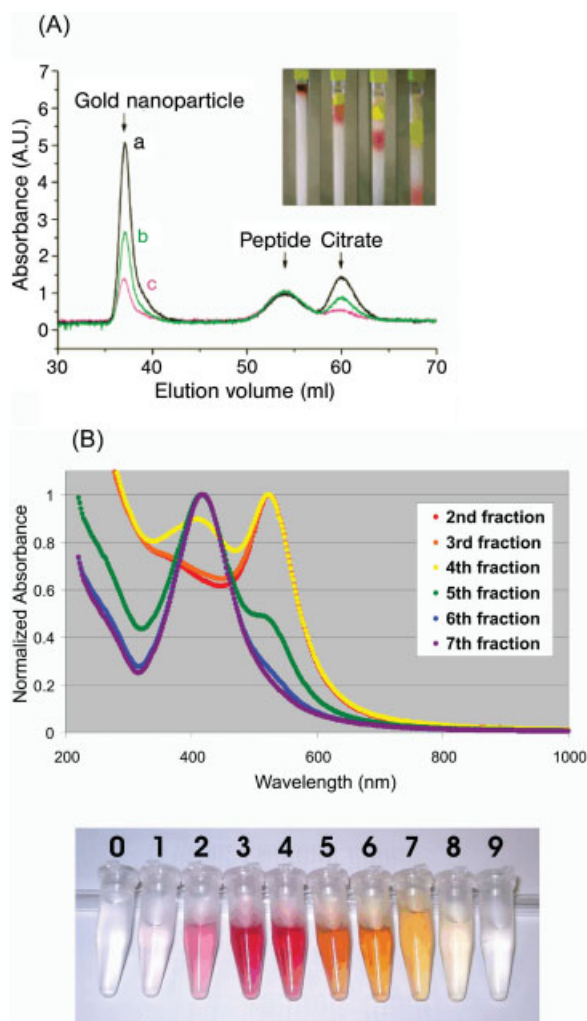

### 8.3.5.2 Affinity Chromatography

Achieving precise control over the number of functional groups per nanoparticle is an important challenge. Its resolution would open up new opportunities to probe the formation of biological complexes and be an important step towards the preparation of well-defined nanostructures. For DNA-labeled peptide-capped particles, Wang and colleagues have shown that the proportion of labeled peptide in the preparation mixture correlates directly with the amount of label at the nanoparticle surface [85]. Therefore, particles having a mean number of labels well below one can be prepared by using a very low percentage of the labeled peptides. In that case, simple combinatorial arguments show that the labeled particles will be mainly particles having a single label. The problem is then analogous to a simple protein purification problem (separation of labeled and unlabeled particles) and can be solved using IMAC (Fig. 8.12). Particles are loaded on a Ni-NTA column, and particles without a histidine tag do not bind, whereas particles having at least one histidine tag are immobilized and then eluted from the column [92].

### 8.3.6

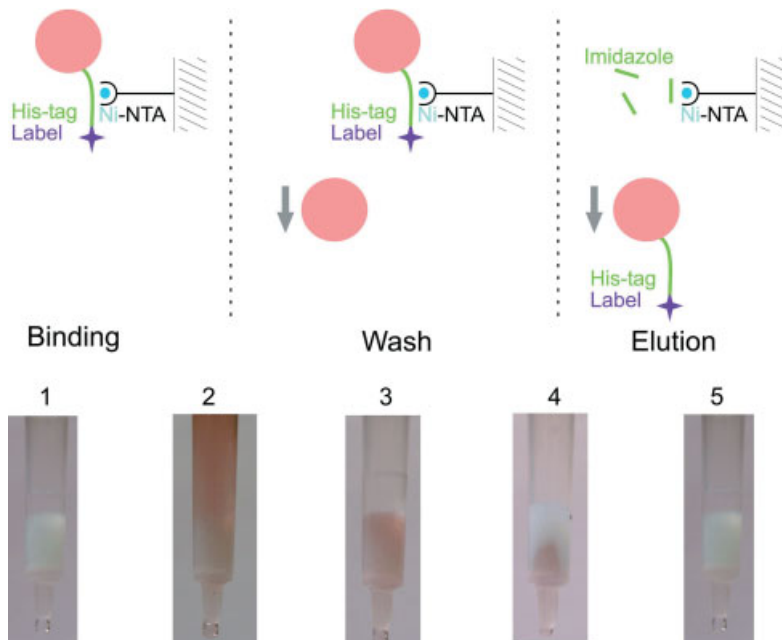

#### Recognition of Materials

The peptide toolbox provides various molecular tools for the specific recognition of materials (Fig. 8.13, see p. 260). Phage display and cell-surface display are *in vivo* combinatorial biology protocols for identifying biological ligands. The power of such technologies relies on the size and diversity of the library used, combined with the efficiency of the molecular biology tools in allowing easy identification and amplification of the DNA encoding the selected peptide sequences. Libraries are generated by inserting randomized oligonucleotides within certain genes encoded on phage genomes or on bacterial plasmids, leading to the incorporation of a random polypeptide sequence within a protein residing on the surface of the organism (e.g., the coat protein of a phage or an outer membrane or flagellar protein of a cell). Following the pioneering work of Brown on genetically engineered binding of *E. coli* to iron oxide [93], these protocols have been used to select peptides that bind to various inorganic compounds [94]. Peptides with semiconductor binding specificity have been selected by phage display. Selective binding as a function of crystal composition (e.g., binding to GaAs but not to Si) and crystalline face [e.g., binding to (100) GaAs, but not to (111)B GaAs] was obtained [95]. A hexapeptide with specific binding to the surface of titanium was selected by phage display [96]. Gold binding sequences were selected by cell-surface display, and their folding

in the presence of crystalline gold has been investigated by computer modeling [94].

*De novo* design and molecular modeling, another strategy for obtaining affinity towards materials, has been applied successfully to the design of a peptide (nano-1) that binds and solubilizes carbon nanotubes [97, 98]. Nano-1 is designed to fold into an amphiphilic  $\alpha$ -helix and coat carbon nanotubes. The hydrophobic face of the helix was intended to interact noncovalently with the aromatic surface of carbon nanotubes, and the hydrophilic face was designed to promote self-assembly through charged peptide–peptide interactions.

### 8.3.7

#### Peptide-based Linkers

The development of crosslinking systems based on noncovalent interactions facilitates the detection and purification of recombinant proteins [99]. Only a handful of these have been applied in the context of nanomaterials, and new affinity pairs are being developed. The capabilities and versatility of peptide-based linkers are illustrated below for peptide–peptide, peptide–DNA and peptide–synthetic organic molecule linkers.

#### 8.3.7.1 A Peptide-Peptide Linker Based on Leucine-zipper Sequences

The peptide-peptide linker designed by Ryadnov and colleagues consists of three leucine-zipper sequences of *de novo* design: one peptide, “the belt”, templates the co-assembly of the other two half-sized peptides, “the braces” [100]. When mixed, the three peptides reversibly formed a predominantly helical and stable 1:1:1 ternary complex. Surface plasmon resonance experiments demonstrated assembly of the complex on gold surfaces, while the ability of the system to bring together peptide-bound cargo was demonstrated using gold nanoparticles derivatized with the brace peptides before the addition of the belt.

#### 8.3.7.2 A Peptide-DNA Linker Based on Metallopeptides

Metallopeptides of the form Cu(II) or Ni(II) Gly-Gly-His are implicated in nucleic acid recognition and reactivity phenomena. Recently, Fang and colleagues have studied the minor-groove recognition of A/T-rich DNA sites by Ni(II)-(L)-Arg-Gly-His and Ni(II)-(D)-Arg-Gly-His [101]. This study has important implications in understanding protein binding to DNA, but it could also form the basis of new assembly systems for DNA- and peptide-capped nanomaterials.

#### 8.3.7.3 A Peptide-Texas Red Linker Obtained by Phage Display

A library of constrained peptides that form stable folded structures has been screened for aptamers that bind with high affinity to the fluorescent dye Texas red [102]. Two selected clones had binding constants to Texas red of 25 and 80 pM. Thus, minimal, constrained peptides can bind to organic fluorescent dyes in biological contexts, allowing *in vivo* imaging with highly sensitive dyes and some degree of genetic control. It also opens up new routes for the assembly of fluorophores and nanoparticles.

### 8.3.8

#### Biologically Active Peptides

Numerous biologically active peptides have been identified and their potential as biomarkers and drugs are under evaluation [103]. Moreover, phage-display technology provides novel peptides that bind protein targets with high affinity and specificity, offering many opportunities in drug discovery [104]. A review of natural and selected biologically active peptides is far beyond the aim of this chapter. The following example illustrates the benefits of conjugating some of these sequences to nanoparticles. The nanoparticles can play the role of geometrically defined support for the simultaneous presence of multiple sequences as well as the role of optical label for the real-time imaging of these conjugates. Tkachenko and colleagues have prepared peptide-BSA conjugated particles that carry both a receptor-mediated endocytosis peptide and a nuclear localization signal [105]. The particles' localization was monitored inside cells using a combination of video-enhanced color microscopy and differential interference contrast microscopy, revealing an effective targeting of the cell nucleus. Particles bearing only one of the two signal sequences did not target effectively the nucleus. Kanaras and colleagues have demonstrated the

use of DNA processing enzymes (restriction endonucleases, ligase) for multistep nanostructure synthesis using DNA-protected nanoparticles [106]. Similarly, nanoparticles conjugated with peptide sequences comprising enzyme recognition sites (e.g., proteases, kinases or phosphatases) will offer new perspectives for monitoring enzyme activity and for the controlled assembly of nanostructures.

### 8.3.9

#### Self-assembling Peptides

Recently, partly driven by the elucidation of the mechanisms of amyloid fibril formation, a series of articles have revealed the fascinating self-assembly properties of peptides into fibers, nanotubes, micelles, vesicles, and hydrogels (Fig. 8.14) [107–109]. These assemblies exploit various interactions and, eventually, mimic existing biological assemblies. Early work includes the development of biomimetic materials based on self-assembly of ionic self-complementary peptides [110].

nanotubes, followed by enzymatic degradation of the peptide backbone, produced discrete nanowires with a length in the micron range and a diameter of around 100 nm [111].

Woolfson and colleagues have focused on fiber-forming peptides based on the alpha-helical coiled coil, which is a widespread and well-understood protein-protein interaction motif. These peptides form fibers that are over 10  $\mu\text{m}$  long with diameters around 100 nm. Interestingly, a degree of control over their morphology was achieved with mutation-inducing kinks or branching [112–115].

Hierarchical self-assembly of a therapeutic octapeptide, namely Lanreotide, has been revealed at an atomic scale using a combination of characterization tech-

niques (optical and electron microscopies, vibrational spectroscopies, and small and wide-angle X-ray scattering) [116]. This peptide forms hexagonal packing of nanotubes with a high degree of monodispersity in tube diameter (24 nm) and wall thickness ( $\sim 1.8$  nm). The diameter is tunable by suitable modifications of the molecular structure.

#### 8.3.9.2 Peptide-based Amphiphiles

Amphiphilic molecules tend to form well-defined assemblies (e.g., micelles and bilayers) to minimize the contact between the hydrophobic moieties and the aqueous environment. Recent major developments in the design and the structures formed by amphiphilic peptides have been reviewed [117]. Selected papers illustrate the variety of structures formed: One of the attractive properties of these systems is the possibility of easily tuning assembly by external parameters such as the pH and temperature. Kretsinger and colleagues have presented a very elegant way to engineer a stimulus-dependant hydrogel [118]. They have designed a peptide with a pH-dependent intramolecular folding. When folded in a beta-hairpin, this peptide has a propensity to self-assemble into rigid hydrogels with shear-thinning properties and quick mechanical strength recovery. Cryo-transmission electron and laser scanning confocal microscopies revealed a water-filled porous scaffold on both the nano- and microscale. Larger block copolypeptides ( $\sim 200$  amino acids) have been studied by Deming and colleagues [119, 120]. In the first study, the authors used charged amino acids (polylysine and polyglutamate) as hydrophilic blocks. This resulted in hydrogels at very low concentration. In the second study, ethylene glycol-modified amino acid building blocks were used in the hydrophilic domain to give polypeptide segments with stable  $\alpha$ -helical conformations, affording giant vesicles into which functionality could be incorporated.

## 8.4

### Concluding Remarks

With the arrival of new detection systems for metallic nanoparticles, e.g., the photothermal method developed by Lounis and co-workers, restrictions on particle size have been greatly reduced. Previously, single-particle detection was limited to particles with diameters  $> 30$  nm (by light scattering). However, now that particles with a diameter of  $< 5$  nm can be detected photothermally, the emphasis for biological applications of nanotechnology has moved from particle stability to particle functionalization, where it belongs. Peptide capping ligands confer protein-like properties to nanoparticles in terms of water solubility, stability and molecular recognition properties. As a result of their protein-like behavior, functionalized particles can be separated easily from unfunctionalized particles by standard chromatographic techniques, i.e., ion-exchange or metal-ion affinity chromatography. Mixed peptide monolayers on nanoparticles might offer a route towards artificial proteins and enzymes. Peptides offer numerous possibilities in terms of self-assembly, molecular recognition, biological activity, etc., and peptide-capped nano-

particles offer a unique opportunity to integrate these properties into new and complex materials.

# Folate-linked Lipid-based Nanoparticles for Tumor-targeted Gene Therapy

Yoshiyuki Hattori and Yoshie Maitani

### 9.1

#### Introduction

Cancer gene therapy has been intensively developed using non-viral vector [1]. Viral vectors such as retroviruses [2], adenoviruses [3], adeno-associated viruses [4] and several other viral types [5], are efficient in transfection, but pose risks to the host from the immunogenicity of viral proteins, a lack of desired tissue selectivity, the potential for oncogenesis due to chromosomal integration, and the generation of infectious viruses due to recombination, making non-viral vectors an attractive alternative. Synthetic vectors such as cationic polymers, liposomes and nanoparticles have been studied widely for DNA delivery due to their potential for tissue-specific targeting, their lack of immunogenicity, the relative safety, and relative ease of large-scale production. For targeted delivery to tumors, vitamin folic acid has been utilized for folate receptor (FR)-mediated drug delivery since the FR is frequently overexpressed on human tumors [6, 7]. Liposomes conjugated to folate ligand have been reported as carriers of chemotherapeutic agents to FR-bearing tumor cells *in vivo* [8–14]. While much has been published on folate-drug conjugates and folate-linked carriers, relatively little is known about the targeting of gene delivery. The use of a folate ligand as a targeting ligand to deliver DNA has also been reported *in vitro* [15–19], but has not been successful in *in vivo* gene therapy [20, 21]. Therefore, in this chapter, we describe the current understanding of tumor-targeting particle vectors and folate-linked lipid-based vectors such as liposomes and nanoparticles. Information pertaining to the formulation of folate-linked lipid-based nanoparticles, their transfection activity *in vitro* and *in vivo* in suicide gene therapy to treat prostate and nasopharyngeal tumors *in vivo* is also included.

### 9.2

#### Gene Delivery and Expression System

Plasmids for gene expression system contain a cDNA coding for either a full gene or minigene and several other genetic elements, including introns, polyadenylation

sequences and transcript stabilizers to control transcription, translation, protein stability and secretion from the host cells [22]. The minimal transcription unit required for expression of a therapeutic protein consists of 5' enhancer/promoter upstream of the gene encoding for the therapeutic protein (e.g., HSV-tk or cytosine deaminase, etc.) and a polyadenylation signal downstream of the gene. Several promoters originating from eukaryotic viruses, such as cytomegalovirus (CMV), simian virus 40 (SV40), Moloney murine leukemia virus (MoMLV), and Rous sarcoma virus (RSV) are widely used. Tumor-specific promoters (e.g., carcinoembryonic antigen (CEA) [23], alpha-fetoprotein (AFP) [24], midkine [25], prostate specific antigen (PSA) [26], etc.) for cancer gene therapy are also designed to interact with transcription factors or other nuclear proteins present in the desired target cells [27].

A major requirement for gene therapy is efficient transport of DNA through the cell membrane by processes that are not well defined. The mechanistic pathway for gene transfection includes the compaction of extended plasmid DNA chain. This process, also known as DNA condensation, has received considerable attention in recent years due to its biological importance in DNA packaging in the development of gene delivery [28, 29]. Multivalent cations such as polyamines (spermidine, spermine), positively charged polymers (polyethylenimine, PEI) and peptides (poly-L-lysine, PLL) provoke the condensation of DNA to nanoparticles [28, 30].

Non-viral particle systems generally entail complex/encapsulation of the gene of interest (present, along with appropriate promoters, etc., in a circular plasmid) with additional molecules, particularly various lipids. These generally display a positive charge and hence interact with the negatively charged DNA molecules. Inside the cytoplasm, endosomes are destabilized and release the plasmid DNA, although this is an inefficient process in many cases [31]. Once plasmid DNA is released into the cytoplasm, it may enter the nucleus. DNA is transported across the nuclear envelope through the nuclear pore. While smaller particles of 25 nm can freely diffuse through the nuclear pore, which is ~55 nm in diameter, larger molecules enter the nucleus through the nuclear pore complex [32, 33]. Finally, therapeutic protein is transcribed and translated from plasmid DNA. Genes introduced into cells using particle vectors are episomal and provide transient expression of transgenes.

### 9.3 Nanoparticles for Gene Delivery System

Systemic administration via intravenous injection rarely achieves meaningful cell transfection. This is most likely due to the high nuclease levels present in serum. Particle vectors can stabilize the DNA, protect it, e.g., from serum nuclease, and ideally interact with the biological system when particles modified with ligands, for example, help target the DNA to particular cells, leading to endocytosis. However, a major limitation of these systems is their inability to cross-intact endothelial barriers and leave general circulation. In general, particle carriers are phagocytosed by the macrophages of the mononuclear phagocytotic cells (MPS), thereby rapidly

localizing predominantly in the liver and spleen [34]. However, sterically stabilized particle carriers such as polyethylene glycol (PEG)-coated nanoparticles have extended circulation times and can remain in the blood [35]. Such nanoparticles, known as long-circulating nanoparticles, tend to accumulate in tumors as a result of increased microvascular permeability and defective lymphatic drainage, a process also referred to as the enhanced permeability and retention (EPR) effect. This is a passive and non-specific process of extravasation that is statically improved by the prolonged residence time of nanoparticles in circulation and repeated passages through the tumor microvascular bed. These ideas have already been realized in liposomal products such as Doxil®.

Liposomes coated with the monoclonal antibodies (mAbs) (immunoliposomes) can provide target-specific binding to the cells [36]. The ligand can be coupled directly to the liposome surface; however, the PEG chains may provide steric hindrance to receptor binding. Alternatively, a bi-functional PEG linker can be used to couple liposomes to one end of PEG chains and ligands to the other end. Steric hindrance is not a problem in the latter approach. The primary focus of their use has been in the targeted delivery of anticancer agents. Hosokawa et al. [37] have reported efficacy of immunoliposomal doxorubicin on cancer models in a cell-surface-antigen-density-dependent manner.

Active targeting increases the affinity of the carrier system for the target site while passive targeting minimizes the non-specific interaction with non-targeted sites by the reticuloendothelial systems (RES). However, gene transfer activity after intravenous injection of a cationic liposome/plasmid DNA complex is most prevalent in the lung [38]. The challenge for tumor-specific targeting using particulate gene delivery systems is to decrease this non-specific gene transfer in the lung while simultaneously maintaining or increasing the level of gene transfer to the tumor tissues. Xu et al. [39] have reported that a cationic immunolipoplex system directed by a single-chain antibody variable region fragment (scFv) against the human transferrin receptor enhanced the transfection efficiency both *in vitro* and *in vivo*. Anti-Her-2 mAb [40], anti-transferrin receptor mAb [39], and growth factor, such as a transferrin, which is a high affinity ligand for the transferrin receptor [41, 42], have been used for tumor-targeting. Other ligands, such as sugar (galactose [43] and glucose [44]), folic acid [45], or RGD-peptide [46], which are associated with asialoglycoprotein receptor on the hepatocyte, folate receptor, and integrin, respectively, in actively growing cells and tumor, can be used.

## 9.4

### Folate-linked Vectors

Folic acid as a targeting ligand offers many potential advantages: (a) a small targeting ligand, often leading to favorable pharmacokinetic properties of the folate conjugates and reduced probability of immunogenicity; (b) convenient availability and low cost; (c) relatively simple and defined conjugation chemistry; (d) high affinity for FR and lack of FR expression in normal tissue; (e) the receptor–ligand complex

can be induced to internalize via endocytosis; and (f) high frequency of FR overexpression among human tumors. Therefore, folate-linked targeting systems show great potential for clinical and therapeutic application.

#### 9.4.1

##### Folate Receptors

Folate receptor (FR) is overexpressed in a wide range of tumors, and is known as a high-affinity membrane folate-binding protein, which mediates uptake of the vitamin by receptor-mediated endocytosis. Therefore, it presents an attractive target for tumor-selective delivery. FR-targeting materials can continuously accumulate into cells due to receptor recycling. FR-targeting imaging agents arrived on the market in 2004. Three isoforms of FR have been identified and two, FR- $\alpha$  and - $\beta$ , are attached to the cell by a glycosylphosphatidylinositol (GPI)-anchor, while FR- $\gamma$  is secreted due to the lack of an efficient signal for GPI modification [7]. The role of FRs in the cellular transport of folate is not well understood, although a potocytosis (caveolin-coated endocytosis) model has been proposed [47]. FR- $\alpha$  was found to be clustered in a membrane region called caveolae or rafts [47]. While an elevated expression of FR has frequently been observed in various types of human tumors, the receptor is generally absent in normal tissues with the exception of the choroid plexus and placenta, with low levels in the lung, thyroid and kidney [48]. FR- $\alpha$  is frequently overexpressed in tumors, including ovarian, colorectal, breast, lung, renal cell carcinomas and brain metastases derived from epithelial cancers [6, 7]. FR- $\beta$  is frequently overexpressed in tumors of non-epithelial cell lineages such as sarcomas and acute myeloid leukemia [49], and FR- $\gamma$  is overexpressed in malignant hemopoietic cells [50]. The causes of FR overexpression in tumors are unclear, but high levels of FR may be associated with increased biological aggressiveness of carcinomas.

#### 9.4.2

##### Folate Receptor-targeting Liposomes

Liposomes used in recent studies have been coated with folate-PEG-lipid to facilitate tumor-targeting by an active mechanism (via FR) and a passive mechanism (prevention/reduction of RES uptake) [20, 51]. PEGylated lipids can significantly reduce non-specific gene transfer activity in the lung, and conjugation of the targeting ligand, folate, to the PEG chain can restore this activity in FR-positive tumors *in vivo* [20]. For intravascular targeting to access tumor cells expressing FR, liposomes must cross the vascular endothelium and diffuse into the interstitial fluid (Fig. 9.1) [51]. The theoretical advantage of FR-targeting over non-targeting is related to a shift in the distribution of the liposomes to the tumor cell compartment and delivery of the genes. The disadvantage of a system targeting a cancer cell receptor such as FR is the difficulty that a large nano-size assembly has in penetrating a solid tumor mass. Many cell types, including most tumor cells, display a low endocytotic capacity. Since the intracellular mechanism of FR-targeted gene deliv-

**Fig. 9.1.** Scheme illustrating the concept of using FR-targeting nanoparticles to deliver plasmid DNA to tumor cells. Dots and helices on the nanoparticles represent the folate ligands and plasmid DNA, respectively. The various steps involved in the targeting process are numbered 1–5. Steps 1 and 2 are common to non-targeted and FR-targeting nanoparticles mixed with plasmid DNA (nanoplex). Steps 3–5 are specific to the FR-targeting vector.

(1) long-circulating nanoplexes make more passages through the tumor microvasculature. (2) Increased vascular permeability in tumor tissue enables nanoplexes to extravasate and reach the tumor interstitial fluid. (3) FR-targeting nanoplexes bind to FR expressed on the tumor membrane via the folate ligand. (4) Nanoplexes are internalized by tumor cells via FR. (5) Internalized nanoplexes release their plasmid DNA in the cytoplasm.

ery with liposomes and nanoparticles is endocytosis, this is a serious limitation to the successful application of FR-targeted lipid-based particle delivery systems. The development of suitable delivery vectors for *in vivo* gene transfer is necessary for the clinical application of therapeutic genes.

Several cationic polymer–folate conjugates and/or cationic liposomes, and cationic nanoparticles incorporating folate-derivatives have been developed for FR-targeted gene delivery (Table 9.1). Folic acid retains its receptor-binding and endocytotic properties when covalently linked to a wide variety of molecules. Polyplexes are composed of charged complexes of plasmid DNA and a cationic polymer, such as poly-L-lysine (PLL), polyethylenimine (PEI) and polyamidoamine dendrimers. For FR-targeted gene delivery, PLL-folate [52–54], PLL-PEG-folate [55], PEI-folate [56], PEI-PEG-folate [56, 57], and poly(dimethylaminomethyl methacrylate) (pDMAEMA)-PEG-folate [58] have been synthesized (Fig. 9.2). These folate-conjugates facilitated efficient FR-targeted gene delivery without additional vector components *in vitro*. It appears that the incorporation of a long PEG spacer between folate and the cationic polymer is important for efficient FR-targeted gene delivery [54].

Tab. 9.1. FR-targeted nonviral vectors; all vectors were used in *in vitro* transfection.

Vector	Description	In vivo	Ref.
Polymer	Poly-L-Lys (PLL)	–	52–55
	Polyethylenimine (PEI)	–	56, 57
	Polydimethylamino methyl methacrylate (pDMAEMA)	–	58
Liposome	Cationic	i.v.	15, 17–20, 59
	Incorporating 0.1 mol% folate-PEG <sub>3350</sub> -DOPE, 5 mol% folate-DOPE, 0.5–5 mol% folate-PEG <sub>3400</sub> -DSPE or 5 mol% folate-PEG <sub>4600</sub> -cholesterol into liposome		
LPDI type	Polyplex prepared from protamine was mixed with cationic liposome containing 0.03 mol% folate-PEG <sub>3400</sub> -DSPE or 2 mol% folate-PEG <sub>5000</sub> -DSPE	i.p. i.v.	21, 60
LPDII type	Polyplex prepared from PLL or PEI was mixed with pH-sensitive anionic liposome containing 0.1 mol% folate-PEG <sub>3350</sub> -DOPE or folate-PEG <sub>3350</sub> -DSPE	–	16, 61
Nanoparticle	Polyplex prepared with cationic dithiol-detergent [(C <sub>14</sub> Corr) <sub>2</sub> ] was mixed with 1 or 2 mol% folate-PEG <sub>3400</sub> -DPPE	–	62
NPI-F, NPII-F	Incorporating 2 mol% folate-PEG <sub>2000</sub> -DSPE into cationic nanoparticle based DC-Chol	i.v. i.t.	63, 64, 73
NPIII-F	Incorporating 1 mol% folate-PEG <sub>2000</sub> -DSPE into cationic nanoparticle based OH-Chol	–	68

i.v.: intravenous injection, i.p.: intraperitoneal injection;

i.t.: intratumoral injection.

**Fig. 9.2.** Preparations of conjugation with folic acid. (A) N-Hydroxysuccinimidyl ester of folic acid (NHS-folate) is prepared by esterification of folic acid with N-hydroxysuccinimide (NHS) in the presence of 1,3-dicyclohexylcarbodiimide (DCC) and pyridine, and is then conjugated with amino-residues in targeted compounds (X). Alternatively, folic acid can be conjugated directly with compounds (X) in the presence of DCC and pyridine. (B) Folate-cysteine conjugate (Folate-Cys) is reacted with maleimide (MAL) conjugated with targeted compounds (Y).

Lipoplexes are composed of charge complexes of plasmid DNA and cationic liposome. Lipopolyplexes are composed of plasmid DNA attached to both polymers and lipids. Cationic liposomes are generally composed of a cationic lipid, such as dioleoyltrimethylammonium chloride (DOTMA), dioleoyltrimethylammonium propane (DOTAP), or 3-[*N*-(*N,N'*-dimethylaminoethanolamine)carbamoyl]cholesterol (DC-Chol), and a helper lipid, such as dioleoylphosphatidylethanolamine (DOPE) or cholesterol (Chol), which provides fusogenicity and stability to the lipoplex. Depending on the preparation, the lipoplex may not be a single aggregate, but an intricate structure in which the condensed DNA is surrounded by a lipid bilayer. FR-targeting cationic liposomes have been incorporated with folate-derivatives, folate-DOPE [59], folate-PEG-DOPE [15, 16], folate-PEG-DSPE [17–21, 60], folate-PEG-Chol [20], etc. (Fig. 9.2). Hofland et al. [20] have shown that both folate-PEG<sub>3400</sub>-DSPE and folate-PEG<sub>4600</sub>-Chol, when combined with a cationic lipid RPR209120 and DOPE, formed lipoplexes with greatly reduced normal tissue gene transfer and efficient *in vivo* tumor gene transfer.

LPDI-type lipoplexes (lipopolyplex) consist of a ternary complex of cationic liposomes, DNA-condensing polycation, and plasmid DNA. In a report by Reddy et al. [21], polyplexes prepared from protamine were mixed with cationic liposomes containing folate-PEG<sub>3400</sub>-DSPE as a targeting ligand and DOPE as a helper lipid. This vector showed superior transfection activity in FR-positive M109 murine lung carcinoma cells as well as in ascitic cells derived from L1210A murine lymphocytic leukemia cells. LPDII-type lipoplexes (lipopolyplex) consist of a ternary complex of anionic liposomes, DNA-condensing polycation, and plasmid DNA. Lee et al. [16] have reported a formulation of LPDII-type vector, in which DNA was first attached to PLL and then mixed with pH-sensitive anionic liposomes composed of DOPE/CHEMS/folate-PEG<sub>3350</sub>-DOPE. The pH-sensitive liposomes are fusogenic at acidic pH and thus can be used to facilitate endosomal disruption and subsequent release of plasmids in the cytoplasm. Shi et al. [61] have reported efficient gene delivery using an LPDII vector that incorporated PEI as a DNA-condensing agent and a cationic/anionic lipid pair, composed of dimethyldioctadecylammonium bromide (DDAB)/CHEMS/polyoxyethylene sorbitan monooleate (Tween80)/folate-PEG<sub>3350</sub>-DSPE.

## 9.5

### Folate-linked Lipid-based Nanoparticles

Preferential expression of a gene in tumor cells contributes to the safety and efficacy of gene therapy. For FR-targeted gene transfection, the concentrations of folic acid and linker in vectors are important.

#### 9.5.1

##### Formulations

For drug delivery, folate-targeting liposomes contained 0.1–0.5 mol% folate-PEG<sub>2000</sub>-DSPE or folate-PEG<sub>3400</sub>-DSPE for targeting, and about 4 mol% PEG<sub>2000</sub>-

DSPE was used for PEG-coating [8–13]. For gene delivery, FR-targeting liposomes and nanoparticles contained 0.03–5 mol% folate-PEG-lipid. Reddy et al. [21] have reported that a cationic liposome formulated with less than 0.03 mol% of folate-PEG<sub>3400</sub>-DSPE showed the greatest cell association. Folate moieties located at the distal end of the PEG spacers would likely not interact at concentrations lower than 0.03%. Bruckheimer et al. [60] have reported that 2 mol% folate-PEG<sub>3400</sub>-DSPE conjugate increased the cellular association with tumor cells and transfection potency. FR-targeting cationic nanoparticles incorporating 2 mol% folate-PEG<sub>3400</sub>-DPPE showed efficient FR-dependent cellular uptake and transfection [62], and cationic liposomes with 5 mol% folate-PEG<sub>4600</sub>-Chol showed high gene transfer activity into a FR-positive cell line, M109 [20]. Xu et al. [59] have reported specific *in vivo* gene delivery to tumors with a liposome containing about 5 mol% folate-DOPE. Dauty et al. [62] have reported that an FR-targeting cationic nanoparticle incorporating folate-PEG<sub>3400</sub>-DPPE and a cationic dithiol-detergent [dimerized tetradecyl-ornithinyl-cysteine, (C14Corn)<sub>2</sub>] shows efficient FR-dependent cellular uptake and transfection.

As a linker of folate, PEG of  $M_r$  2000–5000 has been used (Table 9.1). A certain distance between the folate moiety and the lipid particles is needed for FR-targeting, due to the need for folate to enter the binding pocket of FR on the cell surface. Lee et al. [45] first described the dependence of folate-liposome targeting on the distance between the folate and liposome, and reported that a PEG<sub>3400</sub> linker was necessary for the targeting. Leamon et al. [17] optimized the targeting activity of the liposomes by modifying the length of the PEG-linker, and found that PEGs as small as  $M_r$  1000 could function as effective linkers. Ward et al. [54] have reported that a folate-linked PEG<sub>800</sub>-polymer-modified PLL/DNA complex did not lead to a significant increase in *in vitro* transgene expression. A PEG spacer with  $M_r > 1000$  might be essential for FR-targeting.

Folate-linked microemulsions have been used composed of 0.24 mol% folate-lipid (F0/M), folate-PEG<sub>2000</sub>-DSPE (F2/M) or folate-PEG<sub>5000</sub>-DSPE (F5/M) for targeting, and 6.7 mol% PEG<sub>2000</sub>-DSPE for PEG-coating and forming emulsion (Fig. 9.3) [14]. Selectivity of folate-linked microemulsions for delivery into KB cells was validated by flow cytometry (Fig. 9.4). The mean fluorescence intensities of F5/M

Fig. 9.3. Schematic diagrams of the microemulsion and the folate-linked microemulsions.

**Fig. 9.4.** Association of 1,1'-dioctadecyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate (DiI)-labeled F5/M, F2/M, F0/M and microemulsion with KB cells after 1 h incubation was analyzed by flow cytometry. [14]

and F2/M had ca. 200- and 4-fold greater association than non-folate microemulsion, respectively. In contrast, F0/M showed a similar curve to non-folate microemulsion. These results correspond well with the idea that conjugating folate to a shorter PEG polymer reduces folate exposure by interference with the ability of liposome to interact with FR [9]. Additionally, these increased associations of F5/M and F2/M could be blocked completely by adding 2 mM free folic acid to the medium [14]. Extending the PEG-chain length of the folate-PEG-lipid from 0 to  $M_r$  2000, and  $M_r$  2000–5000, dramatically improved the selective FR-mediated association and the cytotoxicity of folate-linked microemulsions loading anticancer drug *in vitro* [14].

Folate-linked nanoparticles (NPI), consisting of 1 mg mL<sup>-1</sup> DC-Chol as a cationic lipid, 5 mol% conventional Tween 80 (about 50% pure), and 0–1 mol% folate-PEG<sub>2000</sub>-DSPE (f-PEG<sub>2000</sub>-DSPE) or folate-PEG<sub>5000</sub>-DSPE (f-PEG<sub>5000</sub>-DSPE), respectively, have been prepared by a modified ethanol injection method [63, 64]. All nanoparticles were about 100–200 nm in size, with an  $\zeta$ -potential of about 50 mV. Here the definition of a lipid-based nanoparticle is a formula containing no bilayers like liposomes. Cholesterol derivatives are usually unable to form stable bilayers unless used in combination with DOPE or some other neutral lipid. Therefore, these particles may be nanoparticles. Figure 9.5 illustrates some folate-linked nanoparticles.

**Fig. 9.5.** Schematic structure of folate-linked nanoparticles composed of folate-PEG<sub>2000</sub>-DSPE, DC-Chol, OH-Chol and Tween 80 (NPI-, NPII-, NPIII-F).

### 9.5.2

#### Nanoplex and Transfection Activity *In Vitro*

Nanoplexes are composed of charged complexes of plasmid DNA and cationic nanoparticles. The size of nanoplexes of NPI with 0.3 mol% f-PEG<sub>2000</sub>-DSPE at a charge ratio (+/-) of cationic nanoparticle to DNA of 3:1 in the presence of 50% serum increased up to 940 nm. Nanoplexes of NPI with 1 mol% f-PEG<sub>5000</sub>-DSPE did not increase greatly in size in serum-containing medium, but showed lower transfection activity than that with 1 mol% f-PEG<sub>2000</sub>-DSPE [63].

Folate-linked nanoparticles (NPII) have been composed with the same composition as NPI with 1–3 mol% f-PEG<sub>2000</sub>-DSPE except for the substitution of Tween 80 (purity 99%) for conventional Tween 80. Each NPII was, on average, ca. 100–200 nm [64] (Table 9.2). Three mol% of f-PEG<sub>2000</sub>-DSPE may not be incorporated in NPII because no reduction in the  $\zeta$ -potential of NPII was seen upon the addition of f-PEG<sub>2000</sub>-DSPE (about 55 mV) [64]. The concentration of f-PEG<sub>2000</sub>-DSPE in an ethanol–water mixture to prepare NPII-2F containing 2 mol% f-PEG<sub>2000</sub>-DSPE, and NPII-3F containing 3 mol% f-PEG<sub>2000</sub>-DSPE, was about 40 and 60  $\mu\text{M}$ , respectively. f-PEG<sub>2000</sub>-DSPE below the critical micelle concentration (c.m.c.) might lead to efficient incorporation into the particles. However, f-PEG<sub>2000</sub>-DSPE above the c.m.c. may help to stabilize micellized f-PEG<sub>2000</sub>-DSPE and lead to inefficient insertion into the particle. The c.m.c. of f-PEG<sub>2000</sub>-DSPE may be between 40 and 60  $\mu\text{M}$

Tab. 9.2. Formulae, particle size and  $\zeta$ -potential of folate-linked nanoparticles (NPII) and their nanoplexes [64].

Formulation	Mol (%)		Nanoparticle		Nanoplex <sup>[a]</sup>		
	DC-Chol	Tween 80	folate-PEG <sub>2000</sub> -DSPE (F)	Size (nm)	$\zeta$ -potential (mV)	Size (nm)	$\zeta$ -potential (mV)
	NPII	95	5	–	117.2 ± 2.0	53.1 ± 2.5	354.9 ± 8.8
NPII-1F	94	5	1	146.1 ± 12.4	43.9 ± 1.7	515.2 ± 32.3	34.2 ± 1.6
NPII-2F (NPII-F)	93	5	2	165.3 ± 22.1	38.6 ± 1.5	233.7 ± 6.5	30.8 ± 1.9
NPII-3F	92	5	3	118.4 ± 4.3	54.8 ± 6.3	396.0 ± 7.8	35.1 ± 0.9

Nanoparticles prepared with lipids [e.g. DC-Chol/Tween 80/ folate-PEG<sub>2000</sub>-DSPE = 94/5/2, molar ratio = 10:1.3:1.3, weight (mg)] in 10 mL of water by a modified ethanol injection method. Nanoparticles consisted of 1 mg mL<sup>-1</sup> DC-Chol and 5 mol% Tween 80 with 0, 1, 2 and 3 mol% folate-PEG<sub>2000</sub>-DSPE (NPII, NPII-1F, NPII-2F and NPII-3F, respectively). The particle size and  $\zeta$ -potential were measured after the nanoparticle and nanoplex were diluted with water. Charge ratio (+/-) of nanoparticle/DNA = 3:1. Each value represents the mean ± SD (*n* = 3).

**Fig. 9.6.** Comparison of transfection efficiency in KB cells with luciferase expression between NPII nanoparticles and Tfx20. The NPII nanoplex and the lipoplex were prepared by mixing luciferase plasmid (2 μg) with the luciferase gene under the control of the cytomegalovirus (CMV) promoter, with

nanoparticles and Tfx20, respectively. The luciferase assay was carried out 24 h after incubation of nanoplexes in the medium with 10% serum. Each column represents the mean  $\pm$  S.D. ( $n = 3$ ).  $**P < 0.01$ , compared with NPII-F. NPII-F refers to the formulation in Table 9.2.

and might affect the incorporation of f-PEG<sub>2000</sub>-DSPE in NPII-3F with 3 mol% f-PEG<sub>2000</sub>-DSPE.

In the presence of 10% and 50% serum, NPII-2F with 2 mol% f-PEG<sub>2000</sub>-DSPE (NPII-F) formed injectable-sized nanoplexes (Table 9.2), which showed the highest transfection efficiency among NPII with 0–3 mol% f-PEG<sub>2000</sub>-DSPE, at the optimal charge ratio (+/–) of 3:1 in nasopharyngeal cancer KB cells, being comparable to Tfx20, a commercially available DNA transfection reagent (Fig. 9.6) [64].

### 9.5.3

#### Selectivity of Folate-linked Nanoparticle

NPII-F showed greater transfection efficiency in human prostate cancer LNCaP cells, human prostate adenocarcinoma PC-3 cells, and human cervix carcinoma HeLa cells, than in KB cells, in the comparison with Tfx20 (Fig. 9.7A). There were three FR isoforms,  $\alpha$ ,  $\beta$  and  $\gamma$ , each with a distinctive tissue distribution. FR- $\alpha$  mRNA was expressed strongly in KB and HeLa cells, but not in either LNCaP or PC-3 cells (Fig. 9.7B). FR- $\beta$  and - $\gamma$  mRNAs were not detected in any of the cell lines using the RT-PCR method. Reduced folate carrier (RFC), a carrier-mediated folate transporter, was weakly expressed in all cell lines examined (Fig. 9.7B). Cellular uptake of NPII-F in HeLa and KB cells was mediated via FR- $\alpha$ , following the induction of transfection activity. The selectivity of NPII-F to carry genes into KB cells

**Fig. 9.7.** Comparison of transfection efficiency between NP11-F and Tfx20 in the NP11-F nanoplexes and Tfx20 lipoplex delivered with the luciferase plasmid into various cell lines (A). Each column represents the mean  $\pm$  S.D. ( $n = 3$ ). FR- $\alpha$ , RFC and  $\beta$ -actin mRNA expression were detected in various cell lines by RT-PCR (B). NP11-F refers to the formulation in Table 9.2.

was validated using FITC-oligodeoxynucleotide (FITC-ODN) from the result of a competitive experiment in the presence of folic acid by flow cytometry [64].

In LNCaP and PC-3 cells, FR mRNAs were not often observed. In the human prostate, a high-affinity folate binding protein has been characterized [65] and folic acid binds to the membrane fraction that cross-reacts with the anti-prostate-specific membrane antigen (PSMA) antibody. PSMA is a transmembrane protein with a pattern of overexpression restricted to malignant human prostate tissue and LNCaP cells [66]. The physiological role of PSMA in prostate cancer remains unknown, but PSMA shows hydrolase enzymatic activity with a folate substrate [66] and is internalized via an endocytic mechanism [67]. If PSMA functions as a receptor mediating the internalization of a putative ligand similar to folic acid, this suggests that the folate-linked nanoparticle binds to PSMA and is then taken up via an endocytic mechanism by LNCaP cells as we reported [63].

In PC-3 cells, our study using RT-PCR confirmed the presence of RFC mRNA, but found no FR or PSMA mRNA [64]. A FITC-labeled folate-BSA conjugate was taken up by PC-3 cells and the cellular association was significantly decreased in the presence of 1 mM folic acid [64]. Xu et al. [59] also reported that a folate-cationic liposome system could mediate gene therapy with p53 antisense DNA in prostate cancer (DU145 cells). We found that NP11-F is a useful vector for transfection in prostate androgen-dependent and -independent cancer cells as well as KB cells.

Nanoparticles composed of cholesteryl-3 $\beta$ -carboxyamidoethylene-*N*-hydroxylamine (OH-Chol) instead of DC-Chol (NP11) could incorporate up to 5 mol% f-PEG<sub>2000</sub>-DSPE (Fig. 9.5). For FR-targeted vectors, NP11-1F (NP11-F), -2F and -5F

**Fig. 9.8.** Scanning electron micrographs of NPIII-F nanoparticles (A) and NPIII-F nanoplexes (B). In (B), NPIII-F nanoparticles, NPIII with 1 mol% folate-PEG<sub>2000</sub>-DSPE, were mixed for 10 min at a charge ratio (+/–) of 3:1 with plasmid DNA in water. The method used to visualize the nanoparticles and

nanoplexes was adapted [44]. Briefly, aliquots of 10 μL prepared samples were placed on the copper platform and dried. The nanoparticle and nanoplex layers on the copper platform were coated with platinum and observed with a scanning electron microscope (SEM).

consisted of NPIII with 1, 2 and 5 mol% f-PEG<sub>2000</sub>-DSPE, respectively. The average size of each nanoparticle was 100–200 nm (Fig. 9.8A) [68]. When the NPIII nanoparticles were mixed with DNA at a charge ratio (+/–) of 3:1 in water, each NPIII nanoplex increased from 250 to 300 nm (Fig. 9.8B) [68]. When the amount of f-PEG<sub>2000</sub>-DSPE in NPIII was increased, association of plasmid DNA with nanoparticles was inhibited significantly (Fig. 9.9) and a reduction in luciferase activity was observed [68]. A large amount of f-PEG<sub>2000</sub>-DSPE in nanoparticles might prevent enough DNA being carried into the cells, and/or reduce the cellular association with the nanoplex as reported in PEG-lipid [69]. The NPIII-F based on OH-Chol exhibited about 40× higher transfection efficiency than the NP-II-F based on DC-Chol in KB cells [64, 68]. The hydroxyl group of OH-Chol reportedly reduced the stability of the lipoplex, and enhanced transfection efficiency by facilitating the process by which DNA was liberated from the endosome [70].

It is reported that a negatively charged folic acid forms a charge-mediated complex with positively charged particles through its carboxyl groups and has an effect on transfection efficiency [71]. We prepared nanoplexes in water at a charge ratio (+/–) of 1:1 to protect to form complex for co-incubation of the positively charged NPIII with folic acid in the medium, and then incubated them with KB cells. Cellular association of FR-targeting NPIII occurred via FR and the interaction of 1 mol% f-PEG<sub>2000</sub>-DSPE in the NPIII with FR was higher than that of 2 and 5 mol% ones (Fig. 9.10). NPIII-F with 1 mol% f-PEG<sub>2000</sub>-DSPE nanoplexes at a charge ratio (+/–) of NP-F to DNA of 1:1 exhibited higher selectivity to FR, but lower transfection activity relative to that at a charge ratio (+/–) of 3:1 *in vitro*

**Fig. 9.9.** Association of plasmid DNA with NPIII nanoplexes formed in water at various charge ratios (+/-), analyzed using agarose gel electrophoresis. One microgram of Plasmid DNA was mixed with aliquots of NPIII at various charge ratios in water. After a 10 min incubation, the nanoplexes were analyzed by 1.5% agarose gel electrophoresis. Charge

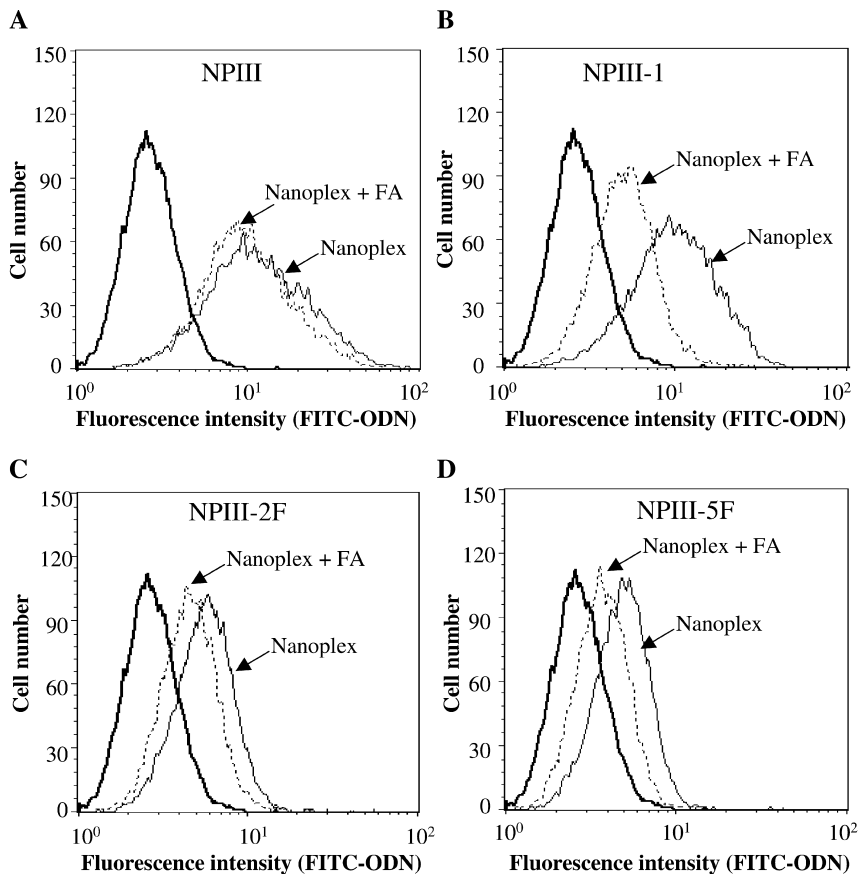

ratios (+/-) of nanoparticle:plasmid DNA = 1:1, 2:1, 3:1, 4:1 and 5:1. O.C. indicates open circular plasmid; S.C. indicates supercoiled plasmid. NPIII refers to the formulation in Table 9.2, substituting OH-Chol for DC-Chol. NPIII-F contains NPIII with 1 mol% folate-PEG<sub>2000</sub>-DSPE.

[68]. From a competitive experiment of luciferase assay in the presence of free folic acid in the medium, gene expression of the NPIII-F with 1 mol% f-PEG<sub>2000</sub>-DSPE nanoplexes was reduced [68]. For selectivity and transfection activity in FR-targeted gene delivery, the charge ratio of folate-linked lipid-based nanoparticles to DNA needs to be optimized.

#### 9.5.4

##### **Transfection Activity *In Vivo***

Both systemic and local administration offers several biological opportunities for gene therapy. The systemic route allows non-invasive access to many target cells that are not accessible otherwise by direct administration. Folate-linked liposomes showed efficient FR-dependent cellular uptake and transfection *in vitro*. However, the use of a folate ligand as a targeting ligand to deliver DNA has not been successful in *in vivo* gene therapy [20, 21]. The major limitation of *in vivo* gene therapy using liposomes is the low transfection efficiency. Several factors can adversely affect FR-targeted gene transfer *in vivo*. The first is the presence of endogenous folate in the systemic circulation, which potentially can block FR-binding. Plasma folic acid may interfere with the binding of FR. The human serum folic acid con-

**Fig. 9.10.** Association of FITC-labeled NPIII nanoplex formed in water with KB cells 3 h after transfection in the absence or presence of free folic acid. Each NPIII nanoparticle was mixed with 2  $\mu\text{g}$  of FITC-ODN at a charge ratio (+/-) of 1:1. Association was determined based on FITC-fluorescence by flow cytometry.

Flow cytometry of cells exposed to the nanoplex (continuous line). Dotted line, plus 1 mM folic acid (FA); Bold line, autofluorescence of the cells. NPIII refers to the formulation in Table 9.2, substituting OH-Chol for DC-Chol. NPIII-F contains NPIII with 1 mol% folate-PEG<sub>2000</sub>-DSPE.

centration, following FDA-mandated dietary supplementation, is  $\sim 42$  nM [72]. Earlier reports [45] indicated that serum folic acid at this concentration should not inhibit significantly the binding of FR mediated by liposomes. Our recent study [64] showed that mice on a folate-deficient were actually able to maintain a plasma folate level within the physiologic range of humans diet. In contrast, mice on a normal diet maintained a much higher serum concentration of folic acid. Therefore, mice on a folate-deficient diet should be considered relevant to humans with respect to serum folate levels. A second concern is that the size of gene transfer vectors, escaping the vasculature and intratumoral diffusion, could be limiting to

targeted delivery. To address this issue, formulation parameters can potentially be optimized to improve the pharmacokinetic properties of the vectors. For example, the vector can be PEGylated to reduce plasma protein binding and RES uptake, resulting in an extended systemic circulation time [35]. In addition, the vector should be kept under 300 nm since this is the approximate limit for efficient tumor extravasation. Non-specific cell uptake by the RES (e.g., Kupffer cells in the liver) is expected to be reduced by incorporating PEGylated lipid within the lipid–DNA complex.

When the NP-II-F nanoplex was injected via a tail vein, DNA in the blood was still detectable 4 h later by PCR [73]. Free DNA has an extremely short  $T_{1/2}$  in blood (0.5–1 h), depending on the DNA dose [38, 74]. The NP-II-F seemed to keep the DNA stable in circulation by forming a nanoplex. NP-II-F induced greater gene expression in liver and kidney than NP (unpublished data). FR is on the brush borders of proximal renal tubes and provides for the reabsorption of folate. Recently, Paulos et al. discovered that activated liver-derived macrophages (Kupffer cells) in mice do express the FR [75]. Kupffer cells in the liver and the tubular cells in kidneys of mice may be responsible for capturing NP-II-F by FR. Therefore, FR-targeted delivery of therapeutic genes damages normal cells in organs such as the liver and kidney and may subsequently cause death [13]. For cancer gene therapy, using a tumor-specific promoter to regulate expression transcriptionally in target cancer cells has promise. It will be essential to use a strong and tissue-specific promoter region if a therapeutic gene is to be selectively expressed in the cancer cells.

Intraperitoneal and intratumoral injections of lipoplex and nanoplex have been applied in mice bearing tumors. Reddy et al. [21] have reported that maximum *in vivo* transfection activity of reporter gene (luciferase) occurred with intraperitoneally administered folate-liposome using a disseminated intraperitoneal L1210A tumor model. When the NP-II-F nanoplexes of the luciferase plasmid were injected directly into the nasopharyngeal tumor, KB, xenografts, NP-II-F showed about 100-fold more luciferase activity than Tfx20, suggesting that the NP-II-F nanoplex remained small enough to migrate into the tumorous tissue [64].

## 9.6

### Application of Suicide Gene Therapy

Cancer gene therapy has become an increasingly important strategy for treating various human diseases [1]. Currently, cancer gene therapy is being researched, especially in the field of cancer treatment [76]. Suicide gene therapy is a strategy whereby a gene is introduced into cancer cells, making them sensitive to a drug that is normally non-toxic. The suicide genes used often encode enzymes that metabolize non-toxic prodrugs into toxic metabolites. One of the most frequently used suicide genes is the herpes simplex virus thymidine kinase (HSV-tk) gene [77], which phosphorylates a prodrug, ganciclovir (GCV), into a toxic form (GCV triphosphate, GCV-PPP). GCV, an acyclic analog of natural nucleoside 2'-deoxyguanosine, is an antiviral agent used against human cytomegalovirus, herpes simplex

**Fig. 9.11.** Schematic representation of the HSV-tk/GCV system's mode of action and the bystander effect. In HSV-tk-transduced cells, GCV is intracellularly phosphorylated and converted into the triphosphate derivative (GCV-PPP), which acts as a competitive inhibitor of deoxyguanosine triphosphate. The production of GCV monophosphate (GCV-P) appears to be catalyzed by HSV-tk in the transduced cells. Subsequent formation of the

diphosphate and triphosphate GCV derivatives (GCV-PP and -PPP) is catalyzed by cellular guanylate kinase. After incorporation of GCV-PPP into DNA, the synthesis of DNA is immediately inhibited in the cells and this leads to cell death. Cell to cell transfer of HSV-tk-activated GCV between HSV-tk-transduced tumor cells and neighboring cells via gap junctions is a major mechanism of the widespread tumor-cell death (bystander effect).

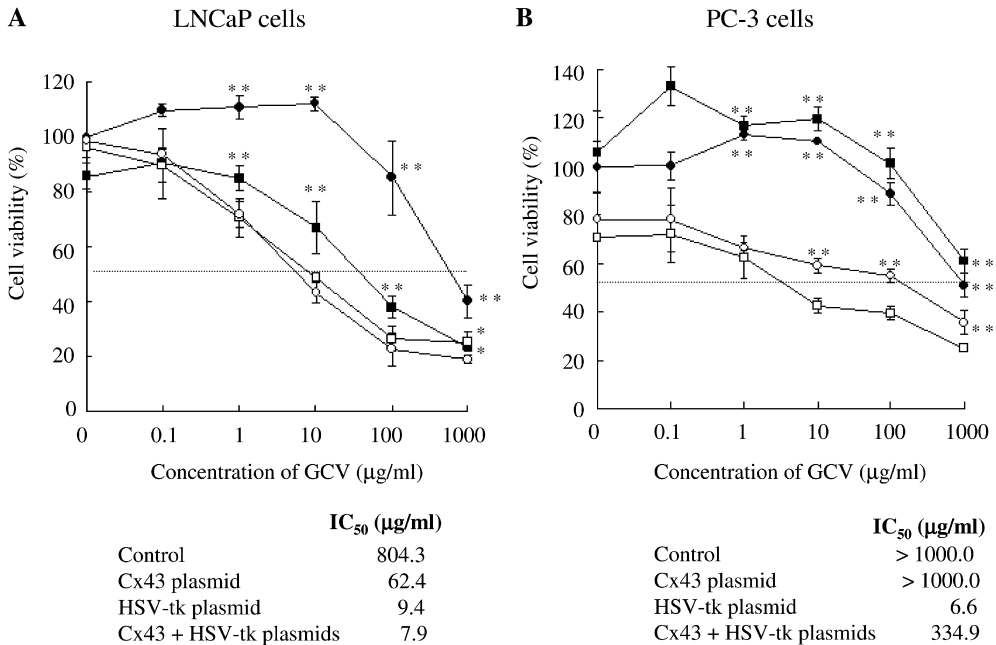

virus type 1 and 2, varicella zoster virus and Epstein-Barr virus [78]. The effect appears when GCV is intracellularly phosphorylated and converted into the triphosphate derivative GCV triphosphate, which acts as a competitive inhibitor of deoxyguanosine triphosphate (Fig. 9.11) [77]. GCV monophosphate (GCV-P) production appears to be catalyzed in the cells transfected with HSV-tk gene. Subsequent formation of the diphosphate and triphosphate GCV derivatives (GCV-PP and -PPP) is catalyzed by cellular guanylate kinase. GCV-PPP, due to its analogy with the purinic nucleotide 2'-deoxyguanosine triphosphate, becomes substrate for DNA polymerase. Once bound to DNA polymerase, GCV-PPP is either incorporated into DNA or inhibits the polymerase. Consequently, chain termination immediately occurs after GCV incorporation into DNA, and leads to cell death [79].

A powerful characteristic of HSV-tk/GCV therapy is that the transduction of a small fraction of tumor cells with the suicide gene can result in widespread tumor-cell death (bystander effect) (Fig. 9.11). The cell to cell transfer of HSV-tk-activated GCV between HSV-tk-transduced tumor cells and neighboring unmodified cells via gap junctions is a major mechanism of the bystander effect [80, 81]. Gap junctions are composed of connexin subunits and connect the cytoplasmic do-

mains of contacting cells, allowing ionic and metabolic exchange between them [82]. However, many cancer cell lines are deficient in gap junctions [83]. Such a deficiency, which is also found in human tumors [84], can limit the extent of the bystander effect in suicide gene therapy. The bystander effect has been reported to be enhanced by introducing a connexin gene with the HSV-tk gene *in vitro* [81]. In the normal human prostate, the cells communicate via gap junctions, whereas in poorly differentiated prostate cancer the expression of connexin 43 (Cx43) decreased and gap junctional intracellular communication failed [83, 84]. Transfection of the Cx43 gene into a Cx43-deficient prostate cancer cells may enhance the bystander effect, and also has been reported to inhibit cell growth, retard tumorigenicity and induce differentiation [85].

The use of a folate ligand as a targeting ligand to deliver DNA has not been successful in *in vivo* gene therapy [20, 21]. In prostate cancer, suicide gene therapy by local injection using adenoviral vectors has been reported as an alternative treatment [86, 87]. The use of non-viral vectors is a novel approach. A NP-II-F nanoplex of HSV-tk was transiently transfected into KB, LNCaP and PC-3 cells. The first evidence of transfection was that GCV-PPP, the most abundant triphosphate produced, was clearly detected in LNCaP cells transfected with the HSV-tk gene after incubation with GCV by HPLC [73]. These findings were also made in KB and PC-3 cancer cells [64]. Further evidence was that HSV-tk plasmid-transfected LNCaP cells showed significantly greater sensitivity to GCV than the controls ( $IC_{50}$   $9.4 \mu\text{g mL}^{-1}$ ) (Fig. 9.12A). Cx43 plasmid-transfected cells showed significantly higher sensitivity to GCV ( $IC_{50}$   $62.4 \mu\text{g mL}^{-1}$ ) than the controls. Cells co-transfected with HSV-tk and Cx43 plasmids exhibited increased sensitivity to GCV ( $IC_{50}$   $7.9 \mu\text{g mL}^{-1}$ ). This result suggests that HSV-tk and Cx43, individually, induced a cytotoxic effect by GCV in the transfected cells, and that the combination of HSV-tk plus Cx43 genes may display a bystander effect. HSV-tk plasmid-transfected PC-3 cells showed significant sensitivity to GCV ( $IC_{50}$   $6.6 \mu\text{g mL}^{-1}$ ) compared with the controls, but Cx43 plasmid-transfected cells did not (Fig. 9.12B) [64]. Sensitivity to GCV was not enhanced in cells transfected with HSV-tk plus Cx43 plasmids. This result suggests that Cx43 plasmid did not display a bystander effect in PC-3 cells.

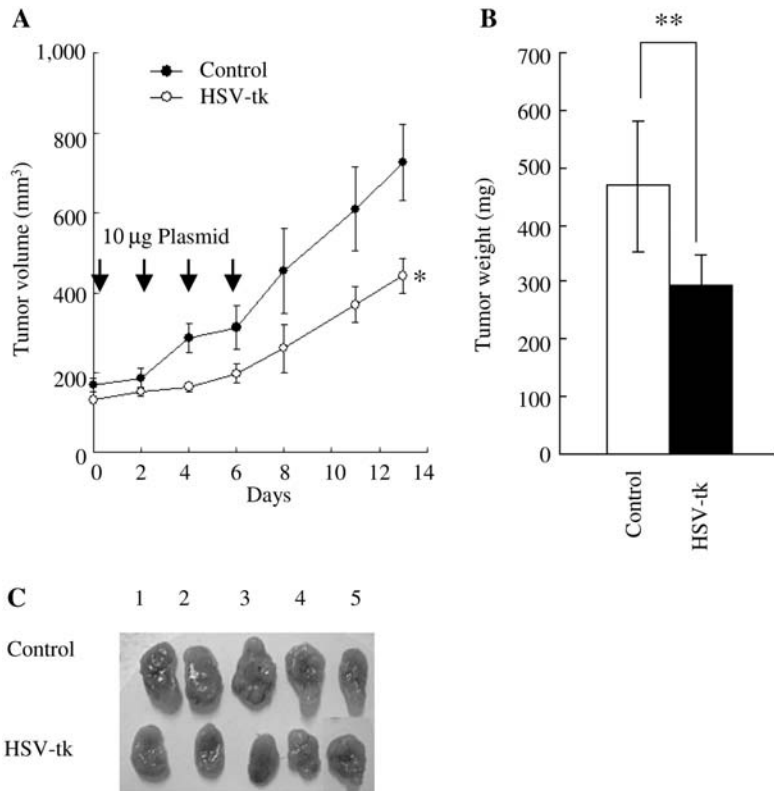

The *in vivo* anti-tumor effect of the NP-II-F nanoplex with the HSV-tk gene has been evaluated. First, we determined the anti-tumor effect by direct injection into KB tumor xenografts with the NP-II-F nanoplex of HSV-tk. When KB cells were transiently transfected with the NP-II-F nanoplex using various plasmids, HSV-tk, Cx43 plasmid and combinations thereof, the HSV-tk-transfected cells showed significant sensitivity to GCV compared with the control, but did not with cells co-transfected with HSV-tk and Cx43 plasmids (unpublished data). Therefore, HSV-tk plasmid was used as a therapeutic gene for KB xenograft. When the NP-II-F nanoplex of the HSV-tk plasmid was injected directly into the tumor, the growth of KB nasopharyngeal tumors was inhibited significantly in mice treated with the plasmid on day 13 (Fig. 9.13A). A comparison of tumor weight and appearance after excision also demonstrated that the tumor growth was attenuated in mice treated with the plasmid (Fig. 9.13B and C) [64].

**Fig. 9.12.** Sensitivity of LNCaP (A) and PC-3 (B) cells to GCV. Cells were transfected with various plasmids using NP11-F. After 12 h incubation, the culture medium was replaced with one containing a concentration of GCV ranging from 0.1 to 1000  $\mu\text{g mL}^{-1}$ . Plasmids used were: control plasmid (●), HSV-tk (□), Cx43 (■), and HSV-tk plus Cx43 plasmids (○).

The number of surviving cells was determined with a WST-8 assay after 4 days exposure to the GCV. Data points indicate the mean  $\pm$  S.D. ( $n = 3$ ). \* $p < 0.05$  and \*\* $p < 0.01$ , compared with HSV-tk and Cx43 plasmids in (A). \*\* $p < 0.01$ , compared with HSV-tk plasmid in B [64].

We then evaluated the anti-tumor effect by direct injection into LNCaP tumor xenografts with the NP11-F nanoplex of HSV-tk plus Cx43 plasmid (Fig. 9.14), because this nanoplex was the most effective in *in vitro* experiments with LNCaP cells (Fig. 9.12A). Tumor growth was suppressed in mice treated with the NP11-F nanoplex of HSV-tk plus Cx43 plasmids, but not in the control mice. The mean survival times of the control mice and the mice treated with the nanoplex of HSV-tk plus Cx43 plasmids were 21.5 and 33 days, respectively [64]. The observed reduction in tumor size may not be wholly due to the direct effect of the phosphorylated GCV on the transduced tumor cells. An indirect mechanism (the bystander effect) might be contributing to the antitumor activity. It is reported that a 1–5% *in vivo* transfection efficiency could generate a significant anti-tumoral effect in suicide gene therapy [88]. However, a deficiency of gap junctions is found in human prostate tumors [83, 84], which may limit the extent of the bystander effect in suicide gene therapy. Therefore, to examine the *in vivo* anti-tumor effects of direct injection into LNCaP prostate xenografts, the nanoplex of HSV-tk plus Cx43 plasmids was used, with the result that the tumor growth was suppressed [64] (Fig. 9.14).

**Fig. 9.13.** *In vivo* suicide gene therapy for KB tumor xenografts with GCV in mice. Mice were divided into two groups: group I, control plasmid (10  $\mu\text{g}$ ); group II, HSV-tk plasmid (10  $\mu\text{g}$ ). NP11-F nanoplexes of the plasmids were injected directly into the tumor four times (day 0, 2, 4, and 6). GCV (25  $\text{mg kg}^{-1}$ ) was administered i.p. at 24 and 36 h after the

injections. Tumor volume (A), excised tumor weight (B) and macroscopic tumor appearance (C) when all the mice in Fig. 9.13(A) were sacrificed at day 14. The results are indicated in (A) and (B) as the mean volume and weight  $\pm$  S.E. or S.D., respectively ( $n = 5$ ). \* $P < 0.05$  and \*\* $P < 0.01$ , compared with control [64].

## 9.7 Conclusions

We have shown that folate-linked lipid-based nanoparticles can deliver DNA with high transfection efficiency and selectivity, inhibiting tumor growth following intratumoral injection into human nasopharyngeal and prostate cancer using an HSV-tk/GCV therapy system. These findings indicate that folate-linked lipid-based nanoparticles have potential as a clinically effective vector in cancer suicide gene therapy. However, several factors have the potential to adversely affect FR-targeted gene transfer *in vivo*. The size of gene transfer vectors, escaping the vasculature and intratumoral diffusion, could be limiting to targeted delivery. They should be

**Fig. 9.14.** Suicide gene therapy for LNCaP tumor xenografts with GCV in mice. Mice were divided into two groups: group I, control plasmid (●); group II, HSV-tk plus Cx43 plasmids (○). NPII-F nanoplexes of the plasmids indicated were injected directly into the tumor four times (day 1, 3, 5, and 7). GCV ( $25 \text{ mg kg}^{-1}$ ) was administered i.p. at 24 and 36 h after the injections. The results are indicated as the mean volume  $\pm$  S.E. ( $n = 6$ ) [64].

kept under 300 nm since this is the approximate limit for long circulation and efficient tumor extravasation. In addition, PEGylated vectors can reduce plasma protein binding and RES uptake, resulting in an extended systemic circulation time. Non-specific cell uptake by the RES (e.g., Kupffer cells in the liver) is expected to be reduced by incorporating PEGylated lipid within the particle/DNA complex. However, PEGylated particles may prevent enough DNA being carried into cells by inhibition of association of plasmid DNA with particles. For gene therapy, a balance of long-circulating vectors and FR-targeting vectors will be key to using folate-PEG-lipid. Further efforts aimed at optimizing FR-targeting vector formulations from a systemic approach should lead to the clinical evaluation of these vectors for cancer gene therapy.

### List of Abbreviations

CHEMS	Cholesteryl hemisuccinate
Chol	Cholesterol
DC-Chol	3-[N-(N',N'-dimethylaminoethane)carbamoyl]cholesterol
DOPE	Dioleoylphosphatidylethanolamine
DPPE	Dipalmitoyl phosphatidylethanolamine
DSPE	Distearoyl phosphatidylethanolamine
FR	Folate receptor

GCV	Ganciclovir
HSV-tk	Herpes simplex virus thymidine kinase
OH-Chol	Cholesteryl-3 $\beta$ -carboxyamidoethylene-N-hydroxylamine
ODN	Oligodeoxynucleotide
PEG	Poly(ethylene glycol)
PEI	Polyethylenimine
PLL	Poly-L-lysine
PEG-DSPE	Poly(ethylene glycol)-distearoylphosphatidylethanolamine
PSMA	Prostate specific membrane antigen
RES	Reticuloendothelial systems
RFC	Reduced folate carrier

## 10 Magnetic Core Conducting Polymer Shell Nanocomposites for DNA Attachment and Hybridization

Jean-Paul Lellouche

### 10.1 Introduction

Micro- and nanosized magnetically responsive particles or particulates have become an important class of micro-/nanomaterials that have found numerous applications in electronics (data storage technology), catalysis, and biotechnology [1–5]. Generally, these nanoparticulate materials display a range of magnetic, electrical, optical, and chemical properties that clearly differ from that of their bulk materials, thus making them very attractive for property-based applications. The main applications of nanosized magnetic particles in biomedical research are magnetism-driven separations of small biological components and cells; magnetic detoxification of undesirable molecules and antigens; magnetic field-guided delivery of drugs (targeting) and genes; relaxation and contrast enhancement in non-invasive magnetic resonance imaging (MRI) of tissues; piezoelectric immunosensors; and magnetic fluid hyperthermia for cancer therapy [6–13].

To exploit the full potential of corresponding magnetic nanoparticles and related nanocomposites, some key general issues need to be consistently addressed regarding their synthesis and further subsequent use. Accordingly, controlling the shape, size, and size distribution of nanoparticles toward spherical or non-spherical anisotropic materials is one significant issue. In addition, magnetic nanoparticles need to be stabilized sterically or by using charge repulsion against aggregation in both organic and/or aqueous media. The versatility of chemical modifications that can be introduced onto particle/composite surfaces is another key question that requires careful investigation. Finally, for *in vivo* use of nanoparticles/related nanocomposites, their biocompatibility profiles and systemic toxicity properties need to be examined in depth.

Related to this field, magnetically responsive core–shell iron oxide-conducting polymer (CP) [14–21] nanosized composites form a relatively recent class of magnetic nanocomposites (NCs) [22, 23]. They display thin outer layers of insoluble CPs, such as doped polypyrrole, that have been oxidatively deposited around nanosized magnetite/magnetite-silica cores. Armes and co-workers, in particular, have

reported the fabrication of colloidal stable core–shell magnetite-silica-polypyrrole NCs with diameters in the range 100–520 nm that are superparamagnetic [24, 25]. Both aqueous oxidants  $\text{H}_2\text{O}_2/\text{Fe}^{3+}/\text{HCl}$  and  $(\text{NH}_4)_2\text{S}_2\text{O}_8$  have been used to chemically oxidize *non-functional* pyrrole around inorganic hybrid magnetite-silica cores (5–20 nm diameter). Nanosized ferromagnetic  $\text{Fe}_3\text{O}_4$ -crosslinked polyaniline NCs have recently been described by the Peng's group using aniline (monomer) and  $(\text{NH}_4)_2\text{S}_2\text{O}_8$  (oxidant) [26]. Related conducting NCs were found polydispersed, 20–30 nm in diameter, and of a core–shell morphology. Consequently, both maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ) and magnetite ( $\text{Fe}_3\text{O}_4$ ) nanoparticles should be considered as attractive inorganic magnetic cores toward related magnetic CPs-based NCs. These readily prepared iron oxide nanoparticles are prone to minimal oxidation, are of low systemic toxicity, and present a high magnetic susceptibility, in the range of 76–81 and 90–98  $\text{emu g}^{-1}$ , respectively.

Notably, in this related framework, various non-magnetic organic and inorganic cores have been engaged as micro-/nanosized supports to polymerize oxidatively *non-functional* and *functional* CPs monomers in their presence. For example, to develop color visual immunodiagnostic assays, core–shell micrometer-sized polystyrene latex-CPs [27–30] and colloidal nanosized silica-CPs [31–37] composites have been produced by oxidative deposition of insoluble CPs around corresponding cores. Tin(IV) oxide-polypyrrole colloidal NCs have been similarly fabricated by the same group for solid-state conductivity studies [38]. The main CPs studied include polypyrrole, polyaniline, poly(3,4-ethylenedioxythiophene), poly(3-pyrrol-1-yl-propionic acid), poly(3-(1*H*-pyrrol-3-yl)-propionic acid), poly(*N*-succinimidyl ester of 3-pyrrol-1-yl-propionic acid), and related copolymers. Interestingly, the last reported example [37] demonstrated that amine-sensitive *N*-succinimidyl ester of pyrrolyl-3-acetic acid survived the aqueous acidic medium that developed during monomer polymerization onto silica core nanoparticles. The resulting NCs were able to covalently attach proteins without the need for any additional post-polymerization activation step. Gold nanoparticles in a 5–200 nm diameter range have been also used as templating metallic cores to polymerize pyrrole and *N*-methylpyrrole monomers around them [39, 40]. Following core gold etching, hollow nanosized polymeric polypyrrolic capsules were synthesized as useful vehicles for drug physical entrapment and targeted delivery.

This chapter describes our most recent progress in the field of magnetically responsive new core–shell iron oxide-CPs NCs. It consists of four main sections, dealing with (a) the modular chemical design and synthesis of oxidizable dipyrrole-(DPyr) and dicarbazole- (DCbz) containing monomers to introduce molecular diversity at the monomer level (Sections 10.2 and 10.3); (b) the fabrication of magnetic NCs (chemical polymerization around magnetite cores) and their thorough characterization by means of modern spectral and analytical methods (Section 10.4); and (c) the investigation of covalent/quasi-covalent DNA attachments and hybridizations at NCs surfaces (Section 10.5). Additionally, Section 10.6 contains robust and reliable typical experimental procedures that relate to each separate step.

## 10.2

## Chemical Design of DPyr- and DCbz-containing Monomers: Introduction of Molecular Diversity

Based on the literature considerations cited above, the full potential of magnetically responsive CPs-maghemite/magnetite nanocomposites (NCs) has still to be developed regarding novel (electro-)chemically oxidizable monomers that possess (a) heterocycles different from nonfunctional pyrrole, as well as (b) appropriate functionalities that can be appended by biological species after polymerizing over nanoparticles, e.g., grafting COOH functions that can be readily amidated using well-known amide chemistry. Considering the above points, four generic chemical structures (Fig. 10.1) of mono/dicarboxylate DPyr- and DCbz-containing monomers **1–2a** (index **a** specific for the DPyr-series) and **1–2b** (index **b** specific for the DCbz-series) readily emerged from the indicated planned innovative chemical design. These generic structures have been designed to be modular and clearly accentuated the key roles played by L- or D-amino acid building blocks and appropriate linkers of variable lengths, in order to introduce chirality and molecular diversity [41–43] at the monomer level.  $C_2$ -Symmetrization operations used have been included based on generally high-yielding, stable amide connections between monocarboxylated or monoaminated Pyr- and Cbz-containing building blocks and diaminated or dicarboxylated linkers, respectively. More precisely, molecular diversity at the monomer level should arise from (a) both types of heterocyclic DPyr- and DCbz-units; (b) the existing number of COOH functions (one or two); (c) absolute (*S*) or (*R*) chiralities of asymmetric centers (from L- or D-amino acid building blocks); and, finally, (d) linkers of different chemical types and lengths.

Another notable aspect is that, in these *bis*-heterocyclic generic structures, both pyrrole and carbazole heterocycles of suitable monomers would be simultaneously engaged in polymer chain propagation at positions 2,5 and 5,5', respectively,

X = OH and/or activated esters, Linker definition (see text)

**Fig. 10.1.** Generic structures **1a/2a** and **1b/2b** of optically active mono- and dicarboxylate DPyr- and DCbz-containing oxidizable monomers.

through C–C bond formation, leading to reticulated and more stable polymers. Literature data more particularly emphasized the lack of stability of polycarbazole polymers in the carbazole series of oxidizable monomers. Accordingly, tentative electrosyntheses of polycarbazole films from N-substituted *monocarbazole* monomers resulted chiefly in short tetramers that are soluble in the electrochemical medium [44, 45]. In contrast, our laboratory has overcome this limitation. Electrochemically stable poly(DCbz)-films containing amine-sensitive pentafluorophenol esters have been formed using the electropolymerization of innovative DCbz-monomers synthesized according to the bis-podant bis-heterocyclic design cited above [46]. An example potential applications of these functional polyDCbz-films is the successful covalent attachment of polyphenol and glucose oxidases onto them as a step towards biosensor constructs [47–49].

### 10.3

#### Synthetic Approaches for Mono- and Dicarboxylated DPyr-/DCbz-based Monomers

According to synthetic approaches described below in Schemes 10.1–10.4, a range of *thirteen* enantiomerically pure mono-/dicarboxylated DPyr- and DCbz-monomers has been routinely prepared and used for the fabrication of targeted polyDPyr- and polyDCbz-magnetite NCs. Several key synthetic steps deserve some comments so as to best grasp the power and maneuverability of our planned chemical design for monomers. First, the well-known Clauson-Kaas reaction, a one-step acid-catalyzed transformation of an aromatic or alkyl NH<sub>2</sub> function into a pyrrole heterocycle unit using 2,5-dimethoxytetrahydrofuran (DMT, **4**) (Scheme 10.1) [50], has been modified to moderate reaction conditions (less acidic, salt buffered, solvent diluted, lower temperatures/shorter reaction times) [46]. Similar preparation of carbazole-based monomers generally required higher temperatures for a while

**Scheme 10.1.** Reagents and conditions: (a) 2,5-Dimethoxytetrahydrofuran (DMT, **4**), NaOAc, H<sub>2</sub>O, AcOH–1,2-dichloroethane, 1 h, 76 °C; (b) DMT (**4**), AcOH–dioxane, 3 h at reflux then overnight at 20 °C.

and longer reaction times. Thus, two separate sets of experimental conditions allowed the synthesis of both DPyr- and DCbz-containing monocarboxylated monomers **5a–b**, as well as of intermediates **7a–b**, and **14–17a–b** from enantiomerically pure L-lysine, L-aspartic, and L-glutamic acid derivatives. However, contrary to what was usually observed under harsher conditions, racemization of existing asymmetric centers was nonexistent (*ee* 97–99%, Schemes 10.1–10.4, steps a and b) [46].

A stability issue has been encountered during the preparation of aminated Pyr-based intermediate **7a**, which readily cyclizes intramolecularly to the corresponding seven-membered lactam **8** (**7a**:**8** = 4:1 assayed by high-field  $^1\text{H}$  NMR for a quasi-quantitative 91% recovery yield after separation from reaction mixture) during chromatographic purifications on silica gel columns. This intramolecular amidation did not, however, occur for the sterically more hindered Cbz-based precursor **7b**, therefore allowing its corresponding  $C_2$ -symmetrization, as described later (Scheme 10.2).

Intermediates and monomer yields were consistently higher in the modified Clauson-Kaas pyrrole synthesis than for the synthesis of carbazoles (70–80% and 25–40%, respectively). In addition,  $C_2$ -symmetrization operations toward bis-heterocyclic oxidizable monomers have been operated straightforwardly, using powerful amide connecting chemistries that do not racemize existing asymmetric centers, e.g., the use of highly reactive diacid dichlorides and of a dicyclohexylcarbodiimide (DCC)/1-hydroxybenzotriazole (HOBT) system in the

**Scheme 10.2.** Reagents and conditions: (a) and (b) same as Scheme 10.1; (c) cyclohexene, MeOH, 10% Pd/C, reflux, 0.5 h; (d) spontaneous cyclization during purification on silica gel column, **7a**:**8a** = 4:1 by  $^1\text{H}$  NMR, 91% recovery; (e) (i)  $\text{CHCl}_3$ – $\text{Et}_3\text{N}$ , terephthaloyl

or isophthaloyl chloride, 2 h, 20 °C, (ii) 1.0 M KOH, 1/1 v/v MeOH– $\text{PhCH}_3$ , reflux, 4 h then 0.1 M HCl; (f) (i)  $\text{CH}_2\text{Cl}_2$ – $\text{Et}_3\text{N}$ , adipoyl chloride, 2 h, 20 °C, (ii) 1.0 M KOH, 1/1 v/v MeOH– $\text{PhCH}_3$ , reflux, 4 h then 0.1 M HCl.

**Scheme 10.3.** Reagents and conditions: (a)–(f): same as Schemes 10.1 and 10.2; (g) (i) Dicyclohexylcarbodiimide (DCC), 1-hydroxybenzotriazole (HOBT),  $\text{CH}_2\text{Cl}_2$ , *N*-methylmorpholine, 1,4-diaminobutane, 3 h,

20 °C, (ii) 1:4 v/v cyclohexene–2-propanol, 10% Pd/carbon, 1.5 h, 20 °C; (h) same conditions as for step g but using a different 1, $\omega$ -diamine, e.g., 4,7,10-trioxatridecane-1,13-diamine.

presence of *N*-methylmorpholine (Schemes 10.2–10.4, Steps e–h). Appropriate monoPyr-/monoCbz-intermediates **7a–b** and **14–17** ( $n = 1$  or  $2$ ) prepared from *L*-lysine(Z)-OMe **6** (Z: benzyloxycarbonyl) and monobenzyl esters of *L*-aspartic/*L*-glutamic acids **12–13** ( $n = 1$  or  $2$ ) presented free  $\text{NH}_2$  and  $\text{COOH}$  groups for  $\text{C}_2$ -symmetrical amide coupling. Diacids as well as diamide linkers variable in length and lipophilicity/hydrophilicity characteristics included aromatic terephthaloyl/isophthaloyl and alkyl adipoyl chlorides, the alkyl 1,4-diaminobutane, and, finally, the more hydrophilic polyoxyethylenyl 1, $\omega$ -diamine 4,7,10-trioxa-1,13-tridecanediamine.

Consequently, these synthetic efforts facilitated routine preparation of five DPyr- and eight DCbz mono-/dicarboxylated homochiral based monomers in a 0.5–1.0 g weight range. From commercially available *L*-amino acid derivatives, and apart from monocarboxylated monomers (*S*)-**5a**/*(S)*-**5b** (Scheme 10.1, *one* synthetic step from **3**, 70 and 25–30% yields), only *three* to *four* synthetic steps were necessary to obtain the entire range of dicarboxylated oxidizable monomers (*S,S*)-**18–21a**, (*S,S*)-**9–11b**, and (*S,S*)-**18–21b** in global 53–58%, 12–14%, and 19–27% yields, respectively (Schemes 10.1–10.4).

All these monomers have been fully characterized, their chemical structures confirmed and their purities checked before fabrication of the corresponding NCs by appropriate analytical means (thin-layer and high-performance liquid chromatographies, optical rotations) and spectroscopic analyses (FT-IR, 1D/2D-high-field  $^1\text{H}/^{13}\text{C}$  NMR, low- and high-resolution FAB-MS). Additionally, and only after completion of synthetic amidations by starting block  $\text{C}_2$ -symmetrization, 1D high-field  $^1\text{H}/^{13}\text{C}$  NMR techniques allowed us to again check that optical purities of resulting

**Scheme 10.4.** Same reagents and conditions as in Schemes 10.1 and 10.3.

monomers were in a 97–98% range, based on the non-detection of meso diastereoisomers arising from asymmetric center racemization.

## 10.4

### Oxidative Polymerization of DPyr-/DCbz-based Monomers around Magnetite Nanoparticles

#### 10.4.1

##### General Considerations

The availability of DPyr- and DCbz-based monomers allowed us to test various oxidative polymerization conditions in the presence of nanosized magnetite particles (Fig. 10.2) towards corresponding magnetic NCs. Numerous methods and related modifications have been reported for the preparation of magnetite nanoparticles, and, significantly, dealing with stabilization against aggregation of the particles [1–4]. With this goal in mind, we modified slightly the original Sugimoto method, and, accordingly, the oxidative hydrolysis of iron(II) sulfate heptahydrate ( $\text{Fe}_2\text{SO}_4 \cdot 7\text{H}_2\text{O}$ ) by  $\text{KNO}_3$  in an alkaline KOH medium under nitrogen [51, 52] (see optimized protocols for NC fabrication in Section 10.6.1) that afforded magnetite sheet-like nanoparticles (mean particle size of 20–40 nm by TEM analysis) as a free-flowing, brilliant black water suspension that can be used immediately or stored under nitrogen if necessary. FT-IR peaks characteristics of pure magnetite ( $\text{Fe}_3\text{O}_4$ ,  $\nu = 410, 510 \text{ cm}^{-1}$ ) confirmed its nature, and, in particular, the absence of contaminating maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ) [51, 52].

**Fig. 10.2.** Oxidative polymerization of DPyr-/DCbz-based monomers in the presence of magnetite nanoparticles.

Regarding oxidative polymerization of DPyr-/DCbz-based monomers in the presence of nanosized magnetite particles toward corresponding magnetic NCs (Fig. 10.2), several experimental parameters were considered important and, subsequently, examined carefully during extensive screening, keeping in mind the best practicality, reliability, and robustness of NC fabrication protocols. Polymerization parameters examined included different (a) polymerization times; (b) mono- or bi-electronic chemical oxidants; (c) molar/weight ratios of DPyr- and DCbz-monomers/magnetite nanoparticles; (d) polymerization solvents (low-molecular weight alcohols, acetone, acetonitrile, dimethylformamide, and their respective mixtures with water, chloroform, hexane); (e) medium temperatures [25–55 °C when using or not ultrasonic irradiation (ultrasonic cleaner Branson at full 42 kHz power)]; and finally (f) magnetite concentrations (0.5–5% w/v range at constant experiment volume).

Two main problems arose that were successfully solved during this selection process, ending with the delivery of optimized protocols for NC fabrication [53]. First, both DPyr- and DCbz-based oxidizable monomers must be minimally soluble in water, since magnetite nanoparticles had an irreversible strong tendency to aggregate in non-aqueous media. For example, the dicarboxylate DCbz-containing (*S,S*)-**18b** (Scheme 10.4) could not be solubilized in any water-miscible organic solvent mixture and, therefore, could not be polymerized around magnetite nanoparticles. Due to the heterocycle type, DCbz-based monomers are consistently more hydrophobic, or less water-soluble than DPyr-related monomers. Therefore, two different polymerization media have been specifically adapted for monomers of both DPyr- and DCbz-type (water–methanol mixtures and acetone, respectively; see typical procedures for NC fabrication in Section 10.6.1). Secondly, DCbz-based monomers that were expected to polymerize with difficulty under usual chemi-

cal oxidative conditions polymerized efficiently when using the *only* oxidizing Ce(IV) salt CAN  $[(\text{NH}_4)_2\text{Ce}(\text{NO}_3)_6]$  among a range of currently tested oxidants  $[\text{FeCl}_3, \text{Fe}(\text{NO}_3)_3, \text{Fe}(\text{ClO}_4)_3, \text{H}_2\text{O}_2/\text{FeCl}_3/0.1 \text{ M HCl}, \text{CuCl}_2, \text{K}_2\text{Cr}_2\text{O}_7, \text{K}_2\text{S}_2\text{O}_8, (\text{NH}_4)_2\text{S}_2\text{O}_8, \text{I}_2, \text{PbO}_2, \text{etc.}]$  [53].

Conversely, DPyr-based monomers readily polymerize when using  $\text{FeCl}_3$  and ammonium peroxodisulfate,  $(\text{NH}_4)_2\text{S}_2\text{O}_8$ , with the latter oxidant being preferred since it affords much cleaner polyDPyr-magnetite NCs (absence of shorter, water-bleachable, dark colored DPyr-oligomers). Interestingly, the resulting carboxylated polyDPyr-/polyDCbz-magnetite nanocomposites did not always show colloidal stability for the entire range of parameter combinations and during storage (at  $4^\circ\text{C}$  in a neutral PBS phosphate buffer). In fact, preliminary TGA (Thermogravimetric Analysis) analyses over  $200\text{--}750^\circ\text{C}$ , together with FT-IR spectroscopic analyses, helped to confirm successful monomer polymerizations. This large screening towards optimized polymerization parameters rapidly disclosed two separate optimal sets of polymerization conditions specific for each DPyr- and DCbz-series of monomers in the presence of nanosized magnetite. Beyond the use of oxidizers specific to each monomer series, the main protocol differences related to (a) optimal polymerization media, e.g., a 45/55 v/v  $\text{H}_2\text{O}\text{--}\text{CH}_3\text{OH}$  mixture for DPyr-based monomers and pure  $\text{CH}_3\text{COCH}_3$  for more hydrophobic DCbz-based ones, and (b) optimal ultrasound-assisted polymerization times, e.g., 1 h for DPyr-based monomers versus 5 h for DCbz-based ones. Typical preparations of magnetically responsive polyDPyr- and polyDCbz-magnetite NCs are reported in Section 10.6.1.

#### 10.4.2

#### Characterization of Magnetically Responsive PolyDPyr- and PolyDCbz-Magnetite Nanocomposites

Magnetically responsive polyDPyr- and polyDCbz-magnetite NCs have been characterized using a range of analytical and spectroscopic methods that included FT-IR and  $^{57}\text{Fe}$  Mössbauer spectroscopies, C,H,N elemental and TGA analyses, magnetism measurements, and low- and high-resolution TEM microscopies with Energy-Dispersive X-Ray Microanalysis (EDAX). Additionally, as discussed in Section 10.5, a DNA-based biological parallel screening system has also been developed to characterize the fabricated NCs. In fact, NCs have been systematically tested for (a) DNA attachment using both covalent amide and noncovalent streptavidin/biotin linkages, and (b) NC surface-confined DNA hybridizations using an amplifying colored HRP-based enzymatic system (HRP: Horse Radish Peroxidase) towards detection and quantification of optically read signal outputs.

In a first step, carboxylated polyDPyr-/polyDCbz-magnetite NCs have been characterized by TGA analysis (TGA-Mettler apparatus, TG-50 DSS50 model, executed temperature profile:  $25\text{--}130^\circ\text{C}$  at  $20^\circ\text{C min}^{-1}$ ,  $130^\circ\text{C}$  for 15 min, and then  $130\text{--}800^\circ\text{C}$  at  $15^\circ\text{C min}^{-1}$  under nitrogen) and high-resolution FT-IR spectroscopy (Bomen-Hartmann & Braun instrument, KBr pellets,  $4 \text{ cm}^{-1}$  resolution) to check the formation of polyDPyr-/polyDCbz-polymers in the presence of nanosized magnetite nanoparticles. TGA curves showed quite similar two-step profiles, which

Fig. 10.3. TGA curves of magnetically responsive polyDPyr/polyDCbz-magnetite NCs.

were more or less pronounced depending on NCs over a 200–750 °C temperature range (Fig. 10.3 and Table 10.1). Observed weight losses match up, most likely, to the evaporation of shorter, more volatile polymeric chains followed by final polymer burning. Interestingly, C,H,N elemental analyses (EA 1110/CHNS-O CE instrument) data, corrected for oxygen (Table 10.1), matched with TGA NC composition data and, therefore, allowed us to check for data homogeneity. Both DPyr- and DCbz-based monomers afforded NCs of similar polymer compositions with polymer deposits in a w/w range of 18–30% and 20–32%, respectively. FT-IR spectra

of NCs showed quite similar absorption peaks. They included mixed absorption peaks characteristic of both freshly prepared non-oxidized magnetite ( $\nu = 1083\text{--}1099$ ,  $1017\text{--}1024$ , and  $568\text{--}585\text{ cm}^{-1}$ ) and of polyDPyr- and polyDCbz-polymeric systems [ $\nu = 2850\text{--}2922$  and  $2958\text{--}2964$  ( $\delta_{\text{Csp}^3\text{-H}}$ ),  $1650\text{--}1750$  ( $\nu_{\text{C=O}}$ , carboxyl),  $1454\text{--}1558$  ( $\nu_{\text{Csp}^2\text{-Csp}^2}$ , polypyrrole and polycarbazole aromatics),  $1258\text{--}1264$  ( $\nu_{(\text{C=O})\text{-O}}$ , acid),  $800\text{--}808$  ( $\delta_{\text{Csp}^2\text{-H}}$ , out of plane stretching)  $\text{cm}^{-1}$ ].

Bulk magnetization versus applied magnetic field experiments (Oxford VSM system Magnetometer equipped with an Aerosonic VSM 3001 controller) have been conducted at 300 K on all magnetically responsive, carefully dried NCs. Saturation magnetizations  $M_s$  have been observed in a range of  $32\text{--}55\text{ emu g}^{-1}$ , with coercivity factors  $H_c$  of  $35\text{--}132\text{ Oe}$  (Fig. 10.4 and Table 10.2). Subsequently, these materials cannot be strictly considered as superparamagnetic materials since they presented a low- to medium-range hysteresis. This resulted most likely from the partial oxidation of the former magnetite  $\text{Fe}_3\text{O}_4$  core during the oxidative processes used for monomer polymerizations. In fact, inorganic magnetic cores were formed of nonstoichiometric magnetite,  $\text{Fe}_{3-x}\text{O}_4$  ( $0 \leq x \leq 0.33$ ), or of  $\gamma\text{-Fe}_2\text{O}_3$  (maghemite)–magnetite mixtures as determined by  $^{57}\text{Fe}$  Mössbauer analysis at 300 K (two superposed magnetic subspectra compatible with  $\text{Fe}^{3+}$  and  $\text{Fe}^{2.5+}$  atoms located in tetrahedral and octahedral sites, respectively, with different relative intensities were obtained). For example, polyDCbz(**9b**)- and polyDCbz(**10b**)-magnetite NCs were analyzed and found to contain 30% and 60% maghemite, respectively.

Interestingly, DCbz-containing monomers, which were more difficult to polymerize oxidatively around magnetite particles, mainly afforded NCs of lower  $M_s$  and higher  $H_c$  than similarly prepared polyDPyr-based NCs (Table 10.2). These data are likely to be related to higher contents of less magnetic maghemite/nonstoichiometric magnetite ( $\text{Fe}_{3-x}\text{O}_4$ ) within corresponding NCs, while magnetic spin blocking effects could arise from formation of oxidized magnetite/polymer interfacial domains.

In a second series of analyses, all these NCs were systematically examined by low- and high-resolution transmission electron microscopies TEM (JEOL-1200EX) and HR-TEM (JEOL-JEM 2010 of Oxford Instruments, 200 kV accelerating voltage, Gatan CCD video camera for microphotograph digitization). Even using ultrasonic irradiation, NC fabrication processes were not found to alter the sheet-like morphology of starting magnetite nanoparticles nor the average particle size (20–40 nm). More interestingly, mixed structures of the discrete polyDPyr-/polyDCbz-particulates–magnetite nanoparticle type could not be detected, clearly emphasizing polymerization processes, during which deposition of insoluble polymer chains occurred around magnetite nanoparticles. These observations are consistent with the relatively low quantities of polymers deposited onto magnetite nanoparticles independent of starting DPyr-/DCbz-monomers ( $\sim 18\text{--}32\%$  w/w).

Since polymer–magnetite NC morphology remained a central issue, unambiguous confirmation of the core–shell nature for *all* the fabricated NCs came from HR-TEM analysis combined with EDAX. For illustration, HR-TEM microphotographs of poly(**5a**)-, poly(**10b**)- and poly(**21a**)-magnetite NCs belonging to both poly-

DPyr- and polyDCbz-series of NCs have been reported that showed clearly amorphous 5.0–7.5 nm thick polyDPyr-/polyDCbz-deposits decorating highly ordered magnetite/maghemite crystals (Fig. 10.5, samples prepared on 400 mesh Au grids free of carbon-containing pollutants). Corresponding elemental compositions have been determined by EDAX microanalysis using an Oxford Instruments X-ray detector and INCA software with electron beams focused at both 15 and 30 nm diameters, depending on the samples. All chemical elements have been analyzed, nor

malized, and their results obtained in weight percentages. Examples of such EDAX microanalyses are shown for poly(**5a**)- and poly(**21a**)-magnetite NCs in Fig. 10.5, wherein crystal edges have been found to be systematically carbon-rich and iron-poor, while crystal centers appear to be carbon-poor and iron-rich, arguing for the presence of organic polymer deposits around magnetite nanoparticles [poly(**5a**)-magnetite NC, spectrum 1: 55.2 and 18.0% for C and Fe versus spectrum 2: 1.9 and 63.4%; poly(**21a**)-magnetite NC: spectrum 9: 39.6 and 44.1% for C and Fe versus spectrum 6: 1.7 and 48.8%].

## 10.5

### Development of a DNA-based Biological System for Nanocomposite Parallel Screening

Among the critical steps identified for screening the properties and optimization of fabricated polyDPyr-/polyDCbz-magnetite NCs, realization of a reliable highly-parallel (use of 96-well microtiter plates), low cost, less laborious and robust biological screening system were quite essential. Accordingly, a natural choice was to turn to a DNA-based hybridization system, supported on these novel nanosized magnetic NCs, because of the extreme relevance of DNA-based diagnostics using magnetically responsive nanomaterials [54, 55]. Although numerous examples of DNA hybridizations onto various non-planar solid phases have been reported, they are mainly concerned with micrometer-sized beads that generally did not suffer from critical aggregation and non-specific binding (NSB) issues often encountered with nanosized materials [56, 57].

During our studies involving polyDPyr-/polyDCbz-magnetite NCs, two different modes of DNA probe attachments were tested – covalent (via amide bonds) and

**Fig. 10.5.** High-resolution TEM microphotographs of selected polyDPyr-/polyDCbz-magnetite NCs.

quasi-covalent (via streptavidin–biotin interactions [58–60]). These brought out the great versatility of the chemistry of surface COOH groups of NCs set up by polycarboxylated polyDPyr-/polyDCbz-deposits. After simple chemical activation of COOH groups by water-soluble carbodiimides [61–63], the addition of an  $\text{NH}_2$ -5'-modified DNA sequence as a model molecular DNA probe resulted in covalent attachment of DNA through stable amide bonds. Alternatively, second-generation streptavidin-modified magnetic NCs could be fabricated using a similar activation protocol of polymeric COOH groups followed by incubation with streptavidin. Covalent attachment of streptavidin occurs via amidation of  $\epsilon$ - $\text{NH}_2$  groups of surface lysines of the protein. Then, the same, albeit biotin-5'-modified, DNA sequence will be quasi-covalently (via streptavidin–biotin interactions) attached to modified NCs upon incubation, resulting in the testing and comparison of DNA-decorated

NCs using both probe attachment methodologies. The streptavidin/avidin-biotin system has many advantages [58–60]. Noncovalent streptavidin–biotin supramolecular interactions are very strong ( $K_d \sim 10^{-15}$  M) and, furthermore, the system is more biocompatible, and is therefore less denaturing for DNA/protein molecular probe attachments. Additionally, its great versatility makes it particularly attractive for a wide range of biological and non-biological probes (sugars, peptides, proteins/antibodies, DNA/RNA sequences, and catalysts, small ligands, fluorescent dyes, quantum dots and nanoparticles/clusters).

### 10.5.1

#### Covalent Attachment of an $\text{NH}_2$ -5'-modified 20-mer DNA Probe onto NCs towards DNA-Biofunctionalized NCs. Covalent Amide Bond Chemistry and Resulting NC-Supported DNA Hybridizations

The simple but powerful DNA-based test described in Fig. 10.6 constitutes the basic biological screening system used to investigate the properties of fabricated polyDPyr-/polyDCbz-magnetite NCs in parallel mode [53]. Whether the covalent (amide bond chemistry) or quasi-covalent (streptavidin–biotin system) DNA probe attachments were used in NC functionalization, DNA hybridizations on NC surfaces were characterized and quantified using a blue color-emitting, HRP-based enzymatic amplifying system (HRP: Horse Radish Peroxidase). Resulting hybridization signal outputs were processed in parallel, using 96-well plastic microtiter plates optically read in an Elisa Plate Reader Anthos ht II at 620 nm.

Practically, the amine-modified 20-mer oligonucleotide DNA<sub>1</sub>  $\text{H}_2\text{N}-(\text{CH}_2)_{12}-5'$  GCACTGGGAGCATTGAGGCT that characterized the 20210 mutation in the Human Factor II gene (G → A single oligonucleotide mutation at position 20210) [64, 65] was chosen as a model DNA probe and, through incubation, has been covalently attached to a full range of fabricated NCs after carboxylate activation in

Fig. 10.6. DNA covalent attachment onto polyDPyr-/polyDCbz-magnetite NCs and hybridization.

a 0.4 M MES buffer (pH 5.0) by the water-soluble carbodiimide EDC [63] [EDC: *N*'-(3-dimethylamino-propyl)-*N*-ethylcarbodiimide hydrochloride, 0.4 M MES buffer, 2 h incubation at 20 °C]. NC-supported DNA hybridizations have been performed with the fluoresceine-labeled *anti*-sense 20-mer oligonucleotide FITC-DNA<sub>2</sub> (fluoresceine-5'AGCCTCAATGCTCCCAGTGC, 60 min, 60 °C). After addition of an *anti*-FITC HRP-labeled mouse monoclonal antibody and incubation (20 min, 20 °C), the HRP substrate TMB (3,3',5,5'-tetramethylbenzidine) was added and reacted with the NC-immobilized amplifying enzymatic construct for 1.5 min at the same temperature before visible signal reading at 620 nm (Elisa Plate Reader Anthos ht II). Accordingly, the resulting optical reading data (OD<sub>Total</sub>) allowed the characterization of all the tested DNA-functionalized NCs. These were systematically averaged for six to ten similar parallel experiments for each separate NC, providing minimal signal output variations in a 5–8% range.

Additionally, and for better characterization of DNA-decorated NCs, Non-specific binding (NSB) data were systematically collected during similar averaged parallel experiments, where the complementary FITC-labeled DNA<sub>2</sub> probe was omitted. NSB data allowed us to estimate the affinity of tested DNA-decorated polyDPyr/polyDCbz-magnetite NCs to physically adsorb the reporter *anti*-FITC HRP-labeled antibody. Furthermore, micrometer-sized COOH-Dynabeads<sup>®</sup> M-270 (∅ 2.8 μm, Dynal AS, Oslo, Norway) [66] that are routinely used for magnetism-driven suspension assays were also included in those experiments as an internal standard for comparison.

In a first series of experiments for screening of NC-supported DNA hybridizations, the concentrations of FITC-5' labeled complementary probe FITC-DNA<sub>2</sub> and tested NCs were 10<sup>-7</sup> M and at 50 μg (1.0% w/v), respectively, per microtiter plate well (Fig. 10.7). From patterns of optical signal outputs (OD<sub>Total</sub>) and specific binding (SB = OD<sub>Total</sub> - NSB)/NSB ratios, the three polyDCbz-magnetite NCs, e.g., polyDCbz(**9b**)-, polyDCbz(**10b**)-, and polyDCbz(**19b**)-magnetite NCs, were as efficient as the COOH-Dynabeads tested under similar conditions. Calculated SB/NSB averaged ratios of 19.0–22.8 were in a high range. In contrast, polyDPyr-magnetite NCs were less efficient than standard COOH-Dynabeads with SB/NSB data in a low to medium (4.2–16.3) range. Here, polyDPyr(**19a**) was the most efficient NC in the polyDPyr-based series of NCs (SB/NSB = 16.3 vs. 22.2 for COOH-Dynabeads).

Interestingly, both couples of NCs polyDPyr(**19a**)/polyDCbz(**19b**)- and polyDPyr(**21a**)/polyDCbz(**21b**)-magnetite fabricated from DPyr-/DCbz-monomers **19/21a–b**, possessing an hydrophobic 1,4-diaminobutane and an hydrophilic 4,7,10-trioxa-1,13-tridecaneamine linker, were related. Among the tested NCs, they exhibited the higher and the lower efficiencies, respectively. Confirming this specific trend, the polyDPyr(**20a**)-magnetite NC built on the same hydrophilic 4,7,10-trioxa-1,13-tridecaneamine linker showed the lowest efficiency of all the tested NCs (SB/NSB = 4.2). Additionally, both polyDPyr(**5a**)- and polyDCbz(**5b**)-magnetite NCs arising from the same monocarboxylated L-lysine-based precursor exhibited similar efficiencies (13.2 and 15.4, respectively).

Subsequently, while keeping other assay parameters constant (see the typical

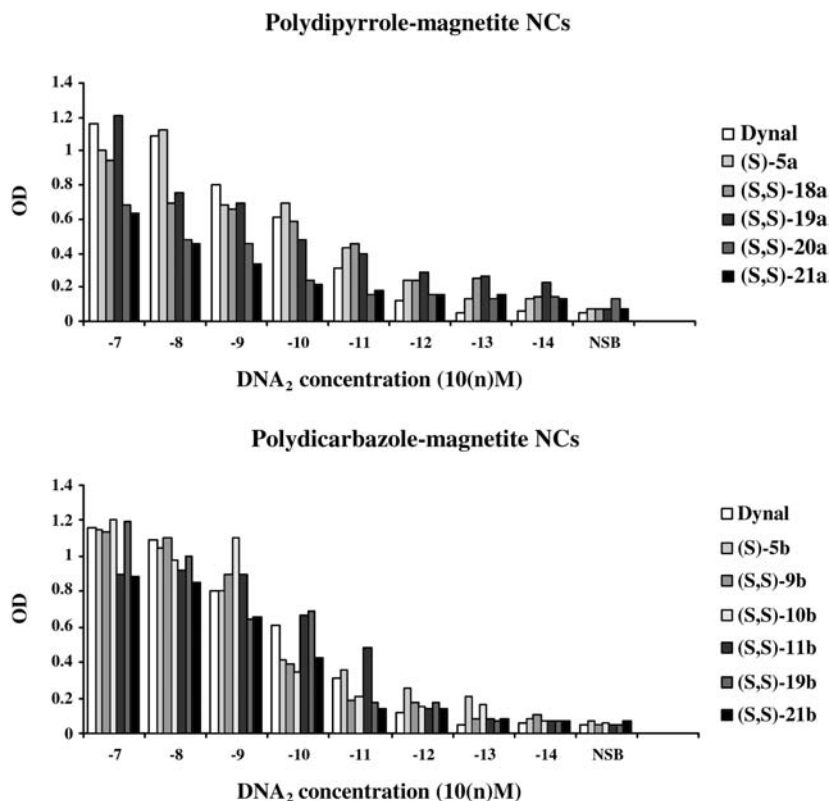

Fig. 10.7. Screening of polyDPyr-/polyDCbz-magnetite NCs at a  $10^{-7}$  M DNA<sub>2</sub> concentration and related specific binding/non-specific binding (SB/NSB) ratios.

procedure reported below), a second larger parallel screening of NC properties was performed to find a minimum assay sensitivity limit to detect the model analyte FITC-labeled DNA<sub>2</sub> (Fig. 10.8). For this purpose, a concentration range of  $10^{-7}$ – $10^{-14}$  M of FITC-labeled DNA<sub>2</sub> was investigated. In this concentration range, NSB averaged data were uniformly observed in a low 0.05–0.09 range for all tested NCs, except for the polyDPyr(20a)-magnetite NC fabricated from the hydrophilic 4,7,10-trioxa-1,13-tridecanediamine (averaged NSB = 0.11). The previously observed trend of being the least efficient system for the SB/NSB ratio was consistent and reproducible for all tested concentrations of FITC-labeled DNA<sub>2</sub>. These data precluded its further use as a sensitive detection of this model analyte. In contrast, three polyDPyr- and three polyDCbz-magnetite NCs were disclosed as the most sensitive NCs, able to achieve reproducible SB/NSB ratios in the range 1.6–2.7, at very low  $10^{-12}$ – $10^{-14}$  M concentrations of FITC-labeled DNA<sub>2</sub>. These NCs were polyDPyr(5a)-, polyDPyr(18a)-, and polyDPyr(19a)-magnetite in the polyDPyr-series and, in the polyDCbz-series, were polyDCbz(5b)-, polyDCbz(9b)-, and polyDCbz(10b)-magnetite. COOH-Dynabeads, tested in parallel under identical concentration range and conditions, were quite inefficient. This emphasized the potential of these novel nanosized magnetic NCs for highly sensitive DNA detec-

**Fig. 10.8.** Sensitivity patterns of PolyDPyr-/polyDCbz-magnetite NCs at decreasing FITC-labeled DNA<sub>2</sub> concentrations.

tion. Interestingly, and among all tested polyDPyr-/polyDCbz-NCs, the unique polyDPyr(**19a**)-magnetite NC was the most sensitive (SB/NSB = 2.7 at  $10^{-14}$  M), while both polyDCbz(**5b**)- and polyDCbz-(**10b**)-magnetite NCs were just an order less sensitive for similar SB/NSB ratios (SB/NSB = 2.0 and 1.6, respectively, at  $10^{-13}$  M).

Importantly, these low-range detection levels were consistently achieved without employing any additional passivating step (Egg albumin, BSA, PEG<sub>1000</sub> or Triton X surfactants, dextran) commonly used in the diagnostic field.

Concentrating on both typical polyDPyr(**5a**)- and polyDCbz(**5b**)-magnetite NCs, sensitivity issues were further examined by investigating the influence of two additional parameters, i.e. minimal amounts of (a) capture NH<sub>2</sub>-modified DNA<sub>1</sub> probe covalently attached onto NCs and (b) NCs used per microtiter plate well to afford reliably quantifiable optical outputs with SB/NSB ratios in a 1.0–1.5 range (Fig. 10.9). First, concentrations of the capture NH<sub>2</sub>-<sup>5'</sup>-modified DNA<sub>1</sub> probe for the covalent functionalization of both NCs were varied in a  $10^{-5}$ – $10^{-16}$  M range. Other

**Fig. 10.9.** Sensitivities of polyDPyr(5a)- and polyDCbz(5b)-magnetite NCs for decreasing DNA<sub>1</sub> and NC concentrations (the value 1% w/v corresponds to 50 µg of NC per microtiter plate well).

protocol parameters were identical to values used in the typical experimental protocol described in Section 10.6.2. For comparison, a DNA<sub>1</sub> concentration of  $10^{-7}$  M for probe attachment onto NCs was used (standardized experimental protocol). Second, variable NC amounts per microtiter plate well were investigated in a  $10^{-2}$ – $10^{-1}$ % w/v range (500.0–0.5 µg) when the same standardized experimental protocol made use of a 1% w/v NC concentration, e.g., use of 50.0 µg of NC per well. The resulting data (Fig. 10.9) led to some interesting conclusions.

A rather wide range of concentrations in NH<sub>2</sub>-5'-modified DNA<sub>1</sub> probe, from  $10^{-9}$  to the very low  $10^{-16}$  M, afforded reliable SB/NSB ratios in a 0.9–4.0 range, depending on NCs and DNA<sub>1</sub> concentrations. In contrast, standard COOH-Dynabeads treated under similar conditions were totally unresponsive. Both polyDPyr(5a)- and polyDCbz(5b)-magnetite NCs were effective even at the lowest tested DNA<sub>1</sub> concentration ( $10^{-16}$  M, SB/NSB = 0.9 and 1.4, respectively). Regarding usable NC concentration per microtiter plate well, only limited decreases in signal outputs were registered when using NC amounts per well as low as 5.0 [0.1% w/v; polyDPyr(5a)- and polyDCbz(5b)-magnetite NCs: SB/NSB = 14.0 and 18.6, respectively] and 0.5 µg [0.01% w/v; polyDPyr(5a)- and polyDCbz(5b)-magnetite NCs: SB/NSB = 13.6 and 14.4, respectively]. In parallel, COOH-Dynabeads af-

forded lower or background-level SB/NSB ratios for both NC concentrations (0.1% w/v: SB/NSB = 13.0; 0.01% w/v: SB/NSB = 0.8).

### 10.5.2

#### **Attachment of a Biotin-<sup>5'</sup>-modified 20-mer DNA Probe to DNA-biofunctionalized NCs. Quasi-covalent Linkage Using the Streptavidin–Biotin System and the Resulting NC-supported DNA Hybridizations**

A second methodology for DNA probe attachment onto polyDPyr(**5a**)/polyDCbz(**5b**)-magnetite NCs has been investigated that exploited the strong quasi-covalent streptavidin–biotin interactions. In the first step, two previously fabricated magnetic polycarboxylated polyDPyr(**5a**)/polyDCbz(**5b**)-magnetite NCs were chemically activated at room temperature by the same water-soluble carbodiimide EDC (COOH activation) in a mixture of neutral PBS and 0.4 M MES (pH 5.0) buffers. This activation step is immediately followed by covalent grafting of a high purity commercial recombinant streptavidin (Roche Inc.), leading to second-generation streptavidin-modified polyDPyr(**5a**)/polyDCbz(**5b**)-magnetite NCs. As usually performed, excess chemical reagents and biological components/buffers were readily eliminated or exchanged by magnetic decantation and appropriate washings before DNA hybridizations (see the typical experimental procedure given below).

In the second step, streptavidin-modified NC-supported DNA hybridizations were similarly tracked using the blue-emitting HRP-based enzymatic amplifying system mentioned previously (Fig. 10.6), providing the use of a biotinylated DNA<sub>1</sub> capture probe biotin–(triethylene glycol) linker-<sup>5'</sup>DNA<sub>1</sub>. Notably, in this particular case, NSB data were attributed to the noncovalent binding affinity of streptavidin-modified NCs (e.g., of protein-decorated, instead of polycarboxylated DNA-decorated, NCs) to physically adsorb the reporter *anti*-FITC HRP-labeled antibody.

Interestingly, efficiency comparisons of both covalent (amide chemistry) and quasi-covalent (streptavidin–biotin system) modes of DNA<sub>1</sub> probe attachment showed a particularly strong dependency on NC concentration (NC weight/Elisa plate well) (Fig. 10.10). For example, at a 1% NC concentration (50.0 μg of NC/Elisa plate well), SB/NSB ratios for streptavidin-modified NCs were in a low to medium range (5.3–10.1), with the streptavidin-modified polyDCbz(**5b**)-magnetite NC being the most efficient system (SB/NSB = 10.1). Streptavidin-modified micrometer-sized Dynabeads, prepared in the same way, were as efficient, with a SB/NSB ratio of 11.0. Though, while in covalent NH<sub>2</sub>-<sup>5'</sup>-linked DNA<sub>1</sub> probe attachment mode, both polyDPyr(**5a**)/polyDCbz(**5b**)-magnetite NCs always exhibited a greater efficiency (SB/NSB = 13.2 and 15.4 respectively), they were not comparable to micrometer-sized DNA<sub>1</sub>-decorated Dynabeads, which performed better as the most efficient support (SB/NSB = 22.2).

Conversely, lowering NC concentration to 0.25% w/v (12.5 μg of NC/Elisa plate well) strongly diminished the previous, detrimentally high NSB, resulting in marked differences. Whatever the covalent or streptavidin/biotin modes of DNA<sub>1</sub> probe attachment, the polyDPyr(**5a**)/polyDCbz(**5b**)-magnetite NCs systematically afforded more efficient responses than that of carboxylated Dynal microbeads

**Fig. 10.10.** Covalent (amide chemistry) and quasi-covalent (streptavidin–biotin system) attachment modes of both NH<sub>2</sub>- and biotin-5'-modified DNA<sub>1</sub> probes onto polyDPyr(5a)- and polyDCbz(5b)-magnetite NCs.

(SB/NSB = 10.6–13.3 vs. 5.0–8.0, respectively). Interestingly for this low NC concentration, both streptavidin-modified polyDPyr(5a)-/polyDCbz(5b)-magnetite NCs displayed better efficiencies than did carboxylated covalently modified ones (SB/NSB = 11.0 and 13.3 vs. 10.6 and 11.5, respectively). These preliminary data featured the important disclosure that optimized conditions dealing with polyDPyr-/polyDCbz-magnetite NCs should be investigated when testing both

types of covalent (amide chemistry) and noncovalent (streptavidin–biotin system) DNA probe attachments.

### 10.5.3

#### Storage: Medium-term Stability of Some PolyDPyr-/PolyDCbz-Magnetite NCs

The colloidal stability of some of these novel polyDPyr-/polyDCbz-magnetite NCs was also examined during storage in a neutral PBS buffer (1% w/v NC concentration) at 4 °C. For this investigation, three freshly prepared polyDPyr- and polyDCbz-magnetite NCs, polyDPyr(**5a**)-, polyDPyr(**19a**)-, polyDPyr(**21a**)-, and polyDCbz-(**5b**)-, polyDCbz(**10b**)-, and polyDCbz(**19b**)-magnetite NCs, and COOH-Dynabeads for reference were stored in the above-described neutral PBS buffer. Regular controls (quadruplicate parallel experiments) were performed on aliquots from these stored NCs on a fifteen day-basis over a period of seven and a half months, using our powerful DNA-based biological screening test. This test was operated using standard conditions of concentrations for DNA<sub>1</sub>, the complementary FITC-labeled DNA<sub>2</sub> and NC components (typical experimental procedure given in Section 10.6.2), for which NSB data were always in a low 0.04–0.05 range.

Importantly, during this period the HRP-based amplifying enzymatic system revealed a slow but regular time-dependent decrease in detection efficiency, probably because of component ageing. This ageing phenomenon, most likely, is due to the natural thermodynamic instabilities of both the HRP-labeled *anti*-FITC antibody (antibody and HRP components), and of the FITC label/epitope of the complementary FITC-labeled DNA<sub>2</sub> (light-induced degradation). Consequently, NC stability data were calculated and presented graphically as ratios of SB data of NCs/SB data of reference COOH-Dynabeads<sup>®</sup> M-270 treated in a similar time-dependent manner. Figure 10.11 depicts the resulting characteristic time-dependent ratio evolutions for each separate NC. More specifically, the three NCs polyDPyr(**5a**)-, polyDPyr(**19a**)- and polyDCbz(**10b**)-magnetite NCs underwent quite noticeable decreases in efficiency (11, 11, and 27%, respectively), most likely due to slow time-dependent NC aggregation. In contrast, the other three NCs belonging to both polyDPyr- and polyDCbz-series displayed reasonable time-dependent stabilities for the examined period and for these specific storage conditions.

## 10.6

### Typical Experimental Procedures for NC Fabrication and NC-Supported DNA Hybridizations

#### 10.6.1

##### Typical Optimized Procedures for NC Fabrication Including Magnetite Preparation

###### 10.6.1.1 Magnetite Preparation Using the Oxidative Hydrolysis of Iron(II) Sulfate in an Alkaline KOH Medium [51, 52]

A solution of iron(II) sulfate heptahydrate (FeSO<sub>4</sub>, 7H<sub>2</sub>O) (17.71 g, 60.0 mmol) in high-purity nitrogen-deoxygenated water (200 mL) was heated at 90 °C in a 1 L

Fig. 10.11. Stability data for polyDPyr-/polyDCbz-magnetite NCs during medium-term storage using a DNA-hybridization screening system.

round-bottomed flask while stirring with an overhead stirrer. In parallel, deoxygenated aqueous solutions of  $\text{KNO}_3$  (10.11 g, 100.0 mmol, 100 mL of  $\text{H}_2\text{O}$ ) and of  $\text{KOH}$  (13.81 g, 250.0 mmol, 50 mL of  $\text{H}_2\text{O}$ ) were prepared and then mixed under nitrogen until complete dissolution of the salts. The resulting basic salt mixture was then slowly added to the  $\text{FeSO}_4$  solution at 90 °C under a constant flow of nitrogen. The oxidative hydrolysis lasted 2 h at 90 °C, affording a brilliant black precipitate of magnetite nanoparticles. After cooling to room temperature (1 h), the black  $\text{Fe}_3\text{O}_4$  nanoparticle suspension was washed twice with  $\text{H}_2\text{O}$  ( $2 \times 2$  L), with 1 M  $\text{HNO}_3$  (2 L), and twice again with  $\text{H}_2\text{O}$  ( $2 \times 2$  L). These washings were repeated if necessary until a visually clear and neutral supernatant aqueous phase was obtained. The suspension volume of precipitated magnetite nanoparticles was adjusted to 1 L with deoxygenated  $\text{H}_2\text{O}$  and kept in a polyethylene storage bottle at 4 °C (stock suspension of magnetite nanoparticles). Preferably, magnetite nanoparticles should be used immediately for polyPyr-/polyCbz-magnetite NC fabrication [final storage concentration of  $\text{Fe}_3\text{O}_4$  nanoparticles: 46 mg (mL of suspension)<sup>-1</sup>].

#### 10.6.1.2 PolyDPyr-Magnetite Nanocomposites

Freshly prepared magnetite nanoparticles (100.0 mg, 2.3 mL of a 3.5% w/v water suspension of magnetite nanoparticles as prepared above) were added with the mono- or dicarboxylated DPyr-monomer (*S*)-**5a** or (*S,S*)-**18–21a** dissolved in MeOH (0.41 mmol, 3.0 mL of MeOH) and sonicated for 1 min (ultrasonic cleaner Bransonic at full 42 kHz power). Thereafter, the oxidizer (ammonium peroxodisulfate,  $(\text{NH}_4)_2\text{S}_2\text{O}_8$ , 98% purity from Riedel-de-Haën, 436.0 mg, 2.05 mmol, 5.0 equiv.) was added in one portion to the sonicated methanolic suspension of magnetite. The resultant fine black suspension (magnetite concentration of 2.0% at constant experiment volume) was then ultrasonicated for 1 h, during which time the medium temperature increased to 55 °C (ultrasound-mediated constant stirring). The resulting brown-black polyDPyr-magnetite NC was magnetically decanted with the help of a powerful external magnet. It was serially washed by  $4 \times 10$  mL of each of the indicated deoxygenated solvents/buffers,  $\text{CH}_3\text{COCH}_3$ , 0.4 M MES buffer (pH 5.0), neutral PBS buffer, TNET buffer (pH 7.5), and, finally, again with neutral PBS buffer to eliminate soluble by-products (inorganic salts, excess oxidants, unreacted monomers, and short, colored monomer-related oligomers). (The preparation of these particular buffers is described in a corresponding typical experimental procedure given in Section 10.6.2.). Colorless supernatants must be obtained at each last separate washing. The resulting magnetically responsive carboxylated polyDPyr-magnetite NCs were suspended in a deoxygenated neutral PBS buffer at a 1% w/v concentration and stored at 4 °C. These colloidal suspensions were stable for at least 2–3 months under these storage conditions.

#### 10.6.1.3 PolyDCbz-Magnetite Nanocomposites [53]

The protocol cited above was modified slightly to take into account the fact that mono- or dicarboxylated DCbz-containing monomers are much more hydrophobic

than DPyr-based ones. Magnetite nanoparticles (same quantity as above) were first magnetically decanted, washed with  $\text{CH}_3\text{COCH}_3$  ( $3 \times 2.0$  mL), and immediately added with the DCbz-based monomer (*S*)-**5b**, (*S,S*)-**9–11b**, or (*S,S*)-**18–21b** solubilized in  $\text{CH}_3\text{COCH}_3$  (0.22 mmol, 2.0 mL of  $\text{CH}_3\text{COCH}_3$ , magnetite concentration of 2.5% at constant experiment volume). After medium sonication for 1 min for best mixing, the ammonium cerium(IV) nitrate oxidizer [CAN:  $(\text{NH}_4)_2\text{Ce}(\text{NO}_3)_6$ ] dissolved in  $\text{CH}_3\text{COCH}_3$  (CAN, 99% purity, Fluka, 0.18 mmol, 100.0 mg, 2.0 mL of  $\text{CH}_3\text{COCH}_3$ ) was added under sonication in one portion. The resultant fine black suspension was ultrasonicated for 5 h at 55 °C (ultrasound-mediated constant stirring). Work-up procedures and storage conditions of the resulting polyDCbz-magnetite NCs were strictly identical to those of the former polymerization protocol.

### 10.6.2

#### Covalent Attachment of an Aminated $\text{NH}_2$ -<sup>5'</sup>-modified DNA Probe. Hybridization Experiments onto PolyDPyr-/PolyDCbz-Magnetite NCs. Typical Experimental Procedures

An appropriate polyDPyr-/polyDCbz-magnetite NC suspension (1% w/v suspension in a neutral PBS buffer, 100  $\mu\text{L}$ , 1.0 mg) was washed by (a) the same PBS neutral buffer ( $3 \times 100$   $\mu\text{L}$ ) and by (b) a 0.4 M MES buffer (pH 5.0, 100  $\mu\text{L}$ ). After magnetically-driven decantation, the supernatant was removed and (a) EDC (0.52 M EDC in 0.4 M MES buffer, 30  $\mu\text{L}$ , 3.0 mg) and (b) the 20-mer amine-modified oligonucleotide DNA<sub>1</sub>  $\text{NH}_2$ - $(\text{CH}_2)_{12}$ -<sup>5'</sup>GCACTGGGAGCATTGAGGCT (0.4 M MES buffer at pH 5.0, 70  $\mu\text{L}$ ,  $1.68 \times 10^{-5}$  M; Danyiel Biotech Ltd, Israel, chemical purity  $\geq 98\%$ ) were added successively at 20 °C. The so-obtained mixture was then incubated at room temperature for 2 h (smooth vortex agitation) for carboxylate activation.

Upon completion, polyDPyr-/polyDCbz-magnetite NCs were washed with  $4 \times 100$   $\mu\text{L}$  of PBS buffer to remove excess DNA<sub>1</sub>. DNA-coated nanocomposites can be stored for weeks at 4 °C at a 1% w/v NC concentration in this same neutral PBS buffer, but containing  $\text{NaN}_3$  (0.02% w/v), without noticeable degradation.

DNA-linked NCs (1.0 mg) were washed in a TNET buffer (100  $\mu\text{L}$ , pH 7.5) and distributed as 5.0  $\mu\text{L}$  (50.0  $\mu\text{g}$ ) portions to the wells of a thermowell polycarbonate non-sterile 96-well microtiter plate, which was then connected to a Dynal MPC<sup>®</sup> magnetic particle concentrator to separate magnetically the nanocomposites. Each well was added with the FITC-labeled *anti*-sense oligonucleotide DNA<sub>2</sub> FITC-<sup>5'</sup>AGCCTCAATGCTCCAGTGC dissolved in a pH 7.5 TNET buffer (50  $\mu\text{L}$ ,  $10^{-7}$  M; Danyiel Biotech Ltd, Israel, chemical purity  $\geq 98\%$ ) and the microtiter plate was incubated for 60 min at 60 °C for hybridization. Hybridized polyDPyr-/polyDCbz-magnetite NCs were washed by a TNET buffer ( $4 \times 100$   $\mu\text{L}$ , pH 7.5) and by 50  $\mu\text{L}$  of a commercially available Assay Solution<sup>®</sup> (Savyon Diagnostics Ltd, Israel) before incubation with the reporter *anti*-FITC HRP-labeled mouse monoclonal antibody (commercially available from Hoffman la Roche Inc., 0.1  $\mu\text{g mL}^{-1}$ , 20 min at 20 °C, 50  $\mu\text{L}$  of an Assay<sup>®</sup> Solution). After magnetically-driven decanta-

tion and plate washings ( $4 \times 100 \mu\text{L}$  of a washing solution), the TMB substrate (0.05% w/w TMB solution in de-ionized water,  $50 \mu\text{L}$ , Savyon Diagnostics Ltd) was added for color development for 1.5 min.

Following decantation, supernatants were removed and  $80 \mu\text{L}$  fractions for each well were transferred to a second PS 96-well microplate for optical reading at 620 nm, using an Elisa plate reader Anthos ht II.

#### 10.6.2.1 Specific Reagents, Buffers and Washing/Assay Solutions

PBS buffer (pH 7.0) prepared from Dubelcco's Phosphate Buffered Saline (Sigma); 0.4 M MES (pH 5.0): prepared using 2-morpholinoethanesulfonic acid hydrate 99%, adjusted to pH 5.0 by addition of 10 M NaOH and stored at  $4^\circ\text{C}$ ; TNET buffer (pH 7.5): prepared from a mixture of 10 mM Tris-HCl, 0.5 M NaCl, 1 mM EDTA and 0.02% Tween-20; washing solution: prepared from a mixture of 3 M NaCl and 2 M Tris-HCl (pH 7.5). Assay solution: prepared from a mixture of 154 mM NaCl, 50 mM Tris-HCl (pH 7.8), 0.5% BSA, and 0.1% Tween 20; EDC: *N*'-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide hydrochloride, >98% purity (Aldrich).

#### 10.6.3

#### Quasi-covalent Attachment of a Biotin-5'-modified DNA Probe and DNA Hybridization Experiments onto Streptavidin-modified PolyDPyr-(5a)/PolyDCbz(5b)-magnetite NCs. Typical Experimental Procedures

Previously prepared polyDPyr(5a)-/polyDCbz(5b)-magnetite NCs (1% w/v suspension in a neutral PBS buffer,  $200 \mu\text{L}$ , 2.0 mg) were first washed by the same neutral PBS buffer ( $3 \times 200 \mu\text{L}$ ), and then gently suspended in a freshly prepared cold 0.4 M MES buffer solution of the activating carbodiimide EDC (100.0 mg EDC/1.0 mL of a 0.4 M MES buffer at pH 5.0,  $60 \mu\text{L}$ ,  $0-4^\circ\text{C}$ ). After 5 min of gentle mixing for carboxylate activation, the commercially available, highly purified recombinant streptavidin dissolved in the same 0.4 M MES buffer [ $0.5 \text{ (mg of protein) mL}^{-1}$  of a 0.4 M MES buffer at pH 5.0,  $140 \mu\text{L}$ ,  $0-4^\circ\text{C}$ , Roche Inc.] was injected for a 1 h of incubation at room temperature (gentle NC mixing/vortexing). The resulting streptavidin-modified NCs were decanted magnetically, washed by a PBS neutral buffer ( $4 \times 200 \mu\text{L}$ ), and finally suspended in the same PBS neutral buffer ( $200 \mu\text{L}$ ) to obtain a 1% w/v suspension of modified NCs ready for use. If necessary, they can be stored at  $4^\circ\text{C}$  for several days without noticeable degradation.

DNA hybridizations operated on streptavidin-modified polyDPyr(5a)-/polyDCbz(5b)-magnetite NCs made use of the 20-mer biotinylated oligonucleotide DNA<sub>1</sub> biotin-(triethylene glycol) linker-5'GCACTGGGAGCATTGAGGCT (1.2 nmol, 0.4 M MES buffer at pH 5.0; Danyiel Biotech Ltd, Israel, chemical purity  $\geq 98\%$  as checked by HPLC analysis, incubation time 2.0 h). DNA hybridizations onto NC surfaces were probed and optically quantified using the same (a) complementary FITC-5'-labeled DNA<sub>2</sub> and (b) HRP-based amplifying enzymatic system, according to the formerly described protocol (covalent amide chemistry). Again, specific (SB) and non-specific binding (NSB) data were averaged values of

three to six parallel experiments so as to minimize dispersion of optical output data.

## 10.7

### Conclusions and Research Outlook

Novel chemically oxidizable COOH-DPyr- and DCbz-monomers have been synthesized using a general modular synthetic route ( $C_2$ -symmetrization of  $NH_2$ -/COOH-amino acid-related building blocks) towards a vast range of functionalized polycarboxylated polyDPyr-/polyDCbz-magnetite NCs. A combination of updated analytical and spectroscopic means has established – without ambiguity – that these magnetically responsive NCs possess a core–shell morphology (sheet-like nanoparticles 20–40 nm in size). This core–shell morphology basically results from chemical oxidative deposition of insoluble polyDPyr-/polyDCbz-polymers from the corresponding DPyr-/DCbz-monomers around magnetite nanoparticles. As a result of NC functionalization [introduction of COOH groups by poly(DPyr)-poly(DCbz)-polymers], DNA attachments and hybridizations have been successfully operated on them under various conditions and attachment formats (covalent and noncovalent) for DNA capture probes. These studies have emphasized their interesting potential for DNA-based diagnostic applications. Additionally, this research clearly offers an original way to combinatorially engineer polyDPyr-/polyDCbz-polymeric shell coverages of these novel magnetic NCs for the optimization of any desired application (NC functionalization by proteins/antibodies/enzymes, small peptides/oligosaccharides, locked nucleic acids, small chemical ligands/receptors). The novel materials, processes, and knowledge produced during this research could also have major applications in materials science and/or sensing technologies. For example, the fabrication of (a) polyDPyr-/polyDCbz-nanorods/nanotubules by template-oxidative polymerization of appropriate monomers within nanosized pores of template membranes, (b) new carbon nanotube–polyDPyr-/polyDCbz NCs, and (c) arrays of nanoporous polyDPyr-/polyDCbz-covered nanoelectrodes for biosensing applications are currently being developed in our laboratory.

### Acknowledgments

This work has been funded under both V<sup>th</sup>/VI<sup>th</sup> Framework European CHEMAG (n° GRD2-2000-30122) and NACBO (n° NMP3-2004-500802-2) projects. J.P.L. warmly acknowledges his close collaborators, Drs. Nurit Perlman, Senthil Govindaraji, Ludmila Buzhanski, and Augustine Joseph for investment in terms of much effort and many ideas during their research period at Bar-Ilan University (Israel). Professor Ian Bruce (Universities of Greenwich, England and of Urbino, Italy), and his main collaborator Dr. M. J. Davies (University of Greenwich, England) contributed much to the success of this research and are particularly

thanked. Many Israeli collaborators/colleagues also supported various aspects of this program, which included specific nanotechnology-related analyses as well as stimulating scientific discussions/support. More particularly, the technical/scientific assistance of Professor Shlomo Margel, Dr. Ishai Bruckental (Departments of Chemistry and Physics, Bar-Ilan University, Israel), and Dr. Erika Rivka Bauminger (Racah Institute of Physics, Hebrew University of Jerusalem, Israel) has been highly appreciated. Drs. Aline Yakir, Nir Navot and Jacob Schlessinger (Savyon Diagnostics Ltd, Ashdod, Israel) are particularly commended for having sensitized us to DNA-based biological techniques.

A hydrophilic outer layer of glycidyl ether provides functional carboxylate groups (150  $\mu\text{mol}$  per g beads). The iron content of the beads is 15% w/w for a magnetic mass susceptibility in a 88–126  $\times 10^{-6} \text{m}^3 \text{g}^{-1}$  range.

## 11 Gelatin Nanoparticles and Their Biofunctionalization

*Sushma Kommareddy, Dinesh B. Shenoy, and  
Mansoor M. Amiji*

### 11.1 Introduction

Progress in nanotechnology and medicine has led to an expansion of novel dosage forms for the delivery of drugs to diseased areas while minimizing toxicity to healthy tissues. Popular nanocarriers include polymeric micelles, dendrimers, micro-nano-emulsions, liposomes, niosomes, supramolecular complexes, nanosuspensions and nanoparticles [1–10]. Most of these can be generally classified as colloidal drug delivery systems (by virtue of their size and physico-chemical properties), each having their own merits and demerits. Nanoparticles, especially those prepared from polymeric materials, enjoy tremendous popularity due to ease of preparation, ease of tuning physico-chemical properties (through an array of polymeric materials), possibility of surface modification, excellent stability and scalability to industrial production. Since their conception in the mid-1970s, nanoparticles have found applicability in almost every section of medicine and biology (besides a host of other fields) in general, in particular for controlled/targeted delivery of drugs and genetic materials [11–21].

Nanoparticles can be categorized as colloidal carrier systems of submicron size that are made from synthetic or natural polymers. Based on the method used for their formation, they could be either nanospheres (or nanoparticles), which are essentially monolithic systems having a solid matrix or nanocapsules that have hollow interior that is filled with the compound of interest and are surrounded by a polymeric shell [16]. Drug-loaded nanoparticles have been developed for almost every route of administration – nasal, ocular, mucosal, inhalation, oral, transdermal and parenteral. Clinically, they have found applications for diagnosing and treating a wide range of pathological conditions.

Polymers used to prepare nanoparticles may be biodegradable or non-biodegradable. An ideal polymer should be biocompatible, biodegradable with minimum toxicity, sterile and non-pyrogenic, and must have a high capacity to accommodate drugs and protect them from degradation. Nanoparticles have been prepared using both natural and synthetic biopolymers. Poly(D,L-lactide-co-

glycolide), poly( $\epsilon$ -caprolactone), polyalkylcyanoacrylates, poly(styrene-co-maleic anhydride), poly(divinylether-co-maleic anhydride), poly(vinyl alcohol), and poly(ethylene glycol) are some of the synthetic, non-immunogenic polymers used extensively for the preparation of nanoparticles [1, 14, 19, 22–25]. Similarly, poly(amino acids), hyaluronic acid, albumin, dextran, chitosan and gelatin are a few of the natural biodegradable polymers [26–32]. While each polymer has its own advantages, nanoparticles can be synthesized with a high degree of reproducibility from most of them; natural polymers, due to their natural origin, are preferred considering non-toxicity and biodegradability. The striking advantage of synthetic polymers is the possibility of synthesizing them reproducibly with well-defined physico-chemical properties. Advances in biotechnology are helping natural polymers overcome this drawback and we can expect a surge in delivery systems based on them. In the sections that follow, the properties of gelatin, its chemical modification, synthesis of nanoparticles using gelatin and its derivatives, characterization of the formed nanoparticles, loading and release of the payload from the nanoparticles and the biocompatibility of gelatin nanoparticles and their conjugates are discussed. Further, the use of these nanoparticles in various drug delivery applications is elaborated.

## 11.2

### Gelatin and Gelatin Derivatives

Gelatin, one of the most versatile, naturally occurring biopolymers, is widely used in food products and pharmaceutical dosage forms. It is a proteinaceous hydrocolloid obtained by partial hydrolysis of collagen. Natural gelatins or recombinant gelatins have been tailored to enhance product performance – thus expanding their applicability in biology and medicine. The following sub-sections give an overview of such gelatins.

#### 11.2.1

##### Gelatin

Gelatin is a heterogeneous mixture of single or multi-stranded polypeptides, each with extended left-handed proline helix conformations and containing between 300 and 4000 amino acids. Figure 11.1 depicts the composition of gelatin in terms of amino acids. The triple helix of type I collagen extracted from skin and bones consists of alpha and beta helical strands together with their oligomers and breakdown (and other) polypeptides and has a molecular mass of  $\sim 95$  kDa, is  $\sim 1.5$  nm wide and  $\sim 0.3$  mm long. It is obtained commercially by acidic or basic cleavage of the intermolecular and intramolecular covalent bonds that stabilize porcine or bovine collagen. Figure 11.2 shows the basic structure of gelatin. Based on the process used for its manufacture, gelatin is obtained either as Type-A or -B. Type-A gelatin is obtained by acidic treatment of collagen and has an isoelectric point (pI) between

Fig. 11.1. Amino acid composition of gelatin.

7.0 and 9.0. Type-B gelatin, however, is obtained by alkaline hydrolysis of collagen and has a pI between 4.8 and 5.0. [33–35].

Gelatin is a polyampholyte that gels below 35–40 °C. The heterogeneous nature of the molecular weight profile of this biopolymer is affected by pH and temperature, which in turn affects the noncovalent interactions and phase behavior of gelatin in solution [35]. The numerous pendant functional groups throughout the polymeric chain present many opportunities for a pharmaceutical chemist to induce novel functionality via chemical derivatization. The purpose could be as simple as crosslinking and/or hardening or could be as complex as ligand-mediated active targeting at the cellular level.

### 11.2.2

#### Chemical Modification of Gelatin

Different modifications of polymer gelatin are carried out to control the biofunctional properties: biodistribution, targetability and stability of the formulations prepared from the modified polymer [36]. Poly(ethylene glycol) (PEG) conjugation (PEGylation), thiolation and conjugation with other synthetic block copolymers and antibodies are some of the currently studied modifications of gelatin.

Fig. 11.2. Basic chemical structure of gelatin.

### 11.2.2.1 PEGylation

PEGylation is the simplest and most popular methodology employed to increase the systemic circulation time of colloidal carriers like liposomes, micelles and nanoparticles [37–41]. It is the most widely accepted and commercially utilized technique to improve drug performance by optimizing pharmacokinetics, increasing bioavailability, decreasing immunogenicity and dosing frequency [42–47]. The basic strategy of PEGylation is to hydrophilize the surface and to induce a steric barrier by anchoring long, mobile PEG chains – thus preventing opsonin recognition in the reticuloendothelial system (RES) based blood clearance pathway. Based on the properties of colloids, the stability can be increased by limiting the mutual interactions (hydrophobic, van der Waal's, electrostatic etc.) by usage of hydrophilic and chemically inert polymers that form a protective layer around each particle, resulting in steric stabilization [48]. The major outcome of PEGylation is the significantly increased circulation time, the advantages of which include maintenance of optimal therapeutic concentration of drug in the blood after single administration of the drug carrier, increased probability of extravasation and retention of the colloidal carrier in areas of fenestrated vasculature and enhancement of active targeting ability to areas of diminished blood supply by using a ligand [11]. Besides PEG, polymers such as poly(vinyl alcohol), poly(acryl amide), poly(vinyl pyrrolidone) are also used to modify the physico-chemical properties of colloidal carriers [36].

PEG is a linear or branched polymer with terminal hydroxyl groups and is synthesized by anionic ring-opening polymerization of ethylene oxide initiated by nucleophilic attack of hydroxide ion on epoxide ring. Monomethoxy PEG (mPEG) is another widely used modification where polymerization is initiated by methoxide ion. To conjugate PEG to molecules such as polypeptides, polysaccharides, polynucleotides or other polymers, a derivative of PEG is generally prepared by functionalizing one or both the hydroxyl end groups and then coupled to the reactive amino, hydroxyl or carboxyl groups present on the molecules of interest [42]. The protective action (Stealth<sup>®</sup> property) of PEG is mainly due to the formation of a dense, hydrophilic cloud of long polyethylene chains on the surface of the molecule/colloidal particle. The tethered/chemically anchored PEG chains can undergo spatial conformations, thus preventing the opsonization of particles by the RES of the liver and spleen and hence improving the circulation time of molecules/particles in the blood. In addition, excellent biocompatibility and lack of toxicity/immunogenicity make PEG the polymer of choice for chemically modifying molecule/particles of interest to induce Stealth<sup>®</sup> properties [49–51]. The best known commercial success that employs the PEGylation technology to increase the circulation half-life of an intravenously injected formulation is the Stealth<sup>®</sup> liposomal formulation of doxorubicin (Doxil<sup>®</sup>) [39].

We have prepared PEG-modified gelatin for drug delivery applications by reacting Type-B gelatin with PEG-epoxide according to the scheme depicted in Fig. 11.3 [52]. Carboxylated mPEG can also be prepared, and subsequently coupled to the amine groups of gelatin by the dichlorohexylcarbodiimide method [53]. FTIR and NMR analysis confirmed the carboxylation and coupling reactions, and by estimat-

Fig. 11.3. Scheme of poly(ethylene glycol) (PEG) conjugation with Type-B gelatin.

ing the unreacted mPEG it was determined that each molecule of gelatin was coupled to 205 molecules of mPEG. In another study, an ester-activated PEG (mPEG) was coupled to the amino group of gelatin to prepare PEG-grafted gelatin (PEG-gelatin). This PEG-gelatin formed a micellar structure with PEG chains positioned on the outer surface of the micelle [54].

When hydrated in an aqueous medium, the chain-like PEG molecule is swiftly hydrated and set in rapid motion. This extended, quick motion causes the PEG to sweep out a large volume around it, preventing the approach and interference of other molecules/particles. As a result, when attached to a drug or a particle, PEG chains can influence not only inter-molecular/particulate interactions but also protect the underlying core from immune response and other clearance mechanisms, thus sustaining drug bioavailability. The size, molecular weight and shape of the PEG fraction and the linkage used to connect it to the entity of interest determine the consequences of PEGylation in relation to protein adsorption and pharmacokinetics (like volume of distribution, circulation time and renal clearance). When formulated into colloidal particles, the PEG density on the colloidal surface can be changed by using a PEG of appropriate molecular weight (hence length of poly(ethylene glycol) chains) and molar ratio (hence the grafting efficiency) between gelatin and PEG. Longer PEG chains offer greater steric influence around the colloidal entity – similar to increased grafting density with shorter PEG chains. Longer PEG chains may also collapse onto the nanoparticle surface, thus providing a hydrophilic shield.

### 11.2.2.2 Thiolation

Thiolated derivatives of gelatin have been prepared by different methods to create disulfide crosslinked hydrogels that can act as substrates for cell growth, improve the mucoadhesive properties of the nanoparticulate material and to functionalize the gelatin for conjugation with other molecules like antibodies or drugs. Thiolated gelatin can be synthesized by carbodiimide-mediated reaction of the carboxyl groups of gelatin with disulfide-containing dithiobis(propionic hydrazide) (DTP) followed by reduction with dithiothreitol (DTT) (Fig. 11.4) [55]. As this chemical reaction is based on the modification of carboxyl groups of gelatin, the carboxyl rich Type-B gelatin is preferred to Type-A. The reaction is carried out at pH 4.7 to obtain gelatin-DTPH after reduction with DTT [55]. Other thiolation reactions that involve modification of carboxyl residues are activation of carboxyl groups using carbodiimide followed by covalent reaction of a sulfhydryl group containing substrate, like cystaminium dichloride [56].

The  $\epsilon$ -amino groups of the proteins can also be modified to introduce a free thiol group. Traut's reagent (2-iminothiolane) undergoes a ring-opening reaction with amino groups to expose the sulfhydryl group. Reagents like succinimidyl 3-(2-pyridyldithio) propionate (SPDP), succinimidyl 4-(*p*-maleimidophenyl) butyrate (SMPB), *N*-succinimidyl[4-iodoacetyl] aminobenzoate (SIAB), succinimidyl 4-[*N*-maleimidomethyl] cyclohexane-1-carboxylate (SMCC) are also used as bifunctional crosslinkers that react with amino groups of proteins to produce a free sulfhydryl group on the surface. Alternatively, gelatin nanoparticles can be thiolated after crosslinking with glutaraldehyde (post-modification). In such cases, aldehyde groups are quenched with cysteine, which generates free sulfhydryl groups on the surface of gelatin nanoparticles [57]. The disulfide content or the free thiol groups can be determined by Ellman's assay or by  $^1\text{H}$  NMR [56].

Thiolated gelatin obtained by utilizing any of the above-mentioned reactions can be further modified by conjugation with moieties like avidin, which is complexed with biotinylated peptide nucleic acids or biotinylated antibodies [58, 59]. Hyaluronan–gelatin hydrogels have been prepared by disulfide crosslinking of thiol derivatives of hyaluronan and gelatin that were synthesized separately. Such disulfide crosslinked hydrogels have been used as a substrate for cell growth [60].

### 11.2.2.3 Other Conjugates of Gelatin

Gelatin has been conjugated with chitosan by the enzymatic action of tyrosinase on gelatin [61]. The enzyme tyrosinase is an oxidative enzyme that converts phenols into *O*-quinones – hence it reacts with tyrosyl groups present on the telopeptide region of gelatin to convert them into *O*-quinones that react with nucleophilic amino groups of chitosan non-enzymatically. Chemical conjugation of gelatin to chitosan was confirmed by UV/Visible, IR and  $^1\text{H}$  NMR spectroscopy. Viscosity measurements carried out at different reaction conditions also indicated the conjugation of gelatin with chitosan, as it has thermal behavior compared with gels formed by cooling gelatin. These studies indicate that the mechanical properties of tyrosinase-mediated conjugates of gelatin can be further explored for medical and industrial applications [61].

Fig. 11.4. Scheme of thiolation of carboxyl groups of gelatin with disulfide-containing dithiobis(propionic hydrazide) (DTP) mediated by carbodiimide.

Semi-synthetic, biodegradable, amphiphilic copolymers of poly(D,L-lactide) grafted gelatins have been prepared by ring-opening polymerization of D,L-lactide onto gelatin and a trimethylsilyl derivative of gelatin in the presence of a catalyst, tin(II) bis(2-ethylhexanoate), at 80 °C [62]. The solution polymerization was carried out in DMSO and the copolymers formed were characterized by elemental and thermal analysis, and IR and <sup>1</sup>H NMR spectroscopy. Molecular weights of the copolymers were calculated and were found to increase with increasing ratio of D,L-lactide to gelatin, indicating the possibility of fabricating polymers with required properties for tissue engineering [62].

Gelatin nanoparticles have recently been conjugated to antibodies by avidin–biotin complex formation [63, 64]. Following crosslinking, some of the reactive amino groups on the gelatin surface were activated with 2-iminothiolane to introduce reactive sulfhydryl groups. The thiolated nanoparticles were coupled to NeutrAvidin™ (NAv) previously activated by a hetero-bifunctional crosslinker. The NAv-modified nanoparticles were then used for the binding of biotinylated antibodies by avidin–biotin complex formation. The biotinylated antibody attached may be an anti-CD3 antibody that is used for specific drug targeting to T-lymphocytes or trastuzumab (Herceptin), which could be used for targeting HER2 overexpressing tumor cells [63, 64].

### 11.3

#### Nanoparticulate Carriers of Gelatin and Gelatin Derivatives

Preparation of nanoparticles from a pre-formed polymer is, in general, relatively straightforward, having high degree of reproducibility. However, the physico-chemical properties of gelatin, especially its heterogeneity in molecular weight distribution, make it a challenging polymer with which to produce stable nanoparticles. Nonetheless, many groups have successfully prepared nanoparticles, from gelatin and its derivatives, that have been evaluated for a range of biomedical applications [65–70]. Desolvation is the most popular technique for preparing gelatin nanoparticles, followed by techniques such as coacervation and water-in-oil emulsification.

##### 11.3.1

#### Desolvation

Desolvation is the process in which solvents of different polarity and hydrogen bonding, when added to solution of proteins, bring about rolling up or controlled precipitation of proteins due to the displacement of water molecules from the surface of proteins [71]. In solution, the gelatin molecules are well stretched and upon addition of (non-)solvents, such as ethanol, acetone or isopropanol, the solubility of gelatin molecules decreases (as the high hydrogen-bonding capacity of these solvents displaces water molecules), resulting in phase separation of the rolled-up gelatin molecules. These molecules have a size range of 100–200 nm and are further

hardened by crosslinking with aldehydes such as formaldehyde or glutaraldehyde. The pH and stirring conditions affect the size range and yield of these particles [15, 35].

#### 11.3.1.1 Desolvation Using Ethanol

The folding of gelatin in solution is determined by noncovalent interactions with the water molecules and the presence of solvents such as ethanol, which in turn affect these interactions. Marty et al. first observed that the complex phase behavior of gelatin was affected by temperature and other experimental conditions [13]. Farugia et al. have investigated the affect of temperature, pH and ethanol concentration on the molecular weight distribution profile of gelatin in solution in order to develop a robust method for preparing gelatin nanoparticles [35]. The molecular weight profile of gelatin remained unchanged at pH 5.0 to 7.0. However, at pH < 6.0, the gelatin particles lacked a net charge, resulting in aggregation. At pH > 7.5, the increased charge on the particles contributed to increased resistance to dehydration. In addition, the turbidity of the solution during nanoparticles preparation was constant at all temperatures within the pH range, and the percentage of molecular weight fractions precipitated was optimum at ethanol concentrations ranging from 62.5 to 75% w/w [35].

We have standardized preparation procedures for gelatin and PEGylated gelatin nanoparticles using the solvent displacement (based on principles of desolvation) process [52, 72]. Typically, ethanol is used as the non-solvent for gelatin. A 1% w/v solution of gelatin is prepared at 37 °C and the pH adjusted to 7.0 with 0.2 M sodium hydroxide. Nanoparticles are formed when the solvent composition is changed from 100% water to 65% (by volume) hydro-alcoholic solution under continuous stirring. The nanoparticles are further crosslinked with a 40% v/v aqueous solution of glyoxal for the desired time and any unreacted aldehyde is quenched with 12% w/v sodium metabisulfite. Particles so-obtained have a size range of 200–500 nm.

#### 11.3.1.2 Two-step Desolvation

Nanoparticles can be prepared from both Type-A and -B gelatins using this method. In the first step gelatin molecules of low molecular weight are separated (through a first-stage desolvation process) and discarded. The sediment obtained is rich in high-molecular weight gelatin fractions and is resolvated (redissolved in suitable aqueous medium) to carry out a second-stage desolvation process. Gelatin nanoparticles obtained by the two-step desolvation process have high stability (predominantly by virtue of high molecular weight) and do not show any aggregation or flocculation [73–75].

### 11.3.2

#### Coacervation

Coacervation is a process of spontaneous phase separation in the presence of two oppositely charged polyelectrolytes in solution. Electrostatic interaction between the electrolytes and the macromolecules results in the separation of a polymer-

rich phase, the coacervate, and a polymer-poor phase, the supernatant [76]. This concept of coacervation or phase separation can be used for preparing nanoparticles to encapsulate proteins and drugs.

Leong et al. [68, 76, 77] have synthesized gelatin nanoparticles as vehicles for gene delivery, by coacervation brought about by desolvation of water molecules using polyelectrolytes. Gelatin nanoparticles so-obtained form at gelatin concentrations ranging from 1.5 to 5% w/v and sodium sulfate from 0.2 to 1.2% w/v. The conditions of coacervation also depend to a great extent on the mixing conditions and presence or absence of electrolytes in solution. When plasmid DNA was co-encapsulated with endolysolytic agents such as chloroquine the required sodium sulfate concentration was reduced by 10–20% w/v. The uncrosslinked nanoparticles formed were relatively stable in acidic pH; however, as they dissociate at high ionic strength and neutral pH, the formed nanoparticles were separated by centrifugation and crosslinked using  $0.1 \text{ mg mL}^{-1}$  (1-ethyl-3-[3-dimethylamino-propyl]-carbodiimide hydrochloride) (EDC); the excess was quenched using glycine at a concentration of 0.2 M in the final solution.

In other instances, the concept of coacervation was used in combination with phase separation, in which a 1% w/v solution of gelatin containing surfactant (polysorbate 20, at 0.5% w/v) was mixed with sodium sulfate (at 20% w/v) to bring about coacervation followed by phase separation using isopropanol under continuous stirring. The nanoparticles formed were stabilized by crosslinking with glutaraldehyde; the excess aldehyde groups were quenched with sodium metabisulfite. The nanoparticles formed were stabilized by crosslinking with glutaraldehyde; the excess was quenched using sodium metabisulfite. Nanoparticles with an average size of 200 nm were separated from the salts by gel-chromatography using Sephadex G-50 [69, 70, 78].

### 11.3.3

#### **Nano-encapsulation by Water-in-oil Emulsion Method**

Nanoencapsulation involves wrapping small amounts of material in individual coatings or sheaths in discrete, sub-micron sized particles. Materials such as proteins or conventional drugs can be encapsulated, wherein the coatings aid in protecting the encapsulated material and in achieving prolonged or controlled release. Gelatin nanoparticles can be prepared by using the emulsifier-free water-in-oil (W/O) emulsion method either by solvent evaporation [67] or homogenization [79]. The gelling property of gelatin enables the separation of the hydrogel particles that are formed in the emulsion, which can be further stabilized/hardened by glutaraldehyde crosslinking [67]. Typically, a W/O emulsion is prepared with a gelatin solution as the internal aqueous phase and a vegetable oil as the external phase. The payload is incorporated in the internal aqueous phase itself and the two phases are emulsified under high-speed. The emulsion is then cooled to below the gelling point of gelatin to facilitate formation of payload-entrapped hydrogel particles. These are then collected by filtration, the oil phase is washed off with a suitable solvent and the hydrogel particles are then freeze-dried to obtain free flowing gelatin nanoparticles with an average size range of 840 nm [79].

The size distribution of these particles was affected by the nanoencapsulation process – mainly by the time and speed of homogenization and the viscosity of the gelatin solution. The size of these nanocapsules decreased with increasing time and speed of homogenization. However, prolonged homogenization resulted in flocculation of the droplets. The particle size was also increased with increasing viscosity, with a 1–3% w/w gelatin solution having optimum viscosity. The nanoencapsulation process was simple, with mild reaction conditions in the absence of emulsifiers and surfactants that might have harmful effects on the protein and peptide drugs co-encapsulated. The gelatin nanoparticulate system thus produced could be used for controlled delivery of protein and peptide drugs by intravenous, subcutaneous or intramuscular injection [79].

In the method involving solvent evaporation, the external phase is an organic solvent mixture (e.g., a 1:1 mixture of chloroform and toluene) containing a stabilizer [such as poly(methyl methacrylate) (PMMA)] and the internal aqueous phase is gelatin in phosphate-buffered saline (PBS). After high-speed homogenization of the mixture, the internal phase is evaporated under controlled conditions of temperature and pressure to obtain nanoparticles. The particles can then be cross-linked with an aldehyde if necessary. The nanoparticles are collected by centrifugation, washed with toluene to remove any excess of polymer and freeze-dried to obtain a free flowing product with a size range of 100–200 nm. The major advantage of this method is the use of PMMA in the oil phase, which prevents coagulation of the gelatin nanoparticles before and after crosslinking [67].

#### 11.4

#### Characterization of Gelatin and Modified Gelatin Nanoparticles

Gelatin nanoparticles prepared by different methods are generally characterized for size, morphology, surface charge and water content. The mean particle size and size distribution of the gelatin nanoparticles can be measured by photon correlation spectroscopy (PCS) or any suitable technique that is sensitive to detecting particles in the nanometric range. Particle size analysis also helps in ensuring batch-to-batch reproducibility of the nanoparticles and hence can be used as a major quality control tool. Most nanoparticles prepared by the above methods have reported mean sizes ranging from 200 to 400 nm. Colloidal stability, drug encapsulation efficiency, loading capacity, drug release and biodistribution profile, cell internalization kinetics etc. are strongly influenced by the particle size.

Scanning electron microscopy (SEM) is widely used to study the morphology and size of nanoparticles. Nanoparticles separated from suspension either by centrifugation or filtration are dried by lyophilization. Cryoprotectants (such as mannitol, trehalose etc.) can be used if necessary to promote stability of the particle during reconstitution. The dried nanoparticles are mounted on an aluminum sample mount, sputter coated with gold–palladium and observed by SEM. SEM images reveal the morphology of these nanoparticles and their actual diameter when compared with the hydrodynamic diameter obtained by PCS. Hence, nanoparticles

**Fig. 11.5.** Scanning electron microscopy image of non-crosslinked gelatin nanoparticles prepared by desolvation using ethanol.

sized by SEM would be relatively smaller than when determined by PCS [13, 52, 72, 73, 80]. Figure 11.5 shows the SEM image of non-crosslinked gelatin nanoparticles prepared by desolvation using ethanol.

The surface charge on the gelatin nanoparticles is measured by the zeta potential (the electrical potential due to the charged particles on the thin film of liquid bound to the surface of nanoparticles). Measurement of the zeta potential is one of the most important parameters in characterizing colloids, denoting their stability. Colloids with high zeta potentials ( $> \pm 30$  mV) are very stable due to electrostatic repulsions, when the zeta potential is close to zero coagulation and sedimentation of the colloidal particles is faster. The gelatin nanoparticles are dispersed in deionized water (or suitable buffer if necessary) and the zeta potential measured at the default parameters of dielectric constant, refractive index and viscosity of water [81].

Measurement of water content is important for any drug delivery system containing a moisture-sensitive compound like proteins. Gelatin nanoparticles are a kind of nano-hydrogel system that consists of a network of polymer with water molecules incorporated and the polymer crosslinked to enhance stability. The high water content in these systems plays a significant role in their biocompatibility, mechanical strength and drug release. Diffusion of water molecules into the hydrophilic matrix and formation of a gel barrier affects the release of drug from the system [82]. Water molecules can be associated with the hydrophilic polymer gels in three ways: freezing or bound water, freezing interfacial or intermediate water and free water [83]. Each molecule of associated water can exert its influence on the stability and reactivity of the polymeric carrier system in different ways.

Li et al. have determined the water content of hydrogel particles of gelatin prepared by the W/O emulsion method [79]. In this method the nanoparticles were suspended in deionized water and left in a water bath at different temperatures overnight; each sample was then vacuum filtered using a nylon filter membrane and the weight of swollen gelatin nanoparticles was compared with the dry weight

of gelatin nanoparticles to calculate the percentage water content at each temperature. The water content of gelatin was linearly dependent on the temperature, taking up about 51.6% water at 15 °C and 71.4% at 42 °C. NMR spectroscopy and differential scanning calorimetry (DSC) are also widely used to determine the water content of gelatin nanoparticles. In addition, NMR spectroscopy is used to study the structure mobility and hydration properties of the polymers [82].

The nano-structured surfaces of the nanoparticles of gelatin and its derivatives can be characterized by electron spectroscopy for chemical analysis (ESCA) – a surface analysis technique that exploits the photoelectric effect to obtain information about elemental composition and identify the functional groups present within a few nanometers-thick surface layers. This method involves irradiating the sample with photons (mainly low energy X-rays) that interact with the surface of the material and eject electrons, which are then analyzed by a spectrophotometer to identify the elements they come from. We have analyzed gelatin and PEG-modified gelatin nanoparticles prepared in our laboratory by ESCA to provide evidence for the presence of surface PEG chains on the nanoparticles. The results showed surface functional groups identified by high-resolution peak analysis of carbon-1S ( $C_{1S}$ ), oxygen-1S ( $O_{1S}$ ) and nitrogen-1S ( $N_{1S}$ ) envelopes that indicate the presence of ethylene oxide residues of PEG on the surface of modified gelatin [52].

## 11.5

### Loading and Release of Payload from Gelatin Nanoparticles

The payload of drugs or other substances such as proteins or plasmid DNA may be distributed throughout the matrix, or encapsulated in the cavity enclosed by the polymer, or adsorbed on the surface of the nanoparticles. Interaction of gelatin with these substances may be through chemical conjugation, ionic interaction or physical entrapment. The extent of drug loading and encapsulation efficiency of the gelatin nanoparticles depends on the molecular weight and also on the nature of the substance incorporated. Studies by Truong-Le et al. have shown that the encapsulation efficiency of gelatin nanoparticles increases with increasing molecular weight, with some exceptions where charge interactions have a profound affect [68].

The amount of substance incorporated into the gelatin nanoparticles is generally estimated either by assaying the supernatant for the free drug or by determining the amount of drug encapsulated in the particles by subjecting them to enzymatic hydrolysis. We have used tetramethylrhodamine-labeled dextran (TMR-dextran) as a model to represent a hydrophilic macromolecular drug. The TMR-dextran was added to the gelatin solution during nanoparticle preparation, the free drug was separated by centrifugation and the drug-loaded nanoparticles were dissolved in protease ( $0.2 \text{ mg mL}^{-1}$ ) containing PBS. The fluorescence intensity of the resulting solution was measured to account for the amount of drug loaded in the gelatin nanoparticles, and the loading efficiency was found to be 51% [52]. In certain cases the loading of conventional drugs like doxorubicin and proteins like bovine serum

albumin (BSA) was estimated by UV/Visible spectrophotometry and that of plasmid DNA by picogreen assay or by radiolabeling the DNA and accounting for its activity [68, 69, 72, 79].

Drug release from the gelatin nanoparticles may be due to leaching, erosion, rupture or degradation of the particulate material. Generally, it is suggested that the release of the payload is via diffusion and bioerosion for the gelatin nanoparticles [52, 72]. The hydrolysis/biodegradation process is accelerated in presence of enzymes (such as hydrolases or proteases). When the drug is distributed throughout the matrix, slow erosion or degradation can lead to prolonged drug release [15].

*In vitro* release studies of drugs from gelatin nanoparticles is generally carried out in a known amount of PBS, with constant shaking in the presence or absence of protease. Samples are removed at predetermined time intervals to analyze the amount of payload released. Sink conditions are maintained throughout the release study by replenishing the released medium with fresh PBS, and the drug released is calculated as a function of time [52].

Leo et al. have studied the release of doxorubicin from gelatin nanoparticles by dynamic dialysis [78]. The release study was carried out in 0.9% w/v NaCl in both the absence and presence of trypsin in the donor compartment separated by dialysis membrane with a cut-off size of 3.5 kDa. About 9 to 13% of the drug was released in the absence of the enzyme compared with 12.6 to 23.5% in the presence of trypsin [78]. The drug release rate from the gelatin nanoparticles was affected by the degree of crosslinking. This indicated the possibility of achieving controlled release by manipulating the degree of crosslinking. Gel electrophoresis indicated that the crosslinking had no effect on the structure and electrophoretic mobility of the encapsulated DNA [68].

## 11.6 Biocompatibility Studies

Gelatin has several unique properties that support its usability in medicine and biology. However, its animal origin and protein nature make it a material with safety risks, too, especially when intended for medical applications. These safety risks are related to the presence of prions and other infectious contaminations. Currently, there are commercial suppliers that produce gelatin by recombinant DNA technology (refer to the websites of companies like FibroGen, Fuji-Tilburg, etc.).

To evaluate cellular biocompatibility, cytotoxicity assays have been carried out to determine the affect of gelatin and modified gelatin nanoparticles on the viability of the cells in culture. Lactate dehydrogenase (LDH), the enzyme present in the cytosol of the cells, is a marker of membrane integrity of the living cells, and the LDH released by the rupture of the membrane of the dead cells is estimated to determine the affect of nanoparticles on the viability of the cells. Brzoska et al. have compared the cytotoxicity of gelatin nanoparticles with that of human serum albumin (HSA) and poly(hexylcyanoacrylate) nanoparticles by incubating them at concentrations of 0–50  $\mu\text{g mL}^{-1}$  for 6 h with pulmonary epithelial cells, monitoring

the levels of LDH up to 96 h after replacing the supernatant. LDH levels of the cells incubated with gelatin nanoparticles were constant and were comparable with that of negative control. The same group has also looked into the ability of gelatin nanoparticles to initiate the expression of interleukin-8 (IL-8) by the pulmonary epithelial cells. ELISA was used to estimate the concentration of IL-8 in the supernatant after 24 h incubation of nanoparticles. Notably, gelatin nanoparticles did not initiate any expression of IL-8 even at concentrations as high as  $100 \mu\text{g mL}^{-1}$  [75].

One of the most popular methods of estimating cytotoxicity is the MTS assay (commercially available as CellTiter 96<sup>®</sup> AQueous Non-Radioactive Cell Proliferation Assay from Promega). It is based on the principle that when a novel tetrazolium compound [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium, inner salt or MTS] is incubated with cells, the metabolically active cell population converts MTS into purple formazan that is soluble in the culture medium (unlike the MTT assay, wherein the formazan salt is not soluble). Mitochondrial dehydrogenase enzymes present in the viable cells cleave the yellow tetrazolium compound to a purple formazan salt that is estimated by calorimetry. We have evaluated the cellular toxicity of gelatin and modified gelatins (PEGylated form) in comparison with polyethyleneimine and lipofectin. Cells incubated with gelatin remained 100% viable even at concentrations up to  $200 \mu\text{g mL}^{-1}$  [52]. These studies indicate that gelatin is biocompatible and non-toxic, and hence is safe and could be used as a vehicle for drug delivery applications.

## 11.7

### Applications of Gelatin and Modified Gelatin Nanoparticles

Gelatin has been widely used for various industrial applications, primarily in food, pharmaceuticals and medicine. It is used extensively in the food industry – confectionary, dairy, meat, desserts, in bakery products as thickening agents, stabilizer and emulsifier. Gelatin is an inexpensive, non-toxic, biocompatible and biodegradable polymer that can be easily formulated – the most popular conventional pharmaceutical dosage form being soft and hard gelatin capsules. Hydrogels, films, micro- and nanoparticles based on gelatin represent a few of the novel formulations, which are being explored widely for pharmaceutical and drug delivery applications.

Gelatin nanoparticles have been used as a carrier for gene delivery applications [84]. Cellular uptake of these nanoparticles is mainly attributed to endocytosis, wherein the cells engulf the nanoparticles, forming a vesicular structure (endosome) that fuses with the lysosomes within the cytoplasmic space. Upon acidification of the endo-lysosomal complex, the nanoparticles degrade and the contents are released into the cytoplasm to exert pharmacological action. Gelatin nanoparticles have several advantages as a non-viral gene delivery vector. They can be conjugated to moieties that stimulate receptor-mediated endocytosis, multiple plasmids or bioactive agents can be encapsulated and the bioactivity of the encapsu-

lated DNA could be improved by preventing digestion by nucleases and by using long-circulating nanoparticles that are modified by PEG [76]. In other instances the DNA is adsorbed onto the surface of the gelatin nanoparticles by modifying the surface of gelatin with cholamine (a quaternary amine) to increase ionic interactions [81].

Gelatin nanoparticles can be crosslinked with dialdehydes (glutaraldehyde, glyoxal etc.) and those aldehyde groups can then be used as chemical handles for further modification. Crosslinking also helps to control the degradation kinetics of the nanoparticles. One limitation of using crosslinked gelatin nanoparticles is that the nature of transfectability of the nanoparticles is reduced due to the reduction in release rate of the DNA from the nanospheres [68, 77].

Nanoparticulate carriers of gelatin have been used for efficient intracellular delivery of the encapsulated payload. Our laboratory is engaged in exploring gelatin and modified gelatin-based nanoparticles for drug delivery. We have carried out cell trafficking studies using gelatin and PEGylated gelatin nanoparticles loaded with TMR-dextran as a model hydrophilic drug in BT-20 cells. We observed the localization of TMR-dextran loaded nanoparticles in the perinuclear region of the cells. The particles were mainly taken up by endocytosis, which later escaped the endosomal system and were found around the perinuclear area in the cytoplasm [52, 72]. In addition, we have reported the gene delivery efficiency of nanoparticles prepared from gelatin and PEGylated gelatin [85]. Most of the administered gelatin and PEGylated gelatin nanoparticles were internalized in NIH-3T3 fibroblast cells within the first 6 h of incubation. A large fraction of the administered nanoparticles was concentrated in the perinuclear region of the cells after 12 h. Green fluorescent protein expression was observed after 12 h of nanoparticle incubation and remained stable for up to 96 h. Flow cytometry results showed that the DNA transfection efficiency with gelatin and PEGylated gelatin nanoparticles was 43% and 61%, respectively, after 96 h. This study illustrates that PEGylated gelatin nanoparticles were rapidly internalized by the cells through nonspecific endocytosis and remained intact in the cytosol for up to 12 h [85]. A similar study was carried out using non-crosslinked gelatin nanoparticles loaded with plasmid DNA; confocal images in Fig. 11.6 show the fluorescence observed at 24 and 96 h post-transfection.

Kushibiki et al. have proven the long-circulation property of PEGylated gelatin by using  $^{125}\text{I}$ -labeled gelatin [54]. The grafted polymer was obtained by incubating succinimidyl succinate methoxy-PEG with gelatin followed by radio-iodination by the chloramine-T method. Nanoparticulates with an average size of 100 nm were prepared by micellization of gelatin and PEGylated gelatin solutions at concentrations ranging from 0.04 to 10 mg mL<sup>-1</sup> in the presence of 5 mM *N*-phenyl-1-naphthylamine (PNA) in methanol. Results of the biodistribution studies indicated a parallel increase in area under the curve (AUC) with an increase in molecular weight of the grafted PEG at the same degree of PEGylation, [54].

We have prepared nanoparticles from gelatin (Type-B) and PEGylated gelatin, radiolabeled with  $^{125}\text{I}$  for *in vivo* biodistribution studies after intravenous (i.v.) administration in mice bearing Lewis lung carcinoma [58]. From the radioactivity in

**Fig. 11.6.** Fluorescence confocal microscopy images of NIH-3T3 murine fibroblast cells transfected with enhanced green fluorescent protein plasmid DNA (EGFP-N1)-loaded gelatin nanoparticles after 24 and 96 h post-transfection.

plasma and various organs collected, most PEGylated nanoparticles were evidently present either in the blood pool or taken up by the tumor mass and liver. For instance, after 3 h, the concentrations of PEGylated gelatin nanoparticles were almost two-fold higher in the blood pool than the control gelatin nanoparticles. PEGylated gelatin nanoparticles remained in the blood pool for a longer due to the steric repulsion effect of the PEG chains as compared with the gelatin nanoparticles. In addition, ca. 4–5% of the recovered dose of PEGylated gelatin nanoparticles was present in the tumor mass for up to 12 h. Plasma and the tumor half-lives, mean residence time, and the AUC of the PEGylated gelatin nanoparticles were significantly higher than those for the gelatin nanoparticles. These results showed that PEGylated gelatin nanoparticles possess long-circulating properties and can preferentially distribute in the tumor mass after systemic delivery.

Leong et al. have studied the *in vivo* transfection efficiency of gelatin nanoparticles containing the LacZ plasmid in the tibialis anterior muscle of 6-week-old BALB/c mice; the muscle was isolated and homogenized 3 weeks after injection to assay the expression of  $\beta$ -galactosidase. The gelatin nanoparticles exhibited a more profound and sustained gene expression than the naked plasmid DNA and lipofectamine complexes [76].

Research carried out by Farrugia et al. has indicated the antitumor activity of empty gelatin nanoparticles, which effectively inhibited the formation of melanoma tumors by binding to the fibronectin surfaces that interfere with tumor growth [80]. This property can allow gelatin nanoparticles to be used as a possible alternative to Bacillus Calmette-Guerin vaccine in the treatment of melanoma [80]. In yet another study, nanoparticles of gelatin and PEGylated gelatin, ranging in size from 100–1000 nm, have been prepared via a self-assembly process. These nanoparticles were degraded by collagenase IV within 1 min and the degraded fragments had a molecular weight of 2000 and below, which is smaller than the

cut-off molecular size for the kidney membrane. This indicates the possibility of using these complexes for anticancer therapy wherein the payload is released by the action of matrix metalloproteases (MMPs) at the cancer site. *all-trans*-Retinoic acid has been used as a model drug, and the loading efficiency was found to be about 92% when loaded at 1% weight of polymer. Release studies of the drug-loaded PEGylated gelatin nanoparticles revealed an accelerated release profile in the presence of collagenase IV – an enzyme present in high concentrations in tumor tissues [53].

Gelatin-based nanoparticulate systems have also been used to deliver protein and peptide drugs. Macromolecules such as proteins are degraded in the gastrointestinal tract when administered orally and these drugs require multiple injections to achieve the desired therapeutic effect if administered via the parenteral route. Li et al. have studied gelatin nanoparticles to overcome these hurdles for the delivery of a model protein (BSA) [59, 79].

Gelatin nanoparticles have been explored to encapsulate antitumor drugs, which resulted in increased efficiency, controlled release, and targeting of drugs to the affected area. Paclitaxel-loaded gelatin nanoparticles were used to enhance the solubility of the drug and its partitioning across biological membranes that are sensitive to Cremophor EL, a constituent used to solubilize paclitaxel in commercial formulations. X-Ray diffraction analysis indicated an amorphous state of the entrapped drug, thus confirming its enhanced solubility. These paclitaxel-loaded gelatin nanoparticles were used to treat dogs with intravesical bladder carcinoma and a 2.6× higher drug concentration was achieved in tumors compared with control dogs treated with Cremophor EL containing a commercial paclitaxel injection [86]. Studies have been conducted by injecting doxorubicin-loaded glutaraldehyde-crosslinked gelatin nanoparticles into rats by intraperitoneal injection [69]. The animals were monitored for side effects by electrocardiogram and body weight and the results indicated that control nanoparticles (without any drug) did not show any toxicity. Although the efficiency of the anticancer drug was enhanced, upon repeated administration the formulation (doxorubicin-loaded gelatin nanoparticles) showed high cardiotoxicity. This was attributed to covalent attachment of the drug to the carrier and the toxicity of the degradation products of these drug-peptide conjugates [69, 78]. Michaelis et al. also observed similar results, by conjugating diethylenetriamine pentaacetic acid (DTPA – an extracellular chelator) to gelatin. The attachment to gelatin enhanced cellular uptake and increased the cytotoxic and antiviral activity of DTPA by five- to eight-fold [74].

## 11.8 Conclusions

The unique physical, chemical and biological properties of gelatin and its modified derivatives make it a best possible alternative for drug delivery and therapeutic applications. The safety of traditional gelatins, especially in terms of immunogenicity, presence of biological impurities and other drawbacks associated with

tissue-derived material are some of the reasons why researchers have developed a complete set of new recombinant gelatins. Advances in biotechnology have provided gelatins with well-defined molecular weights, pI, guaranteed lot-to-lot reproducibility, and the ability to tailor the molecule to match a specific application. They are also biodegradable, non-immunogenic, have excellent cell binding properties, and can be delivered with a purity of >99.9%. Thus the new generation recombinant gelatins are the most appropriate materials for a range of medical and pharmaceutical applications, including hydro-gels for controlled release functions, tissue engineering scaffolds, and stabilizing additives of vaccines or bio-pharmaceuticals. It is also evident that gelatin is useful in maintaining the therapeutic activity of biotechnological products such as proteins, peptides and oligonucleotides, in reducing the toxicity of cytotoxic compounds such as doxorubicin and help in improving the targeting ability of various drugs to the diseased site. The examples cited in this chapter show a broad potential for a wide range of clinical and therapeutic applications using gelatin, and ongoing studies should help to improve therapeutic approaches for the effective use of this natural polymer.

## Contents

	<b>Preface</b>	XIV
	<b>List of Contributors</b>	XVII
<b>I</b>	<b>DNA-based Nanomaterials</b>	<b>1</b>
<b>1</b>	<b>Self-assembled DNA Nanotubes</b>	<b>3</b>
	<i>Thom LaBean and Sung Ha Park</i>	
1.1	Introduction	3
1.2	DNA Nanotubes Self-assembled from DX Tiles	4
1.3	3DAE-E DX Tile Nanotubes	5
1.4	DAE-O DX Tile Nanotubes	9
1.5	TX Tile Nanotubes	11
1.6	4 × 4 Tile Nanotubes	14
1.7	6HB Tile Nanotubes	16
1.8	Applications	18
1.9	Summary and Perspectives	19
	References	20
<b>2</b>	<b>Nucleic Acid Nanoparticles</b>	<b>23</b>
	<i>Guy Zuber, Bénédicte Pons and Andrew W. Fraley</i>	
2.1	Introduction	23
2.2	The Chemical and Physical Properties of Therapeutic DNA	25
2.3	Preparation of Nucleic Acid Nanoparticles: Synthesis and Characterization	27
2.3.1	Rationale	27
2.3.2	Synthesis, Characterization and Optimization of Surfactants	31
2.3.3	Organization of the Surfactant–DNA Complexes	35
2.3.4	Quantification of the Stability of Surfactant–DNA Complexes	35
2.4	DNA Functionalization for Cell Recognition and Internalization	37
2.4.1	Strategies for Functionalization	37
2.4.2	Intercalation	38
2.4.3	Triple Helix Formation with Oligodeoxyribonucleotides	39

2.4.4	Peptide Nucleic Acids (PNAs)	41
2.4.5	Interactions of DNA with Fusion Proteins	42
2.4.6	Agents that Bind to the Minor Groove	43
2.5	DNA Nanoparticles: Sophistication for Cell Recognition and Internalization	43
2.5.1	Preparation of DNA Nanoparticles Enveloped with a Protective Coat and Cell Internalization Elements	43
2.5.2	Biomedical Application: Cell Targeting and Internalization Properties of Folate-PEG-coated Nanoparticles	46
2.6	Concluding Remarks	46
	References	47
<b>3</b>	<b>Lipoplexes</b>	<b>51</b>
	<i>Sarah Weisman</i>	
3.1	Introduction	51
3.2	DNA Lipoplexes	51
3.2.1	Composition	51
3.2.2	Nanostructure and Microstructure	52
3.2.2.1	Equilibrium Morphology	52
3.2.2.2	Nonequilibrium Morphology	55
3.2.2.3	Lipoplex Size	57
3.2.3	Lipofection Efficiency	57
3.2.3.1	<i>In Vitro</i>	57
3.2.3.2	<i>In Vivo</i>	59
3.3	ODN Lipoplexes	60
3.4	siRNA Lipoplexes	62
	Acknowledgments	62
	References	62
<b>4</b>	<b>DNA-Chitosan Nanoparticles for Gene Therapy: Current Knowledge and Future Trends</b>	<b>68</b>
	<i>Julio C. Fernandes, Marcio José Tiera and Françoise M. Winnik</i>	
4.1	Introduction	68
4.2	Chitosan as a Carrier for Gene Therapy	69
4.2.1	Chitosan Chemistry	69
4.2.2	General Strategies for Chitosan Modification	71
4.2.3	Chitosan-DNA interactions: Transfection Efficacy of Unmodified Chitosan	71
4.3	Modified Chitosans: Strategies to Improve the Transfection Efficacy	79
4.3.1	The Effects of Charge Density/Solubility and Degree of Acetylation	79
4.3.2	Improving the Physicochemical Characteristics of the Nanoparticulate Systems: Solubility, Aggregation and RES Uptake	80

4.3.3	Targeting Mediated by Cell Surface Receptors	81
4.3.4	Hydrophobic Modification: Protecting the DNA and Improving the Internalization Process	83
4.4	Methods of Preparation of Chitosan Nanoparticles	84
4.4.1	Complex Coacervation	84
4.4.2	Crosslinking Methods	86
4.4.2.1	Chemical Crosslinking	86
4.4.2.2	Ionic Crosslinking or Ionic Gelation	86
4.4.2.3	Emulsion Crosslinking	87
4.4.2.4	Spray Drying	88
4.4.2.5	Other Methods	89
4.5	DNA Loading into Nano- and Microparticles of Chitosan	91
4.6	DNA Release and Release Kinetics	93
4.7	Preclinical Evidence of Chitosan–DNA Complex Efficacy	95
4.8	Potential Clinical Applications of Chitosan–DNA in Gene Therapy	97
4.9	Conclusion	99
	Acknowledgments	99
	References	99
<b>II</b>	<b>Protein &amp; Peptide-based Nanomaterials</b>	<b>115</b>
<b>5</b>	<b>Plant Protein-based Nanoparticles</b>	<b>117</b>
	<i>Anne-Marie Orecchioni, Cécile Duclairoir, Juan Manuel Irache and Evelyne Nakache</i>	
5.1	Introduction	117
5.2	Description of Plant Proteins	118
5.2.1	Pea Seed Proteins	119
5.2.2	Wheat Proteins	119
5.3	Preparation of Protein Nanoparticles	120
5.3.1	Preparation of Legumin and Vicilin Nanoparticles	121
5.3.2	Preparation of Gliadin Nanoparticles	122
5.4	Drug Encapsulation in Plant Protein Nanoparticles	124
5.4.1	RA Encapsulation in Gliadin Nanoparticles	124
5.4.2	VE Encapsulation in Gliadin Nanoparticles	125
5.4.3	Lipophilic, Hydrophilic or Amphiphilic Drug Encapsulation	126
5.5	Preparation of Ligand–Gliadin Nanoparticle Conjugates	127
5.6	Bioadhesive Properties of Gliadin Nanoparticles	129
5.6.1	<i>Ex Vivo</i> Studies with Gastrointestinal Mucosal Segments	130
5.6.2	<i>In Vivo</i> Studies with Laboratory Animals	131
5.7	Future Perspectives	135
5.7.1	Size Optimization	135
5.7.2	Immunization in Animals	136
5.8	Conclusion	137
	References	137

<b>6</b>	<b>Peptide Nanoparticles</b>	<b>145</b>
	<i>Klaus Langer</i>	
6.1	Introduction	145
6.2	Starting Materials for the Preparation of Nanoparticles	146
6.3	Preparation Methods	148
6.3.1	Nanoparticle Preparation by Emulsion Techniques	148
6.3.1.1	Emulsion Technique for the Preparation of Albumin-based Microspheres and Nanoparticles	148
6.3.1.2	Emulsion Technique for the Preparation of Gelatin-based Microspheres and Nanoparticles	151
6.3.1.3	Emulsion Technique for the Preparation of Casein-based Microspheres and Nanoparticles	153
6.3.2	Nanoparticle Preparation by Coacervation	154
6.3.2.1	Complex Coacervation Techniques for the Preparation of Nanoparticles	154
6.3.2.2	Simple Coacervation (Desolvation) Techniques for the Preparation of Nanoparticles	155
6.4	Basic Characterization Techniques for Peptide Nanoparticles	159
6.5	Drug Targeting with Nanoparticles	161
6.5.1	Passive Drug Targeting with Particle Systems	163
6.5.2	Active Drug Targeting with Particle Systems	163
6.5.3	Surface Modifications of Protein-based Nanoparticles	164
6.5.4	Surface Modification by Different Hydrophilic Compounds	164
6.5.5	Surface Modification by Polyethylene Glycol (PEG) Derivatives	165
6.5.6	Surface Modification by Drug-targeting Ligands	166
6.5.7	Different Surface Modification Strategies	168
6.6	Applications as Drug Carriers and for Diagnostic Purposes	169
6.6.1	Protein-based Nanoparticles in Gene Therapy	170
6.6.2	Parenteral Application Route	172
6.6.2.1	Preclinical Studies with Protein-based Particles	172
6.6.2.2	Clinical Studies with Protein-based Particles	172
6.6.3	Topical Application of Protein-based Particles	174
6.6.4	Peroral Application of Protein-based Particles	175
6.7	Immunological Reactions with Protein-based Microspheres	175
6.8	Concluding Remarks	176
	References	176
<b>7</b>	<b>Albumin Nanoparticles</b>	<b>185</b>
	<i>Juan Manuel Irache and Socorro Espuelas</i>	
7.1	Introduction	185
7.2	Serum Albumin	186
7.3	Preparation of Albumin Nanoparticles	187
7.3.1	“Conventional” Albumin Nanoparticles	188
7.3.1.1	Preparation of Albumin Nanoparticles by Desolvation or Coacervation	189

7.3.1.2	Preparation of Albumin Nanoparticles by Emulsification	192
7.3.1.3	Other Techniques to Prepare Albumin Nanoparticles	193
7.3.2	Surface-modified Albumin Nanoparticles	193
7.3.3	Drug Encapsulation in Albumin Nanoparticles	194
7.4	Biodistribution of Albumin Nanoparticles	196
7.5	Pharmaceutical Applications	198
7.5.1	Albumin Nanoparticles for Diagnostic Purposes	198
7.5.1.1	Radiopharmaceuticals	198
7.5.1.2	Echo-contrast Agents	199
7.5.2	Albumin Nanoparticles as Carriers for Oligonucleotides and DNA	199
7.5.3	Albumin Nanoparticles in the Treatment of Cancer	201
7.5.3.1	Fluorouracil and Methotrexate Delivery	201
7.5.3.2	Paclitaxel Delivery	202
7.5.3.3	Albumin Nanoparticles in Suicide Gene Therapy	203
7.5.4	Magnetic Albumin Nanoparticles	204
7.5.5	Albumin Nanoparticles for Ocular Drug Delivery	205
7.5.5.1	Topical Drug Delivery	205
7.5.5.2	Intravitreal Drug Delivery	205
7.6	Concluding Remarks	207
	References	208
<b>8</b>	<b>Nanoscale Patterning of S-Layer Proteins as a Natural Self-assembly System</b>	<b>219</b>
	<i>Margit Sára, D. Pum, C. Huber, N. Ilk, M. Pleschberger and U. B. Sleytr</i>	
8.1	Introduction	219
8.2	General Properties of S-Layers	220
8.2.1	Structure, Isolation, Self-Assembly and Recrystallization	220
8.2.2	Chemistry and Molecular Biology	221
8.2.3	S-Layers as Carbohydrate-binding Proteins	223
8.3	Nanoscale Patterning of S-Layer Proteins	224
8.3.1	Properties of S-Layer Proteins Relevant for Nanoscale Patterning	224
8.3.2	Immobilization of Functionalities by Chemical Methods	225
8.3.3	Patterning by Genetic Approaches	226
8.3.3.1	The S-Layer Proteins SbsA, SbsB and SbsC	226
8.3.3.2	S-Layer Fusion Proteins	228
8.4	Spatial Control over S-Layer Reassembly	241
8.5	S-Layers as Templates for the Formation of Regularly Arranged Nanoparticles	242
8.5.1	Binding of Molecules and Nanoparticles to Functional Domains	242
8.5.2	<i>In Situ</i> Synthesis of Nanoparticles on S-Layers	244
8.6	Conclusions and Outlook	244

## Preface

While the recently published first volume of the *NtLS* series, *Biofunctionalization of Nanomaterials*, dealt with approaches to tailoring nanomaterials to be useful in biomedical applications, this second volume of the series, which I am pleased to present to you herewith, focuses on nanomaterials derived from biologically and pharmaceutically important substances. Twelve chapters describe in depth the various nanotechnological aspects behind using DNA, proteins, peptides, chitosan, lipoplexes, lipids and drugs. DNA is the most important and well studied biological molecule which itself is in the nano size regime. One of the attractive features of products containing DNA is the potential for producing materials of biological nature. Although DNA-based nanotechnology is currently in its infancy, it is likely to impact future applications in industrial segments such as electronics, sensors, medicine, and many other fields. The book has four chapters on DNA based nanomaterials. It begins with a chapter entitled *Self-Assembled DNA Nanotubes*, which is a contribution from the laboratories of Thom LaBean and Sung Ha Park from Duke University, USA, on self-assembled one-dimensional (1D) DNA nanotubes with unique design schemes and characteristics. In this chapter, approaches to assembly of artificially designed tiles, DX, TX, 4×4, and 6BH branched-junction tiles to form 1D DNA nanotubes have been described. The second chapter illuminates on the importance of development of effective nucleic acid nanocarriers and provides approaches to prepare DNA nanoparticles containing a single DNA molecule (the minimal particle size possible) as well as their characterization and properties. This chapter, *Nucleic Acid Nanoparticles*, presented by Guy Zuber and co-workers from the Genetic Chemistry Laboratory of Illkirch University, France, reviews strategies for synthesis of DNA nanoparticles and possibilities to functionalize them with cancer cell targeting elements. Mixing DNA with cationic lipids leads to spontaneous self assembly of ordered aggregates known as lipoplexes whose size can range from around 100 nm to several microns depending on preparation conditions. The third chapter, *Lipoplexes*, written by Sarah Weisman from Technion Israel Institute of Technology in Haifa, Israel, gives an overview of the current state of knowledge about lipoplexes, with special attention to their microscopic structure, and the relationships between structure and gene delivery efficiency. Julio C. Fernandes and co-workers from the Medical Faculty of Montreal University, Canada, brought out an exhaustive review on DNA-Chitosan polyplexes presented

in the fourth chapter, *DNA-chitosan Nanoparticles for Gene Therapy: Current Knowledge and Future Trends*. In addition to the basic concepts, the chapter provides information on different procedures to obtain nano- and micro DNA-chitosan particles and their clinical application as non-viral vectors in gene therapy.

Switching gears from DNA to proteins, the book provides a further four chapters on different facets of peptide and protein based nanomaterials. Proteins are a class of natural molecules that have unique functionalities and potential applications in both biological as well as material fields. Nanomaterials derived from proteins, especially protein nanoparticles, are biodegradable, metabolizable and can also be easily amenable for surface modification and covalent attachment of drugs and ligands. In the fifth chapter, Anne-Marie Orecchioni and co-workers from the Laboratory of Galenic Pharmacy of Rouen University, St. Etienne du Rouvray, France, provide an exhaustive account of plant based proteins, their synthesis and applications. This particular chapter, *Plant Protein-based Nanoparticles*, not only provides information on conventional plant protein nanoparticles but also describes 'decorated' (i.e., conjugated) storage protein nanoparticles. Continuing on a similar theme, Klaus Langer from the Biocenter of Frankfurt on Main University, Germany, provides a comprehensive account in chapter six, *Peptide Nanoparticles*, on preparation techniques for peptide and protein-based nanoparticles with focus on their application in drug delivery. Narrowing down from a broad perspective on protein nanoparticles described in chapters two and three, chapter seven has the title *Albumin Nanoparticles*, indicating a review on a specific protein, Serum Albumin, which is extremely important in physicochemical, immunochemical and drug delivery applications. In this chapter, Juan Manuel Irache and Socorro Espuelas from the Galenics Center of Navarra University in Pamplona, Spain, summarize preparation and main applications of albumin nanoparticles for pharmaceutical purposes. Chapter eight, *Nanoscale Patterning of S-Layer Proteins as a Natural Self-Assembly System*, by Margit Sára and co-workers from the Center for Nanobiotechnology of the Agricultural University of Vienna, Austria, provides a survey of the general principles of crystalline bacterial cell surface layer (S-layer) proteins and fusion proteins which are being exploited as building blocks and templates for generating functional nanostructures at the meso- and macroscopic scale for both life and non-life science applications.

Pharmaceutical research and development has recently moved into a new direction thanks to the possibility of obtaining nanoformulation of drugs, i.e. formulation of drugs using nanoparticles. Keeping in tune with this trend a separate chapter specifically on drug nanoparticles has been included in this volume. Chapter nine, *Preparation Methods of Drug Nanoparticles* by Jonghwi Lee and co-workers from the Department of Nano Materials Science at Sejong University in Seoul, Korea, describe methods of preparation of drug nanoparticles, their characterization and advantages over conventional methods. In addition, chapter ten provides a review on Solid-Lipid Nanoparticles delineating the concept of differential protein adsorption as the concept of functionalization of SLN via surface modification from a practical point of view. In this chapter entitled *Production of Biofunctionalized Solid Lipid Nanoparticles for Site-specific Drug Delivery*, Rainer H. Müller and

co-workers from the Department of Pharmaceutical Technology of Free University Berlin, Germany, review methods used for the functionalization of solid lipid nanoparticles by modification of their surface characteristics followed by examples for their application in site-specific drug delivery. Mostafa Sadoqi and co-workers from the Physics Department of St John's University at Jamaica, USA, discuss near-infrared dye (NIR) indocyanine green (ICG) loaded PLGA drug nanoparticles and their application in cancer diagnosis and therapy in chapter eleven, *Biocompatible Nanoparticulate Systems for Tumor Diagnosis and Therapy*. Finally, since membrane transport plays an important role in cellular and subcellular pathways, including multidrug resistance (MDR), cellular signaling and cell-cell communication, an exclusive chapter, placed in twelfth position, discusses general information on cell membranes and the problems encountered by drugs when trying to cross them, and why drug nanoparticles are preferred. This chapter, *Nanoparticles for Crossing Biological Membranes*, is presented by Rajendra P. Pawar, A. Avramoff and Abraham J. Domb from the Department of Medicinal Chemistry of the Hebrew University of Jerusalem, Israel.

I do hope that the information that has been painstakingly accumulated by several researchers in this second volume will help in furthering better understanding of the nanosystems derived from biological materials, leading to new and potent applications. I am very grateful to all the authors for their excellent presentation of their topics, providing timely inputs and corrections in making the second volume a reality. I am always thankful to my employers, family, friends and Wiley-VCH publishers for their continued support and encouragement. Finally, my special thanks to you, the readers, for making attempts to utilize the knowledge base provided in this book. I look forward to receiving your comments and suggestions.

## DNA-based Nanomaterials

## 1

## Self-assembled DNA Nanotubes

*Thom LaBean and Sung Ha Park*

## 1.1

### Introduction

DNA, well-known as the predominant molecule for the storage of genetic information in biology and biochemistry, has also been recognized as a useful building material in the field of nanotechnology [1–3]. DNA provides basic building blocks for constructing functionalized nanostructures with four major features: molecular recognition, self-assembly, programmability and predictable nanoscale geometry. The limitations of conventional methods of top-down fabrication make bottom-up self-assembled nanostructures using DNA molecules a fascinating and attractive technique for near-term nano/biotechnologies. Recently, self-assembled DNA nanostructures utilizing branched DNA tiles have been reported on (a) various artificial geometrical structures like one- (1-D) and two-dimensional (2-D) periodically patterned structures [4–14], and three-dimensional (3-D) polyhedra [15, 16], and (b) functionalized lattices such as mechanical devices [17–23], molecular computers [24–30] and scaffolds for organizing other functionalized molecules [31–33]. DNA nanostructures are created via self-assembly during the slow annealing of aqueous solutions of carefully designed single-strand DNA, thereby facilitating hybridization of complementary nucleotide sequences, and the formation of double-strand domains and Holliday junction-like crossover points.

In this chapter, we review recent results on self-assembled 1-D DNA nanotubes with unique design schemes and characteristics. DNA nanotubes are characterized by (a) a high aspect ratio, (b) a long, narrow central channel and (c) DNA sidewalls. The 1-D nanotubes are typically made from rolled-up sheets of DNA lattice containing tiles with a variety of motifs: double-crossover (DX) [34], triple-crossover (TX) [35] and four four-arm junctions ( $4 \times 4$ ) [36]. Schematic drawings of four distinct DNA tile motifs which have been used for constructing complex 1-D DNA nanotubes are shown in Fig. 1.1.

The DNA tiles shown in Fig. 1.1 have each been shown to form large two-dimensional lattice sheets up to 10  $\mu\text{m}$  on an edge, as well as nanotubes formed by lattices which curl and close upon themselves. Superstructure morphology

**Fig. 1.1.** Four distinct DNA motifs for constructing complex 1-D DNA nanotubes. The structures DAE, DAO and TAO are named by acronyms describing their basic characteristics. Names begin with “D” for DX (two helical domains) and “T” for TX (three helical domains). The second character indicates the relative orientations of their two double-helical domains. Here, “A” stands for antiparallel and indicates that, upon crossing over, the strands

change direction of propagation along the helical axes. The third character refers to the number of helical half-turns between cross-overs, “E” for an even number and “O” for an odd number. The  $4 \times 4$  tile contains four four-arm branched junctions pointing in four directions (north, south, east and west in the tile plane). Arrows indicate simplified strands running from 5' to 3'.

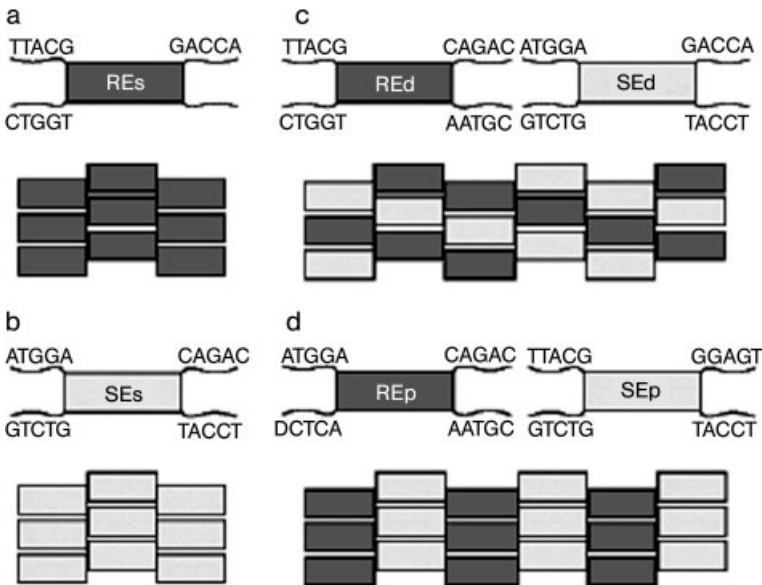

(sheet versus tube) is controlled in these tiling systems by a variety of means, including counterion concentration, lattice corrugation schemes and disulfide bridge formation. As explained in detail below, curled lattice DNA nanotubes have been observed with either stacked, circular layers of tiles or with spirally wound, chiral configurations. DNA nanotubes have also been intentionally constructed by stacking six-helix bundle (6HB) tiles one on top the other to form tubes with only a single tile per layer and a single double-helix diameter channel through the center [37].

## 1.2 DNA Nanotubes Self-assembled from DX Tiles

Recently, several varieties of nanotubes constructed from DX tiles have been reported [10–12]. Two distinct types of nanotubes made from DNA DX complexes are DAE-E and DAE-O (where the final letter in the acronym indicates the even/odd parity of helical half-turns between neighboring strand-exchange points within inter-tile joints). DAE-E DX tile nanotubes have diameters between 7 and 20 nm and lengths as long as 50  $\mu\text{m}$  with a persistence length of around 4  $\mu\text{m}$ ; they can be programmed to display a variety of patterns. The DAE-O tile lattice can form ribbon structures many micrometers in length and 40–250 nm in width after hybridization.

### 1.3 DAE-E DX Tile Nanotubes

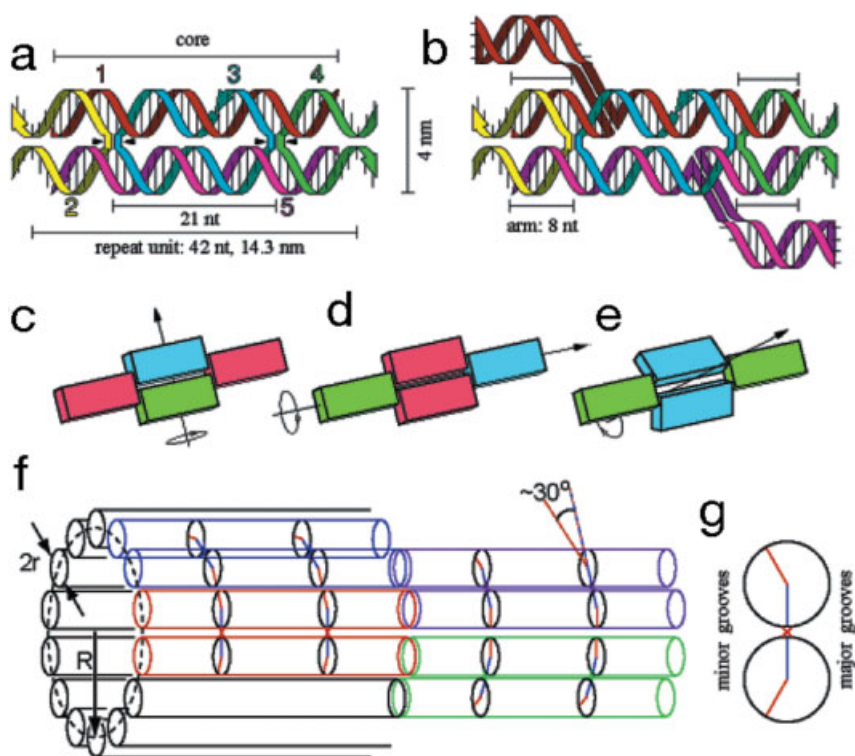

The construction and characterization of programmable DAE-E nanotubes displaying several tiling schemes as well as the kinetics of their assembly have been studied and reported [10, 11]. DX tiles were first described over 10 years ago [34]. DNA tiles can be thought of as having two parts: (a) a central core of duplex DNA (illustrated by rectangles in Fig. 1.2) and (b) four single-stranded sticky ends which allow it to bind to other tiles (shown protruding from the tile corners). In this first case, the tile core is made up of five oligonucleotides strands that form two double-helical domains held in rigid orientation with parallel axes by a pair of strand-exchange crossover points (Fig. 1.3a). In the study, two different sequence assignments were made to yield two different cores, which the authors called RE and SE [10]. Given an appropriate set of sticky ends, a single core yields a single tile and the unique sequences for sticky end allows the interactions between tiles to be

**Fig. 1.2.** Schematics of lattices utilizing DAE-E tiles. (a) Top: a single REs tile, based on the RE core and carrying four sticky ends. Bottom: complementarity between sticky ends directs the tiles to form a regular lattice. (b) A single SEs tile, based on a different core, SE, and its lattice. (c) Two tiles, REd and SEd, which assemble into a lattice with diagonal stripes; alone each tile could assemble into a linear strip. (d) Another pair of tiles, REp and SEp, cannot assemble independently, but together can form a lattice with stripes perpendicular to the long axis of the tiles. Note: lowercase letters “s”, “d” and “p” denote a particular choice of sticky ends and were chosen to represent the pattern generated by the tile set in which they appear: single tile type, diagonally striped or perpendicularly striped lattice. (From Ref. [10].)

programmed (Fig. 1.2). Figure 1.2(c and d) shows how tile sets have been used to create lattices with stripes either diagonal to or perpendicular to the long axis of the tiles. The authors viewed a set of tiles as a program for the construction of a particular structure including a diagonally striped or perpendicularly striped lattice.

In this system, hybridization of complementary sticky end pairs determines whether or not a set of tiles will form a lattice, but the set of sticky ends does not determine whether the lattice will be flat or curved. Curvature is profoundly affected by the choice of lattice symmetry as shown in Fig. 1.3(c–e). The symmetries depicted in Fig. 1.3(c and d) are compatible with flat lattice sheets since deviations

**Fig. 1.3.** (a) Structure of a DAE-E tile showing numbered strands and their paths through the complex. Tiles contain five single strands with 5-nt sticky ends on strands 2 and 4. (b) Tile structure with hairpins (8-nt stem, 4-nt loop) on strands 1 and 5 between nt 14 and 15 from their 5'-ends. Molecular models suggest that these hairpins attach underneath the molecule, as depicted here; in a tube they would be on the outside. (c and d) Two in-plane rotational symmetries that, if satisfied by a patch of tiles, encourage molecular strain to balance, resulting in a flat sheet. (e) A rotational symmetry, satisfied by DAE-E molecules, that permits curvature. (f) Heptagonal tube of radius  $R$ . In each tile, two cylinders of radius  $r$  represent the double helices. Black circles mark crossover points. Blue and orange lines connect the position of phosphate backbones to the center of a helix. The smaller angle between the blue and orange lines defines the minor groove. (g) Cross-section of the red tile from (f) at a crossover point. (From Ref. [10].)

**Fig. 1.4.** Microscopic images of nanotubes. DNA filaments visualized by (a) fluorescence microscopy and (b) AFM. The solution in (a) contains FAM-labeled REp + SEp and in (b) contains REp + SEp. (c) A time series of AFM images indicates that filaments are tubes (REp + SEp). (Left panel) A thick filament (closed tube) runs the length of the image. Heights of closed tubes suggest they are flattened onto the substrate. An already-open

tube is seen on the right. (Center panel) The tube opens progressively from the top, revealing a one-tile-thick lattice. (Right panel) The fully opened tube resembles the lattice on the left. An arrow marks a discrete change in tube width before opening and in the number of tiles after opening, suggesting a defect in the tile lattice. (d) At greater magnification, individual tiles are resolved. (From Ref. [10].)

from planar geometry can be compensated for; thus, molecular strain that could cause curvature may be balanced by symmetric molecular strain elsewhere. Other possible lattice symmetries, such as the one depicted in Fig. 1.3(e), are compatible with intentionally curved lattices and the formation of DNA nanotubes.

DNA nanotubes constructed according to RE- and SE-core tiles were examined by atomic force microscopy (AFM) and by fluorescence microscopy using fluorescein (FAM)-labeled strands. Characterization by AFM showed parallel and diagonal striped patterns, as expected, providing proof that the structural programming functioned properly. AFM studies also revealed that nanotubes flatten out on the mica substrate and were abraded by the AFM tip from double-layer to single-layer structures by imaging repeatedly at the same place on the sample (Fig. 1.4). The dynamic character of the interactions of nanotubes and lattices with mica was seen by re-imaging a sample by AFM under solution over the course of several hours, and observing tubes coming to and diffusing away from the surface. Fragments of lattice were often left on the mica when a nanotube diffused away. For this reason, the dimensions of the filaments were difficult to measure using surface-based AFM.

**Fig. 1.5.** Experimental determination of nanotube persistence length. (a) Epifluorescence image of 400 nM solution of FAM-labeled SEs tubes. Tubes were observed diffusing freely in and out of the focal plane. (b) As (a), but diluted to 40 nM. Occasionally, rings (left) and looped structures (right) are found. (c) Histogram of linear tube lengths

with an average of around 7  $\mu\text{m}$ ; approximately 10% are over 15  $\mu\text{m}$  long, consistent with an exponential distribution. Some tubes of around 50  $\mu\text{m}$  were observed. (d) Circularized tubes averaged 12  $\mu\text{m}$  in perimeter with a unimodal distribution. The ring shown is typical; most rings are free of kinks that would indicate local weakness. (From Ref. [10].)

Fluorescence microscopy was used to measure the length and stiffness of DAE-E nanotubes in solution. At the highest concentration (400 nM tiles) the density of tubes was too high to identify individuals and clump-like aggregates were common (Fig. 1.5a). Upon 10-fold dilution, single tubes were well dispersed and occasionally a ring or frayed bundle was seen (Fig. 1.5b). Only short tubes were observed directly following annealing and tube lengths continued to increase until about 16 h later when the distribution appeared to stabilize (at which point data were collected; Fig. 1.5c). The mean tube length was around 7  $\mu\text{m}$  with a small proportion of tubes with lengths up to 50  $\mu\text{m}$  being observed.

Tube stiffness was inferred from the distribution of ring perimeters by assuming that the rate of ring formation for a tube of length  $L$  is approximately proportional to the fraction of time that the ends of the tube are colocalized at equilibrium. Over brief intervals in which the length distribution does not change significantly, this ring closure probability can be calculated a function of tube length  $L$  and persistence length  $p$ . Under these conditions, the distribution of ring perimeters should be the product of the distribution of tube lengths and the ring closure probability. The mean perimeter distance was around 12  $\mu\text{m}$ . Using the distributions of Fig. 1.5(c and d), the persistence length was calculated to be  $3.85 \pm 0.35 \mu\text{m}$ .

Rothemund *et al.* performed the most thorough examination of the program-

mability and structural properties of DNA nanotubes [10]. They were able to identify the tile faces hidden inside and exposed outside the tubes, and drew important conclusions regarding the placement of hairpins on tiles and their effects on lattice stability. A subset of the authors went on to study the breaking and joining reactions among SE tile nanotubes and concluded that the growth of DNA tile nanotubes to multimicron length occurs through joining or fusion of preformed nanotubes rather than by sequential addition of individual tiles [11].

#### 1.4 DAE-O DX Tile Nanotubes

A similar system of DNA tiles which was originally designed to form 2-D flat lattice using DAE-O tiles (Fig. 1.6a) was also observed to form nanotubes either with flat ring layers or with spiral layers producing a range of chiral tubes (Figs. 1.6a and 1.7) [12]. As with the study described above, DX tiles (this time of the DAE-O variety) with the four single-stranded sticky ends on each tile were arranged such that  $\alpha$  and  $\beta$  tiles tessellate as shown in Fig. 1.6(b). The  $\beta$  tiles contained a 5'-biotinylated strand to enable streptavidin binding to be used as an observable marker. Hybridization was accomplished by cooling the solution by a linear gradient from 96 °C to room temperature over the course of 96 h.

**Fig. 1.6.** Self-assembly of DAE-O tiles into sheets and tubes. (a) Structure of the DX tiles: colored arrows indicate simplified strands running 5' to 3'. The 6-nt single-stranded sticky ends on the  $\alpha$  tile are complementary to those on the  $\beta$  tile (represented schematically by complementary shapes). A 5' biotin label on

the  $\beta$  tile is shown as a black dot. (b) The  $\alpha$  and  $\beta$  tiles can tessellate to form extended 2-D arrays. The 2-D sheets curl and close upon themselves to form tubes, producing either alternating rings (c) or nested helices (d) of  $\alpha$  and  $\beta$  tiles. (From Ref. [12].)

**Fig. 1.7.** Transmission electron micrographs of negatively stained DNA nanotubes and arrays. White features correspond to points of heavy metal stain exclusion where protein labels are bound to the  $\beta$  tiles. (From Ref. [12].)

In a standard  $1 \times \text{TAE}/\text{Mg}^{2+}$  buffer, containing 20 mM Tris–acetate, pH 8.3, supplemented with 12.5 mM  $\text{MgCl}_2$ , the tiles form ribbon structures many micrometers in length and 40–250 nm in width after hybridization (Fig. 1.7a). Higher magnification reveals transverse streptavidin bands with a periodicity of  $31 \pm 2$  nm (Fig. 1.7b and c), consistent with the designed 2-D array structure with the long axis of the tiles aligned along the long axis of the ribbons. A natural explanation for the parallel edges of these structures is that arrays of tiles curl and close upon themselves to form tubes. Unambiguous evidence for the formation of tubes is provided by micrographs such as Fig. 1.7(c) in which lines of streptavidin labels zigzag across a ribbon. In all such cases the line is continuous where it changes direction at the edge of the ribbon, proving they represent helical (spiral) tubes with a structure such as that illustrated in Fig. 1.6(d). Mixed superstructure morphologies (tubes and sheets) were observed in buffer with higher salt concentrations.

The authors point out that, as with carbon nanotubes [38], the structure of a DNA nanotube may be characterized by the indices  $(m, n)$  of the wrapping vector  $\mathbf{c} = m\mathbf{a}_1 + n\mathbf{a}_2$  where  $\mathbf{a}_1$  and  $\mathbf{a}_2$  are basis vectors shown in Fig. 1.6(b), and the tube is formed from a sheet by joining equivalent points separated by  $\mathbf{c}$ . For nonhelical tubes  $n = 0$  (Fig. 1.7b);  $n = 1$  where all labels lie on a single helix (Fig. 1.7c). The short dimensions of the tiles are not resolved (the streptavidin labels are larger than the tile width); assuming  $\mathbf{a}_1 = 4$  nm, then  $m \sim 40$  (Fig. 1.7c). It is likely that tube diameters are determined by nonequilibrium processes, since once a tube has closed, an activation barrier prevents further lateral growth. Tube formation reduces the free energy of a tile array by satisfying all inter-tile bonds except those at the ends of the tube. Intrinsic curvature of the array would facilitate tube formation; however, the odd number of helical half-turns along the arms joining cross-over points on adjacent tiles means that in this system the intrinsic curvatures of  $\alpha$  and  $\beta$  tiles are opposed.

## 1.5

### TX Tile Nanotubes

DNA nanotubes composed of TX tiles have also been constructed and characterized [14]. TX tiles modified with thiol-containing double-stranded DNA stems projected out of the tile plane were used as the basic building blocks. TX nanotubes display a constant diameter of around 25 nm and have been observed with lengths up to 20  $\mu\text{m}$ . In this section, we present high-resolution images of the constructs (TX nanotubes) and experimental evidence of their tube-like nature. DNA nanotubes represent a potential breakthrough in the self-assembly of nanometer-scale circuits for electronics layout because they can be targeted to connect at specific locations on larger-scale structures and can subsequently be metallized to form nanometer-scale metallic wires (see Section 2.6).

TX nanotube self-assemblies were formed from two DNA tile building blocks, a TAO (tile A) and a TAO + 2J (tile B) as shown in Fig. 1.8(a). The B tile contains two extra double-stranded DNA stems, which form junctions with the central helix of the tile such that they project out of the tile plane, with one stem protruding on each side of the tile. The B tiles used here are modified by the replacement of the loop on one protruding stem with a blunt end containing two thiol groups, one on a 3' and the other on a 5' strand terminus. Figure 1.8(b, right) shows a section of the proposed structure of the nanotubes with B tile layers alternating with A tile layers, double-stranded DNA helix axes aligned parallel with the tube axis, and thiol groups are located inside the tubes. Imaging of TX AB flat lattice sheets (Fig. 1.8c, left) demonstrates lattice fragments with widely varying dimensions and often with uneven edges. On the other hand, DNA nanotubes (Fig. 1.8c, right) exhibit uniform widths of around 25 nm for lengths of up to 20  $\mu\text{m}$ .

Figure 1.9(a) shows a typical AFM image (tapping mode in air) of the TX nanotube. Stripes perpendicular to the long axis of the filaments are clearly visible and indicate closed ring structures in successive layers rather than a spiral structure, which would have given stripes with a noticeable diagonal slant. Figure 1.9(b) shows a high-resolution AFM image (tapping mode in buffer) of the TX nanotube in which one can discern three gaps and four tiles in some of the layers. The gaps and tiles are arrayed parallel with the axis of the flattened tube.

Burial of the sulfur moieties within the tubes makes logical sense because disulfide bridges are preferred structures formed by thiol groups under physiologic-like solution conditions such as those used here. The formation of disulfide bonds between neighboring B tiles would cause the lattice to curve and form tubes. The possible existence of free thiols on the outer surface of the nanotubes was probed by using two different gold reagents with reactivity toward sulfur: monomaleimido Nanogold (Nanoprobes, Yaphank, NY) and fresh colloidal gold nanoparticles. The monomaleimido Nanogold failed to react with the tube surfaces, whereas the colloidal gold displayed the interesting reactivity shown in Fig. 1.9(d and e). With very low background levels of unbound gold, the bound gold particles showed a very high probability of attachment to the ends of nanotubes and not to the outer surface anywhere else along the length of the tubes. The indication is that sulfur

**Fig. 1.8.** (a) Schematic drawings showing the strand traces through the two tile types used in the constructions. Oligonucleotides are shown in different shades of gray and with arrowheads marking the 3'-ends. Short vertical hash marks indicate base pairing within double-helical regions; paired vertical lines represent crossover points. The central helices of both tile types are terminated with  $T_4$  loops. Two extra stem-loops (2J) on the central helix of the B tile are designed to protrude, one into and one out of the tile plane. (b) (Left) Cartoon of a section of TAO flat lattice constructed from A and B tiles. Tubes repre-

sent double-helical regions; for simplicity, the 2J stem-loops on the B tiles are not shown. (Right) Cartoon model of a section of TAO nanotube shown with eight tiles per layer of tube. (c) (Left) TEM image of platinum rotary shadowed TAO lattice. The B tiles appear darker than the A tiles, having picked up more platinum on their protruding 2J stem-loops; alternating stripes of A and B tiles are clearly visible with approximately the expected distance of 28 nm. (Right) TEM image of negative-stained TAO nanotubes. (From Ref. [14].)

which is buried within the tubes is exposed to some extent at the open ends of the nanotubes and available for binding with gold. This observation, in addition to offering evidence of the location of the thiol groups, may also be exploited in future work on targeted binding or formation of electrical contacts with the ends of TX nanotubes. Final evidence of the involvement of disulfide bridges in TX nanotube formation was provided by annealing the DNA in the presence of the reducing agent dithiothreitol and observing a complete lack of tubes.

Figure 1.10 shows a series of *in situ* zoomed images showing a TX nanotube being converted to a flat lattice by the physical effect of the AFM tip. The series of

**Fig. 1.9.** (a) AFM image of a TAO nanotube taken by tapping mode in air. The *B* tile layers are visible as brighter stripes (because of increased height) oriented perpendicular to the long axis of the tube. (b) High-resolution image of a nanotube taken by tapping mode under buffer. Single-helix holes between adjacent tiles are visible as darker patches in

several layers. (c) TEM image of a negative-stained sample, showing a section of a nanotube that appears to have split into a flat lattice. (d and e) Negative-stained TEM images of TAO nanotubes with gold nanoparticles attached to the ends, apparently by interaction with thiol sulfurs partially exposed at the tube termini. (From Ref. [14].)

images was collected by repeatedly re-imaging the same nanotube under buffer with an AFM. The high-resolution image in Fig. 1.10(d) shows the detailed nanostructure of the completely torn open DNA nanotube with alternating layers of *A* and *B* tiles clearly discernible. Whole tiles have been scratched away from the opening nanotube by the force of the AFM tip and therefore the tile layers no longer contain all of the tiles that were present in the nanotube. A few layers are seen that still contain six tiles. The combination of the high-resolution AFM images (Fig. 1.9b and 1.10d) provides supporting evidence for the model in which individual tile layers in intact nanotubes contain eight tiles.

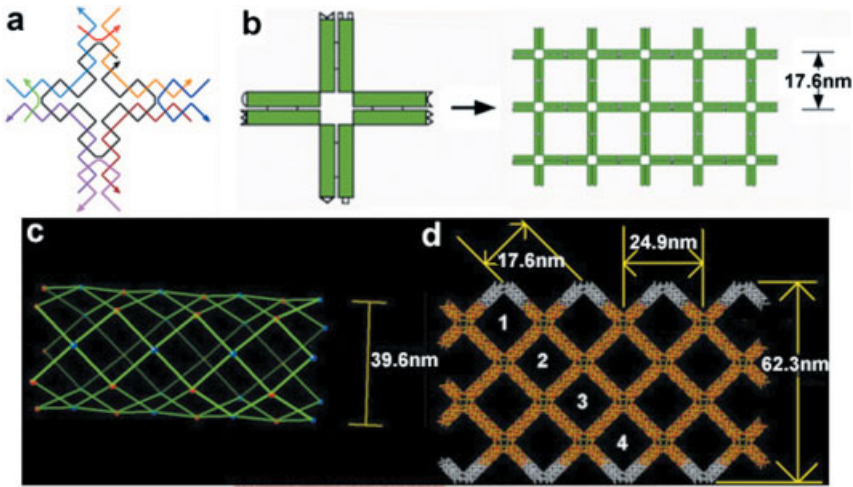

**Fig. 1.10.** A series of AFM images captured by repeatedly re-imaging and zooming in on the same nanotube, which appears mostly tube-like in (a), with increasing wear-and-tear through (b) and (c) until a section of unfolded tube becomes a single-layer, flat lattice (d) displaying stripes composed of lighter (higher) B tiles and darker (shorter) A tiles. (From Ref. [14].)

## 1.6

### 4 × 4 Tile Nanotubes

More complicated 1-D tube-like structure utilizing 4 × 4 tiles has also been reported [36]. Programmable self-assembly of this DNA nanostructure results in a uniform width nanoribbon which displays periodic square cavities. The 4 × 4 DNA tile (Fig. 1.11a) contains four four-armed DNA branched junctions pointing in four directions – north, south, east and west in the tile plane. It is composed of nine strands, with one of the strands participating in every junction. Bulged T<sub>4</sub> loops are placed at each of the four corners inside the tile core in order to decrease the probability of stacking interactions between adjacent four-arm junctions and

**Fig. 1.11.** Self-assembly of DNA nanoribbons using the  $4 \times 4$  DNA tile. (a) The  $4 \times 4$  tile strand structure. The tile contains nine oligonucleotides, shown as simplified backbone traces in different colors. Each four-arm junction is oriented in four directions. The black strand participates in all four junctions and contains  $T_4$  loops connecting adjacent junctions. (b) Left: double-helical domains are illustrated as rectangles and paired rectangles represent four-arm junctions. Watson–Crick complementary sticky ends are shown as matching geometric shapes. Right: designed structure of the self-assembled lattice. There are four full helical turns between tile centers

so the tiles will be oriented in the same direction in the lattice. (c) Schematic model of the proposed  $4 \times 4$  nanotube. (d) Overhead view of a tube squashed onto the mica substrate and forming a ribbon with four diagonal square cavities with a width of around 62.3 nm. Note the saw-tooth edge formed by folding one row of  $4 \times 4$  tiles along a diagonal running through their most flexible region, the  $T_4$  loops between adjacent arms. The jagged edges along with the  $45^\circ$  diagonal containing four cavities are typically observed in high-resolution AFM images of the ribbons. (From Ref. [36].)

allow the arms to point to four different directions. Characterization of structure formation by nondenaturing gel electrophoresis and thermal transition analysis (see Fig. 1.13 below) shows that the  $4 \times 4$  tile structure is stable and well behaved.

Constructions following the design shown in Fig. 1.11(b) produce a high preponderance of uniform width ribbon structures. In this design the distance between adjacent tiles is an even number of helical half-turns (four full turns) so that the identical face of each tile points toward the same lattice face. Figure 1.12 shows four AFM images of the nanoribbons with lengths of up to around  $20 \mu\text{m}$  and a typical uniform width of around 60 nm. The regularity of the periodic cavities is striking, as well as the observation that some of the nanoribbons revealed a single-layer, flat grid lattice unrolled at the open end of the ribbon (see Fig. 1.12d). This observation strongly suggests that the ribbon structure results from tube-like structures which flatten when the sample is deposited on mica. The AFM image height profile clearly shows that the nanoribbon structure has two layers compared to the flat lattice. Also, the edges of the ribbon appear slightly higher, about 0.12 nm,

Fig. 1.12. AFM images of  $4 \times 4$  nanoribbons at various scan sizes. (From Ref. [36].)

than the middle, indicating a finite radius of curvature for the squashed tube structure. The formation of tube-like lattices could be due to the fact that each component tile is oriented in the same direction in the designed lattice planes, and therefore any incidental curvature resident in each tile could accumulate and cause circularization of the lattice. This hypothesis is supported by the AFM analysis and by subsequent experiments showing that corrugation schemes where tiles are flipped in the lattice plane to compensate for tile curvature form large flat lattice sheets.

## 1.7

### 6HB Tile Nanotubes

Very recently, a new strategy for the creation of hollow DNA nanotubes was described which made use of tiles that are intrinsically 3-D and formed from a rigid

**Fig. 1.13.** Characterization of the  $4 \times 4$  tile structure using nondenaturing electrophoresis and thermal transition experiments. (a) An 8% polyacrylamide gel (ethidium bromide stained) showing association complexes between various equimolar combinations of the  $4 \times 4$  DNA complex component strands. Equimolar mixtures at  $1 \mu\text{M}$  concentration per included strand were annealed and run on the gel at room temperature. Strands included in the annealings are indicated in the drawing above each lane. Lane 8 contains a 50-bp DNA ladder size marker. The  $4 \times 4$  complex runs as a single band on nondenaturing gels, without

any higher-molecular-weight byproducts (from unexpected base pairings between two or more complexes) or lower-molecular-weight byproducts (from dissociated complex), indicating the  $4 \times 4$  tile complex is a stable structure in the buffer used. (b) Thermal transition profile. The left panel shows the relative change in optical density at 260 nm as a function of temperature. The right panel shows the first derivative of the  $4 \times 4$  complex melting data. The results show that the  $4 \times 4$  complex melts cooperatively, as a single transition, with  $T_m \sim 60^\circ\text{C}$ . (From Ref. [36].)

cluster of double-helical domains with a single-helix width pore running down through its entire length [37]. The 6HB (shown schematically in Fig. 1.14) contained six double helices with each pair of neighboring domains linked by strand exchange at each of two crossover points. With complementary pairs of sticky ends appended to each end of the helices, the tiles were induced to assemble into long 1-D arrays with lengths up to around  $15 \mu\text{m}$ . These are the first described DNA nanotubes with perfectly designed widths and tube layers made up of single tiles.

**Fig. 1.14.** Cross-sectional and transverse views of the 6HB tile model. The cross-sectional view emphasizes the cylindrical hole through the center of the tile (From Ref. [37].)

## 1.8 Applications

Self-assembled 1-D nanotubes made from artificially designed tiles show great promise for applications that range from fabrication of nanoelectronic devices to biological studies. Electrical transport in bare DNA molecules has been recognized as an interesting research field for last few decades. Although some of the conductivity experiments of DNA molecules had been shown superconducting [39] or semiconducting [40] properties, DNA molecules mostly show insulating characteristic [41]. The DNA molecule's poor conductivity prevents its direct use in electronic nanodevices. Thus, properly designed DNA lattices can serve as a precisely controllable and programmable scaffold for organizing functionalized nanomaterials in the design and construction of functionalized electronic nanodevices. Nanometer-scale fabrication with reliable DNA-templated metallic nanowires is an example demonstration of DNA's scaffolding capability. Several varieties of DNA tile nanotubes have been shown to be useful templates for the specific chemical deposition of metal for nanowire formation.

Until now, mostly natural  $\lambda$  DNA molecules have been used as a template for fabricating various metallic nanowires such as silver [42], gold [43], palladium [44, 45], platinum [46] and copper [47]. More complex and uniform width 1-D nanotubes can also serve as templates for highly conductive metallic nanowires. One example is shown in Fig. 1.15. Here,  $4 \times 4$  nanoribbons have been metallized with silver using a novel electroless chemical deposition technique [36] and demonstrated electrical measurements through silver nanowires. The resulting nanowires have been characterized by scanning electron microscopy (SEM) and AFM. The metallized nanoribbons have heights of  $35 \pm 2$  nm, widths of  $43 \pm 2$  nm and lengths of up to about 5  $\mu\text{m}$ . The current–voltage curve of the metallic silver  $4 \times 4$  nanoribbon shows linear behavior and the resistance of this sample is around 200  $\Omega$  as measured between the two central contacts at a bias voltage of 0.1 V (Fig. 1.15c). This number corresponds to a bulk resistivity of  $2.4 \times 10^{-6}$   $\Omega\text{m}$ . This nanowire is easily reproducible and has markedly higher conductivity than previously reported double-helix DNA-templated silver nanowires [42]. Other potential uses of DNA nanotubes are inspired by analogy with the roles of nanotubes and nanowires in living cells, e.g. as structural supports for the cytoskeleton, as tracks for

**Fig. 1.15.** Metallization and a conductivity measurement of metallized  $4 \times 4$  nanoribbons. (a) SEM image of nonmetallized  $4 \times 4$  nanoribbons. (b) SEM image of silver-seeded silver nanoribbon. The change in the signal contrast between (a) and (b) is apparent. (c) SEM image of the actual device (scale bar:  $2 \mu\text{m}$ ). the transport of microscopic cargo and as moving parts for cellular motility. DNA nanotubes may eventually be engineered to mimic all these functions.

## 1.9 Summary and Perspectives

DNA-based nanotechnology is currently being developed as a general assembly method for nanopatterned materials that may find use in electronics, sensors, medicine and many other fields. In this chapter, we have described a novel assembly of 1-D nanotubes made from artificially designed tiles, DX, TX,  $4 \times 4$  and 6BH branched junction tiles. Nanotubes, consisting of DAE-E tiles, range from 7 to

20 nm in diameter, grow as long as 50  $\mu\text{m}$  with a persistence length of around 4  $\mu\text{m}$ , and can be programmed to display a variety of patterns. DAE-O DX tiles can form sheets or ribbons with periodic banding controlled by salt concentration. TX nanotubes display a constant diameter of around 25 nm and have been observed with lengths up to 20  $\mu\text{m}$ . Tube formation is controlled by disulfide bonds between tiles augmented with thiol moieties. The  $4 \times 4$  DNA nanoribbon contains four four-armed DNA branched junctions pointing in four directions. The formation of tube-like lattices is due to the fact that each component tile is oriented in the same direction in the designed lattice plane, and therefore any incidental curvature resident in each tile can accumulate and cause circularization of the lattice. The 1-D arrays of 6HB tiles form DNA nanotubes with one tile per tube layer and represent the smallest possible hollow DNA nanotube. Nanotubes formed from DNA tile lattices have been used as metallization templates for the formation of conductive nanowires. Utilizing DNA molecules as scaffolds for making functionalized nanowires offers certain advantages such as site-specific alignment and massive, parallel self-assembly for future electronic nanodevices. It has also been pointed out that DNA nanotubes, by analogy with cellular microtubules, might be useful as tracks along which artificial bionanomachines might transport molecular cargo [10, 12].

### 2.1

#### Introduction

Primarily located in a cell's nucleus, 2'-deoxyribonucleic acid (DNA) provides the cell with the ability to store and copy the genetic information required for the synthesis of proteins that are in charge of all chemical transformations underlying the cell's metabolism. DNA is composed of four 2'-deoxynucleotides connected into a polymer via 5'-3' phosphodiester, where the sequence of the nucleotides allows the encoding of genetic information. The composition and position of heterocyclic functional groups provide a specific arrangement of hydrogen bond donors and acceptors enabling a nucleotide to hydrogen bond (or base pair) with a second nucleotide exhibiting a complementary donor/acceptor arrangement. This allows two strands of DNA to anneal in a sequence-dependent manner, where 2'-deoxyadenosine pairs with 2'-deoxythymidine and 2'-deoxyguanosine pairs with 2'-deoxycytidine, and thus further facilitates a mechanism for DNA replication and RNA transcription. Cellular DNA typically conforms to a B-form helix as first proposed in 1953 by Watson and Crick [1], where the two strands are antiparallel with the hydrophobic bases in the center of the helix and the negatively charged hydrophilic sugar-phosphate backbone on the outside (Fig. 2.1).

Although DNA is composed of only four monomers, prior to the 1970s DNA remained difficult to analyze as the typical eukaryotic cell contains nearly  $3 \times 10^9$  bp of a linear double helix with an extended length of approximately 1 m [2]. Today, nucleic acids are readily manipulated by specific enzymes, produced in large quantities and progress in automation has enabled the sequencing of entire genomes, including the human genome.

Such progress coupled with an increase in the understanding of the molecular mechanisms and genetic implications underlying many diseases has triggered the hope that nucleic acids could treat disease at the source. However, many hurdles remain that must be overcome in order for gene therapy to be of practical use in the clinic. Gene therapy implies the administration of a foreign DNA fragment into a host with subsequent delivery into the nuclei of selected organ cells, where cellular machineries can, in turn, employ the new DNA for production of thera-

**Fig. 2.1.** Molecular and chemical structure of the DNA double helix. Self-complementation of the helical strands is based on the guanine (G)–cytosine (C) and adenine (A)–thymine (T) Watson–Crick base pairs.

peptic proteins. Although this method is simple in theory, naked DNA is unable to navigate the route from the needle to the nuclei and thus requires other elements to facilitate delivery into the correct cell nucleus while inhibiting the degradation of therapeutic DNA.

Viruses are natural supramolecular assemblies with gene delivery properties. Their diversity and efficiency fulfill most requirements for gene delivery in the clinic [3], but they do have drawbacks [4, 5]. They are by definition infectious and parasitic, and viral shell proteins are understood to elicit adverse immune responses from the host [6]. The production and exploitation of even weakened viral particles has risks because mass production largely exceeds recombination and mutation frequencies. The chance of producing an undesirable and harmful virus increases, and thus can present a significant risk [7]. One alternative is the development of synthetic vectors that interact with DNA in abiotic systems to form virus-like nanoparticles [8]. The requirements for safe DNA transportation into the nucleus have been set by studies on the fate and trafficking of viruses or drug delivery systems at the animal and cellular levels [9]. *In vitro*, gene delivery is predominantly concerned with barriers presented by the cell itself. In an animal, the delivery systems must also be concerned with supracellular barriers that restrict the size of the drug delivery system to less than 100 nm in diameter. Larger par-

ticles introduced in the body intravenously encounter all the blood constituents and cannot cross the blood vessel walls. They are eliminated by hepatic or renal uptake. Local administration, if possible, could circumvent the circulation problems, but particles still encounter barriers in the form of the extracellular matrix that prevent cell accessibility to low-mobility particles. Ligand-mediated cellular uptake might be size dependent as well. It was shown, for instance, that glycolipid-containing liposomes with a size of 30–70 nm were effectively taken up by the asialoglycoprotein receptor *in vitro* and *in vivo*, whereas 90-nm particles were not [10]. The next step, intracellular trafficking and nuclear import, is also a size-restricted process. It was shown by measuring cytoplasmic diffusion of microinjected fluorescent DNA that DNA molecules larger than 1 kbp are essentially immobile. Finally, assisted nuclear pore crossing through nuclear pore complexes (gates between the cytosol and the nucleus) was reported to be restricted to particles up to 39 nm. An ideal vector must interact with a plasmid in such a way to: (a) form particles of minimal size, (b) protect the DNA from nuclease degradation, (c) provide efficient circulation properties in the host, (d) mediate cell-specific internalization, (e) allow mobility in the cytosol and (f) favor intracellular routing into the nucleus, where the genetic material must be effectively liberated from carrier molecules (Fig. 2.2).

The development of effective nucleic acid carriers must consider the above properties, while accounting for the chemical and physical properties of the therapeutic DNA. Section 2.2 gives an overview of the chemical and physical properties of therapeutic DNA. Section 2.3 presents an approach to prepare DNA particles containing a single DNA molecule (the minimal particle size possible) as well as their characterization and properties. Section 2.4 presents strategies for the functionalization of DNA particles and Section 2.5 presents an example of how to prepare DNA nanoparticles with cancer cell targeting elements.

## 2.2

### The Chemical and Physical Properties of Therapeutic DNA

DNA administered into an animal (*in vivo*) must physically contact the surface of a target cell before cellular uptake can occur. The stability, size and charge of the therapeutic DNA coupled with the organization of host tissues into specialized organs seriously complicates the accessibility of targeted cells.

First, native DNA in the blood stream is subjected to fast degradation. Upon injection into a mouse vein, plasmid DNA is removed from the circulation and degraded within a few minutes by hepatic clearance at a rate almost identical to the hepatic plasma flow rate ( $1.6 \text{ mL min}^{-1}$ ) [11]. The delivery of DNA in either *in vivo* or *in vitro* systems is further impeded by the immense mass of DNA that must be delivered (Fig. 2.3). Not only is a gene almost 20 times heavier than the protein it encodes, additional sequences must be added to enable *in vivo* handling and production. To facilitate cellular activity the gene is then cloned into a plasmid, which contains accessory sequences for expression in mammalian cells or cloning into

Fig. 2.2. Intracellular pathway for gene delivery. NPC: nuclear pore complexes.

bacteria. Typically, a recombinant plasmid is circular and around 5000 bp in length, with a molar mass of more than 3 MDa. Finally, the polyanionic character of the DNA deoxyribose–phosphate backbone prevents not only passive diffusion across cellular membranes consisting of hydrophobic lipid bilayers, but also the folding of the plasmid into a compact and globular tertiary structure. DNA prefers to exist in a stiff helix that occupies a large volume, which considerably limits mobility [12], particularly in the dense cytoplasm packed with intertwined filaments [13]. Foreign DNA entering fast dividing cells in culture is more readily expressed as it is possible that free and intact DNA plasmids, sitting immobile in the cytoplasm, are transported with chromosomes during mitosis and become incidentally sequestered in the nuclei of daughter cells after reconstruction of the nuclear membrane [14].

**Fig. 2.3.** Comparison of sizes of a plasmid, a virus and a cell. The length of a plasmid and its worm-like behavior in solution, as represented by electron microscopy, greatly limits its diffusion properties. The natural polymer is rather degraded. Optical microscopy shows an epithelial cell in culture.

For its expression, the gene must contact the cell, cross the plasma membrane, diffuse into the cytoplasm and go into the nucleus without being degraded. Its condensation in specialized assemblies such as 80-nm viral particles greatly improves its biodistribution and transport into the cell nuclei.

Theoretically, both *in vivo* biodistribution and intracytoplasmic trafficking of a plasmid into a given nucleus is improved by the condensation of a single plasmid molecule. By calculation, the volume occupied by a plasmid corresponds to a sphere approximately 25 nm in diameter. Single plasmid condensation into minimal size particles may even permit gene delivery into nondividing cells as nuclear localization signal peptide (NLS) sequences derived from the viral SV40 large tumor antigen assist the entry of macromolecules as large as 39 nm in diameter into the nucleus through nuclear pore complexes [15].

## 2.3

### Preparation of Nucleic Acid Nanoparticles: Synthesis and Characterization

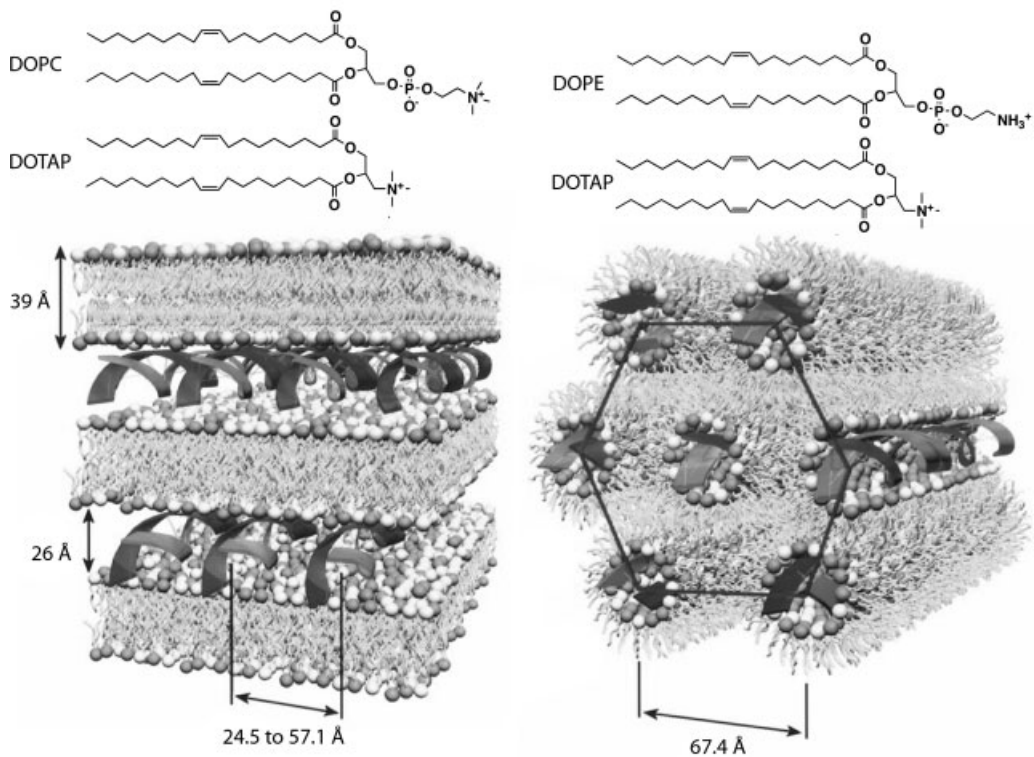

#### 2.3.1

##### Rationale

Condensation of the worm-like DNA polymer into a dense particle does not only enhance chemical stability, but additionally improves the dynamic properties of

the polymer with a  $10^4$ – $10^5$  decrease in the effective volume [16]. To give a macroscopic example, a firemen's hose is best transported and handled in a condensed state around a reel, even though the reel adds weight to the system. The compaction of naked DNA into a dense particle is a highly unfavorable process due to the electrostatic repulsion of the charged phosphodiester groups distributed every 7 Å along the backbone. The increase in electrostatic repulsion and competition with other anions could be annihilated by additive effects of Coulomb's interactions using polycationic polymers [16] or cationic surfaces obtained by aggregation of cationic amphiphiles into bilayers or micelles [17]. Although the number and variety of cationic agents are infinite, the formation of DNA condensates is almost entirely driven by electrostatic contributions. Fast kinetic associations of cationic materials with the long DNA polymer typically yield the entrapment of several DNA plasmids and detailed mechanistic studies indicated that DNA condensation proceeds through folding rather than winding. Overall, the nature of the cationic vector dictates the supramolecular organization of the complexes, whereas the stoichiometry and incubation conditions (temperature, ionic forces) impact the final sizes of the DNA condensates [18]. Structural investigations using atomic force microscopy [19, 20] or electron microscopy [21] showed that DNA–cationic polymer complexes display a toroidal or spherical structure of 40–100 nm in diameter. Interaction of DNA with cationic lipid organized in bilayers produces DNA sandwiched into lamellar phases (Fig. 2.4). On the other hand, DNA–cationic lipid complexes adopt an inverted hexagonal phase structure in the presence of DOPE, a lipid well known to induce an inverted hexagonal phase in solution because of its conical shape (Fig. 2.4) [22]. The large contribution of electrostatic interactions also impacts on the colloidal stabilities of these particles. Additional aggregation occurs when ionic surfaces become shielded by other ions (such as physiological conditions) or when the vector/DNA charge ratio approaches the isoelectric point [23, 24]. For transfection into cultured cells, large and positive complexes are advantageous because they sediment onto cells and enter cells by adhesion to ubiquitously expressed anionic receptors present on the cell membranes [25]. Cationic DNA nanoparticles are currently being evaluated for clinical applications [26, 27]. Covalent conjugation of a layer of polyethylene glycol (PEG) onto surfaces greatly enhances the stability and lifespan of biomaterials in the bloodstream [28] or in nasal mucosa [29] by its hindrance and inertness. Inclusion of cell-targeting motifs has further been demonstrated to improve gene delivery to tumors [30] or to liver [31]. Covalent prosthetic groups may interfere with proper DNA condensation [32], complicating these modifications. Theoretically, drastic improvements could be achieved by lowering further the size of the delivery systems to the minimal size (a particle containing a single plasmid) [33].

Cationic detergents, such as cetyltrimethylammonium bromide (CTAB) (see Fig. 2.9 below), have been reported to condense DNA plasmids into homogeneous particles consisting solely of a single plasmid [34]. The formation of these complexes is governed by electrostatic interactions between a single surfactant cationic head and the DNA phosphate group. This initial bimolecular adhesion is immediately followed by aggregation of the surfactant in a highly cooperative manner, leading

**Fig. 2.4.** Structure of DNA–cationic lipid complexes in lamellar and inverted hexagonal phases. The inverted hexagonal phase is a consequence of the high content of DOPE (70%) in the lipid phase. (Adapted from Ref. [22].)

to single DNA plasmid collapse. However, fast equilibration between monomeric surfactants and micelle domains produces a fast destabilization of surfactant–DNA complexes upon dilution or addition to cellular bilayer membranes.

An appealing solution to this problem is to combine the favorable features of cationic surfactants for DNA condensation and cationic lipids for assembly stability. The chemical transformation of a cationic detergent into an amphiphile within a DNA–vector complex should lead to stable and monomolecular DNA particles. A chemical transformation of this type must remain inert toward the proximal DNA plasmid to ensure the integrity of genetic information. The air-oxidation of two thiols into a disulfide is a suitable answer and has the additional benefit that thiol-based cationic detergents are readily synthesized.

The proof of this concept was demonstrated by Blessing et al. using a cationic detergent containing a cysteine and a  $C_{10}$  alkyl chain ( $C_{10}CysG^+$ ) (Fig. 2.5) [35, 36]. A plasmid was first condensed with a cationic detergent having a free thiol. The concentration of the detergent was kept slightly below its critical micellar con-

**Fig. 2.5.** Formation of stable 25 nm diameter globular assembly containing a single DNA plasmid. The plasmid is condensed by a thiol-containing detergent ( $C_{10}CysG^+$ ) and the resulting particles are stabilized by template-assisted oxidation of the thiol functions into disulfides.

centration to protect polycationic surfaces from micelle formation and the entrapment of more than one plasmid. Under these conditions, individual phosphate neutralization of the plasmid yields favorable hydrophobic association of detergent molecules into micelle–DNA complexes and the increased concentration of thiol groups around the collapsed DNA polymer in turn favors intracomplex detergent dimerization. According to this theory, oxidative detergent dimerization is expected to be prone to a template effect from the DNA. Kinetic studies confirm this theory – an enhanced thiol oxidation rate was observed in the presence of plasmid DNA (Fig. 2.6).

Upon dimerization of the detergent  $C_{10}CysG^+$ , single plasmids of 5.6 kbp are condensed into a homogeneous population of spherical liponucleic assemblies with a mean diameter of  $25 \pm 4$  nm as determined by transmission electron microscopy. A rough calculation using the volume occupied by a plasmid of 5.6 kbp and  $1.1 \times 10^4$  detergent molecules (the charge equivalent) yields a spherical assembly with a diameter of 28 nm, confirming monomolecular collapse of the plasmid into a single particle. Moreover, diameters of particles resulting from detergent-mediated aerobic collapse of supercoiled pCMVLuc (5.6 kbp) as well as linear phage  $\lambda$  (48 kbp) and phage T4 (166 kbp) were measured by laser light scattering (Fig. 2.7). Particle diameters plotted against the cubic root of the number of DNA base pairs fit a straight line crossing the origin. Since the volume of a sphere varies as the cube of its size, this result provides further evidence of DNA monomolecu-

Fig. 2.6. Oxidation of C<sub>10</sub>CysG<sup>+</sup> occurs faster in the presence of template DNA.

lar collapse. Interestingly, the  $\zeta$  potentials of (C<sub>10</sub>CysG<sup>+</sup>)<sub>2</sub>-DNA complexes were found to be negative (−45 to −40 mV) at the isoelectric point. This particular property may be explained by the fact that the DNA backbone constitutes the interface between the aqueous phase and a frozen micellar core. A negative  $\zeta$  potential also suggests that charge repulsion of the nanoparticles may account for the observed colloidal stability. Unfortunately, this short-chain cysteine detergent C<sub>10</sub>CysG<sup>+</sup> and its corresponding gemini cysteine-lipid proved unsatisfactory for biological applications, but led to further investigation of novel amphiphiles.

### 2.3.2

#### Synthesis, Characterization and Optimization of Surfactants

The design of a dimerizable detergent must be tuned so the critical micellar concentration for its monomeric form exceeds the DNA phosphate concentration to elicit monomolecular plasmid collapse. Additionally, once oxidized, the gemini surfactant must also exhibit a low solubility to enable stability in biological conditions. Exploration of dimerizable detergents with the above qualities was accomplished by preserving the cysteine as the reactive agent, but with modification to the polar head group and hydrocarbon chain length. Solid-phase synthesis is well adapted for this investigation and provides a mean for the preparation of a large number of different surfactants (Fig. 2.8) [37].

Fortunately, knowledge of surfactant behavior reduces the possible molecules to only a small quantity (Fig. 2.9). Changing the polar head group to ornithine (two positive charges) or spermine (four positive charges) increases both DNA affinity and detergent solubility (e.g. the critical micellar concentration), while lengthening the hydrocarbon chain, in turn, favors an increase in surfactant association and off-

Fig. 2.7. Particle sizes vary as the cubic root of the DNA size, adding more evidence to DNA monomolecular collapse. Particle diameters were determined by light scattering.

sets the increase in solubility (Table 2.1). Typical plasmid concentrations for gene delivery experiments are in the 10–50  $\mu\text{M}$  range, suggesting that  $\text{C}_{14}\text{CO}$  (critical micellar concentration = 45  $\mu\text{M}$ ) is the most likely surfactant/gemini lipid candidate for effective monomolecular plasmid condensation [38].

**Fig. 2.8.** Solid support synthesis of the cationic detergent  $C_{14}CO$ . Inset: preparation of protected cysteine. (a) **2**, DIEA,  $CH_2Cl_2$ ; (b) 20% piperidine, DMF; (c) Bis-Boc-ornithine, PyBOP, DIEA, DMF; (d)  $Pd(PPh_3)_4$ ,  $CHCl_3$ /AcOH/*N*-methylmorpholine (37:2:1); (e) tetradecylamine, PyBOP, DIEA, DMF; (f) TFA. (Adapted from Ref. [37].)

Validation of the  $C_{14}CO$  detergent for stable DNA nanoparticle formation was accomplished by employing a circular 5.6-kbp DNA plasmid with the surfactant at 1/1 charge ratio close to the isoelectric point. The complexes stabilized via DNA-templated air oxidation of the free thiol groups. A gel-retardation assay was used to assess complex formation between plasmid DNA and cationic surfactant (Fig. 2.10). Upon application of an electrical field, molecules or complexes move through the agarose gel at a rate proportional to their charge, but inversely proportional to their volume. Examination of the DNA particle cohesion by agarose gel electrophoresis resulted in a single band with an increase in electrophoretic mobility with respect to the naked plasmid. This result provides evidence that these particles are highly stable in an electric field, where reversible electrostatic interactions would easily be destroyed. Charge neutralization of the DNA phosphate groups and an increase in molecular mass due to the addition of the surfactants should yield a slower migration. However, when one considers that naked DNA tends to move through agarose gel in a snake-like motion, the compaction of the plasmid into a small globular structure can speed migration as there is less entanglement with the gel matrix [37].

### 2.3.3

#### Organization of the Surfactant–DNA Complexes

Lipid/surfactant domain stabilities can be further evaluated from examination of morphologies within the lipid phase of DNA complexes. The presence of order within DNA particles indicates strong DNA packing and, by extension, quasi-irreversible amphiphile aggregation. Transmission electron microscopy of oxidized  $(C_{10}CysG^+)_2$ -DNA complexes resulted in a homogeneous population of nearly spherical objects that do not display an internal orderly structure (Fig. 2.11). In contrast, oxidized  $(C_{14}CO)_2$ -DNA particles appeared as a population of 25 nm diameter spheroids that display variable texture from one particle to another. The irregular particle texture appears to be a consequence of close DNA packing induced by quasi-irreversible  $(C_{14}CO)_2$  associations into tubes. A similar ultrastructure was observed previously with lipoplexes formed with another polycationic lipid (Transfectam) [39].

### 2.3.4

#### Quantification of the Stability of Surfactant–DNA Complexes

Association of detergents/amphiphiles with a plasmid can further be characterized by determination of the critical aggregation concentration [40]. The critical aggrega-

**Fig. 2.11.** Morphology of surfactant–plasmid complexes. Observation was performed by electron microscopy and complexes were stained with uranyl acetate.

gation concentration corresponds to the concentration of free surfactant necessary to initiate the formation of a micelle like domain on the DNA template. This value depends both on the affinity of the cation for DNA phosphate and the ability of the lipid chain to form micellar structures (characterized by the critical micellar concentration). Using fluorescence quenching of the DNA intercalating agent YOYO-1 upon DNA condensation, critical aggregation concentrations of 1, 2.5 and 5  $\mu\text{M}$  were obtained for  $\text{C}_{14}\text{CO}$ ,  $\text{C}_{10}\text{CysG}^+$  and CTAB, respectively. These values followed the same trend as the critical micellar concentration, but shifted to lower values (by a factor of 40–50), highlighting the critical role played by electrostatic interactions in the DNA condensation around micelle domains. The stabilities of the gemini surfactant after DNA-assisted oxidation could be also quantified by determination of their critical aggregation concentration. The critical aggregation concentration of the dimeric surfactant  $(\text{C}_{10}\text{CysG}^+)_2$  is still in the micromolar range and is reduced only by a factor of 3 by comparison to the critical aggregation concentration of the corresponding monomer. On the contrary, the critical aggregation concentration of the dimeric  $(\text{C}_{14}\text{CO})_2$  falls in the nanomolar range and is dramatically reduced by a factor of  $10^3$  by comparison to the critical aggregation concentration of the monomeric  $\text{C}_{14}\text{CO}$ .

One critical aspect in the use of surfactants for gene therapy is the stability of the DNA–surfactant complexes during dilution in the cell culture medium and in the presence of cellular plasma membranes. External and internal leaflets of the plasma lipid bilayer are modeled by using either neutral or anionic lipid vesicles. Surfactant displacement from DNA complexes into bilayers induces, in turn, DNA decondensation that can be easily monitored using fluorescence probes (Fig. 2.12). With CTAB–DNA and  $(\text{C}_{10}\text{CG}^+)_2$ –DNA complexes, the addition of anionic lipid vesicles, and to a lower extend neutral lipid vesicles, leads to almost complete DNA decondensation. In contrast, the addition of both types of vesicles to  $(\text{C}_{14}\text{CO})_2$ –DNA particles is unable to induce DNA release, confirming the stabilities of these particles and their putative biomedical applications.

## 2.4

### DNA Functionalization for Cell Recognition and Internalization

#### 2.4.1

##### Strategies for Functionalization

Preparation of nanometric DNA vehicles with the minimal size is necessary, but not sufficient, for gene delivery. (C<sub>14</sub>CO)<sub>2</sub>–DNA nanoparticles have overall negative surfaces and are unable to anchor to cell membranes. As a consequence, they do not transfect cells. The use of such scaffolds requires various components for cell-specific internalization. The decoration of surfactant–DNA complexes with components can be accomplished by anchorage within the hydrophilic surfactant core of a lipid bearing a selected ligand or by anchorage to DNA itself. Characterization of stabilized micelle–DNA complexes indicates that the plasmid is at the surface of the particles, which allow possible anchorage to DNA.

The view that DNA is only a polyanionic polymer is in reality a gross oversimplification. Multiple factors such as base stacking, Watson–Crick hydrogen bonding and sugar conformation enable two negatively charged strands of DNA to anneal into the classical B-form helical duplex (Fig. 2.13). The DNA helical structure affords the binding of other molecules by three common motifs. Without disrupting the Watson–Crick base pairing, planar aromatic molecules are able to intercalate between base pairs. The availability of hydrogen bond donors and acceptors in the major groove allows for triple helix formation via Hoogsteen base pair formation.

**Fig. 2.13.** DNA recognition by molecules may use (a) the major groove with formation of Hoogsteen base pairs, (b) the phosphate backbone by electrostatic interaction, (c) the minor groove by shape recognition or (d) base pair stacking with intercalation. Alternatively, one strand could be invaded with polymer forming novel Watson–Crick base pairs.

Likewise, the shallow minor groove enables binding of small molecules such as distamycin or Hoechst 33258 [41].

#### 2.4.2

##### Intercalation

Several planar aromatic small molecules are able to intercalate into the DNA duplex [2]. Intercalation occurs generally where the base-pair stacking association is higher and produces a sequence preference binding in between stacked 5'-GC-3' base pairs. The affinity of a single intercalator is relatively weak (in the micromolar range). Kinetic analysis indicates that intercalation is in the millisecond range and is preceded by fast diffusion binding at the outside of the double helix, presumably by interaction in the minor groove. Dimerization of two intercalating agents increases the stability of intercalation to where bis-intercalators are able to be used to fluorescently tag DNA duplexes for cellular trafficking studies [42].

The quasi-irreversible properties of intercalation have been exploited to functionalize plasmids with transferrin, a protein that is understood to facilitate cellular entry via receptor-mediated endocytosis (Fig. 2.14) [43]. Human transferrin tethers two identical carbohydrate chains attached by *N*-glycosylation to asparagines 413 and 611, where the glycans are composed of a mannotriosidodi-*N*-acetylchitobiose core bearing two *N*-acetylneuraminy-*N*-acetylglucosamine units. The glycans do

**Fig. 2.14.** Selective conjugation of a strong DNA binding intercalator to the two glycosylation sites of transferrin (Tf). (Adapted from Ref. [43].)

not have any known involvement or influence on cell surface receptor binding and thus have the potential for exploitation as spacers for the site-specific attachment of nucleic acid-binding domains. Within the sugar chain, the terminal *N*-acetyl neuraminic acid has vicinal diols that are readily oxidized by sodium periodate, producing a transferrin displaying aldehyde groups. Reductive amination of the aldehydes with a bis-intercalating ethidium homodimer results in a new transferrin covalently linked to a DNA high-affinity anchor. Although anchorage efficiency was not fully characterized, DNA–transferrin conjugate complexes were observed to enter cells by endocytosis, presumably after transferrin binds to its corresponding cellular membrane receptor.

### 2.4.3

#### Triple Helix Formation with Oligodeoxyribonucleotides

In 1987, Claude Hélène's and Peter Dervan's research groups simultaneously demonstrated that oligodeoxyribonucleotides form stable sequence-specific triple

**Fig. 2.15.** DNA recognition from the major groove by triple helix formation with an oligonucleotide forming Hoogsteen or reverse Hoogsteen base pairs.

helices in the major groove of DNA duplexes under conditions close to physiological conditions [44, 45]. DNA triplex formation obeys specific rules imposed by structural constraints; consequently, only a few sequences are viable targets for triplex formation. (Fig. 2.15).

Specifically, homopurine tracts are required for the third strand homopyrimidine to bind via Hoogsteen hydrogen bonds. This binding motif yields the third strand in a parallel orientation to the homopurine strand in the duplex. Additionally, homopurine stands can specifically bind with homopurine tracts in an antiparallel fashion by forming reverse Hoogsteen-type hydrogen bonds between the same nucleobase (recognition of dG by dG and dA by dA) [46]. Thermodynamic and kinetic parameters indicate that selected triplex-forming oligonucleotides of about 20 nucleotides have high affinities for their corresponding duplex targets. In particular, a 24 mer homopurine sequence coupled to the NLS forms a stable triplex with a target duplex at intracellular potassium concentrations with a residence time of 24 h (Fig. 2.16) [8].

DNA third strand–NLS conjugates have further been exploited to functionalize plasmids specifically cloned with several triplex host sequences. Although cova-

**Fig. 2.16.** Conjugation of a NLS peptide (–PKKKRV–) to a plasmid by triple helix formation. The system requires the preparation of the plasmid with tags for triplex formation in unread regions of the plasmid.

lently functionalized plasmids are not the ideal constructs for gene delivery, triple helix formation may provide a mechanism to sequence specific covalent attachment to plasmids at unread sequences [47]. Covalent sequence-specific peptide conjugation employing triplex formation was accomplished using a psoralen–DNA–peptide conjugate. After triplex formation, the psoralen was in the correct location to adduct formation of a site-specific peptide–DNA conjugate by UV activation.

#### 2.4.4

#### Peptide Nucleic Acids (PNAs)

A PNA is an oligonucleotide analog in which the phosphodiester–sugar backbone is replaced by a polyamide composed of a repeating *N*-(2-aminoethyl)-glycine unit (Fig. 2.17). The nucleobases are attached to the polyamide through methylene carbonyl linkers to produce a polymer remarkably isomorphic in terms of geometry and spacing in comparison to native oligonucleotides. The neutrality of the polyamide favors hybridization to target DNA sequences compared to the charge repulsion of native duplex formation. Plasmid denaturation and annealing in the presence of PNA enables sequence specific PNA hybridization via Watson–Crick base pairing and displacement of the complement strand.

Branden et al. conjugated a NLS peptide to a PNA strand that hybridized to 11

**Fig. 2.17.** Size comparison between a natural DNA strand and its isomorphous “peptide nucleic acid” based on a *N*-(2-aminoethyl)glycine backbone. B: nucleobase.

sites previously cloned into a plasmid containing the gene for the green fluorescent protein (GFP). The NLS–PNA conjugates were docked by a heat-induced denaturation of the plasmid (hybridization by strand displacement), and the (NLS–PNA)<sub>11</sub>–plasmid complexes were delivered into cells using polyethylenimine (PEI) or a cationic lipid formulation. Transfection efficiency was increased 8-fold with respect to the untagged plasmid [48]. Recently, Vaysse et al. reported the employment of a NLS–PNA conjugate for strand invasion at room temperature via a triple-helix motif [49]. Unfortunately, delivery of stable plasmid–NLS–PNA complexes by cationic lipids has not significantly improved gene delivery efficiency when compared to plasmid–PNA complexes lacking NLS peptides. Apart from nuclear targeting, PNAs have also been used to tether transferrin to plasmids [50], where condensation of a plasmid–transferrin–PNA complex with the proton sponge PEI enhanced enzymatic expression of the luciferase gene, a standard reporter, about 4-fold over the plasmid–PEI complex. Competition studies using excess free transferrin resulted in lower transfection, suggesting that DNA–transferrin–PNA–PEI complexes mediated this improvement by binding to the transferrin receptor.

#### 2.4.5

#### Interactions of DNA with Fusion Proteins

Recent progress in biotechnology has enabled the design and production of a variety of fusion proteins, where either whole or subunits of differing proteins have

been cloned together to produce a chimeric protein. Chimeric proteins including cell-anchorage domains, fusogenic peptides, NLS sequence or DNA condensation/recognition elements have been prepared and evaluated as gene delivery agents [51]. Unfortunately, most of the time, *in vitro* reconstruction of viral particles from protein and nucleic acid does not lead to single DNA condensation or nanometric nucleic acid particles [52], but rather to precipitates. Immune response induced by proteins in the host seriously limits the large-scale utilization of exogenous protein [6]. Nonetheless, host-derived protein (as in the case of transferrin) or protein that could be buried within the particles when immune effectors are present, but exposed in the cytoplasm to assist in passage through nuclear pores, could be used. In one study, the fusion between the TetR protein and the NLS peptide exploited the high affinity of the TetR to bind to a short palindromic DNA sequence and the nuclear import capacities of the NLS peptide [49]. Similar to the previous experiment (Fig. 2.16), binding sites for the fusion protein were cloned into a plasmid for NLS anchorage. Gel-shift assays resulted in a lower electrophoretic mobility of the plasmid in the presence of the fusion protein, providing evidence that the TetR protein retains the ability to bind with DNA when conjugated to the NLS peptide. In addition, improved cationic lipid-mediated delivery was observed in mitosis-arrested cell cultures, suggesting that intracellular trafficking to the nucleus mediated by the NLS peptide is improved.

#### 2.4.6

##### **Agents that Bind to the Minor Groove**

The high sequence specificity of PNA, triplex forming oligodeoxynucleotides and proteins to corresponding DNA sequences requires cloning of a target or tag sequence into a nonfunctional section of the plasmid. This hinders not only the target sequence, but further limits the number of elements present on the DNA plasmid. Agents that bind to the minor groove such as distamycin or bisbenzimidazole may overcome the need for tag sequences as they bind with less sequence specificity. Although bisbenzimidazole or distamycin binds in the DNA minor groove with high affinity to AATT sites (dissociation constants in the nanomolar range), they also ramp along the DNA minor groove. Additionally, linking several DNA minor groove binding modules by aliphatic spacers increases DNA duplex affinity and interaction time, but with degenerated sequence selectivity [53].

## 2.5

### **DNA Nanoparticles: Sophistication for Cell Recognition and Internalization**

#### 2.5.1

##### **Preparation of DNA Nanoparticles Enveloped with a Protective Coat and Cell Internalization Elements**

The necessity of DNA protection from aggressive media, such as the blood, demands, at first, particles to be coated with multiple elements. Among the above-

Fig. 2.18. Structure of the DNA anchor 1.

mentioned possible DNA anchors, minor groove agents may prove to be the best choice for noncovalent functionalization of the DNA plasmid with the cell-targeting element. Zuber et al. prepared a minor groove binding anchor (Fig. 2.18, 1) to equip plasmid with folic acid for cell internalization through the folate receptor and PEG to protect the plasmid from degradation in the bloodstream [54].

A distamycin analog and two bisbenzimidazoles were linked by disulfide bond formation, as the presence of disulfide bonds permits the reversion of the anchorage in the cytoplasm by oxidation from glutathione, an intracellular reducing agent. Disulfide bridge cleavage should in turn lead the dissociation of the prosthetic group from the plasmid and therefore facilitate a higher level of expression.

The interaction of 1 with a plasmid of 5.5 kbp was analyzed by agarose gel electrophoresis (Fig. 2.19). Plasmid mobility was reduced and a decrease in ethidium bromide staining was observed in a concentration-dependent manner, suggesting that 1 effectively binds with the plasmid. To test the reversion of the binding in the cytoplasm, glutathione was added to the plasmid–1 complex in solution, resulting in almost complete restoration of plasmid electrophoretic mobility and ethidium bromide staining. The presence of the still-retarded plasmid in lane 4 suggests that some residual bisbenzimidazoles bind to the plasmid; nevertheless, the binding studies indicate the feasibility of release in the cytoplasm.

A PEG–folic acid coat of nanometric DNA particles should not only enhance stability, but further provide cell-targeting and internalization properties. The preparation of monomolecular DNA particles by condensation with lipid-based detergents as previously described in this chapter was accomplished with 1/1 charge equiva-

**Fig. 2.19.** Agarose gel electrophoresis shows complex formation between DNA plasmid, the cationic detergent C<sub>14</sub>CO and compound **1**. Plasmid was mixed with increasing amount of **1** as indicated. Lane 4: DNA-**1** complexes were incubated with glutathione for release test. Lanes 5–8: nanometric DNA-(C<sub>14</sub>CO)<sub>2</sub> particles were prepared as described in

**Fig. 2.4.** After overnight incubation, coverage was effected simply by addition of **1** to the particles. Lane 8: a 1-h incubation of the complexes with excess DNA does not displace the anchor. Transmission electron microscopy image of the final DNA-C<sub>14</sub>CO-**1** complexes shows monomolecular DNA condensation into compact particles. (Adapted from Ref. [54].)

lents of the cationic detergent C<sub>14</sub>CO to the plasmid (see Fig. 2.4). After oxidation of the detergent thiols to disulfides, the electrophoretic mobility of the particles through agarose gel was observed to be faster than the corresponding naked DNA (Fig. 2.19). While addition of the PEG-folic acid coat somewhat decreased electrophoretic mobility, competition experiments with excess DNA confirmed quasi-irreversible binding of **1** with the plasmid. Finally, PEG-folate-enveloped DNA particle morphology was observed by transmission electron microscopy. Complexes appeared as a homogeneous population of compact spherical particles with an average diameter of 35 nm. Assuming full DNA association, enveloped particles prepared as in Fig. 2.11 (lane 7) are coated with around 360 molecules of the PEG-folate conjugate, which corresponds to approximately one PEG polymer every 10 nm. This polymer density is sufficient for polymer overlapping onto the surface (termed “weakly overlapping mushroom regime”), [55] and hence should provide both stealth delivery properties and folate receptor-binding properties to the particles.

**Fig. 2.20.**  $(C_{14}CO)_2$ -DNA-1 complexes specifically bind to folate receptor-presenting KB cells. Cells were incubated for 3 h with fluorescent DNA complexes. FACS analyses

indicated cellular binding. A Complementary experiment using confocal microscopy indicated that the complexes (darker spots) are further internalized into endosomes.

### 2.5.2

#### **Biomedical Application: Cell Targeting and Internalization Properties of Folate-PEG-coated Nanoparticles**

The abilities of folate-PEG-enveloped DNA particles to carry genes into carcinoma cells were examined using flow cytometry and confocal microscopy (Fig. 2.20). KB cells derived from a human nasopharyngeal cancer were chosen as targets because they conditionally express a large number of folic acid receptors upon folic acid starvation. The  $(C_{14}CO)_2$ -DNA particles were labeled with the fluorescent DNA intercalating dye YOYO and incubated 3 h with the KB cells that expressed large quantity of folate receptors (about  $10^6$  receptors per cell). Flow cytometric analyses show an increased in fluorescence binding to cells with folate-PEG-coated nanoparticles in comparison to untreated cells. To examine whether cell anchorage was followed by endocytosis, the cellular fate of the DNA nanoparticles was observed by confocal fluorescence microscopy. As shown in Fig. 2.20, complexes were internalized in cell perinuclear compartments that very much resemble lysosomes.

## 2.6

### **Concluding Remarks**

Following initial findings from over a decade ago that cationic lipids and polymers carry genes into eukaryotic cells, a lot of effort has been dedicated to improve transfection efficiency by structural modification of the carriers. Exploration of classical pharmacological methods (such as structure and function) has led to molecules capable of transfecting fast dividing cells in culture at a multiplicity of infection of about  $10^6$  gene copies per cell. Their ease of handling as well as their general efficiency for almost all adherent cell lines has made them common tools in cellular

biology. Today, these vectors remain far too simple for *in vivo* gene delivery; the prerequisite to gene therapy. Efforts are currently being made to stabilize these DNA–vector “nanoparticles” in the 100- to 1000-nm range with an inert coat and to equip them with targeting elements [33]. As discussed in this chapter, size restriction of the DNA delivery vehicles is crucial for diffusion *in vivo*. Chemical solutions were found to condense DNA into stable particles with the minimal size (single plasmid condensation). In turn, vehicles incorporating fewer copies of effectors need more activity and specificity. Strategies developed for tethering novel functions onto DNA–surfactant complexes had allowed the preparation of DNA particles having key viral properties such as stability and small size for diffusion and ligands for receptor-mediated endocytosis. However, at this stage, key parameters such as endosome escape or nuclear import are still missing. The pending challenge is in adding these extra functions to the DNA delivery vehicle without interfering with all the other ones. Development of supramolecular systems is still in its infancy and will definitely benefit from a better understanding of biochemistry of the cell and how macromolecules interact together to produce wanted events. Gene therapy relies on the development of effective multicomponent delivery vectors. Following initial findings from over a decade ago that cationic lipids and polymers can facilitate gene transportation into eukaryotic cells, a great deal of effort has been dedicated to improve transfection efficiency by structural modification of the carrier. Exploration of classical pharmacological methods (such as structure and function) has led to molecules capable of transfecting fast dividing cells in culture at a multiplicity of infection of about  $10^6$  gene copies per cell. Their ease of handling as well as their general efficiency for almost all adherent cells lines has made them common tools in cellular biology. The size of a DNA plasmid limits the number of gene copies in delivery vehicles for achieving cell contact in an organism. As discussed in this chapter, stable nanoparticles consisting of a single DNA plasmid can be prepared, and even coated with some functional elements for cell targeting and internalization. Today, DNA nanoparticles are still inefficient in escaping endosomes and require further sophistication. The next obstacle to overcome is the disruption of endosomal membranes, most likely facilitated by the attachment of endosomal disrupting agents such as DOPE or fusogenic peptides. Needless to say, DNA delivery systems with the smallest size incorporate fewer copies of effectors. The implication is that effectors should be more active and specific. The development of nanometric supramolecular systems capable of effective *in vivo* gene delivery is still in its infancy, and will benefit from a better understanding of cellular biochemistry and the interactions between constructed nanoparticles and cellular components.

# Lipoplexes

*Sarah Weisman*

### 3.1

#### Introduction

The introduction of nucleic acids into cells, either plasmid DNA for gene expression or antisense oligodeoxynucleotides (ODN) or small interference RNA (siRNA) for gene silencing, is a valuable tool for biological research and a promising therapeutic treatment for genetic disease. The prevalent means of transport for gene therapy is the use of viral vectors [1]. A synthetic alternative, cationic lipid-mediated nucleic acid delivery (lipofection) [2], has been intensively studied over recent years [3–7]. Lipofection has low efficiency compared to viral vectors, but its advantages include negligible immunogenicity, ease of large-scale production and no limit on the size of the gene transported. Eighty-seven clinical trials of gene therapy via lipofection are currently in progress, aiming to treat cystic fibrosis, arterial disease and many types of cancer [8].

Mixing anionic nucleic acids with cationic lipids leads to spontaneous self-assembly of ordered aggregates known as lipoplexes. Lipoplexes have great potential, but our understanding of the mechanisms of lipoplex function is still incomplete. This chapter will give a brief overview of the current state of knowledge about lipoplexes, with special attention to their microscopic structure, and the relationships between structure and delivery efficiency. The chapter will first address the composition, structure and function of DNA lipoplexes, and then discuss ODN and siRNA lipoplexes in terms of their differences from DNA complexes.

### 3.2

#### DNA Lipoplexes

##### 3.2.1

#### Composition

Cationic lipids do not usually occur in nature, but a wide variety of lipids have been synthesized for the purposes of gene therapy. Cationic lipids contain a cationic

head group, a linker and a hydrophobic moiety, most often two hydrocarbon chains. The effects of variations in lipid structure on the properties of lipoplexes have been recently reviewed elsewhere [7, 9]. The chemical structures of some popular cationic lipids from different families are presented in Table 3.1.

Cationic lipids are often combined with neutral (helper) lipids in order to improve lipofection efficiency. The presence of helper lipids can tune the surface charge density, the preferred microstructure and the stability of lipoplexes. The chemical structures of the three most common helper lipids are presented in Table 3.1. Mixed cationic–neutral lipid systems self-assemble in aqueous solution, usually forming liposomes, which are bilayer membranes closed in upon themselves (Fig. 3.1).

Mixture of anionic DNA with cationic liposomes in aqueous solution leads to spontaneous and nearly instantaneous complexation. The DNA–lipid interaction is endothermic [10, 11]; the driving force for lipoplex formation is the entropy gain from the release of bound counterions [12] and water molecules [13]. The process of lipoplex formation is shown schematically in Fig. 3.1.

DNA in lipoplexes is located in close contact with the lipids and can neutralize the cationic lipid head group charges [14]. In positively charged complexes (with an excess of lipid) the DNA is fully protected from degradation by nucleases or interaction with fluorescent dye [15, 16]. Hence, we infer that DNA is condensed and encapsulated within lipoplexes.

### 3.2.2

#### Nanostructure and Microstructure

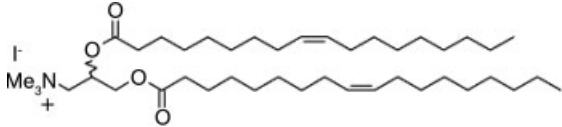

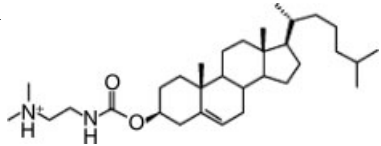

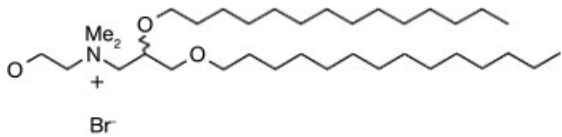

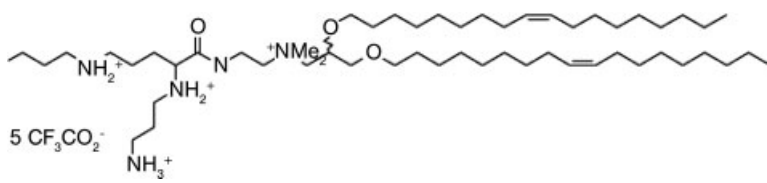

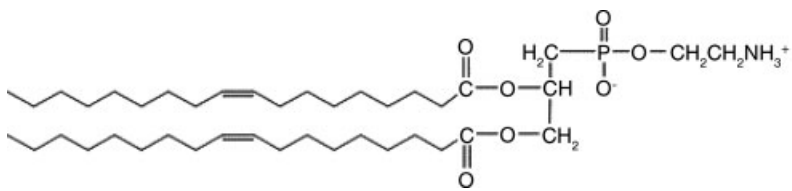

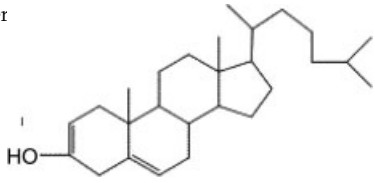

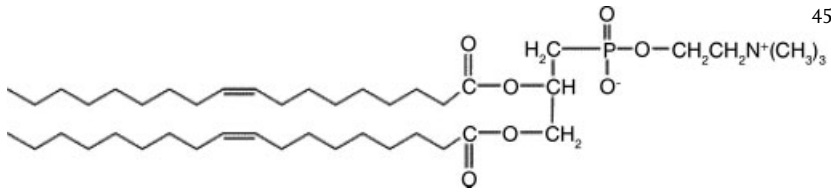

##### 3.2.2.1 Equilibrium Morphology

There are two known supramolecular structures adopted by DNA lipoplexes at equilibrium. The lamellar phase consists of DNA molecules sandwiched between cationic membranes [18, 19]. The inverted hexagonal phase contains DNA molecules coated by monolayers of cationic lipid and arranged in a hexagonal matrix [20, 21]. The different morphologies are shown schematically in Fig. 3.2.

The condensed lamellar ( $L_{\alpha}^C$ ) or “sandwich” phase is characterized by a constant interlamellar water gap,  $w \sim 2.6$  nm, corresponding to the diameter of a DNA helix surrounded by a thin hydration shell [18]. DNA organizes within the monolayer as a lattice of parallel helices. As DNA molecules are rigid, with a persistence length of around 50 nm, this is the only efficient packing regime. The interhelical DNA spacing,  $d$ , is variable, depending on both the membrane charge density and the DNA/lipid charge ratio. Under isoelectric conditions, with full neutralization of lipid and DNA charges,  $d^* = e/(l_0\sigma_M)$ , where  $e$  is the electron charge,  $l_0$  is the distance between anionic charges on the DNA backbone and  $\sigma_M$  is the cationic membrane charge density (dependent on the cationic/neutral lipid ratio). If the cationic membrane includes helper lipids, DNA may induce lipid demixing. Cationic lipids concentrate close to the DNA helices to achieve local charge matching [19].

The inverse hexagonal ( $H_{II}^C$ ) or “honeycomb” phase has a typical water tube diameter of about 2.8 nm, sufficient to contain a hydrated DNA helix [20]. The DNA

is tightly and symmetrically enveloped, so this structure can provide very effective charge neutralization. Adding DNA to lamellar lipid bilayers sometimes induces the formation of an inverse hexagonal complex. This phenomenon occurs in soft membranes with low bending rigidity, e.g. systems where short-chain alcohols have been added as cosurfactants.

The preferred structure of lipoplexes consisting of two or more lipid species depends on the packing geometry of the lipid components. Most lipids with two hydrocarbon chains are roughly “cylindrical”, meaning that the cross-sectional areas of their head group and their tail group are comparable. These lipids favor the formation of planar bilayers. Thus, lipoplexes where all lipid molecules are cylindrical usually form only a lamellar complex. Some neutral lipids with small head groups, e.g. DOPE, have “inverse conical” shapes and can promote the formation of an inverse hexagonal phase.

**Fig. 3.2.** Schematic representation of equilibrium structures of lipoplexes. (A) The  $L_x^C$  lamellar phase, promoted by cylindrically shaped helper lipids. (B) The  $H_{II}^C$  inverse hexagonal phase, promoted by inverse conical

helper lipid molecules. In (A),  $w$  is the constant interlamellar water gap,  $d$  is the variable interhelical DNA distance and lipids can locally demix to efficiently neutralize DNA charge. (Adapted from Ref. [5].)

Phase diagrams of DNA lipoplex systems have been constructed both experimentally and theoretically [22–24]. In a mixed lipid system, increasing the mole fraction of DOPE or a similar inverse conical helper lipid can drive a structural transition from lamellar to inverse hexagonal lipoplexes. At high DNA/lipid charge ratios lipoplexes coexist with free DNA and at low DNA/lipid charge ratios lipoplexes coexist with pure lipid phases. Lamellar lipoplexes can be negatively overcharged at excess DNA ( $d < d^*$ ) or positively overcharged at excess lipid ( $d > d^*$ ) and can accommodate different fractions of helper lipid, so there is a single-phase  $L_x^C$  region over a range of component ratios. Inverse hexagonal lipoplexes have no structural or compositional degrees of freedom, thus they only exist as isoelectric complexes in equilibrium with other phases.

Some DNA lipoplex systems that form the condensed lamellar phase have demonstrated three-dimensional interlayer correlations [25–27]. These occur if the cationic lipid membranes are flexible and can partially wrap around the DNA in order to improve charge matching. This produces periodic membrane undulations, as shown in Fig. 3.3. The orientation of DNA helices in different layers is correlated and there is some positional coupling between DNA helices in different layers. The range of the interactions depends on the membrane properties.

The size and sequence of DNA molecules apparently does not affect the lipoplex microstructures formed [28]. The structure of DNA helices within lipoplexes remains in a B-conformation, though in a variant form in which the base–base interactions are perturbed [29].

### 3.2.2.2 Nonequilibrium Morphology

Lipoplex systems under conditions relevant for gene therapy often have not reached thermodynamic equilibrium. Lipoplexes are usually prepared by adding DNA to cationic liposomes. Direct imaging by transmission electron microscopy (TEM) has demonstrated that this procedure can produce a variety of metastable morphologies [30–33]. Slight differences in preparation conditions can apparently cause large variations in the dynamics of complex formation.

Figure 3.4(b) shows a model mechanism for the formation of lamellar lipoplexes [33]. The mechanism suggests that in the first step of complexation anionic DNA coats the surface of cationic liposomes. Following this, liposomes adsorb, rupture and roll over a host liposome, adding layers one by one to form a multilamellar

**Fig. 3.3.** Schematic representation of bilayer undulations and interlayer DNA correlations within lamellar lipoplexes. The lamellar repeat distance is denoted by  $h$ . (Adapted from Ref. [5].)

**Fig. 3.4.** (Above) Cryo-TEM image of a DOTAP/DOPC/DNA lipoplex with excess lipid. Black arrowheads indicate liposomes adsorbed to each other; black arrows mark pairs of concentric membranes adsorbed to each other; black double arrows indicate a stack of concentric membranes adsorbed to each other; white arrowheads mark parallel DNA helices clearly visible between adsorbed membranes. (Below) Model mechanism for interactions

between cationic liposomes and DNA. (A) DNA coats a liposome. (B) Two liposomes adsorb to each other. (C) One liposome ruptures after deformation and (D) rolls over the second liposome, yielding a pair of concentric membranes adsorbed to each other, possibly with an open membrane edge. Further layers adsorb similarly. (Adapted from Ref. [33].)

particle. This mechanism is in agreement with calorimetric measurements suggesting that lipoplex formation is a two-step process [34]. A fast exothermic interaction corresponds to DNA binding to liposome surfaces and a slower cooperative endothermic process is probably the reorganization of liposomes into lamellar complexes.

Figure 3.4(a) shows an example of a polymorphous lipoplex, imaged at our laboratory. The lipid composition of the system is expected to favor the lamellar phase at equilibrium. Several of the intermediate stages in the model mechanism of lipoplex formation are observed. The prevalence of metastable structures is a function of the time since preparation. It is also probably promoted by conditions of excess lipid, causing a shortage of free DNA to drive the complexation process forward. In systems with higher DNA charge ratios, multilamellar complexes form much more quickly.

Some DNA lipoplexes have been found to form “spaghetti” tubule structures, with individual DNA molecules coated by cationic lipid bilayers [30]. It has been demonstrated that these structures are metastable [21]; they may be intermediates in the formation of the inverse hexagonal phase.

### 3.2.2.3 Lipoplex Size

Lipoplex particles, with different compositions and under different preparation conditions, range in size from around 100 nm to several microns. At low or high DNA/lipid charge ratios the complexes are charged (with positive or negative  $\zeta$  potential, respectively), and their size is stabilized by electrostatic repulsions. At charge ratios approaching the isoelectric point the  $\zeta$  potential is near zero, and lipoplexes undergo extensive and irreversible aggregation [35]. Size growth is promoted by membrane defects that are believed to result from phase separations between DNA–lipid lamellar domains and uncomplexed bilayers [36].

Increasing mole fraction of helper lipids increases lipoplex size [35]. This is probably due to lower membrane charge density and thus weaker electrostatic repulsions. A medium of high ionic strength masks electrostatic repulsions and facilitates lipoplex growth [37].

Lipoplexes prepared from large cationic liposomes are larger than those prepared from small liposomes [35]. The extent of lipoplex aggregation increases with time.

## 3.2.3

### Lipofection Efficiency

#### 3.2.3.1 *In Vitro*

Lipoplexes must surmount many barriers to successfully deliver DNA to the cell nucleus. A diagram of the most likely mechanism of lipofection is shown in Fig. 3.5. The first stage is binding of a lipoplex to the cell due to nonspecific electrostatic interactions between cationic membranes and anionic proteoglycan residues on the cell surface [38]. Cell association is enhanced for positively charged lipoplexes and for large aggregates, the latter probably due to a faster rate of settling on the cultured cells [39]. The most efficient DNA/lipid mixing ratio for lipofection is a moderate excess of cationic charge [40].

The primary pathway for lipoplex entry into cells is endocytosis [41, 42]. Fusion of lipoplexes with the cell membrane also occurs, but there is no correlation between the degree of lipid mixing and the lipofection efficiency [43]. Possibly a fusion event releases DNA outside the cell, or inside the cell, but too distant from the cell nucleus.

**Fig. 3.5.** Schematic representation of the most likely mechanism of lipofection. (A) A lipoplex approaches the cell. (B) Adsorption to the cell surface due to electrostatic interactions. (C) Entry to the cell by endocytosis. (D) Transport within an endosome. (E) Fusion or disruption of the endosome. (F) Release of DNA. (G) Entry to the nucleus by intracellular trafficking. (Adapted from Ref. [59].)

A recent report has demonstrated that small particles (200 nm or below) enter cells mainly by clathrin-mediated endocytosis and larger particles (around 500 nm) by caveolae-mediated endocytosis, while very large particles (1  $\mu\text{m}$  or above) are not internalized at all [44]. Small particles are delivered to lysosomes for digestion within a few hours, but larger particles have an extended residence time within endosomal compartments, increasing their probability of escape into the cytosol [44]. These results may explain the common empirical finding that lipoplex size has a significant influence on transgene expression. There is an optimal lipoplex size for greatest lipofection efficiency [35, 37, 45].

Release of lipoplexes from endosomal compartments is widely considered a rate-determining step for lipofection. Efficient lipoplex formulations are able to escape from endosomes, while inefficient formulations remain trapped [46, 47]. The endosome membrane can be disrupted by lipid exchange or fusion with lipoplexes. Inverse hexagonal phase lipoplexes are reported to fuse rapidly with anionic membranes, disrupting the membrane and releasing DNA [20] and hexagonal lipoplex structure has been correlated with efficient lipofection [48, 49]. Lipid mixing between cationic lipids and anionic lipids found in the endosomal membrane can also induce local formation of a hexagonal phase, due to ion pair charge neutralization [50, 51]. This destabilization of bilayers is hindered by the presence of cylindrically shaped helper lipid, but is facilitated by inverse conical shaped helper lipid. Formation of a nonbilayer phase in lipoplex–membrane mixtures appears to be critical for efficient endosome escape [51].

A recent report has proposed that the barrier preventing lamellar lipoplex fusion with the anionic endosomal membrane is kinetic rather than thermodynamic [47]. The height of the activation barrier depends on lipoplex membrane bending rigidity and cationic charge density. Efficiency of lipofection increases exponentially with membrane charge density to a plateau, where delivery efficiency of the lamellar phase competes with that of the hexagonal phase [47]. Other studies have suggested that increased membrane fluidity (decreased bending rigidity) enhances lipofection efficiency [52, 53].

DNA may dissociate from lipoplexes during endosomal escape or intact lipoplexes may be released into the cytoplasm [54]. Direct microinjection of lipoplexes into either the cytoplasm or the nucleus results in efficient complex dissociation, so intracellular release of DNA is probably not a limiting step for lipofection [55]. Interestingly, microinjection of lipoplexes or naked DNA into the cytoplasm produces significantly less gene expression than endocytosis-mediated lipofection. Endosomes may play a role in lipofection by transporting the lipoplexes close to the cell nucleus [3].

Transfer of DNA into the nucleus is a very inefficient process. Particles with diameters of up to around 40 nm are able to enter the nucleus by active transport through the nuclear pores [56], but most genes delivered by lipoplexes are much larger than this. Shorter DNA molecules are correlated with increased lipofection efficiency [28]. Dividing cell lines have an alternative nuclear access pathway, as the nuclear envelope fragments during mitosis. Transgene expression is enhanced immediately following mitosis [57], but the duration of the mitosis phase is only around 1 h in a typical cell cycle of 24 h. DNA located in the cytoplasm is degraded by nucleases, with a half-life of approximately 90 min [58].

In general, increasing the lipoplex dose administered improves lipofection efficiency. However, this approach is limited by the toxicity thresholds of cationic lipids [59–61]. Efforts to develop less-toxic lipid formulations for both *in vitro* and *in vivo* applications are in progress.

In addition to the factors described here, lipofection efficiency also depends on the interrelations between cationic/helper lipid formulation, DNA sequence and target cell type. The reasons behind these effects are poorly understood.

### 3.2.3.2 *In Vivo*

The ultimate aim of research in the field of lipoplexes is to achieve effective systemic delivery of therapeutic genes to humans. Unfortunately, lipofection efficiency *in vivo* is much lower than *in vitro*, due to a number of extracellular barriers. Intravenous injection of lipoplexes is followed by unfavorable interactions with blood components and by highly restricted uptake to tissues.

Exposure of cationic lipoplexes to blood serum dramatically inhibits *in vitro* DNA delivery in some systems [62, 63], but not others [64]. Serum does not displace DNA from lipoplexes, but it reverses the  $\zeta$  potential of the complexes due to anionic serum proteins binding to lipoplex surfaces [63]. Incubation with low concentrations of serum can promote bridging and extensive lipoplex aggregation, which is correlated with reduced *in vivo* lipofection efficiency. Incubation with

high concentrations of serum yields homogenous coating of serum proteins and sterically stabilizes lipoplex size [65].

Inclusion of inverse conical helper lipids in lipoplexes significantly reduces their *in vivo* lipofection efficiency [66]. It has been reported that lipoplex structures of this type disintegrate in serum, with penetration and binding of serum proteins to all cationic membranes, inside and out [65]. This both exposes DNA to nucleases in the blood and has detrimental implications for intracellular processing. Even in less extreme cases, serum can interfere with mixture between lipoplexes and anionic liposomes, an analog of endosomal membranes [63]. In agreement, lipoplexes incorporating serum have been shown to fail to escape from endosomes [64].

Long-term incubation (above 30 min) of lipoplexes in blood causes partial degradation of DNA, due to imperfect protection from nucleases [67]. However, this may not be a significant effect, as more than 97% of lipoplexes have been cleared from the blood within 5 min of intravenous injection into mice. At this time the majority of lipoplexes are associated with the lungs, probably partially due to entrapment in the extensive pulmonary microvasculature. Later a large fraction of lung lipoplexes relocates to the liver [67].

Lipoplex particles are, in general, too large to extravasate from the bloodstream. Uptake and expression of lipoplexes in the lungs and most other organs is predominantly by capillary endothelial cells [68]. Uptake of lipoplexes in the liver and spleen is primarily due to elimination of foreign particles by macrophages, which does not lead to significant transgene expression [68]. Some success has been reported in lipofection of tumor tissue, as tumors have a permeable endothelial barrier [69, 70]. An ability to extravasate under these conditions has been attributed to a specific lipoplex structure, bilamellar invaginated vesicles, which yields relatively small and very flexible particles.

Intravenous administration of lipoplexes is an excellent technique for gene delivery to endothelial cells [71]. Efficient targeting of other cell types requires modification of lipoplexes. One current direction of research is development of “stealth lipoplexes”, an analog of well-known stealth liposomes. Lipoplexes are coated with the biocompatible polymer polyethylene glycol (PEG), with the possible addition of a targeting ligand. PEGylation provides steric protection from interactions with serum proteins and reduces nonspecific uptake by the lung endothelial cells, so it greatly extends the residence time of lipoplexes in the circulation [72]. However, PEGylation has been shown to strongly inhibit lipofection in cell culture, due to stabilization of the lamellar phase and preclusion of endosomal escape, unless the PEG molecules desorb [73, 74]. This approach is promising, but needs further work.

### 3.3 ODN Lipoplexes

Antisense ODN, short single-strand DNA molecules, are designed to target and bind a specific messenger RNA, blocking gene expression. Antisense design is

not straightforward, but one ODN drug has been approved and many others are in clinical trials [75]. Cationic lipid-mediated delivery of ODN increases antisense activity by several orders of magnitude [76, 77].

The structure of ODN lipoplexes is similar to that of DNA lipoplexes; both lamellar [78] and inverse hexagonal [79] phases have been observed. In ODN lamellar lipoplexes, however, there is no evidence of ordering within the ODN monolayers. As ODN molecules are relatively short and flexible, they probably orient randomly between the cationic membranes [80].

The thickness of ODN monolayers in the lamellar phase has been measured as around 1.2 nm [80]. This suggests that there is insufficient room for a hydration layer between ODN molecules and cationic membranes as is seen in DNA lipoplexes. In agreement, ODN molecules neutralize cationic lipid charges more efficiently than DNA does, implying that ODN is located in closer contact with the membrane [81, 14]. We consider complete dehydration of ODN unlikely, so we speculate that ODN may adopt a different conformation between cationic mem-

**Fig. 3.6.** (A) Cryo-TEM image of a DOTAP/ODN lipoplex with excess lipid. A condensed multilamellar phase is seen. (B) Schematic representation of the ODN-lipid lamellar phase. The interlamellar water gap is denoted by  $w$ . We speculate that ODN molecule side-groups may penetrate into the lipid bilayer.

branes than in aqueous solution. Instead of a helical backbone with side-groups facing inwards to maximize base-stacking interactions, side-groups may point outwards, leaving a central water tube. Bases would then penetrate into the head-group area of the cationic membranes. Figure 3.6(A) shows an example of a condensed lamellar lipoplex imaged at our laboratory. Figure 3.6(B) shows our suggested model of lamellar structure with ODN bases intercalated between lipid head groups. This hypothesis needs further investigation.

ODN lipoplexes enter cells by endocytosis [77, 82] as DNA lipoplexes do. However, the nuclear membrane is not a major barrier for ODN molecules. After microinjection into the cell, ODN is found to preferentially locate in the nucleus [83], with the rate of uptake inversely proportional to molecular size [84]. ODN is delivered to the nucleus by active transport through nuclear pores [85].

### 3.4

#### siRNA Lipoplexes

siRNA, short double-strand RNA molecules, has recently become a popular tool for gene silencing [86]. Successful cationic lipid-mediated delivery of siRNA has been reported [87], but as yet little research has focused on the properties of siRNA lipoplexes. siRNA lipoplexes would be expected to be similar to DNA lipoplexes, but an early report suggests that the effect of lipoplex size may be less critical for siRNA delivery than for DNA delivery [88].

Nuclear entry is probably not a significant barrier for siRNA lipofection, as RNA interference activity seems to be primarily located in the cytoplasm [86]. Further research into the structure and function of siRNA lipoplexes is needed in order to optimize siRNA delivery and to facilitate the development of this exciting field.

#### Acknowledgments

Cryo-TEM work was performed at the Hannah and George Krumholz Laboratory for Advanced Microscopy at the Technion, part of the Technion Project on Complex Fluids, in collaboration with Y. Talmon, Y. Barenholz and D. Hirsch-Lerner, funded by an Israel Science Foundation grant. Thanks to Y. Talmon for help in editing this manuscript.

# DNA–Chitosan Nanoparticles for Gene Therapy: Current Knowledge and Future Trends

*Julio C. Fernandes, Marcio José Tiera and Françoise M. Winnik*

### 4.1

#### Introduction

Chitosan is a polysaccharide usually obtained from deacetylation of chitin, which after cellulose is the second most abundant natural biopolymer found in nature. It may be extracted from various sources, particularly from exoskeletons of arthropods such as crustaceans, fungi, insects, annelids, mollusks, coelenterates, etc. [1, 2].

Approximately 1000 clinical trials are listed on the *Journal of Gene Medicine's* online “Gene Therapy Clinical Trials Worldwide” and more than 25% of these use nonviral vectors. This broad category encompasses a variety of technologies, essentially all of which involve complexing and sometimes condensing DNA with an agent that allows it to nonspecifically enter a cell, either by membrane fusion, endocytosis or a membrane-disrupting event. Chitosan is positively charged [1, 2] and thus can be complexed with DNA. It does not need sonication or organic solvents for its preparation, therefore minimizing possible damage to DNA during complexation.

The goal of this chapter is to introduce the reader to chitosan as a DNA carrier, as well as different variables and strategies to improve cellular transfection. The first two sections present the fundamental properties of chitosan as well as how different parameters related to the nonmodified structure affect the transfection efficiency. The third section provides the reader with an understanding of the multiple barriers that must be solved prior to practical use, discussing all the approaches employed and their limitations. The following sections present different procedures to obtain nano- and microparticles for gene therapy, and the potential clinical applications of chitosan–DNA polyplexes.

**Fig. 4.1.** Chemical structure of chitin and chitosan, and the deacetylation process to produce the highly deacetylated product. The commonly used numbering for the carbon atoms is shown in the 2-amino-2-deoxy-D-glucopyranose ring.

## 4.2

### Chitosan as a Carrier for Gene Therapy

#### 4.2.1

##### Chitosan Chemistry

The structures of chitin and chitosan correspond to those of poly[ $\beta(1 \rightarrow 4)$ -2-acetamido-2-deoxy-D-glucopyranose] and poly[ $\beta(1 \rightarrow 4)$ -2-amino-2-deoxy-D-glucopyranose], respectively (Fig. 4.1). Chitosan is mainly manufactured from crustaceans (crab, krill and crayfish), primarily because a large amount of the crustacean exoskeleton is available as a byproduct of food processing. In general, the isolation of chitin from crustacean shell waste consists of three basic steps: demineralization (calcium carbonate and calcium phosphate separation), deproteinization (protein separation) and decolorization (removal of pigments). These three steps are the standard procedure for chitin production [3]. Chitosan is obtained after hydrolysis of the acetamide groups of chitin. However, both units are commonly found in the commercialized samples, since chitosans having high degree of deacetylation (DA > 99%) are obtained only through successive hydrolysis with strong bases such as KOH and NaOH, and the degree of deacetylation is strongly dependent of the alkali concentration and temperature (Fig. 4.1) [4]. The source of chitin and the deacetylation process can dramatically change the properties of the final product and deacetylation in alkaline medium leads to depolymerization [5, 6]. However, it has been recently reported that chitin extracted from squid pens can be hydrolyzed under conditions that allow us to obtain chitosans of high molecular weight [7]. The homopolymer is a weak base with a  $pK_a$  value of the D-glucosamine residue of about 6.2–7.0, and is therefore insoluble at neutral and alkaline pH values. In acidic media the amine groups will be positively charged, conferring a high charge density to the polysaccharide. As in all polyelectrolytes, the dissociation constant of chitosan is not constant, but depends on the degree of dissociation at

which it is determined. The  $pK_a$  value can be calculated using Katchalsky's equation [2]:

$$pK_a = \text{pH} + \log[(1 - \alpha)/\alpha] = pK_0 - \varepsilon\Delta\psi(\alpha)/kT$$

where  $\Delta\psi$  is the difference in electrostatic potential between the surface of the polyion and the reference,  $\alpha$  is the degree of dissociation,  $kT$  is Boltzman's constant and  $\varepsilon$  is the electron charge. Extrapolation of the  $pK_a$  values to  $\alpha = 1$ , where the polymer is uncharged and hence the electrostatic potential becomes zero, makes it possible for the value of the intrinsic dissociation constant of the ionizable groups,  $pK_0$ , to be determined. The value obtained does not depend of the degree of *N*-acetylation, whereas the  $pK_a$  value is highly dependent on this parameter, since the electrostatic potential will vary depending on the amount of the free amino groups. The  $pK_0$  value is called the intrinsic  $pK_a$  of the chitosan. However, chitosans of low molecular weight having degrees of deacetylation higher than 0.4 are also easily soluble in weakly acidic solvents such as acetic acid and formic acid [8]. The physicochemical behavior in aqueous solution is highly dependent of the pH and degree of acetylation, and has received more attention only recently. Berth et al., working on chitosans from 95 to 175 kDa, have recently determined the radius of gyration of chitosan ( $R_G$ ) [9, 10]. The  $R_G$  is an alternative measure of the size of the polymer chain and it can be measured by light scattering measurements.  $R_G$  expresses the square mean radius of each one of the elements of the chain measured from its center of gravity. The study established the relationship between the molecular weight and  $R_G$  of chitosan in aqueous solution, and the author indicated that chitosan behaved more like a Gaussian coil instead of the worm-like chain model found in common polyelectrolytes. At the same time the presence of *N*-acetyl groups on the chitosan backbone imparts hydrophobic properties. Schatz et al. [11] have studied a homogeneous series of chitosans with different degrees of acetylation and almost the same degree of polymerization in ammonium acetate buffer. Their results indicate that the aqueous solution behavior depends only on the degree of acetylation. Three distinct domains of degree of acetylation were defined and correlated to the different behaviors of chitosans: (a) a polyelectrolyte domain for DA < 20%, (b) a transition domain for DA = 20–50% where chitosan loses its hydrophilicity and (iii) a hydrophobic domain for DA > 50% where polymer associations can arise. Conformations of chitosan chains varying from 160 to 270 kDa were studied by the calculations of the persistence lengths ( $L_p$ ). The average value was found to be close to 5 nm, in agreement with the wormlike chain model, but no significant variation of  $L_p$  with the degree of acetylation was noticed. Pa et al. [12] have also reported that the particle sizes of chitosan molecules in dilute acetic acid/water solutions increased with decreasing pH. Light scattering studies data also demonstrated that the second virial coefficient ( $A_2$ ) increased with decreasing pH, suggesting that the solubility of chitosan in water increased with increasing acetic acid concentration. Signini et al. [13] have also shown that acid-free aqueous solutions of chitosan hydrochloride

of variable ionic strengths ( $0.06 \leq \mu \leq 0.3 \text{ M}$ ) are free of aggregation as evaluated by the values of the Huggins constants ( $0.31 \leq k \leq 0.63$ ).

As with other polysaccharides, the biodegradation and biocompatibility are important properties of chitosan, making it an attractive polymer for a variety of biomedical and pharmaceutical applications. In addition to the degradation by chitinases [14], chitosanases [15], papain [16–19] and other proteases [20], partially acetylated chitosan may be also degraded by lysozymes of the human serum [21], by oxidative/reductive depolymerization [22] and by acid hydrolysis reactions [23]. In the acid hydrolysis the protonation of the glycosidic oxygen is recognized as the first step of the mechanism, which leads to formation of a cyclic carbonium–oxonium ion, yielding the reducing sugar end group after the addition of water [24, 25]. In addition to enzymatic and acid hydrolysis, alkaline treatment with ultrasonication can be used to obtain either chitosan of decreasing molecular weight [26] or oligomers having a few glucosamine units [27].

#### 4.2.2

##### **General Strategies for Chitosan Modification**

In the chitosan structure, two groups are particularly susceptible to react through nucleophilic attack, i.e. the free amine and/or acetamide groups and the hydroxyl groups linked to the glucopyranose ring. The hydroxyl groups can be modified by substitution of the hydrogen atoms, but their reactivities are smaller than that of the amino group. Various procedures targeting the hydroxyl groups employ a sequence of protection/deprotection reactions aimed at obtaining derivatives with a well-defined structure [28]. However, under appropriate conditions, a variety of other reactions can be easily conducted to selectively modify the free amine groups. The literature presents a wide range of procedures to target the amine group, aiming to improve the properties of chitosan for a particular purpose. The modifications include those aiming at the separation technologies of chiral molecules [29], recovery of metals [30, 31], antimicrobial activity [32], antitumoral carriers [33], biomedical applications [34, 35] and vectors for gene therapy [36–39] (Figs. 4.2 and 4.3). Kumar et al. [40] and Kurita [41] have recently reviewed the procedures for the modification of chitosan, and those of major importance are summarized in Tables 4.1 and 4.2.

#### 4.2.3

##### **Chitosan–DNA interactions: Transfection Efficacy of Unmodified Chitosan**

The first report on chitosan as a possible carrier for gene therapy was made by Mumper et al. in 1995 [125]. Since then it has been reported that besides its immunogenicity, chitosan molecules condense efficiently with DNA to form tight polyplexes avoiding degradation by DNases [126]. However, before using chitosan–DNA nanoparticles *in vivo*, one must study their interaction and cell behavior. Since macrophages play an important role in inflammatory processes, Chellat et al. [127] have investigated the effects of chitosan–DNA nanoparticles on the hu-

**Fig. 4.3.** Chemical structure of *O*-chitosan derivatives obtained either by regioselective substitution or by controlling the reaction conditions.

man THP-1 cell line. Cytokine [tumor necrosis factor- $\alpha$ , and interleukin (IL)-1b, IL-6 and IL-10] and metalloproteinase (MMP-2 and MMP-9) release as well as their inhibitors (TIMP-1 and TIMP-2) were assessed after incubation with different amounts of nanoparticles. Cytokine secretion was not detected even in the presence of high amounts of nanoparticles. On the contrary, the secretion of MMP-9 in cell supernatants increased significantly after 24 and 48 h in comparison to non-treated cells. MMP-2 secretion was augmented only after 48 h for the highest con-

centrations of nanoparticles ( $10$  and  $20$  mg mL<sup>-1</sup> DNA content). The authors have concluded that exposure of THP-1 macrophages to chitosan–DNA nanoparticles did not induce the release of proinflammatory cytokines.

The chitosan–DNA interaction is driven mainly by the electrostatic interaction between the amino groups of chitosan and the charged phosphate groups of DNA [35]. In a slightly acid medium this interaction is fully favored since almost all amine groups will be charged. MacLaughlin et al. [128] have studied the interaction of oligomeric chitosans (8–102 kDa) with plasmids containing a cytomegalovirus (CMV) promoter and a chloramphenicol acetyltransferase. On the basis of transmission electron microscopy they have observed that chitosan of 8 kDa condensed plasmids into toroids and rod-shaped particles. Using the microcalorimetry technique, the interaction could be followed and the exothermic heat output was indicated to provide a significant contribution to the free energy of the interaction. The authors have also observed a small endothermic peak at the ratio of neutrality, which was attributed to an entropic contribution to the free energy. The sizes of the particles were estimated to be 66 nm by light scattering measurements. The sizes of the particles were also shown to be dependent on the chitosan molecular weight and plasmid concentration. Complexes of a 1:6 (+/–) charge ratio showed a decrease in size as the molecular weight of the chitosan decreased and an increase in size was observed by increasing the plasmid concentration [38]. Recently, Danielsen et al. [129], employing atomic force microscopy (AFM), have confirmed that polyplexes made from mixing plasmid DNA (pDNA) with chitosan from 10 to 200 kDa yielded a blend of toroids and rods (Fig. 4.4). The ratios between the fractions of toroids and rods were observed to decrease with increasing degree of acetylation (DA) of the chitosan, indicating that the charge density of chitosan, proportional

**Fig. 4.4.** Image galleries of toroidal and rod-like ensembles for complexes obtained using chitosan with various degrees of acetylation (DA). The chitosans ( $^*DA = 0.01$ ,  $M_n = 162$  kDa) (A) and ( $^*DA = 0.15$ ,  $M_n = 196$  kDa) (B)

were used to form complexes with pDNA pBR322. cDNA  $4$   $\mu$ g mL<sup>-1</sup> and average charge ratios was adjusted to 1. (Adapted from Ref. [129], with permission.)

to  $(1 - DA)$ , is important in determining the shape of the compacted DNA. The amount of chitosan required to fully compact DNA into well-defined toroidal and rod-like structures was found to be strongly dependent on the chitosan molecular weight, and thus its total charge. A higher charge ratio (+/–) was needed for the shorter chitosans, showing that an increased concentration of the low degree of polymerization (DP) chitosan could compensate for the reduced interaction strength of the individual ligands with DNA. Liu et al. [130] have showed that the charge density is an important parameter by studying the formation of polyplexes at different pH values. Working with 99% deacetylated 5-kDa chitosan their results indicated that upon interacting with chitosan, the DNA molecules retained a B conformation and the binding affinity of chitosan to DNA was dependent on the pH of media. At pH 5.5, highly charged chitosan had a strong binding affinity with DNA; in pH 12.0 medium, only weak interactions existed. However, the authors have reported that no typical toroidal patterns were observed, which was attributed to the strong compaction of DNA caused by highly charged chitosan.

In a recent report, Kiang et al. have showed that in fact the electrostatic interaction with the chitosan chain is very important to efficiently bind DNA. They reported that the charge (+/–) ratio to achieve complete DNA complexation increases for chitosans having smaller degrees of deacetylation, which in turn affects the stabilization of the particles, affecting the transfection *in vitro* and *in vivo* [131]. However, other interactions such as hydrogen bonding and hydrophobic interactions cannot be neglected since hydrophobic interactions have also been detected in aqueous solutions of the polyelectrolyte itself, leading to formation of polymer chain aggregates [132, 133]. Therefore, it is reasonable consider that the formation of polyplexes may result from a combined electrostatic/hydrophobic driving force leading to the packing of chitosan–DNA polyplexes.

Various parameters such as molecular weight, charge (+/–) ratio, pH and particle size have been shown to affect the transfection efficiency. Koping Hoggard et al. [134, 135] prepared monodisperse oligomers of chitosan that were fully deacetylated (6, 8, 10, 12, 14 and 24mers) with very low polydispersity and ultrapure chitosan (UPC) of 154 kDa. Depending on the chain length of chitosan, charge ratio and buffer properties, chitosan–DNA complexes appeared as different physical shapes such as coils, soluble globules, soluble aggregates, precipitated globules and precipitated aggregates. It was shown that only UPC and 24mer chitosans could form stable complexes with DNA, and the 24mer was more efficient in mediating gene expression *in vitro* and *in vivo* than was UPC. Sato et al. [136] have also found that molecular mass of chitosan, pH of medium and serum concentration are very important to promote transfection efficiency. Working on chitosan samples whose average molecular weights were 15, 52 and 100 kDa, they found that transfection efficiency mediated by chitosan of 100 kDa was less than that by chitosan of 15 and 52 kDa, but clearly indicating that a dependence on cell lines was also observed. However, Bozkir et al. [137] have suggested that formulations with high-molecular-weight (HMW) chitosan can be an effective nonviral gene vector in animal studies. The authors have studied the influence of two different prep-

aration methods, i.e. solvent evaporation and complex coacervation method, on the encapsulation of a model plasmid with chitosan. Protection of encapsulated pDNA from nuclease attack offered by these nanoparticles was confirmed by assessing degradation in the presence of DNase I and the transformation of the plasmids with incubated nanoparticles was examined by the  $\beta$ -galactosidase assay. The results obtained showed that pDNA existed as a mixture of both supercoiled (84.2%) and open circular (15.8%) forms, and that the formulation prepared by the complex coacervation method effectively protected the supercoiled form of pDNA. There were no significant changes in nanoparticle size and  $\zeta$  potential values at pH 5.5 for a period of 3 months, but differences in particle sizes were observed after lyophilization with a cryoprotective agent. The efficiency of nanoparticle-mediated transformation to *Escherichia coli* cells was significantly higher than naked DNA or poly-L-lysine (PLL)–DNA polycation complexes. The transfection studies were performed in COS-7 cells. A 3-fold increase in gene expression was produced by nanoparticles as compared to the same amount of naked pDNA.

The charge (+/–) ratio of the polyplexes has also been indicated as important to effectively proceed with the transfection process. Assuming that DNA wrapped in inter-polyelectrolyte complexes is well protected from DNase degradation, the following step is then to reach its target, i.e. the cell. Although the mechanism of internalization contact and crossing of the cell membrane is not fully understood, it is well accepted that the polyelectrolyte complex chitosan–DNA, exhibiting a net positive charge, binds to the negatively charged cell membrane [138]. Therefore, a net positive charge is fundamental in the process and the level of transfection is shown to increase with the charge (+/–) ratio, reaching a maximum and decreasing at higher stoichiometries. It has been reported by Ishi et al. that the level of transfection with plasmid–chitosan complexes was found to be highest when the charge (+/–) ratio was between 3 and 5, and transfection medium contained 10% serum at pH 7.0 [139]. Lee et al. using low-molecular weight (LMW) chitosan found the most efficient transfection was obtained at a charge (+/–) ratio 3:1 [140], while MacLaughlin et al. have reported that the highest level of expression was obtained at a ratio of 2:1 complex made with chitosan 102 kDa [128]. However, it must be considered that the transfection efficiency of chitosan–DNA nanoparticles is also cell-type dependent and the chitosan:plasmid ratio must be controlled to obtain the appropriate particle size when aiming to maximize the transfection [141]. The particle size is recognized as a key parameter since it may affect blood circulation time and cellular uptake. It has been reported that polycation–DNA gene delivery systems mostly enter the cell by endocytosis or pinocytosis, having a size requirement of less than 100 nm [141, 142]. However, the experimental results available are contradictory and reasonable transfection efficiencies were reported for particles having sizes varying from 100 nm [143] to 2.0  $\mu$ m [144]. Recently, on the basis of AFM images, Liu et al. have proposed that chitosan–DNA complexes in the range of several hundreds of nanometers are transferred into the cell mainly via endocytosis [145].

After internalization, the following crucial step in gene delivery with cationic

polymers is the escape of the polymer–DNA complexes from the endosome. The inefficient release of the DNA–polymer complex from endocytic vesicles into the cytoplasm is indicated as one of the primary causes of poor gene deliver. In this respect the approach is to enhance endosomal escape by using cationic polymers with a  $pK_a$  slightly below the physiological pH. The endosomal escape is believed take place through the mechanism named the “proton sponge”, and the importance of this step has been recognized and reviewed recently by Cho et al. [146]. This hypothesis has been proposed to explain the high transfection activity of polyethyleneimine (PEI) [147]. It has been demonstrated that PEI has a buffering capacity over a broad pH range; hence, once PEI-based polyplexes are present in the endosome, they can absorb protons that are pumped into this organelle. Due to repulsion between the protonated amine groups, swelling of the polymer occurs. Moreover, to prevent the build up of a charge gradient due to the influx of protons, an influx of  $Cl^-$  ions also occurs. The influx of both protons and  $Cl^-$  ions increases the osmolarity of the endosome and causes water absorption. The combination of swelling of the polymer and osmotic swelling of the endosome leads to a destabilization of the endosome and release of its contents into the cytoplasm [147]. Subsequently, transport to and uptake in the nucleus as well as dissociation of the polyplex has to occur before transcription of the DNA takes place. However, Funhoff et al., working with a series of synthetic polymers [148], indicated that endosomal escape is not always enhanced by polymer buffering at low pH. In this respect, research focusing on chitosan is scarce, but it is believed that protonation of the free amine groups of chitosan must contribute to the unpacking of the DNA, delivering it in the cytoplasm. Ishi et al. [139] have indicated that when the transfection is performed at pH 6.5 chitosan cannot release from the endosome due to the fact that chitosan is drastically protonated when the pH of medium is altered from pH 7 to 6. Recently, to enhance the transfection efficiency of chitosan, water-soluble chitosan (WSC) was coupled with urocanic acid (UA) and the transfection efficiency was investigated [149]. The authors reported that the transfection efficiency of chitosan into 293T cells was greatly enhanced after coupling with UA and increased with an increase of UA content in the urocanic acid-modified chitosan. Kiang et al. [150] have used poly(propyl acrylic acid) (PPAA) as an approach to enhance the release of endocytosed drugs into the cytoplasmic compartment of the cell. The release of pDNA from the endosomal compartment was enhanced by incorporating this polymer in chitosan nanoparticles. *In vitro* transfection studies confirmed that the incorporation of PPAA into the chitosan–DNA nanoparticles enhanced gene expression in both HEK 293 and HeLa cells compared to chitosan nanoparticles alone. The dose and time at which PPAA was incorporated during the complex formation affected the release of DNA and transfection efficiency. The authors have suggested that the PPAA triggered membrane disruption resulting in the release of DNA from the endosomal compartment.

Therefore neither high cellular uptake, membrane destabilizing activity, endosomal escape nor nuclear localization alone is adequate for high transfection. More studies aiming at a better understanding of these steps as well how the released DNA is expressed will be necessary to improve the transfection efficacy.

**Fig. 4.5.** Schematic gene therapy mechanism. (A) Bioavailability and extracellular trafficking, and gene-vector complexation (1); (B) internalization and endocytosis by the cell membrane (2); (C) intracellular trafficking and uptake of the vector complex into intracellular endolysosome: (3) DNA–chitosan release from the endosome into the cytoplasm and (4) internalization of the complex into the nucleus; (D) gene expression: (5) DNA dissociation from the vector, (6) mRNA transcription from the gene and (7) protein translation from mRNA. The protein can be secreted out of the cell, released into the cytoplasm or fixed onto the membrane. (Adapted from Ref. [251].)

### 4.3

#### Modified Chitosans: Strategies to Improve the Transfection Efficacy

##### 4.3.1

##### The Effects of Charge Density/Solubility and Degree of Acetylation

Many strategies have been employed to improve the transfection efficiency taking into account the biological steps involved in gene delivery (Fig. 4.5). The literature on this subject shows that the main method is the modification of chitosan structure aiming at providing the necessary capabilities to overcome the barriers previously mentioned, i.e. decreasing the interaction with blood components, vascular endothelial cells and uptake by the reticuloendothelial system (RES), avoiding the degradation of therapeutic DNA by serum nucleases, improving the particle size, internalization, endosomal escape and nuclear import. The attachment of a group or a polymer chain may be either at the main-chain or at the preformed nanoparticles.

The simplest modification in the chitosan structure is to vary the degree of acetylation. This is expected to affect the chitosan–DNA interactions since the charge density is decreased, i.e. the number amino groups is decreased, giving the polymer chain an increased hydrophobic character. Kiang et al. have recently studied the effect of the degree of chitosan deacetylation on the efficiency of gene transfection [131]. They concluded that a decreased degree of deacetylation resulted in a decrease in overall luciferase expression levels in HEK 293, HeLa and SW756 cells due to particle destabilization in the presence of serum proteins. The degree of deacetylation was shown to affect DNA binding, release and gene transfection efficiency *in vitro* and *in vivo*. Various workers aiming to increase the transfection have also investigated trimethylation (quaternization) of the amino groups [81, 84, 151, 152]. The advantage of trimethylated chitosans arises from their higher solubility when compared with the nonmodified polymer. Trimethyl chitosan (TMO) derivatives of 40% (TMO-40) and 50% (TMO-50) degrees of quaternization were synthesized, and examined for their transfection efficiencies in two cell lines: COS-1 and Caco-2 [81, 84]. Results showed that quaternized chitosan oligomers were able to condense DNA and form complexes with a size ranging from 200 to 500 nm. Chitoplexes were shown to transfect COS-1 cells to a lesser extent than DOTAP (*N*-[1-(2,3-dioleoyloxy)propyl]-*N,N,N*-trimethylammonium sulfate)–DNA lipoplexes. Both DOTAP–DNA lipoplexes and chitoplexes resulted in lower transfection efficiency in Caco-2 cell cultures than in COS-1 cells; however, quaternized chitosan oligomers proved to be superior to DOTAP.

#### 4.3.2

##### **Improving the Physicochemical Characteristics of the Nanoparticulate Systems: Solubility, Aggregation and RES Uptake**

After administration, the DNA must be capable of surviving in the bloodstream for a significant length of time so that it can reach the target tissue. Therefore, circulation time is a fundamental factor for reaching the target cells in successful gene delivery, especially in cases of intravenous injection [153]. Nanoparticles will usually be taken up by the liver, spleen and other parts of the RES depending on their surface characteristics. Particles with more hydrophobic surfaces will preferentially be taken up by the liver, followed by the spleen and lungs [154]. Cationic polymer–DNA complexes also show short plasma circulation times with rapid hepatic uptake and accumulation or deposition in organs such as the skin and intestine. Aggregation of cationic particles, such as cationic polymer–DNA complexes, can occur following interaction with blood components. Albumin is known to bind to cationic particles. The binding of albumin may be enough to cause aggregation of particles in the bloodstream, by reducing their  $\zeta$  potential and, hence, reducing the charge repulsion between particles. Extensive aggregation could lead to physical deposition in the capillary bed. Therefore, it is necessary to prevent unwanted interactions between particles and the dynamic environment of the blood circulation by introducing hydrophilic surfaces to the cationic particles. In the absence of a hydrophilic surface, opsonization prepares the particles for uptake by fixed macro-

phages of the mononuclear phagocytic system (MPS). The MPS is a collection of phagocytic cells that are present in tissue of the RES and are collectively responsible for clearance of particles from the circulation. The activity of RES is not to clear charged particles. In practice, typically 80–90% of hydrophobic particles are opsonized and taken up by fixed macrophages of the liver and spleen, often within a few minutes of intravenous administration. Opsonization represents a major biological barrier to the delivery of DNA using condensed particles. Therefore, the modification of chitosan by introducing hydrophilic polymers may create a “cloud” of hydrophilic chains at the particle surface, which may avoid interactions with proteins and phagocytes, thus prolonging the circulation time in the bloodstream [154].

Many hydrophilic groups can be attached to the chitosan backbone or to preformed nanoparticles to improve solubility in water [43–47]. Sashiva et al. [43] have used the Michael reaction of chitosan in water containing acetic acid with various acryl reagents. The modification was controlled by varying the temperature, reaction time and amount of the acryl reagent, and has provided chitosan derivatives showing good biodegradation characteristics. Nanospheres synthesized by salt-induced complex coacervation of cDNA, and gelatin and chitosan were evaluated as gene delivery vehicles [155]. These nanospheres were subsequently modified by introducing PEG<sub>5000</sub> chains. The attachment of these groups avoided the aggregation of particles during lyophilization and storage for 1 month did not alter the properties of the nanospheres. Chitosan–DNA nanospheres were effective in transfecting HEK 293 cells, but not HeLa cells, and the transfection efficiency was not affected by PEG derivatization. Poly(vinyl pyrrolidone) was also grafted on galactosylated chitosan (GCPVP) and showed improved physicochemical properties over the unmodified chitosan [156]. The binding strength of GCPVP 10K–DNA was superior to that of GCPVP 50K–DNA, which was attributable to its higher flexibility due to the smaller size. However, DNase I protection of GCPVP 10K–DNA was inferior to that of GCPVP 50K–DNA. The DNA-binding properties mainly depended on the molecular weight of chitosan and composition of PVP.

#### 4.3.3

##### **Targeting Mediated by Cell Surface Receptors**

It is well known that some kinds of saccharides play important roles in biological recognition on cellular surfaces. Liver parenchymal cells exclusively express large numbers of asialoglycoprotein receptors that strongly bind with galactose [157, 158]. The asialoglycoprotein receptor (ASGP-R) is known to be present only on hepatocytes at a high density of 500 000 receptors per cell and retained on several human hepatoma cell lines [159, 160]. This characteristic may be explored in many ways to target the cells. In a recent study on the biodegradability it was demonstrated that chitosan modification with gluconic acid enhanced susceptibility to lysozyme [161]. D-Gluconic acid is a hydrophilic sugar derivative that may be covalently attached to the chitosan backbone, providing multifunctional properties. As a consequence, by simple modification with gluconic acid and acetic anhydride, it is possible to control the aqueous solubility. The ASGP-R system cannot only bind

galactose-containing ligands, but can also internalize them within membrane-bound vesicles or endosomes [162]. Once a ligand binds to the galactose receptor, the ligand–receptor complex is rapidly internalized and the receptor recycles back to the surface [163, 164], allowing high binding capacity and efficient uptake of galactosylated ligands by liver cells. Murata et al. have suggested that the utilization of a prequaternized and subsequently galactosylated chitosan could be used to transfect cells HepG2 cells [164]. Park et al. have used this specificity to synthesize galactosylated chitosan (GC) in an attempt to transfect HepG2 human hepatoblastoma cells and HeLa human cervix epithelial carcinoma cells [165–167]. The particle sizes for the DNA complexes using GC-13K and GC-18K show a tendency to decrease with increasing charge ratio of GC to DNA, and had minimum values around 240 and 100 nm, respectively, at the charge ratio of 5. The cytotoxicity study showed that GC prepared by water-soluble chitosan had no cytotoxic effects on cells. The results showed that the transfection efficiency into HepG2, which has ASGP-Rs, was higher than that into HeLa without ASGP-Rs. The attachment of PEG to GC (GPC) was also performed in other work by the same group with the aim to improve the stability in water and enhance the cell permeability [168]. In this case it was reported that GCP–DNA complexes were only transfected into HepG2 having ASGP-Rs, indicative of a specific interaction of ASGP-Rs on cells and galactose ligands on GCP. The transfection with GCP–DNA complexes was subsequently investigated by confocal laser scanning microscopy using primary hepatocytes and HepG2 human hepatocarcinoma cell line [169]. The more efficient transfection of the complex occurred in the human-derived HepG2 cells than in primary hepatocytes. Erbacher et al. [170] synthesized lactosylated-modified chitosan derivatives (having various degrees of substitution) and tested their transfection efficiencies in many cell lines. The *in vitro* transfection was found to be cell-type dependent. HeLa cells were efficiently transfected by this modified carrier even in the presence of 10% serum, but neither chitosan nor lactosylated chitosans have been able to transfect HepG2 and BNL CL2 cells. Gao et al. [171] have used highly purified LMW chitosan (LMWC) to attach lactobionic acid (LA) bearing a galactose group. A series of galactosylated LMWC (gal-LMWC) having different group contents was obtained. The transfection efficiency was evaluated in human hepatocellular carcinoma cells (HepG2), L-02, SMMC-7721 and human cervix adenocarcinoma (HeLa) cell lines *in vitro*. The transfection of the gal-LMWC–DNA complex showed a very selective transfection to hepatocytes and the efficiency was shown to increase with the improvement of the degree of galactosylation.

Transferrin is another interesting targeting ligand to attach to the chitosan backbone. Transferrin receptors are found on the surface of most proliferating cells, and, in elevated numbers, on erythroblasts and on many tumors where they have been linked to drug resistance [172]. Leong et al. have reported the conjugation of PEG to preformed nanoparticles of gelatin and chitosan using different procedures [141, 155]. Transferrin was bonded to nanospheres utilizing a sulfhydryl derivative obtained from the protein reaction with 2-iminothyalone, while PEG conjugation was performed utilizing PEG derivatives containing the succinimidyl attached to

the end of the backbone. For the chitosan carrier, the plain nanospheres were reported as effective as the pegylated chitosan-modified nanospheres. However, the conjugation of PEG to the surface of the nanospheres minimized any aggregation in solution [155]. In a subsequent work, Mao et al. attached transferrin to the nanospheres employing two different procedures – periodate oxidation and disulfide linkage [141]. The KNOB protein was also conjugated to the nanoparticles using a bis-succinimidyl PEG derivative. The conjugation of KNOB protein to chitosan–DNA nanoparticles was reported to increase the transfection efficiency 130-fold in HeLa cells and several fold in HEK 293 cells. Chitosan has also been investigated for its ability to form polymeric targeted vesicle drug carriers. Glycol chitosan modified by attachment of a strategic number of fatty acid pendant groups (11–16 mol%) assembles into unilamellar polymeric vesicles in the presence of cholesterol [173, 174]. These polymeric vesicles were found to be biocompatible and hemocompatible, and capable of entrapping water-soluble drugs aiming to target receptors overexpressed in some tumors. Recently, the *in vivo* biological evaluation of doxorubicin formulated in transferrin targeted polymeric vesicles made from palmitoylated glycol chitosan (GCP) was reported. The transferrin-conjugated vesicles showed a statistically significant uptake advantage when compared to the non-targeted vesicles [175].

Use of the folic acid receptor is another approach that can be used to target tumors since cancerous cells divide rapidly and need folic acid to DNA synthesis. This morphological phenomenon is best noted by upregulation of membrane folate binding protein expression for a subsequent increase in folate internalization. The conjugation of folic acid with PEI was done previously by Guo and Lee [176], and more recently by others authors [177, 178]. Guo et al. found that attaching folates to the distal termini of PEG-modified PEI greatly enhanced the transfection activity of the corresponding DNA complexes over polyplexes containing PEG-modified PEI. The enhancements were observed at all charge (+/–) ratios tested and could be blocked partially by coincubation with 200  $\mu\text{M}$  of free folic acid, which suggested the involvement of the folate receptor (FR) in gene transfer. Folate conjugation, therefore, presents a potential strategy for tumor-selective targeted gene delivery. Recently, Mansouri et al. [105] have reported the first conjugation with chitosan. The nanoparticles obtained for folic acid-modified chitosan (FA-CH) showed a very low toxicity and the coacervation process utilized to obtain the FA-CH–DNA did not affect the integrity of the utilized plasmid. These new nanoparticles are currently being tested in transfection studies.

#### 4.3.4

#### **Hydrophobic Modification: Protecting the DNA and Improving the Internalization Process**

Hydrophobic modification is expected to improve the interaction between the DNA and the chitosan since, apart from the electrostatic interactions, the hydrophobic interactions will be increased, which may provide better protection for DNA. *N*-dodecylated chitosan (CS-12) has been synthesized and assembled with DNA to

form a polyelectrolyte complex (PEC) [71]. Dissociation of CS-12–DNA complexes was investigated by the addition of LMW electrolytes and these small molecular salts dissociated the CS-12–DNA complex, inducing the release of DNA. The ability of  $Mg^{2+}$  to dissociate the CS-12–DNA complex was greater than compared to that of  $Na^+$  and  $K^+$ . The incorporation of CS-12 could enhance the thermal stability of DNA and AFM images showed a globule-like structure composed of 40–115 DNA molecules. Lee et al. synthesized deoxycholic acid-modified chitosan (DAMC) which contained 0.6–5.1 deoxycholic acid groups per 100 anhydroglucose units [102]. The mean diameter of DAMC in PBS solution was less than 180 nm with a unimodal size distribution [103, 104]. Complex formation between DAMC and pDNA was confirmed by electrophoresis on an agarose gel. In other work by the same authors the structure of DAMC was found to strongly depend on the molecular weight of chitosan ranging from 5 to 200 kDa [179]. The size of the chitosan aggregates was not precisely controlled by varying the degree of substitution, pH and ionic strength of the medium. Due to the chain rigidity of chitosan, the structure of self-aggregates was suggested to be a cylindrical bamboo-like structure when the molecular weight of chitosan was larger than 40 kDa, which might form a very poor spherical shape of a birdnest-like structure. Complex formation showed a strong dependency on the size and structure of chitosan self-aggregates, and significantly influenced the transfection efficiency of COS-1 cells (up to a factor of 10). Recently, Liu et al. proposed that hydrophobic modification increases internalization process, thus increasing the transfection efficiency [145]. A series of alkylated chitosans (ACSS) derivatives from alkyl bromides was synthesized employing a 99% deacetylated chitosan (CS). The CS and ACSSs were used as vectors for gene transfection, and the effects of hydrophobicity of the alkyl side-chain on the transfection activity were evaluated. It was reported that the complex formation between the ACSSs and DNA requires a relatively smaller amount of ACS compared to unmodified chitosan due to the hydrophobic interaction. The transfection was evaluated in C2C12 cell lines using pcDNA 3.1 plasmid encoding chloramphenicol acetyltransferase. The transfection level was reported to increase upon elongating the alkyl side-chain. The disadvantage of the hydrophobic modification is that the particles are more easily recognized by macrophages of the RES; hence, amphiphilic chitosan may in the future present more advantages than that exhibited by the hydrophobic modification alone [180–182].

#### 4.4

#### Methods of Preparation of Chitosan Nanoparticles

##### 4.4.1

##### Complex Coacervation

Numerous works using different methodologies have been published on the preparation of chitosan micro and nanoparticles; however, for gene therapy, complex coacervation has been the procedure most employed and most of the references

discussed in the previous sections of this chapter relate to this method. The process is a spontaneous phase separation that occurs when two oppositely charged polyelectrolytes are mixed in an aqueous solution. The electrostatic interaction between the two species of macromolecules results in the separation of a coacervate (polymer-rich phase) from the supernatant (polymer-poor phase). This phenomenon can be used to form microspheres and encapsulate a variety of compounds. The encapsulation process can be performed entirely in aqueous solution and at low temperatures, and has a good chance, therefore, of preserving the bioactivity of the encapsulant. In developing an injectable controlled release system, various authors have used the complex coacervation of chitosan and DNA as the main procedure to obtain nanoparticles. In general, chitosan is dissolved in acetic acid/sodium acetate buffer and vortexed rapidly with a pDNA solution at room temperature. Sato et al. [136] reported that complexes of luciferase plasmid (pGL3) with chitosan were prepared only by mixing 100  $\mu\text{L}$  of pGL3 solution ( $1 \text{ mg mL}^{-1}$ ) with a given amount of chitosan solution ( $2.95 \text{ mg mL}^{-1}$ ). The mixtures were gently stirred at room temperature for a couple of hours. Koping-Hoggard et al. [134] reported the preparation chitosan–pDNA complexes were formulated by adding chitosan and then pDNA stock solutions to the solvent (deionized MilliQ water,  $\text{pH } 6.2 \pm 0.1$  or 25 mM acetate buffer,  $\text{pH } 5.0$ ) under intense stirring on a vortex mixer. The sizes of the aggregates (200–3400 nm) were determined by photon correlation spectroscopy, and found to be dependent of the DNA type, chitosan molecular weight and pH. Nanoparticles having sizes ranging from 170 to 180 nm were obtained by Kiang et al. [131] by heating chitosan and DNA solutions separately to 50–55  $^{\circ}\text{C}$ , and then mixing equal volumes of both solutions under high vortexing for 30 s.

It has been reported that, depending of the molecular weight of chitosan, complexes of chitosan–DNA with mean sizes between 50 and 6000 nm can be obtained only by simple mixing followed by incubation [136, 139, 141]. In general, stable complexes are formed only when chitosan is added in molar excess relative to DNA, with  $\zeta$  potential values between 10 and 20 mV, depending upon the degree of excess. Recently, Danielsen et al. [129] reported that the shape of the nanoparticles can vary depending on the degree of acetylation, molecular weight and concentration of chitosan. The DNA stock solution was diluted in  $\text{NH}_4\text{Ac}$  (150 mM,  $\text{pH } 7.4$ ) and complexes were then prepared by adding the chitosan solution to the DNA solution. The average contour length  $\langle L_c \rangle$  of the toroidal and rod-like DNA–chitosan polyplexes was found to be about 130 nm, independent of the linear or toroidal geometry of the complex and the chitosan employed (30–200 kDa). The complex sizes were found less than 1/10 of the contour length of the uncomplexed plasmid (pBR322, 4363 bp; Boehringer Mannheim) of 1.5  $\mu\text{m}$ . Decreasing the charge density of the chitosan resulted in a decrease in the toroid-to-rod ratio, indicating that the strength of the intersegment interaction, mediated by the charge of the chitosan, is important in determining the shape of the DNA–chitosan complexes, with the toroid being the preferred structure for high intersegment attractions. The stability of these DNA–chitosan complexes was studied after exposure to heparin and hyaluronic acid (HA) using AFM and ethidium bromide (EtBr) fluo-

rescence assay. Studies of polyplex stability when challenged by HA showed that whereas HA was unable to dissociate the complexes, the degree of dissociation caused by heparin depended on both the chitosan chain length and the amount of chitosan used for complexation [183].

#### 4.4.2

### Crosslinking Methods

#### 4.4.2.1 Chemical Crosslinking

The crosslinking procedures can be classified as (a) chemical crosslinking and (b) ionic crosslinking. The first involves the formation of covalent bonding between the chitosan chains and the chemical agents. The use of crosslinked nanospheres of chitosan for gene therapy has not been frequently found in the literature because after formation, chitosan–DNA nanoparticles obtained from the coacervation process are reported to be stable. At physiological pH, most of the positive charges would be neutralized and the hydrophobic chitosan becomes insoluble. This unique property ensured that nanoparticles formed at low pH could remain physically stable at physiological pH without chemical crosslinking; however, this was not observed, for example, for gelatin–DNA nanoparticles, which required a crosslinking agent to remain stable [141]. The process involves the precipitation of the polymer followed by chemical crosslinking [184, 185]. Precipitation can be done by sodium sulfate followed by chemical crosslinking using glutaraldehyde, formaldehyde or even using a natural crosslinking agent such as genepin [186, 187]. Recently, glutaraldehyde was used to obtain chitosan microparticles encapsulating an IL-2 expression plasmid [188]. Chitosan microspheres containing recombinant (r) IL-2 were prepared by using the precipitation technique. The rIL-2 encapsulation efficiency in the microspheres was high (75–98%) and the size was reported to vary from 1.45 to 2.00  $\mu\text{m}$ . The authors noted that IL-2 was released from chitosan microspheres over a period of 3 months and remained biologically active, being completely recovered from the release medium. Akbuga et al. [189] have studied the effect of formulation variables (concentration and molecular weight of chitosan, plasmid amount, use of glutaraldehyde as a crosslinker) on microsphere properties. Plasmid-loaded chitosan microspheres were prepared by adding the pDNA to 50 mL of sodium sulfate solution (20% w/v) and this mixture was dropped into 50 mL of acidic solution of chitosan and stirred for 1 h at 500 rpm. The microspheres formed were washed with bidistilled water, separated by centrifugation, freeze-dried and then stored at 4 °C in a desiccator. A high level of IL-2 expression was reported with plasmid-loaded chitosan microspheres in MAT-LyLu, a rat prostate adenocarcinoma cell line, but the authors noted that addition of glutaraldehyde was not necessary for the formulation. Although no damage has been observed in the DNA structure after using glutaraldehyde as a co-crosslinker, it reduced pDNA release from microspheres.

#### 4.4.2.2 Ionic Crosslinking or Ionic Gelation

In ionic crosslinking methods a variety of negatively charged compounds, from small ions to HMW polymers, can be used to produce micro- and nanoparticles

[37]. Ionic crosslinking in aqueous solution occurs due to the electrostatic interaction between the charged amino groups of chitosan and a salt or polyanion. The reactions with negatively charged components, either ions or molecules, can lead to the formation of a network between polymeric chains through ionic bridges. In ionic crosslinking, the entities reacting with chitosan are ions or ionic molecules with a well-defined molecular weight. In contrast, in polyelectrolyte complexation, the entities reacting with chitosan are polymers with a broad molecular weight distribution. In addition to its simplicity [190, 191], the method can be considered a safer alternative, since it avoids chemical crosslinking, and the possible toxicity of reagents and other undesirable effects [192]. There are two salts that have been frequently used in the preparation of chitosan particles by the ionic crosslinking mechanism: sodium tripolyphosphate (PSTP) [193, 194] and sodium sulfate [195]. Li et al. [196] prepared nanoparticles with a size range of 40–200 nm by an ionic gelation procedure using tripolyphosphate, sodium citrate and sodium hydroxide. Chitosan particles formed on the basis of ionic gelation with PSTP were demonstrated to be much more stable than those obtained with sodium citrate and sodium hydroxide. The ability of particles to complex DNA was investigated using gel retardation. Results showed that these chitosan particles have potential as vectors for the transfer of DNA into mammalian cells. Cellular transfection by the chitosan-pGL3-control particles showed a sustained expression of the luciferase gene for about 10 days. Jiang et al. [197] have also prepared chitosan microparticles with tripolyphosphate. The microparticles were tested for nasal vaccination loaded with *Bordetella bronchiseptica* dermonecrototoxin (BBD), a major virulence factor of a causative agent of atrophic rhinitis. The average particle size of the BBD-loaded chitosan microparticles was 4.39  $\mu\text{m}$ . The results reported that released BBD from chitosan microparticles had immune-stimulating activity of the atrophic rhinitis vaccine *in vitro*. Numerous works have been published on ionic crosslinking (ionic gelation) [198–205]; however, these works mainly focused on the various pharmaceutical applications which have been recently reviewed by Kumar et al. [40], Agnoutri et al. [192] and Sinha et al. [37].

#### 4.4.2.3 Emulsion Crosslinking

This method utilizes an acetic acid solution of chitosan, which is added to an organic solvent containing an emulsifier to form a water-in-oil emulsion (w/o). The chitosan solution is added dropwise under different conditions of stirring and temperature. The degree of stirring (i.e. time and speed of stirring during emulsification) determines the size of the dispersed droplets. By varying any one or both of these parameters, the size of droplets can be changed to obtain the product (i.e. chitosan microspheres) in the desired size range. Liquid paraffin is frequently used as the oil phase and, after the formation, the particles are crosslinked using chemical agents as glutaraldehyde or formaldehyde [206]. The literature abounds with reports wherein chitosan microspheres have been prepared for drug delivery. Akbgua and Durmaz [207] prepared chitosan microspheres containing furosemide from a w/o emulsion system using liquid paraffin as the external phase and a solution of chitosan in acetic acid as the disperse phase. Discrete spherical furosemide microspheres having a diameter range of 350–690  $\mu\text{m}$  were produced. Micro-

sphere properties were affected by the preparation variables such as the type and concentration of chitosan, drug concentration, crosslinking process, viscosity of oil, and stirring rate during the preparation. An emulsification/solvent evaporation process was carried out under mild conditions for Genta et al. [208] to entrap the hydrophobic drug ketoprofen. Glutaraldehyde at different concentrations was used as the chemical crosslinking agent on microspheres constituted by different theoretical ketoprofen/chitosan ratios (1:2, 1:4 and 1:6 w/w). Chitosan microspheres were morphologically characterized for shape, surface characteristics and size distribution; chitosan/ketoprofen interactions inside microspheres were investigated by differential scanning calorimetry and powder X-ray diffraction. Recently, Kumbar et al. [209] have used the emulsion crosslinking method to prepare chitosan microspheres to encapsulate diclofenac sodium using three crosslinking agents: glutaraldehyde, sulfuric acid and heat treatment. Microspheres were spherical with smooth surfaces. The size of the microparticles ranged between 40 and 230  $\mu\text{m}$ . Among the three crosslinking agents used, glutaraldehyde crosslinked microspheres showed the slowest release rates, whereas a quick release of diclofenac sodium was observed by the heat crosslinked microspheres. The influence of different parameters as well as the incorporation of different drugs has been extensively studied [210–217], including chitosan-coated systems (hybrid systems) [218, 219]. In these systems emulsions, nanocapsules and nanoparticles are coated by introducing chitosan into the external aqueous phase in which the formation of the colloidal structures take place. The chitosan coating is a result of the ionic interaction with nanoemulsions and nanocapsules, and no crosslinking is needed. In a recent work, Lee et al. [220] used chitosan as a condensing agent to enhance the transfection efficiency of a cationic emulsion-mediated gene delivery vehicle in human hepatoma cells (HepG2). The authors reported that the size of the complexes was reduced after condensation of DNA by chitosan. The results suggested that the use of chitosan enhanced the *in vitro* transfection efficiency and extended the *in vivo* gene transfer.

#### 4.4.2.4 Spray Drying

Spray drying is a method based on drying atomized droplets in a stream of hot air. In this method, chitosan is first dissolved in aqueous acid solution containing a dissolved or dispersed drug, in which a suitable crosslinking agent is added. Particle size depends upon the size of nozzle, spray flow rate, atomization pressure, inlet air temperature and extent of crosslinking. He et al. [221] have prepared crosslinked and noncrosslinked chitosan microspheres. The authors reported that the particle size ranged from 2 to 10  $\mu\text{m}$ , and that the size and  $\zeta$  potential of the particles were influenced by the crosslinking level. The particles sizes as well as the  $\zeta$  potential were observed to increase with decreasing amounts of the crosslinking agents (glutaraldehyde and formaldehyde). Mi et al. [222] have reported the preparation of microspheres with small size and good sphericity. A histological study of the genipin-crosslinked chitosan microspheres injected intramuscularly into the skeletal muscle of a rat model showed a less inflammatory reaction than its glutaraldehyde-crosslinked counterparts. The authors have suggested that the genipin-crosslinked chitosan microspheres may be a suitable polymeric carrier for

long-acting injectable drug delivery. Chitosan microspheres with hydrocortisone and hydrocortisone–hydroxypropyl- $\beta$ -cyclodextrin inclusion complex were studied by Filipovi et al. [223]. Microspheres were studied with respect to particle size distribution, drug content and *in vitro* drug release. The results indicate that the hydrocortisone–hydroxypropyl- $\beta$ -cyclodextrin inclusion complex is more water soluble than hydrocortisone alone. The hydrocortisone release rates from chitosan microspheres were influenced by the drug/polymer ratio in the manner that an increase in the release rate was observed when the drug loading was decreased. The influence of acid type on the release behavior of sodium diclofenac microspheres was studied by Orienti et al. [224]. Among the salts used, glutamic and aspartic salts provided the best control of release. Huang et al. [225] prepared chitosan microspheres by a spray-drying method using type A gelatin and ethylene oxide–propylene oxide block copolymer as modifiers. The microspheres were investigated using scanning electron microscopy (SEM) and microelectrophoresis. The particle shape, size and surface morphology of microspheres were affected by the concentration of gelatin. Betamethasone disodium phosphate (BTM)-loaded microspheres demonstrated good drug stability (less than 1% hydrolysis product), high entrapped efficiency (95%) and a positive surface charge (37.5 mV). The *in vitro* drug release from the microspheres was related to gelatin content. Microspheres containing gelatin/chitosan 0.4–0.6 (w/w) had a prolonged release pattern for 12 h. These formulation factors were correlated to particulate characteristics for optimizing BTM microspheres in pulmonary delivery. Recently, various systems have shown potential application for nasal [226, 227], pulmonary [228] and DNA [229] delivery.

#### 4.4.2.5 Other Methods

Apart from those methods mentioned above, a number of other methods have been reported for the preparation of chitosan micro- and nanoparticles, such as the reverse micellar [231–233], emulsion droplet coalescence [234–238] and sieving [239] methods.

The reverse micellar method is similar to emulsion crosslinking in the sense that in both methods a w/o aggregate is formed; however, the reverse micelles are thermodynamically stable liquid mixtures of water, oil and surfactant. Macroscopically, they are homogeneous and isotropic, structured on a microscopic scale into aqueous and oil microdomains separated by surfactant-rich films. The main advantage of the reverse micellar method is a better control of particle sizes. In the phase diagram of a system in which reverse micelles exist, there is plenty of room to adjust the proportions of the organic solvent and water as well as the surfactant ratio. This allows the dimensions of the reverse micellar particles to be modulated by varying the degree of hydration (molar ratio of  $[\text{H}_2\text{O}]/[\text{surfactant}]$ ) of the system. When the surfactant is kept at a constant concentration, increasing the water content will increase the volume of the reverse micelles. Alternatively, if the water content constant is kept constant, then increasing the surfactant concentration will cause the volume of reverse micellar particles to become smaller. Finally, if both the water and the surfactant concentrations are increased in a constant ratio, the volume of reverse micelles will not change, but the number of vesicles will

increase. Aghnoutri et al. have described this process in the following steps – preparation of the reverse micellar system, adding chitosan and drug, adding cross-linking agent, stirring overnight, evaporation of solvent, and purification [36]. Banerjee et al. [231] reported a procedure to prepare ultrafine crosslinked chitosan nanoparticles in an AOT–*n*-hexane reverse micellar system. They observed that the particle size is influenced by the degree of crosslinking and was found to be 30 nm when 10% of the amino groups in the polymeric chain had been crosslinked, whereas it was 110 nm when all the amino groups were crosslinked. These particles were thoroughly characterized, and electron micrographs reveal that the particles were spherical in shape and that lower crosslinking of the particles leads to smaller aggregates, while highly dense aggregates were formed at 100% crosslinking. The biodistribution of the particles after intravenous injection in mice showed that these particles remain in the blood for a considerable amount of time, and distribute in the heart, liver, kidneys, bladder and vertebral column. Other than these organs, the particles were distributed in the bone marrow, opening the possibility of using these particles for bone imaging and targeting purposes [231]. Andersson and Lofroth [232] investigated a new microemulsion based on heparin–chitosan complex suitable for oral administration. The microemulsion is based on ingredients that are acceptable to humans. These microemulsions were studied with or without biologically active ingredients by dynamic light scattering, turbidity, diffusion nuclear magnetic resonance and conductivity. Appropriate mixing and modifications of these microemulsions lead to nanometer-sized heparin–chitosan complexes [232].

In the emulsion droplet coalescence method, two w/o emulsions are prepared – one containing chitosan and the drug, and other a stable aqueous emulsion of NaOH. The solutions are mixed under high-speed stirring, which leads particle collision, forming solid microparticles that are centrifuged and washed. Gadopentetic acid-loaded chitosan nanoparticles have been prepared by this method for gadolinium neutron capture therapy – a cancer therapy that utilizes  $\gamma$ -rays emitted during the reaction  $^{157}\text{Gd}(n, \gamma)^{158}\text{Gd}$  to kill tumor cells [234, 235]. The bioadhesive characteristics of chitosan and its capacity to recognize, to a certain extent, the tumor cells prompted research on the delivery of gadolinium with the aid of chitosan. Tokumitsu et al. [236] have reported that particles produced using 100% deacetylated chitosan had a mean particle size of 452 nm with 45% drug loading. Nanoparticles were obtained within the emulsion droplet. The size of the nanoparticle did not reflect the droplet size. Since gadopentetic acid is a bivalent anionic compound, it interacts electrostatically with the amino groups of chitosan, which would not have occurred if a crosslinking agent is used that blocks the free amino groups of chitosan. Thus, it was possible to achieve higher gadopentetic acid loading by using the emulsion droplet coalescence method compared to the simple emulsion crosslinking method.

Fully deacetylated chitosan was dissolved in 10% gadolinium diethylenetriamine-pentaacetic acid (GdDTPA) solution to obtain 2.5% chitosan concentration. Then, 1 mL of this solution was added to liquid paraffin (10 mL) with Arlacel 5% and stirred with a homogenizer to form a w/o emulsion. Separately, a similar emulsion

was prepared with NaOH and then the two emulsions were combined to solidify the chitosan droplets. Washing was done with toluene, ethanol and water. The mean particle diameter was around 400 nm and the gadolinium content was around 9%. The GdDTPA chelate was strongly retained by chitosan, so that gadolinium was not released to an isotonic phosphate buffer over 7 days. Actually, the gadolinium concentration in the tumor tissue was about 100 times higher compared to Magnevist controls at the time of the thermal neutron irradiation. Endocytic uptake of nanoparticles, strongly holding GdDTPA, was suggested by transmission electron microscopy studies that indicated that GdDTPA has a high affinity for the cells, contributing to the long retention of gadolinium in tumor tissue. The treatment led to suppression of tumor growth in the *in vivo* studies. In the controls, 14 days after irradiation, the increase of the tumor volume was 20–25%, while the tumor was suppressed in mice treated with the gadolinium preparation; also, the survival time was remarkably prolonged [237–240].

Agnihotri and Aminabhavi [241] have used a sieving method to obtain microparticles. The first step was the crosslinking of chitosan to obtain a nonsticky glassy hydrogel followed by passing through a sieve. A suitable quantity of chitosan was dissolved in 4% acetic acid solution to form a thick glassy hydrogel followed by passing through a sieve. A suitable quantity of chitosan was dissolved in 4% acetic acid solution to form a thick jelly mass that was crosslinked by adding glutaraldehyde. The nonsticky crosslinked mass was passed through a sieve with a suitable mesh size to obtain microparticles. The microparticles were washed with 0.1 N NaOH solution to remove the unreacted excess glutaraldehyde and dried overnight in an oven at around 40 °C. Clozapine was incorporated into chitosan before crosslinking with an entrapment efficiency up to 98.9%. Microparticles were irregular in shape, with average particle sizes in the range 543–698  $\mu\text{m}$ . The *in vitro* release was extended up to 12 h, while the *in vivo* studies indicated a slow release of clozapine.

#### 4.5

#### DNA Loading into Nano- and Microparticles of Chitosan

DNA loading into micro/nanoparticulates of chitosan is mainly done either during the preparation or by adsorption on the preformed particles. The process is very efficient since, as mentioned before, it is mainly driven by electrostatic interactions between the chitosan chain and the charged phosphate groups of DNA. However, the intrinsic characteristics of the carrier (chitosan and its derivatives) may affect the loading, such as the chitosan/DNA ratio and degree of acetylation, molecular weight, as well as experimental conditions like the pH and the presence of additives.

Leong et al. [44] have evaluated the encapsulation efficiency and loading level of DNA into nanospheres having a size range of 200–750 nm. The nanospheres were prepared by complex coacervation in the presence of sodium sulfate aqueous solution, using chitosan 390 kDa and two different pDNAs. The DNA loading level

was determined by the PicoGreen assay (Molecular Probes, Eugene, OR) after the nanospheres were digested with trypsin or chitosanase and lysozyme. The authors reported that over 95% of the DNA was captured by the phase separation, and also that the encapsulation efficiency and loading level were observed to increase with the molecular weight of the encapsulant.

In general, complete binding may be achieved by increasing the amount of chitosan in the formulation. Kiang et al. [131] have evaluated chitosans with various degrees of deacetylation for efficacy of nanoparticle formation, DNA binding efficiency, morphology, and *in vitro* and *in vivo* gene transfection efficiency. The nanoparticles obtained by complex coacervation had a particle size of approximately 150–200 nm. The authors reported that when comparing chitosans with similar degrees of deacetylation, HMW chitosan (390 kDa) with a degree of deacetylation of 90% binds DNA at a charge (+/–) ratio of approximately 3.3, medium-molecular-weight chitosan (209 kDa) with degree of deacetylation of 93% binds DNA at a charge (+/–) ratio of 4.0, while LMW chitosan (138 kDa) with a degree of deacetylation of 85% requires a charge (+/–) ratio of 5.0 to completely bind the DNA. Similarly, at constant molecular weight, when the degree of deacetylation is decreased, the DNA-binding capacity is decreased, i.e. more chitosan is required to completely bind the DNA. This result was observed by comparing gel electrophoresis assays. For HMW chitosan, the charge (+/–) ratio for complete DNA binding increased from 3.3 to 8.0 as the degree of deacetylation decreased from 90 to 62%.

Mao et al. [141] evaluated encapsulation efficiency and DNA loading level by measuring the difference between the total amount of DNA added in the nanoparticle preparation buffer and the amount of nontrapped DNA remaining in the aqueous suspension after the coacervation process. Under optimal conditions, almost all DNA (pRELuciferase, 11.9 kb) and chitosan were captured in the nanoparticles. Using the chitosan (390 kDa)–DNA system, nanoparticles were prepared in the presence of 25 mM Na<sub>2</sub>SO<sub>4</sub> at a charge (+/–) ratio of 3.3, and the encapsulation efficiencies were  $98.0 \pm 2.0$  and  $92.7 \pm 3.7\%$ , respectively, for DNA and chitosan. According to these results, the composition of the nanoparticles was calculated as  $35.6 \pm 0.9$  and  $64.4 \pm 0.9\%$  weight for DNA and chitosan, respectively. Recently, Bozkir and Saka [242] have formulated chitosan–pDNA nanoparticles using complex coacervation and solvent evaporation techniques. The important parameters for the encapsulation efficiency were investigated, including molecular weight and degree of deacetylation of chitosan. They found that the encapsulation efficiency of pDNA is directly proportional to the degree of deacetylation, but there is an inverse proportional relationship with the molecular weight of chitosan. The surface charge of the nanoparticles prepared by the complex coacervation method was slightly positive, with a  $\zeta$  potential of +9 to +18 mV; nevertheless, nanoparticles prepared by the solvent evaporation method had a  $\zeta$  potential around +30 mV. The pDNA–chitosan nanoparticles prepared by using highly deacetylated chitosan having 92.7, 98.0 and 90.4% encapsulation efficiency protected the encapsulated pDNA from nuclease degradation.

Recent studies on DNA-loaded microcapsules have also shown that higher amounts of DNA can be encapsulated into the chitosan particles. Akbuga et al.

[144] have studied pDNA-loaded chitosan microspheres for *in vitro* IL-2 expression. In order to study the effect of formulation variables (concentration and molecular weight of chitosan, plasmid amount, use of glutaraldehyde as a crosslinker, etc.) on microsphere properties, different microsphere formulations were prepared. For microsphere preparation, the pDNA was added to 50 mL of sodium sulfate solution (20% w/v) and this mixture was dropped into 50 mL of acidic solution of chitosan and stirred for 1 h at 500 rpm. Encapsulation efficiency was calculated by measuring the difference between the total amount of DNA added in the preparation medium and the amount of nontrapped DNA remaining in the aqueous supernatant suspension after the coacervation process. For this purpose, the supernatant was spectrophotometrically analyzed at 260 and 280 nm for DNA concentration. Microspheres prepared were about 1.45–2.00 mm in size and spherical in shape. The plasmid encapsulation efficiency of microspheres was about 85%. Plasmid encapsulation efficiency was affected by the initial plasmid amount – a higher encapsulation efficiency was obtained with a lower amount of plasmid. However, the authors reported that other factors (chitosan concentration, using LMW chitosan and the addition of glutaraldehyde) did not affect the encapsulation efficiency significantly.

Aral et al. [243] have prepared chitosan microspheres containing pDNA:PLL complexes. The pDNA:PLL complexes were added to a sodium sulfate solution (20% w/v) before dropping and this mixture was dropped into the chitosan solution (0.35% w/v in 1% Tween 80 and 2% acetic acid) and stirred for 1 h at 500 rpm. The encapsulation efficiency of chitosan microspheres was estimated by measuring the amount of drug in the supernatant after centrifugation. The encapsulation efficiency for pDNA:PLL complexes was about 90% (data not shown). The average sizes of chitosan microspheres were between 3.41 to 3.69  $\mu\text{m}$  and independent of the pDNA:PLL ratio. Chitosan microspheres were evaluated for sustained-release of human rIL-2 and the effects of different formulation factors, such as chitosan and protein concentrations, the volume of sodium sulfate solution, technique of addition of rIL-2, and presence of glutaraldehyde during the encapsulation process, on the microsphere characteristics were investigated [244]. Protein loading of chitosan microspheres was achieved by using two different methods – rIL-2 was added to the sodium sulfate solution during the preparation or it was adsorbed onto the surface of empty microspheres. Spherical microspheres having diameters ranging from 1.11 to 1.59  $\mu\text{m}$  were obtained. The microspheres had a narrow size distribution and the authors reported that higher amounts of rIL-2 could be encapsulated into the chitosan microspheres by both methods (more than 90%).

#### 4.6 DNA Release and Release Kinetics

DNA release from chitosan nanoparticles can be understood as a mechanism occurring through a combination of release from the surface and/or inner of the

nanoparticles and release due to polymer erosion. The definition “kinetics of *in vitro* release” is more commonly used to describe DNA release in a buffer solution, in which salts and/or enzymes are added to test the stability of the particles. Another important subject is the “kinetics of *in vitro* gene expression”, which is a terminology to denote the release process in the presence of targeting cells. Limiting our discussion primarily to kinetics of *in vitro* release from nano- and microparticles, various parameters may affect the release, such as molecular weight of chitosan, charge (+/–) ratio, plasmid size, extent of crosslinking, method of preparation and the presence of additives. Studies on the kinetics of pDNA release from chitosan nanoparticles are not frequently found in the literature, and only recently has more quantitative work been performed on chitosan microparticles. Dastan and Turan [245] have studied the *in vitro* release of DNA microparticles (2.0  $\mu\text{m}$ ) suspended in phosphate buffer at pH 7.4. The suspension was shaken in a water bath at 37 °C, and at defined time intervals the supernatant was collected by centrifugation and microparticles were resuspended in fresh buffer. pDNA (pSV-Gal 6820 bp, pEGFP-N1 4733 bp and pBluescript SK<sup>+</sup> 2961 bp) release into the supernatant was quantified by spectrophotometry. The authors reported that about 10–15% of total DNA loaded into the chitosan microparticles was initially released within the first hour followed by very slow release over 40–50 days. The results obtained showed that the release is dependent on both chitosan and pDNA concentration, as well as of pDNA molecular weight. It was shown that the DNA release rate from microparticles was higher for nanoparticles having a higher pDNA concentration and a lower chitosan concentration. The HMW plasmids were released slower than the smaller ones. Aral and Akubga [243, 246] have also studied the release of pDNA:PLL complexes (pUC18 2.69 kbp, that encoded galactosidase) from chitosan microspheres of about 3.5  $\mu\text{m}$ . Release profiles of the chitosan microspheres were determined by incubating 10 mg samples of microspheres in phosphate-buffered saline (PBS, pH 7.4, BP) at 37 °C. Release studies were continued up to 40 days. All samples were measured spectrophotometrically and fluorometrically using Hoechst 33258 dye that specifically binds to DNA. The release of pDNA:PLL complexes from the microspheres showed no initial burst release. On the first day, 2.1–4.8% of the pDNA:PLL complexes was released from the studied formulations. This was attributed to the high positive charge of chitosan which could hinder the release of surface localized pDNA. At day 40, from 42–70% of the initial drug was released from chitosan microspheres.

Chitosan microspheres containing human rIL-2 were prepared by using the precipitation technique. The average diameter of microspheres was between 1.11 and 1.59  $\mu\text{m}$  [244]. Protein release from chitosan microspheres was determined in PBS buffer in a water bath at  $37 \pm 0.5$  °C. In general, the rIL-2 release profiles were biphasic, characterized by an initial protein burst followed by slow release. Among the different formulation parameters, for some of them the concentration of chitosan as well as the amount of glutaraldehyde affected the release. However, as the protein concentration increased, *in vitro* release significantly decreased. Moreover, the volume of sodium sulfate solution used in the microsphere preparations affected the release pattern of protein from chitosan microspheres. rIL-2 was re-

leased rapidly from chitosan microspheres when a larger volume of sodium sulfate solution was used during the preparation. In other work, Ozbas-Turan et al. [246] have encapsulated two plasmids (pGL2 6046 bp and pMK3 7213 bp) in the same microsphere structure and investigated *in vivo* release and transfection characteristics of chitosan microspheres (1.15–1.28  $\mu\text{m}$ ). They reported that very little burst effect was seen in the release profiles of two plasmid-loaded microspheres and that pDNAs were continuously released from chitosan microspheres. The *in vitro* release of pDNAs from microspheres was dependent on the plasmid amount and chitosan concentration. As the amount of plasmids increased, release decreased significantly. The same results were obtained with microspheres containing different concentrations of chitosan. The authors concluded that there was no significant difference between the release patterns of single- and double-plasmid loaded microspheres. In more a recent paper [144], the same group studied pDNA-loaded chitosan microspheres (1.5–2.0  $\mu\text{m}$ ) for *in vitro* IL-2 expression. They reported that all release profiles of the microspheres were similar and showed a small burst release of about 10–20% in the first 24 h and then slow release at a constant rate. DNA release was reported to change significantly with the chitosan concentration. Microspheres prepared with the highest concentration of chitosan exhibited the lowest DNA release. Microspheres prepared with HMW chitosan exhibit slow DNA release. As the molecular weight of chitosan increased, the release of pDNA from microspheres decreased. The molecular weight of chitosan was previously shown to be important in DNA release as reported by Xu and Du studying the release of bovine serum albumin from chitosan nanoparticles (20–200 nm) [200]. Moreover, DNA release was affected by the amount of plasmid entrapped. An increase in DNA content of microspheres resulted in a decrease in plasmid release.

The studies on the release of chitosan nanoparticles found in the literature mainly focus on the release of proteins and other drugs rather than on pDNAs. The importance of studying the release from nanoparticles is due to the advantages of nanoparticles over microspheres; it has been observed that nanoparticles can enter the cell by endocytosis or pinocytosis, having a size requirement less than 100 nm [141, 142]. Also the number of nanoparticles that cross the epithelium is greater than the number of microspheres [247]. Bozkir and Saka [242] have recently studied the effect of chitosan molecular structure and type of formulation on the release characteristics of chitosan nanoparticles. They found that the release of pDNA from the formulation prepared by complex coacervation was completed in 24 h, whereas the formulation prepared by evaporation technique released pDNA in 96 h; however, these release profiles were not statistically significant compared with formulations with similar structure.

#### 4.7

#### Preclinical Evidence of Chitosan–DNA Complex Efficacy

We have previously demonstrated that chitosan–DNA complexes appear spherical with a mean size of less than 100 nm and a homogenous distribution of DNA

within the particle [249]. Our results are in agreement with previous studies [248]. The size of the complexes is of crucial importance to cellular uptake. Illum et al. have synthesized chitosan–DNA nanoparticles ranging from 20 to 500 nm and thus our complexes are smaller than other polymeric systems [248]. The smaller size complexes have the advantage of entering the cells through endocytosis and/or pinocytosis, and therefore increasing the transfection rate. The transfection efficacy seen *in vitro* is cell-type dependent and cell viability studies following incubation with nanoparticles confirmed the lack of toxicity of chitosan compared to cationic lipids such as lipofectamine [84, 136, 249].

In addition to condensing the pDNA, an efficient gene delivery system is required to transport the gene into the cell and see to its eventual release, leading to gene expression and subsequent protein synthesis (Fig. 4.5). It is thus necessary to test a gene carrier on different cells lines, especially cells that resemble those that will be targeted. We have incubated chitosan–DNA polyplexes with MG63 cells, which have characteristics resembling those of osteoblasts, and with mesenchymal stem cells (MSCs), which are implicated in the formation of tissues such as cartilage, bone, tendons and muscle [250]. Nanoparticles composed of chitosan of molecular weight 400 kDa and a DNA quantity equivalent to 10 mg resulted in a transfection that was statistically significant compared to cells received solely DNA. MG63 cells did not demonstrate the same level of transfection. This can be explained by a delayed internalization of the nanoparticles when compared to HEK 293 cells. In fact, fluorescent microscopy observations undertaken by our group on nanoparticles incubated with human osteoblasts indicate that the particles remain bound to the surface for as long as 1 week following incubation (Fernandes et al., personal observations). However, MSCs did demonstrate gene expression when transfected with chitosan–DNA nanoparticles. This was clearly seen by a number of cells turning blue following X-gal staining; however, their transfection efficacy is not statistically significant when compared to cells receiving solely naked DNA [249].

One major pitfall of *in vitro* studies is their lack of reproducibility *in vivo*. We addressed this question recently by injecting either 0.15 M NaCl (control) or 1 mg of naked or complexed VR1012 plasmid coding for the  $\beta$ -Gal gene (Vical, Anaheim, CA) with chitosan or lipofectamine in the anterior tibialis muscle of 6-week-old male BALB/c mice. One major finding of this pilot study was that chitosan–DNA nanoparticles administered in the anterior tibialis mice muscle revealed a high signal corresponding to  $\beta$ -Gal gene expression within 48 h [251]. In contrast, the administration of naked or DNA–lipofectamine in the anterior tibialis muscle did not reveal any  $\beta$ -Gal gene expression. From these preliminary data, we proposed that chitosan–DNA nanoparticles have the potential ability to transfect muscle cells *in vivo* and lead to protein synthesis.

To improve transfection efficiency, several derivatives of chitosan have been prepared based on reactions with the free amino groups. Mao et al. demonstrated that transferrin and KNOB protein conjugation improved transfection efficiency in HEK 293 and HeLa cells [141]. Trimethylated chitosan is prepared with different degrees of quaternization to increase the solubility of chitosan at neutral pH [84];

deoxycholic group-conjugated chitosan has been synthesized to develop a colloidal carrier for DNA [102]; both quaternarized chitosan and deoxylated modified chitosan have been shown to transfect COS-1 cells effectively *in vitro*. A lactosylated chitosan has also been shown to be able to complex with DNA and effectively transfect HeLa cells [143]. It has been noticed that transfection efficiency also depend on the cell type used and the chitosan derivatives.

Folic acid was chosen by our group as a ligand for targeting cell membrane and allowing nanoparticles endocytosis via the FR for a higher transfection yield. Importantly, the high affinity of folate to bind its receptor (1 nM) [252] and the small size of folate allows its use for specific cell targeting. Moreover, the ability of folic acid to bind the FR that enables endocytosis is not altered by covalent conjugation of small molecules [253–255]. FR is overexpressed on many human cancer cell surfaces [252] and the nonepithelial isoform of FR (FR $\beta$ ) is expressed on activated synovial macrophages present in large numbers in arthritis joints [256]. Folic acid has been used by many researchers like a ligand with cationic liposome and other polymers to target cells expressing FR. For example, Guo et al. showed that folic acid enhanced PEI-mediated transfection activity in the presence of serum into cultured mammalian cells [257]; Reddy et al. showed that folate-mediated endocytosis can be exploited to target transgenes to cancer cells expressing FR and that folate-derivatized DOPE have a high transfection activity [258].

#### 4.8

#### Potential Clinical Applications of Chitosan–DNA in Gene Therapy

The chitosan–DNA system has been used in a novel gene transfer approach against respiratory syncytial virus infection, which at a single dose of about 1 mg/kg body weight is capable of decreasing viral titers by two orders of magnitude (100-fold) on primary infection. The immunologic mechanisms for the effectiveness of this prophylaxis include the induction of high levels of both serum IgG and mucosal IgA antibodies, the generation of an effective control response, and elevated lung-specific production of interferon (IFN)- $\gamma$  with antiviral action. Although effective as a single-dose, it is possible that dose-escalation and prime-booster strategies of the intranasal gene transfer (IGT) vaccine might further enhance its effectiveness. In addition, IGT significantly decreases pulmonary inflammation and does not alter airway hyperresponsiveness, thus making it safe for *in vivo* use [259].

Coxsackievirus B3 (CVB3) infections are common causes of acute and chronic myocarditis for which no effective prophylactic treatment is available. Xu et al. [260] have described a prophylactic strategy using chitosan–DNA intranasal immunization to induce CVB3-specific immune responses. Intranasal administration of a chitosan–DNA complex prepared by votexing DNA with chitosan resulted in transgenic DNA expression in mouse nasopharynx. Mice immunized with chitosan–DNA (pcDNA3-VP1) encoding VP1, major structural protein of CVB3, produced much higher levels of serum IgG and mucosal secretory IgA compared

to mice treated with pcDNA3-VP1 or pcDNA3. Increased virus-specific cytotoxic activity of spleen cells derived from chitosan–DNA-vaccinated mice was also determined. Chitosan–pcDNA3-VP1 intranasal immunization resulted in 42.9% protection of mice against lethal CVB3 challenge and a significant reduction of viral load after acute CVB3 infection. The authors indicated that intranasal delivery of the chitosan–DNA vaccine successfully induced mucosal SIgA secretion and might be a promising vaccine candidate to protect against CVB3 infection.

The zona pellucida (ZP), the extracellular matrix surrounding oocytes, has received considerable attention as a potential target for contraception because of its key role in many reproductive processes, e.g. gamete interaction during fertilization, induction of acrosome reaction. Sun et al. [261] have constructed a eukaryotic expression vector pVAX1-pZP3a as an oral ZP DNA contraceptive vaccine and successfully encapsulated in nanoparticles with chitosan. After 5 days of feeding to mice, the transcription and expression of pZP3a was found in mouse alvine chorion. The authors suggested that the chitosan–pVAX1-pZP3 pDNA nanoparticles can successfully transfect the alvine chorion cells in mice *in vivo*.

In order to investigate the potential of chitosan in the form of an inhaled powder as a gene delivery system, Okamoto et al. prepared powders using pCMV-Luc as a reporter gene and a LM chitosan (3000–30 000) as a cationic vector with supercritical CO<sub>2</sub>. The chitosan–DNA powders obtained were administered to the lungs of mice. The transfection efficiency of these powders was compared with that of DNA solutions and DNA powders without the cationic vector. The gene powder with the cationic polymer was found to be an excellent gene delivery system to the lungs, as evidenced by a high transfection rate and high expression of the luciferase protein. The benefits of the chitosan–DNA powders examined were summarized as follows: (a) the addition of chitosan suppressed the degradation of pCMV-Luc during the supercritical CO<sub>2</sub> process, (b) the addition of chitosan increased the yield of powders and (c) the chitosan–DNA powders increased the luciferase activity in the mouse lung compared with pCMV-Luc powders without chitosan or pCMV-Luc solutions with or without chitosan [262]. Bivas-Benita et al. [263] have proposed chitosan–DNA nanoparticles for pulmonary delivery of a DNA vaccine encoding HLA-A\*0201-restricted T cell epitopes of *Mycobacterium tuberculosis*. The authors used an HLA-A2 transgenic mouse model to investigate the effects of pulmonary delivery of a new pDNA encoding eight HLA-A\*0201-restricted T cell epitopes from *M. tuberculosis* formulated in chitosan nanoparticles. It was shown that the chitosan–DNA formulation was able to induce the maturation of dendritic cells, whereas chitosan solution alone could not, indicating the DNA was released from the particles and was able to stimulate dendritic cells. Pulmonary administration of the pDNA incorporated in chitosan nanoparticles was shown to induce increased levels of IFN- $\gamma$  secretion compared to pulmonary delivery of plasmids in solution or the more frequently used intramuscular immunization route. The authors indicated that pulmonary delivery of DNA vaccines against tuberculosis may provide an advantageous delivery route compared to intramuscular immunization and that increased immunogenicity can be achieved by delivery of this DNA encapsulated in chitosan nanoparticles.

## 4.9

**Conclusion**

Gene therapy offers a promising approach for the treatment of genetic disorders, vaccine development and tissue engineering. However, such opportunities will only be attainable by the development of safe and efficient gene delivery systems. Such systems must protect the DNA, and allow it to enter the targeted cell and reach the nucleus where genetic expression will take place. Several nonviral approaches have been developed and improved for use in different clinical settings. Substantial progress has also been made in improving plasmid expression vectors. It is now possible to achieve gene expression in a controllable manner using gene switch systems. A number of *in vitro* and *in vivo* studies, including ours, showed that chitosan is a suitable material for efficient nonviral gene therapy. Several groups are conducting studies using different strategies that can be linked to chitosan–DNA nanoparticles (including targeting cell membrane receptors) for a higher transfection yield.

Chitosan–DNA nanoparticles, due to their reduced cytotoxicity and ability to transport and release genes intracellularly, where expression of the encoded protein occurs, are considered as a potential candidate for a nonviral gene carrier. Further improvements in nonviral gene therapy will rely on a better understanding of the cellular and *in vivo* barriers to gene transfer.

### Protein & Peptide-based Nanomaterials

## 5

### Plant Protein-based Nanoparticles

*Anne-Marie Orecchioni, Cécile Duclairoir, Juan Manuel Irache and Evelyne Nakache*

#### 5.1

##### Introduction

Biopolymers, such as proteins, lipids or polysaccharides, are commonly used to encapsulate drugs in order to protect them from rapid degradation by environmental stress (e.g. light, heat, oxygen or pH sensitivity). Drug loading of carriers seems to be an attractive opportunity, especially if they are made from bioacceptable macromolecules, e.g. plant proteins. Colloidal carriers, in the form of nanoparticles with a diameter of 50–500 nm and up to a few micrometers, have the potential to deliver drugs to specific target sites and to achieve sustained drug release. Moreover encapsulation can modify the drug biodistribution and increase its bioavailability [1–4]. Nanoparticles can be formed from a variety of materials including synthetic polymers and biopolymers (i.e. natural compounds), such as proteins, lipids and carbohydrates [5]. Natural macromolecules from vegetable sources appear to be a very promising alternative to synthetic polymers due to their proven safety, especially those that are used as food sources. The selection of a suitable structural material has an important influence on its potential medical use. Comparing plant and animal proteins, it appears that vegetal proteins may be more disposable and cheaper than animal proteins. Moreover, for plant proteins, the purification process might be also simplified.

In general, protein nanoparticles display a number of interesting advantages. Among them, these carriers are biodegradable and metabolizable. Moreover, they can be prepared under “soft” conditions, without the use of toxic organic solvents or materials, and they can incorporate a wide variety of drugs in a relatively non-specific fashion [6]. Moreover, due to their defined primary structure, protein-based nanoparticles may offer various possibilities for surface modification and covalent attachment of drugs and ligands [7, 8].

Taking into account all of these advantages of plant proteins, this chapter will focus solely on the use of storage proteins from pea (legumin and vicilin) and wheat (gliadins) when used as a structural material to prepare nanoparticles, and their possible applications in pharmacy and medicine. These proteins are not the

only ones able to produce nano/microparticles for use as drug carriers – studies have also been performed on other plant proteins like soy glycinin from soybean seeds [9] and zein from corn [10]. However, the numbers of studies with these two proteins are very low. This chapter also includes an overview of the fabrication and applications of both conventional and “decorated” (i.e. conjugated) storage protein nanoparticles.

## 5.2

### Description of Plant Proteins

Plant proteins are characterized by their three-dimensional organization. Two classes can be distinguished:

- Fibrous proteins composed of polypeptide chains joined together along a linear axis. They are involved in the structural material of living organisms.
- Globular proteins composed of one or, more frequently, several polypeptide chains rolled up to give a three-dimensional structure. Most of them are storage proteins.

Most vegetal proteins play an active role in biological processes, e.g. enzymes, and they can be classified by their physicochemical and extraction properties [11]. Four classes are listed:

- Vegetable albumins are hydrosoluble and rich in ionic residues (arginine, glutamic acid, lysine, tryptophan, etc.).
- Globulins are complex molecules and their amino acids composition is similar to that of albumins. However, their solubility needs an electrolyte medium.
- Prolamins are soluble in hydroalcoholic mixtures due to their high content of amino acids with hydrophilic residues.
- Glutelins cannot be dissolved in any of the aforementioned solvents, due to their high molecular mass and the presence of disulfide bonds; they are rich in lipophilic amino acids.

Storage proteins comprise proteins generated mainly during seed production and stored in the seed that serve as nitrogen sources for the developing embryo during germination [12, 13]. It is obviously more effective for the plant to use proteins instead of secondary plant products for this purpose. The average protein content of cereal grains is 10–15% of their dry weight [14], whereas for leguminose seeds it is about 20–25% [15, 16]. In addition to seeds, storage proteins can also be found in root and shoot tubers, e.g. potatoes.

No clear definition exists of what a storage protein is. The term is operational and was coined for all those proteins whose ratio in the total protein amount of the cell is greater than 5%. All of these proteins are characterized by the absence of enzymatic activity, act as a nitrogen source during seed germination and, usually, occur in an aggregated state confined in a membrane [17, 18].

Storage proteins are important for human nutrition (plant proteins), and numerous studies concerning their structure and biosynthesis have been published. For leguminoses, a simplifying rule says that they contain two types of storage proteins – legumin and vicilin. The legumins (as well as the vicilins) are very similar in different leguminose species. However, Gramineae contain a third type of storage proteins – prolamin – and, depending on the origin, it is distinguished between zein (from *Zea mays*) [19], hordein (from *Hordeum vulgare*) [20] and gliadin (from *Triticum aestivum* L.). In contrast to legumins and vicilins that are mainly located in the cotyledons of seeds, prolamines are found in the endosperm [21].

### 5.2.1

#### Pea Seed Proteins

Globulins are the main storage proteins in pea seeds [22]. These globulins were characterized by Osborne [23] according to their insolubility in distilled water and, on the contrary, by their solubility in buffered aqueous neutral salt solutions. When they are fractionated by centrifugation techniques, three different fractions have been described (with sedimentation coefficients of 2, 7 and 11S). The so-called 7 and 11S globulins represent the major pea seeds storage proteins – vicilin and legumin, respectively. These proteins display a number of similarities, including the adopted shape when solved in an aqueous solution and the similar size of the domains of the subunits forming these proteins [24, 25]. However, they can be differentiated by their molecular weight [22, 26] and different behavior at high temperature. In fact, vicilin has a size of about 200 kDa, whereas legumin is about 360 kDa [22, 26]. Furthermore, legumin does not coagulate at high temperature [27].

- Vicilin belongs to the group of so-called 7S globulins. It has a complex globular structure composed of two different types of subunits with molecular weights of about 50 and 60–70 kDa. These subunits form trimeric holoproteins in different combinations [22, 28]. Vicilin is rich in acidic amino acids (aspartic and glutamic acids), leucine and lysine [29, 30].
- Legumin belongs to the group of so-called 11S globulins [26]. This protein has a complex globular structure made of six pairs of subunits. Each of the subunits is composed of disulfide-linked acidic  $\alpha$ -chains (molecular weight 40 kDa) and basic  $\beta$ -chains (molecular weight 20 kDa) [31]. Although the three-dimensional structure of legumin has not been yet determined, the sequence alignment of this protein appears to show some similarities with that of vicilin [24, 32].

### 5.2.2

#### Wheat Proteins

Storage proteins from the wheat seed are able to form a unique viscoelastic network called gluten. The properties of gluten make it useful in the production of food products such as bread, pasta and semolina, and more recently in biopackag-

ing materials [33]. The rheological properties of gluten are dependent on the protein interactions that are formed in the network, and these properties were found to be mainly influenced by physical parameters such as temperature and pressure [34–36].

Two main fractions are present in gluten – gliadin, which is soluble in 70% ethanol, made of single-chain polypeptides with an average molecular weight of 25–100 kDa linked by intramolecular disulfide bonds, and glutenin, an alcohol-insoluble fraction consisting of gliadin-like subunits stabilized by intermolecular disulfide bonds in large aggregates with a molecular weight greater than 106 kDa [37]. Because they account for about half of the total wheat gluten proteins, gliadin constitutes an important class of proteins that are involved in the various properties of the gluten [38, 39]. These proteins are polymorphic, and can be separated and classified on the basis of their electrophoretic mobility at acid pH values [40] in the following four fractions:  $\alpha$  (molecular mass about 25–35 kDa),  $\beta$  (30–35 kDa),  $\gamma$  (35–40 kDa) and  $\omega$  (55–70 kDa) groups [41–44]. All fractions have remarkably low solubility in aqueous solution except at extreme pH. This low water solubility has been attributed to the presence of interpolypeptide disulfide bonds and to the cooperative hydrophobic interactions which cause the protein chains to assume a folded shape. The amino acid composition shows that gliadin has equal amounts of apolar and neutral amino acids, mainly glutamine (about 40%). Furthermore, gliadin also has a high proline content (14%) and a very low proportion of charged amino acids [41, 45].

$\omega$ -Gliadin presents an isoelectric point ( $pI$ ) ranging from 5.5 to 7 and has a few charged molecules with six to 11 basic amino acids per molecule. In contrast,  $\alpha$ -,  $\beta$ - and  $\gamma$ -gliadins, with a  $pI$  range of 6.5–8, are still less charged than  $\omega$ -gliadin [46].

### 5.3

#### Preparation of Protein Nanoparticles

Several methods have been reported in the literature for the preparation of nanoparticles from protein raw materials. Coacervation or controlled desolvation methods have been developed using solvent or electrolyte as the coacervation agent [47, 48] or by adjusting the pH or ionic strength [49, 50]. In the coacervation methods promoted by solvents, the first step consists of dispersing the macromolecules in an adequate solvent, then adding the mixture to a second solvent which is a nonsolvent of the macromolecules. A required condition is that the solvent and the nonsolvent phases are miscible.

The coacervation process is applied to a macromolecular solution to reduce the solubility in the system to such a degree that appropriate phase separation of the macromolecule takes place, i.e. the formation of a macromolecule-rich phase. The desolvation leads to macromolecule precipitation or to coacervate formation. It is assumed that, before phase separation is observed, a conformational change in the macromolecule occurs. The addition of a desolvating agent shrinks the macromolecule coil which becomes smaller and smaller until the phase separation from

**Fig. 5.1.** Scanning electron micrograph of legumin nanoparticles. (From Ref. [52], permission pending).

the solvent occurs. It is possible to monitor the phenomenon by turbidity measurement. A desolvation agent decreases the turbidity because of the decrease in macromolecular size. To prepare small particles, it is important to maintain the system just outside the coacervation region. The addition of the coacervation agent should stop as soon as the Tyndall effect bounded to aggregation of macromolecules turns the system turbid [7]

### 5.3.1

#### Preparation of Legumin and Vicilin Nanoparticles

Legumin and vicilin have an aqueous solubility that is strongly pH and ionic strength dependent [30]. Nanoparticles from these pea proteins (Figs. 5.1 and 5.2) can be obtained by a simple coacervation or controlled desolvation method [50–52]. It was observed that extreme pH values enable their solubilization in aqueous medium. The coacervating or desolvating agent induces a progressive modification of the tertiary structure of the proteins, giving an increasing hydrophobic material which leads to submicronic aggregates or coacervates [53]. These coacervates are generally unstable and must be hardened for stabilization by physical or chemical

**Fig. 5.2.** Scanning electron micrograph of vicilin nanoparticles. (From Ref. [50]).

crosslinkage. In the case of these pea proteins, a three-step procedure can be employed to obtain nanoparticles.

In a first step, an unstable coacervate is obtained by mixing a solution of the chosen protein (pH 9) with a phosphate buffer solution. In a second step, the coacervates have to be hardened with a crosslinking agent in order to stabilize the just-forming coacervates. The most popular crosslinking agent is glutaraldehyde. This reagent reacts with the amino groups of the proteins, predominantly with the amino group of lysines, to form a Schiff base [54]. Finally, after the crosslinking, for pharmaceutical purposes, the obtained nanoparticles have to be purified. For this purpose, unreacted aldehyde can be neutralized with a sulfite and nanoparticles centrifuged in order to eliminate the nontransformed protein fraction onto particles.

Some comprehensive explanations of nanoparticles formation can be given. It is observed that, at a pH value close to 7, the coacervates show a submicronic size, but the percentages of coacervates yields are under 40% of the added protein. Similarly, the ionic strength of the buffer greatly influences the coacervate size and yield. The best experimental conditions to obtain small-sized particles (average diameter 500 nm) were found to be pH 6.8 and ionic strength 0.15 M for legumin, and pH 6.4 and ionic strength 0.10 M for vicilin [50, 52].

The isoelectric points of the two proteins are about 4.5. Thus, the balance between negative carboxyl groups (from glutamic and aspartic acids) and positive groups (from lysine and arginine) changes when the pH of the protein solution is less or greater than 4.5. Consequently, under environmental conditions close to the isoelectric point, these globulins would present a reduced interfacial charge which may enhance coacervate precipitation and phase separation. In other respects, for neutral pH values, legumin and vicilin would have a charge which may probably act against coacervate formation.

Concerning vicilin, in particular, a hypothesis for protein coacervate formation has been proposed. Under defined conditions, solubilized vicilin (7S form) may associate to yield an 11S insoluble form. This 11S form (probably a dimer of vicilin) may be responsible for the initial precipitation of vicilin which aggregates up to a critical size depending on environmental conditions (pH and ionic strength). The coacervate must be quickly hardened by crosslinkage in order to prevent the aggregates coalescing to a separate phase.

### 5.3.2

#### **Preparation of Gliadin Nanoparticles**

Gliadin nanoparticles (Fig. 5.3) can be prepared by a desolvation method in which a dissolution of gliadin in an organic solvent/water mixture is desolvated by the addition of a nonsolvent aqueous phase [50, 55]. Note that gliadin nanoparticles prepared in this way are stable and further treatment by heat or chemical crosslinking is not necessary to stabilize them. This fact can be explained by the extremely low solubility of gliadin in an aqueous medium and represents an advantage when compared with other protein nanoparticles (i.e. albumin, gelatin).

**Fig. 5.3.** Scanning electron micrograph of a gliadin nanoparticle. (From Ref. [8]).

In any case, gliadin nanoparticles can be hardened by chemical stabilization in order to modulate the drug release characteristics of nanoparticles or their *in vivo* distribution and interaction with the body.

Once produced (and eventually hardened by chemical crosslinkage), they have to be purified. The organic solvents are eliminated by evaporation under reduced pressure, whereas the amounts of protein not transformed onto nanoparticles and other impurities (i.e. the chemical crosslinker) are eliminated by dialysis, gel-permeation chromatography or, more frequently, subsequent centrifugations. Finally, nanoparticles can be also lyophilized to preserve their physicochemical properties for a long period of time. For lyophilization of gliadin nanoparticles, a solution of glucose 5% w/v has been proposed as a cryoprotector [56, 57].

In summary, this simple method allows the preparation of reproducible particle sizes with a narrow distribution. The main advantages are the production of nanoparticles in the absence of toxic organic solvents and the possibility of avoiding the chemical stabilization step to obtain stable nanoparticles. The selection of the solvent phase of gliadin has a significant influence on the size of the resulting nanoparticles. In this context, mixtures between either ethanol and water or acetone and water enable production of both smaller particle sizes and reproducible results. Another key factor concerns the nonsolvent of gliadin. In this case, an aqueous solution of NaCl (0.9% w/v) has been proposed [50]. When a mixture of ethanol and water is used, the size of the resulting nanoparticles is close to 450 nm and the yield of the process, determined by gravimetry and reverse-phase high-performance liquid chromatography (RP-HPLC), is about 90% [50, 56].

More recently, in order to understand the influence of environmental parameters governing gliadin nanoparticles size, a thermodynamic approach was investigated, i.e. the determination of the solubility parameter of the protein [58]. According to Hildebrand theory [59], the solubility parameter of gliadin was determined using a panel of solvents or mixtures of them. It is assumed that the solvent which best solubilizes gliadin has the same solubility parameter as the protein [60]. Different mixtures were prepared with bioacceptable solvents such as ethanol, ethylene glycol, propylene glycol and ultra-pure water. These solvents are usually considered

as references for the determination of the solubility parameters of biological compounds.

When a mixture of ethanol and water is used, the size of the resulting nanoparticles is close to 450 nm and the yield of the process, determined by gravimetry and RP-HPLC, is about 90% [50, 56]. However, a mixture of propylene glycol and water (73/27%) appears to be the best selection to obtain small gliadin nanoparticles of about 150 nm [58].

#### 5.4

##### Drug Encapsulation in Plant Protein Nanoparticles

In order to evaluate the encapsulation ability of gliadin nanoparticles, different drugs were tested, chosen for their medical and/or pharmaceutical interest. The objective of this research was to determine the feasibility of nanoparticles loaded with hydrophilic or lipophilic drugs and furthermore in order to obtain as small-sized particles as possible. Attention was focused on the drug release mechanism. Four drugs were chosen – two lipophilic vitamins, i.e. all-*trans* retinoic acid [vitamin A (RA)] and  $\alpha$ -tocopherol [vitamin E (VE)], and two hydrophilic drugs, i.e. a slightly polar mixture of linalool–linalyl acetate (LLA), components of the essential lavender oil, and the cationic amphiphilic benzalkonium chloride (BZC). For all these particulate systems, nanoparticles sizes were determined by scanning electron microscopy or photon correlation spectroscopy.

##### 5.4.1

##### RA Encapsulation in Gliadin Nanoparticles

RA is involved in the proliferation and differentiation of epithelial tissues. This vitamin in acidic form reduces the size of sebaceous glands and sebum secretion, making it an attractive agent for the treatment of skin disorders such as acne, psoriasis, hyperkeratosis, ichthyosis and epithelial tumors [61, 62]. In the treatment of acne, it was demonstrated that RA prevents inflammatory lesions by loosening follicular impactions (microcomedones) and clearing the follicular canal of retained keratin [63]. Furthermore, RA has been proven effective against a range of malignancies in human clinical trials, although many patients relapsed after a remission [64]. *In vivo* studies have shown that RA is active against acute promyelocytic leukemia [65, 66]. Unfortunately, the limited duration of RA activity in this leukemia is a pharmacological adaptation resulting in reduced serum concentration after prolonged treatment [67]. Nevertheless, in spite of a real therapeutic interest, several drawbacks (e.g. teratogenicity) have been reported for the currently available dosage forms [62]. To overcome these inconveniences, and in an attempt to increase the therapeutic efficacy of RA, alternative dosage forms have been suggested – microemulsions [68] and liposomes for intravenous [69] and topical administration [70]. Another system suitable for controlled drug release could be nanoparticles from biopolymers. For this purpose, we have chosen nanoparticles from gliadin

din. They were prepared by the aforementioned desolvation method [50, 58]. These particles can be obtained by using only bioacceptable solvents such as ethanol and water. Their size, which is one of the determinant characteristics for medical purposes, can be optimized. These nanoparticles, showing good stability in phosphate-buffered saline (PBS), were assayed as carriers for RA. They have shown a quite good entrapment efficiency – about 75% of added drug at  $60 \mu\text{g} (\text{mg gliadin})^{-1}$  and a payload of  $74 \mu\text{g} (\text{mg gliadin})^{-1}$  nanoparticles [58]. In order to quantify more precisely the solvent effect, the size diameter was optimized through a solubility parameter study. The smallest size was reached for protein solubility solvent equal to that of gliadin. The average diameter of the particles was about 150 nm [58]. RA was released from these nanoparticles, in a two-step mechanism, characterized by an initial rapid release followed by a continuous diffusion process. The first release was found to be about 20% of the loaded drug and can be related either to the release of the drug entrapped in the peripheral domains of the nanoparticle matrix or to a simple desorption of superficial RA, whilst the second slower period was linear with respect to time and appeared to be a diffusion phenomenon. Furthermore, in this second step, about 20% of the drug was released by diffusion in 3 h.

These observations offer interesting prospects for the preparation of drug-loaded carriers for medical applications.

#### 5.4.2

#### **VE Encapsulation in Gliadin Nanoparticles**

Drug carriers are interesting systems to prevent drawbacks related to the drug itself by decreasing its degradation rate. In order to test the protective power of nanoparticles against environmental stresses, a second lipophilic vitamin, VE, was encapsulated into gliadin nanoparticles. VE is known to act as a strong antioxidant or nitrosamine blocker to prevent the build-up of cellular peroxide [71]. The exposure to free oxygen species induces a rise in lipid peroxidation, which may cause injury at different sites of the body. For instance, the action of free radicals produced by a variety of environmental stresses (among them sun exposure) may promote skin damage, such as premature skin ageing [72], skin fragility and even skin cancers (melanoma or others) [73] related to a decrease in cellular immunity of the skin. VE appears to be one of the strongest free radical scavengers through its action as a chain-breaking antioxidant in membranes [74], preventing acute or chronic damage [75]. In addition to these biological activities, VE also exerts cosmetic functions; notably, it helps delay the progression of aging [76] and possesses a skin moisturizing power [77]. However, VE is degraded by oxygen, and dosage forms must be protected from light, heat and prolonged contact with air. Previous work has shown that the preparation of gliadin nanoparticles could be easily performed by a simple coacervation method. It is for this reason that gliadin has been chosen. Moreover, gliadin possesses the ability to interact with epidermal keratin due to its richness in proline [78]. VE-loaded gliadin nanoparticles have been characterized by their size,  $\zeta$  potential, VE payload and entrapment efficiency.

When loaded, the gliadin particle size is about 900 nm and their charge is close to zero. They are suitable drug carriers with an optimum encapsulation rate of about  $100 \text{ VE } \mu\text{g (mg gliadin)}^{-1}$  with an efficiency of more than 77%. The release behavior of VE-loaded nanoparticles may be interpreted as a “burst” effect, followed by a diffusion process through a homogeneous sphere [3].

#### 5.4.3

#### Lipophilic, Hydrophilic or Amphiphilic Drug Encapsulation

In order to study the influence of drug polarity on nanoparticle characteristics such as particles size, drug loading and drug release, three different drugs with different polarities were chosen [79]. VE, studied in a previous paper [3], was employed as a model of a lipophilic drug, and the slightly polar LLA and the amphiphilic cationic benzalkonium chloride (BZC) as hydrophilic models. Their dielectric constants are, respectively, 4, 8 and 45 [80]. The choice of these drugs was governed by their utilization in pharmaceutical dosage forms:

- VE, widely used as strong antioxidant in many medical and cosmetic applications, is rapidly degraded because of its light, heat and oxygen sensitivity [3].
- Linalool and linalyl acetate are the major components of essential lavender oil used in aromatherapy. They possess antibacterial and antifungal properties [81]. They are used in topical formulations. They may cause skin irritation by reason of a potential caustic power. Gliadin encapsulation could be a fruitful method for LLA formulations. Furthermore, the interaction of gliadin proline with skin keratin associated with the controlled release of LLA may avoid some drawbacks of this drug.
- BZC is a quaternary ammonium used as an antiseptic and bactericide, spermicide [82], and virucide [83]. However, BZC can promote some allergies followed by mucous lesions. It is assumed that encapsulation into gliadin nanoparticles could minimize or avoid lesions promoted by this irritant quaternary ammonium and could improve the dosage form by delaying drug release.

Drug entrapment and efficiency were tested after encapsulation. The results showed that the amount of entrapped VE and LLA is higher than that of the cationic BZC, confirming a strong interaction between gliadins and apolar compounds, due to the apolarity of the proteins. When comparing drug entrapment, results show that the optimal VE concentration is obtained for  $972.0 \text{ VE } \mu\text{g (mg gliadin)}^{-1}$ , with an efficiency of 79.2%, the optimal LLA concentration corresponds to  $980.0 \text{ LLA } \mu\text{g (mg gliadin)}^{-1}$ , with an efficiency of 82.4%, and the optimal BZC concentration corresponds to  $550.3 \text{ BZC } \mu\text{g (mg gliadin)}^{-1}$ , with an efficiency of 52.3% (Table 5.1).

For drug release quantification, only VE and BZC were studied. The reason being that LLA should be studied under a controlled atmosphere and not in a liquid medium. Such differences between media used did not allow an easy comparison to other drugs. For VE and BZC, drug releases were, respectively, 13 and 11% after

Tab. 5.1. Drug encapsulation characteristics in gliadin nanoparticles.

<b>Drug</b>	<b>Polarity (dielectric constant)</b>	<b>Payload (%)</b>	<b>Encapsulation efficacy (%)</b>
VE	Apolar (4)	97.2	79.2
LLA	slightly polar (8)	82.4	98.0
BZC	polar (amphiphilic cationic) (45)	66.0	52.3

1 h, and 30.6 and 11.7% after 30 h. The phenomenon observed can be interpreted as a burst effect completed by a drug diffusion process through a homogeneous sphere. Both release diffusion parts of the profiles have been modeled with a diffusion process in a homogenous sphere. However, the diffusion coefficients are different according to VE or BZC, i.e.  $1.12 \times 10^{-20}$  and  $6.36 \times 10^{-21} \text{ m}^2 \text{ s}^{-1}$ , respectively. This could be related to the different affinity of the gliadin for the two drugs. In organic phases, diffusion coefficients are usually about  $10^{-9} \text{ m}^2 \text{ s}^{-1}$ . Here, the coefficients are clearly much lower, which confirm that the drug is retained by the nanoparticle matrix.

In conclusion, it can be observed that whatever the polar drug character, this gliadin nanoparticulate system is able to entrap the drug with an acceptable payload and encapsulation efficiency [79].

## 5.5

### Preparation of Ligand–Gliadin Nanoparticle Conjugates

In general, proteins produce biodegradable particles whose physicochemical properties can be modulated by the crosslinking process employed for their stabilization. Furthermore, due to the presence of numerous functional groups (i.e. amino and carboxylic residues), proteins are excellent candidates for the preparation of conjugates, formed by the attachment of molecules capable of providing specificity to the surface of nanoparticles. In this context, different ligands have been proposed, including antibodies [84, 85], lectins [86, 87], carbohydrates [88] and other biological ligands, in order to recognize or bind particular molecules [89, 90].

However, the association of ligands with nanoparticles can be achieved by different procedures, including covalent linkage and adsorption processes [91]. Ideally, the ligand should be conjugated to particles through a covalent linkage, which is more stable than adsorption procedures, without affecting its specificity. Noncovalent attachment relies on a fortuitous process. Further, it is difficult to control the amount of ligand which is associated and this process is useful only for those proteins that will associate nonspecifically [92]. Different techniques for covalent attachment may be envisaged, depending on the principal functional groups located on the carrier surface. The most widely used methods of ligand coupling are the use of cyanogen bromide [84, 93] and periodate [94, 95] for hydroxyl

### Protein solvent phase

**Fig. 5.4.** Route for the preparation of ligand–gliadin nanoparticle conjugates by desolvation of gliadin followed by CDI activation and further incubation with the ligand.

groups, glutaraldehyde [96, 97] and ethylene glycol diglycidyl ether [98] for amino groups, and carbodiimide (CDI) for carboxylic groups [99, 100].

This last technique is the one preferred in order to obtain conjugates between a ligand and protein nanoparticles [87, 101–103]. CDI involves the activation of carboxylic acid groups to give NH-activated carboxylic acid groups which can react with free amino groups of the ligand polypeptide chains [104]. In proteins, these carboxylic groups can be found on aspartic and glutamic acid residues. For vicilin, these amino acids represent about 19 groups per 1000 amino acid residues [101]. For gliadin, these amino acids only represent 21 and 71 groups per 1000 amino acid residues, respectively [45, 105]. In spite of gliadin having a very low proportion of these two amino acids, it appears that the coupling reaction is efficient enough to provide acceptable lectin binding.

Figure 5.4 summarizes the preparation of lectin–nanoparticle conjugates. In brief, the first step of the manufacturing protocol involves the activation of the carboxylic groups on the gliadin nanoparticles by addition of a CDI derivative [i.e. 1-(3-dimethylaminopropyl)-3-ethyl-carbodiimide hydrochloride]. After incubation, the suspension of “activated” nanoparticles has to be centrifuged in order to remove the unreacted reagent. Then, the nanoparticles are dispersed in an aqueous medium and incubated with the desired ligand for the coupling reaction by overnight incubation at room temperature [101, 102]. Finally, the resulting conjugates are purified and lyophilized using glucose as a cryoprotector [103].

Different parameters can influence the yield of the process. In spite of the fact that the CDI reaction can effectively occur up to at least pH 7.5 without any significant loss of yield, it has been reported that the optimal pH ranges between 4.7 and 6 [106]. This fact was also observed by Arangoa et al. who showed evidence of superior binding of a *Dolichus biflorus* lectin (DBA) to the surface of gliadin nanoparticles with 2-(*N*-morpholino)ethanesulfonic acid (MES) buffer (1 mM, pH 5.5) rather than with PBS (1 mM, pH 7.4) [103]. This may be explained as being due to the proton of the carboxylic group facilitating the rupture of one double link of the CDI molecule [107], forming the *O*-acylisourea intermediate. This active residue is then able to react directly with primary amines forming amide bonds and

releasing the CDI derivative. Moreover, at neutral pH, the overall charge of both the nanoparticles and the ligand would be negative. Therefore, ligand approaches to a nanoparticle surface and subsequent binding would not be favored by the phenomenon of charge repulsion [108].

Another critical factor affecting ligand binding to the surface of protein nanoparticles is the reaction time between the CDI and the gliadin. Therefore, an increase in the reaction time induced a dramatic decrease in the amount of the ligand binding to the nanoparticle surface. This could be due to the degradation of the reactive *O*-acylisourea complex. In fact, this complex is rapidly hydrolyzed in aqueous solution, having a constant rate measured in seconds [109]. If the target amine does not interact with the *O*-acylisourea intermediate before its hydrolysis, the desired binding cannot occur. This is especially problematic when the target molecule is in low concentration [106], as usually occurs in the binding of active ligands to the surface of nanoparticles. Another possible explanation for the DBA binding decrease could be the formation of the stable *N*-acylurea derivative [110].

However, the amount of CDI used to activate functional groups on the surface of nanoparticles is also important. A low amount of CDI may require longer reaction periods. However, the use of high amounts of CDI may induce irreversible aggregation of nanoparticles. This may be explained by the presence of both carboxylic and amine groups on the surface of the nanoparticles. Therefore, at high CDI concentrations, self-polymerization may take place [106]. In any case, in order to obtain a good binding efficiency, it is necessary to find a balance between the reaction time and the amount of CDI used to activate the nanoparticles.

Finally, another important factor concerns the amount of ligand used in the incubation with the activated nanoparticles. For gliadin nanoparticles, a maximum of ligand binding occurs when the amount of ligand incubated with activated nanoparticles is about  $50 \mu\text{g} (\text{mg gliadin})^{-1}$  nanoparticles [103].

## 5.6

### Bioadhesive Properties of Gliadin Nanoparticles

Bioadhesion is classically defined as the ability of a material to adhere to a biological substrate with the objective of improving the therapeutic efficiency of drugs by increasing the residence time at the site of activity or absorption [111, 112]. It is interesting to note that a number of drugs remain poorly available when administered by the oral route. Among other reasons, this fact can be related either to a low mucosal permeability for the drug or to its low solubility in the mucosal fluids. In both cases, an important fraction of the given dose is eliminated from the alimentary canal prior to being absorbed. The use of bioadhesive nanoparticles can be an adequate strategy to improve drug bioavailability. In fact, these carriers may enhance the drug absorption rate by reducing the diffusion barrier between the dosage form and the site of action or absorption. Similarly, they may prolong the residence time of the drug in the gut and, therefore, increase the time during which absorption can occur.

For bioadhesion studies, gliadin nanoparticles were labeled with carbazole, which is a hydrophobic fluorescent molecule.

### 5.6.1

#### **Ex Vivo Studies with Gastrointestinal Mucosal Segments**

In order to evaluate the bioadhesive capacity of these carriers, nanoparticles were incubated with fresh portions of rat gastrointestinal mucosa using a plate of aluminum with a slit in the center [113]. The mucosa in the slit of the plate was covered with 1 mL of suspensions (containing  $4 \text{ mg mL}^{-1}$  nanoparticles) and the incubation time was fixed for 30 min. After incubation, the suspensions were sucked off and the samples were rinsed with 5 mL 0.9% NaCl solution to eliminate the non-attached particles. Then, the mucus layer including the adsorbed particles was drawn from the membrane and digested with NaOH for 24 h. After total dissolution of mucus, carbazole extraction was performed with 1.5 mL methanol, vortexed for 1 min and centrifuged at  $20\,000 \text{ g}$  for 10 min. Finally, the amounts of adhered nanoparticles or conjugates were estimated by fluorometry [103].

Gliadin nanoparticles were able to develop rapid interaction with the gut mucosa. In fact, the adsorption equilibrium for nanoparticles and conjugates was reached in less than 30 min [103]. Similarly, under the experimental conditions used [ $4 \text{ mg}$  (particles or conjugates)  $\text{mL}^{-1}$ ], no saturation was observed on the apparent surface of mucosa delimited by the device.

Figure 5.5 shows the interactions of gliadin nanoparticles with intestinal mucosa samples. Comparing the different anatomical regions, gliadin nanoparticles

Fig. 5.5. Adhesive interactions of gliadin nanoparticles in isolated intestinal segments ( $n = 4$ ).

showed a high affinity for the small intestine segments. However, no significant differences in the extent of interaction were found between the duodenum, jejunum and ileum ( $P < 0.05$ ). Therefore, for ileum or duodenum portions, the amount of nanoparticles interacting with the mucosa was calculated to be close to  $8 \text{ g m}^{-2}$ , which represents about 40% of the nanoparticles placed in contact with the gastrointestinal tract. In this context, the interaction of poly(styrene) nanoparticles with intestinal segments (under similar experimental conditions) was size dependent and the largest amount of latex able to interact with the mucosa was about  $1 \text{ g m}^{-2}$  [113, 114]. Similarly, gliadin nanoparticles interacted about 8-fold more with the intestinal mucosa than poly(isobutyl cyanoacrylate) nanoparticles [115]. For large intestine portions, the interaction of gliadin nanoparticles strongly decreased. This may be explained by a reduction of both the mucosa surface and the mucin concentration along the gastrointestinal tract. According to these results, it appears that gliadin nanoparticles would be useful for improving the bioavailability of drugs. These powerfully adhesive carriers may prolong the residence time and enhance drug absorption, thus reducing the diffusion pathway.

However, DBA–gliadin nanoparticle conjugates displayed a different ability to develop adhesive interactions with the gut mucosa. In the small intestine, these conjugates showed an adhesive interaction similar to the controls ( $P < 0.05$ ) and, for all segments, this interaction was close to 10% of the initial concentration placed in contact with the mucosa. However, in the large intestine a significant increase of about 100% was found for DBA conjugates. This fact can be explained by the reported capability of DBA to strongly react with the colonic epithelial surface [116, 117] due to the presence of *N*-acetyl-D-galactosamine (specific sugar for DBA) residues, which provide the substrate for their site-specific interaction.

Finally, concerning the interaction of gliadin nanoparticles with Peyer's patches, it was found that gliadin nanoparticles showed 3.5 times more capacity of interaction with these lymphoid tissues than DBA conjugates [103].

All of these results confirmed that gliadin nanoparticles displayed a high interactive potential with biological surfaces. However, the possible interaction between the biological substrate and these nanoparticles is of a nonspecific nature. This fact means that these colloidal systems interact in the same way with a number of components of the biological substrate, without showing target properties for a particular region or cell structure [118].

## 5.6.2

### ***In Vivo* Studies with Laboratory Animals**

In order to evaluate the *in vivo* bioadhesive capacity of gliadin nanoparticles and their influence on the pharmacokinetics of the loaded drug, animals were gavaged with a single dose of nanoparticle formulations dispersed in 0.5 mL water. For the bioadhesion study, the gastrointestinal tract of animals was cut in different portions, rinsed with saline and digested with sodium hydroxide. The fluorescent marker was extracted with methanol and determined by spectrofluorimetry. The amount of carbazole, determined in the mucosa segments, was used for the

**Fig. 5.6.** Gastrointestinal transit profile of gliadin nanoparticles. Single administration of a single oral dose of 30 mg. Data expressed as the mean  $\pm$  SD ( $n = 4$ ). (Adapted from Ref. [102]).

estimation of the interacted nanoparticulate fractions. For the pharmacokinetics studies, blood samples were taken from the ophthalmic venous plexus, centrifuged and assayed for carbazole content by an HPLC method with fluorescent detection [57]. *In vivo* studies demonstrated that gliadin nanoparticles displayed a high adhesive potential with a clear tropism for the stomach mucosa (Fig. 5.6). Thus, thirty minutes post-administration, about 30% of the initial dose remained adhered within the gut. However, around 90% of the adhered nanoparticles were localized in the stomach. Similarly, 1 h after administration, only 18% of the initial dose could be found in the stomach and their presence in other intestinal regions was also negligible. Finally, at 2 h post-administration, only about 8% of the given dose was found adhered to the mucosa [119]. This profile of bioadhesion (tropism for the stomach mucosa and rapid decline of the adhered fraction over the time) was not significantly affected when nanoparticles were coated with DBA [103].

Nevertheless, in order to study the influence of the degree of crosslinking on the bioadhesive profile of nanoparticles and carbazole absorption, two different formulations were prepared. The first one resulted from the crosslinking of gliadin nanoparticles with glutaraldehyde with 2 h prior purification (CL-NP). The second one (DCL-NP) was obtained after treatment of gliadin nanoparticles with a CDI derivative for 1 h and subsequent treatment with glutaraldehyde for 2 h [57] (Tab. 5.2).

Within the stomach, the bioadhesive profile of gliadin nanoparticles was found to be influenced by the crosslinkage. Thus, noncrosslinked nanoparticles displayed a higher initial ability to develop adhesive interactions than crosslinked nanoparticles. However, the elimination rate of the adhered fraction was higher for noncrosslinked than for stabilized nanoparticles [57, 119]. On the contrary, the crosslinking process allowed a similar amount of carriers adhered to the mucosa to be

**Tab. 5.2.** Physicochemical characteristics of the different formulations based on gliadin nanoparticles ( $n = 6$ ).

	Size (nm)	$\zeta$ potential (mV)	Fixed ligand ( $\mu\text{g mg}^{-1}$ )	Loaded carbazol ( $\mu\text{g mg}^{-1}$ )
NP	460 $\pm$ 19	27.5 $\pm$ 0.8	–	12.6 $\pm$ 1.2
CL-NP	453 $\pm$ 24	24.5 $\pm$ 0.5	–	12.2 $\pm$ 0.8
DCL-NP	478 $\pm$ 31	21.2 $\pm$ 1.3	–	12.1 $\pm$ 1.6
BSA-NP	514 $\pm$ 18	34.7 $\pm$ 1.7	20.8 $\pm$ 1.7	12.5 $\pm$ 0.6
DBA-NP	521 $\pm$ 13	32.4 $\pm$ 0.9	23.5 $\pm$ 2.6	12.6 $\pm$ 0.9

CL-NP: nanoparticles crosslinked with glutaraldehyde; DCL-NP: nanoparticles crosslinked with CDI and glutaraldehyde; BSA-NP: bovine serum albumin–gliadin nanoparticle conjugates (control); DBA-NP: *D. biflorus* lectin–gliadin nanoparticle conjugates.

maintained for at least 1 h, which was calculated to be around 15% of the given dose (Fig. 5.7).

Another interesting point is that, within the stomach, the adhered nanoparticles appear to accumulate in the nonglandular region [119]. In this last region, cross-linked nanoparticles have a 1.5 times higher adhesive intensity than nonhardened nanoparticles. Similarly, the mean residence time of the adhered fraction to the stomach mucosa was about 95 min higher for crosslinked than for conventional gliadin nanoparticles [119].

This high adhesive capacity of gliadin nanoparticles may be explained by the protein composition with a high content of neutral and lipophilic residues. Neutral amino acids may promote hydrogen-bonding interactions with the mucosa, while

**Fig. 5.7.** Evolution of nonhardened gliadin nanoparticles (NP), nanoparticles crosslinked with glutaraldehyde (CL-NP), and nanoparticles crosslinked with CDI and glutaraldehyde (DCL-NP) in the stomach mucosa, as a function of

time, after single oral administration 20 mg particles ( $1.14 \text{ mg carbazole kg}^{-1}$ ). The results are expressed as the percentage of the given dose ( $n = 6$ ).

Fig. 5.8. Carbazole plasma levels after the oral administration of a single dose of  $1.14 \text{ mg carbazole kg}^{-1}$  loaded in NP, CL-NP or DCL-NP ( $n = 12$ ).

the lipophilic components may develop hydrophobic interactions with the biological support [115, 118, 120]. On the other hand, a more energetic crosslinking process reduces the ability of nanoparticles to develop adhesive interactions within the mucosa; however, this process would decrease the degradation rate of gliadin nanoparticle and, thus, provide a prolonged residence in the mucosa. For crosslinkage with glutaraldehyde, the adhered fraction of nanoparticles is constant for at least 1 h, whereas for nanoparticles crosslinked with CDI and glutaraldehyde, the adhered fraction (around 10% given dose) remained constant for at least 2 h.

Concerning the pharmacokinetic study, Fig. 5.8 shows the carbazole plasma concentration provided by nonhardened and crosslinked nanoparticles when administered by the oral route. It is interesting to note that when carbazole was formulated as an aqueous suspension it was not possible to determine the  $T_{\max}$ ,  $C_{\max}$  and the elimination rate. Similarly, the area under of curve (AUC) was around zero since their absorption was negligible. This fact is typical for hydrophobic drugs with very poor aqueous solubility [121–124].

However, when formulated in nonhardened nanoparticles, the bioavailability of carbazole was calculated to be about 40% of the dose. For crosslinked nanoparticles, the bioavailability was close to the 50%. Moreover, the crosslinkage enables us to increase the  $T_{\max}$ , and to decrease the  $C_{\max}$  and the elimination rate. Similarly, the mean residence time was significantly increased in comparison with nonhardened nanoparticles and an aqueous solution of carbazole [57].

These pharmacokinetic results can be explained by the ability of gliadin nanoparticles to develop bioadhesive interactions within the stomach mucosa. Once gliadin nanoparticles are adhered to the mucosa, they would release the loaded molecules to the absorbing cell layer, minimizing losses to the luminal environment and increasing the local drug concentration. In this context, the active molecule (carbazole in this study) would be able to show a first-order absorption process. However,

the digestion of nanoparticles either in luminal fluids or adhered in the mucus may provide an instantaneous release component which may be related to a first-order absorption. In fact, the interactions developed by gliadin nanoparticles within the stomach mucosa are the key phenomena influencing carbazole absorption. This hypothesis was confirmed by a deconvolution model [57].

## 5.7

### Future Perspectives

For pharmaceutical dosage forms it is well known that, whatever the administration mode, the principal objectives to be reached are the enhancement of the efficiency associated with a reduced toxicity and controlled drug release. Furthermore, if administered by a parenteral route, it is hoped that a major amount of the drug reaches the target site avoiding undesirable side-effects, i.e. a modification of drug distribution is required [125, 126].

Colloidal carriers in the form of nanoparticles have this potential to deliver drugs to specific target sites and to achieve sustained drug release. The bioacceptability of such nanoparticulate systems is strongly size dependent and, for intravessel administration, the diameter must be smaller than that of the smallest blood capillary. Consequently, size optimization is a very important parameter.

Furthermore, for medical applications, it is of interest to test their potential for parenteral administration, and particularly the humoral and cellular responses of protein particles after injection in animals. The first reports have been published describing these responses for native legumin and legumin nanoparticles after intradermal injection in rats [127].

#### 5.7.1

##### Size Optimization

Bearing in mind this important condition, all the parameters involved in the preparation of gliadin nanoparticles have been optimized (some results have been published [55]; other are in progress). The studied parameters were:

- Choice of the protein solvent
- Protein concentration
- Temperature during the experimental procedure
- Solvent/nonsolvent ratio
- Shear rate imposed during mixing
- Nanoparticle size evolution with time

Concerning the choice of the protein solvent, it was demonstrated that the closer the solubility parameter of the protein is to that of the solvent, the smaller the particle size (and correspondingly higher the amount of protein solubilized), under the experimental conditions chosen.

Other important experimental conditions were the solvent/nonsolvent ratio, the

temperature and the shear rate during the procedure. The data available showed that the best ratio must be less than unity and that an elevated temperature (compatible with protein thermolability, about 35 °C) decreases the particle size. Moreover, an optimum shear rate was observed for each protein concentration in the medium.

Concerning the size evolution of the nanoparticles with time, the first results showed that this parameter is a determinant for high protein concentrations. For instance, for a supersaturated solution of protein, the size increases 10 times in 100 min, ranging from 70 nm after 1 min to about 700 nm after 100 min. This is in favor of a spontaneous nucleation which occurs as soon as the non-solvent is added to the medium. In order to obtain a large range of nanoparticle sizes, it now remains to resolve the stabilization of the particles whatever their size.

In all of these abovementioned works the particle sizes of nanoparticles were greater than 100 nm. There are currently limitations on achieving nanoparticles with a size less than 100 nm and new developments are anticipated in the future.

### 5.7.2

#### **Immunization in Animals**

Preliminary experiments were performed on legumine nanoparticles in order to evaluate the capacities of biodegradable plant protein nanoparticles as drug delivery systems. More particularly, as it is possible to think that these nanoparticulate carriers could be considered as safe for oral or topical administrations, it was of interest to test their potential after injection [127]. In this context, humoral and cell-mediated responses were analyzed in rats. They were immunized with an intradermal injection of legumin or legumin nanoparticles of about 250 nm. Legumin and legumin nanoparticles were suspended in a sterile saline solution mixed with complete Freund's adjuvant (CFA). A control group of rats was inoculated only with saline solution and CFA.

*Humoral responses.* These responses against legumin and legumin nanoparticles were examined by usually appropriate techniques, i.e. Western blot and ELISA [127]. Both techniques showed that sera from rats immunized with legumin strongly expressed antibodies against this protein. On the contrary, serum samples from rats inoculated with legumin nanoparticles did not contain detectable amount of antibodies. Hence, legumin appears to be a potent inductor of the humoral immune response, while the use of legumin nanoparticles seems able to avoid the production of antibodies against them. However, the mechanism implicated in the absence of any humoral response to the legumin nanoparticles is far from clear. Mirshahi et al. [127] suggested some explanations: the chemical cross-linkage with glutaraldehyde [52] may produce some irreversible conformational changes in the protein tertiary structure making it less antigenic than the native protein [128], glutaraldehyde release could modify the surrounding cells and thus the lymphocyte response to antigens [129] or legumin nanoparticles were not sufficiently degraded to allow antigen formation during the period over which

experiment was carried out (1 month). Work is in progress to better understand this behavior.

*Cell-mediated response.* This was evaluated by *in vitro* lymphocyte proliferation assay 10 and 30 days after intradermal injection. Neither legumin nor legumin nanoparticles stimulated an immunogenic response [127]. This absence of response may be explained by a cytostatic effect of legumin. In a previous work (unpublished observations) it was noticed that legumin and legumin nanoparticles have a suppressive effect on *in vitro* fibroblast proliferation. These observations have to be confirmed.

Taking into consideration this cytostatic effect of legumin nanoparticles, it should be interesting to use them as pharmaceutical devices for the delivery of antitumor drugs in local cancer treatment.

Similar experimental work has to be carried out with the other plant proteins, gliadin and vicilin, in order to explore their medical and pharmaceutical potential as drug delivery systems.

From these *in vivo* and *in vitro* results, it can be assumed that plant proteins possess a role exceeding that of inert excipients. They have an influence on the entrapment efficiency of the drug and compatibility with tissues (essentially gliadin). In the future, it will be of interest to test these natural materials as encapsulating agents for the protection of sensitive drug from degradation (peptides, insulin, genes, etc.) and their ability to control drug release.

## 5.8

### Conclusion

The method used to prepare all plant proteins nanoparticles was a controlled desolvation method using only bioacceptable solvents. This procedure, avoiding toxic solvents, allowed the preparation of submicronic nanoparticulate systems with a narrow size distribution, and quite good yields and entrapment efficiency, making them susceptible to scale-up and industrial use. For gliadin, either hydrophilic or lipophilic drugs could be entrapped satisfactorily. Furthermore, gliadin nanoparticles possess a high interactive potential with biological surfaces, as demonstrated by *ex vivo* and *in vivo* animal experimentations. It appears that gliadin nanoparticles are interesting oral carriers to improve bioavailability of drugs. Nevertheless, in the future, efforts should be made to obtain a complete understanding of all the mechanisms implicated in the metabolism of these colloidal systems at the biomolecular level, in order to use them for medical applications.

## 6 Peptide Nanoparticles

Klaus Langer

### 6.1 Introduction

The primary objective of a therapy with pharmacological active compounds is the controlled delivery of the compound to its site of action. After administration most drugs show a certain distribution throughout the body which depends mainly on their physicochemical characteristics. Only a certain fraction of the drug reaches its site of action; the other fraction may be responsible for unwanted or toxic side-effects. Therefore, a lot of concepts and drug delivery systems for the targeting of drugs to their specific site of action have been developed. A promising method is drug loading to colloidal drug carrier systems such as microemulsions, liposomes and nanoparticles. Liposomes, mainly consisting of phospholipids and cholesterol, are characterized by good biocompatibility; however, they suffer from the disadvantage of a short shelf-life and drug leakage. In comparison to liposomes, nanoparticles are solid colloidal particles in the size range between 10 and 1000 nm. They consist of macromolecular material and can be prepared by a polymerization reaction starting with the corresponding monomers or by the dispersion of preformed polymers [1]. In principle, a drug compound can be bound to the surface of such a nanoparticulate system after particle preparation, or can be entrapped or dissolved into the particle matrix (Fig. 6.1).

The ideal colloidal delivery system should be nontoxic and able to be degraded *in vivo* after reaching its site of action. Among the different materials used for the preparation of drug carrier systems, proteins would appear promising, since they can lead to biodegradable and nonantigenic drug carrier systems [2]. Protein-based nanoparticles are relatively easy to prepare and their size distribution can be monitored easily [3]. As a result of the defined primary structure of proteins, the protein-based nanoparticles may offer various possibilities for surface modification as well as the attachment of drugs and compounds for drug-targeting purposes such as antibodies or ligands for cell-specific receptor complexes.

This chapter gives an overview of nanoparticulate, and in some cases microparticulate, systems based on proteins. Only nanoparticles intended to be used as drug carrier systems and in some rare cases for diagnostic purposes will be described.

**Fig. 6.1.** Schematic representation of drug binding (small circles) to particulate drug carrier systems (large circles).

The chapter provides an overview of the preparation techniques for protein-based particle systems starting with the first attempts during the 1960s. Based on this earlier work, the attempts to optimize the preparation techniques in order to achieve nanoparticles instead of microparticles are outlined. Different emulsion techniques are compared to the desolvation or coacervation techniques. After the description of the preparation techniques the idea of particle surface modification in order to modify the particle properties under *in vivo* and *in vitro* conditions will be outlined. Nanoparticle systems which focus on cell-specific drug targeting are illustrated. After the preparation and surface modification review, up-to-date applications of protein-based particle systems for clinical studies, therapy and diagnostics are presented.

## 6.2

### Starting Materials for the Preparation of Nanoparticles

Many preparation techniques for nanoparticles were established in the 1970s and 1980s, and these methods were developed further during the following years. The starting materials for particle preparation can be subdivided depending on the preparation technique used [4]:

- I. Preparation by polymerization reactions
  1. Polyacrylamide [5, 6]
  2. Poly(alkyl methacrylates) [7–9]

**Fig. 6.2.** Schematic representation of the most important synthetic polymers used for the preparation of nanoparticles as drug delivery systems.

3. Poly(alkyl cyanoacrylates) [10]
  4. Polyglutaraldehyde [11]
- II. Preparation by dispersion of preformed polymers
1. Natural macromolecules: serum albumin, gelatin, alginate [12–14]
  2. Synthetic macromolecules: poly(lactic acid) (PLA), poly(lactic-co-glycolic acid) (PLGA), polyacrylate, poly- $\epsilon$ -caprolactone [15–17]
- III. Preparation by dispersion of solid lipids [18, 19]

The structures of the most important synthetic polymers for the preparation of nanoparticles are outlined in Fig. 6.2. For the preparation of nanoparticles as drug delivery systems, artificial polymers such as poly(alkyl methacrylates) and poly(alkyl cyanoacrylates) were most often used, and nanoparticles were formed by polymerization reactions of the respective monomers. These polymers mainly differ in their biodegradation behavior. Whereas poly(alkyl methacrylates) are poorly biodegradable, the biodegradability of poly(alkyl cyanoacrylates) depends mainly on the length of the ester side-chain [20]. In addition to poor biodegradability, a further disadvantage of nanoparticle preparation by polymerization reactions can be seen in the fact that the resulting drug carrier system may contain unreacted toxic monomers. To avoid this problem and to achieve particle systems of high biocompatibility, preparation techniques involving the use of purified natural

macromolecules or preformed synthetic polymers have been developed. Due to their enhanced biocompatibility, nanoparticles based on PLA, PLGA, solid lipids as well as particle systems based on proteins as starting materials are of growing interest.

### 6.3

#### Preparation Methods

As previously outlined, nanoparticles based on artificial polymers such as poly(alkyl methacrylates) and poly(alkyl cyanoacrylates) are prepared by polymerization reactions starting with the corresponding monomers. Whereas poly(alkyl methacrylate)-based nanoparticles are usually prepared by polymerization in a continuous phase in the presence of a polymerization initiator [7, 21], poly(alkyl cyanoacrylate) nanoparticles are prepared by an emulsion polymerization technique initiated by bases present in the polymerization medium [10]. In comparison to these preparation conditions, nanoparticles based on proteins such as serum albumin, casein or gelatin are prepared by dispersion techniques of the preformed polymer. Different methods for their preparation have been described, based on emulsion formation, desolvation or coacervation. In addition to drug carrier systems consisting of either natural or artificial polymers, recently mixed compositions consisting of bovine serum albumin (BSA) loaded gelatin nanoparticles incorporated in hydrophobic PLGA microspheres have been described [22].

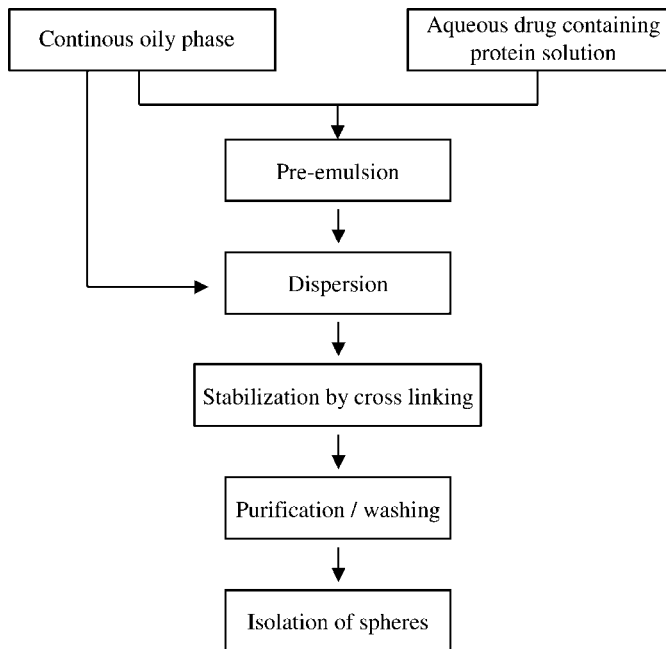

#### 6.3.1

##### Nanoparticle Preparation by Emulsion Techniques

Emulsification of an aqueous drug-containing protein solution in an oily phase was most often used as an established method for the preparation of microspheres (Fig. 6.3). The resulting droplets of the water-in-oil emulsion were stabilized by a crosslinking procedure in the presence of bifunctional aldehydes such as glutaraldehyde or by thermal denaturation. The resulting particle size depends on the droplet size of the protein-containing aqueous phase dispersed within the oily phase. Most of the emulsion techniques described in the literature result in the formation of particles in the size range of several micrometers (i.e. microparticles/microspheres). In some cases the emulsion techniques can be optimized for the preparation of nanoparticles [23]. Most often serum albumin of different origin as well as gelatin have been used as starting materials for the preparations. In the following sections the preparation techniques are divided with regard to the nature of the protein; preparation techniques leading to the formation of microparticles are described as well as methods resulting in the formation of nanoparticles.

##### 6.3.1.1 Emulsion Technique for the Preparation of Albumin-based Microspheres and Nanoparticles

Human serum albumin (HSA) is widely used as a microsphere material since it is considered nonantigenic for human use, biodegradable and readily available. Fur-

**Fig. 6.3.** Flow chart of nanoparticle preparation by emulsion techniques.

thermore, HSA is a well-defined starting material with a well-known primary structure (Table 6.1) enabling modifications by protein chemistry under stoichiometric conditions. In addition to the use of HSA, other albumin derivatives such as BSA [3] and rabbit serum albumin [24] have been described for the preparation of colloidal drug carrier systems. Although microaggregates and microspheres based on albumin derivatives were reported as early as the 1940s and 1950s, the first descriptions of albumin-based microspheres with a uniform size and predictable physicochemical characteristics were at the end of the 1960s by Rhodes et al. [25] and Zolle et al. [26] who used the system in a radioactive-labeled form for diagnostic purposes. Several further diagnostic applications for such kinds of serum albumin-based microspheres were published in the following years [27–29]. The emulsification methods for the preparation of microspheres had to be modified in order to produce nanoparticulate drug carrier systems instead of microparticles. The group of Scheffel et al. was the first to produce HSA-based particles in the nanometer size range between 300 and 1000 nm, so-called nanospheres, by a modified emulsion technique, and used the system after radioactive labeling to investigate the toxicity and body distribution of such a carrier system [30]. The first description of albumin nanoparticles prepared by a modified method of Scheffel et al. for drug delivery purposes was published by Kramer [31]. In the manuscript the incorporation of the anticancer agent mercaptopurine was outlined, and it was shown that over 85% of the drug present in the original emulsion was associated

with the microspheres in the size range between 200 and 1200 nm. Further experiments with the more hydrophilic drug daunorubicin were performed and it was observed that the amount of incorporated drug could be increased with the hydrophilicity of the drug compound. Kramer outlined that such carrier systems are of growing need for drugs with pronounced systemic toxicities and enable drug delivery to target tissues in precise dosages and with minimal interaction with normal tissues.

The main problems with the preparation in an oil-in-water emulsion are the purification of the resulting nanoparticles and the thermal stress for the incorporated drug in the case of particle stabilization by heat denaturation. In most cases the nanospheres have to be washed several times with organic solvents such as diethyl ether and these solvents have to be eliminated prior to the application of the carrier system. To circumvent the problem of the thermal stress during particle stabilization Widder et al. described the chemical crosslinking of HSA microspheres in the size range of about 1  $\mu\text{m}$  by the use of 2,3-butanedione [13]. The group incorpo-

rated doxorubicin into different particle preparations and compared the heat-denatured microspheres with their proposed chemical crosslinked systems, and showed that the stability of both preparations was identical, but that the drug release behavior was mainly influenced by the stabilization procedure. In the following years the group mainly focused on the incorporation of magnetite particles as well as the drug compound into the microsphere matrix in order to achieve drug targeting by magnetic guidance. The applications of such magnetic microspheres were described in the field of diagnostics [32–34] and tumor therapy [35–40].

A complete and systematic study regarding the influence of HSA concentration, emulsification time and power, stirring rate, heat stabilization temperature, and the type of the nonaqueous phase was carried out by Gallo et al. [14]. As an initial procedure for particle preparation they used an aqueous solution of BSA and dispersed this solution in cottonseed oil by ultrasonication. The resultant emulsion was added dropwise to a larger amount of cottonseed oil at 125 °C under stirring in order to stabilize the resulting microspheres by heat denaturation. The influences of different preparation parameters such as albumin concentration, emulsification time, emulsification power and aqueous-to-oil phase volume ratio on the final particle size were evaluated. They found that the procedure for preparing albumin microspheres can withstand a large range of variability until significant changes in the particle characteristics can be observed. Optimal conditions for the preparation of smaller and more uniform microspheres were found by increasing the protein concentration as well as the temperature of heat stabilization. The group of Gupta et al. described in detail the preparation of albumin microspheres loaded with adriamycin [41, 42] as well as adriamycin and magnetite [43]. They focused on the *in vitro* drug release characteristics of these kinds of microspheres and found that the drug release was dependent on the presence of magnetite as well as on the stabilization temperature during the preparation process.

In a systematic study based on a central composite design, Müller et al. proposed a new emulsion method for the preparation of albumin nanoparticles [23]. They established an emulsion method using ultrasound and static mixing for the preparation of sub-200 nm particles. The statistical method used for the evaluation of the different process parameters revealed that only albumin concentration and aqueous phase volume showed a significant influence on the parameters of particle size, polydispersity and yield.

A comprehensive review of the preparation of albumin microspheres by emulsion techniques was given by Gupta and Hung [44–46]. In a methodological review Arshady et al. discussed the main basic features of the preparation procedure such as the crosslinking technique, droplet formation and stabilization, particle size, and size distribution [47].

#### 6.3.1.2 Emulsion Technique for the Preparation of Gelatin-based Microspheres and Nanoparticles

In principle, the emulsion method for the preparation of serum albumin microspheres can be adapted for gelatin microsphere preparation. Gelatin offers some advantages as a matrix material: it is a natural, inexpensive, low-immunogenic,

nontoxic and good biodegradable macromolecule which is registered as an excipient for pharmaceutical formulations. As a protein-based product, gelatin possesses several functional groups which are available for covalent modifications. Due to the preparation of gelatin by hydrolysis of collagen, no defined primary structure can be given and, therefore, the composition of gelatin is most often described by the percentage amount of the respective amino acids (Table 6.2).

The influence of the preparation parameters on the physicochemical characteristics of drug-loaded gelatin microspheres was investigated by Esposito et al. [48]. As model drugs clonidine hydrochloride, TAPP-Br and bromocriptine mesylate were chosen in order to evaluate their encapsulation efficiency and release characteristics. As previously observed for drug incorporation in albumin-based particles [31], the drug loading was mainly dependent on the hydrophilic–hydrophobic balance of the drug molecule, with hydrophobic drugs showing a reduced trapping efficiency. This was due to an increased drug concentration in the oily phase of the emulsion system with increasing hydrophobicity of the drug. The release profile of

the hydrophilic drug TAPP-Br was characterized by a biphasic behavior, whereas the more hydrophobic drugs were released by a fast first-order release mechanism.

The nanoencapsulation of BSA in the matrix of gelatin-based nanoparticles was described by Li et al. [49]. BSA-containing gelatin nanoparticles of a spherical shape and a diameter of 840 nm were achieved. *In vitro* studies revealed BSA release by a diffusion-controlled mechanism. The release kinetic was mainly influenced by the water content of the particles as well as by the temperature of particle stabilization.

### 6.3.1.3 Emulsion Technique for the Preparation of Casein-based Microspheres and Nanoparticles

As well as the application of albumin and gelatin for the preparation of particulate drug carrier systems, the emulsion techniques described so far can also be applied to other proteins. In order to achieve microspheres with an enhanced hydrophilicity, casein was used as a further starting material for microsphere preparation. Chen et al. compared casein and albumin for the preparation of microspheres and their efficiency as a drug carrier system for doxorubicin [50]. They prepared the microspheres based on a water-in-oil emulsion technique in combination with glutaraldehyde stabilization. Compared with albumin, the surface charge of the casein system was more negative and the microspheres exhibited a slower release of drug *in vitro*. Under *in vivo* conditions in a tumor model in rats the casein system showed greater antitumoral potency than did the albumin system at equal amounts of the drug. Due to this observation it was considered that the carrier matrix can influence the potency of the incorporated drug.

The disadvantage of the casein-based microspheres was their poor spherical geometry. Therefore, the preparation of casein microspheres was further optimized by a new emulsion technique using aliphatic polyurethane in a mixture of hexane and dichloromethane as the dispersion medium, which achieved spherical, glutaraldehyde crosslinked microspheres [51, 52]. In comparison to established emulsion techniques, the avoidance of surfactants during particle preparation with this new method was advantageous. The proposed emulsion technique was used for the preparation of microspheres loaded with the cytotoxic drug methotrexate [53]. The versatility of the method was demonstrated by the synthesis of albumin as well as casein microspheres, leading to mean particle sizes of 54 and 172  $\mu\text{m}$ , respectively. They compared both preparations and observed a comparable drug loading as well as a comparable drug release of about 35% in 24 h for both the casein and albumin systems. The applicability of the preparation method of casein microspheres in the presence of the stabilizer polyurethane was demonstrated in combination with different drugs such as methotrexate [53], theophylline [54], 5-fluorouracil [55] and progesterone [56]. Under *in vivo* conditions it was shown that progesterone-loaded casein microspheres hold promise for sustained drug release up to 5 months. After intramuscular injection into rabbits over this time period constant plasma concentrations of 1–2  $\text{ng mL}^{-1}$  were observed without any significant burst release of the drug.

With regard to surface modification, Latha et al. reported that the hydrophilicity

of the casein spheres can be imparted by an end-capping process of the residual aldehyde groups present from the glutaraldehyde crosslinking with glycine or 2-aminoethanol. Comparable end-capping procedures were described earlier by Longo et al. for the preparation of HSA microspheres which were sterically stabilized by the incorporation of artificial polymers such as poly(methyl methacrylate) [57, 58].

### 6.3.2

#### **Nanoparticle Preparation by Coacervation**

As previously described, the disadvantages of the emulsion methods for particle preparation are (a) use of organic solvents for the removal of the oily residues of the preparation process, and (b) removal of surfactants that are used for emulsion stabilization during the preparation and remain on the particle surface. Even in the case of optimized emulsion techniques using aliphatic polyurethane in a mixture of hexane and dichloromethane [51, 52] the resulting nanoparticles have to be purified from the organic compounds of the dispersion medium. In addition to the disadvantage of extensive purification steps, the emulsion techniques preferentially lead to microparticles instead of particles in the nanometer size range, which mostly impedes an intravenous route of administration. Therefore, as alternative methods, the coacervation techniques and desolvation methods, derived from the coacervation method of microencapsulation, have been described for the preparation of nanoparticles. Compared to the emulsion techniques, coacervation methods are simpler and the resulting particles can more easily be cleaned. Beyond these advantages, the resulting particles are mostly in the nanometer size range.

Coacervation is defined as the separation of a colloidal dispersion into a colloid-rich and a colloid-poor phase by careful control of temperature, pH, electrolyte addition or other factors. The coacervate or colloid-rich phase forms as droplets, which makes the system opaque. In principle, coacervation techniques can be subdivided in simple and complex coacervation. Simple coacervation is characterized by the use of only one colloid and involves removal of the associated water from around the dispersed colloid by agents with greater affinity for water, such as various alcohols and salts. The dehydrated molecules of the colloidal dispersion tend to aggregate with surrounding molecules to form the coacervate. Simple coacervation techniques for the preparation of nanoparticles are often described by the term “desolvation”. In contrast, complex coacervation involves the use of more than one colloid. The coacervation is accomplished mainly by charge neutralization of the colloids carrying opposite charges rather than by dehydration.

#### **6.3.2.1 Complex Coacervation Techniques for the Preparation of Nanoparticles**

An example of complex coacervation is the preparation of nanoparticles based on albumin and heparin described by Liu and Leong [59]. The group described a coacervate from complexation of HSA and heparin as the clinically used components for the entrapment, and controlled release of drugs in the molecular weight range between 262 and 67 000 Da. Particle preparation was performed by simply mixing

an acidic HSA solution, which contained the respective drug, with a heparin solution. Due to the opposite charges of both polymers, phase separation under the preparation conditions occurs leading to the formation of nanoparticles. The resulting particles were stabilized by a crosslinking procedure with a carbodiimide derivative. Drug-loading studies were performed with a multitude of compounds showing that a high loading efficiency was observed especially with positively charged drugs. Due to a proteolytic degradation of the carrier system, the *in vitro* release of the drugs was faster in cell culture medium than in phosphate-buffered saline. In addition to the use of albumin, complex coacervation techniques can be carried out with different proteins such as casein [60] and gelatin [61]. In combination with gelatin, complex coacervation was most often used for the incorporation of plasmid DNA in particulate systems. For example, a method for the incorporation of plasmid DNA into a gelatin-based nanoparticle system by salt-induced complex coacervation followed by a crosslinking step with 1-ethyl-3-(3-dimethylamino-propyl)carbodiimide (EDC) was reported [61–64]. Comparable coacervation procedures for the preparation of plasmid DNA-containing nanoparticles based on the polysaccharide chitosan were described by Mao et al. and Roy et al., with the exception that the chitosan–DNA coacervate was stable without any further crosslinking step [65, 66].

#### 6.3.2.2 Simple Coacervation (Desolvation) Techniques for the Preparation of Nanoparticles

As previously outlined, nanoparticle preparation by simple coacervation techniques is often described by the term “desolvation”. Using desolvation techniques, the phase separation of the colloidal solution is carried out by salting out, temperature change, pH variation or addition of water-miscible organic solvents such as alcohols. In the field of nanoparticle preparation, the addition of salts such as sodium sulfate or ammonium sulfate as well as the addition of organic solvents such as alcohols or acetone is most often used. In a second preparation step the nanoparticles have to be stabilized either by chemical crosslinking using bifunctional aldehydes or by thermal denaturation (Fig. 6.4).

The first paper describing desolvation procedures for the preparation of nanoparticles as drug carrier systems was at the end of the 1970s by Marty et al. [12]. The group established a general method for the preparation of nanoparticles based on HSA, BSA, ethylcellulose and casein. In principle, an aqueous macromolecule solution was prepared and the desolvation was performed under the control of turbidimetric measurements by the addition of either a sodium sulfate solution or ethanol. After the addition of a small amount of a resolating agent the resulting nanoparticles were stabilized by chemical crosslinking with glutaraldehyde. The resulting nanoparticles could be purified by a gel-filtration procedure and stored in a solid form after freeze-drying. For the drug loading of the nanoparticles Marty et al. described the incorporation method in which the drug is either added to the aqueous macromolecule solution or to the solution of the desolvating agent. A comparable desolvation procedure was used by El-Samaligy and Rohdewald in order to incorporate triamcinolone diacetate in gelatin-based nanoparticles [67, 68].

**Fig. 6.4.** Nanoparticle preparation by desolvation (simple coacervation) of an aqueous protein solution followed by particle stabilization by crosslinking.

They prepared nanospheres in the size range of about 200 nm by addition of isopropanol to an ammonium sulfate coacervated HSA system.

The binding and *in vitro* release of the nucleoside analogue ganciclovir (GCV) in combination with BSA prepared by desolvation techniques was studied in several publications [69–72]. The binding of the drug to preformed nanoparticles was compared to the entrapment of GCV during nanoparticle formation. The highest drug-loading capacity was observed for nanoparticles prepared by the addition of the drug to a solution of albumin leading to adsorptive drug binding prior to the formation of the carrier by desolvation. The release profile of the nanoparticle preparations was characterized by a biphasic pattern with an initial and rapid release followed by a slower step for up to 5 days [70]. The amount of rapidly released GCV was highest for nanoparticles with drug bound by adsorption to the preformed carrier. Under cell culture conditions the latter preparation was the most active formulation in the antiviral test assays, whereas the formulation with incorporated drug produced the highest decrease on cytotoxicity of the free drug [72]. The nanoparticles were intended to be used after intravitreal injection as a drug delivery system for therapy of cytomegalovirus infection. Therefore, the ocular disposition after intravitreal injection as well as the toxicity induced by the prolonged presence of BSA nanoparticles was studied [71]. It was observed that a significant amount of the nanoparticles remained in the vitreous cavity for a prolonged period of time in combination with no signs of autoimmune phenomena or alterations in the behavior of ophthalmic cells. The same group investigated nanoparticles pre-

pared by the same techniques for suitability as a drug carrier system for antiviral phosphodiester and phosphorothioate oligonucleotides [73] as well as for their ability to reach the central nervous system in an experimental allergic encephalomyelitis animal model [74].

The suitability of HSA-based nanoparticles to target drugs into cells of the reticuloendothelial system (RES) and to establish a potential therapy of the HIV infection was investigated in a number of studies. The nanoparticles were prepared by desolvation techniques and desolvation was performed by the addition of ethanol. After purification, the nanoparticles were incubated with primary human monocytes/macrophages in order to evaluate cell accumulation. Nanoparticles with a diameter of 200 nm were found to be most useful for targeting antiviral substances such as azidothymidine to macrophages [75]. It was observed that cells infected with a monocytotropic HIV isolate possessed an even higher particle uptake than noninfected cells and thus HSA nanoparticles were recommended as promising carrier systems for targeting drugs into HIV-infected cells of the RES. In an electron microscopy study, the process of cellular particle uptake was demonstrated to be phagocytosis [76]. In this study the intracellular degradation of the nanoparticles was followed and it was observed that particle degradation started within some hours after particle uptake. Within 3 days after particle incubation the process was almost terminated. Based on these observations HSA nanoparticles loaded with the drugs azidothymidine (AZT) and dideoxycytidine (ddC) were tested for their ability to prevent HIV infection in monocytes/macrophages [77]. According to the proposed methods of Marty et al. [12], drug loading was performed by the incorporation method in which the drug is added to the aqueous macromolecule solution prior to protein desolvation. Under cell culture conditions the nanoparticles loaded with the nucleoside analogs were effective against HIV infection, but they showed no superiority in relation to free drug. This was attributed to a fast and easy cellular uptake of the tested substances in free form which does not require drug delivery by nanoparticles.

The suitability of albumin nanoparticles as drug carrier systems for antisense oligonucleotides was studied by Arnedo et al. [78]. Nanoparticles were prepared based on BSA by a simple coacervation process and a phosphodiester oligonucleotide was either incorporated into the particle matrix by incubation with the albumin prior the coacervation process or adsorbed to preformed nanoparticles. Due to the electrostatic interactions that were responsible for drug adsorption to preformed nanoparticles, the adsorbed amount was susceptible to changes in pH and ionic strength of the medium. In comparison to drug loading by adsorption, the incorporation of the drug during nanoparticle formation resulted in a stable entrapment of the antisense oligonucleotide, which complies with earlier results achieved with the nucleoside analog GCV [70]. Only the incorporative method of drug binding was suitable for protection of the antisense compound against enzymatic degradation.

In most of the studies described so far the effective drug loading to the nanoparticles was of major importance, but preparation parameters influencing the physicochemical characteristics of the particles were virtually ignored. The first sys-

tematic investigations for selective control of particle size and size distribution during the desolvation procedure were described in 1993 by Lin et al. [79]. They proposed the preparation of HSA nanoparticles of diameter around 100 nm using a surfactant-free pH-coacervation method. The particles were prepared by the dropwise addition of acetone to an aqueous HSA solution at pH values between 7 and 9, followed by glutaraldehyde crosslinking and purification by gel-permeation chromatography. It was found that particle size was reduced with increasing pH of the HSA solution, apparently due to increased ionization of the HSA (isoelectric point  $pI = 5.3$ ) which leads to repulsion of the HSA molecules and aggregates during particle formation. HSA nanoparticles were obtained in a size range between 90 and 250 nm by adjusting the pH and by controlling the amount of added acetone. The described nanoparticles were of spherical shape, but transmission electron microscopy (TEM) revealed a broad size distribution. No further data concerning the polydispersity of the nanoparticles prepared under different conditions was given. A major shortcoming of the paper is that the pH was adjusted in the absence of salt, whereas it is well known that, under these conditions, pH measurements applying glass electrodes are of limited reliability, in particular in the presence of high concentrations of protein [80].

The process of protein desolvation for the preparation of nanoparticles was adopted and studied in more detail by the group of Langer et al. with the objective to establish particle preparation under well-defined conditions [81–85]. In an earlier study a desolvation method for the preparation of nanoparticles based on HSA and gelatin was described, and the resulting particles were characterized with respect to size,  $\zeta$  potential and number of available amino groups on their surface [81]. In this study the amount of the desolvating agent ethanol in the desolvation process was found to control particle size, but the variability in size at a given ethanol amount was high. The high size variability was confirmed by sedimentation velocity analysis in an analytical ultracentrifuge and electron microscopy [84]. In part, this variability has to be attributed to the manual performance of the desolvation process, characterized by a drop-by-drop addition of the desolvating agent. The conditions of particle stabilization by chemical crosslinking in the presence of the bifunctional compound glutaraldehyde or by heat denaturation showed no influence on the resulting particle size, but the degree of chemical crosslinking mainly influenced the number of amino groups on the surface of HSA nanoparticles as well as the  $\zeta$  potential of the colloid. With regard to a controllable particle size in combination with a reproducible desolvation method, a pump-controlled preparation method was established in a following study which enabled particle preparation under defined conditions (Fig. 6.5) [85]. Based on this new preparation procedure several factors of the preparation process such as rate of ethanol addition, pH value and ionic composition of the HSA solution, protein concentration, and conditions of particle purification were evaluated. Most of the parameters studied showed only a minor influence on the particle characteristics. Only the pH value of the HSA solution prior to the desolvation procedure was identified as the major factor determining particle size. These observations were in good agreement with the earlier work of Lin et al. [79] which was described above. By

Fig. 6.5. Simple pump-controlled system for reproducible protein desolvation.

sedimentation velocity analysis it was demonstrated that application of a pump-controlled system in combination with a defined pH adjustment leads to well-defined mean particle sizes as well as narrow size distributions.

#### 6.4

#### Basic Characterization Techniques for Peptide Nanoparticles

A rational development of a protein-based colloidal carrier system requires a systematic characterization of the resulting nanoparticles. In particular, physicochemical parameters such as particle size, size distribution,  $\zeta$  potential and surface morphology are of major importance.

Photon correlation spectroscopy (PCS) was used in most of the pharmaceutical studies as the standard method for determination of particle size and size distribution. In principle, PCS uses Brownian motion to measure the size of particles. In brief a diffusion coefficient  $D$  of the particles in suspension is determined by laser light scattering. Based on this coefficient  $D$  and the well-known Stokes–Einstein equation, a “Stokes’ diameter” or hydrodynamic diameter is calculated, which is not equivalent to a weight or number diameter. The advantage of PCS can be seen in a rapid determination of particle size within several seconds or minutes. However, the user has to be aware of the limitations of PCS, such as low resolving power and well-known problems of mathematically ill-conditioned analysis of the autocorrelation function. The resulting particle size distributions can be strongly biased, being critically dependent on the model used for raw data analysis.

As well as PCS, sedimentation velocity analysis in an analytical ultracentrifuge, a standard technique for characterizing particle size distributions in macromolecular chemistry, can also be used in the field of pharmaceuticals as an appropriate technique for particle sizing. In principle, during the centrifugation process the apparent absorbance (turbidity) of the nanoparticle sample versus radius is measured followed by data modeling as a distribution of nondiffusing spherical particles. As

the migration of particles in a gravitational field of an ultracentrifuge shows a stronger size dependence than the diffusion coefficient  $D$  measured by PCS, this method has the potential for significantly higher resolution [86, 87] and therefore is much less mode dependent. Therefore, due to the superior resolving power of this technique more detailed information about the particle size distribution can be obtained. The suitability of ultracentrifugation for characterization of HSA nanoparticles was confirmed by Vogel et al. [84]. The study revealed that HSA nanoparticles prepared by a manual performed desolvation process, characterized by a drop-by-drop addition of the desolvating agent, showed a high variability in particle size. The same technique can also be applied to confirm the reproducibility of particle preparation under optimized preparation conditions [85].

Different microscopic techniques such as electron microscopy (reflection and transmission) and atomic force microscopy (AFM) are useful for determination of particle shape and surface morphology. For example, knowledge of particle shape is a basic requirement for reasonable application of analytical techniques such as PCS and analytical ultracentrifugation – spherical particle shape is an imperative prerequisite for particle size analysis by PCS. In the field of analytical ultracentrifugation, information about particle shape is necessary to apply the proper mathematical model to the apparent absorbance versus radius raw data. For instance, using TEM, it was confirmed that the process of protein desolvation described above for the preparation of HSA nanoparticles led to a spherical particle shape [84]. Therefore, the particle system was well suited for size analysis using PCS or sedimentation velocity analysis. Directly after manual particle preparation and purification, the samples showed a slightly broader size distribution which could be fractionated into narrow distributions by preparative density gradient centrifugation (Fig. 6.6).

In addition to TEM, AFM is another useful technique to obtain more detailed information about surface morphology. AFM is a widely used experimental technique for the characterization of nanostructures. In particular, due to its ability to map variations in material properties with nanometer resolution, AFM is well suited to probe potential subcomponents or substructures of nanoparticles. An AFM picture of HSA nanoparticles prepared by protein desolvation under the same conditions described for the sample in Fig. 6.6 is depicted in Fig. 6.7. The height image of the sample confirms the spherical nature of the nanoparticles, whereas the phase image reveals a substructure in the size range of about 15 nm, showing the crosslinked nature of these particles.

The stability and electrical behavior of nanoparticles can be assessed by determination of the  $\zeta$  potential of the particle colloid under varying pH and buffer conditions. Titration experiments are useful to find the optimal handling and storage conditions for the particle system as well as to determine the isoelectric point of the nanoparticles. For example, the group of Langer et al. used titration experiments for the determination of the  $\zeta$  potential in order to take a more detailed look at the effect of pH and buffer variation on the stability of HSA nanoparticles [85]. They observed positively charged nanoparticles at a pH of 3. With increasing pH value the  $\zeta$  potential was reduced to about  $-50$  mV at pH values between 7 and 10. The salt dependency of the  $\zeta$  potential was determined by titration experiments

**Fig. 6.6.** Morphology of HSA nanoparticles by means of TEM of negatively stained samples: (a) unfractionated particles, (b) particles in the fraction of highest turbidity from a sucrose gradient and (c) three arbitrary selected particles of sample (b) on films glow discharged for 30 s. Bar length = 200 nm. (From Ref. [84].)

with concentrated buffer systems. As could be expected, due to a shielding of the surface charge with increasing buffer concentration the  $\zeta$  potential of the colloid was reduced. However, it became obvious that a phosphate buffer can be used at least up to concentrations of 150 mM without reducing particle surface charge to a degree that leads to isoelectric aggregation of the particles. Furthermore, the effect of crosslinking on the isoelectric point ( $pI$ ) of HSA nanoparticles was determined. Glutaraldehyde crosslinking of the particle matrix was found to decrease the  $pI$  value of the particles significantly. Such a reduction could be expected for a covalent reaction of glutaraldehyde with lysine side-chains of the protein HSA.

In addition to the basic characterization techniques outlined within this chapter, drug-loading efficiency as well as characterization of the chemical surface structure is of major importance. The influence of drug properties and particle preparation techniques on the drug-loading efficiency was described above within the overview of preparation methods. The analysis of the chemical surface structure depends mainly on the nature of the functional groups on the particle surface or the surface modification strategy used. Different ways of surface modification and the methods suitable for characterization of the resulting particle surface structures are outlined below.

## 6.5

### Drug Targeting with Nanoparticles

Most often nanoparticulate drug carrier systems were prepared in order to modify the body distribution of the entrapped drug and to transport the drug to its site of

**Fig. 6.7.** Morphology of HSA nanoparticles by means of AFM in tapping mode on a Nanoscope IIIa (Digital Instruments, Santa Barbara, CA) with rotated tapping mode etched silicon probe (RTESP) tips. (a) Height image of nanoparticles on mica. (b) Phase image of the

action (i.e. drug targeting). When nanoparticles are administered intravenously they are quickly recognized by the mononuclear phagocyte system (MPS) and cleared from the circulation. The size of the nanoparticles as well as the hydrophobicity of their surface determine the *in vivo* fate of the system, with larger particle size and higher hydrophobicity leading to a more pronounced adsorption of blood components (i.e. opsonization) followed by a more rapid clearance from circulation. Therefore, hydrophilic surface structures in combination with small particle sizes (100–200 nm) are crucial parameters for developing nanoparticulate drug carriers with extended half-lives in blood.

### 6.5.1

#### Passive Drug Targeting with Particle Systems

After intravenous injection, unmodified nanoparticles enable passive drug targeting, which is characterized by particle uptake in cells of the MPS. Particle accumulation in macrophages of the liver, spleen and bone marrow as well as in circulating monocytes is observed. The resulting body distribution of the particulate carrier systems is mainly influenced by two physicochemical properties – particle size and surface characteristics [88]. Concerning particle size, the particles should be small enough not to be removed by simple filtration mechanisms in a capillary bed after intravenous injection. On the other hand, surface characteristics such as hydrophilicity/lipophilicity represent the major determinants for protein adsorption in biological fluids and may modify particle interaction with specific plasma membrane receptors, thus leading to elimination of the particles from the systemic circulation. The mechanism of protein adsorption on particle surfaces in conjunction with the recognition of such coated particles by monocytes and macrophages is named opsonization. After intravenous administration of nanoparticle suspensions the particles are normally rapidly coated by adsorption of specific blood components known as opsonins. After this coating the particles are recognized by the MPS and are rapidly eliminated from the central blood circulation. As well as the surface characteristics, the opsonization process seems to be influenced by the surface curvature of the carrier system, with smaller carriers leading to a reduced adsorption of proteins and opsonins, and in turn to a reduced uptake of such systems by phagocytic cells [89].

Therefore, a reduction of the opsonization process leading to a prolongation of the plasma half-life is of major importance in order to achieve a modified body distribution. Coating of the particles with opsonins can be reduced by the introduction of a more hydrophilic surface structure in combination with a reduced particle size. Different techniques to achieve a hydrophilic particle surface are outlined below.

### 6.5.2

#### Active Drug Targeting with Particle Systems

In contrast to passive drug-targeting strategies, active drug targeting enables the transport of the particle system to body compartments not accessible to the un-

modified system. Therefore, in a first step of particle preparation it is required to achieve a more hydrophilic surface structure which leads to a prolongation of the plasma half-life. In a second step, the particle system has to be equipped with ligands, so-called drug-targeting ligands, which enable cell-specific accumulation of the particle system.

### 6.5.3

#### **Surface Modifications of Protein-based Nanoparticles**

In order to achieve a prolonged circulation half-life and to enable active drug targeting the opsonin adsorption has to be reduced by (a) the choice of a suitable particle size and (b) surface modification of the drug carrier system. An appropriate approach in this direction is the modification of the particle surface by different hydrophilic compounds.

As well as modification of the particle surface with hydrophilic compounds in order to modify the pharmacokinetic behavior, surface modification techniques with the aim of enhanced drug loading have also been described. For example, in a paper by Hnatowich and Schlegel, albumin microspheres were synthesized and the particle surface was modified by the covalent attachment of the chelating agents EDTA and DTPA [90]. The resulting particles were used for the attachment of the radionuclide  $^{67}\text{Gd}$  by transcomplexation from a gadolinium acetate solution.

### 6.5.4

#### **Surface Modification by Different Hydrophilic Compounds**

In the field of protein-based nanoparticles the first attempts to achieve a more hydrophilic particle surface were made on the basis of albumin nanoparticles [91, 92]. Based on the method of Longo et al. [57], microspheres were prepared and stabilized by glutaraldehyde crosslinking. Hydrophilic surface modifications were achieved by quenching free aldehyde groups of glutaraldehyde with different amino-functional compounds such as ethanolamine and glycine. The stability of the chemical surface modification was confirmed in fresh human serum and in aqueous solutions of different pH values. Under cell culture conditions the phagocytic uptake of the surface-modified nanoparticles was mainly dependent on the resulting  $\zeta$  potential, with a higher particle charge leading to a more pronounced cellular uptake. Contrary to the results of the cellular uptake study, no differences in blood circulation times and organ accumulation between different nanoparticle preparations were observed after intravenous injection in rats [93]. Therefore, the effect of surface modification by hydrophilic low-molecular-weight compounds remained questionable.

With regard to active drug targeting with nanoparticles (see below), hydrophilic systems with functional groups at their surface are necessary to which ligands such as antibodies can be attached. The emulsion methods for particle preparations employ a lipophilic external phase and therefore produce microspheres with a hydrophobic surface due to the preferential orientation of lipophilic amino acids

of the albumin molecules to the outer lipophilic phase of the water-in-oil emulsion. MacAdam et al. developed a method for the preparation of albumin microspheres which had chemically reactive groups such as carboxylic and amino groups on the surface to which ligands could be attached [3]. Carboxylic groups were introduced by the reaction of amino groups with iodoacetic acid under alkaline conditions. The group described methods for the quantitative determination of these groups at the particle surface using the radioactive probes [ $^{14}\text{C}$ ]glycine ethyl ester and [ $^{14}\text{C}$ ]sodium acetate.

#### 6.5.5

#### Surface Modification by Polyethylene Glycol (PEG) Derivatives

In addition to the modifications with low-molecular-weight compounds described above, several approaches were taken to introduce a hydrophilic steric barrier at the particle surface, i.e. by modification of the particle surface with PEG derivatives. Lin et al. performed several approaches for the introduction of PEG chains onto the surface of HSA nanoparticles. Based on their established preparation method for HSA nanoparticles [79] outlined above, Lin et al. compared HSA nanoparticles either stabilized by the glutaraldehyde method or a novel Dextranox-MPEG crosslinking procedure [94]. Dextranox-MPEG is a methyl PEG-substituted oxidized dextran which created a sterically stabilizing polyethylene oxide surface layer surrounding the nanospheres. They tested the electrolyte- and pH-dependent flocculation of both preparations, and concluded that the higher stability of the proposed nanospheres depended mainly on a hydrated steric barrier surrounding the Dextranox-MPEG crosslinked nanospheres, whereas the glutaraldehyde cross-linked system was mainly stabilized by electrostatic repulsive forces. As an alternative method for steric stabilization of HSA nanoparticles, Lin et al. established a nanoparticle preparation based on two different PEG–HSA conjugates, namely a poly(amidoamine)–poly(ethylene glycol) copolymer grafted HSA (HSA–PAA–PEG) and a poly(thioetheramido acid)–poly(ethylene glycol) copolymer grafted HSA (HSA–PTAAC–PEG) [95]. As with the Dextranox-MPEG crosslinked nanoparticles, they confirmed the existence of a hydrated steric barrier surrounding the nanospheres by electrolyte- and pH-dependent flocculation tests, and showed a reduced plasma protein adsorption on the particle surface compared with unmodified nanoparticles. More recently, Lin et al. developed a third method for surface modification of HSA nanoparticles with PEO chains on the basis of methoxy-PEG modified HSA (HSA–mPEG) and evaluated the resulting nanoparticles as outlined for copolymer grafted HSA [96]. The  $\zeta$  potential of the resulting nanoparticles was significantly lower than that of unmodified nanoparticles and the existence of a hydrated steric barrier was confirmed. The two PEG-modified albumin nanoparticle systems prepared on either HSA–PTAAC–PEG or HSA–mPEG were compared to HSA-based nanoparticles with regard to drug loading and *in vitro* drug release using the model compound rose Bengal [97]. The drug-loading efficiency of HSA–mPEG-based nanoparticles was much lower than that of nanoparticles prepared with unmodified HSA, indicating that less drug–protein binding

sites were available in the HSA–mPEG molecule as compared to the HSA molecule. The *in vitro* drug release of the different particle preparations in the presence of trypsin was mainly dependent on the PEG modification, with a slower drug release in the case of PEG-modified nanoparticles. This observation suggests that not only the behavior in biological systems will be modified by surface modification, but that the existence of a steric barrier on the surface of the nanoparticles mainly influences the enzymatic degradation and consequently the drug release properties of the particles.

#### 6.5.6

#### Surface Modification by Drug-targeting Ligands

In order to achieve a system which enables active drug targeting, in addition to a hydrophilic steric barrier at the particle surface which prevents opsonization, the particle system has to be equipped with drug-targeting ligands. In combination with nanoparticulate systems, in most cases antibodies were described as drug-targeting ligands. The first conjugation reactions between particle surfaces and cell-specific antibodies were described in the 1970s for latex particle systems based on synthetic polyacrylates [98, 99]. The first reports of antigen-specific binding were achieved with these particles. In a further step, the nanoparticles were loaded with magnetite, and were used as magnetic microspheres for labeling and separation of lymphocytes and erythrocytes [100]. In the following years antibody-modified synthetic nanoparticles intended for active drug targeting have been synthesized and characterized in detail [101–104]. Apart from polyacrylate-based nanoparticles, other starting materials such as silica [105], PLA [106] and proteins [107–109] were used for the preparation of ligand-modified nanoparticles in later studies.

A first study with protein-based nanoparticles surface modified with cell-specific antibodies was described by Akasaka et al. [107]. An antitumoral antibody was covalently attached to primary amino groups of BSA nanoparticles prepared with glutaraldehyde crosslinking by covalent linkage (Schiff's base formation) of aldehyde groups at the surface of the nanospheres with amino groups of the antibody. Although in this first study with antibody-modified albumin nanoparticles the specificity of the free antibody for tumor cells was clearly demonstrated, tumor cell binding after conjugation of the respective antibody to the nanoparticles remained unclear. After intravenous administration of the antibody-modified nanoparticles in tumor-bearing mice the carrier system was found to be localized mainly in the liver, lungs and kidneys of the animals.

In a further study, antimucus polyclonal antibodies were covalently linked to the surface of albumin microspheres in order to achieve an oral drug delivery system with delayed gastrointestinal transit [110]. Three different particle systems with either a hydrophobic, a hydrophilic or a carboxymethylated surface were used [3] and the linkage was performed by the carbodiimide reaction using 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide. The group observed that only hydrophilic and carboxymethylated microspheres with surface-attached antibody bound significantly more mucin from suspension. The same particle preparations also showed stronger

**Fig. 6.8.** Schematic representation of antibody-loaded avidin-modified nanoparticles for cell-type-specific targeting.

binding to isolated gut segments than the other control preparations. The results supported the finding that the combination of a hydrophilic particle surface with a drug-targeting ligand is a precondition for a site-specific carrier system.

In a recent study by Wartlick et al., gelatin as well as HSA nanoparticles were described for cell-type-specific targeting of different breast cancer cells with varying HER2 expression levels [108]. Both particle preparations were prepared by established desolvation techniques and were surface modified in a first step by the covalent attachment of the avidin derivative NeutrAvidin<sup>TM</sup>. The avidin binding was performed with the heterobifunctional PEG-based crosslinker NHS-PEG3400-Mal. The humanized monoclonal antibody trastuzumab (Herceptin<sup>TM</sup>) was used as drug targeting ligand. For the attachment of the antibody to the nanoparticle surface trastuzumab was biotinylated and bound to the particle surface by avidin–biotin complex formation (Fig. 6.8). Under cell culture conditions the resulting antibody-modified nanoparticles showed a highly specific targeting to HER2-overexpressing breast cancer cells. The attachment to the surface of the cells was time and dose dependent, and effective intracellular uptake by receptor-mediated endocytosis was demonstrated. The results indicated that the proposed preparations hold promise for selective drug targeting of tumors expressing a specific tumor antigen.

The same group described a comparable nanoparticulate system based on gelatin for specific drug targeting to T lymphocytes [109]. Using avidin–biotin complex formation a biotinylated anti-CD3 antibody was bound to the surface of NeutrAvidin-modified nanoparticles. The objective of the work was the comprehensive quantification of every chemical reaction step during the preparation procedure of the nanoparticles, including determination of the molecular weight distribution of the starting material gelatin, characterization of the particle surface and determination of the integrity of the covalently attached proteins after conjugation reaction. High compatibility of the nanoparticles with tumor cells was demonstrated under cell culture conditions. The suitability of the proposed particles for receptor-mediated cellular uptake in lymphocytic cells was demonstrated in a separate paper [111].

## 6.5.7

**Different Surface Modification Strategies**

In the case of protein-based nanoparticles the covalent attachment needs a well-defined particle system with functional groups on its surface, which can be used for the respective coupling reaction with the drug-targeting ligand. Therefore, in a number of papers the characterization of the particle surface with regard to functional groups as well as techniques for the introduction of functional groups was described. In the field of protein chemistry, it is mainly amino groups and carboxylic groups that can be used for covalent coupling reactions. In example, proteins such as HSA offer several target sites for covalent modification such as the  $\epsilon$ -amino groups of lysine and the carboxylic groups of asparaginic and glutaminic acid. For glutaraldehyde-stabilized nanoparticles the remaining carbonyl residues of the crosslinker can be used as a further target site.

In a first study by Weber et al., as well as the optimization of the desolvation process for the preparation of HSA and gelatin nanoparticles, the number of available amino groups on the surface of the nanoparticles was determined spectrophotometrically using the reagent 2,4,6-trinitrobenzenesulfonic acid (TNBS) [81]. It was observed that the number of amino groups was mainly dependent on the amount of the crosslinking agent glutaraldehyde used for particle stabilization. As could be expected, increasing amounts of glutaraldehyde led to a decreasing number of available amino groups on the particle surface.

Protein conjugation most often is achieved by the use of established bifunctional crosslinkers, which can be subdivided into homobifunctional and heterobifunctional crosslinkers (Fig. 6.9). Most often heterobifunctional crosslinkers were used which combine two different specific binding sites – one for primary amino groups and one for sulfhydryl groups – in one molecule. Examples for such bifunctional crosslinkers are the homobifunctional substances 1,6-bis-maleinimido-hexane (BMH) [112], disuccinimidyl tartrate (DST) [113] and the heterobifunctional compounds *m*-maleimidobenzoyl-*N*-hydroxysulfosuccinimide ester (sulfo-MBS) [108, 109, 114] or sulfosuccinimidyl-4-*N*-maleimidomethylcyclohexane-1-carboxylate (sulfo-SMCC) [115]. In order to attach an amino group-containing compound to protein-based nanoparticles by the use of such crosslinkers, it is imperative that the nanoparticles expose reactive sulfhydryl groups on their surface. However, as the primary structure of most proteins reveal, there is only a negligibly small number of reactive sulfhydryl groups available in the genuine protein. Therefore, different methods for the introduction of reactive sulfhydryl groups onto the particle surface were described. The objective of a study by Weber et al. was to establish several methods for the introduction of thiol groups onto the surface of HSA nanoparticles [116]. In addition to the  $\epsilon$ -amino groups of lysine, the carboxyl groups of asparaginic and glutaminic acid, and the carbonyl groups of the crosslinker glutaraldehyde were used for the introduction of reactive sulfhydryl groups. In principle, the thiol groups were introduced by the reaction with dithiothreitol or 2-iminothiolane, by quenching reactive aldehyde residues with cystaminiumdichloride, or by coupling L-cysteine and cystaminiumdichloride by the aqueous car-

## 1. homobifunctional cross linkers

## 2. heterobifunctional cross linkers

**Fig. 6.9.** Examples of different bifunctional crosslinkers in use for protein chemistry. The reactive groups of the respective crosslinker are outlined in grey.

bodiimide reaction. The resulting nanoparticulate systems were characterized with regard to the number of available sulfhydryl groups and it was shown that the proposed reaction conditions enabled surface modification under well-defined conditions.

In a further step, the sulfhydryl-modified nanoparticles were used for the covalent attachment of functional proteins via bifunctional crosslinkers which reacted in a first step with amino groups of the protein and in a second step with the sulfhydryl groups introduced onto the particle surface [109, 114].

## 6.6

### Applications as Drug Carriers and for Diagnostic Purposes

Protein-based nanoparticles as well as microspheres have been described as drug carrier systems and for diagnostic purposes under *in vitro* and *in vivo* conditions in many studies. A brief overview over the different fields of application will be given below. The main focus is on particle preparations tested under *in vivo* condi-

tions in animals or under clinical conditions in humans; the overview of the *in vivo* studies is divided by the route of application. As well as the often used parenteral application route, topical or peroral administration of the nanoparticles and microspheres was described in some studies.

### 6.6.1

#### Protein-based Nanoparticles in Gene Therapy

The main goal in gene therapy is the formulation of optimal gene delivery vehicles that can achieve efficient gene transfer without immunogenic, cytotoxic and inflammatory effects. In a multitude of previous studies different vectors of viral origin were described, based on either recombinant forms of viruses such as retrovirus, adenovirus or adeno-associated virus (AAV) [117, 118]; however, these systems often suffered from the above-mentioned disadvantages. Nonviral approaches, including lipoplexes, polyplexes and nanoparticles, have advantages over viral systems such as safety, low cost, stability, ease of manufacturing and high flexibility concerning the size of the delivered transgene. However, their lack of specificity and their inability to deliver prolonged gene expression have proved to be drawbacks. Although the current synthetic systems are less efficient than viral vectors, rapid advances have achieved efficient levels of gene transfer. One promising approach is the development of nanoparticles which contain a gene construct inside a protective matrix, which protects them from immune recognition and destruction after systemic application.

In the field of protein-based nanoparticles there are many papers describing the preparation of plasmid DNA-loaded nanoparticles by different coacervation methods, and the subsequent quantification of the transfection efficiency under *in vitro* and *in vivo* conditions. For example, Truong-Le et al. reported a method for the incorporation of plasmid DNA coding for firefly luciferase into gelatin-based nanoparticle system. The nanoparticles were prepared by a salt-induced complex coacervation and were stabilized by crosslinking with EDC [61]. The authors described the incorporation of chloroquine in the particle matrix as well as the binding of transferrin and calcium ions to the resulting system. The transfection efficacy was tested in human kidney epithelial (HEK) 293 cells, and it was shown that the highest gene transfer efficiency was seen when transferrin,  $\text{CaCl}_2$  and chloroquine were simultaneously built into the microspheres.

In 1997, the same group described a crosslinked DNA–gelatin nanosphere preparation containing a  $\beta$ -galactosidase plasmid construct driven by an AAV promoter [62]. The nanospheres showed improved stability of the incorporated DNA in comparison to free DNA in the presence of serum. The *in vivo* application of the plasmid-loaded nanospheres in mice resulted in a 10–30 times higher  $\beta$ -galactosidase expression than that observed for naked DNA whereas the injection of a AAV preparation showed a 50–100 times higher expression. The application of the nanoparticle preparation was characterized by a modest anti- $\beta$ -galactosidase antibody response and a potent cytotoxic T lymphocyte response.

Comparable nanoparticle preparations containing either a cystic fibrosis [cystic

fibrosis transport regulator (CFTR)] or a green fluorescent protein (GFP) gene construct were described by the same group as gene delivery systems for the treatment of cystic fibrosis [119, 120]. The preparations were administered to the lung of rabbits by the use of a bronchoscope. Gene expression of the GFP reporter gene was observed in 43% of the brushed airway epithelial cells from the nanosphere-treated animals. The coencapsulation of sodium 4-phenylbutyrate into DNA–gelatin nanoparticles led to a correction of the cAMP-stimulated chloride conductance in cystic fibrosis epithelial cells. In 1998, Truong-Le et al. described the application of their DNA–gelatin nanospheres for the transfection of HEK 293 cells [63]. The nanospheres were characterized with regard to their DNA encapsulation efficiency, particle size, particle matrix structure as well as their stability in different media. The DNA release was mainly influenced by the nature of the incubation medium as well as by the amount of EDC used for particle stabilization. The highest DNA release was observed in trypsin solution and with low amounts of crosslinking reagent EDC, indicating the possibility to prepare a controlled release nanosphere preparation by variation of the crosslinking conditions. The results of the *in vitro* transfection showed that the most effective nanosphere preparation consisted of a DNA–gelatin coacervate, which was surface modified by the attachment of transferrin, and exhibited incorporated chloroquine and calcium chloride. The cell incubation with the optimal nanosphere preparation achieved a transfection level comparable to Lipofectamine<sup>TM</sup>, Lipofectin<sup>TM</sup> and Ca–DNA coprecipitate techniques. The quantification of *in vivo*  $\beta$ -galactosidase expression subsequent to an intramuscular injection in mice revealed that the nanosphere preparation was much more effective than naked DNA or DNA in Lipofectamine complexes, but that the expression rate was significantly lower than that after DNA delivery with an AAV vector system.

Leong et al. compared the gelatin–DNA nanospheres with chitosan–DNA nanospheres surface modified by the covalent introduction of PEG and transferrin [121]. In comparison to the gelatin–DNA nanospheres the chitosan–DNA nanospheres showed enhanced *in vitro* transfection efficiency in HEK 293 cells, but without further enhancement effects of transferrin or by coencapsulated chloroquine. The authors showed that the optimal DNA delivery preparation mainly depended on the respective cell line and marker gene under evaluation: gelatin–DNA nanospheres were effective in transfecting HeLa cells; however, as mentioned above, when compared to chitosan, nanospheres showed only a reduced effect in HEK 293 cells. The group showed that the transfection efficiency of chitosan–DNA nanospheres was neither influenced by the storage time in suspension nor by a lyophilization step after particle preparation.

In 1999, Truong-Le et al. further characterized the coacervation conditions for the preparation of gelatin–DNA nanospheres of defined physicochemical characteristics [64]. The biological integrity of the proposed nanosphere preparations was demonstrated by a more than 50% transfection of human tracheal epithelial cells with DNA encoding CFTR. The DNA-loaded nanospheres were able to complement human bronchial epithelial cells defective in CFTR-mediated chloride transport activity with a functional CFTR.

Apart from the application of gelatin as the starting material for the preparation of plasmid DNA-loaded systems, nanoparticles based on albumin were described as well. In a study by Rhaese et al., the preparation and characterization of nanoparticles consisting of DNA, HSA and polyethyleneimine was described, and their transfection efficiency was tested in HEK 293 cells [122]. A high transfection efficiency that was nearly in the range of commercially available transfection reagents such as Superfect™ and DOTAP™ was observed when the particles were prepared at a N/P ratio of 6.0. The efficiency was comparable to that exerted by the classical calcium phosphate-mediated transfection.

### 6.6.2

#### Parenteral Application Route

The body distribution of particulate systems after parenteral administration and the modification of the distribution by variation of the particle characteristics have been determined in many studies. Some of these studies that used magnetite-loaded particles under external magnetic guidance have been addressed previously [35–40]. These studies used albumin-based particles as drug carrier systems for cytostatic agents such as doxorubicin for tumor therapy. However, such particles systems are also well suited as superparamagnetic resonance contrast material for the diagnosis of organs of the MPS and tumor diagnosis [34].

##### 6.6.2.1 Preclinical Studies with Protein-based Particles

The influence of covalent surface modification on the body distribution of albumin nanoparticles after intravenous application was studied by Roser et al. [93]. An accumulation of the particles in the central nervous system of rats was observed in an experimental animal model of allergic encephalomyelitis. A later immunohistochemical study of Merodio et al. revealed that circulating macrophages, which migrated to the damaged sites, and resident activated microglial cells were involved in the distribution of the nanoparticles [74].

Albumin-based particles have been used for varying applications. For example, Martodam et al. studied albumin microspheres as drug carriers for an inhibitor of the leukocyte elastase (EC 3.4.21.11) leading to drug accumulation in the lung of rats [123]. Kinsey et al. used albumin particles for transfection under *in vivo* conditions [124]. They described a covalent conjugation between HSA and polyethyleneimine using a reductive cleavable spacer structure. Under elevated temperature and acidic reaction conditions the resulting conjugate was transferred to macroaggregates which were drug loaded with plasmid DNA encoding for GFP. The intravenous application of the preparation in mice resulted in a local transfection in the lung, whereas other tissues were not affected.

##### 6.6.2.2 Clinical Studies with Protein-based Particles

The clinical application of particle systems based on HSA has also been described. In all of these studies the administration of the particle systems was by the parenteral route.

In an early study cisplatin-loaded albumin microparticles were used for clinical chemotherapy. An infusion of the particle system through the lingual artery was performed in seven patients with advanced carcinoma of the tongue [125]. Due to a particle size of about 56  $\mu\text{m}$  an arterial embolism in the tumor area was achieved. Specimens were taken at different time intervals after administration, and it was observed that by the fourth week almost all carcinoma cells were killed and that microspheres were hydrolyzed and vanished within 6 weeks. A combined effect of cytotoxicity and ischemic necrosis of the tumor after microembolism was discussed.

The ability of albumin nanoparticles to act as a carrier system for paclitaxel was investigated in many clinical studies. The albumin-stabilized nanoparticle formulation ABI-007 (American Bioscience, Santa Monica, CA) was designed to overcome insolubility problems encountered with paclitaxel and eliminates the need for toxic solvents such as Cremophor EL, which is part of the commercially available paclitaxel formulation Taxol<sup>TM</sup>. Toxicities and antitumor activity of intra-arterial administration of paclitaxel-loaded albumin nanoparticles were determined in patients with advanced head and neck carcinoma [126]. The intra-arterial administration of the particles to 43 patients was well tolerated by most of the patients and required no premedication. In total, 120 treatment cycles were completed and the cytostatic activity of the particulate preparation was compared with Taxol. The maximum tolerated dose of the particle formulation in a single administration was 270  $\text{mg m}^{-2}$  and most dose levels showed considerable antitumor activity. Complete and partial response was observed in 80.9% of the patients. In a later study, the antitumor activity of the same preparation ABI-007 was studied in patients with advanced squamous cell carcinoma of the tongue [127]. Twenty-three previously untreated patients received intra-arterial therapy with paclitaxel-loaded albumin nanoparticles. Within this study about 78% of the patients had a clinical and radiologic objective response, 13% showed a stable disease, and 9% showed disease progression. The pharmacokinetic behavior and toxicity profile of ABI-007 was studied by Ibrahim et al. [128]. In comparison to the commercially available preparation Taxol, no acute hypersensitivity reactions were observed during the infusion of the nanoparticle formulation. Compared to Taxol, the nanoparticle formulation offered several features of clinical interest such as rapid infusion rate, no requirement for premedication and a high maximum tolerated dose. Further clinical trials in metastatic breast cancer patients were completed, and the evaluation for the treatment of other tumors such as nonsmall lung cancer, ovarian cancer, melanoma and cervical cancers was reported [129, 130]. Based on the promising results of the clinical trials, the FDA recently approved ABI-007 under the trade mark Abraxane<sup>TM</sup> as a new protein-bound breast cancer drug.

In the field of diagnostic applications, protein-based nanoparticles are mainly used as ultrasound contrast agents. The concept of contrast enhancement using gas-filled microspheres was developed during the past two decades. A multitude of clinical trials were performed and different commercially preparations are available. In the field of protein-based systems, Alburnex<sup>TM</sup> was described as air-filled albumin microspheres prepared from sonicated 5% HSA. After intravenous or in-

tracoronary injection the microspheres are ideal agents for myocardial contrast echocardiography. Animal studies showed that although the microspheres are mainly in the size range of several micrometers, Albunex did not alter coronary blood flow, left ventricular function or systemic hemodynamics [131]. Comparable results were achieved under clinical conditions, and it was demonstrated that intravenous injection of Albunex appears to be safe without any adverse hemodynamic and respiratory effects [132]. After intravenous injection the albumin microspheres were found to cross the pulmonary circulation. A further clinical study in 71 patients with three intravenous doses of Albunex showed that all injections were well tolerated and no serious side-effects were noted in any of the patients [133]. An extensive physical and biochemical characterization of Albunex microspheres was described by Christiansen et al. [134]. They found out that the preparation contains mainly air-filled microspheres in a size range from 1 to 15  $\mu\text{m}$  with less than 5% being larger than 10  $\mu\text{m}$ . In particular, the microsphere fraction between 4 and 10  $\mu\text{m}$  was assumed to give the main contribution to the ultrasound signal in the left ventricle of the heart after intravenous injection. Only 1.5% of the total protein in suspension represents the microsphere protein, whereas the remaining protein was soluble albumin molecules. In addition to Albunex, a second preparation based on heat-denatured HSA was licensed as an echocardiographic contrast agent: Optison<sup>TM</sup> consist of gas-filled albumin microspheres, but contains octafluoropropane instead of air entrapped in the particle system. Due to incorporation of the less soluble octafluoropropane the microspheres persist much longer *in vivo* as compared to microspheres filled with air [135].

As well as the diagnostic applications, several attempts have been made at therapeutic applications of gas-filled microspheres such as Albunex, including ultrasound-intensified thrombolysis, tissue targeting and drug delivery [136, 137]. For example, albumin-coated microbubbles were used as a drug carrier system for plasmid DNA [138]. The preparation was injected intramuscularly in mice and even in the absence of ultrasound significantly improved transfection efficiency was observed. In the presence of ultrasound the transfection efficiency was significantly increased in older animals. Therefore, protein-based microbubbles are considered as a promising approach for gene delivery in muscle.

### 6.6.3

#### Topical Application of Protein-based Particles

Apart from parenteral application, other routes such as topical or peroral applications have been described for protein-based particle systems. With regard to topical application, albumin particles were used as drug carrier systems for the ophthalmic administration of pilocarpine [139–141]. After drug binding to the particulate systems a significant prolongation in reduction of the intraocular pressure (IOP) was observed. Based on the kinetic data of IOP reduction and miosis, an increase in pilocarpine bioavailability of 50–70 and 50–90% was calculated, respectively.

#### 6.6.4

#### Peroral Application of Protein-based Particles

At first sight, due an enzymatic degradation in the gastrointestinal tract, peroral administration of protein-based particles seems to be a difficult approach. However, the peroral application was investigated in a number of studies. Widder et al. described a suspension of magnetite-loaded albumin microspheres as a paramagnetic oral magnetic resonance contrast agent [34]. Under *in vitro* conditions the proposed microspheres were stable over a broad range of pH and tolerated proteolytic enzyme exposure over 24 h. The peroral administration of the microspheres was studied under *in vivo* conditions in rabbits and dogs, and the system appeared effective as a small bowel contrast material.

In a further study, protein microspheres were described as adjuvants for oral vaccination [142]. The model antigen ovalbumin was entrapped into gelatin microspheres which were stabilized with different amounts of the bifunctional aldehyde glutaraldehyde. In comparison to ovalbumin in solution, the oral administration of the particulate system in mice led to a significantly increased secretion of anti-ovalbumin IgA antibodies at the intestinal mucosa as well as by urinal excretion. This effect was attributed to an effective accumulation of the particles in immunocompetent regions of the gastrointestinal tract the so called Peyer's patches.

The body distribution after peroral administration of radioactively labeled alginate BSA nanoparticles to rats was investigated by Yi et al. [143]. Nanoparticles about 166 nm and drug loaded with 5-fluorouracil were used for the pharmacokinetic study. After oral administration the nanoparticles were mainly distributed in the liver, spleen, lungs and kidneys of the rats. Using micro-autoradiographic experiments, particle accumulation in Kupffers cells of the liver, liver parenchymal cells and phagocytes of the spleen was observed. Therefore, the group proposed protein-based nanoparticles suitable to enter the body circulation after gastrointestinal passage.

### 6.7

#### Immunological Reactions with Protein-based Microspheres

As was outlined previously, the formulation of a device for the controlled release of biologically active substances has been a goal for many researchers. For injectable preparations it is advantageous to use a matrix material that is well tolerated and produces no adverse immunological reactions. Since protein-based particle systems undergo structural alterations induced during the preparation process of the colloid the formation of new epitopes that may provoke an immunological response in recipients may occur. Different animal and clinical studies have been described in order to access the possible immunogenicity of particulate systems.

In 1981, Lee et al. reported the preparation of hormone-containing albumin microspheres as a sustained release drug delivery system for progesterone [24]. For their immunological studies they prepared a particle matrix based on rabbit serum albumin in the size range of about 100  $\mu\text{m}$ , and injected the resulting spheres in-

tramuscularly and subcutaneously in male rabbits. They described a good tolerance of the carrier system after application. No significant fluctuations of body temperature or weight were observed during the experiment. Rabbits that had received injections for several months did not show any adverse immunological symptoms.

The immune response of Alburnex microspheres was studied by Christiansen et al. [144]. Within this study 34 healthy volunteers received four injections of either Alburnex or 5% HSA at 4-week intervals. Analysis of blood samples did not reveal any formation of IgE or IgG antibodies directed against the microsphere protein or albumin in any of the recipient. Likewise, no adverse reaction was observed when Alburnex was administered to allergic individuals having cat albumin as one of their allergens. The authors concluded from their data that there is no evidence that heat-aggregated albumin of the Alburnex microspheres may provoke an immunological reaction upon repeated injection of the preparation. In a following study, the safety of Alburnex administration was confirmed [145]. Within this study the albumin microspheres were repeatedly administered to 12 healthy volunteers over a period of time long enough to allow development of immune reactions. No formation of microsphere-specific IgE and IgG antibodies was observed after multiple Alburnex exposure.

Clinical evaluations of adverse reactions were performed in the preliminary stages of ABI-007 (Abraxane) approval as a new protein-bound breast cancer drug. Within these studies adverse reactions against the particulate formulation were compared to events after administration of the commercial paclitaxel formulation Taxol. The particulate formulation was characterized by a reduced number of total and severe hypersensitivity reactions.

## 6.8

### Concluding Remarks

Many studies have described nanoparticles and microparticles promising drug carrier systems. Among the different materials used for particle preparation, proteins are especially promising, since they can lead to biodegradable carrier systems for a multitude of application routes. This chapter has summarized the preparation techniques of protein-based particle systems as well as the potentials of surface modifications and drug targeting. The promising results of the particle systems under preclinical and clinical evaluation have been outlined. Recently, the first protein-based particle system was approved by the FDA for tumor therapy. Therefore, there is hope that in future years protein-based particle systems will improve the treatments of several disease and will give patients a better quality of life.

# Albumin Nanoparticles

*Juan Manuel Irache and Socorro Espuelas*

### 7.1

#### Introduction

Albumin is generally regarded to mean serum albumin or plasma albumin; however, the word albumin is also used to describe a protein or a group of proteins defined by its solubility in water [1, 2]. The albumin literature, already vast, is well served by a number of comprehensive reviews [3–7]. This particular contribution will focus solely on the use of serum albumin as a structural material to prepare nanoparticles, and their possible applications in pharmacy and medicine.

Albumin has substantial value in physicochemical and immunochemical applications. Since serum albumin is so common in the blood and so easy to purify, it was one of the first proteins to be studied by scientists. Its stabilizing and growth supplement properties make albumin ideal for use in cell culture and other commercial applications in which expensive reagents, such as hormones, enzymes and antibodies, require stabilization and/or dilution to maintain their functional integrity for long periods of time [3]. Clinically, albumin is indicated for use as a volume expander for hypovolemia, for treatment of hypoalbuminemia, thermal injuries and certain edematous states, and as an adjunct to cardiopulmonary surgery [8–11]. In North America alone, where it is estimated that the amount of albumin required for a 70-kg patient is approximately 175 g, around 100 000 kg year<sup>-1</sup> are consumed in surgery and shock trauma [12].

Another important field of application is the use of this material in the development of drug delivery systems. In the last 30 years, both bovine serum albumin (BSA) and human serum albumin (HSA) have been widely employed to prepare microparticles and nanoparticles. More than 100 different drugs or diagnostic molecules have been incorporated in albumin particles to be administered by different routes, including intravenous, intramuscular, ophthalmic and nasal routes. A great deal of research has already been conducted in the field of microparticles to determine and evaluate the different possibilities of their use as drug delivery systems and diagnosis tools. Some of these successful efforts have enabled the development of new products as contrast agents for diagnostic purposes (i.e. Optison<sup>TM</sup>). However, albumin nanoparticles, whose development was later than that for mi-

roparticles, are currently being studied by a number of research groups. These carriers appear to offer promising applications, including new therapeutic strategies for both the treatment of cancer and neurological diseases.

This chapter presents an overview of the fabrication and applications of both conventional and “decorated” albumin nanoparticles. After a description of the different preparative processes, representative applications of the albumin nanoparticles are also presented.

## 7.2

### Serum Albumin

Serum albumin or plasma albumin is an abundant, multifunctional protein. It is the major protein component of blood plasma, occurring there at a concentration of around 0.6 mM (range 35–50 g L<sup>-1</sup>), but this represents only approximately 40% of the albumin present in the body. The remainder is found in the extravascular space of tissues.

Serum albumin is a single-chain protein, soluble in water, without any prosthetic groups or covalently bound carbohydrate and lipid [7]. HSA has 585 amino acid residues, whereas BSA is built from 583 amino acid residues [7, 13]. The molecular mass of both molecules is 66.5 kDa. In contrast, the secondary and tertiary structures are not completely known. Based on hydrodynamic experiments [14, 15] and low-angle X-ray scattering [16], serum albumin was postulated to adopt an oblate ellipsoid with dimensions of 140 × 40 Å [17, 18]. However, studies using <sup>1</sup>H nuclear magnetic resonance indicated that this structure was unlikely; rather, a heart-shaped structure has been proposed [19]. This last structure of serum albumin was also confirmed from X-ray crystallographic data [20].

On the basis of the amino acid sequence, Brown proposed a three-domain model for the protein [21]. Each domain is believed to consist of six helices forming a hydrophobic channel with basic and hydrophobic amino acid residues placed at the ends. According to Fourier transform IR (FT-IR) spectra, X-ray crystallographic and differential scanning calorimetry analyses, albumin has about 67%  $\alpha$ -helix, 10% turn and 23% extended chain, but no  $\beta$ -sheet [22, 23]. The analyses have also shown that the three homologous domains (I, II and III) are comprised of two subdomains (A and B) with distinct helical folding patterns that are connected by flexible loops [6, 24]. In addition, albumin domains appear to be stabilized by an internal network of disulfide bonds, bearing a number of ionizable groups with opposite signs [7, 23].

Modifications in the secondary as well as tertiary structures of BSA and HSA occur in dependence of pH, temperature and various kinds of denaturants. A number of studies have been carried out by use of various spectroscopic techniques to explore heat-induced denaturation of albumin [25–29]. The major conclusions reached from them were that conformational changes of the albumin molecule are reversible in the temperature range of 42–50 °C, but unfolding of alpha-helices

are irreversible in the temperature range of 52–60 °C. Above 70 °C, the gel formation by unfolding of albumin advances further [23, 30].

Albumin is synthesized by the liver and released into the circulation, where it possesses a half-life of 19 days [31, 32]. In the blood, serum albumin slowly diffuses across the endothelial linings of the capillaries. The bulk flow of water in the interstitial fluids and lymphatic vessels provides a means of removing albumin from the tissues. Albumin also diffuses into the cerebrospinal fluid, but the rate is so slow compared to the rate of production of the fluid that the concentration is virtually immeasurable [32]. When there is a breakdown in the blood–cerebrospinal fluid barrier, e.g. as occurs in meningitis [33] or multiple sclerosis [34], albumin is found in the fluid as a result of an increased rate of entry.

In mammals, the principal function of albumin is to provide colloid osmotic pressure, preventing plasma loss from the capillaries [6]. Other important functions of serum albumin are to maintain the pH between physiological limits and act as a source for rapid replacement of tissue proteins [35, 36]. Perhaps the most outstanding property of albumin is its ability to bind reversibly to an incredible variety of ligands. Albumin is the principal carrier of fatty acids that are otherwise insoluble in circulating plasma [37]. In fact, each albumin molecule can carry seven fatty acid molecules in deep crevices of the protein, burying their carbon-rich tails safely away from the surrounding water. More recently, serum albumin has been shown to be an important reservoir of the biological regulator and neuro-modulator, nitric oxide [38].

Serum albumin is also a versatile carrier protein, active against a variety of substances with widely differing properties (hydrophobic or hydrophilic, anionic or cationic, etc.). Thus, albumin assists in the distribution, metabolism or regulation of many marginally soluble substances such as calcium ions, tryptophan, various steroid hormones and many drugs [39]. In fact, serum albumin possesses a unique capability to bind, covalently or reversibly, a great number of various endogenous and exogenous compounds. Binding to serum albumin controls the free, active concentration of a drug, provides a reservoir for a long duration of action, and ultimately affects drug absorption, metabolism, distribution and excretion.

### 7.3

#### Preparation of Albumin Nanoparticles

Albumin nanoparticles (Fig. 7.1) have been studied as suitable carriers for drug delivery. The major reported advantages are their biodegradability [40, 41], absence of toxicity [42] and easy preparation by relatively simple methods [43]. Because of their defined primary structure, albumin-based nanoparticles may offer various possibilities for surface modification and covalent attachment of drugs and ligands. Furthermore, the albumin-based nanoparticles could allow the electrostatic adsorption of positively or negatively charged molecules without the requirements of other compounds. In addition, protein nanoparticles can be easily prepared under

**Fig. 7.1.** Scanning electron microscope image of albumin nanoparticles with an average diameter of about 250 nm. (From Ref. [48].)

soft conditions and incorporate several types of molecules [44, 45]. All of these advantages make albumin one of the most versatile materials to prepare nanoparticles.

### 7.3.1

#### **“Conventional” Albumin Nanoparticles**

Several different methods for the preparation of albumin nanoparticles have been described in the literature; however, many of them are modifications of the two basic techniques – emulsification and coacervation or controlled desolvation.

Emulsification is a relatively simple method to prepare albumin particles; however, control of the particle size is difficult. In fact, albumin particles below 500 nm are difficult to obtain by this procedure [46]. On the other hand, coacervation is more versatile and permits a certain control of the particle size, although careful selection of encapsulation conditions and materials is needed to yield high encapsulation efficiencies.

Once albumin particles have been prepared, the carriers have to be stabilized. Two main methods are used in the stabilization of albumin nanoparticles – thermal treatment at elevated temperatures (95–170 °C) or via the use of chemical reagents. This stabilization or “hardening” process affects the biodegradability and stability of nanoparticles and, thus, their drug release properties [40, 47, 48]. In fact, this step is necessary to prolong the *in vitro* and *in vivo* half-life of the resulting albumin nanoparticles [49].

In heat stabilization, albumin particles are hardened by thermal means, rendering the albumin insoluble by formation of interchain amide links between neighboring amino and carboxylic groups of the protein. [50–52]. This method of stabilization is usually associated with the preparation of nanoparticles by emulsification [40, 43, 47, 53]. The major drawback of the heat-stabilization method relates to the fact that during the formation of the particles and the drug-entrapment

Tab. 7.1. Studies describing the preparation of conventional albumin nanoparticles

Type of albumin	Method of preparation	Desolvating agent	Crosslinking agent	Size (nm)	Yield (%)	Reference

ND: not determined.

process, the temperature is sometimes very high. Although a higher temperature may be of little consequence for highly stable drugs, it can potentially lead to degradation and loss of drug efficiency.

To alleviate this problem, room-temperature chemical stabilization methodologies have been developed involving the use of formaldehyde [54, 55], glutaraldehyde [46–48, 50, 51, 56–58], 2,3-butadione [54] and, more recently, methyl polyethylene glycol (PEG)-modified oxidized Dextran (Dextranox-MPEG) [59]. Among all these chemicals, glutaraldehyde is the most popular agent for chemical crosslinkage. The reaction between albumin (proteins in general) and glutaraldehyde leads to the coupling of two amino groups located in the same protein molecule or to form bridges between albumin chains [51]. Glutaraldehyde predominantly reacts with the  $\epsilon$ -amino group on lysine and the N-amino terminal groups of the albumin [47, 60, 61].

Table 7.1 summarizes some of the studies concerning the optimization and preparation of unmodified or conventional albumin nanoparticles.

#### 7.3.1.1 Preparation of Albumin Nanoparticles by Desolvation or Coacervation

The desolvation of albumin with organic solvents followed by chemical crosslinkage is a commonly used method for the preparation of protein nanoparticles. In general, the coacervating agent induces some progressive modifications of the protein's tertiary structure to give an increasingly hydrophobic material, which tends to form submicronic aggregates of desolvated protein (coacervates) [68]. These co-

Fig. 7.2. Route for the preparation of albumin nanoparticles by a coacervation method followed by chemical stabilization with glutaraldehyde.

acervates are usually unstable and have to be hardened by physical or chemical crosslinkage. Stabilized coacervates are known as nano- or microparticles depending on their size.

The preparation of albumin nanoparticles by desolvation involves a three-step procedure. In the first step, an unstable dispersed system (coacervates) is obtained by addition of a desolvating agent of albumin (usually, acetone or ethanol) to an aqueous solution of the protein. Then, the coacervates are hardened by thermal stabilization or, more frequently, chemical crosslinkage and, finally, the resulting nanoparticles are purified and lyophilized. Figure 7.2 summarizes this process.

(a) *First step: preparation of albumin coacervates.* Albumin coacervates are obtained from an aqueous solution of the protein and after the addition of a desolvating agent of albumin. Among the different desolvating agents of proteins, acetone and ethanol have been widely employed. The reasons for this selection are their acceptability by pharmaceutical regulations and their easy elimination from the aqueous medium containing the albumin coacervates.

In 1993, Lin et al. described the preparation of HSA nanoparticles using a surfactant-free pH coacervation method [44]. These particles, in a size range between 90 and 250 nm, were prepared by the dropwise addition of acetone to an aqueous albumin solution at pH values between 7 and 9. The size of the resulting nanoparticles appeared to be dependent on the pH and the protein concentration [44].

Another interesting desolvating agent is ethanol. In this case, the addition of ethanol to an aqueous solution of albumin induces the formation of coacervates, whose size increased by increasing the volume of ethanol added up to a ethanol:water ratio of 1.5. Above this ratio, the particle size of albumin coacervates remains constant, but the particle concentration (yield of the process) continues to increase [48, 52]. Similarly, the rate of ethanol addition may influence the width of the particle size distribution – a higher rate of ethanol addition leads to a decrease of the heterogeneity of the albumin coacervates [65].

As a function of the pH and ionic strength of the albumin solution, the appear-

ance of the coacervate changed markedly and it is possible to prepare coacervates with different sizes. Thus, higher pH values lead to smaller nanoparticles; however, the yield of the process decreases [44, 48, 65]. Using acetone as a desolvating agent, the key parameter controlling the size of the resulting nanoparticles appears to be the pH of the medium. It was found that with increasing pH value of the albumin solution, particle size was reduced. This fact can be explained to an increased ionization of the HSA, by increasing the pH of the medium (the isoelectric point of albumin is 5.3) which leads to a repulsion of the albumin molecules and aggregates during particle formation. However, increasing salt concentration of the aqueous solution of the protein induces the formation of large particles. The presence of salts or the use of buffers interferes with the desolvation process. With phosphate buffers (pH 7–8), salt precipitation occurs during desolvation with ethanol. On the contrary, alkaline borate buffers (pH 8–9) or HEPES (pH 7.5) induce the precipitation of albumin in large aggregates [65].

Another important factor affecting the size and yield of nanoparticles produced by desolvation is temperature. Thus, preparation at 4 or 40 °C produces significantly smaller particles than at 20 and 30 °C. In addition, at 30 and 40 °C, clearly more particles are produced than at lower temperatures due to the lower solubility of albumin at higher temperatures under these conditions [52].

(b) *Second step: stabilization of albumin coacervates.* Once albumin coacervates are generated they have to be stabilized to reduce the rate of dissolution of albumin in water. The most popular technique is chemical stabilization with glutaraldehyde. In principle, two factors are important to consider – reagent concentration and duration of the crosslinking process. For the production of stable nanoparticles, the lowest required concentration appears to be at least up to 40% of the theoretical amount of glutaraldehyde that is necessary for the quantitative reaction with the amino groups in the albumin molecule [6, 46, 52]. The crosslinker reacts during variable periods of time ranging from 1 to 24 h. In any case, a large amount of glutaraldehyde or a long reaction time may result in a significant increase in both the size and polydispersion of the resulting nanoparticles [48]. Recently, the chemical stabilization process of albumin nanoparticles was optimized with 1.56 µg glutaraldehyde (mg protein)<sup>-1</sup> for 2 h. Under these conditions, no significant differences in the size, polydispersity and yield of albumin coacervates and nanoparticles were observed [63].

Again, the presence of buffers may negatively affect the stabilization process. Thus, the use of a Tris buffer (pH 8–9), characterized by the presence of amino groups, may negatively affect the efficacy of the crosslinking process with glutaraldehyde [65].

Another possibility is thermal stabilization. Chen et al. described the stabilization of HSA microspheres prepared by desolvation in acetone/water mixtures at 75 °C for 15–30 min [69]. Similar results were obtained by Weber et al. preparing albumin nanoparticles by desolvation with ethanol [52].

(c) *Third step: purification.* Purification of nanoparticles for pharmaceutical purposes is mandatory. The addition of sodium metabisulfite can be a good strategy to block unreacted aldehyde groups [70]. Other possibilities are dialysis, gel-

Fig. 7.3. Route for the preparation of albumin nanoparticles by an emulsification method followed by thermal stabilization.

permeation chromatography or, more frequently, subsequent centrifugations to eliminate any remaining protein molecules not transformed onto nanoparticles.

Finally, nanoparticles can be also lyophilized to preserve their physicochemical properties for a long period of time. For lyophilization of albumin nanoparticles, glucose [71], mannose [72] and mannitol [48, 73] have been proposed as cryoprotectors.

In summary, the main advantage of the desolvation process is the absence of toxic organic solvents and its application to the encapsulation of hydrophilic molecules. However, one of the main drawbacks appears to be that there is a close relationship between the size and yield of nanoparticles obtained by this manufacturing method. Therefore, a smaller particle size corresponds to a smaller amount of protein transformed into the nanoparticles.

#### 7.3.1.2 Preparation of Albumin Nanoparticles by Emulsification

Figure 7.3 summarizes a flow diagram of the preparation of albumin nanoparticles by an emulsification technique. For this purpose, an aqueous solution containing the protein is first emulsified in a lipophilic phase (i.e. cotton seed oil or an organic solvent). The two nonmiscible phases are dispersed with the help of high surfactant concentrations and/or energetic stirring procedures (i.e. ultrasounds). Thus, the albumin droplets are thermally stabilized by heating at a temperature higher than 110 °C for a variable period of time (10–30 min) [74, 75]. Then, nanoparticles are centrifuged, washed several times with organic solvents (i.e. diethyl ether or alcohol) and resuspended by sonication to remove residual oil [74, 76, 77].

With respect to emulsion techniques applying serum albumin, a complete and systematic study concerning the influence of protein concentration, emulsification time and power, stirring rate, heat stabilization temperature, and the type of non-aqueous phase was carried out by Gallo et al. [54]. More recently, a method for the preparation of BSA nanoparticles in the sub-200 nm range was described by Müller et al. [62]. In this case the aqueous solution of albumin was injected with a syringe in a solution of organic solvents containing a thickening agent (hydroxypropylcellulose). This emulsion was sonicated and forced to circulate during homogenization through a static mixing device. Finally, nanoparticles were cross-

linked with glutaraldehyde, isolated by centrifugation and washed with *n*-hexane. The emulsification process was carried out in a home-made apparatus, allowing transfer to larger scales [62].

The preparation of nanoparticles by this technique is not easy and involves a number of important drawbacks, including the use of surfactants for emulsion stabilization and the use of organic solvents to eliminate oil residues. In addition, the complete removal of the dispersion agents or oil residues remaining on the particle surface is difficult and time consuming.

#### 7.3.1.3 Other Techniques to Prepare Albumin Nanoparticles

Recently, a new procedure to produce albumin nanoparticles of about 250 nm has been proposed by pH control and heat treatment [67]. In this new procedure, an aqueous solution of albumin at pH 10.65 is heated at 80 °C for a set period. Then, the solution is rapidly cooled to room temperature, the pH of the solution adjusted to 6.04 and the resulting solution stirred for 90 min. Under these conditions, the solution becomes turbid and the albumin nanoparticles are formed.

Another possibility to obtain albumin nanoparticles is by using the sonochemical method. This method was developed by Suslick et al. for the synthesis of non-aqueous liquid-filled microcapsules and air-filled microbubbles [78, 79]. According to this process, the particles are formed by chemically crosslinking cysteine residues of the protein with an HO<sub>2</sub> radical formed around a micrometer-sized gas bubble or a nonaqueous droplet. The chemical crosslinking is responsible for the formation of the albumin particles and is a direct result of the ultrasound radiation on an aqueous medium [80]. However, this technique yields heterogeneous batches with wide size distributions, i.e. between 400 and 2800 nm [81].

#### 7.3.2

#### Surface-modified Albumin Nanoparticles

The surface of albumin nanoparticles possesses several amino and carboxylic groups which are available for covalent modification and drug or protein attachment [82]. These functional groups can be employed to couple targeting ligands such as primary amines [83], avidin [84] and PEG derivatives [59] as well as to covalently bind a variety of drugs.

An interesting approach to modify the surface of albumin nanoparticles is their association with PEG derivatives (or pegylation). PEGs are one of the most popular polymers for surface modification of colloidal drug carriers. In fact, PEGs were found to reduce interactions of the nanoparticles with the cells of mononuclear phagocyte system (MPS), thereby prolonging nanoparticle circulation in the blood stream after parenteral administration [85–87]. The steric repulsion resulting from a loss of conformational entropy of the bound PEG chains upon the approach of a foreign substance and the low interfacial free energy of PEG in water contribute to the extraordinary physiological properties of nanoparticles covered with PEG [85, 88]. Similarly, PEG grafted to surfaces of biomedical devices showed an increase of their biocompatibility [89, 90].

Concerning the preparation of pegylated albumin nanoparticles, little differences with respect of the preparative methods of conventional nanoparticles are observed. The mode of PEG attachment to these nanoparticles is carried out mainly by covalent grafting [91, 92], which is preferable than simple adsorption because of the higher stability of the resulting PEG layer around particle surface. This covalent attachment can be obtained by either synthesis of the PEG–albumin complex before manufacture of nanoparticles or by direct pegylation during the process of nanoparticle formation. The first attempt to prepare pegylated nanoparticles was developed by Lin et al. [59]. In this case HSA nanoparticles with a size of about 170 nm were prepared by a pH coacervation method, using acetone as desolvating agent and crosslinking with Dextranox-MPEG, which created a sterically stabilizing polyethylene oxide surface layer surrounding the nanoparticles.

Later, this same research group proposed the preparation of surface-modified albumin nanoparticles with PEG–albumin conjugates previously synthesized. Thus, pegylated albumin nanoparticles of around 100–140 nm were prepared from either poly(amidoamine)–PEG copolymer-grafted HSA (HSA–PAA–PEG) or poly(thioetheramido acid)–PEG copolymer-grafted HSA (HSA–PTAAC–PEG). These nanoparticles were produced using a pH coacervation method and cross-linked with glutaraldehyde [93].

In all cases, the existence of a hydrated steric barrier surrounding the nanoparticles was confirmed and these pegylated nanoparticles showed reduced plasma protein adsorption on their surface compared with unmodified particles. However, the use of PEG–albumin conjugates, rather than crosslinkage with Dextranox-MPEG, was more useful to obtain nanoparticles with a sole polyoxyethylene barrier on albumin nanoparticles [94]. More recently, pegylated nanoparticles prepared from mPEG–albumin conjugates have been reported [94]. However, when albumin is modified with mPEG, the amphipatic nature of the PEG molecule confers a higher solubility of albumin–PEG conjugates in organic solvents. This fact makes it difficult to induce coacervation of albumin, and thereby form nanoparticles, by using water miscible solvents. To solve this problem, ethyl acetate was introduced in the coacervation method [94]. Table 7.2 summarizes some of the reported methods to prepare pegylated albumin nanoparticles.

### 7.3.3

#### **Drug Encapsulation in Albumin Nanoparticles**

Albumin particles can load a high variety of drugs; however, the best results are obtained with hydrophilic molecules having high albumin-binding abilities. The association of a given drug or active molecule with albumin nanoparticles can be carried out by simple adsorption to the surface of the freshly prepared nanoparticles or during the process of fabrication of these carriers. In any case, the drug-loading efficiency is significantly influenced by the degree of binding between the drug and the albumin molecule [95, 96]. The higher the degree of binding between drug and the albumin molecules, the greater the loading capacity.

Tab. 7.2. Studies describing the preparation of pegylated albumin nanoparticles

Type of albumin	Method of preparation	Desolvating agent	Crosslinking agent	Size (nm)	Reference
HSA	pH coacervation (pH 9) and chemical stabilization	acetone	Dextranox-mPEG	170	59
HSA-PTAAC-PEG	pH coacervation (NaOH 0.5 M, 10 $\mu$ L) and chemical stabilization	acetone	glutaraldehyde	128–130	93
HSA-PAA-PEG	pH coacervation (NaOH 0.5 M, 10 $\mu$ L) and chemical stabilization	acetone	glutaraldehyde	106–138	93
HSA-mPEG	coacervation and chemical stabilization	acetone/ ethylacetate	glutaraldehyde	155	94

The incorporation of a drug (or active molecule) into the albumin nanoparticles by adsorption postparticle preparation can be carried out by simple dispersion of nanoparticles in an aqueous solution of the drug. This process is quite simple and has been used to load pilocarpine nitrate [71, 97] or hydrocortisone [70]. The adsorption capacity of molecules on the surface of albumin nanoparticles appears to be dependent on both their polarizability and hydrophobic properties [98]. For diluted solutions of model dyes (as generally used in drug delivery), the adsorption isotherms of these molecules on unloaded albumin particles exhibited Langmuir behavior suggesting monolayer formation in the initial stages of the sorption process. In addition, the amount of dye adsorbed to the surface of albumin particles increased with increasing hydrophobicity [98].

Adsorption and chemical stabilization can also be performed at the same time. Furthermore, in some cases, chemical crosslinkage can be also used to bind the given drug to the surface of albumin nanoparticles. This fact can be of interest to increase the loading capacity of albumin nanoparticles and to obtain more sustained drug release profiles. This strategy was applied for the loading of urokinase [99], ganciclovir (GCV) [48] and interferon- $\gamma$  [64]. Finally, albumin nanoparticles can be also used as a substrate to covalently bind active molecules by means of other chemical reactions involving different functional groups than that used by glutaraldehyde. This is case for the binding of the chelating agent diethylenetriaminepentaacetic acid [100] and cytochrome *c* [67] to the surface of albumin nanoparticles.

The second possibility consist of simultaneous incubation between the drug and protein before emulsification or desolvation. This strategy was followed for the loading of a number of drugs, including rose Bengal [72], GCV [48], 5-fluorouracil (5-FU) [101], methotrexate [102] and antisense oligonucleotides [63, 103]. An interesting modification of this “incubation step” consist of the use of a complex coacer-

vation method to load DNA. In this case, albumin nanoparticles can be formed by interaction of DNA with albumin in the presence of polyethylenimine (PEI) with the aid of sodium sulfate as a desolvating agent. It is assumed that during complex formation DNA and PEI get entangled into the forming matrix of albumin, thus building up nanoparticles of a spherical shape. The particles were stabilized by using a carbodiimide derivative as crosslinking agent [104]. A more simple method to load oligonucleotides in nanoparticles containing albumin was developed by Vogel et al. [105]. In this case, nanoparticles or proticles (as they were called by the authors) were obtained by simple incubation of protamine, oligonucleotide and albumin in an aqueous solution buffered at pH 7.0.

In general, the incubation method is preferred because it is simpler and gives higher encapsulation efficiencies than the adsorption procedure. Furthermore, this incubation previous to the protein coacervation or emulsification permits the dispersion of drugs or materials with low aqueous solubility and, thus, their incorporation to albumin nanoparticles.

However, the presence of modified albumins or surface “decorated” nanoparticles can also negatively affect the encapsulation or adsorption of the given drug. Thus, Lin et al. reported the lower incorporation of rose Bengal in pegylated nanoparticles when compared with undecorated nanoparticles. This fact appears to be a consequence of the blockage of active binding sites in the albumin molecule by the PEG derivative [72].

#### 7.4

#### Biodistribution of Albumin Nanoparticles

Few biodistribution or pharmacokinetic studies of albumin nanoparticles have been conducted. In healthy animals, no significant differences in the targeting properties of nanoparticles from albumin or from other materials have been reported. Thus, 15 min after the intravenous injection of a single dose of albumin nanoparticles, around 80% of the given dose was localized in the liver [83]. Figure 7.4 shows the capture of fluorescently labeled albumin nanoparticles for phagocyte cells in the liver. Similarly, no significant differences were found in the distribution of albumin nanoparticles when these carriers were coated to render them with positive, neutral or negative surface charges [83].

Nevertheless, the coating of polymer nanoparticles with albumin has been used as strategy to prevent their rapid clearance by mononuclear phagocyte system *in vitro* [106] and *in vivo* [107, 108]. It appears that albumin coating of nanoparticles may impair the adsorption of other serum proteins, such as opsonins C3b or IgG, that promote the receptor-mediated uptake by phagocyte cells. However, some evidence suggests that albumin, during nanoparticles formation, undergoes conformational changes (unpublished data) and the behavior of albumin nanoparticles would not be comparable with albumin-coated particles.

**Fig. 7.4.** Capture of fluorescently labeled albumin nanoparticles by cells of the MPS in the liver.

Merodio et al. studied the distribution of albumin nanoparticles in a model of multiple sclerosis in order to evaluate the potential of these carriers to cross the blood–brain barrier (BBB) [109]. The BBB is a unique membranous barrier that tightly separates the brain from the circulating blood. The capillaries of the brain and spinal cord lack the small pores and fenestrations of general capillaries, and are sealed with tight junctions [110]. The endothelial cells together with glial cells (i.e. astrocytes and pericytes) and the basal membrane constitute this barrier [111]. The result is a complex obstacle for many drugs. Many neurological disorders are characterized by significant alterations in the BBB, such as Alzheimer’s disease, multiple sclerosis, tumors, cytomegalovirus (CMV) or HIV infections [112].

The pathogenesis of multiple sclerosis includes white and grey mater lesions, myelin breakdown, and active inflammation [113]. The study of this disease was extensively performed with the induction in mice of experimental allergic encephalomyelitis (EAE), which displays similar neurological disorders to those observed in the multiple sclerosis disease [114]. Different strategies have been proposed to target pathological tissues within the central nervous system (CNS), including liposomes [115] and recombinant adeno-associated virus [116]. Similarly, Kumagai et al. proposed that cationized albumin is able to traverse the capillary walls of isolated brain capillaries and can be used for brain delivery [117].

More recently, the distribution of albumin nanoparticles (of about 300 nm) in the EAE animal model was carried out [109]. These nanoparticles were administered intraperitoneally, and 4 h after their administration were localized in the damaged and inflamed areas of the CNS, mainly in the lumbar portion of the spinal cord, the optic chiasma or the cerebellar lobules [109]. Immunohistochemical

studies revealed that circulating macrophages, which migrate to the damaged areas within the CNS, and resident activated microglial cells were involved in the distribution of albumin nanoparticles.

## 7.5

### Pharmaceutical Applications

Albumin micro- and nanoparticles have a wide range of biomedical applications, including their use as diagnostic agents, oligonucleotide and DNA delivery, cancer treatment, and ocular drug delivery.

#### 7.5.1

##### Albumin Nanoparticles for Diagnostic Purposes

Albumin nanoparticles have been proposed for imaging purposes because of a number of advantages, including their increased stability, prolonged *in vivo* half-life, reduction of possible adverse effects, concentration of the agent resulting in lower doses and ease of administration [118]. Their main uses are as radiopharmaceuticals and echo-contrast agents.

##### 7.5.1.1 Radiopharmaceuticals

One of the first attempts to use albumin nanoparticles as diagnostic tools was carried out by Scheffel et al. in 1972 [76]. In this case,  $^{99m}\text{Tc}$ -labeled albumin nanoparticles (of about 0.3–1  $\mu\text{m}$  size) were successfully used to visualize the liver and spleen by measuring gamma-rays coming from the isotope with a gamma camera [76]. Later, albumin nanoparticles were proposed for the study of the lymphatic system and identify sentinel nodes in breast cancer [119]. The sentinel node procedure for breast cancer allows for accurate staging of the axilla, while axillary node dissection can be avoided in patients with no sentinel node metastasis [120]. For this purpose, the radioactive tracers most commonly used are  $^{99m}\text{Tc}$  sulfur colloid (US) and  $^{99m}\text{Tc}$ -labeled albumin nanoparticles (Europe) [121]. They are distinctly different in size, and the smaller albumin nanoparticles show earlier retention and higher uptake into the sentinel nodes [122]. Nevertheless, both have been shown to be more effective in the identification of these nodes than microparticles, which show a tendency to remain in the injection site and a lower ability to enter into the lymphatic system [123, 124]. In addition, with albumin nanoparticles the subdermal/intradermal injection appears to be a reliable alternative [125, 126]. These albumin nanoparticles appear also to be effective in the diagnosis of melanoma [127], head and neck squamous cell carcinoma [128], and cervical cancer [129]. Finally, it is interesting to note that these radiopharmaceutical agents have also been proposed for the treatment of solid cancers [130, 131].

### 7.5.1.2 Echo-contrast Agents

Albumin nanoparticles, containing very small amounts of gas, are adequate echo-contrast agents [80, 132, 133]. These particles are prepared by sonication and can be used as an ultrasound contrast agent in echocardiography for the diagnosis of cardiac disease [134] and monitoring of myocardial perfusion [132, 135]. Two-dimensional contrast echocardiography uses the reflection of ultrasound to image heart tissue *in vivo*. To enhance image quality, a solution containing micro- or nanobubbles of albumin (size lower than 10  $\mu\text{m}$ ) may be injected intravenously to perfuse the cardiovascular system; these bubbles change the acoustic impedance of the blood flow, resulting in dramatically improved echo contrast with the surrounding tissues [136].

### 7.5.2

#### Albumin Nanoparticles as Carriers for Oligonucleotides and DNA

Antisense oligonucleotides are very potent drugs for the treatment of important diseases such as oncogene-related cancers or viral infections. Although antisense therapy provides a level of selectivity not available with traditional drugs, their therapeutic potential is currently hampered by their poor biological stability, limited cellular uptake and the poor cytoplasm delivery, where they have to reach their complementary targets. The use of colloidal carriers is a possible strategy to circumvent both stability and permeability problems. Cationic lipids and liposomes have been the most widely exploited, as long as polyanionic oligonucleotides interact spontaneously with positive molecules. However, they are toxic and show instability in presence of serum. Biodegradable nanoparticles made of several types of polymers have been also studied, i.e. polylactic acid (PLA)–PEG, poly(alkylacrylates), chitosan or alginates. Several groups have reported the advantages of using albumin nanoparticles as carriers for oligonucleotides, as compared with other types of polymers [63, 103, 137, 138]. Apart from protecting unmodified oligonucleotides from degradation [63, 138] and improving the cellular uptake [103] protein nanoparticles were able to load appreciable amounts of oligonucleotides without additional positive components [63]. What is more, albumin nanoparticles not only improved the cellular uptake of the oligonucleotides, but led to a significant accumulation of the oligonucleotide in the cytosol compartment of cells, in the absence of endosomolytic agents [103, 138].

The rationale for using albumin nanoparticles for cytoplasmic delivery of oligonucleotides is supported by the spontaneous interaction between these molecules and the protein as well as the fusogenic activity of albumin at low pH. Plasma albumin is their endogenous carrier that governs their transport and tissue distribution. Srinivanan et al. [139] (for HSA) and Arnedo et al. [137] determined values of binding constants that confirmed the high affinity between the protein and the oligonucleotides. It seems that the oligonucleotides bind to site I within the albumin [139]. The affinity was affected by the presence of other molecules associated to the protein (e.g. fatty acids). Also, the length and nature of the backbone in the

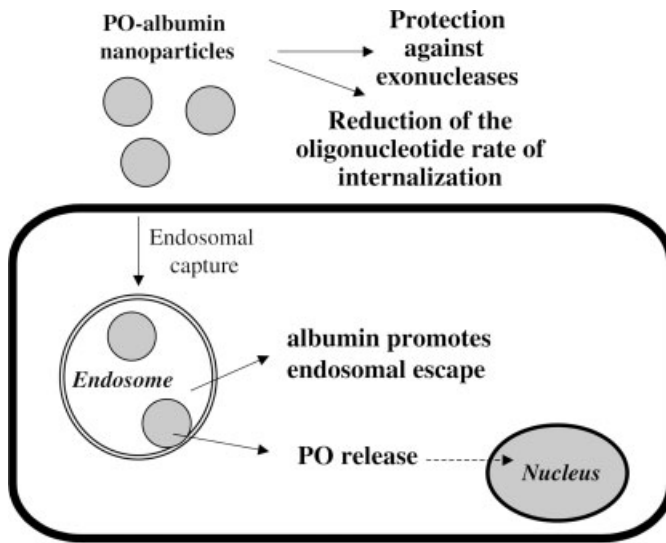

**Fig. 7.5.** Effect of albumin nanoparticles on the subcellular distribution pattern of a fluorescent phosphodiester oligonucleotide loaded in albumin nanoparticles after 24 h incubation time at 37 °C with MRC-5 fibroblasts.

oligonucleotides and the drug/albumin ratio had an influence in the stoichiometry of the interaction [103, 137, 139]. The consequence was that albumin nanoparticles were able to load oligonucleotides by simple incubation between the protein and the polyanions before desolvation, and further crosslinking of the protein coacervates with glutaraldehyde [63, 103]. Also, the adsorption of the oligonucleotides onto preformed nanoparticles was possible [63] and mainly addressed by electrostatic interactions. In addition, albumin nanoparticles encapsulated modified oligonucleotides with more efficiency than unmodified ones in accordance with a higher binding affinity of the native protein with a phosphorotioate backbone [103, 138].

The influence of albumin nanoparticles in cellular uptake and further intracellular distribution has also been evaluated. With an unmodified oligonucleotide Arnedo et al. [138] observed that albumin nanoparticles delayed and decreased the uptake of the oligonucleotide in MRC-5 cells. More important was the effect of albumin nanoparticles in the pattern of intracellular distribution of the oligonucleotide, from a punctate pattern for being concentrated in vesicular compartments to a more diffused cytoplasmic distribution [66, 103, 138]. Figure 7.5 shows this distribution of albumin nanoparticles within the cytoplasm of fibroblasts. This modification in the pattern of intracellular distribution was attributed to fusogenic properties of albumin at low pH, as previously tested in artificial systems with liposomes [140]. Figure 7.6 summarizes the proposed mechanism for the cell internalization and transport of antisense oligonucleotides by albumin nanoparticles.

The oligonucleotides are small molecules that bind to site I in the molecule of native albumin, DNA forms a complex much better with cationized albumin [141]. The system was less toxic than other positive molecules [142], but also it was unable to transfect cells. More frequently, the native protein has been co-associated to DNA-PEI complexes [104] or DNA-protamine lipoplexes [143, 144]. The presence of albumin stabilized the complexes through a decrease in their positive charge that prevented their aggregation in the presence of serum. With similar stabilization role, albumin was also incorporated into oligonucleotide-protamine particles [105].

### 7.5.3

#### Albumin Nanoparticles in the Treatment of Cancer

Albumin nanoparticles have been proposed as carriers for different antitumor drugs, including 5-FU, methotrexate and paclitaxel.

##### 7.5.3.1 Fluorouracil and Methotrexate Delivery

The use of albumin nanoparticles of about 660 nm containing 5-FU for cancer chemotherapy was investigated several years ago [145–147]. Upon intravenous injection into healthy mice, the nanoparticles were found accumulated in the liver and other elements of the MPS. However, when nanoparticles were injected intraperitoneally in Ehrlich ascites carcinoma-bearing mice, phagocytosis of the albumin carriers by tumoral cells was observed and suppression of tumor growth was noted [146]. Furthermore, following injection of multiple doses of 5-FU-loaded albumin nanoparticles, the lifespan of the mice increased by about 30% compared to a control treatment with the free drug [146]. More recently, a similar formulation of 5-FU-loaded albumin nanoparticles (size about 640 nm) was found effective in mice with a 2-fold increase in the antitumor activity of this drug compared with a free 5-FU solution [101]. Another interesting work concerns the ability of sodium alginate–BSA nanoparticles to increase the oral bioavailability of 5-FU. These carriers (about 170 nm) were able, after oral administration, to enter into the circulation and target the tissues rich in phagocytes, such as the liver and spleen [148].

However, albumin nanoparticles induced a markedly different biodistribution of

methotrexate when administered in animals by an intravenous route [102]. In fact, the incorporation of this drug in albumin nanoparticles increased its accumulation in the lungs of animals [102].

#### 7.5.3.2 Paclitaxel Delivery

The more interesting and complete studies of the potential of albumin nanoparticles to deliver antitumor drugs have been carried out with paclitaxel. Paclitaxel (Taxol®) is used extensively in the treatment of breast cancer [149], and, due to its low aqueous solubility, is currently formulated with ethanol and the nonionic surfactant Cremophor EL (polyoxyethylated castor oil) to enhance drug delivery [150]. However, these excipients may contribute to the side-effects associated with the use of paclitaxel, ultimately reducing the quality of life in patients undergoing treatment. Cremophor may contribute to side-effects induced by paclitaxel, as well as the hypersensitivity reactions that occur in 25–50% of patients during infusion that require premedication with histamine blockers and glucocorticoids [151]. Furthermore, the formulation including Cremophor and ethanol leaches plasticizers from PVC bags and infusion sets, resulting in the need for preparation and administration of paclitaxel in glass bottles or non-PVC infusion systems [152].

In order to overcome these drawbacks and to increase its antitumor efficacy, paclitaxel was covalently bound to albumin nanoparticles. This new formulation of about 150 nm allows for a higher concentration of paclitaxel, resulting in a decreased infusion volume and time, and does not require nonstandard infusion sets [149, 153]. In animal models, paclitaxel–albumin nanoparticles resulted in increased delivery of chemotherapeutic drugs to the tumor compared with solvent-based drugs. The mechanism for this advantage is being actively studied and may be related to albumin-activated transport of molecules into tissues by binding to the gp60 albumin receptor on blood vessels with subsequent accumulation of albumin nanoparticles in tumors [154].

In metastatic breast cancer, a pivotal randomized controlled phase III clinical trial was recently completed comparing the safety and efficacy of 260 mg m<sup>-2</sup> of paclitaxel–albumin nanoparticles versus paclitaxel injection (Taxol) at a dose of 175 mg m<sup>-2</sup>. Despite a 50% higher dose of chemotherapy infused over 30 min without premedication for hypersensitivity, paclitaxel–albumin nanoparticles were well tolerated and provided better results than the conventional formulation [154, 155]. In January 2005, the FDA approved this new albumin nanoparticle formulation (Abraxane™) for metastatic breast cancer [156].

Paclitaxel-loaded albumin nanoparticles have also been proved to be effective in the treatment of squamous carcinomas of the head and neck, uterus, and anal canal. In phase I/II studies, complete pathological responses occurred in 1.16, 20 and 18.8% of patients, respectively [157, 158]. In another study, the intra-arterial infusion of paclitaxel incorporated into human albumin nanoparticles for use as induction chemotherapy before definitive treatment of advanced squamous cell carcinoma of the tongue proved to be reproducible and effective to preserve this organ [159]. In fact, 78% of the treated patients had a clinical and radiological objective response (complete, 26%; partial, 52%) and only 9% showed disease progression.

Another interesting attempt concerning the delivery of paclitaxel is its association with pegylated albumin nanoparticles. Due to their low interaction and recognition by the MPS, these pegylated carriers appear to be of interest to passively target inflamed regions within the body, including the CNS and the colon [160].

### 7.5.3.3 Albumin Nanoparticles in Suicide Gene Therapy

In recent years, suicide gene therapy has been proposed for the treatment of a number of cancers. This therapy implies the use of suicide genes that code for enzymes which can transform a prodrug into a cytotoxic product [161]. Thus, the tumoral cell is rendered sensitive to a type of chemotherapy which is relatively nontoxic for the rest of the body [162]. In this context, the therapeutic combination of the herpes virus thymidine kinase (HSV-tk) and GCV has shown great clinical promise as gene therapy for the treatment of a number of cancers including hepatocarcinoma [163], neuroblastoma [164], ovarian [165], pancreatic [166] and prostate cancers [167]. The viral transfection can be carried out by adenoviruses [162, 163, 165, 166] and the expression of this gene in the cell yields the enzyme that converts the nontoxic prodrug GCV into a highly toxic metabolite [168].

In a recent work, the ability of albumin nanoparticles to concentrate GCV in the hepatocytes evidenced by the increase in the antitumoral efficacy of the HSV-tk/GCV combination [169]. In this work, mice were previously treated with  $4 \times 10^{10}$  pfu  $\text{kg}^{-1}$  adenovirus (AdCMV-tk) by intravenous administration and 48 h later received the GCV treatment. The use of albumin nanoparticles demonstrated a higher ability to concentrate this drug in the liver of animals as compared with the conventional formulation. In addition, the histologic analysis of the liver also revealed great cellular damage in terms of necrotizing area and perivascular inflammatory reactions (Fig. 7.7). It seems that the greater and more prolonged hepatic concentration of GCV released from the nanoparticles led to the accumulation of the toxic metabolite of GCV in the liver. These nanoparticulate carriers offered the additional advantage of increasing the plasma half-life of the drug and its tissue distribution, as determined by the pharmacokinetic analysis [169]. There-

**Fig. 7.7.** (a) Liver section from mice that were treated with  $4 \times 10^{10}$  pfu  $\text{kg}^{-1}$  AdCMV-tk and, 48 h later, received GCV-loaded albumin nanoparticles. (b) Liver section of a nontreated

mouse. Hematoxylin & eosin dye; magnification:  $\times 100$ . Green arrows: ballooning and acidophilic bodies; yellow arrow: apoptotic bodies; V: vessel. (From Ref. [169].)

fore, the use of these nanoparticles permits a higher distribution to the liver, which can be of interest to decrease the drug dose and frequency of administration.

#### 7.5.4

#### **Magnetic Albumin Nanoparticles**

Magnetic drug delivery by particulate carriers is a very efficient method of delivering a drug to a localized disease site. Very high concentrations of chemotherapeutic or radiological agents can be achieved near the target site, such as a tumor, without any toxic effects to normal surrounding tissue or to the whole body [170]. It is thus possible to replace large amounts of freely circulating drug with much lower amounts of drug targeted magnetically to localized disease sites, reaching effective and up to several-fold increased localized drug levels [55, 74, 171, 172].

In magnetically targeted therapy, a cytotoxic drug is attached to a biocompatible magnetic nanoparticle carrier (size in the range of 10–500 nm), such as albumin-coated magnetite [170]. When the particles are administered intravenously, external, high-gradient magnetic fields are used to concentrate the complex at a specific target site within the body. The process of drug localization is based on the competition between forces exerted on the particles by the blood compartment and magnetic forces generated from the magnet, i.e. the applied field. When the magnetic forces exceed the linear blood flow rates in arteries ( $10 \text{ cm s}^{-1}$ ) or capillaries ( $0.05 \text{ cm s}^{-1}$ ), the magnetic particles are retained at the target site and may be internalized by the endothelial cells of the target tissue [173, 174]. The drug can be released from drug/carrier either via enzymatic activity or changes in physiological conditions such as pH, osmolality or temperature [175] and be taken up by the tumor cells. This system, in theory, has major advantages over the normal, non-targeted methods of cytotoxic drug therapy.

The use of magnetic particles for the treatment of liver cancer was proposed for the first time at the end of the 1970s by Widder et al. The intra-arterial injection of these particles containing ultrafine ferroferric oxide and a prototype drug, doxorubicin hydrochloride, in the same target site resulted in 100-fold higher dose compared to free doxorubicin administered intravenously [78, 176–178]. Since those studies, success in cytotoxic drug delivery and tumor remission has been reported by several groups using animals models including pigs [179, 180], rabbits [175] and rats [181]. This technique has also been employed to target cytotoxic drugs to brain tumors [182]. More recently, magnetic albumin nanoparticles containing adriamycin have shown their ability to target a malignant liver tumor in rats [183]. In the presence of the magnetic field, these albumin nanoparticles accumulate in the liver tumor rather than in the normal tissue. Even if the magnetic field is not applied, magnetic albumin nanoparticles in tumor tissues still increase to 2.8 times that of normal liver tissues. In addition, the authors report that, in the presence of magnetic fields, these albumin nanoparticles may drive the drug to the tumoral tissues, preserving normal organs against exposure to chemotherapeutic drugs [183].

### 7.5.5

#### **Albumin Nanoparticles for Ocular Drug Delivery**

##### **7.5.5.1 Topical Drug Delivery**

Ocular administration is associated with rapid elimination of drug formulations from the precorneal area due to drainage through the naso-lacrimal duct and dilution by tear turnover. These processes result in a very low percentage of the drug administered (less than 5%) that could penetrate through the cornea and reach the intraocular tissues. Many studies have demonstrated an enhanced accumulation of nanoparticles in the conjunctival cul-de-sac and better drug bioavailability compared to conventional ophthalmic dosage forms, such as solutions and ointments [184, 185]. The colloidal systems can be administered as simple eye drops and, due to their low viscosity, minimize the temporary hindrance of the patient sight. The frequency of application could be reduced due to sustained drug delivery from the nanoparticle matrix.

Albumin nanoparticles have proved effective for the administration of pilocarpine and hydrocortisone in the interior of the eye [70, 72, 186]. In inflamed conjunctiva, the application of hydrocortisone-coated albumin nanoparticles (size between 100 and 300 nm) led to a higher drug bioavailability than the reference solution, which was rapidly eliminated by lacrimation. In addition, the albumin particles were more efficiently retained at the inflamed area than the normal conjunctiva. Consequently, in the inflamed eye, hydrocortisone-loaded nanoparticles enabled targeting to the precorneal area away from the inner segments of the eye [70].

Similarly, pilocarpine-coated albumin nanoparticles dramatically increased the ocular bioavailability of the drug compared with a reference solution [71]. The association of albumin nanoparticles with bioadhesive polymers was proved effective to increase the residence time of nanoparticles in contact with the eye and, thus, increase drug bioavailability [97]. In the presence of bioadhesives, the nanoparticles induced a significant improved pharmacological response in rabbits (i.e. miotic activity and reduction in the intraocular pressure) when compared with particle dispersions in buffer or free solutions. The best results were obtained with the association of albumin nanoparticles with either bovine submaxillary mucin or carbopol. This fact was due to the higher interaction of these bioadhesive polymers with both nanoparticles and precorneal mucus than other viscosity-enhanced polymers [97].

##### **7.5.5.2 Intravitreal Drug Delivery**

Another problem associated with the treatment of ocular pathologies is the difficulty for a given drug, topically administered, to absorb and reach therapeutic concentrations in the inner tissues of the eye for prolonged periods of time. Sometimes, when chronic treatment is necessary, local intravitreal administration becomes necessary. However, due to the short half-life of the given drugs, frequent injections are necessary to maintain the therapeutic levels. These continuous ad-

ministrations increase the risk of cataracts, retinal detachments, hemorrhages or endophthalmitis [187, 188].

Human CMV (HCMV) is a member of the Herpesviridae family of viruses, which are large DNA viruses that share biological properties of latency and reactivation [189]. In patients with AIDS and those immunocompromised due to hematopoietic stem cell transplantation or solid organ transplantation, HCMV is a major cause of morbidity and mortality [189, 190]. HCMV infections are the major cause of visual loss in these patients. Thus about 20–25% of patients with AIDS develop CMV retinitis during the course of their illness [191]. Without treatment this necrotizing retinitis progresses, resulting in irreversible blindness [192]. In cardiac and liver transplant patients, HCMV infection doubles the 5- and 3-year rates of graft failure, respectively [193]. In the absence of antiviral prophylaxis, symptomatic infections occur in approximately 39% of heart/lung recipients, 25% of heart transplants, 29% of liver transplants and 8% of patients receiving renal transplants [194].

For the treatment of HCMV retinitis, local intravitreal therapy with different antivirals is currently used. In this context, albumin nanoparticles have been proposed as carriers for intravitreal controlled delivery of diethylenetriaminepentaacetic acid (DTPA) [100], GCV [48, 73, 195] and the antisense oligonucleotide fomivirsen [138]. In all cases, these carriers allowed significant increases of the anti-HCMV activity of the loaded drug *in vitro*. These results of antiviral activities seemed to be directly correlated to drug internalization by infected cells [73, 100, 138]. For DTPA-loaded nanoparticles, it appears that these particles were internalized by UKF-NB-3 cells and HFF. This cellular uptake mediated by the drug carrier systems may explain the increased anti-HCMV and cytotoxic effects of DTPA coupled to protein-based drug carrier systems. Another interesting key point is that the improvement of the antiviral activity of GCV when loaded in albumin nanoparticles was not related to any cytotoxic effect on fibroblasts or corneal cells [73].

In order to study the distribution and toxicity of albumin nanoparticles within the eye, these carriers were dispersed in saline and administered to laboratory animals by the intravitreal route [196]. Two weeks after the single injection, a large portion of the administered dose appeared to be localized, quite broadly distributed, overlying the inferior portion of this cavity (see Fig. 7.8). However, some minor fractions were also located in the iris and ciliary body, which can be explained by the higher porosity of these ocular organs and, probably also, by an elimination mechanism of the particles via the ophthalmic anterior chamber. This route of elimination has been described for macromolecules and takes several days to be completed [197]. However, the histological evaluation of the different ocular tissues suggested that albumin nanoparticles are well tolerated after their intravitreal injection. These analyses were confirmed by the absence of cellular infiltrations following the association of the nanoparticles to ocular cells. In addition, no sign of degeneration of the eye receptors was observed [196]. In all cases, the retina kept its cytoarchitecture, with no signs of alteration in the photoreceptor and neuronal

**Fig. 7.8.** Immunofluorescence detection of albumin nanoparticles by streptavidin–FITC staining 2 weeks after their injection in the vitreous cavity (a) and in the blood–aqueous barrier adjacent area and ciliary muscle (b).

layers of the retina. Finally, immunohistochemistry studies also confirmed the lack of ability of albumin nanoparticles to generate autoimmune phenomena, which can stimulate the generation of pathogenic immune responses such as “retinitis pigmentosa” [198] and autoimmune uveoretinitis [199]. In summary, albumin nanoparticles appear to be safe carriers for the intravitreal delivery of drugs.

## 7.6

### Concluding Remarks

This chapter summarizes the preparation and main applications of albumin nanoparticles for pharmaceutical purposes. The use of albumin nanoparticles can offer a number of advantages, including their biodegradability, and the simplicity of preparation in an aqueous environment without the need for harmful solvents and chemicals. Furthermore, the inherent ability of albumin to spontaneously bind a high variety of molecules facilitates their loading in the resulting nanoparticles. In addition, drugs or ligands can also be easily bound to the protein and, thus, modify the surface properties of the resulting nanoparticles. All of these possibilities make albumin nanoparticles versatile carriers for pharmaceutical purposes.

Albumin nanoparticles are currently used as diagnostic tools and as adjuvants to improve the efficacy of the treatment with paclitaxel. However, in the future, the possibility exists that albumin nanoparticles may offer adequate solutions to some pharmaceutical problems such as the delivery of antisense oligonucleotides (and DNA) and the targeting of the CNS for the adequate treatment of neurological disorders.

# Nanoscale Patterning of S-Layer Proteins as a Natural Self-assembly System

*Margit Sára, D. Pum, C. Huber, N. Ilk, M. Pleschberger and U. B. Sleytr*

### 8.1

#### Introduction

Nanobiotechnology uses concepts from molecular biology, biochemistry and chemistry to identify components, processes and principles for the construction of self-assembling materials and devices. In particular, biological systems provide an enormous diversity of higher-order functional structures and patterns arising from molecular self-assembly. Most frequently, the initial step of molecular organization into functional units and complex supramolecular structures requires arrangement of molecules into ordered arrays. Recently, considerable efforts have been devoted to exploit natural self-assembly systems and to introduce variations into natural molecules (e.g. proteins and DNA) to achieve basic building blocks for specific structures and applications [1–8].

This chapter is intended to provide a survey of the unique general principles of crystalline bacterial cell surface layer (S-layer) proteins and fusion proteins thereof. In general, S-layer proteins form the outermost cell surface structure of many bacteria and archaea. Monomolecular S-layer protein lattices are composed of single species of protein or glycoprotein subunits with the inherent ability to self-assemble into two-dimensional arrays on the bacterial cell surface, or after isolation, on artificial supports, such as silicon wafers, noble metals, plastics, Langmuir lipid films or liposomes [4–8]. Thus, genetically and/or chemically modified S-layer proteins are exploited as building blocks and templates for generating functional nanostructures at the meso- and macroscopic scale for both life and nonlife science applications. In addition, S-layer-specific heteropolysaccharides are used as biomimetic linkers to solid supports and lipid layers to achieve binding and recrystallization in uniform orientation.

## 8.2

### General Properties of S-Layers

#### 8.2.1

##### Structure, Isolation, Self-Assembly and Recrystallization

Transmission electron microscopic (TEM) studies on the mass distribution of S-layers and subsequent two- and three-dimensional analysis including computer image enhancement led to structural information down to a range of 0.35–1.5 nm [4, 9]. Bacterial S-layer lattices are generally 5–20 nm thick, whereas S-layer lattices of archaea reveal a thickness up to 70 nm. High-resolution images of the surface topography of S-layers under biological conditions were obtained by applying scanning force microscopy (SFM) [4, 9, 10–12]. A common feature of S-layers is, with respect to the orientation on the cell, their smooth outer surface and more corrugated inner surface. The proteinaceous subunits of S-layers are aligned either in lattices with oblique (p1, p2), square (p4) or hexagonal (p3, p6) symmetry with a center-to-center spacing of the morphological units of approximately 3.5–35 nm. Hexagonal lattice symmetry is predominant among archaea [13, 14]. S-layers are highly porous protein lattices with a surface porosity of 30–70%. As S-layers are mostly composed of a single species of subunits, they exhibit pores of identical size and morphology [4]. However, in many S-layer proteins, two or even more distinct classes of pores with diameters in the range of 2–8 nm were identified.

Most techniques for isolation and purification of S-layer proteins involve mechanical disruption of bacterial cells and subsequent differential centrifugation to separate cell wall fragments [4, 15]. Complete solubilization of S-layers into their constituent subunits and release from the bacterial envelope can be achieved by treatment with high concentrations of hydrogen bond breaking agents (e.g. guanidine hydrochloride) or by dramatic changes in the pH value of the environment. Bacterial S-layer proteins are not covalently linked to each other or to the supporting cell wall component. While different combinations of weak bonds (hydrophobic, ionic and hydrogen bonds) are responsible for the structural integrity of S-layers, bonds holding the S-layer subunits together are stronger than those binding S-layer proteins to the underlying cell envelope layer [15, 16]. S-layer proteins reassemble into two-dimensional arrays during removal of the disrupting agent used in the dissolution procedure. Self-assembly products may have the form of flat sheets, open-ended cylinders or closed vesicles [4–8, 15].

Recrystallization of S-layer proteins on technologically relevant substrates, such as silicon wafers, noble metals, plastics, flat lipid layers or liposomes, revealed a broad application potential for these crystalline arrays in micro- and nanotechnology [4–8]. The formation of coherent crystalline arrays strongly depended on the S-layer protein species, the environmental conditions of the bulk phase (e.g. temperature, pH, ion composition and ionic strength) and, in particular, on the surface properties of the substrate [17, 18]. Crystal growth was simultaneously initiated at many randomly distributed nucleation points and proceeded in-plane

until the crystalline domains met, thus leading to a closed, coherent mosaic of individual, several micrometer large S-layer patches [17, 18].

Reassembly of isolated S-layer subunits at the air/water interface and on Langmuir films proved to be an easy and reproducible way for generating coherent S-layer lattices at a large scale [19, 20]. In accordance with S-layer proteins recrystallized on solid surfaces, the orientation of the protein arrays at liquid interfaces was determined by the anisotropy in the physicochemical surface properties of the protein lattice. Electron microscopic examination revealed that recrystallized S-layer proteins were oriented with their outer charge neutral, more hydrophobic surface against the air/water interface and with their negatively charged, more hydrophilic inner surface against the positively charged or zwitterionic head groups of phospholipid or tetraether lipid films [19, 20]. According to the recrystallization on solid supports, a closed mosaic of individual monocrystalline domains was formed.

Furthermore, isolated S-layer proteins were capable to recrystallize on liposomes and on nanocapsules [21–25], thereby forming closed S-layer cages. However, electron microscopic investigations showed that numerous lattice faults were introduced into the crystalline array as necessary for bending the two-dimensional protein lattice.

### 8.2.2

#### Chemistry and Molecular Biology

Chemical analyses and genetic studies revealed that the monomolecular S-layer is the result of the secretion and subsequent crystallization of a single homogeneous protein or glycoprotein species with a molecular mass ranging from 40 to 200 kDa [4, 26]. Most S-layer proteins are weakly acidic with isoelectric points ( $pI$ s) in the range of 4–6 [26]. Exceptions were reported for the S-layer proteins of lactobacilli [27] and that of *Methanothermobacter feravidus* [28] which possess  $pI$ s of 9–11 and 8.4, respectively. Typically, S-layer proteins have a large portion of hydrophobic amino acids (40–60 mol%), possess little or no sulfur-containing amino acids and consist of about 25 mol% charged amino acids. The most frequent posttranslational modification of S-layer proteins is glycosylation [29–31]. The glycan chains of S-layer proteins from Gram-positive bacteria closely resemble the architecture of lipopolysaccharides (LPS) occurring in the outer membrane of Gram-negative bacteria than that of eukaryotic glycan structures.

Information regarding the secondary structure of S-layer proteins is either derived from the amino acid sequence or from circular dichroism (CD) measurements indicating that approximately 20% of the amino acids are organized as  $\alpha$ -helices and about 40% occur as  $\beta$ -sheets. Aperiodic foldings and  $\beta$ -turn content may vary between 5 and 45%. Secondary structure predictions based on protein sequence data revealed that most  $\alpha$ -helical segments are arranged in the N-terminal part.

During the last two decades, numerous S-layer genes from bacteria and archaea of quite different taxonomical position were sequenced and cloned [26]. At least for S-layer proteins of Bacillaceae, common structural organization principles were

identified, as they typically contain three S-layer homology (SLH) motifs [32] on the N-terminal part. Each SLH motif consists of 50–55 amino acids, from which 10–15 are conserved. In most S-layer proteins, three SLH motifs form the SLH domain which specifically recognizes a distinct type of pyruvylated cell wall heteropolysaccharide, termed secondary cell wall polymer (SCWP), as the proper anchoring structure to the rigid cell wall layer [33–41]. This binding mechanism between SLH domains and pyruvylated SCWPs is widespread amongst prokaryotes, and is considered as having been conserved during evolution [40]. The construction of knockout mutants in *Bacillus anthracis* and *Thermus thermophilus* in which the gene encoding a putative pyruvyl transferase was deleted demonstrated that the pyruvic acid residues play an essential role for the binding process [34, 40]. This observation was supported by surface plasmon resonance (SPR) spectroscopy measurements in which native and chemically modified SCWPs devoid of pyruvic acid residues were used for interaction studies [38]. By applying the dissection approach [41], it became apparent that at least in the case of the S-layer protein SbsB of *Geobacillus stearothermophilus* PV72/p2, the SLH domain (rSbsB<sub>32–208</sub>) corresponded to the SCWP-binding domain, whereas the larger C-terminal part (rSbsB<sub>209–920</sub>) represented the self-assembly domain [38, 41].

Although the S-layer proteins SbsA, SbsC and SgsE from *G. stearothermophilus* wild-type strains do not possess an SLH domain on the N-terminal part [42–45], they reveal a highly conserved N-terminal region which specifically recognizes a cell wall heteropolysaccharide containing 2,3-dideoxy-diacetamido mannosamine uronic acid [46] as negatively charged component [42–44]. In these S-layer proteins, arginine and tyrosine typically occurring in carbohydrate binding proteins such as lectins [47] are accumulated on the N-terminal part. In S-layer proteins of *Lactobacillus helveticus*, *L. crispatus* and *L. acidophilus* strains, the conserved C-terminal part was found to be responsible for cell wall anchoring [48], which is most probably mediated by a neutral cell wall polysaccharide [49]. According to the suggestion that S-layer proteins represent cell surface located, carbohydrate-binding, lectin-like proteins [50], the N-terminal region of the S-layer protein from the Gram-negative bacterium *Caulobacter crescentus* recognizes a distinct type of LPS as a binding site to the outer membrane [51, 52]. In *Campylobacter fetus*, a pathogenic organism, two serotypes are distinguished that depend on the type of LPS in the outer membrane. In type A cells, the S-layer protein SapA and its homologs are bound via a conserved N-terminal region to type A LPS, while in type B cells, specific binding was observed between the N-terminal part of SapB and its homologs and type B LPS [53].

For S-layer-carrying bacteria with a generation time of 20 min, about 500 subunits must be synthesized per second, translocated through the plasma membrane and incorporated into the existing protein lattice [15, 16]. Thus, promoters preceding S-layer genes must be very strong [26]. For some S-layer genes, two or even more promoters were identified which are most probably used in different growth stages [26, 27, 37, 43]. With the exception of the S-layer proteins from the Gram-negative bacteria *C. crescentus* and *C. fetus*, all others sequenced so far are produced with an N-terminal secretion signal peptide. For *C. crescentus* and *C. fetus*, type I

secretion signals were detected on the C-terminal part [54]. In contrast, a conserved gene (*abcA*) was identified in the downstream region of the genes encoding the S-layer proteins of the Gram-negative bacteria *Aeromonas salmonicida* and *Aeromonas hydrophila*. This gene encodes a protein that has ATP-binding activity and belongs to the ABC family of transporter proteins, regulates the synthesis of S-layer-specific O-polysaccharide chains in LPS and activates transcription of the S-layer genes [55, 56]. The existence of a translational autoregulation system was reported for *T. thermophilus* [57]. Three genes specifically repressing the expression of the S-layer gene promoter were identified. One of these genes corresponds to the C-terminal fragment of the S-layer protein SlpA which binds to the 5'-untranslated region of the *slpA* mRNA [57].

S-layer variation leads to the expression of alternate S-layer proteins, and was described for pathogens and non-pathogens. In non-pathogens, S-layer variation is frequently induced in response to altered environmental conditions, such as increased oxygen supply [58–60], whereas in pathogens, altered cell surface properties most probably protect the cells from the lytic activity of the immune system [53]. In general terms, two different types of S-layer variation can be distinguished. In the first type, which was observed for *C. fetus* [53, 61] and *G. stearothermophilus* ATCC 12980 [62], only the C-terminal part of the S-layer protein was exchanged, but both the N-terminal region and the S-layer-specific LPS or SCWP remained conserved. In the second type of S-layer variation, which was described for various *G. stearothermophilus* strains, a completely new type of S-layer protein and SCWP was synthesized, and S-layer variation also led to a change in the lattice type [59, 60]. At the molecular level, S-layer variation was either caused by intrachromosomal DNA rearrangement, as observed for *C. fetus* [53, 63], or variant formation depended on recombinational events between a naturally occurring plasmid and the chromosome [64]. In contrast, in *Lactobacillus brevis*, S-layer variation involved activation of transcription by a soluble factor rather than by DNA rearrangement [58]. Regarding the development of S-layer-deficient strain variants, the importance of insertion sequence (IS) elements was demonstrated for various organisms [65–67].

### 8.2.3

#### S-Layers as Carbohydrate-binding Proteins

As described above, the interaction between the N-terminal part of the S-layer proteins SbsB and SbpA and the corresponding SCWP was found to be highly specific [35, 38, 41]. The most detailed interaction studies were carried out with the SLH domain of SbsB (rSbsB<sub>32–208</sub>) and the corresponding SCWP of *G. stearothermophilus* PV72/p2 [38]. Data evaluation from SPR measurements and the setup where the SLH domain was immobilized to the sensor chip indicated the existence of at least two binding sites on a single SCWP molecule with an overall  $K_d = 7.7 \times 10^{-7}$  M. In order to distinguish between the different binding sites, the inverted setup where the SCWP was immobilized to the sensor chip and the SLH domain represented the soluble analyte was investigated. Data analysis was performed according to an extension of the heterogeneous ligand model which allowed us to

**Tab. 8.1.**  $K_d$  values for rSbpA<sub>31–1268</sub>, rSbpA<sub>31–318</sub> and rSbsB<sub>32–209</sub>

S-layer protein	$K_{d1}$	$K_{d2}$	$K_{d3}$
rSbpA <sub>31–1268</sub>	$8.4 \times 10^{-12}$	$7.0 \times 10^{-9}$	$2.1 \times 10^{-4}$
rSbpA <sub>31–318</sub>	$1.2 \times 10^{-11}$	$3.0 \times 10^{-8}$	$2.4 \times 10^{-2}$
rSbsB <sub>32–209</sub>	$6.7 \times 10^{-11}$	$6.1 \times 10^{-8}$	$2.6 \times 10^{-5}$

discriminate between three different kinds of binding sites with low ( $K_d = 2.6 \times 10^{-5}$  M), medium ( $K_d = 6.1 \times 10^{-8}$  M) and high ( $K_d = 6.7 \times 10^{-11}$  M) affinity. Although the existence of three different kinds of binding sites can be explained by structural heterogeneities frequently associated with naturally occurring polysaccharides, it cannot be excluded that the high-affinity binding site resulted from avidity effects caused by binding of at least SLH dimers (Table 8.1) [38]. The existence of three potential binding sites and similar affinity constants were demonstrated for the S-layer protein SbpA and the SCWP of *Bacillus sphaericus* CCM 2177 [35]. However, in the case of SbpA, the three SLH motifs and an SLH-like motif were required for reconstituting the functional SCWP-binding domain (Table 8.1).

For the exploitation of SCWPs as biomimetic linkers to solid supports to guarantee an oriented binding and recrystallization of S-layer proteins, these heteropolysaccharides were extracted from peptidoglycan-containing sacculi with hydrofluoric acid and precipitated with ethanol [68, 69]. After purification by size-exclusion chromatography, the latent aldehyde group of the reducing end of the polymer chain was modified with carbodihydrazide and the Schiff base was reduced with sodium borohydride [38]. Sulfhydryl groups were introduced by reaction of the free amine group with 2-methyl mercaptobutyrimidate (2-iminothiolane). Such modified SCWPs carrying a free terminal sulfhydryl group were used for direct adsorption to gold substrates, as required for SPR [70–72] or surface plasmon field enhanced spectroscopy [73]. For covalent binding to supports carrying free amine groups, the sulfhydryl group of the polymer chain (termed thiolated SCWP) was activated with *m*-maleimidobenzoyl-*N*-hydroxysuccinimide ester (MBS) which, as a heterobifunctional crosslinker, could react with amine groups, e.g. of amine-modified cellulose microbeads [72]. Another possibility to activate thiolated SCWP can be seen in the use of the heterobifunctional crosslinker sulfosuccinimidyl 6-[3'-2-(pyridyldithio)-propionamido]hexanoate (Sulfo-LC-SPDP) [38].

### 8.3

#### Nanoscale Patterning of S-Layer Proteins

##### 8.3.1

##### Properties of S-Layer Proteins Relevant for Nanoscale Patterning

S-layers represent a first order self-assembly system that has been optimized in the course of evolution. As S-layers are composed of single protein or glycoprotein species, they have repetitive (physicochemical) properties down to the subnanometer scale [4–8, 74]. Furthermore, functional groups such as amine and carboxylic acid

groups have identical positions and orientation on each subunit in the protein lattice. In the case of S-layer glycoproteins, the carbohydrate chains are attached to the same amino acid positions in the primary sequence [45]. Isolated S-layer subunits frequently maintain the ability to self-assemble in suspension and to recrystallize into a monomolecular protein lattice on various types of solid supports, such as gold chips, silicon wafers, plastics or glass, as well as on flat lipid layers or liposomes [4–8, 74]. The N-terminal region of S-layer proteins specifically recognizes a distinct type of SCWP as the proper anchoring structure in the rigid cell wall layer. These heteropolysaccharides can be exploited as biomimetic linkers to solid supports [38, 70–72], so that the S-layer subunits attach with their inner surface carrying the N-terminal region. S-layer proteins are ideal candidates for genetic engineering. So far, a single cysteine residue has been inserted at various amino acid positions, leading to numerous mutated S-layer protein forms [75]. As S-layer proteins usually do not possess sulfur-containing amino acids, this modification is particularly attractive, since the whole spectrum of sulfur chemistry can be applied to covalently link functional entities via the cysteine residue to the S-layer subunits. Studies on the structure–function relationship of selected S-layer proteins by producing N- or C-terminally truncated forms revealed that the N-terminal region functions as cell wall anchoring domain, whereas the middle and C-terminal part are responsible for lattice and pore formation [35]. However, in some S-layer proteins even more than 200 amino acids in the C-terminal part could be deleted without any influence on the self-assembly and recrystallization properties [37, 44].

To sum up, S-layer lattices are composed of identical protein or glycoprotein species. This implies that functional sequences introduced by genetic engineering and/or chemical modification are repetitively aligned in exact positions down to the subnanometer scale. This cannot be achieved with amorphous polymers which are three-dimensional networks where only random immobilization can occur [4]. In contrast, functional sequences fused to S-layer proteins or inserted into their primary sequence have identical positions and orientation on each S-layer subunit. Moreover, two or even more sequences with different functionalities can be fused to or inserted into a single S-layer protein, leading to multifunctional S-layer fusion proteins. Another possibility can be seen in the co-recrystallization of different types of engineered S-layer proteins which would also lead to multifunctional protein lattices. Apart from this variability, it is possible that the functional sequences or domains are exposed on the outermost surface of the monomolecular protein lattice and are therefore easily accessible to further binding and reaction partners or they may be inserted inside the pores, which could be advantageous for nanoparticle binding. Thus, S-layer proteins can be considered as an extremely versatile and flexible self-assembly system with considerable application potential in nanobiotechnology.

### 8.3.2

#### **Immobilization of Functionalities by Chemical Methods**

Chemical modification and labeling experiments revealed that S-layer lattices possess a high density of functional groups on the outermost surface. For covalent at-

tachment of foreign (macro)molecules, the carboxylic acid groups originating from either aspartic acid or glutamic acid were activated with carbodiimide and subsequently reacted with free amine groups of functional macromolecules, such as Protein A [76–78], monoclonal antibodies [70, 79–82] or various enzymes [4]. In order to prevent inter- and intramolecular crosslinking reactions, the  $\epsilon$ -amine groups from lysine residues were first modified with monofunctional imidoesters or the S-layer lattice was crosslinked with amine group-specific bifunctional reagents, such as imidoesters or glutaraldehyde. For immobilization of macromolecules, S-layers were either used as self-assembly products which were mostly double layers or as S-layer-carrying cell wall fragments which consisted of the peptidoglycan-containing layer and two mirror-symmetrically arranged S-layer lattices [76]. The amount of monoclonal antibodies, enzymes and streptavidin that could be immobilized to S-layer lattices corresponded approximately to a monolayer of randomly oriented molecules [4]. Quantification of immobilized Protein A, which is extremely elongated, revealed that the molecules were bound in preference with their long axis perpendicularly to the plane of the S-layer lattice [76, 78, 79]. Thus, binding capacities of 290 ng Protein A  $\text{cm}^{-2}$  S-layer lattice were obtained, which was more than 3 times above the theoretical saturation capacity of a planar surface of 90 ng  $\text{cm}^{-2}$  when calculated with the Stoke's radius. S-layer-carrying cell wall fragments deposited on microporous supports and carrying a monolayer of monoclonal antibodies were exploited for the development of novel types of dipstick-style solid-phase immunoassays, which due to the low nonspecific adsorption of S-layer proteins for serum components showed excellent signal-to-noise ratios [80, 81]. In the case of Protein A, affinity microparticles with a size of approximately 1  $\mu\text{m}$  were prepared, which represented cup-shaped structures with a complete outer and inner S-layer arranged in mirror symmetric fashion [76]. Such affinity microparticles were used as IgG-specific adsorbents in affinity crossflow filtration systems for the removal of human IgG from serum [77], as required for blood purification of patients suffering from autoimmune disease [78]. Due to their high surface to volume ratio and the high density of immobilized Protein A, affinity microparticles revealed an excellent binding capacity for IgG which was in the range of 40  $\mu\text{g mg}^{-1}$  wet pellet [76–78].

### 8.3.3

#### Patterning by Genetic Approaches

##### 8.3.3.1 The S-Layer Proteins SbsA, SbsB and SbsC

The S-layer protein SbpA of *B. sphaericus* CCM 2177 consists (including a 30-amino-acid long signal peptide) in total of 1268 amino acids [37]. SbpA self-assembles into a square (p4) lattice structure with a center-to-center spacing of the morphological units of 13.1 nm. The self-assembly process is strongly dependent on the presence of bivalent cations, such as calcium ions [36]. In the absence of bivalent cations, this S-layer protein stays in the water-soluble state. The N-terminal part of SbpA comprises three typical SLH motifs, but for reconstituting the functional SCWP-binding domain, an additional 58-amino-acid long SLH-like

motif located behind the third SLH motif was required [35]. The SCWP of *B. sphaericus* CCM 2177 consists of disaccharide repeating units that are composed of N-acetyl glucosamine (GlcNAc) and N-acetyl mannosamine (ManNAc). The ManNAc residues carry a pyruvate ketal which endows the polymer chains with a negative net charge [36]. Studies on the structure–function relationship revealed that up to 237 C-terminal amino acids could be deleted without influencing the formation of the p4 lattice structure [35, 36]. However, the deletion of 350 C-terminal acids was linked to a change from square (p4) to oblique (p1) lattice symmetry. By producing various C-terminally truncated forms and performing surface accessibility screens, it became apparent that amino acid position 1068 is located on the outer surface of the square lattice [37]. This was the reason why the C-terminally truncated form rSbpA<sub>31–1068</sub> was exploited as base form for the construction of several S-layer fusion proteins [70–72, 83]. An N- and C-terminally truncated form (rSbpA<sub>203–1031</sub>) was capable of self-assembly into the square (p4) lattice structure with a center-to-center spacing of the morphological units and a protein mass distribution similar to that formed by full-length rSbpA [35]. These findings indicated that the segment between amino acids 203 and 1031 is responsible for the self-assembly process and for pore formation.

The S-layer protein SbsB of *G. stearothermophilus* PV72/p2 consists (including a 31-amino-acid long signal peptide) in total of 920 amino acids [84]. By applying the dissection approach, it could be demonstrated that SbsB is composed of the N-terminal SCWP-binding domain which corresponds to the SLH domain and the C-terminal self-assembly domain [38, 41]. As the removal of fewer than 10 C-terminal amino acids led to water-soluble rSbsB forms, the C-terminal part can be considered extremely sensitive against deletions [75, 85]. When the C-terminal end of full-length SbsB was exploited for linking foreign functional sequences, water-soluble S-layer fusion proteins were obtained [85], which recrystallized into the oblique (p1) lattice only on solid supports precoated with SCWP of *G. stearothermophilus* PV72/p2. As demonstrated by SPR spectroscopy, the SLH domain comprising the three SLH motifs specifically recognizes the SCWP of *G. stearothermophilus* PV72/p2 as a binding site [35]. The polymer chains are composed of GlcNAc and ManNAc in the molar ratio of approximately 2:1 [69], and contain pyruvate ketals which provide a net negative charge. The use of chemically modified SCWP in SPR interaction studies clearly showed that it is not the N-acetyl groups of the amino sugars, but the pyruvic acid residues that play a crucial role in the recognition and binding process [38]. Furthermore, thermal as well as guanidine hydrochloride-induced equilibrium unfolding profiles monitored by intrinsic fluorescence and CD spectroscopy allowed us to characterize the SLH domain (rSbsB<sub>32–208</sub>) as an  $\alpha$ -helical protein with a single cooperative unfolding transition. The C-terminal self-assembly domain (rSbsB<sub>209–920</sub>) could be characterized as a  $\beta$ -sheet protein with typical multidomain unfolding and a lower stability as stand-alone protein [41].

Recently, chimeric S-layer proteins either comprising the N-terminal part of SbpA and the C-terminal part of SbsB (rSbpA–SbsB), or vice versa, the N-terminal part of SbsB and the C-terminal part of SbpA (rSbsB–SbpA), have been con-

structed [35]. The aim was to create a spectrum of S-layer proteins that bind to the same type of SCWP, but assemble into different lattice types. Accordingly, rSbsB and rSbsb-SbpA specifically recognized the SCWP of *G. stearothersophilus* PV72/p2 as a binding site, but in contrast to rSbsB which assembled into an oblique (p1) lattice, the chimeric protein rSbsb-SbpA formed a square (p4) lattice structure. In addition, in rSbsB-SbpA the surface-located amino acid position 1068 of the SbpA primary sequence was exploited as a fusion site for foreign functional sequences [37, 74]. However, rSbpA and the chimeric protein rSbpA-SbsB recognized the SCWP from *B. sphaericus* CCM 2177 as a binding site, but they self-assembled into different lattice types, i.e. square (p4) for rSbpA and oblique (p1) for rSbpA-SbsB [35].

SbsC is the S-layer protein of *G. stearothersophilus* ATCC 12980 and consists (including a 30-amino-acid long signal peptide) in total of 1099 amino acids [43]. Isolated SbsC self-assembles into an oblique lattice. SbsC does not possess an SLH domain on the N-terminal part, but reveals a conserved N-terminus region which was also found in S-layer proteins of other *G. stearothersophilus* wild-type strains, such as PV72/p6, DSM 2358 [42] and NRS 2004/3a [45], as well as in a temperature-derived strain variant of strain ATCC 12980 [62]. This type of N-terminal part which comprises amino acids 31–257 specifically recognizes the SCWP that contains 2,3-dideoxy-diacetamido mannosamine uronic acid as a negatively charged component [42, 46]. Studies on the structure–function relationship of SbsC revealed that the N-terminal part is responsible for cell wall anchoring via the specific SCWP. In the C-terminal part, up to 179 amino acids leading to rSbsC<sub>31–920</sub> could be deleted without interfering with the formation of the oblique lattice structure [44]. Further deletion of C-terminal amino acids led to SbsC forms that were still able of self-assembling, but such self-assembly products did not show a regular lattice structure (rSbsC<sub>31–880</sub>), whereas rSbsC<sub>31–844</sub> even represented a completely water-soluble form which was used for three-dimensional crystallization experiments [86].

### 8.3.3.2 S-Layer Fusion Proteins

In general, a broad spectrum of chimeric S-layer fusion proteins was constructed and heterologously expressed in *Escherichia coli*. S-layer fusion proteins were based on the S-layer proteins SbsB, SbpA and SbsC. For generating a universal affinity matrix for binding any kind of biotinylated molecules, S-layer–streptavidin fusion proteins were constructed [73, 85]. The strong interaction between streptavidin and biotin as a biomolecular coupling system is commonly used in biotechnology [86]. Minimum-sized core streptavidin (118 amino acids) was either fused to N- or C-terminal positions of SbsB, the S-layer protein of *G. stearothersophilus* PV72/p2, or to the C-terminal end of rSbpA<sub>31–1068</sub> [37]. The S-layer proteins SbsB and SbpA show different lattice characteristics. SbsB forms an oblique S-layer lattice with p1 symmetry and lattice parameters of  $a = 10.4$  nm,  $b = 7.9$  nm and a base angle of  $\gamma = 81^\circ$ , while SbpA forms a square S-layer lattice with a center-to-center spacing of 13.1 nm.

The genes encoding the fusion proteins and core streptavidin were expressed in-

**Fig. 8.1.** Schematic drawing illustrating the disintegration and rapid dilution step leading to functional heterotetramers of a C-terminal S-layer-streptavidin fusion protein.

independently in *E. coli* and isolated from the host cells [73, 85]. To obtain functional heterotetramers, a refolding procedure was developed by subjecting a mixture of fusion protein with excess core streptavidin to denaturing and renaturing (Fig. 8.1). Two dominant tetramer species, one consisting of one molecule of fusion protein and three molecules of streptavidin (heterotetramers), and the other one consisting of four molecules of streptavidin (homotetramers) were formed during rapid dilution. Heterotetramers were separated from homotetramers and from the S-layer-streptavidin fusion protein by gel-permeation and affinity chromatography. In the latter, the pH-dependent affinity of iminobiotin to streptavidin was exploited. The exceptional stability of streptavidin in 5% SDS at room temperature and denaturation upon boiling allowed the application of the gel-shift assay to control rapid dilution and purification (Fig. 8.2). The desired properties of heterotetramers consisting of one chain of S-layer-streptavidin fusion protein and three chains of streptavidin were the maintenance of the recrystallization properties of the S-layer protein moiety, as well as biotin binding.

Recrystallization experiments were either performed in suspension, on peptidoglycan-containing sacculi, on liposomes or on various solid supports, such as silicon or gold chips which were optionally precoated with thiolated SCWP of *B. sphaericus* CCM 2177 or *G. stearothersophilus* PV72/p2. Heterotetramers comprising the N-terminal rSbsB-streptavidin fusion protein formed self-assembly products in suspension, and recrystallized on liposomes and silicon wafers [85], whereas heterotetramers based on the C-terminal rSbpA<sub>31-1068</sub>-streptavidin fusion protein showed dirigible self-assembly formation due to the calcium ion dependency of lattice formation of SbpA. Such heterotetramers recrystallized on gold surfaces which were optionally precoated with SCWP [73] (Fig. 8.3). Analysis of negatively stained preparations of self-assembly products formed by heterotetramers revealed that neither the oblique S-layer lattice of SbsB nor the square lattice of SbpA was changed due to the presence of the fusion partner. Due to unhindered lattice formation and unchanged lattice parameters, the streptavidin moiety was considered as being located above the plane on the outer surface of

**Fig. 8.2.** Gel-shift assay of SDS extracts from heterotetramers purified by gel-permeation and affinity chromatography. The heterotetramers show the specific property of remaining in the

native state in 5% SDS at 25 °C, but dissociate into the S-layer–streptavidin fusion protein and streptavidin in 5% SDS at 100 °C.

the protein lattice. Digital image reconstructions of self-assembly products of heterotetramers containing the N-terminal rSbsB–streptavidin fusion protein in comparison to the SbsB lattice showed an additional protein mass on the SLH domain which resulted from the fused streptavidin [85] (Fig. 8.4). All self-assembly experiments confirmed that the first of the desired properties was present, i.e. unhindered recrystallization of the fusion protein into a two-dimensional crystalline array.

Since the fusion proteins were constructed from the wild-type streptavidin sequence, the biotin-binding sites were assumed to show the typical high affinity to

**Fig. 8.3.** SFM image of heterotetramers consisting of one chain of rSbpA<sub>31–1068</sub>–streptavidin fusion protein and three chains of streptavidin. The heterotetramers recrystallized

into the square lattice structure on gold chips precoated with thiolated SCWP of *B. sphaericus* CCM 2177. Right: deflection mode. Left: height mode.

biotin. However, it remained to be investigated if biotin-binding sites were sterically blocked by the large fusion partner SbsB or SbpA. The biotin-binding ability of soluble heterotetramers was determined by fluorescence quenching of tryptophan residues in the binding pockets of streptavidin upon biotin binding [73, 85, 87, 88]. Biotin, as well as biotinylated insulin ( $M_r$  6 kDa), biotinylated horseradish peroxidase ( $M_r$  44 kDa) and biotinylated serum albumin ( $M_r$  66 kDa) were used for the fluorescence titration experiments. In comparison to free streptavidin which was used as reference protein, heterotetramers showed an even higher binding capacity for D-biotin, biotinylated insulin and biotinylated horseradish peroxidase. For biotinylated serum albumin, a similar binding capacity was determined.

In general, heterotetramers based on S-layer streptavidin fusion proteins are considered a universal affinity matrix for binding biotinylated molecules. As proof-of-principle, heterotetramers comprising C-terminal S-layer streptavidin fusion proteins were recrystallized on peptidoglycan-containing sacculi which were subsequently incubated with biotinylated ferritin as a marker that can be visualized by TEM. As shown in Fig. 8.5, heterotetramers based on the rSbpA<sub>31–1068</sub>–streptavidin fusion protein showed excellent recrystallization properties, as well as high affinity to biotinylated ferritin.

As a first application approach, monolayers of heterotetramers based on the rSbpA<sub>31–1068</sub>–streptavidin fusion protein were recrystallized on gold surfaces which were optionally precoated with thiolated SCWP. The obtained affinity matrix was used to perform hybridization experiments. In a first step, biotinylated oligonucleotides (30mers) were bound to the streptavidin moiety of the heterotetramers. Subsequently, complementary oligonucleotides were hybridized carrying one or two mismatches or they were without any mismatch (Fig. 8.6). Evaluation of the

**Fig. 8.5.** Electron micrographs of negatively-stained preparations of heterotetramers consisting of one chain of rSbpA<sub>31-1068</sub>-streptavidin fusion protein and three chains of streptavidin. hybridization experiments were performed by applying surface-plasmon-field-enhanced fluorescence spectroscopy which combines the advantages of the high optical field intensities of surface plasmon waves with the sensitive detection of fluorescence light emission [89, 90]. For generating functional monomolecular protein lattices, two strategies were pursued – direct recrystallization of heterotetramers on plain gold chips or recrystallization on SCWP-coated gold chips. In both cases, the amount of recrystallized heterotetramers corresponded well to the theoretically calculated value for a monolayer [85]. The advantage of recrystallization on plain gold chips was seen in the strong interaction between the inner surface of the S-layer subunits and gold. This fact could be exploited to regenerate the

**Fig. 8.6.** Schematic drawing of heterotetramers consisting of one chain of rSbpA<sub>31-1068</sub>-streptavidin fusion protein and three chains of streptavidin, either recrystallized on plain gold chips or on gold

chips precoated with thiolated SCWP. After recrystallization into a monomolecular protein lattice, biotinylated oligonucleotides were bound to which fluorescently labeled oligonucleotides could hybridize.

sensor surface without any loss of heterotetramers, which could not be removed from the gold chip even with ethanol or chaotropic agents such as urea or guanidine hydrochloride. However, the advantage of using SCWP-coated gold chips lies in the unambiguously oriented recrystallization of the heterotetramers via their SCWP-binding domain located on the inner surface, as well in the lower detection limit for fluorescently labeled oligonucleotides. The latter can be explained by the fact that a higher distance between the gold surface and the fluorescently labeled oligonucleotides reduces quenching of fluorescence signals caused by the gold layer. However, monolayers generated on SCWP-coated gold chips were less stable, which was attributed to the rather labile gold-thiol linkage acting between the thiolated SCWP and the gold support. Nonspecific adsorption of DNA did not play a role which could be demonstrated by incubation of the sensor surface with oligonucleotides carrying two mismatches. For hybridization experiments on monolayers generated by recrystallization of heterotetramers on gold chips precoated with thiolated SCWP, fluorescently labeled oligonucleotides carrying one mismatch were used. The fluorescence intensity increased linearly at the beginning of the hybridization reaction, so that the linear slope of the increase in fluorescence intensity plotted versus the concentration of the hybridizing oligonucleotides showed a linear correlation [73]. In a different set of hybridization experiments which were performed on monolayers generated by direct recrystallization of heterotetramers on plain gold chips, the concentration of oligonucleotides carrying one mismatch was stepwise increased. The Langmuir isotherm which indicated that oligonucleotides in solution were in equilibrium with those bound to the monolayer carrying the biotinylated oligonucleotides could be established from the obtained fluorescence intensities (Fig. 8.7) [73]. The detection limit was found to be 1.57 pM on monolayers generated by recrystallization of heterotetramers on gold chips precoated with thiolated SCWP, whereas on plain gold chips the detection limit was determined to be at least 8.2 pM.

To conclude, the results obtained with heterotetramers consisting of one chain of S-layer streptavidin fusion protein and three chains of core streptavidin showed that the self-assembly properties of the S-layer protein moiety could be combined with the biotin-binding properties of streptavidin. First hybridization experiments indicated that a functional sensor surface could be generated by recrystallization of heterotetramers on gold chips, which could find numerous applications in (nano)biotechnology.

In a first approach, an S-layer fusion protein comprising the C-terminally truncated form rSbpA<sub>31-1068</sub> and the variable region of a heavy chain camel antibody directed against lysozyme was constructed. The *Camelidae* is the only taxonomic family known to possess functional heavy chain antibodies lacking light chains and the first constant region. These unique antibody isotypes interact with the antigen by virtue of a single variable domain, termed VHH. A single VHH domain has a molecular mass of only 15 000 and is the smallest known complete antigen-binding fragment from a functional immunoglobulin (Fig. 8.8). The single-domain nature of VHHs gives rise to several unique features as compared to antigen-binding derivatives of conventional antibodies. As well as the advantage of

**Fig. 8.7.** Langmuir adsorption isotherm experiment of fluorescently labeled oligonucleotides carrying one mismatch hybridizing to complementary, biotinylated oligonucleotides bound to heterotetramers consisting of one chain of rSbpA<sub>31-1068</sub>-streptavidin fusion protein and three chains of streptavidin. By increasing the concentration of the fluorescently labeled oligonucleotides, higher equilibrium levels were reached (left side). The fluorescence intensities at the equilibrium are plotted against the concentrations of the solutions giving the Langmuir adsorption isotherm (right side).

single-gene cloning and selection from an *in vivo* matured library, recombinant VHs have other technological, functional and physicochemical advantages, such as (a) high expression yields and ease of purification, (b) a highly soluble and stable single domain immunoglobulin fold, (c) the generation of antigen-specific, high-affinity binders, (d) the recognition of unique conformational epitopes with the dominant involvement of its enlarged complementary determining regions, and

**Fig. 8.8.** Schematic drawing showing conventional (top) and heavy chain IgG antibodies (bottom) present in the serum of *Camelidae*. The complete light chains (dotted areas) and CH1 domains (black areas) are absent in heavy chain camel antibodies. The antigen-binding domains (Fv) of conventional antibodies as obtained after proteolysis or after

expression of the gene encoding VH or VL fragments are shown. The recombinant VHH (curved areas), the variable domain of a heavy chain camel antibody, can be obtained after cloning and expression. The VHH is the minimal intact antigen-binding fragment that can be generated.

(d) the close homology to human VHs (variable domain of the heavy chain) fragments [91, 92]. These features can be expected to lead to a number of applications in which VHHs perform better than conventional antibody fragments, e.g. as enzyme inhibitors, as modular building units for multivalent or multifunctional constructs, or as immunoadsorbents and detection units in biosensors. Due to these properties, VHHs clearly offer an improvement over conventional, more complex, antibody fragments, e.g. in diagnostic applications, for which the stability of the biomolecular probes is critical. Moreover, VHHs constitute ideal modular building blocks for manifold molecular constructs [91, 92]. To explore the potential advantages of camel single-domain antibodies and to gain insight into how they recognize their target, the crystal structure of a camel VHH complexed with hen's egg lysozyme was solved [93].

For construction of an S-layer fusion protein comprising the sequence of a single variable region of a camel heavy chain antibody directed against lysozyme (cAb-Lys3), the C-terminal truncation rSbpA<sub>31-1068</sub> was selected as the base form. The obtained S-layer fusion protein, termed rSbpA<sub>31-1068</sub>/cAb-Lys3 was considered as a model system for the construction of further chimeric proteins, which comprised rSbpA<sub>31-1068</sub> and cAbs directed against various antigens. Independent of the use of soluble or self-assembled rSbpA<sub>31-1068</sub>/cAb-Lys3, the camel antibody sequence remained accessible to lysozyme binding [70]. This was also observed for monolayers which were generated by recrystallization of the S-layer fusion protein on polystyrene substrates or on gold chips precoated with thiolated SCWP. In both cases, cAb-Lys3 was located on the outer S-layer surface and remained functional. As proof-of-principle could be provided with this model system, an S-layer fusion

protein incorporating the sequence of a variable domain of a heavy chain camel antibody (cAb-PSA-N7) directed against the prostate-specific antigen (PSA) was constructed [71]. PSA is a useful marker to screen potential prostate cancer patients. The current diagnostic test systems determine the concentration of total PSA with monoclonal antibodies that recognize free as well as PSA complexed with  $\alpha_1$ -antichymotrypsin (ACT). For their application in a PSA biosensor, VHHs recognizing free and complexed PSA are desired. Moreover, the kinetic requirements in the biosensor impose a high probe density that can probably only be achieved with single domain VHHs.

To generate a PSA-specific sensing layer for SPR measurements, the S-layer fusion protein rSbpA<sub>31-1068</sub>/cAb-PSA-N7 was recrystallized on gold chips precoated with thiolated SCWP [71]. The formation of the monomolecular protein lattice was confirmed by SFM, as well as by the level of the measured SPR signal. As derived from response levels measured for binding of PSA to a monolayer consisting of rSbpA<sub>31-1068</sub>/cAb-PSA-N7, the molar ratio between bound PSA and the S-layer fusion protein was 0.78, which means that at least three PSA molecules were bound per morphological unit of the square S-layer lattice [71]. To summarize, by using thiolated SCWP as a biomimetic linker to gold chips, a sensing layer for SPR could be generated by recrystallization of this S-layer fusion protein (Fig. 8.9). Due to the crystalline structure of the S-layer lattice, the fused ligand sequence showed a well-defined distance in the protein lattice and, according to the selected fusion site in the S-layer protein, they were located on the outermost surface, which reduced diffusion-limited reactions. A further advantage can be seen in the constant and low distance of the ligands from the optically active gold layer, which is exclusively determined by the thickness of the S-layer and lies in the range of only 10–15 nm. Thus, S-layer fusion proteins incorporating camel antibody sequences can be considered as key elements for the development of label-free detection systems such as SPR, surface acoustic wave (SAW) or quartz crystal microbalance (QCM-D), in which the binding event can be measured directly by the mass increase without the need of any labeled molecule.

The sequence encoding rSbpA<sub>31-1068</sub> was also used as a base form for the construction of an IgG-binding fusion protein [72]. As fusion partner, the sequence

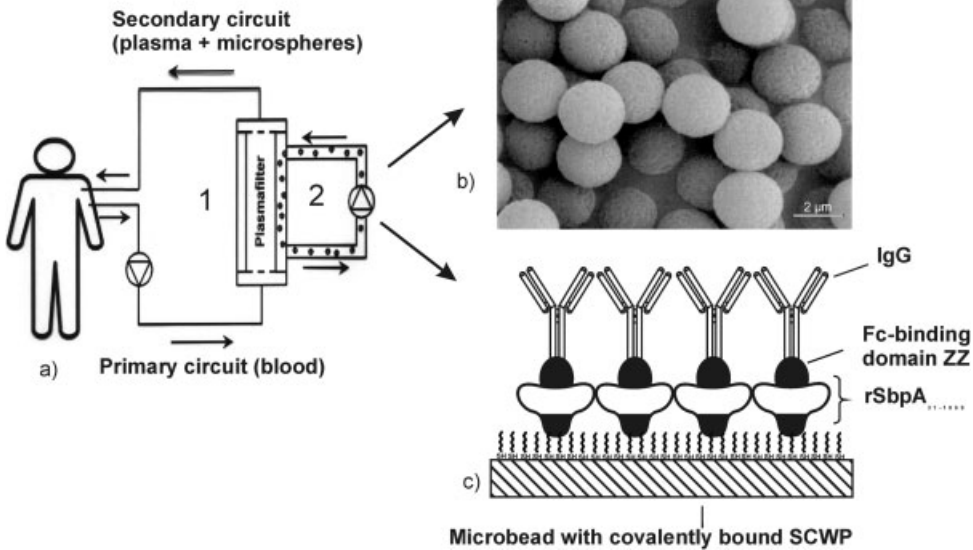

**Fig. 8.9.** Schematic drawing of the S-layer fusion protein rSbpA<sub>31-1068</sub>/cAb-PSA-N7 which was recrystallized on gold chips precoated with the thiolated SCWP. The monomolecular protein lattice was able to specifically bind PSA on the outermost surface.

encoding the Z domain, a synthetic analog of the IgG-binding domain of Protein A from *Staphylococcus aureus* was used. Protein A consists of a cell-wall-targeting domain and five other domains, termed C, B, A, D and E, with C next to the cell wall. X-ray analysis revealed that the B domain of Protein A consists of two contact sites that interact with the Fc part of IgG [94], leaving the Fab regions free for binding the antigen. Based on this knowledge, the synthetic Z domain which is 58 amino acids long and binds to the Fc part of IgG was constructed [95]. To generate the S-layer fusion protein, the 5'-end of the sequence encoding two copies of the Z domain was fused via a short linker to the gene encoding rSbpA<sub>31-1068</sub> [72]. After heterologous expression in *E. coli*, the S-layer fusion protein was isolated from the host cells, purified by size-exclusion chromatography under denaturing conditions in guanidine hydrochloride, dialyzed and recrystallized on SPR gold chips which were precoated with thiolated SCWP of *B. sphaericus* CCM 2177. As shown by SFM, a monomolecular protein lattice with square symmetry was formed. The resonance units indicating the amount of bound protein corresponded to  $4.3 \times 10^{-5}$  nM mm<sup>-2</sup>, which was in good accord with the theoretical value for a monolayer of  $3.9 \times 10^{-5}$  nM mm<sup>-2</sup>. Native monolayers or monolayers crosslinked with the bifunctional imidoester dimethylpimelinimidate (DMP) were finally exploited for binding of human IgG. The amount that could be bound by the native monolayer was  $2.9 \times 10^{-5}$  nM or 4.35 ng IgG mm<sup>-2</sup>, whereas in the case of the DMP-crosslinked monolayer  $2.8 \times 10^{-5}$  nM or 4.20 ng IgG mm<sup>-2</sup> could attach. These values corresponded to 65 and 67% of the theoretical saturation capacity of a planar surface for IgG (6.5 ng mm<sup>-2</sup>) with the Fab regions in the condensed state. As derived from these binding capacities, on average 2.7 and 2.6 IgG molecules were bound per morphological unit of the square S-layer lattice consisting of four identical subunits of the S-layer fusion protein.

For preparing biocompatible microparticles for the microsphere-based detoxification system (MDS) [78] to remove autoantibodies from sera from patients suffering from autoimmune disease, the S-layer fusion protein was recrystallized on SCWP-coated, 3- $\mu$ m cellulose-based microbeads. The MDS is an alternative approach to conventional immunoadsorption systems, in which the plasma does not perfuse on an adsorption column, but is recirculated into a filtrate compartment of a membrane module (Fig. 8.10). The addition of microbeads to the plasma circuit allows the rapid removal of the pathogenic substrates. In the case of microbeads that were covered with a native monolayer, the binding capacity was 1065  $\mu$ g human IgG mg<sup>-1</sup> S-layer fusion protein. For DMP-treated microbeads, a binding capacity of 870  $\mu$ g IgG mg<sup>-1</sup> S-layer fusion protein was determined. These values corresponded to 78 or 65% of the theoretical saturation capacity of a planar surface for IgG having the Fab regions in the condensed state. Bound IgG could be eluted with glycine-HCl buffer at a pH value of 2.2 and the microbeads were used for further IgG-binding experiments [72].

The major birch pollen allergen Bet v1 shares IgE epitopes with all tree pollen allergens from closely related species (e.g. alder hazel, hornbeam, beech). Because of high sequence identities among these allergens and well-studied cross-reactions with B cell epitopes, Bet v1 represents a model allergen [96]. The gene encoding

## Microspheres Based Detoxification-System

**Fig. 8.10.** (a) Schematic drawing demonstrating the working principle of the MDS. (b) Amine-modified cellulose microspheres. (c) Schematic drawing of microbeads covered with a monolayer consisting of rSbpA<sub>31-1068</sub>/ZZ. The S-layer

fusion protein was recrystallized on amine-modified cellulose microbeads to which thiolated SCWP had been covalently bound before. The fused ZZ domains could bind human IgG via the Fc part.

the chimeric S-layer proteins rSbsC<sub>31-920</sub>/Bet v1 and rSbpA<sub>31-1068</sub>/Bet v1 carrying Bet v1 at the C-terminal end were cloned and expressed in *E. coli*. Ultrathin sections of whole *E. coli* cells induced to express the gene encoding rSbsC<sub>31-920</sub>/Bet v1 revealed the presence of intracellular sheet-like or cylindrical structures [97], whereas rSbpA<sub>31-1068</sub>/Bet v1 accumulated in the form of inclusion bodies in the cytoplasm of the host cells [37]. The fusion proteins maintained the ability to self-assemble, as well as the functionality of the fused allergen to bind a Bet v1-specific monoclonal mouse antibody BIP1 (Fig. 8.11). The location and accessibility of the allergen moiety on the outer surface of the S-layer lattice were demonstrated by immunogold labeling of rSbsC<sub>31-920</sub>/Bet v1 or rSbpA<sub>31-1068</sub>/Bet v1 recrystallized on native peptidoglycan-containing sacculi of *G. stearothermophilus* ATCC 12980 or *B. sphaericus* CCM 2177 [37, 97]. Thereby, the specific interaction between the N-terminal part of the S-layer proteins and the corresponding SCWP was exploited. The aim for the production of these S-layer fusion proteins was to use them for the development of diagnostic test systems to determine the concentration of Bet v1-specific IgE in patients' whole blood, plasma or serum. For that purpose, rSbpA<sub>31-1068</sub>/Bet v1 recrystallized as a monolayer on SCWP-coated plastic foils

**Fig. 8.11.** (a) Electron micrograph of a negatively stained preparation demonstrating immunogold-labeling of rSbpA<sub>31-1068</sub>/Bet v1 recrystallized on peptidoglycan-containing

sacculi of *B. sphaericus* CCM 2177 using the Bet v1-specific monoclonal mouse antibody BIP1. (b) Schematic drawing of (a).

was used as reaction zone in dipstick-style solid-phase immunoassays for determination of Bet v1-specific IgE in serum samples of patients suffering from atopic allergy. In a recent study, the applicability of rSbsC<sub>31-920</sub>/Bet v1 as a novel approach to design vaccines with reduced allergenicity in combination with strong immunomodulating capacity for immunotherapy of type I allergy was demonstrated [98]. This fusion protein exhibited all relevant Bet v1-specific B and T cell epitopes, but was significantly less efficient in releasing histamine than free Bet v1. In cells of birch pollen-allergic individuals, the fusion protein was capable of modulating the allergen-specific T<sub>H</sub>2-dominated response into a more balanced T<sub>H</sub>1/T<sub>H</sub>0-like phenotype accompanied by enhanced production of interferon- $\gamma$  and interleukin-10 [98]. To conclude, rSbsC<sub>31-920</sub>/Bet v1 could find applications as carrier/adjuvants to design vaccines for specific immunotherapy of type 1 allergy with improved efficacy and safety.

Artificial lipid vesicles termed liposomes are widely used as delivery systems for enhancing the efficiency of various biologically active molecules [99]. S-layer-coated liposomes (S-liposomes) revealed an enhanced stability towards thermal and mechanical stress factors [24], and they represent simple model systems resembling features of virus envelopes. Thus, S-liposomes could find application in drug delivery or in gene therapy. In a recent study, the nucleotide sequence encoding enhanced green fluorescent protein (EGFP), a red-shifted green fluorescent protein (GFP)-derivative possessing a 30 times brighter fluorescence intensity at 488 nm than wild-type GFP [100], was fused to the 3'-end of the sequence encoding the C-terminally truncated form rSbpA<sub>31-1068</sub> [83]. The chimeric gene encoding rSbpA<sub>31-1068</sub>/EGFP was cloned and expressed in *E. coli* host cells. As confirmed by fluorescence microscopy, 1 h after induction of expression an intense EGFP fluorescence was detected in the cytoplasm of the host cells. Expression at 28 °C instead of 37 °C, as usual for *E. coli* expression strains, resulted in clearly increased fluorescence intensity, indicating that the folding process of the EGFP moiety was

**Fig. 8.12.** Fluorescence excitation and emission spectra of rEGFP and of the fusion protein rSbpA<sub>31-1068</sub>/EGFP. Both proteins were applied in the same molar ratio and exhibited identical excitation peaks at 488 nm and emission peaks at 507 nm.

temperature sensitive. Electron microscopic investigation of ultrathin-sectioned preparations revealed that the S-layer fusion protein was located in inclusion bodies within the cytoplasm of the *E. coli* cells. To protect the EGFP portion against oxidation and to maintain the *in vitro* EGFP fluorescence capability, isolation of rSbpA<sub>31-1068</sub>/EGFP and purification by gel-permeation chromatography was performed in the presence of reducing agents. Comparison of excitation and emission spectra of rEGFP and rSbpA<sub>31-1068</sub>/EGFP indicated identical maxima at 488 and 507 nm, respectively (Fig. 8.12). Because of its intrinsic fluorescence, the fusion protein was recrystallized on positively charged liposomes and their uptake by eukaryotic cells was investigated by confocal laser scanning microscopy. The major part of the liposomes was internalized within 2 h of incubation and entered the HeLa cells by endocytosis [83]. In further studies, the uptake of liposomes coated with rSbpA<sub>31-1068</sub>/EGFP in combination with other S-layer fusion proteins, such as heterotetramers, by target cells and the functionality of transported drugs could be investigated simultaneously without any additional labeling.

Furthermore, this fusion protein was used for recrystallization on silicon wafers covered with polyelectrolytes, as well as for coating of hollow polyelectrolyte capsules. Fluorescence spectroscopy proved that the adsorption of rSbpA<sub>31-1068</sub>/EGFP on hollow capsules did not shift the fluorescence emission of the chromophore [25].

## 8.4 Spatial Control over S-Layer Reassembly

For many technical applications of S-layers, spatial control over reassembly is mandatory. For example, when S-layers are used as affinity matrix for the development of biochips or as templates in the fabrication of nanoelectronic devices, it is not necessary that the monolayer covers the entire area. Micromolding in capillaries is a well known soft-lithographical technique. In this technique, a poly(dimethylsiloxane) (PDMS) mold is first brought in conformal contact with a flat substrate, such as a silicon wafer. Subsequently, the S-layer protein solution is dropped onto the substrate in front of the channel openings of the attached mold and then the solution is sucked in so that the S-layer protein can recrystallize at all surfaces including the silicon. After removal of the mold, a patterned S-layer remains on the support. SFM is best suited to control the crystallinity of the S-layer monolayer and the border line to the blank areas. As micromolding in capillaries restricts the reassembly of the S-layer proteins to certain areas on a solid support, it offers the advantage that all preparation steps can be performed under ambient conditions. Proof-of-principle was shown for patterning the S-layer protein SbpA from *B. sphaericus* CCM 2177 on a silicon wafer with several different line-and-space ratios [101]. The S-layer protein showed perfect long-range order, and no visible leakage of the proteins into the tight interface between substrate and mold.

An alternative to micromolding in capillaries is patterning by conventional optical lithography using deep ultraviolet light (DUV) for exposure. In this approach, the S-layer protein was recrystallized on a silicon wafer covering the entire surface area. In the following step, the S-layer monolayer was dried in a stream of dry nitrogen prior to exposure in order to remove any water layer between the sample and the mask [102]. This is a critical step as denaturation of the S-layer protein and consequently loss of its structural integrity and functionality may occur. Then, a microlithographic mask was brought in conformal contact with the S-layer. The mask is usually made of a patterned chromium layer on quartz glass. Two different wavelengths of DUV were tested: argon fluoride excimer laser radiation (ArF; wavelength 193 nm) and krypton fluoride excimer laser radiation (KrF; wavelength 248 nm). SFM demonstrated that the S-layer protein was completely removed by ArF radiation with two pulses of  $100\text{--}200\text{ mJ cm}^{-2}$  each and retained its structural integrity in the unexposed regions. Section analysis revealed a height difference between exposed and unexposed areas of about 8 nm, clearly demonstrating that the S-layer was completely removed in the exposed areas. According to the well-known paradigm of optics stating that the resolution is determined by the wavelength of the irradiating light, the highest achievable resolution was in the range of 100 nm. In contrast, the S-layer was not ablated by KrF irradiation. Instead, investigation of the irradiated S-layer lattice showed that increasing the electron dose from 10 pulses of about  $100\text{ mJ cm}^{-2}$  to 10 pulses of about  $35\text{ mJ cm}^{-2}$  only led to carbonization, but not to ablation, of the protein lattice.

## 8.5

### S-Layers as Templates for the Formation of Regularly Arranged Nanoparticles

An important key to the fabrication of highly ordered functional arrays of nanoparticles is to provide suitable templates for spatially controlled particle deposition. The application of self-assembly systems for achieving perfect positional control at the molecular level appears feasible, both theoretically and experimentally, and offers striking advantages in the manufacturing process. S-layer proteins seem to be perfectly suited for this purpose as they have the intrinsic property to reassemble into two-dimensional arrays at various interfaces including silicon surfaces. Moreover, functional groups are repeated with the periodicity of the S-layer lattice at a distance of approximately 10 nm, thereby leading to regular arrays (superlattices) of bound foreign molecules and particles.

#### 8.5.1

##### Binding of Molecules and Nanoparticles to Functional Domains

Geometrically confined binding of molecules on S-layer lattices may be induced by noncovalent and covalent forces. The pattern of bound molecules frequently reflects the lattice symmetry, the size of the morphological units and the surface properties of the underlying S-layer. For example, polycationic ferritin (PCF) is a 12 nm large, topographical marker for labeling negatively charged groups for TEM analysis. In several studies, PCF was used to determine the net charge of the outer and inner S-layer surface. In the case of the strictly anaerobic, hyperthermophilic archaeon *Thermoproteus tenax*, PCF was bound to the outer S-layer surface in an absolutely regular manner and reflected the hexagonal symmetry of the underlying S-layer [103]. The distance between the PCF molecules was about 30 nm and corresponded exactly to the center-to-center spacing of the morphological units (Fig. 8.13). The hexagonal super-lattice generated by the bound PCF exhibited the same orientation as the unlabeled S-layer with one axis perpendicularly to the longitudinal axis of the cells. *Methanospirillum hungatei* is a methanogenic archaeon which possesses a hollow tubular sheath that surrounds chains of cells. The sheaths show oblique (p2) lattice symmetry and they are composed of individual hoops [104]. The sheaths could be densely labeled with PCF molecules, which fitted to the widths of the hoops and were thus bound in exact rows. A superlattice of PCF was also observed on the hexagonal S-layer of *Thermoanaerobacter thermohydrosulfuricus* L111-69 after converting the hydroxyl groups from the carbohydrate chain of this S-layer glycoprotein into carboxylic acid groups which was achieved by succinylation [105]. The size of the PCF molecules corresponded well to the center-to-center spacing of the morphological units of the hexagonal lattice of 14.2 nm. Ultrathin-sections of such modified S-layers revealed that due to the length of the carbohydrate chains, the PCF molecules formed even two superimposed layers. In contrast, covalent attachment of ferritin to the carbodiimide-activated carboxylic acid groups of the acidic amino acids led only to small patches of hexago-

**Fig. 8.13.** TEM image of a freeze-dried preparation of PCF regularly bound to the hexagonally ordered S-layer of *Thermoproteus tenax*. The signal-to-noise ratio was enhanced by crosscorrelation averaging. Bar: 50 nm.

nally ordered ferritin molecules. On the glutaraldehyde-treated, crosslinked outer S-layer surface of the square lattice from *B. sphaericus* CCM 2177 with a lattice constant of 13.1 nm, PCF molecules were bound to the net negatively charged carboxylic acid groups of the acidic amino acids and clearly reflected the square symmetry of the underlying S-layer lattice.

In another approach the S-layer protein SbpA from *B. sphaericus* CCM 2177 was recrystallized on SiO<sub>2</sub>-coated grids [106]. These grids were mimicking the surface properties of silicon wafers, but allowed investigation of the preparations by TEM. In particular, when rendered hydrophilic by oxygen plasma treatment, the S-layer protein formed a monolayer with the outer surface exposed to the environment. It could be demonstrated that after crosslinking the free amine groups in the S-layer lattice with glutaraldehyde and activation of the free carboxylic acid groups with carbodiimide, a close-packed monolayer of 4 nm amino-functionalized CdSe nanoparticles was covalently bound to the protein lattice. However, the amine-functionalized nanoparticles did not resemble the lattice parameters of the S-layer very well as approximately  $1.6 \times 10^6$  carboxylic acid groups  $\mu\text{m}^{-2}$  offered too many equivalent binding sites. Furthermore, for studying the noncovalent binding of nanoparticles, anionic citrate-stabilized gold nanoparticles (5 nm diameter) were used [106, 107]. The negatively charged gold nanoparticles were bound at the inner surface of S-layer self-assembly products. The amount of bound gold nanoparticles per unit area depended on the size of the nanoparticles. Gold nanoparticles with a size of about 10 nm were only randomly bound, whereas 2 nm nanoparticles were densely packed on the S-layer surface. Nevertheless, 5 nm gold nanoparticles were regularly bound, resembling the underlying square S-layer lattice.

## 8.5.2

**In Situ Synthesis of Nanoparticles on S-Layers**

As an alternative to the regular binding of preformed nanoparticles, S-layers can be also used as periodic nanometric templates in the nucleation of inorganic nanoparticles. The very first experiments were performed almost two decades ago and used S-layer fragments deposited onto a solid substrate as a porous mask [108]. In this and the following works [109–111], various metals were evaporated onto the S-layer fragments forming nanoparticles arrays on the substrate due to the periodic arrangement of the pores in the protein lattice. After removal of the S-layer and excess material by ion milling, the regular pattern of metallic nanoparticles became available for further use. It was also demonstrated that S-layer proteins recrystallized on solid supports or S-layer self-assembly products which were deposited on such supports could be used to induce the formation of CdS particles [112] or gold nanoparticles [113]. Inorganic superlattices of CdS with either oblique or square lattice symmetries were fabricated by exposing the S-layer lattices to cadmium ion solutions followed by slow reduction with hydrogen sulfide. Precipitation of the inorganic phase was confined to the pores of the S-layers with the result that CdS superlattices with prescribed symmetries were obtained. In a similar procedure a square superlattice of uniform 4–5 nm gold particles with a 13.1 nm repeat distance was fabricated by exposing a square S-layer lattice which carried thiol groups that had been introduced by chemical modification before to a tetrachloroauric(III) acid solution [113]. TEM analysis showed that the gold nanoparticles were formed in the pore region during electron irradiation of an initially grainy gold coating covering the whole S-layer lattice. The shape of the gold particles resembled the morphology of the pore region of the square S-layer lattice. Electron diffraction patterns revealed that the gold nanoparticles were crystalline, but in the long-range order not crystallographically aligned. Furthermore, this technique was also used for the precipitation of metal nanoparticles from solutions, such as palladium from PdCl<sub>2</sub>, nickel from NiSO<sub>4</sub>, platinum from K<sub>2</sub>PtCl<sub>6</sub>, lead from Pb(NO<sub>3</sub>)<sub>2</sub> and ferrum from KFe [Fe(CN)<sub>6</sub>]. Wet chemistry was also applied for producing platinum nanoparticles on the S-layer of *Sporosarcina ureae* [114–117]. One morphological unit of the S-layer lattice of *S. ureae* revealed seven platinum cluster sites with a diameter of around 1.9 nm. These experiments clearly demonstrated that nanocrystal superlattices can be induced by S-layers as templates with a broad range of particle sizes (5–15 nm diameter), interparticle spacings (up to 30 nm) and lattice symmetries (oblique, square or hexagonal).

## 8.6

**Conclusions and Outlook**

Basic research on the structure, genetics, chemistry, assembly and function of S-layers has led to a broad spectrum of applications in nanobiotechnology and biomimetics. The remarkable intrinsic feature of S-layer proteins and the possibilities for

genetic modifications and combining S-layer lattices with other functional molecules in a spatial predictable way turns them into unique patterning elements for bottom-up strategies. Although, up to now the development of S-layer technologies has primarily focused on life science applications, an important field of future applications concerns nonlife sciences and bioinspired nanomaterials.

## 9.1

**Introduction**

The recent rapid progress in techniques supporting drug discovery such as genomics, proteomics, high-throughput methods, etc., has exponentially increased the number of newly introduced potential drug candidates [1]. A new drug candidate undergoes a series of time-consuming investigations. Currently, only about five to 10 drugs among 3000–10 000 candidates go into phase I clinical studies and only one of them finally reaches the market [1]. Among the numerous research steps to launch a new drug, the formulation study is becoming one of the most critical bottlenecks, mainly because of the relatively slow advance of formulation-related technologies. What is worse is that the physical and chemical properties of drugs are being diversified, and so more intelligent and functional drug delivery systems are required. As a consequence, the development of novel drug delivery systems and formulation techniques are critical issues in the pharmaceutical research.

Nanoformulation, i.e. formulation using nanoparticles, is at the center of the recent pharmaceutical research and development. The industrial application of nanoparticles of active pharmaceutical ingredients (API) ranges from traditional simple emulsion [2–5] to solid dispersion systems developed a few years ago mainly with the help of the rapid progress of wet comminution techniques [6–19].

Various benefits have been achieved by using nanoparticles [6–22]. First of all, distinct increases in dissolution rate, bioavailability and rate of absorption have helped the formulation of relatively insoluble API (Figs. 9.1 and 9.2). It is known that, in general, as the size of API particles decreases, their processability decreases and bioavailability increases (Fig. 9.1). The burden of processing difficulty can be released by using advanced nanotechnologies. The increase of surface area as a function of particle size is schematically illustrated in Fig. 9.2, which triggers the increase of dissolution rate and bioavailability. Furthermore, the increases have made the early phase of drug discovery more effective. They also enable higher dose loading into a smaller dosage volume. Nanoparticles can be incorporated into various drug delivery systems for more effective and intelligent delivery [23,

Fig. 9.1. Dependence of bioavailability and processability of a formulation on the particle size of the drug.

24]. Reformulation using nanoparticles often removes harsh excipients, extreme pH and organic solvents currently used. Longer retention in blood and tumors, improvement in the stability of drugs, taste masking, and reduction in fed/fasted variability are often also obtained [24].

As particle size decreases, the extra Gibbs free energy resulting mainly from the surface energy of nanoparticles significantly increases [25]. Therefore, how to deal with the extra Gibbs free energy is the major issue in the preparation and subsequent treatment of nanoparticles. If a nanoparticulate system is considered to be a system having  $N$  smaller noninteracting systems (ensembles), the total Gibbs equation will be:

$$E_t = TS_t - pV_t + \sum \mu_i N_{it} + EN \tag{1}$$

Structure of Drug Nanocrystals

Effect of Size Reduction

Fig. 9.2. Schematic illustration of the structure of drug nanocrystals, and the relationship between particle size and surface area.

where  $t$  indicates total,  $\mu_i$  is the chemical potential of component  $i$ ,  $N_i$  is the number of molecules of component  $i$  and  $E$  is the “subdivision potential” [25]. The fourth term on the right-hand side is an extra one for the nanosize effects (e.g. surface tension), which increases as API particle size decreases.

Nanoparticle preparation techniques under active development can be categorized into two major routes – kinetic and thermodynamic approaches. The kinetic approach relies on external energies to compensate for the elevated Gibbs free energy of nanoparticles, such as high energy flow, sonication and electrostatic fields. The thermodynamic approach makes use of interfacial energy. For example, the stabilization ability of polymers and surfactants or supercritical fluids (SCFs) can be successfully employed for reducing the fourth term. The stabilizers can cover the surface of nanocrystals, and pay the thermodynamic penalty of the fresh interface between drug and liquid medium. Proteins and lipids can be stable in nanoparticulate forms in water if their conformation makes the fourth term negligible.

In the kinetic approach, the utilization of various energies has been tried to achieve the maximum efficiency. Without the external energies, the resulting particles cannot maintain their stability and so a poststabilization mechanism which remains active after processing is often employed. As a result, the actual processing of nanoparticles often combines both approaches. The combination usually offers better efficiency.

## 9.2

### Structures of Drug Nanoparticles

Pharmaceutical nanoparticles can take various physical forms depending on their final delivery routes and API properties. They can be classified on the basis of their physical states and internal structures. Solid or liquid monolithic nanoparticles are the simplest cases. They require a proper medium to minimize their interfacial energy. Emulsions and lipids have their unique structures to adjust themselves to the surrounding environments. A solid dispersion has a different structure from emulsions and lipids, but the structure is determined by the same thermodynamic origin. By controlling surface/interface energy and kinetic obstacles, various internal structures of nanoparticles from a simple core/shell to more complicated structures can be engineered.

## 9.3

### Thermodynamic Approaches

The interfacial energy related to the preparation of nanoparticles can be minimized by using proper materials in proper regions. Thermodynamic approaches mainly rely on the chemical identity and self-assembly behavior of materials. The micelle structures of traditional surfactants provide good examples, although their pharma-

ceutical applications are often limited due to their poor biocompatibility. Water soluble polymers can form nanoparticles in water by adding a crosslinking agent such as chitosan nanoparticles crosslinked by tripolyphosphate [26, 27], or by simple emulsion or dispersion preparation methods using oil and water mixtures [2–5]. Protein nanoparticles are also available by crosslinking or desolvation [28]. Precipitation by salting-out or solvent evaporation, or other phase separation phenomena, has been intensively investigated to conveniently prepare nanoparticles [29]. Surface active agents such as surfactants or block copolymers can adapt unique structures at the interface, resulting in a reduction in interfacial energy and successful preparation of nanoparticles [30–34]. Lipid systems, which have been intensively examined and widely adapted in the pharmaceutical area, provide typical examples of the thermodynamic approaches. Before moving on to a deeper discussion on lipid systems, it might be helpful to mention that the terminology “thermodynamic approaches” does not necessarily imply that the methods use only thermodynamically stable states.

### 9.3.1

#### **Lipid-based Pharmaceutical Nanoparticles**

Lipid-based drug delivery systems have been used to improve pharmacokinetic profiles, to reduce side-effects and to improve patient compliance. These lipid-based drug delivery systems can utilize various macro- and microstructures that lipids form in a variety of settings. Most popular lipid-based pharmaceutical particles include liposomes and oil-in-water-type lipid emulsions. Parenteral lipid emulsion has been around for more than 40 years to provide nutrition to patients who cannot consume food orally. Parenteral emulsion consists of vegetable oil particles dispersed in an aqueous environment by the use of the natural lipid emulsifier, lecithins. While the oil and lipid themselves or the emulsions as a whole are used to improve the health of the patients, they are used as tools to carry API to the destinations in the body when they are used as drug carriers. The drugs marketed in the form of lipid emulsion-based drug delivery systems include diazepam (Pharmacia) and propofol (Baxter and Astra Zeneca).

It took longer time for liposomes to appear on the market as drug carriers due to the instabilities of the formulation. Commercialization of the liposomal doxorubicin formulation Doxil<sup>®</sup> has been realized by designing a very stable liposome both *in vitro* and *in vivo* [35, 36]. The success has boosted the morale of the scientists working in the field, and has initiated a flurry of research and discovery of novel and innovated lipid-based pharmaceutical particles. Nowadays, new lipid-based drug delivery systems based on original designs appear frequently in the literature. Even though not all of them can be successful drug carriers, they can serve as stepping stones to understand lipid phase behavior and to improve current formulations. In this chapter, the physical characteristics of lipids will be introduced as a background to understand how and why lipids behave as they do, together with frequently encountered lipid-based particulate systems.

## 9.3.2

**What is a Lipid?**

Lipids can be defined as fatty acids, their derivatives and related molecules that are soluble in organic solvents and sparingly soluble in water. The major role of lipids in the living organism is to build the cell membrane. The majority of lipids encountered in nature are amphiphilic in that they embody both polar and apolar elements in one molecule. Dietary lipids are mostly neutral lipids or triglycerides with very low aqueous solubility. There are also classes of lipids that can self-assemble and form a variety of lyotropic liquid crystalline phases having crystalline periodicity and liquid-like molecular diffusibility. This nature of hydrated lipids can help us to design lipid-based nanoparticles.

Lipid phase behavior can be understood by realizing that there exists a lateral pressure function across a lipid monolayer [37–40]. A force profile can be drawn along the direction normal to the lipid monolayer since different forces are dominant in different regions along the lipid molecules (Fig. 9.3). A lipid molecule can be divided roughly into the head group, polar/nonpolar interface and hydrocarbon chain regions. Head groups repel each other due to steric, hydration and electrostatic effects. There is an attractive force in the polar/nonpolar interfacial region in order to minimize the exposure of the interfacial area to the surroundings. Hydrocarbon chains repel each other due to thermally induced rotational motion around the carbon atoms. A lipid monolayer compensates for the imbalance in the lateral stress and can become a planar or curved surface as a result if there exist no other energy terms. In reality, the contributions from other energy terms could easily override the spontaneous tendency of bending the lipid monolayers. These other energy terms include electrostatic interactions, van der Waals interactions and others.

Since the energy of bending is an important energy term to understand in lipid self-assembly, it will be discussed in more detail. The curvature elastic energy describes the energy associated with bending the surface as follows [41]:

$$\Delta G = k_c/2 \langle H - H_0 \rangle^2 - k_g \langle K \rangle \quad (2)$$

**Fig. 9.3.** The lateral stress profile along a lipid monolayer. A positive value along the  $f(z)$ -axis represents the attractive force.

where  $k_c$  and  $k_g$  are the rigidity or bending modulus and the Gaussian curvature constant, respectively, and  $\langle \rangle$  denotes the average obtained by integrating over a unit surface. Curvature is defined as a reciprocal of the radius of a circle that can be drawn to the tangent of the surface. The principal curvatures  $C_1$  and  $C_2$  are the minimum and maximum of the normal curvatures at a point. Two orthogonal principal curvatures or their average and product values, the mean [ $H = (C_1 + C_2)/2$ ] and the Gaussian ( $K = C_1 C_2$ ) curvatures, can define the curvature of the surface at a given point.

### 9.3.3

#### Liquid Crystalline Phases of Hydrated Lipids with Planar and Curved Interfaces

The vast variety of naturally occurring lipids adopt one or more of the liquid crystalline phases at, or close to, physiological conditions either with planar or curved interfaces. In this section, the lamellar, hexagonal and cubic phases of hydrated lipids will be described although they are bulk phases since they can be micronized into useful pharmaceutical nanoparticles such as liposomes, hexosomes and cubosomes, respectively.

Biomembranes usually incorporate a lipid bilayer structure that has been successfully modeled by the lamellar liquid crystalline ( $L_\alpha$ ) phase at physiological conditions. In the  $L_\alpha$  phase, lipid molecules arrange into stacked sheets (Fig. 9.4). The apolar hydrocarbons are located inside and the head groups line up at the surface of the sheets. Water molecules are located between the layers formed by the head groups. The lamella is a planar structure with zero curvature. The lamellar phase is often described as a frustrated structure since the bilayers cannot overcome an

**Fig. 9.4.** Liquid crystalline phases of hydrated lipids and the principal curvatures at the interface between hydrocarbon chain termini.

energy barrier to curl up (called the “packing energy”) even when a curved surface is preferred and, thus, remain flat [42].

The so-called inverted hexagonal ( $H_{II}$ ) phase composed of long cylinders with hexagonally packed aqueous cores is found in hydrated lipids (Fig. 9.4). The lipid head groups coat the surface of the central water-filled cylinders and the hydrocarbon chains constitute the continuous medium. One of the principal curvatures along the cylinder is zero, but the other is around  $0.02 \text{ \AA}^{-1}$ . Another curved liquid crystalline phase encountered in hydrated lipids is the bicontinuous cubic phase [43]. In the bicontinuous cubic phase, each component, lipid or water, forms separate and continuous channels, and the interface between the lipid and water forms the networks of tubes that have three-dimensional cubic symmetry. The interface between the termini of hydrocarbon chains in the cubic phase can be described as the infinite periodic minimal surface whose mean curvature is zero everywhere since the two principal curvatures are identical in quantities with different signs [44, 45].

The appearance and the texture of the hexagonal and the cubic phase are similar to white toothpaste and waxy gel, respectively. They both are very viscous and do not dilute in water. Drugs can be encapsulated in the water channels, hydrocarbon regions as well as interfacial regions.

#### 9.3.4

##### **Oil-in-water-type Lipid Emulsion**

Neutral lipids such as triglycerides phase-separate and form thermodynamically stable bulk oil phases ( $L_2$  phase) in the aqueous system. Fractionizing them into micronized particles would create a large interface between the particles and water. However, this process is entropically favorable – the increased interfacial area between oil and water increases the Gibbs free energy [46]. Emulsification occurs when external energy is provided in the form of stirring, sonicating or microfluidizing. Spontaneous emulsification can also occur when the interfacial energy between oil particles and water is close to zero.

Lipid emulsions have been widely used in pharmaceutical and medical fields as drug carriers. To be applied as parenteral, oral or topical formulations, emulsions must be physically stable and nontoxic [47]. The diameter of oil droplets in stable lipid emulsions is typically less than 500 nm. Many emulsion products are currently on the market, including propofol injectable emulsion (Baxter and Astra Zeneca).

To formulate stable emulsions, suitable emulsifiers should be added to the formulation [48]. It is also important to choose an appropriate oil to increase the stability and biocompatibility of the emulsion [49].

#### 9.3.5

##### **Liposomes**

A liposome is a vesicle made of lipid shells and filled with a portion of an aqueous phase. Liposomes used as drug delivery systems are mostly small unilamellar vesicles (SUV) and smaller-sized multilamellar vesicles (MLV) between 50 and 100

nm in diameter. For pharmaceutical use, a hydrophobic drug can be incorporated in the shell or in the inner aqueous phase. Since a liposome is not a thermodynamically stable system, it can be produced by applying sufficient mechanical force to break up the lamellae and overcome the curvature energy cost to form a closed constrained vesicle from the bulk lamellar liquid crystalline phase [50].

Even though liposomes have been used widely as drug delivery systems, there have been many problems in using conventional liposomes. Phospholipid liposomes are very unstable and form aggregates upon storage. In the blood stream, they are cleared out by the reticuloendothelial system (RES) as they can be recognized as foreign bodies [51, 52]. The breakthrough occurred when long-circulating liposomes were designed by incorporating lipids with covalently attached polyethylene glycol (PEG) [53]. These, so-called, “stealth” liposomes have a relatively long half-life (approximately 1 day) in blood circulation and can be targeted to a desired tissue *in vivo*. The repulsive barrier properties of lipid-grafted PEG polymer chains originate mainly from a steric pressure and this simple polymer steric stabilization is the basis for the extended *in vivo* circulation times observed for polymer-grafted liposomes [53].

Along with “stealth” technology, another novel technique has been put into the development of successful liposome formulations. Conventionally, drug encapsulation efficiency into the liposome has been very low since a liposome is prepared by dispersing the bulk  $L_{\alpha}$  phase in the aqueous system containing drugs. Considering a liposome with a radius of 50 nm and a shell with a single bilayer whose thickness is 5 nm. If the total lipid concentration was 3% (w/w) in the aqueous system at the beginning, a rough calculation gives around 8% (v/v) of the trapped aqueous phase inside the liposome. In reality, the bilayer has one to three layers and therefore the drug trapping efficiency is almost always lower than 8%. A revolutionary technique called remote loading technology was devised to increase the trapping efficiency of drugs [54]. A relatively hydrophobic drug, e.g. doxorubicin, can penetrate the lipid bilayer freely. The inner aqueous phase is rendered acidic with the bulk aqueous phase at a higher pH, then the protonated doxorubicin forms precipitates out inside and cannot escape from the liposome droplet.

When a single lipid species is used to form liposome, different mean curvatures of the outer and inner bilayers could destabilize the liposome. Adding a small amount of lipids with different spontaneous curvature could release the tension by being preferentially distributed in one of the leaflets.

Many attempts have been made to prepare stable liposomes as drug delivery systems and probes to identify proteins by adding the polymerizable lipids with conjugated double or triple bonds that can be polymerized by applying heat or UV light [55] or metal-chelating lipids [56].

### 9.3.6

#### **Cubosomes and Hexosomes**

In the early 1990s, Swedish scientists succeeded in dispersing the lipid cubic phase in water by adding emulsifiers [57, 58]. They have termed the dispersed cubic

## Cubosome

## Hexosome

**Fig. 9.5.** Cryo-transmission electron microscopy photograph of cubosomes and hexosomes formed in the monoolein–water system. (Reproduced with permission from Ref. [58].)

phase as a “cubosome”. A cubosome is prepared by micronizing the hydrated lipid cubic phase in water. The interior of a cubosome comprises a thermodynamically stable cubic phase wherein lipid and water components constitute continuous, but separate, three-dimensional channels, and there exists a curved interface between the lipid head group and water (Fig. 9.5). Therefore, cubosome formulations could be advantageous over the conventional emulsion- or liposome-type formulations as they can solubilize amphiphilic as well as hydrophobic and hydrophilic drugs. To increase the stability of cubosome preparation, different preparation procedures have been devised. Precursor type formulation that forms a cubosome spontaneously in the presence of water has been developed [59, 60]. A dry-powder-type formulation was also prepared [61]. Cubosomes have been elegantly described in mathematical terms [62] and have been developed as drug carriers by the scientists in Camurus AB ([www.camurus.se](http://www.camurus.se)). Like liposomes, cubosomes have also been polymerized successfully by utilizing reactive monoglyceride [63]. The term “hexosome” refers to a dispersed hexagonal phase and can also be produced by mechanically micronizing the hydrated hexagonal phase in water (Fig. 9.5).

### 9.3.7

#### Other Lipid-based Pharmaceutical Nanoparticles

A hollow lipid microcylinder has been produced by cooling a liposome solution composed of chiral diacetylenic lipids [64, 65]. Diacetylenic lipids are those with conjugated triple bonds in the middle of hydrocarbon chains. Due to the chirality of the diacetylenic lipid, the bilayer twists to form a tubular structure. Microtubules have a diameter of approximately 0.5  $\mu\text{m}$  and a length ranging up to a few centi-

**Fig. 9.6.** Electron micrographs of lipid tubules in methanol/water (7:3) at lipid concentrations of 1 (a and b) and 5 mg ml<sup>-1</sup> (c and d). The scale bar represents 1  $\mu$ m. (Reproduced with permission from *Proc. Natl Acad. Sci. USA* **1996**, 93, 12943–12946.)

meters. The bilayer forms a band arranged like a wrapping paper of a cigar, separated by layers of water (Fig. 9.6). The inside (in the place of the cigar itself) is hollow and filled with water in an excess water environment. Antifouling agents have been encapsulated into the interior of the microtubules and released in a sustained fashion [66].

Lipid cochleates are stable precipitates made from phosphatidylserine and calcium ions [67]. The structure of cochleates consists of a continuous, solid lipid bilayer sheet rolled up in a spiral (Fig. 9.7). Unlike lipid tubules, there is no hollow space for water in the cochleate system. The amphotericin B/cochleate system has been shown to treat *Candida* infection when administered orally [68]. Cochleates have also been used to deliver proteins and peptides for vaccine applications [69].

## 9.4

### Mechanical Approaches

#### 9.4.1

##### Types of Processing

The subdivisional potential penalty in Eq. (1) can be paid by mechanical energy input to produce and maintain nanoparticles. Comminution to prepare pharmaceu-

**Fig. 9.7.** Scanning electron micrographs after freeze-fracturing cochleate cylinders. Scale bar: 200 nm. (Reproduced with permission from *J. Controlled Rel.* **2002**, *81*, 7–23.)

tical nanoparticles uses mechanical energy. As the size of particles decreases, the required mechanical energy dramatically increases. To relieve the burden of energy input, additional support by surface active agents is generally used (Fig. 9.2) [9–10]. A series of recent successful commercializations of nanoformulations using this technique proves its efficiency.

Based on the type of mechanical energy employed, two typical types of processing exist – shearing and fracturing [70]. For shear force generation, high-speed stirrers and high-shear mills are commonly used in the processing of low-viscosity systems [71]. When a high-viscosity system is involved, shear force generation requires different types of equipment such as extruders, roll mills, heavy-duty mixers, etc. Fracturing is conveniently triggered by impact mills such as ball and jar mills.

Comminution processes using media such as ceramic balls have commonly been used to reduce the size of API. Both the wet and dry conditions can be used, but individual nanoparticles in the dry state are relatively unstable. When a liquid medium is used, heat dissipation is much more effective, and, more importantly, the surface of nanoparticles can properly be wetted and stabilized by surface active agents. Therefore, wet comminution is more common in pharmaceutical nanoparticle processing. Ball and jar mills, vibratory mills, various attritors, etc., are of this type [18, 19, 70].

In ball milling, grinding media is put into a cylindrical vessel with the drug. The vessel is designed to rotate along an axis and the grinding media undergo a cascading action that provides mechanical energy to reduce the particle size [8]. The critical speed is a speed where cascading stops due to high centrifugal force. Ball milling should use a speed lower than the critical speed to maintain its cascading action. Attrition contributes more to particle size reduction below the critical speed. The shape, size and density of grinding media affect comminution process.

**Fig. 9.8.** Particle size reduction as a function of time during wet milling. The concentration of hydroxypropyl cellulose in the mother liquid is shown. (a) Nanoparticles on a glass slide ( $2 \times 2 \mu\text{m}$ ). (b) Nanoparticulate compact ( $1 \times 1 \mu\text{m}$ ) (compaction pressure = 136 MPa). (Reproduced with permission from Ref. [6].)

An increase in the density and hardness of grinding media usually increases the speed and amount of particle size reduction. A decrease in the size of media produces the same results. Nonetheless, in wet comminution using surface active ingredients, the surface properties of materials appear to be more important than the properties of the grinding media [6]. Figure 9.8 shows a typical result of particle size reduction as a function of milling time in the presence of a polymeric stabilizer.

High-speed stirrers such as blade stirrers and rotor-stator dispersers produce the same high-shear flow to obtain nanoparticles as high-shear mills such as colloid mills, homogenizers, ultrasonic dispersers, etc. [8, 70, 71]. In a typical design of high-pressure homogenization, the initial mainstream of a liquid (a dispersion system) is separated into two liquid streams, and then they collide with each other producing severe deformation and cavitation in the dispersion system [72]. Particle size reduction mainly results from the deformation and cavitation action of high-pressure liquid streams. The final particle size and its distribution significantly depend on the various processing parameters.

#### 9.4.2

##### Characteristics of Wet Comminution

In the wet comminution processes of nanoparticles, comminution continually fractures organic crystals while polymer chains adsorb onto fresh surfaces and stabilize each broken particle. The “primary” particle size produced by wet milling is not necessarily the same as the particle size actually measured in water by a light scattering method (Fig. 9.8). It is possible that some primary particles form aggre-

gates. Ideally, the smallest size of primary particles that can be achieved by mechanical breaking is related to the size of the damage zone ahead of the crack tip. According to the Irwin's equation of linear elastic fracture mechanics, the size of the damage zone ( $r_d$ ) (lower particle size limit) is related to the stress intensity factor ( $K_{IC}$ ) and yield stress ( $\sigma_y$ ) as follows [6, 73]:

$$r_d = 1/6\pi(K_{IC}/\sigma_y)^2 \quad (3)$$

If a set of typical values of  $K_{IC}$  (0.05 MPam<sup>1/2</sup>) and  $\sigma_y$  (50 MPa) for organic crystals is used [6, 74],  $r_d$  is around 50 nm. Accurate calculation is rarely possible due to the anisotropy of crystals and uncertainty in  $\sigma_y$  values, as well as the difficulty in measuring the stress state, loading rate and temperature in wet milling. However, the size of the damage zone ( $r_d$ ) will put a lower limit on the particle size that can be attained by wet comminution [75, 76].

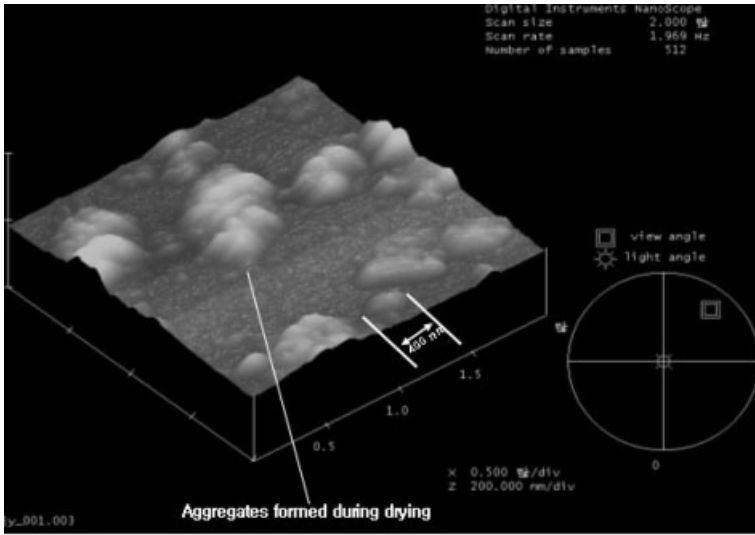

In the actual successful processing as shown in Fig. 9.8, the mean size of drug particles depends more on polymeric stabilizers than on mechanical energies. In semidilute polymer solutions, the adsorption of polymer chains will occur if the free energy reduction associated with adsorption can compensate for the accompanying entropy loss [77]. Since steric stabilization involves adsorption/desorption processes and masking of dispersion forces, it naturally depends on the concentration of polymer in bulk solution (concentration in mother liquid), the size of particles, type of solvent, etc. The amount of adsorbed polymers was found to initially increase with an increase in the concentration of polymer in bulk solution and eventually reach a saturation point [6].

For polymers to provide effective steric stabilization, strong adsorption at full coverage and a long time scale for desorption are necessary [77]. The common minimum layer thickness requirement for stabilization is around  $(0.05\text{--}0.2) \times$  particle size [77] and previous reports showed enough surface coverage based on a simple approximation [6]. When naproxen and hydroxypropyl cellulose were used as a drug and a stabilizer, the surface coverage of hydroxypropyl cellulose in 150-nm particles was estimated to be around  $1.5 \mu\text{g cm}^{-2}$ , which corresponds to an average polymer layer thickness of around 15 nm. It is uncertain whether this result can be generalized for other polymer-stabilized nanocrystal systems. More precise calculation requires an understanding of the polymer morphology on the surface of drugs. Unfortunately, direct measurement of the thickness of polymeric stabilizers has remained unsatisfactory. The atomic force micrographs in Fig. 9.9 clearly show nanoparticles, but no detailed information on polymeric stabilizers.

### 9.4.3

#### Drying of Liquid Nanodispersions

In the wet comminution processes, the steric stabilization of polymers is effective only in a liquid medium. While the use of a liquid medium is convenient for nanoparticle preparation, solid dosage forms are generally more important than liquid forms in the pharmaceutical industry. Therefore, a drying process should be em-

a) Nanoparticles on glass slide (2x2  $\mu\text{m}$ )

b) Nanoparticulate compacte (1x1  $\mu\text{m}$ ) (compaction pressure = 136 MPa)

**Fig. 9.9.** Tapping mode atomic force microscopy images of nanoparticles dried on a glass side from an aqueous dispersion (a) and the surface of a nanoparticulate compacte (b). (Reproduced with permission from Ref. [6].)

ployed to connect the wet process and the conventional unit operations of solid dosage formulation. Various drying processes such as spray drying, fluidized bed drying, freeze drying, etc., can be used to prepare dried nanoparticles.

Since the initial thermodynamic and kinetic compensations of the wet comminution process become inactive as drying progresses, nanoparticles easily form aggregates too strong to be dispersed in a liquid medium later. Nanoparticles slowly dried under ambient conditions show their aggregation tendency as can be seen in Fig. 9.9(a). Special care needs to be taken to keep each nanoparticle apart from each other (“re-dispersible”). Otherwise, the advantages of nanof ormulation cannot be fully utilized in solid dosage forms. The drying process of nanoparticle dispersions has become a critical issue in the pharmaceutical industry.

Drying nanoparticle dispersions using conventional processes such as spray drying, freeze drying, etc., is not a trivial process development [16–20]. Solid dosage formulation needs well-dispersed API nanocrystals (Figs. 9.8 and 9.9). For that reason, the key property of dried nanoparticles is their “re-dispersibility”, i.e. whether they can restore their initial nanometer sizes when they are re-dispersed into an aqueous medium. The re-dispersibility can be defined as  $D_0/D$  (%), where  $D_0$  is the initial mean particle size after preparation of the nanoparticle dispersion and  $D$  is the particle size of re-dispersed powder in water. Then, 100% re-dispersibility indicates that dried powders can fully revert to the original nanoparticles upon re-dispersion into water.

Drying certainly increases the chances of aggregation of nanocrystals and polymers. Steric stabilization requires active polymer chain movement in water, which will be restricted as water is frozen or removed. Thus, it is a natural consequence for nanocrystal dispersion to become less stable during drying or freezing (freeze drying). Furthermore, the crystallization (crystal growth) of water in freeze drying tends to exclude foreign particles from crystal regions and lead them to aggregate. Therefore, for better re-dispersibility, fast drying or freezing is necessary and a soluble compound such as a cryoprotectant is frequently added to serve as a medium where solid nanoparticles are dispersed after drying. It was reported that there is a critical freezing rate for a solid dispersion below which its re-dispersibility decreases from 70–100 to 2–3% [78].

Since drug nanoparticles are covered by adsorbed polymer chains, the breaking strength of aggregates into primary nanoparticles would depend on how strongly the polymer chains become entangled during drying [79]. Therefore, to prevent strong entanglement, the frequency and duration time of contacts between nanoparticles need to be minimized by increasing drying speed. In an extreme case of aggregation, API nanoparticles may fuse together. The re-dispersion of fused aggregates can hardly be expected.

For a dispersion system, re-dispersibility might be treated as a result of competition between drying speed and particle collision frequency. The motion of an “ideal” spherical particle could be characterized by using its hydrodynamic diameter,  $d$ . The average apparent velocity of the particle,  $v_{app}$ , is:

$$v_{app} = x/t = (2D/t)^2 \quad (4)$$

where diffusion coefficient,  $D = kT/3\pi\eta d$ ,  $x$  is the average distance traveled by a particle,  $t$  is the time,  $k$  is the Boltzmann constant,  $T$  is the temperature and  $\eta$  is the viscosity [70, 77]. If a set of typical values is employed,  $v_{\text{app}}$  can be obtained for a certain time interval,  $t$ . The apparent velocity  $v_{\text{app}}$  is only an approximation and often fails to describe actual particle motion. However, it seems to hold true that as the concentration increases, the collision frequency increases, resulting in an increase in aggregation tendency. It requires the detailed analysis of interparticle force fields, polymer chain mobility, local heat and mass transfer, etc., to determine how fast a nanoparticle dispersion should be dried.

## 9.5

### SCF Approaches

The use of near critical or SCFs for micro/nanoparticle formation has recently been shown to be good in improving particle characteristics such as size, size distribution, shape and morphology. SCF technology can be an attractive recrystallization method for some difficult-to-comminute materials such as certain explosives, “waxy” or “soft” dyes, polymers and pharmaceutical compounds, etc., that require very small particles and narrow size distribution. Once used, the SCFs can be recycled from dissolved solutes by just depressurizing. Thus, the SCF processes are environmentally benign. The stainless construction, small number of moving part and totally enclosed system are also favorable for the pharmaceutical current good manufacturing practice (cGMP) requirements.

#### 9.5.1

##### SCF Characteristics

More than 100 years ago it was found that SCFs could dissolve nonvolatile compounds [80]. In the pressure–temperature diagram for a pure substance (Fig. 9.10), two nearby phases coexist at the solid curves and three phases (liquid, vapor and solid) exist together at the triple point (TP). “Supercritical” means the state of matter where the temperature and pressure of a single fluid are above the critical point (CP) where the liquid–vapor phase boundaries (equilibrium curve) diminish. The temperature and pressure at the CP are referred to as the critical temperature ( $T_c$ ) and critical pressure ( $P_c$ ), respectively. By literal definition, the SCF is a fluid that is at temperature and pressure higher than those at CP, and the area is called a SCF region. In that region the substance can be brought into the vapor and liquid without an abrupt phase change by lowering the pressure and temperature, respectively. However, due to economic considerations, SCF processing is generally carried out in the vicinity of the CP with reduced temperature ( $T/T_c$ ) in the range of 1.01–1.1 and reduced pressure ( $P/P_c$ ) in the range of 1.0–4.0.

SCFs have advantageous properties of gases and liquids such as a liquid-like density (high solvation power), and gas-like diffusivity and viscosities (high mass transfer rates, i.e. good mixing properties). In addition, near zero surface tension

Fig. 9.10.  $P$ - $T$  diagram of a pure substance.

enables SCFs to easily migrate into various microstructures. For particle formation, SCFs are very compressible near the CP, and their density and solvent power can be changed dramatically by a small change of either pressure or temperature. Consequently, their density and solvent power are continuously controlled for selective operation in the SCF region a little distant from the CP. The solvent power can be explained by a high enhancement factor of  $10^4$ – $10^6$  (a dimensionless measure of solvent power defined as the measured solubility of a substance in the solvent divided by the solubility in an ideal gas) [81].

Carbon dioxide is one of the most extensively used SCFs ( $\text{SCCO}_2$ ) due to its relatively low  $T_c$  (31.1 °C) which makes it attractive for processing heat-labile substances such as pharmaceutical ingredients (Fig. 9.11). Additionally, it has a moderate  $P_c$  (73.8 bar) and a good solvation power compared to other SCFs. It is nontoxic, nonflammable and relatively inexpensive (US\$0.11–0.15  $\text{kg}^{-1}$ ) with high purity.

### 9.5.2

#### Classification of SCF Particle Formation Processes

There have been a number of review articles for micro- and nanoparticle formation using SCFs recently [82–88]. In the past 20 years various types of SCF particle formation processes have been developed using different nucleating and growth mechanisms, such as rapid expansion of supercritical solution (RESS), gas antisolvent (GAS) process, supercritical antisolvent (SAS) process, solution-enhanced dispersion by SCFs (SEDS), particles from gas-saturated system (PGSS), etc. Among these techniques, RESS, SAS and SEDS are generally known to achieve nanoparticle formation.

Fig. 9.11. Reduced density–reduced pressure diagram for CO<sub>2</sub> at various reduced temperatures ( $T_r$ ) in the vicinity of the CP.

### 9.5.3

#### RESS

This process is used for materials soluble in a SCF. As shown in Fig. 9.12, the RESS process simply uses a pump, extractor, nozzle and precipitator. Using the compressed SCF, the solutes located in the extractor are dissolved and the supercritical solution is introduced into the precipitator at low pressure (normally atmospheric pressure) through capillary or laser-drilled disk-type nozzles. The resulting rapid pressure drop in solution causes fast evaporation of SCFs and a dramatic decrease in the solvation power of the solution, which leads to a high degree of homogeneous supersaturation and simultaneous formation of very small particles. This high supersaturation ratio, rapidly propagating mechanical perturbation and thermal cooling enable the production of nanoparticles with a narrow size distribution.

This technique can be used without any toxic organic solvent and, thus, is considered a contamination-free process. The general limitation of this process comes from the low solubility of hydrophilic or high-molecular-weight pharmaceuticals, resulting in poor throughput capacity even though a cosolvent is added to improve the solvent power of SCF.

Many works have focused on atomization of pharmaceuticals, either to obtain very fine particles with a narrow size distribution [89–93] or microcapsules which include an API in the carrier [94–96].

Fig. 9.12. RESS process.

#### 9.5.4

#### SAS

This process can be used for the crystallization of substances insoluble in SCF (Fig. 9.13). Some similar techniques are called the aerosol solvent extraction system (ASES) or precipitation with a compressed antisolvent (PCA) process. Drug and/or carrier are first dissolved into a liquid solvent, and the solution is sprayed from the top of and into a precipitator through a nozzle, where the SCF flows concurrently downward acting as an antisolvent for particle formation (Fig. 9.13). Two particle precipitation mechanisms proceed simultaneously at a high speed, i.e. the diffusion of a SCF into a liquid solution droplet (volumetric expansion of the organic solvent) and the evaporation of the liquid solvent into a SCF (depletion of the solvent from the liquid solution droplet). These phenomena generate a high degree of supersaturation of the solution, resulting in fast nucleation and growth, and consequently produce solute nanoparticles. After collection of a sufficient amount of particles, liquid solution pumping is stopped and pure SCF continues to flow through the vessel to remove residual solvent from particles.

The operation pressure, temperature, jet breakup, droplet size and mass transfer rates between droplets and the antisolvent phase control the particle size and morphology. In this process, the rate of SCF mass transfer into droplets influences particle formation, whereas the rate of solvent mass transfer into the SCF from droplets has an effect on particle agglomeration. This process can also be operated in a continuous mode that facilitates scaleup for the mass production of particles.

Many investigations have been carried out on atomization of pure pharmaceutical components such as insulin [97–100], ascorbic acid [101], pure biopolymer microspheres (dextran [102] and polylactic acid (PLA) [103]), and microcapsules

Fig. 9.13. SAS process.

which include an API in the carrier (chemotrypsin in PLA [104], lysozyme in PLA [104] and naproxen in PLA [105]).

#### 9.5.5 SEDS

The SEDS process is a modified version of the SAS. It enhances mixing efficiency by adopting a two- or three-coaxial-channel nozzle (Fig. 9.14) to facilitate smaller particle production. In this process, SCF is used both as an antisolvent and as a

Coaxial nozzle system

Fig. 9.14. Three-coaxial-channel nozzle system for SEDS process.

solution dispersion enhancer. Due to the high velocity of a SCF stream, faster breakup of solution and high mass transfer rates are achieved between the SCF and the solution, and so very fine particles are attained. With a three-coaxial-channel nozzle, one SCF stream and two organic solutions or two SCF streams and one organic solution can be combined. An aqueous solution can also be treated to form particles of water-soluble compounds such as proteins (lysozyme and trypsin [106]) and sugars (lactose, maltose, threhalose and sucrose [107]) using an aqueous solution of API/ethanol or methanol/SCCO<sub>2</sub> system.

## 9.6

### Electrostatic Approaches

The recent advance of spraying techniques under a high electrical field has opened unique possibilities for nanoformulation [108–113]. Electro spraying to prepare monodisperse pharmaceutical nanoparticles is currently being under active investigation and many intriguing successes have been reported. Herein, electro spraying will be briefly introduced as an emerging technology.

#### 9.6.1

##### Electrical Potential and Interfaces

The effect of electrical charges on the surface energy of a solid or liquid has been an interesting subject under thorough investigation. Common electrical charges are generated by the preferential adsorption of ions. In the electro spraying processes, an intentionally applied electrical field can effectively facilitate nanoparticle preparation [70]. When the interface between a solid and water is charged, the interfacial tension is reduced because of the greater interaction with water. This effect is much smaller with an oil drop. The contact angle actually follows the decrease of interfacial tension.

When an electrical field is applied between a nozzle and a collection part in spraying, the size of drop generated from a nozzle is reduced depending on the amount of applied charge (Fig. 9.15). Without an electrical field, the final size of a drop from a nozzle depends on the surface energy and the gravitational force of the drop (dripping mode in Fig. 9.16). With the aid of an electrical field, drops of smaller size overcome their surface energy and detach themselves from the tip of the nozzle (microdripping mode in Fig. 9.16) [114, 115]. As the electrical field increases further, the decrease of drop size reaches a different stage. The charged surface of the drop can no longer sustain its integrity and induces total breakup into droplets of much smaller size (Fig. 9.16). Usually, the droplets are of invisible nanometer size. Transition into this stage is easily confirmed by checking the formation of a Taylor cone (cone-jet in Fig. 9.16) structure at a nozzle tip [114].

The cone-jet mode was successfully explained by Talyor in 1964 [114]. The size of droplets is determined by the hydrostatic balance between electrical and surface tension forces. Further elaboration of the phenomena was later performed by Fer-

Fig. 9.15. Electro spraying induces the breakup of charged drops by a surface electrostatic force.

Fig. 9.16. Different stages of electro spraying drops (cyclohexanol): dripping mode (top left), microdripping mode (top right) and cone-jet mode (bottom). (Reproduced with permission from Ref. [115].)

nández de la Mora and Loscertales [116, 117] and Gañán-Calvo *et al.* [118–120]. The detailed relationship between current and flow rate was established depending on the properties of liquids employed. Particle size can be predicted in an ideal case from various parameters such as current, flow rate, permittivity and conductivity, etc. For example, when conductivity and viscosity are relatively low, particle diameter,  $d$ , is:

$$d \sim [(b - 1)^{1/2} Q \epsilon_0 / K]^{1/3} \quad (5)$$

and when both the viscosity and conductivity is high,  $d$  is:

$$d^{3/2} \sim Q/I \quad (6)$$

where  $I$  is the current,  $Q$  is the flow rate,  $b$  is the liquid to vacuum permittivity ratio,  $K$  is the electrical conductivity and  $\epsilon_0$  is the vacuum permittivity [116–120].

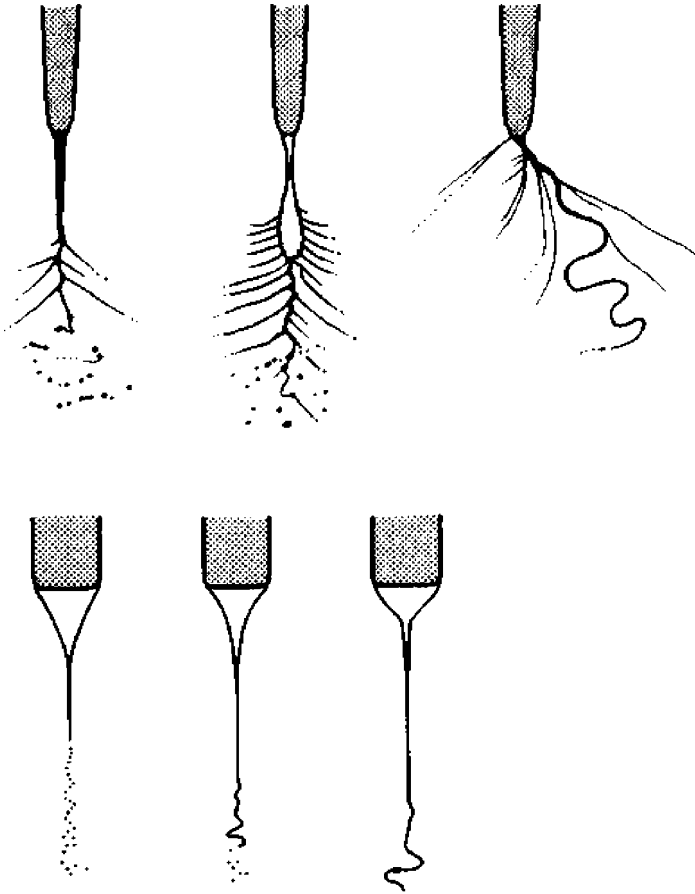

When the flow rate is relatively high, a ramified jet results instead of the cone-jet mode (Fig. 9.17). With relatively high conductivity and viscosity, electro spraying works in the spindle mode, which is often used to prepare nanofibers (Fig. 9.17) [114, 115]. Various factors such as flow rate, current, electrical conductivity, permittivity, liquid/gas surface tension, viscosity and density need to be considered to obtain a specific spraying mode, [117, 119–121].

## 9.6.2

### Electrospraying

In a simple electro spraying case, an electrically conductive liquid is slowly injected into a capillary having a potential difference of at least several thousand volts between a plate and itself. Liquids turn into charged droplets out of the “Taylor cone” at the capillary tip (Figs. 15 and 16). Proper posttreatments lead the droplets to form stable pharmaceutical nanoparticles. When a coaxial capillary is used, core/shell-type nanoparticles can be obtained (Fig. 9.18); recently, nanoparticles with more complicated internal structures have been reported [116, 119, 122].

Conventional spraying gives unique advantages for pharmaceutical applications when combined with an electrical field. First, relatively monodisperse pharmaceutical nanoparticles can be conveniently prepared (Fig. 9.19). Since the size of droplets is determined by electrical surface charge, monodispersity can readily be accomplished, and size control is relatively easy. It is also an important bonus that organic solvents are not necessary for this technique. Compared to other preparation methods, electro spraying can be applied to pharmaceutical materials of various physical properties since this method does not significantly rely on the hydrophilicity of solvents and pharmaceutical materials. Proteins can be processed regardless of their surface hydrophilicities. Moreover, protein is known to be stable in high electrical fields. While other methods using organic solvents or mechanical energies often destroy the viability of proteins, electro spraying does not cause such

**Fig. 9.17.** Different stages of electro spraying: ramified jet and random spraying (top), and spindle mode (bottom). (Reproduced with permission from Ref. [115].)

problems [123]. As a result, nanoformulation of many different types of drugs, including proteins, can be developed using electro spraying technique.

Core/shell nanoparticles are especially useful for drug delivery systems (Fig. 9.18) [116]. Two liquids are injected into two coaxial capillaries under an electrical field and form nanoparticles as a result of the electrohydrodynamic force. The sizes of two capillaries can range from a few micrometers to several millimeters and the electrical field is applied to the outer capillary. The electrical potential of the inner capillary depends on the electrical conductivity of the liquid in the outer capillary. By changing flow rates and the electrical field, nano-encapsulated particles can be prepared. The size of core/shell particles and the thickness of coating shells depend on the various physical properties of materials, but they are easily controlled by adjusting flow rates of two liquids.

**Fig. 9.18.** Schematic illustration of coaxial electrospaying equipment to prepare core/shell drug particles. (Reproduced with permission from Ref. [116].)

**Fig. 9.19.** Nanoparticles prepared from electrospaying.

The current during coaxial electrospraying mainly relies on the flow rate of more conductive liquid (driving liquid) between the two liquids employed. Whether the driving liquid is injected into the outer or inner capillary affects the core/shell particle formation mechanism. Once it is decided, the flow rate of driving liquid needs to be carefully controlled to obtain a proper current, and resulting particle size and internal structure.

# Production of Biofunctionalized Solid Lipid Nanoparticles for Site-specific Drug Delivery

Rainer H. Müller, Eliana B. Souto, Torsten Göppert and Sven Gohla

### 10.1

#### Introduction

The concept of site-specific drug delivery using particles has greatly benefited from the fast development of nanotechnology to a stage where it is possible not only to produce such small particles (less than 1  $\mu\text{m}$ ) in a very narrow size distribution range, but also to modify the particle surface in order to provide site-specific delivery of drugs.

It is well known that the size of nanoparticles and their surface characteristics are crucial factors to determine the success of the particles when used *in vivo*. With regard to the particle dimensions, it has been shown that nanometer-sized particles could be used for drug targeting, especially to the mononuclear phagocyte system (MPS) and the polymorphonuclear leukocytes, a mechanism that is based on their natural tropism and their biophysical properties [1, 2]. Concerning the surface characteristics, such as hydrophobicity and electrical charge, the internalization of nanoparticles by cells other than MPS cells is severely limited by the short residence time of particles in the blood. The modification of nanoparticle surface induces alterations in cell behavior distinct from the unmodified particles, suggesting that cell response and uptake can be directed via specifically engineered particle surfaces. The surface of nanoparticles can be modified using hydrophilic chains, such as polyethylene glycol (PEG), to prolong the circulation time of those carriers in the blood by resisting protein adsorption, reducing or avoiding the natural blood opsonization process and therefore their intracellular uptake by macrophages from the liver and spleen [2, 3]. The electrical charge of the nanoparticles also affects their *in vivo* fate [4–7].

This approach has been applied to target drug substances incorporated into colloidal drug carriers such as liposomes [8] and polymeric nanoparticles [9]. However, the use of those systems had some disadvantages. In spite of being one of the most extensively investigated drug delivery systems, liposomes show some chemical and physical stability problems that can lead to aggregation and drug degradation or expulsion of drug during storage, limiting their therapeutic performance [10]. Regarding the use of polymeric nanoparticles, the cytotoxicity of polymers

and the problems with polymer chemistry, as well as the need for  $\gamma$ -irradiation for production of sterile formulations, which can cause decomposition of incorporated drug and/or polymer and formation of potentially carcinogenic radicals, are the main disadvantages. Several synthetic polymers, such as poly(lactic acid) (PLA), poly( $\beta$ -hydroxybutyrate) (PHB) and poly(lactide-co-glycolide) (PLGA), have shown good histocompatibility and biodegradability, and their safety has been extensively documented. However, even those polymers which are accepted for use as microparticles and implants can show cytotoxic effects when delivered as nanoparticles or as very small microparticles [11].

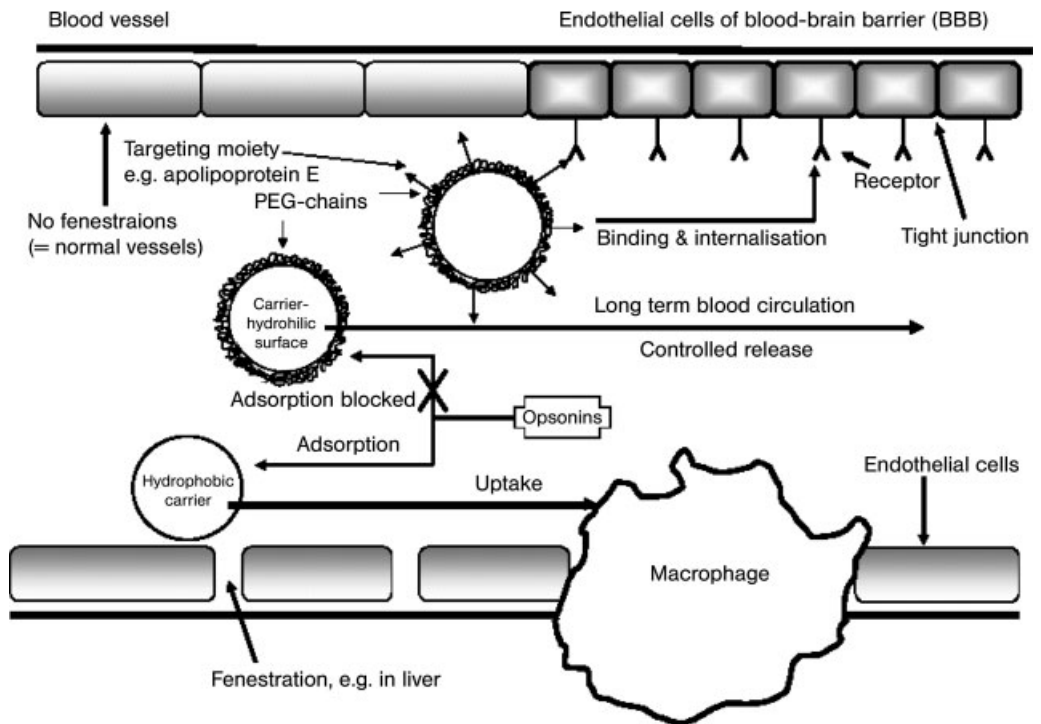

Cytotoxic effects can occur both on the outside of the phagocytic cells or after ingestion in the interior of the cell. Therefore, both surfactants and matrix material can lead to cytotoxic degradation products [12, 13]. Furthermore, there is a lack of large-scale production methods for polymeric nanoparticles which are acceptable to the regulatory authorities and at the same time cost-effective. As a consequence – in contrast to liposomes – no polymeric nanoparticulate product is on the market (only polymeric microparticles).

In order to achieve higher viability of cells (i.e. better tolerability) and decrease the risk of toxicity, nanoparticles can be produced by using lipids which are solid both at room and at body temperature. Such systems are called solid lipid nanoparticles (SLN) [14], and they have been recently tested as site-specific carriers particularly for drugs that have a rapid metabolism and are quickly eliminated from the blood, i.e. peptide and protein-loaded SLN [15, 16]. A clear advantage of these particles is the fact that the lipid matrix is composed of physiological lipids, e.g. generally recognized as safe (“GRAS”) status, which decreases the risk of acute and chronic toxicity [17]. SLN prepared with several lipids and emulsifying agents do not exhibit any cytotoxic effects *in vitro* up to concentrations of 2.5% lipid. In fact, it has been shown that even concentrations higher than 10% of lipid phase led to a viability of 80% with human granulocytes in culture [12]. For comparison, PLA nanoparticles showed complete cell death at 0.5% [12, 18]. In addition, a high loading capacity for a broad range of drugs can be achieved, especially if they have lipophilic properties [17, 19].

Due to their physiological and biodegradable properties, SLN have been tested for several administration routes [20], such as the oral and peroral routes [21, 22], pulmonary route, ocular [23], topical, dermal and transdermal administration [24–29], as well as for gene therapy [30–32], as new adjuvants for vaccines [33], and for parenteral delivery [34–38]. Concerning the latter, SLN can accumulate in target tissues based on their natural host cell tropisms and on their biophysical properties (passive targeting). In practice, active targeting to cells other than MPS cells is often insufficient for rapid and specific accumulation in target tissues. Further improvement of tissue selectivity can be achieved by engineering the surface of SLN with hydrophilic polymers [39, 40] or coupling targeting ligands [41–43].

In the present chapter, the concept of differential protein adsorption as well as the concept of functionalization of SLN via surface modification will be defined and discussed from a practical point of view. First, a brief introduction to the concept of differential adsorption after intravenous administration will be given, fol-

**Fig. 10.1.** Approaches to achieve passive targeting, long-circulating carriers for prolonged drug release and target-specific carriers (active targeting) via the intravenous route. (With permission after Ref. [80].)

lowed by a description of the methods used for the preparation of coated SLN. The last section will focus on the functionalization of SLN by modification of their surface characteristics, where some examples will be presented.

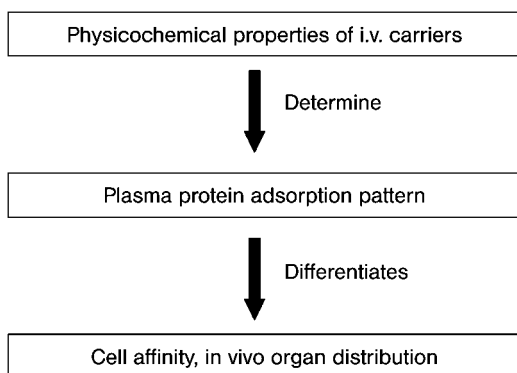

## 10.2 Concept of Differential Adsorption

By far the greatest attention to deliver drugs to selected sites in body has been focused on the intravenous route. Figure 10.1 reviews the main approaches to achieve both passive and active targeting. After injection, hydrophobic carriers will adsorb opsonins leading to uptake by the macrophages. In the liver, the macrophages are located in the layer of the endothelial cells. In case carriers are surface modified with hydrophilic polymers, e.g. PEG chains, the adsorption of opsonins will be minimized or avoided. Long-term blood circulation is achieved with such carriers which can be used, for example, for the controlled release of drugs. By at-

taching targeting moieties to these “stealth” carriers, location at specific cells can be achieved which carry the appropriate receptor and are accessible from the blood, e.g. the endothelial cells of the blood–brain barrier (BBB) or cells which are behind fenestrated blood vessels, such as liver or bone marrow.

Since the 1950s attempts have been made in order to correlate the organ distribution of intravenous injected drug carriers with their physicochemical properties, such as particle size [44] or electrical charge [7]. At the end of the 1980s it was realized that such a complex process like organ distribution could not be explained only by the physicochemical characteristics of the above-mentioned carriers [45]. After intravenous injection colloidal drug carriers immediately interact with plasma proteins, which are adsorbed onto the surface of the carriers. These adsorbed plasma proteins are generally accepted as the determining factor for the *in vivo* fate of the carriers. Drug carriers with different protein adsorption patterns will be recognized by different macrophage subpopulations (“concept of differential adsorption” [45, 46]), carrying proteins such as opsonins, like immunoglobulins or complement factors. When these are preferentially adsorbed onto the carriers’ surface, these carriers are immediately recognized by the MPS as foreign bodies and are therefore “cleared” from the blood. In contrast, when dysopsonins, such as hydrophilic proteins like albumin [47], are enriched on the carriers’ surface the systems will not be so easily recognized by macrophages. Such carriers are useful as circulating depots for the controlled release of drugs. Thus, in order to achieve an active drug targeting with these nonrecognizing carriers, it is important to have an additional enrichment of a protein mediating uptake into the target cells.

The decisive adsorption patterns acquired after intravenous injection depend on the physicochemical properties of the carriers [45, 48]. Therefore, there is a correlation between the physicochemical surface characteristics of the carriers, the plasma protein adsorption patterns and the resulting organ distribution (Fig. 10.2). Knowledge of this basic correlation can be exploited to develop site-specific intravenous carriers in a controlled way.

**Fig. 10.2.** Basic correlation exploited in the development of site-specific colloidal drug carriers (concept of “differential protein adsorption”).

In the middle of the 1990s, Kreuter et al. showed the possibility of site-specific targeting of various drugs, such as dalargin, enkephalin, tubocurarine and doxorubicin, into the brain by using polysorbate-coated poly(butyl cyanoacrylate) (PBCA)-nanoparticles [49–52]. The efficiency of drug delivery into the brain depended on the coating of those particles with polysorbate surfactants, particularly polysorbate 80, but also polysorbate 20, 40 and 60. Other surfactants such as poloxamers (e.g. poloxamer 338) led to no effects [53]. Using two-dimensional polyacrylamide gel electrophoresis (2-D PAGE), Müller et al. observed an enrichment of apolipoprotein E (apoE) on the surface of PBCA nanoparticles after incubation in human plasma. No apoE adsorption was seen after incubation with the other surfactants mentioned before [54]. ApoE seemed to play an important role in the transport of lipoproteins into the brain via the low-density lipoprotein receptor at the BBB [55]. Thus, it is possible that apoE-adsorbing drug carriers mimic lipoprotein particles leading to their brain uptake by endocytic processes. This theory was confirmed by turning the negative control in the Kreuter experiments [uncoated PBCA nanoparticles (no polysorbate adsorbed), loaded with dalargin] into a brain-specific carrier. ApoE was preadsorbed prior to injection and then the particles were able to carry dalargin across the BBB. Figure 10.3 summarizes the Kreuter experiments [49, 56].

In the experiments performed by Kreuter et al. the drug was adsorbed onto the surface, leading to a limited loading capacity. Furthermore, these polymeric nanoparticles exhibit the already mentioned toxicity problems. Due to the limited loading capacity, too much matrix material is required to deliver a sufficient amount of the drug to the brain. In addition, the *in vivo* biodegradation will be relatively slow, i.e. depending on the dose, the carrier material might accumulate in the target cell. In addition, the degradation leads to a release of toxicologically problematic formaldehyde [57], whereas it is a controversial discussion if the formaldehyde is really

Fig. 10.3. Scheme of the experiments performed by Kreuter et al. (Modified after Ref. [56].)

a problem. Thus, the “concept of differential adsorption” and the analytical methodology to investigate the decisive adsorption patterns were transferred to the *in vivo* well tolerable SLN. Special SLN were produced using different surfactants and the influence on plasma protein adsorption patterns was investigated by 2-D PAGE.

### 10.3

#### Production of SLN

SLN of narrow size ranges can easily be produced and coated with hydrophilic polymers, providing convenient, readily targetable systems [15, 34, 36]. In order to prepare SLN with adsorbed hydrophilic polymers onto their surface, the literature describes three main production methods. These methods are the high-pressure homogenization (HPH) technique developed by Müller and Lucks [14], the microemulsion-based SLN technique developed by Gasco [58] and the solvent emulsification-evaporation technique described by Sjöström and Bergenstahl preparing SLN dispersions by solvent evaporation in oil-in-water (o/w) emulsions [59]. However, methods such as the solvent displacement and the emulsification-diffusion techniques, which have been used to prepare polymeric nanoparticles, have also been tested for SLN preparation [60].

Production of SLN by HPH can be done using either the hot or the cold homogenization technique. For both techniques, the active compound is dissolved or dispersed in the melted lipid prior to HPH [19, 20]. Concerning the hot technique, which is the most frequently applied technique, two different phases are prepared at the same temperature – the lipid phase consisting of melted lipid mixed with drug and the aqueous phase consisting of a hot solution where the hydrophilic coating polymer or protein is dissolved. Both phases are mixed by high-speed stirring or by ultrasound breaking the large droplets of the internal lipid phase into smaller ones yielding a pre-emulsion. This pre-emulsion is then passed through a high-pressure homogenizer applying, for example, a homogenization pressure of 500 bar and one to three homogenization cycles. The obtained nanoemulsion is cooled and solidifies, forming an aqueous SLN dispersion. This technique can process lipophilic and insoluble drugs. Even temperature-sensitive compounds (e.g. retinol) can be incorporated into the SLN matrix by hot HPH once the exposure time to elevated temperatures is relatively short [19]. However, this technique is not suitable for incorporating hydrophilic drugs because they will partition from the melted lipid to the water phase during the homogenization step, resulting in a too low loading capacity.

With regard to the cold technique, the drug-containing lipid melt is cooled and solidified. Dry ice or liquid nitrogen are added to increase the brittleness of the lipid and to ease the further milling procedure. The high cooling rate favors a homogeneous distribution of the drug within the lipid matrix. After solidification, the lipidic mass is ground by means of ball or mortar milling to yield lipid microparticles with a diameter between 50 and 100  $\mu\text{m}$ . The lipid microparticles are then

dispersed in a cold surfactant solution by stirring, yielding a macro-suspension. This suspension is passed through a high-pressure homogenizer at/or below room temperature and the microparticles are broken down to form SLN. The cavitation and shear forces in the homogenization gap are sufficiently high to break the microparticles and to yield SLN. The cold HPH technique minimizes the thermal exposure of the sample, but does not avoid it completely due to the melting of the lipid in the initial step of the process. Therefore, this technique is recommended for extremely temperature-sensitive or hydrophilic drugs, which might partition from the liquid lipid phase to the water phase during hot HPH. SLN prepared by this procedure possess slightly higher mean particle sizes and polydispersity indices compared to those obtained by the hot HPH technique of the same lipid at identical homogenization parameters (pressure, temperature and number of homogenization cycles). To further reduce the mean particle size and to minimize the polydispersity, a higher number of homogenization cycles can be applied. The cold HPH technique can also be employed when the lipid matrix is composed by lipids with high melting points [61]. Note that this technique is less effective in dispersing the lipids. During the production process, the lipid matrix remains mainly in the solid state despite possible high (but extremely short) temperature peaks occurring in the high-pressure homogenizer. The homogenization can be performed slightly below the melting point of the lipid (e.g. 5–10 °C), which seems to lead to a softening of the lipid during the homogenization process. The softened lipid can be more easily dispersed, leading to a more uniform product of smaller mean SLN diameter. The homogenization temperature needs to be carefully selected because otherwise the loss of hydrophilic drugs to the water phase might be too high.

For the preparation of SLN using the microemulsion technique developed by Gasco, the lipid phase is melted and at the same temperature (approximately 60–70 °C) an o/w surfactant/cosurfactant-containing aqueous phase is prepared [58, 62]. Both lipid and aqueous phases are added, and mixed in such a ratio that a microemulsion results. SLN are obtained when the hot microemulsion is diluted into excess of cold water leading to a “breaking” of the microemulsion, converting it into an ultrafine nanoemulsion, which recrystallizes forming SLN. The reasons for the breaking of the emulsion are the dilution with water and the reduction of temperature narrowing the microemulsion region.

Regarding the preparation of SLN by solvent evaporation in o/w emulsions described by Sjöström and Bergenståh, the lipid phase is dissolved in a water-immiscible organic solvent, such as cyclohexane, chloroform or methylene chloride. Then the drug is dissolved or dispersed producing an organic phase containing the drug [63, 64]. This organic phase is emulsified in an o/w surfactant-containing aqueous phase by mechanical stirring. Upon evaporation of the organic solvent from the obtained o/w emulsion under mechanical stirring or reduced pressure, a nanoparticle dispersion is formed by precipitation of the lipid in the aqueous medium.

In the solvent displacement technique described Fessi et al. [65], the lipid phase is dissolved in a semipolar water-miscible solvent, such as ethanol, acetone or

methanol, where the active compound is also dissolved or dispersed. Simultaneously, an o/w surfactant-containing aqueous phase is prepared. The organic phase is injected into the aqueous phase under magnetic stirring. A violent spreading is observed because of the miscibility of both phases. Droplets of solvent of nanometer size are torn from the o/w interface. These droplets are rapidly stabilized by the surfactant molecules presented in the aqueous phase, until diffusion of the solvent is complete and lipid precipitation has occurred. Removal of solvent can be performed by distillation. SLN are formed after total evaporation of the water-miscible organic solvent.

With regard to the emulsification-diffusion methodology described by Quintanar-Gerrero and Fessi, this technique involves the use of a partially water-soluble solvent, such as benzyl alcohol [66] or tetrahydrofuran [67], which is saturated with water to ensure the initial thermodynamic equilibrium between those two liquids (water and solvent). The lipid is dissolved in the saturated solvent producing an organic phase where the drug is added. This organic phase is then emulsified, under vigorous agitation, in an aqueous solution containing a stabilizer agent obtaining an o/w emulsion. The subsequent addition of water to the system, under moderate mechanical stirring, causes solvent diffusion into the external phase and the lipid starts precipitating. Depending on its boiling point, the solvent can be eliminated by distillation or ultrafiltration. After the organic solvent is totally eliminated, an aqueous dispersion of SLN is formed.

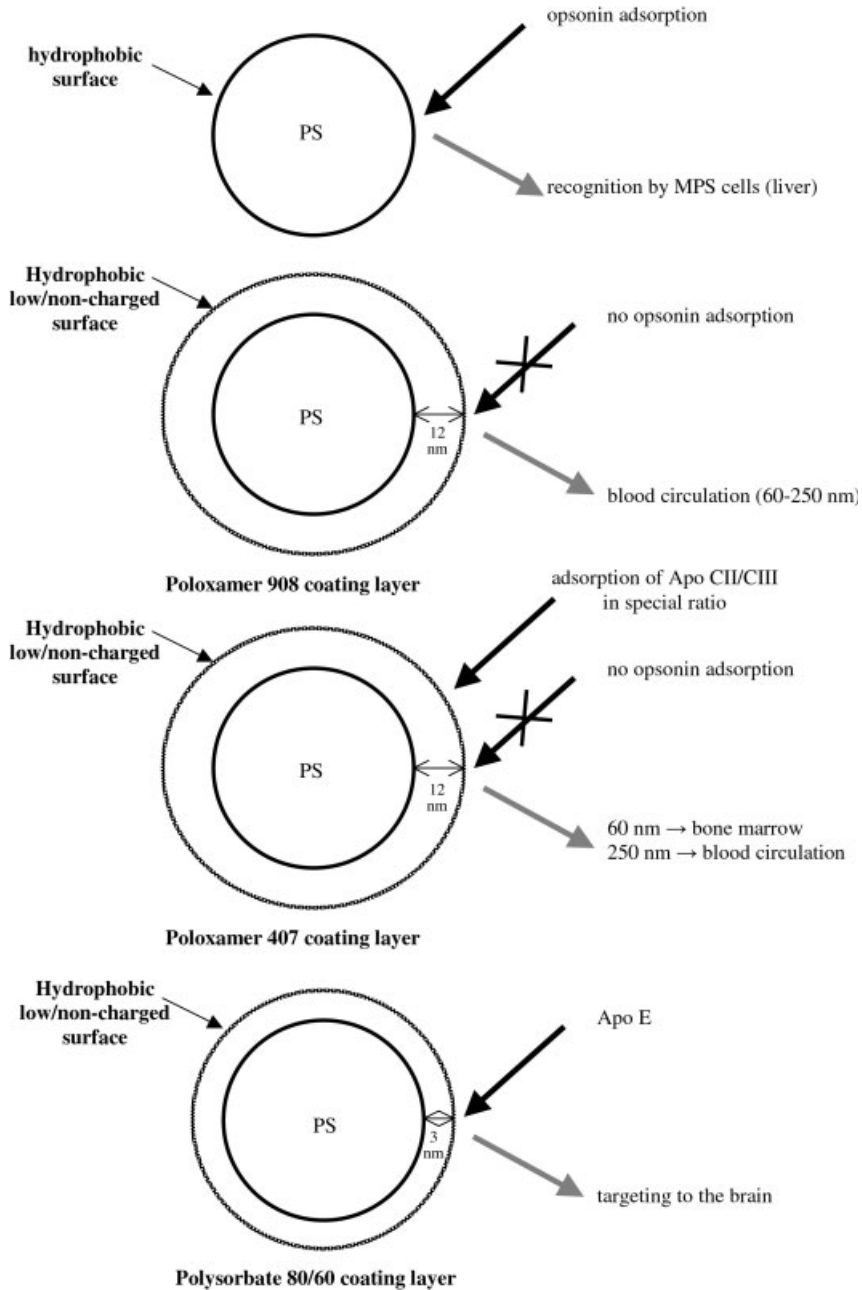

Comparing the different methodologies described above, HPH is the most broadly used in different areas and it is also established in pharmaceutical production, e.g. the production of emulsions for parenteral nutrition (Intralipid® and Lipofundin®) [17]. This technique overcomes a major problem of other methods, i.e. large scale production. HPH also leads to nanoparticles with a relatively homogeneous size distribution, which increases the physical stability of the aqueous SLN dispersion.

The microemulsion method has the disadvantage of the dilution of the particle suspension with water, which needs to be removed. However, it avoids the collapse of the hydrophilic chains coating the surface of the particles [20]. Methods requiring solvent evaporation from o/w emulsions have the inconvenience of using organic solvents. In addition, evaporation must be fast in order to avoid collapse of the hydrophilic chains and potential aggregation.

#### 10.4

##### Functionalization by Surface Modification

As already mentioned, targeting of drugs to different sites of the body via intravenous administration requires avoidance of recognition of the carrier system by macrophages of the MPS. To achieve this goal, nanoparticles were engineered by modifying the surface using nonionic surfactants such as poloxamers, poloxamines or polysorbates, reducing adsorption of proteins and blood opsonins compared to uncoated particles [68] (Fig. 10.4).

**Fig. 10.4.** Functionalization by surface modification of nanoparticles with poloxamer and polysorbate surfactants and resulting effects obtained *in vivo* (PS, polystyrene particle; PBCH, polybutylcyanoacrylate nanoparticle).

Once the phagocytic uptake is dependent on the surface hydrophilicity, i.e. it increases with the increase of hydrophilicity, it would be beneficial to have an enrichment of hydrophilic proteins (so-called dysopsonins) on the carriers' surface [69–71]. Such dysopsonins are, for example, albumin and apolipoproteins. Apolipoproteins are inherently adsorbed onto the surface of hydrophobic lipids such as triacylglycerols, cholesterol and cholesterol esters, forming lipoproteins in the blood. They show a relatively flexible molecular structure, which is able to change its conformation when adsorbing onto surfaces (“soft proteins”) [72]. This ability of changing its multiple  $\alpha$ -helical segments in the interface in contact to water is the crucial property of these proteins for the efficient removal of nonpolar residues. Therefore, it has been anticipated that apolipoproteins would have a great affinity to SLN as well, because these particles also have a lipid core like lipoproteins. Indeed, a 5-min incubation of different SLN formulations with human plasma at 37 °C and subsequent 2-D PAGE analysis revealed apolipoprotein adsorption of up to 90% of the total amount of proteins adsorbed.

Figure 10.5 shows the plasma protein adsorption patterns obtained after 2-D PAGE analysis (2-D PAGE separation and subsequent silver staining) of cetyl palmitate-based SLN (10% m/m), stabilized with polysorbate 60 (PS60-SLN) and stabilized with poloxamer 338 (1.2% m/m) (PX338-SLN).

The adsorption patterns did not differ greatly with regard to the qualitative aspects of the adsorbed proteins. However, the apolipoproteins showed particularly distinct quantitative changes in the adsorbed amounts, showing the importance of the surfactant used for production of functionalized SLN.

**Fig. 10.5.** Plasma protein adsorption patterns of PS60-SLN (left) and PX338-SLN (right) obtained after 2-D PAGE separation and silver staining. The whole 2-D gels are shown;  $pI$  4.0–9.0 (from left to right, non-linear) molecular weight 250–60 000 Da (top to bottom, non-linear); 1, albumin; 2, IgM  $\mu$

chain; 3, fibrinogen  $\alpha$  chain; 4, fibrinogen  $\beta$  chain; 5, fibrinogen  $\gamma$  chain; 6, apoH; 7,  $\alpha_1$ -antitrypsin; 8, apoA-IV; 9, apoJ; 10, apoE; 11, apoA-I; 12, transthyretin; 13, apoC-III; 14, apoC-II; 15, apoA-II; 16, haptoglobin  $\beta$  chain. (With permission after Ref. [46].)

Interestingly, apoE, which is hardly detectable on 2-D PAGE gels of human plasma, was enriched on the PS60-SLN (Fig. 10.5, left, spot 10), whereas no apoE could be detected on the PX338-SLN. ApoE was also adsorbed onto SLN surface, stabilized by polysorbate 20, 40 and 80 (in similar amounts). This result is in agreement with the findings documented by Müller et al., who investigated the brain specificity of PBCA nanoparticles coated with polysorbates and the lack of brain specificity of PBCA nanoparticles coated with poloxamers (e.g. poloxamer 338) [54].

The spot intensity was evaluated using special software from Bio-Rad (MELANIE III). For data evaluation it has to be taken into account that the silver-staining density is characteristic for each protein [73]. A quantitative comparison between identical protein types on different 2-D PAGE gels is valid, but not between different protein types on an identical gel. Therefore, quantitative 2-D PAGE data assessment is called "semi-quantitative". Nevertheless, it can be used for a reliable approximation of the amount of protein adsorbed.

Typical opsonins, such as immunoglobulins or complement factors, were not detected or were detected in a very low amount (below 5%) on both types of SLN. However, it must be pointed out that PX338-SLN shows higher quantities of fibrinogen adsorbed onto their surface, which has an opsonic function. However, apolipoproteins dominate the protein adsorption patterns (about 86% on PS60-SLN and about 70% on PX338-SLN). From these results, it can be concluded that both SLN types should have the potential to circulate in the blood stream for a prolonged time; in particular, PS60-SLN should be able to target drugs to the brain. The first results of *in vivo* experiments conducted with Nile Red-labeled PS60-SLN indeed nicely showed adherence of particles to the endothelial cells of the brain vessels [74, 75]. Pictures obtained by confocal laser scanning microscopy of the mouse brain tissue showed the particles adhering to the endothelium of the brain vessels, as well as the dye diffusing into the brain tissue. See Fig. 10.6.

Studying a full range of different poloxamer polymers as stabilizers for different SLN formulations revealed that apoE was preferentially adsorbed on the surface of SLN which were stabilized with a poloxamer having a low number of polyethylene oxide (PEO) units. There was an exponential relationship between adsorbed apoE and the PEO chain length, showing highest adsorption of apoE when using poloxamer 184 and poloxamer 235 [76]. These results are in good agreement with the apoE values obtained by Blunk [77] with o/w emulsions (20% w/w soya oil) stabilized with the respective poloxamers (2.5% w/w). Again, highest apoE adsorption occurred when using polymers with short PEO blocks in the molecule.

On cetyl palmitate SLN stabilized with egg lecithin, apoE was enriched up to 5% on their surface [78]. Recently, interesting accumulations in the brain were reported after intravenous injection of SLN with camptothecin [34], paclitaxel [79] and 3',5'-dioctanoyl-5-fluoro-2'-deoxyuridine [15]. All of these workgroups used lecithin as a stabilizer among other surfactants. From this, it can be assumed that apoE was also enriched on the surface of these SLN, leading to their uptake into the endothelial cells of the BBB.

According to these observations, it can be assumed that SLN are suitable car-

**Fig. 10.6.** Semiquantitative plasma protein composition on PS60-SLN and PX338-SLN expressed in percent (percentage of the overall detected protein pattern); error bars represent the standard deviation ( $n = 2$ ). (With permission after Ref. [46].)

riers, especially when stabilized with polysorbates, to be biofunctionalized with apoE in the blood to have a high potential to deliver drugs to the brain.

## 10.5

### Conclusions

Over recent decades, significant efforts have been made towards the surface modification of various polymeric drug carriers with PEG, not only to improve their biocompatibility and blood circulation times, but also to resist protein adsorption and to increase target cell uptake efficiency.

The surface characteristics of intravenously administered particulate drug carriers decisively influence the protein adsorption, which is regarded as a key factor for the *in vivo* fate of the carriers. It has already been shown that immobilization of PEG on nanoparticles reduces uptake by MPS cells and subsequently increases the amount of nanoparticle uptake into cancer cells in comparison to unmodified nanoparticles. For brain-targeting, substances such as the hexapeptide dalargin, loperamide and doxorubicin have been adsorbed into coated polymeric nanoparticles with a surfactant. In order to reduce toxicological problems of polymeric nanoparticles, biodegradable lipid nanoparticles such SLN can be used. This chapter has given a brief review of the state of the art of biofunctionalized SLN, as well as a brief description of the main production methods of these carriers. *In vivo* data

about achievements in targeting with SLN are summarized. The results obtained with lipid nanoparticles systems are quite promising for further developments in this research field.

## 11 Biocompatible Nanoparticulate Systems for Tumor Diagnosis and Therapy

*Mostafa Sadoqi, Sunil Kumar, Cesar Lau-Cam and Vishal Saxena*

### 11.1

#### Introduction

Nanotechnology is the development and engineering of materials, devices and systems so small that they can be measured on a molecular scale. This emerging technological field has received considerable attention in the past two decades due to its numerous medical, pharmaceutical, environmental and military applications.

The development of nanoparticles and nanodevices capable of navigating in the bloodstream and of reaching specific destinations remains an attractive and most desirable biomedical endeavor since, for example, it can provide the clinician with an effective and powerful means for detecting and/or treating pathological abnormalities such as solid tumors. Ideally, a nanodevice suitable for diagnostic and therapeutic use should exhibit good physical stability within the biological environment it needs to travel, be fully biocompatible, and show high affinity and selectivity for its final target.

One possible way of maximizing the clinical capabilities of nanodevices is to combine nanotechnology with photonics [1]. For this purpose, nanoparticles carrying a suitable photoexcitable molecule are converted *in situ*, under the activating influence of laser radiation, to a chemical form that will make a tumor more sensitive to the action of conventional chemotherapeutic agents or emit a spectral signal with an output that can be electronically manipulated to provide information on the presence of pathological growth.

This chapter offers an overview of the different methodological approaches that can be used for the fabrication of nanoparticulate systems for medical purposes, of the ways these devices can sense changes within specific biological surroundings and of the medical applications that can be derived from the interaction of loaded nanoparticles within biological matter with laser radiation, particularly as it relates to the imaging and therapy of tumors.

Particular attention will be given to the near-infrared dye (NIR) indocyanine green (ICG), and to the potential of this dye for tumor diagnosis and therapy when administered encapsulated within polymeric nanoparticulate systems. ICG was found to be free of perceptible toxicity, to exhibit good chemical stability within polymeric nanoparticles, to be appreciably taken up by tumor cells following its

delivery as a nanoparticulate formulation and to cause singlet oxygen-induced oxidative damage in target cells when photoexcited. A discussion of the benefits of photodynamic therapy (PDT) with ICG as a means of eradicating unwanted abnormal growths such as tumors will also be presented.

## 11.2

### **Nanoscale Particulate Systems and their Building Blocks/Components**

Nanoscale particulate systems are 100 to 100 000 times smaller than human cells and hair. At present, a vast choice of sensing devices are commercially available for detecting and measuring specific bacteria or hazardous chemicals, for checking acidity levels and for monitoring changes in biological and nonbiological environments. In nanomedicine, nanoscale systems can easily enter most types of cells and can move undisturbed out of blood vessels as they circulate through the body. Furthermore, biomedical nanoscale systems can interact with surface and intracellular biomolecules, can make their way into tissues through capillaries, can get through fenestrations present in epithelial linings such as those of the liver and can diffuse through the blood–brain barrier (BBB) by following openings created at tight junctions by a hyperosmotic mannitol solution [2]. As a result, they can be used to efficiently deliver both low-molecular-weight compounds, such as drugs, and macromolecules such as proteins, peptides and genes, to tissues of interest by either localized or targeted delivery.

In recent years, a great deal of effort has been devoted to the application of nanotechnology to drug delivery, molecular imaging, the assessment of therapeutic efficacy, targeted and multifunctional therapeutics, and the early detection, prevention and control of cancer. Some of the nanoparticulate formulations that have been developed for the delivery of therapeutic agents in a biocompatible form have included nanoparticles, nanocapsules (nanoshells), polymeric micellar systems, buckyballs, nanotubes, dendrimers, quantum dots and immunoconjugates.

Although this chapter will address a select few nanoscale systems, emphasis will be placed on nanoparticle systems of the type developed in our laboratory, since experiments conducted in this laboratory have been focused on the use of nanoparticles to deliver photoexcitable molecules to normal and cancer cells, allowing the study of the interaction of light with the incorporated nanoparticulates in real time and during the earliest stages of the cancer process [3]. In this way, it has been possible to determine that nanoparticles can be used to detect cancer even when the process is still limited to a few cells and that they have the potential as a better alternative to therapy with conventional drug formulations since they can reduce or even eliminate drug side-effects.

#### 11.2.1

##### **Dendrimers**

Dendrimers are a large and complex group of highly branched polymerized macromolecules with well-defined chemical structures and exhibiting monodispersity,

i.e. having the same structure, composition and molecular weight. The three major architectural components of a dendrimer are the core, branches and end groups of the precursor monomeric units. The core is usually an amine, although ammonia, sugars and other molecules can also be used. Regardless of the type of constitutive molecule present, the core exhibits multiple and identical reaction sites. The dendrimer can start with a few branches of atoms, usually three or four, radiating from a central core, with a branch point occurring every six atoms. At each branch point, the current chain of atoms becomes two chains of atoms. As a result, a structure resembling a tree with numerous branches is formed.

In general, a dendrimer consists of layers or shells of branches, each one known as a generation (G), built around a small core molecule. As the number of generations increases to G4, the regular and highly branched architecture of a dendrimer starts to develop into a sphere, whose preferred three-dimensional structure starts to become apparent by G5. Synthetic procedures available for the fabrication of dendrimers allow for the nearly complete control of critical molecular parameters such as size, shape, interior/surface chemistry, flexibility and topology, as well as for a very easy control of the chemical composition and reactivity. Manufacture of cone-shaped, spherical or disk-like dendrimers with a size in the range of 2–12 nm is possible.

The synthesis of a dendrimer is a stepwise iterative process. In its most basic form, it is started by reacting all of the reactive groups of the core molecule with an excess of a monomeric building unit possessing different reactive groups on each end. Reaction of one end of this monomer with the core will produce the first set of branches and reaction of the second end with a different type of monomer, also having two different reactive groups at each end, will generate a second set of branches. At this point, the first shell and the first generation of the dendrimer are complete. The unreacted ends of the first shell will serve as the starting point for new branching and for the next shell.

The two main techniques for the synthesis of dendrimers with a unique combination of properties are the Starburst divergent method [4, 5] and the convergent growth method [6], but a self-assembly method [7] has also been developed. In the divergent method, the dendrimer is started from the periphery (i.e. the tips of the branches) and made to grow inwards. Two of the end tips are connected to a branched monomer to form a dendron (or dendrimer segment) and the process is repeated until a desired size is achieved. In the final step, the interconnected branches are attached to a core molecule. Since the growing dendrimer is undergoing multiple simultaneous reactions, the final product may lack uniformity. Building a dendrimer by a convergent approach requires the same number of steps as by the divergent approach, but starting with a central initiator core around which dendrimer segments are assembled. More importantly, since only two reactions take place at each step of the growing process, the resulting final product is of a high purity.

The self-assembly method, first studied with surfactant molecules in aqueous media, is now being applied to water-soluble dendrimeric polymers and their supra-molecular analogs. Taking advantage of the abundance of surface active end groups on dendrimers, nanoparticulate aggregates having micellar properties can be made

to form from dendrimers at an interface. In turn, these unimolecular micelles can serve as hosts for hydrophobic molecules to enhance solubility in water with an efficiency than may exceed that derived from a conventional surfactant such as sodium dodecylsulfate [8]. By reacting the amino end groups of poly(propylene imine) with various aliphatic acid chlorides it was possible to prepare a series of nonaggregating inverted unimolecular dendritic micelles with a compact hydrophobic shell, a hydrophilic interior and high generation numbers ( $n \geq 4$ ). In contrast to normal micelles, these inverted unimolecular micelles were able to bind hydrophilic molecules in the interior and to solubilize the guest molecule in apolar solvents.

Dendrimers have been more commonly synthesized from polymers such as poly(amidoamine) (PAMAM dendrimers) by a divergent method initiated by ammonia or ethylenediamine as a core or from poly(propylene imine) (PPI dendrimers) by a divergent method initiated by a core of 1,4-diaminobutane, but poly(aminoalcohol), cyclotriphosphazene and phenylacetylene have also been used.

Due to the large number of active chemical groups located at the surface of each generation and to their well-defined chemical structure, dendrimers are good candidates for creating biomedically useful nanodevices. While suitable modifications of the surface properties of dendrimers will allow them to be made electrically charged into a polyelectrolyte or to be linked to biological agents, their cavities can serve as depots or be used as pumping devices for small guest molecules such as organic dyes, drugs and metal clusters [9]. In this respect, a most interesting departure from a conventional dendrimer is the so-called “core dendrimer”, which is synthesized by crosslinking the peripheral groups of the dendrimer and then removing the core by hydrolysis [10].

From a technical and commercial standpoint, some of the most interesting applications of dendrimers are in the pharmaceutical and biomedical fields. For example, sufficient flexibility exists to create dendrimers that are either biologically active or inert and of a sufficiently small size that will permit their entry into cells to deliver drugs, genetic material and organic and inorganic chemical markers without triggering an immune response. In addition, dendrimers can be used to deliver diagnostic and chemotherapeutic agents to target sites for the diagnosis, treatment and eradication of malignant tumors. Medical researchers envision that one day tecto-dendrimers will be used to carry out a five-step task when diagnosing and treating tumors: (a) the search of tumor cells throughout the body, (b) the binding to receptors on tumor cells, (c) the entry into tumor cells upon crossing the cell membranes, (d) the release of chemotherapeutic or radioactive agents inside the tumor cell and (e) the confirmation of the presence, location or death of tumor cells through the use of appropriate medical devices.

### 11.2.2

#### **Buckyballs and Buckytubes**

Buckyballs, also known as  $C_{60}$ , buckminsterfullerenes or fullerenes, are clusters of up to 60 carbon atoms arranged in a series of interlocking hexagons and pentagons to form a structure resembling a soccer ball [11]. In actuality,  $C_{60}$  is a “truncated

icosahedron" consisting of 20 hexagons and 12 pentagons. Buckyballs can be easily manufactured in quantity by heating graphite rods to a high temperature and passing an electric current between them. The crystals of  $C_{60}$  are separated from other carbon compounds, especially  $C_{70}$ , found in the soot fraction. It is the only molecule known to mankind to be composed of a single element and to exist in the form of a hollow spheroid. Possible ways of utilizing a buckyball for biomedical purposes would be to use its spherical structure to carry molecules with diagnostic or therapeutic value in the body after they have been added to its outer surface through chemical reaction or introduced into its cage-like interior. As a delivery system, buckyballs appear well suited because of their nanometer size, and perfectly smooth surface and round shape. In addition, they are inert, nontoxic and, due to their small size, capable of interacting with cells, proteins, and viruses.

Buckytubes, variously designated as nanotubes (NTs) or carbon nanotubes, are molecular-scale nanomaterials of pure carbon that have been prepared in a relatively efficient way by the laser vaporization of graphite in the presence of cobalt nickel catalyst in a furnace at 1200 °C. In this way, a product that can be thought of as a sheet of graphite rolled into a single-wall seamless cylinder and closed at both ends by hemispherical endcaps (SWNTs) can be obtained. In the absence of a catalyst, a group of graphite layers will coil around each other to produce a multi-wall cylinder (MWNTs). Their diameter is in nanometers, their length up to a few millimeters and, depending on their helicity, they can be either electrically conductive (metallic) or semiconductive. In addition to their unusually high strength, buckytubes are light, flexible, with good thermal stability, chemically inert, and have extraordinary electrical conductivity, heat conductivity and mechanical properties. Given their high electrical conductivity and sharpness of their tips, buckytubes are unsurpassed as field emitters, especially at low voltage, and can carry as much as  $10^{13}$  A  $cm^{-2}$  [12].

A demonstration that single-wall buckyballs absorb light and emit it at a single wavelength in the NIR spectrum has opened the door to a new field of potential biomedically related applications for these materials [13]. For the fluorescence to be measurable, however, the buckytubes must be isolated from one another since aggregation into bundles quenches fluorescence and considerably broadens the absorption spectra due to intertube energy transfer from the semiconducting to the metallic nanotubes within each bundle [14], followed by rapid nonradiative carrier cooling in the metallic nanotubes [15]. Time-resolved spectroscopy of these buckyball bundles reveals extremely rapid excited state relaxation [14, 15].

As a result of their small size that allows them to migrate through cell walls, buckyballs could be used as optical biosensors for seeking out specific targets within the body such as tumor cells or inflamed tissues. To increase their specificity toward their targets, buckyballs could be wrapped with proteins that will serve as ligands for surface receptors on target cells. Covalently linked adducts of SWNTs with biomolecules such as biotin or DNA have great potential in biosensing and as a possible means of implementing nanoscale assembly onto selected locations on a surface [16]. By combining buckytubes of a different diameter size one could simultaneously study different target cells. A most promising application of bucky-

tubes has been the imaging of cells. SWNTs were found to be actively ingested by macrophages suspended on a growth medium through phagocytosis and to be held in phagosomes within the macrophages. Cell viability was not affected by the buckytubes and the intracellular fluorescence remained detectable in the harsh oxidizing environment of the phagosomes. These results suggest that the high-contrast NIR detection of SWNTs can lead to valuable methods for tracing the interactions of buckytubes with organisms, and may form the basis for future families of biological contrast agents and fluorescent markers.

On account of the natural fluorescence of SWNTs, and the transparency of human tissues and biological fluids in the NIR region of the spectrum, buckyballs wrapped with a molecular sheath that responds to a particular biological molecule and modulates the optical properties of the buckyball can be constructed. Based on this model, a sensor for tracking blood glucose in diabetics was built by organizing a monolayer of the enzyme glucose oxidase on the surface of SWNTs suspended in water. Reaction of glucose with the enzyme generates hydrogen peroxide which, when exposed to ferricyanide ions, increases the fluorescence emission of the sensor in direct proportion to the concentration of glucose present [17]. In view of their high resistance to degradation, it could be possible to construct buckyballs for implantation into thick tissues or biological fluids for long-term monitoring of specific body components.

### 11.2.3

#### **Quantum Dots**

Quantum dots, also known as nanocrystals, are tiny semiconducting inorganic crystals with unique quantum properties, typically between a nanometer and a few microns in size, and containing from one to several thousand free electrons. The size and the shape of these structures and, hence, the number of electrons they contain, can be precisely controlled. Quantum effects arise from the confinement of electrons and “holes” (an electronless region that behaves as if it were a positively charged particle) in the material. The small size also leads to changes in the electrical and nonlinear optical properties of a material relative to its bulk form. They are made of silicon, germanium, lead, zinc and cadmium salts – materials that can absorb white light and reemit it a couple of nanoseconds later at a higher frequency. The type and intensity of the color is dependent on the size of the crystal. For example, the larger the dot, the redder the light; but as the size shrinks, the wavelength of emission becomes shorter and moves toward the blue or green. Hence, a gamut of colors can be obtained by a simple change in the size of the dot. Moreover, when excited, the smaller the dot the higher the energy and intensity of the emitted light.

These particles represent a convenient alternative to fluorescent dyes in a variety of analytical, biological and biomedical applications since their emitting radiation can be measured over the entire visible spectrum, they have a broader excitation spectrum, and their fluorescence is extremely stable over time. On these bases, a mixture of quantum dots of different sizes can be excited by a light source with a

single wavelength, allowing simultaneous detection and imaging of different biological molecules simultaneously within living organisms. In contrast, the use of more than one organic dye to accomplish the same purpose might meet with difficulties since their spectra may overlap with each other because each dye emits light over a wide range of wavelengths.

The utility of quantum dot nanomaterials as a result of their optoelectronic properties can be further expanded not only by changing their size and composition, but also by incorporating them into a wide variety of polymers and material forms that will make them stable in water. Core quantum dots with fewer surface defects, improved physical stability and enhanced fluorescence brightness are already commercially available. Quantum dots represent a powerful new approach to genetic analysis, disease diagnosis and the monitoring of cell responses to certain drugs or viruses [18, 19]. However, their application to the detection of tumors, in particular, and of cancer, in general, remains to be realized because of their intrinsic toxicity and lack of biocompatibility.

#### 11.2.4

##### **Polymeric Micelles**

Polymeric micelles are a viable form of targeted delivery system for water-insoluble and amphiphilic drugs [20, 21]. Like surfactant-based micelles, polymeric micelles are core/shell structures; however, unlike their traditional counterparts, they are physically more stable and capable of solubilizing substantial amounts of hydrophobic compounds within their inner core. Due to their hydrophilic shell and small size they may prolong the circulation of drugs in body fluids and increase drug accumulation in tissues [20]. The shell is responsible for micelle stabilization and interaction with plasma proteins and cell membranes. The hydrophobic core, usually made from a biodegradable polymer, serves as a reservoir for an insoluble drug and shields the drug from the aqueous surroundings. Polymers used for fabricating polymeric micelles have included pluronics, polyethylene glycol (PEG)-lipid conjugates and pH-sensitive poly(*N*-isopropylacrylamide)-based micelles or polyion complex micelles.

Polymeric micelles have also been used for encapsulating and delivering photosensitizing drugs and dyes. However, the biodistribution characteristics of the polymeric micelle formulations thus far investigated have not been entirely satisfactory. For example, greater selectivity and effectiveness could be gained by introducing targeting ligands and site-controlled releasing capabilities, respectively, and excessive nanoparticulate accumulation and long-term toxic effects could be reduced by utilizing biodegradable polymers with good clearance properties.

#### 11.2.5

##### **Liposomes**

A liposome is a spherical vesicle of colloidal dimensions composed of one or more lipid or phospholipid bilayers. The size of liposomes varies from 20 nm to 100 μm,

although each lipid bilayer is about 4 nm thick. Various amphipathic molecules have been used to fabricate liposomes, especially lecithins from natural or synthetic sources. To increase mechanical stability and decrease the leakage of the contents, charged phospholipids like phosphatidylserine or phosphatidylglycerol and cholesterol can be added. Depending on its physicochemical characteristics, a drug can become trapped in the aqueous space, intercalated or dissolved within the lipid bilayer, or form ionic or hydrophobic complexes with nucleic acids and other macromolecules without physical entrapment [22]. For medical use, a liposome suspension must be precisely defined with respect to drug and lipid concentrations, size distribution, percentage of entrapped drug, pH, osmolarity, conductivity, and presence of degradation products. Specific methods exist to manufacture liposomes of a particular size, morphology and surface characteristics, parameters that together will determine the biologic fate of the liposomes [22].

Due to similarities in both structure and chemical composition to biomembranes, liposomes have been extensively investigated as carriers for enhancing the incorporation of an assortment of drug molecules into target cells [23, 24]. Through the use of liposomes one can achieve a variety of therapeutic goals, including enhanced drug uptake and reduced toxicity. Numerous studies have been conducted on the use of liposomes to deliver chemotherapeutics to tumor cells; however, in spite of some impressive results in animal models, acceptance of liposomes as a drug delivery system for human use has only been realized in a very few instances. In addition to a relatively high cost, additional shortcomings associated with this form of drug delivery are short residency time in the circulation due to rapid removal by phagocytic cells of the reticuloendothelial system (RES), physical and chemical instability on storage, and the lack of generally uniform and applicable techniques for their production on a commercial scale [23, 24].

Conventional liposomes are unstable *in vivo* and show little or no affinity towards tumors. These shortcomings have served as the impetus for the development of more complex liposomal preparations where the surface and/or composition of the structural components have undergone chemical modification. Moreover, in the case of conventional liposomes a significant fraction of the injected dose ends up in organs rich in phagocytic (monocytes, macrophages, Kupffer) cells such as the liver and spleen, which eventually sequester and, thus, reduce the amount of drug that is available for antitumor action. To counteract this situation, liposomal surfaces have been variously modified to limit irrelevant recognition and reduce the uptake of the liposomes into cells of the immune system, thus extending the half-life of drugs in the circulation. Alternatively, these liposomes can be targeted to cells expressing specific receptors by equipping them with specific surface ligands. This delivery modality has been successfully used to provide selective binding and enhanced entry into tumor cells of liposomes loaded with a photosensitizer for PDT purposes and bearing surface tumortropics with the ability to recognize specific target molecules expressed on tumor cell membranes [23, 24].

Through a combination of polymer physics, organic chemistry, biochemistry, pharmacology, ecology and anatomy, sterically stable (“stealth”) liposomes have been developed. This type of lipid-based particles is represented by polymorphic

liposomes designed to change their structure in response to a particular signal such as a change in temperature or pH in the presence of specific molecules. These reactive liposomes can be made to fuse or increase in permeability, or triggered to disintegrate to release their contents upon arrival to the target site. An important breakthrough in chemotherapy with stealth liposomes is the substantial improvement in longevity that is observed in biological systems. This stability arises from the sterile nature of the surface polymer, which limits the clearance of the liposomes from the circulation by opsonization and subsequent macrophage uptake, and by disintegration upon interactions with plasma proteins and lipoproteins. Commercial stealth liposomes of doxorubicin and daunorubicin have received approval by the FDA for the parenteral treatment of Kaposi's sarcoma and solid tumors. Apart from drugs, liposomes can be made to carry a significant load of signal molecules such as dyes, radionuclides or contrast agents for *in vitro* and *in vivo* diagnostic work.

### 11.3

#### Biodegradable Nanoparticles

In recent years, polymeric nanoparticles have received recognition as a promising type of colloidal drug carrier [25]. They have been widely used for controlled drug delivery by the intravenous, ocular and oral routes of administration. An additional positive feature of this form of drug delivery is that they have shown potential as a carrier for anticancer agents. It has been verified that the tissue distribution characteristics, specificity and pharmacokinetic properties of anticancer drugs can be better controlled upon their incorporation into nanoparticles [26, 27]. Furthermore this form of drug delivery may contribute to reducing the side-effects and toxicity normally associated with anticancer drugs, while increasing therapeutic efficacy, and can lead to drug accumulation in the solid tumor since they have been found to escape from the vasculature through the leaky endothelial tissue that surrounds a solid tumor [28, 29].

Nanoparticles can overcome the multidrug-resistance phenotype mediated by P-glycoprotein and bring about an increase in drug content inside neoplastic cells [30]. This finding is of special significance for patients with cancer undergoing treatment with paclitaxel and who, after some time, develop resistance to the drug [31]. Other important advantages derived from the use of nanoparticles include the ease of their preparation, the availability of well-defined biodegradable polymers for their manufacturing [e.g. poly(D,L-lactide-co-glycolide) (PLGA)], and their high stability in biological fluids and during storage [32]. Moreover, nanoparticles can permeate cells and tissues to become internalized and can efficiently deliver a particular drug to its target tissue without clogging the capillaries [33].

The ability of nanoparticles to improve drug diffusion through biological barriers is particularly useful for the delivery of biomarkers and photodynamic agents to the brain without the need for preliminary pharmacological intervention to overcome the BBB [34]. Some studies on nanoparticle-bound antitumor agents have in-

licated that nanoparticles can prolong the retention of the drug by tumors, reduce tumor growth and prolong the survival of tumor-bearing animals [30, 35–37].

### 11.3.1

#### Preparation of Nanoparticles

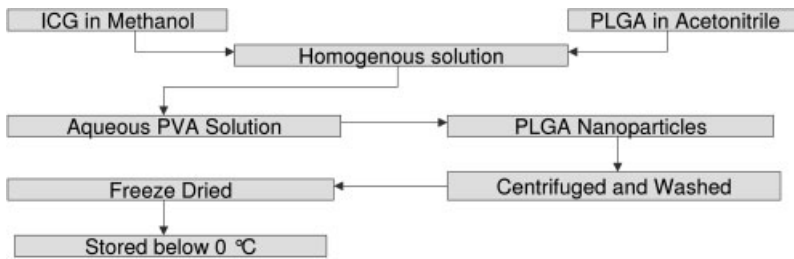

Several synthetic and natural polymers have been described for the manufacturing of biodegradable nanoparticles [38]. One advantage of synthetic polymers over natural ones is that they can yield nanoparticles with the ability to sustain the release of the encapsulated therapeutic agent over longer periods of times (days to several weeks). However, the use of synthetic polymers in nanoparticle technology is limited by the need to use often toxic organic solvents and relatively harsh formulation conditions. Synthetic polymers for formulating nanoparticles have included polylactic acid and its copolymerization with glycolic acid (PLGA), polyacrylates and polycaprolactones.

Among natural polymers, albumin, gelatin, alginate, collagen and chitosan have been evaluated [38]. Of these polymers, polylactides (PLA) and PLGA are the ones most extensively investigated for achieving controlled release of conventional drug molecules, peptides and proteins. PLGA is the most common choice in pharmaceutical formulations probably because of its good biocompatibility and biodegradability and of its approval by the FDA for use in humans [39]. These polyesters undergo hydrolysis upon implantation in body tissues to biologically compatible and metabolizable moieties (e.g. lactic acid and glycolic acid) that are eventually removed from the body by the citric acid cycle.

In addition, since the biodegradation products are formed at a very slow rate, they appear not to interfere with normal cell functions to a significant extent. Extensive testing for toxicity and safety in laboratory animals has found these polymers to be safe, and, thus, suited for use in humans as contraceptive implants [40, 41], graft materials for artificial organs and, more recently, as supporting scaffolds in tissue engineering research [42–44].

Some of the methods described for the preparation of nanoparticles from preformed biodegradable polymers are solvent evaporation [45], salting out [46], nanoprecipitation [47], extrusion [48], spray drying [49] and supercritical fluid extraction [50].

The most popular method of making nanoparticles is the emulsification-solvent evaporation method, also known as the solvent displacement techniques [51–53]. This methodological approach, schematically shown in Fig. 11.1, usually involves the following major steps: (a) emulsification of a water-immiscible organic solution of the polymer and an organic or inorganic material of interest with an aqueous phase containing stabilizers, (b) stabilization of the particles by chemical crosslinking or by heat, (c) evaporation of the organic solvent to precipitate the encapsulating polymer as nanoparticles, and (d) isolation of the nanoparticles by filtration or centrifugation [54]. This method is suitable for hydrophilic drugs since the drug dissolves in the inner water phase of the double emulsion. In most cases, a stabilizer is added to the formulation to stabilize the emulsion formed during particle

**Fig. 11.1.** Flow diagram of the manufacturing of ICG-loaded PLGA nanoparticles by a modified spontaneous emulsification-solvent diffusion method.

preparation. In this method, the type and concentration of the stabilizer may exert a modifying effect on the properties of the particles being formed. By occupying the boundary between the aqueous and organic phases, the stabilizer can become incorporated onto the surface of the forming particles and, in this way, influence particle properties such as the  $\zeta$  potential and mucoadhesion [55, 56]. In turn, these physicochemical parameters can modify the physical stability of the formulation as well as certain biopharmaceutical properties such as drug release rate, biodistribution and cellular uptake. Although polyvinyl alcohol (PVA) is the stabilizer most often used for the production of PLGA nanoparticles, other available choices are cellulose derivatives such as methylcellulose, hydroxyethylcellulose and hydroxypropylcellulose, gelatin types A and B, carbomer, and poloxamer [57].

One way to construct nanoparticles with long circulating characteristics is to modify their surface with the hydrophilic, flexible and nonionic polymer, PEG [58–60]. The resulting PEG-coated nanoparticles have shown good potential as a biodegradable colloidal type of formulation for the delivery of therapeutic agents to specific sites.

## 11.4

### Biodegradable Optical Nanoparticles

#### 11.4.1

##### Optical Nanoparticles as a Potential Technology for Tumor Diagnosis

Solid tumors and other forms of cancer are commonly localized inside the body by screening diagnostic methods based on imaging techniques or radiology [61–64]. Images of internal parts of the human body can be obtained by using X-rays (tomography, scan or mammography), a powerful magnetic field (magnetic resonance imaging), radioactive isotopes (nuclear scan or radionuclide imaging) and high-frequency sound waves (ultrasound) [65–68]. Examples of nuclear scanning include single-photon emission computed tomography (SPECT) and positron emission tomography (PET) scans. There are also diagnostic methods whose use

is determined by the location of the cancer (e.g. endoscopy for cancers in body openings like the mouth, anus or urethra, tests for measuring estrogen and progesterone receptors in suspected cases of breast cancer, and the Pap smear test for detecting cancers of the cervix and vagina) [69–74]. Once a tumor has been detected in the body by any of the aforementioned screening techniques, confirmatory evidence is gathered by histopathological examination of a tissue sample obtained by biopsy of the suspected area. In spite of their widespread use, these forms of tumor diagnosis suffer from serious limitations. For example, there is a strong safety concern attached to the use of harmful radioactive substances and X-rays, both of which are in themselves risk factors for cancer. Furthermore, harmful adverse reactions may develop from the use of contrast agents, the test may not be sensitive enough to detect very small tumors and the diagnostic procedure may be expensive in comparison to other laboratory medicine procedures.

Nanoparticles loaded with photosensitizer molecules can be an alternative method for tumor diagnosis as well as for drug delivery purposes. Their ability to be readily detected, to show selectivity, and to be easily transported through the blood stream is inherent to the nature of the dye, the specific agent linked to the particulate system (e.g. antibodies) and the physical as well as chemical structure of the polymer used. Nanoparticulate systems have the means to detect the cancer at an early stage and they have the potential as a better alternative to therapy with conventional drug formulations since they can greatly minimize drug side-effects.

#### 11.4.2

#### **Optical Nanoparticles as a Potential Technology for Tumor Treatment**

After detection of a tumor, its treatment usually relies on chemotherapy with specific anticancer agents to ensure that the cancer cells have not metastasized to the other parts of the body [75–83], localized radiation therapy with ionizing radiation such as X-rays and  $\gamma$ -rays [84–87], biologic therapy based on the defense provided by the body's immune system [88–108], and invasive approaches for localized cancer such as surgery [109–111]. Although effective and beneficial, these therapeutic approaches are surrounded by certain drawbacks, among which the main ones are intrinsic toxicity, serious side-effects and damage to healthy tissues by the radiotherapy itself. Consequently, there is a pressing need for simpler, safer, noninvasive imaging systems and technologies than those currently available, offering the required selectivity to detect and/or destroy a tumor while sparing the surrounding areas. At the same time there is also a need for developing diagnostic and therapeutic systems and technologies based on the use of agents that are nontoxic, not requiring systemic distribution or capable of obviating the use of harmful radiation, particularly as it relates to tumors of the skin and breast.

As stated earlier, a nanoparticulate system encapsulating a dye that can be photoexcited to produce singlet oxygen will be a better system for tumor detection and therapy than conventional approaches. The uptake of these nanoparticles by tumor cells can serve as an optical indicator of the presence of the tumor, and can be used

to trigger a laser system for oxidizing and, thus, eradicating tumors or unwanted tissues from the body in a noninvasive manner. Based on these considerations, we have developed nanoparticles loaded with ICG, a photoexcitable molecule with NIR fluorescence properties, good penetrating ability into tumor cells and a long residency time within tissues. The novelty of this approach is to combine the tools and principles of optics, chemistry, physics and engineering for the development and manufacturing of a multifunctional smart nanodevice with the capability of navigating in the blood stream, looking for uptake into abnormal growths such as tumors or for specific areas where to deliver a particular drug. In turn, the drugs thus delivered can emit a measurable signal that can help to locate the abnormality or be made to eliminate the abnormality upon photoactivation with laser radiation via PDT (Fig. 11.2) [3].

Fig. 11.2. ICG encapsulated in nanoparticles preferentially locates in tumors to allow the noninvasive imaging and destruction of superficial tumors. (from Ref. [3].)

## 11.5

### Optical Imaging and PDT

#### 11.5.1

#### Optical Imaging

Optical imaging is a form of tumor diagnosis based on the interaction between light and biological matter [112]. Two of the most salient advantages this technique can offer to the clinician over traditional diagnostic modalities are a non-reliance on both ionizing radiation and radioactive material, and the wealth of information that it can generate about the structure, dynamics and interactions in biological bulk specimens such as tissues. Optical imaging takes advantage of the spatial variation in the optical properties of a biological specimen, whether it is a cell, a tissue, an organ or an entire live organism [113]. With this diagnostic technique, an optical image is obtained by monitoring the spatial variation of light that is reflected, scattered, absorbed or emitted as fluorescence. The use of lasers as an intense and convenient light source to generate an optical response has considerably expanded the boundaries of optical imaging, particularly as it relates to tumor diagnosis [114–116].

##### 11.5.1.1 Fluorescence-based Optical Imaging

Fluorescence is a radiative phenomenon whereby a molecule becomes excited upon absorbing light of a given wavelength and later on returns to the ground state by emitting light of a longer wavelength. The major advantages of fluorescence detection over other optical imaging techniques are high sensitivity (low signal-to-noise ratio), high speed and safety. In this instance, safety refers to the fact that the sample is neither altered nor destroyed and that no hazardous byproducts are generated in the process [117].

##### 11.5.1.2 NIR Fluorescence Imaging

NIR fluorescence imaging is increasingly gaining importance in the diagnosis of tumors [118, 119]. The NIR region is that portion of the light spectrum extending from 700 to 900 nm. At least four main reasons are responsible for the increasing importance of this imaging technique:

- (a) Blood and other biological tissues are relatively transparent across this spectral wavelength range, thus creating an optical window [113, 119].
- (b) The excitation of chemical agents or dyes for imaging by NIR radiation produces practically no autofluorescence from any endogenous cellular components, a factor that dramatically improves the sensitivity of the detection signal detection, often limited by background autofluorescence [120].
- (c) The NIR excitation and emission wavelengths reduce scattering in tissues, and, thus, increase both the penetration depth and the efficiency of the detection signal [113, 119].

Tab. 11.1. Common NIR dyes

<b>Name</b>	<b>Wavelengths of excitation/emission (nm)</b>
Cy-3 iodoacetamide	565/590
Cy-5 N-hydroxysuccinimide	648/669
Cy-7 isothiocyanate	750/777
Rhodamine 800	680/700
Indocyanine green	782/830
Azure B	638/660
Thiazole orange	735/765
Nile Blue	638/660
Al phthalocyanine	662/680
Oxazine 1	643/658
BODIPY™	665/676

(d) Commercial NIR lasers used as exciting sources are low in cost and convenient to use because of a compact design [113].

#### 11.5.1.3 NIR Dyes for Fluorescence Imaging

The dyes for NIR fluorescence imaging listed in Table 11.1 are either long-wavelength probes such as cyanine, rhodamine, oxazine, phthalocyanine and naphthalocyanine dyes or extended conjugated systems [119, 121–125]. The cyanines, which were initially developed for use as membrane probes, are probably the most commonly used NIR dyes. Typical examples include, in increasing order of wavelength, Cy-3, Cy-5 and Cy-7 [126].

The phthalocyanine and naphthalocyanine dyes are less popular due to their water insolubility, tendency to aggregate, lack of conjugateable forms, and environmental and photochemical instability. Among dyes categorized as extended conjugated systems, ICG has been extensively investigated for use as a long-wavelength probe. By encapsulating this dye within nanoparticles, the authors were recently able to develop a delivery system for the imaging of cancer cells that would overcome most of the problem commonly encountered with other NIR dyes used in biophotonics.

#### 11.5.2

##### PDT

PDT, also referred to as photoradiation therapy, phototherapy or photochemotherapy, is a promising new form of treatment for a variety of oncological, cardiovascular, dermatological and ophthalmic diseases [127, 128]. PDT is an emerging therapy for the treatment of tumors that are accessible to light radiation such as those of the head, neck, digestive tract, skin and breast. PDT has been proposed in several studies as an alternative to overcoming “multidrug resistance phenotype” (MDR), a frequent reason for the failure of conventional chemotherapy. PDT has been approved by the FDA for the treatment of both early- and late-stage lung cancer, for certain types of esophageal cancer and for non-small cell lung cancer, and

most recently it was also approved for the treatment of actinic keratosis, a precancerous skin condition. Clinical trials are currently in progress in the US and abroad to evaluate the effectiveness of PDT in the treatment of several types of cancer and precancerous conditions [113].

PDT is a form of light-activated chemotherapy based on the activation of an exogenous chemical agent, known as the photosensitizer, by light. The photosensitizer is administered either systemically by the intravenous route or locally into the malignant growth, after which light of a specific wavelength is used to irradiate the photosensitizer in a specific part of the body. Upon absorbing light, the photosensitizer will produce reactive oxygen species (ROS) with the ability to destroy the tumor with minimal damage to the surrounding cells [129, 130].

The advantages of PDT are numerous. For example, it circumvents systemic treatment since the light is focused only on the site occupied by the tumor, thus sparing the patient from side-effects commonly associated with conventional chemotherapy such as hair loss, nausea and vomiting. It exhibits more selectivity than conventional chemotherapy and radiotherapy toward tumors because of preferential accumulation of the photosensitizing agent in tumor tissue and the spatially confined photodynamic effects achieved with light radiation. PDT will be a suitable option in patients that cannot undergo removal of a tumor by surgery, e.g. in the upper bronchi, since it can kill cancer cells without damaging adjacent collagenous tissue structures, a situation that allows for the repopulation of these structures by new normal cells. It is expected to be cost-effective and, unlike radiation therapy, amenable to be repeated as many times as deemed necessary, thus providing a way for the long-term management of cancer and the complete removal of the tumor. Additionally, in contrast to surgery, it is a noninvasive form of therapy that does not cause pain or discomfort in the patient or lead to such complications as surgery-related secondary infections.

#### 11.5.2.1 Basis of PDT

In PDT, cytotoxicity by a photosensitizer molecule is attained when the photosensitizer, after undergoing activation by laser light energy, proceeds to return to the ground state by either radiative or nonradiative decay [131–133]. In nonradiative decay, the energy absorbed by the photoactive molecule can be converted to heat (internal conversion) that can then be transferred to nearby intracellular molecules (photooxidation type I) to cause cellular damage by raising the intracellular temperature. Alternatively, the energy absorbed by the photosensitizer can be transferred to molecular oxygen by means of a triplet state (photooxidation type II), to form reactive intermediates such as singlet oxygen that, in turn, can cause irreversible destruction of biological substrates [134, 135]. ROS such as the superoxide anion, and hydroperoxyl and hydroxyl radicals may also be involved in mediating irreversible damage to biologic components [127]. Singlet oxygen possesses a reactive distance of only 0.1  $\mu\text{m}$ , so its cytotoxicity is restricted to the immediate vicinity of the photoactivated drug. When used within their standard doses, neither the photosensitizer nor the light source is active against the target when used independently of each other.

Tab. 11.2. Common photosensitizers

<i>Name</i>	<i>Chemical type</i>	<i>Absorption wavelength (nm)</i>
Photofrin®	porphyrin	630
Bonellin	chlorin	625
MTHPC	chlorin	652
SnET2	chlorin	660
Mono-L-aspartyl chlorine e6	bacteriochlorin	654
HPPH	pyropheophorbide	670
Veteroporphin	benzoporphyrin	690
Protoporphyrin IX	ala	630
Lu-TeX	texaphyrins	732
Indocyanine green	tricyanocyanine	786
AlPcS	phthalocyanine	674
Methylene blue	cationic	660
Tetrabromorhodamine	cationic	540

#### 11.5.2.2 Photosensitizers for PDT

Photosensitizers for PDT are selected taking into account various physiological factors. In brief, an ideal photosensitizer should possess the following properties: (a) ability to selectively accumulate in the cancerous or precancerous tissue, (a) capability of absorbing light significantly in the region of maximum transparency of biological tissues and (c) minimal drug toxicity. Table 11.2 lists some of the common photosensitizers used in PDT [136–149].

#### 11.5.3

#### ICG: An Ideal Photoactive Agent for Tumor Diagnosis and Treatment

Among the photosensitizing agents listed in Tables 11.1 and 11.2, ICG stands out as unique because it possesses both NIR fluorescent properties and PDT capabilities, thus becoming suited for both NIR fluorescence imaging and PDT of tumors. ICG may be more advantageous than other photoactive agents since it causes minimal toxicity, is commercially available in a very pure form, has a low cost, and, more importantly, has been approved by the FDA as a diagnostic agent for use in ophthalmology and other medical specialties. Moreover, in other countries ICG has received approval for use in PDT. On these bases, it would appear that the development of a commercial ICG-based nanoparticulate system for tumor imaging and treatment would meet fewer hurdles for obtaining federal approval for use in humans than would be possible with other related agents.

#### 11.5.3.1 Clinical Uses of ICG

ICG is a photoactive dye approved by the FDA for medical diagnostic studies, and is widely used in the clinical setting for the evaluation of cardiac output, liver function and microcirculation of skin flaps, the visualization of the retinal and choro-

Fig. 11.3. Chemical structure of ICG.

dal vasculatures, in pharmacokinetic analysis, to localize objects within tissues, as a fluorescence probe for enzyme and proteins, and in tissue welding [150, 151].

#### 11.5.3.2 Structure and Physicochemical Properties of ICG

Chemically ICG (FW 775) is a tricyanocyanine dye containing an extended conjugated system. The structure of ICG, shown in Fig. 11.3, is made up of two polycyclic moieties, each known as a benzoindotricarbocyanin, connected to each other by a carbon chain. While the polycyclic moieties are responsible for the lipophilic properties of ICG, the sulfate groups attached to each polycyclic component impart hydrophilicity. As a result, ICG is, overall, amphiphilic in nature and, because of its amphiphilicity, ICG is soluble in organic solvents [e.g. methanol and dimethylsulfoxide (DMSO)] and in aqueous media, including buffers.

#### 11.5.3.3 Binding Properties of ICG

ICG binds rapidly and almost completely (98%) to most plasma proteins. Thus, in the circulation it binds to albumin, globulins and lipoproteins. Due to its amphiphilic nature, ICG can interact with both lipophilic and hydrophilic molecules. Furthermore, because of its three-dimensional structure, ICG can simultaneously bind to the lipophilic and hydrophilic parts of amphiphiles such as phospholipids.

ICG binds to human serum albumin (HSA) through its hydrophobic core. In this case, about one or two molecules of ICG become bound to one molecule of HSA [152]. ICG has also been found to bind to  $\alpha_1$ -lipoproteins and  $\beta$ -lipoproteins [153] in human serum. In general, the binding of ICG to plasma proteins will impact negatively on its potential intracellular effects since the bound form will be primarily confined to the vascular compartment and hindered from entering tumors [154–156]. Numerous reports have described the binding of ICG to phospholipids [157–159]. These binding interactions are relevant to photoimaging since the emission spectrum and fluorescence yield of ICG are influenced by the resulting quenching [158, 160–163].

Several studies have been carried out on the interactions of ICG with model membranes. It was observed that ICG is able to interact with phospholipid bilayers and that the binding takes place at the interface of the model membrane. The

physicochemical and fluorescence spectral characteristics of ICG in aqueous solution have been evaluated in the presence of micelles and liposomes [162]. ICG was found to be tensioactive, and to aggregate or become embedded at the interface of micelles and liposomes. The fluorescence of ICG was very low in the aggregated form due to quenching and very high when embedded at the interface.

#### 11.5.3.4 Metabolism, Excretion and Pharmacokinetics of ICG

The excretion of ICG follows a hepatobiliary route in the human body. After intravenous injection, most of the circulating ICG is taken up into the liver where, rather than being metabolized, it is excreted as part of the bile into the intestinal tract. Upon reaching the intestine it is neither reabsorbed through the intestinal mucosa nor put through the enterohepatic circulation [156]. Negligible uptake of the dye occurs in the kidneys, lungs and peripheral tissues. ICG does not undergo significant renal excretion [164] and it is not detected in the cerebrospinal fluid [156].

The metabolic fate and excretion of ICG correlate well with its lipophilic characteristics. As a result, ICG is rapidly eliminated from the circulation after an intravenous injection, with the plasma half-life being about 2–4 min [164–167]. The plasma disappearance rate of ICG in healthy human subjects is from 18 to 24%  $\text{min}^{-1}$ . The normal biological half-life has been determined to be from 2.5 to 3 min, so single blood samples taken from healthy subjects 20 min after an intravenous injection should contain not more than 4% of the initial concentration of dye [168].

Spectrophotometric studies on ICG have shown the blood levels of this dye to follow a biexponential decay curve following intravenous injection. The plasma clearance of ICG is biphasic, showing a rapid initial phase with a half-life of 3–4 min and a secondary phase with a half-life of more than 1 h at low concentrations [165, 169, 170].

#### 11.5.3.5 Toxicity of ICG

ICG produces minimal toxicity in animals and its  $\text{LD}_{50}$  after intravenous administration ranges from 50 to 80  $\text{mg kg}^{-1}$  [171]. Although no equivalent data exists for humans, the maximum recommended human dose is 5  $\text{mg kg}^{-1}$ . The safety of intravenous ICG in humans is well documented, with severe adverse reactions occurring in only 0.05% of recipients [172].

#### 11.5.3.6 Tumor Imaging with ICG

ICG is rapidly gaining acceptance as a diagnostic agent for tumor imaging purposes due to its NIR fluorescence characteristics. Li et al. [173] have studied the efficiency of ICG as a sensitive contrast agent for tumor detection and localization. These authors assessed the differences in fluorescence signals of ICG between opposite tumor-bearing and tumor-free areas after the intravenous administration of a low, 80  $\mu\text{g kg}^{-1}$  body weight, dose of ICG to rats implanted with a tumor in one leg. In this way it was possible to determine that a difference in fluorescence exists between the tumor side and tumor-free side, and that the difference was detectable

even when the tumor was very small (about  $0.15 \text{ cm}^3$ ). During the exponential growth phase of the tumor, the ratio of these two signals was approximately 2.5 and the ratio of the initial ICG clearance velocity in the tumor leg to that in the control leg was about 3.

Preliminary investigations with human subjects affected with breast tumors were conducted using an ICG dose of  $400 \mu\text{g kg}^{-1}$  body weight. The results of this study indicated the existence of differences in the fluorescence emanating from a tumor-bearing breast and that from a tumor-free breast. Additional evidence in support of the use of ICG in the imaging of breast tumors has been gathered in dogs [174]. By using a gain-modulated, image-intensified, charge-coupled, camera these authors were able to obtain intensity-modulated fluorescence signals from canine mammary tumors. By means of a continuous wave diffuse optical tomography apparatus, Intes et al. [175] have demonstrated the usefulness of ICG as a diagnostic tool for differentiating benign from malignant pathologies in breast cancer patients.

A number of studies have also reported on the use of ICG as a fluorescence contrast imaging agent to obtain two- or three-dimensional images from experimental phantoms, rats and synthetic samples [176]. It is quite clear that a great deal of interest exists in finding new diagnostic applications for ICG by NIR imaging, optical spectroscopy and tomography, and that there is still room for improving the sensitivity, specificity and cost-effectiveness of currently available ICG-based optical techniques, especially of those intended for the detection of breast and skin tumors.

#### 11.5.3.7 PDT with ICG

Due to its photosensitizing properties, ICG has great potential for application in PDT. An important reason for using ICG in PDT is that its strongest absorption and emission bands occur at around 800 and 820 nm, respectively [177, 178]. Since these two wavelengths are the wavelengths at which blood and other tissues are relatively transparent, and at which the penetration depth of light in biological tissue is at its maximum (5 mm or more) [179, 180], they confer ICG an advantage over comparable chemical agents that work in the visible spectral range. In addition, like other second-generation photosensitizers, ICG demonstrates those features that are considered desirable in PDT, including rapid biodistribution, low skin phototoxicity, and ease of administration and monitoring [181].

Fickweiler et al. [182] were the first to provide concrete evidence on the photodynamic action of ICG. Using HaCaT cells, an immortalized human keratinocyte cell line, they were able to examine the dose-dependent phototoxic effects of ICG *in vitro*. In their experiments, keratinocytes were incubated with 0–50  $\mu\text{M}$  aqueous solutions of ICG for 24 h, after which the cells were irradiated with diode laser (805 nm) of a different energy density (0, 12, 24 and 48  $\text{J cm}^{-2}$ ). Under these conditions, photoactivated ICG demonstrated a cell killing effect at concentrations above 5  $\mu\text{M}$ . In addition, the participation of ROS in the cell killing process was suggested by the results of an experiment in which sodium azide, a quencher of ROS, protected against the cytotoxicity of ICG [182].

A different approach was later used by Baumler et al. [135] to elucidate the mechanism responsible for the cytotoxicity of ICG in PDT. In their study, HT-29 cells, an immortalized human colon carcinoma cell line, were first incubated with different concentrations of ICG (10–100  $\mu\text{M}$ ) for 24 h and next irradiated with a continuous wave diode laser (805 nm, 30  $\text{J cm}^{-2}$ ). Apart from demonstrating light-induced cytotoxicity, these investigators also observed that the cytotoxicity increased when heavy water ( $\text{D}_2\text{O}$ ) was used in place of normal water. These results were interpreted as indicative of the production and participation of singlet oxygen during laser irradiation of ICG since  $\text{D}_2\text{O}$  is known to prolong the lifetime of singlet oxygen. Moreover, evidence for the occurrence of lipid peroxidation upon the addition of  $\text{D}_2\text{O}$  was gathered from the concomitant elevation of the levels of malondialdehyde, a marker of lipid peroxidation. This line of thought was further examined with quenchers of singlet oxygen species such as sodium azide, histidine, and with specific quenchers of superoxide anion and hydroxyl radical such as mannitol. Since only sodium azide and histidine protected against the photodynamic killing effect of ICG on HT-29 cells, the participation of singlet oxygen and of lipid peroxides, but not of superoxide anion and hydroxyl radicals, was inferred. Virriale et al. [183] have also provided proof of the involvement of singlet oxygen in the photodynamic antitumor action of ICG. In photosensitization experiments performed by this research group, irradiation of U-937 human monocytes (histiocytic lymphoma, CRL-1593), a leukemia cell line, with a diode laser (805 nm) source providing a dose of radiation of 18  $\text{J cm}^{-2}$  in the presence of 12  $\mu\text{M}$  of ICG and dithiothreitol, an oxidizable substrate, caused the cells to undergo programmed cell death (apoptosis).

Urbanska et al. [184] have reported the potential utility of ICG as a photosensitizer for the treatment of melanoma, a common type of skin cancer. PDT with ICG is particularly suited to control melanoma because the melanin present in these cells absorbs the wavelength of visible light commonly used for photodynamic effect but not the NIR wavelengths at which ICG exerts its cytotoxic effects. In this study a very high photosensitizing efficiency was demonstrated for ICG upon exposing SKMEL 188 cells, a human melanoma cell line, to 100  $\mu\text{M}$  of ICG followed by irradiation with a diode laser (830 nm) delivering a radiation dose of 30–100  $\text{J cm}^{-2}$ . Costa et al. [181] have described an *in vivo* photodynamic study on ICG that demonstrated the potential utility of the dye in the occlusion of choroidal neovascularization. Using pigmented rabbits as an animal model, doses of ICG between 10–20  $\text{mg kg}^{-1}$  and an activating light dose of 6.3  $\text{J cm}^{-2}$  from a diode laser, ICG was shown to be effective in occluding choriocapillaries.

#### 11.5.3.8 Limitations of ICG for Tumor Diagnosis and Treatment

The *in vivo* value of ICG in tumor imaging and treatment is severely limited by two intrinsic characteristics – a very high tendency to bind to plasma proteins (95–98%) and a rapid elimination from the body (plasma  $t_{1/2} = 2\text{--}4$  min) [158, 178]. As a result, a very small amount of ICG will accumulate in tumor tissue following intravenous dosing since the dye will remain largely confined in the blood before its removal by the liver for eventual rapid elimination into the small intestinal

tract. Needless to say that for both imaging and PDT applications, it will be essential to deliver a substantially higher quantity of ICG to the tumor site than it is possible with a conventional aqueous solution and that this objective will be only realized when its limiting characteristics are appropriately minimized.

Another important factor that limits the clinical use of ICG is extreme instability in aqueous media. In addition to preventing its storage for a significant period of time, aqueous solutions of ICG are only suitable for conducting *in vivo* imaging and other types of diagnostic procedures for a short time [150, 185]. The chemical stability of ICG at ambient temperature has been found to decrease in inverse proportion to its concentration [177, 186], and it can be easily monitored by following the changes of its visible absorption spectrum over time [177, 186–188]. Light appears to be the major determining factor in the stability of ICG since degradation is much greater for samples exposed to ordinary light than for samples kept in the dark [186, 189]. A similar photodegradation has been verified with aqueous solutions of ICG that were exposed to laser radiation [185]. Since most current clinical applications of ICG are carried out with aqueous solutions, the development of a more stable preparation for parenteral use is clearly warranted.

#### 11.5.3.9 Recent Approaches for Improving the Blood Circulation Time and Uptake of ICG by Tumors

No specific mechanism has been described for the localization of ICG in tumors [190]. Moreover, since ICG lacks tumor selectivity, its use as a diagnostic tool for differentiating among various types of tumor will not be reliable. Several approaches have been tested as ways of attaining greater tumor selectivity with ICG. One attempt has been to synthesize dye–peptide conjugates that are receptor specific [190]. The experimental results suggest that small dye–peptide conjugates are effective as contrast agents for optical imaging purposes. Even when covalently united to each other, the dye and the peptide were found to retain the native fluorescence characteristics and the affinity for peptide receptors, respectively. These newly synthesized conjugates, identified as Cytate and Cybesin, preferentially localized for over 24 h in tumors known to overexpress somatostatin and bombesin receptors, respectively. In contrast, the dye moiety was not retained in these two tumor models when they were no longer conjugated to a peptide [190]. This behavior and the lack of data on the chemical stability of dye–peptide combinations *in vitro* and *in vivo* represent a significant impediment to the potential commercialization of dye–peptide conjugates.

Devoisselle et al. [191] have developed an emulsion formulation to increase the blood circulation time of ICG. To test this formulation, Wistar rats were intravenously dosed with 7.5 mg kg<sup>-1</sup> body weight of ICG, given as either an aqueous solution or as an oil-in-water emulsion formulation. It was verified that the emulsion increased the plasma clearance time of ICG in the first 15–60 min and the residence time in the skin as compared to an equipotent dose of an aqueous solution. However, no information was given on the chemical stability of ICG in water or in an *o/w* emulsion *in vitro* and no experiments were conducted to determine the efficiency of an emulsion in tumor targeting under *in vivo* conditions.

#### 11.5.3.10 Recent Approaches for ICG Stabilization *In Vitro*

An early way of ensuring the stability of ICG in solution was to substitute water by nonaqueous solvents. For this purpose, methanol, 1,2-propanediol and dimethylformamide were evaluated [192]. It was found that under ordinary conditions of illumination, ICG was more stable in methanol than in any of the other solvents. Moreover, the thermostability of ICG was greater in methanol and 1,2-propanediol than in dimethylformamide. A later study examined the photodegradation and thermodegradation of ICG in a wide variety of aqueous and organic solvents [185]. This study indicated that ICG exhibited a low photostability in water, D<sub>2</sub>O and aqueous sodium azide (NaN<sub>3</sub>) solutions, and a good photostability in methanol, DMSO and human plasma. In addition, the thermal stability of ICG was moderate in water, D<sub>2</sub>O and aqueous NaN<sub>3</sub>, and very high in human plasma, methanol and DMSO. Thus, excluding human plasma, ICG appears to remain quite stable in organic solvents. Unfortunately these results are of no value in trying to develop an appropriate photostable, thermostable and biocompatible injectable solution of ICG for use in human subjects inasmuch as they all possess intrinsic toxicity.

A different solution to improving the stability of ICG in aqueous media has been to complex the dye with water-soluble cyclodextrins [193]. The stability of ICG in water increases because the dye can fit in the torus of  $\gamma$ -cyclodextrin to form an inclusion complex at pH 6.0 and 25 °C that will somewhat shield the dye from the external environment. Although in this manner the stability of ICG increases in aqueous media, the effect is short-lived due to the tendency of ICG to leave the cavity of  $\gamma$ -cyclodextrin to form an equilibrium mixture with its complexed form. Also, complexation of ICG with a cyclodextrin will make accurate assessment of the thermostability of ICG a difficult task.

The stability of ICG in aqueous solutions has also been achieved by conjugating it noncovalently with a polymeric carrier molecule [151, 194]. The conjugate is formed by gently stirring a solution of ICG plus the anionic polymer sodium polyaspartate (PASP), added in a respective molar ratio of 1:2.6, at ambient temperature. Under ordinary conditions of illumination and ambient temperature, an aqueous solution of conjugated ICG emitted a fluorescence that remained quite stable for up to 24 days. In contrast, the fluorescence of a solution of plain ICG was only stable for 4 days. However, this gain is offset by the failure of the ICG–PASP conjugate to show a sufficiently long blood clearance rate for ICG that would allow the dye to accumulate in tumors in a therapeutically effective concentration.

A more recent attempt to prevent the photodegradation of ICG has been to place this compound in close proximity to colloidal gold [195]. Although the interaction of ICG with colloidal gold allows ICG to form a metallic conjugate with better photostability than plain ICG, the utilization of metallic nanoparticles raises concerns about the biodegradability and biocompatibility of the formulation. An additional concern is the efficiency and effectiveness of this type of conjugate under *in vivo* conditions since none of these issues has, thus far, been experimentally substantiated.

## 11.6

### PLGA-based Nanoparticulate Delivery System for ICG

#### 11.6.1

##### Rationale of Using a PLGA-based Nanoparticulate Delivery System for ICG

From the foregoing statements, it is apparent that the use of ICG in tumor diagnosis and treatment will only become a reality when its present shortcomings in terms of chemical stability in solution, circulation half-life and adequate uptake by tumor cells are solved.

One attractive and novel approach to achieving these objectives may be to encapsulate ICG within a biocompatible and biodegradable nanoparticulate system. Among possible candidates for use in the preparation of nanoparticles for drug delivery purposes, PLGA and several of its derivatives stand out since they meet the requirements of biocompatibility and biodegradability, and, in addition, have been extensively used by the pharmaceutical industry. Further advantages to be gained from the use of PLGA in nanoparticles are, among others, (a) enhanced uptake into a tumor site because of increased endocytosis and of leakiness of the vasculature permeating a tumor, i.e. they are suited for the passive targeting of tumors [196], (b) amenability to surface modification by special targeting moieties such as antibodies to enhance specificity toward a target site, i.e. active targeting [196], (c) attainment of a long circulation half-life (14 min, which is about 3–7 times that of plain ICG [197], and which can be increased further by coating the surface of the nanoparticles with specific polymers such as PEG [198]), (d) confirmation by *in vitro* studies with PLGA nanoparticles of their ability to be enter human cell lines such as arterial smooth muscle cells (HASMC) and vascular smooth muscle cells (VSMC), and accumulate at the tumor site [199, 200], (e) demonstrable stability in aqueous media for intravenous delivery and which, unlike that of micelles and liposomes, is independent of surfactant/lipid concentrations, and (f) ease of preparation which, unlike the synthesis of delivery systems based on a antibody–drug conjugate, does not entail the formation of covalent linkages. It is expected that as a result of future advances in nanotechnology, fully biocompatible and biodegradable PLGA-based nanoparticles will be engineered on an industrial scale to meet the clinical demands imposed by human tumors.

PLGA was used to entrap ICG into nanoparticles. The amount of each ingredient was varied to represent ratios of dye to polymer ranging from 1:10 to 1:800. The ICG content appeared to vary within a narrow range (0.17–0.29%) regardless of the dye to polymer ratio (Table 11.3) [201–203]. A similar trend was noted for the particle size and polydispersity of the nanoparticles (Table 11.4). The  $\zeta$  potential was more negative with a dye to polymer ratio of 1:800 than with the other ratios used (Table 11.4). The surface of the nanoparticles was porous in nature (Fig. 11.4), a feature that may facilitate the fairly rapid release of the dye into an aqueous environment during the first 8 hours (Fig. 11.5). The incorporation of ICG into nanoparticles not only isolated the dye from a potentially hostile external environment, but at the same time contributed to enhance its chemical stability to the degrading

action of an aqueous medium, ambient light and heat (Figs. 11.6–11.8, and Tables 11.5 and 11.6) [202].

The uptake of PLGA nanoparticles into cells is by endocytosis and this uptake mechanism appears to take place even at low concentrations of ICG. As shown in Fig. 11.9, the amount of ICG taken up as nanoparticles into B16-F10 and C-33A cells, two types of cancer cells, increased in liner proportion to the concentration of extracellular ICG and the rate of uptake was greater into B16-F10 cells than into C-33A cells.

Figure 11.10 compares the uptake of ICG into B16-F10 and C-33A cells from aqueous solutions and from nanoparticles. For each type of formulation, the uptake of ICG was always slightly better into B16-F10 cells than into C-33A cell and the resulting uptake versus concentration profiles were virtually parallel to each other. Irrespective of the extracellular concentration of ICG used (0.0005–50 μM), in all instances ICG was better taken up into cells as nanoparticles than in the free form [204].

The entry of a nanoencapsulated compound into the cytoplasm was investigated by fluorescence microscopy after incubating B16-F10 cells with PLGA nanoparticles loaded with coumarin 6 serving as a fluorescence probe (mean diameter  $300 \pm 10$  nm, polydispersity index = 0.01). There were three main reasons for using coumarin 6 in place of ICG to make the nanoparticles for cell uptake studies. First, since ICG fluoresces in the NIR portion of the light spectrum, it cannot be detected using an ordinary fluorescence microscope. Second, coumarin 6 emits a

characteristic green fluorescence when excited with red light, thus becoming suited for detection by fluorescence microscopy [200]. Third, due to a higher degree of lipophilicity than ICG, coumarin 6 tends to remain longer within PLGA nanoparticles exposed to an aqueous environment than ICG [202, 205, 206]. As seen in Fig. 11.11, coumarin 6 was found to be evenly distributed throughout

the cytoplasm apart from the nucleus, and to bind to intracellular proteins and structures.

Incubating B16-F10 cancer cells in the dark with either ICG added as an aqueous solution or as nanoparticles was without apparent effect on cell viability at all concentrations of ICG examined (Figs. 11.12 and 11.13). Irradiating the cancer cells with a laser source emitting at 786 nm had no apparent effect on the viability of cells incubated with various doses (1–100  $\mu$ M) ICG as a solution (Fig. 11.14) or with empty nanoparticles (Fig. 11.15), but reduced viability by 22 and 24% in cells incubated with ICG nanoparticles providing 11 and 22  $\mu$ M of dye, respectively (Fig. 11.15) [205].

#### *In Vivo* Pharmacokinetics of ICG Solutions and Nanoparticles

Assessment of the plasma kinetics and biodistribution of ICG following administration as an aqueous solution and as a nanoparticle suspension was conducted in mice. This type of study will also be of help in the future optimization of ICG-containing nanoparticulates in terms of dye load, and selectivity for and improved uptake into target sites.

**Fig. 11.10.** Uptake of ICG from a solution and a suspension of nanoparticles into B16-F10 and C-33A cells (mean  $\pm$  SD,  $n = 3$ ). Extracellular concentration of ICG: 0.0005–50  $\mu\text{M}$ .

The temporal changes of ICG in plasma and in various tissues that follow a single intravenous dose of ICG (10  $\mu\text{g}$  per mouse) as a solution and as nanoparticles was investigated. The results of these studies are presented in Figs. 11.16 and 11.17. For the ICG solution, the highest levels of ICG were found in the liver, followed in decreasing order in the kidney, spleen, heart and lung. These data confirm the role of the liver as the major organ for the removal of ICG from the general circulation and supports the clinical use of ICG as a test for liver function. In

**Fig. 11.11.** Fluorescence microscopic images of B16-F10 cells incubated with 0.1  $\text{mg mL}^{-1}$  coumarin-6-loaded nanoparticle suspension. Differential contrast image (left) and fluorescence image (right). A Nikon 100/1.40 oil lens was used.

**Fig. 11.12.** Subcellular localization of ICG in C-33A cancer cells (using free ICG solution). Treated cells incubated with 100  $\mu\text{M}$  ICG (left) and control cells without ICG (right).

**Fig. 11.13.** Effect of ICG in solution on the viability of B16-F10 cells (mean  $\pm$  SD,  $n = 5$ ). Extracellular concentration of ICG: 1–100  $\mu\text{M}$ .

**Fig. 11.14.** Effect of ICG-loaded nanoparticles on the viability of B16-F10 cells (mean  $\pm$  SD,  $n = 5$ ). Nanoparticle concentration: 0.5 and 1  $\text{mg mL}^{-1}$ .

**Fig. 11.15.** Photodynamic activity of ICG-loaded nanoparticles on the viability of B16-F10 cells (mean  $\pm$  SD,  $n = 5$ ). Extracellular concentration of ICG was 11 and 22 nM. \*Significantly different from dark at  $p < 0.05$ .

the case of ICG nanoparticles, while the liver again accumulated the highest concentrations of dye, the biodistribution pattern for other organs was somewhat different than with a solution, since the concentrations decreased in the order spleen, lungs, heart and kidneys. It is evident that ICG nanoparticles are preferentially taken up into liver and spleen, two organs that form part of the RES that is responsible for the removal of foreign particles from the blood through an active phagocytic activity.

**Fig. 11.16.** Biodistribution of ICG (solution) in mouse tissues following an intravenous dose of ICG (10  $\mu\text{g}$  per mouse).

Fig. 11.17. Biodistribution of ICG (nanoparticles) in mouse tissues following an intravenous dose of ICG (10 µg per mouse).

Interestingly, the administration of ICG as a nanoparticle formulation led to a blood ICG level that was significantly higher than from a solution and which remained elevated for up to 4 h posttreatment. We believe that these results reflect the slower hepatic clearance of circulating ICG nanoparticles than of free ICG [155]. Also, nanoparticles may enhance the entry and retention of ICG into organs since the levels of ICG in organs were higher from a suspension of nanoparticles than from an equivalent aqueous solution. This feature should be of particular value in the targeting of tumors with ICG-loaded nanoparticles. In the body, the elimination of ICG appears to follow a biphasic pattern, with a rapid initial phase of maximum dye removal followed later by a slower removal phase.

## 11.7

### Conclusions and Future Work

Nanoparticulate systems can serve as an ideal carrier system for drugs used in tumor imaging and PDT. By forming a wall around the drug they contain, nanoparticles can effectively protect the drug from the altering effects of the surrounding aqueous environment and from potential degradation by light and temperature. Taking advantage of the leaky vasculature of tumors, nanoparticles can enhance the passive uptake into and ultimate accumulation of antitumor drugs at the target site by an enhanced permeation and retention effect. Furthermore, in comparison to a drug solution, nanoparticles can provide a longer half-life and retention of a drug in the body due to their size and surface characteristics. Finally, nanoparticulates loaded with photoactive antitumor drugs can show photodynamic activity in tumor cells.

We have shown the feasibility of manufacturing PLGA nanoparticles of ICG with good potential as an agent for the diagnosis and treatment of tumors. These nanoparticles should be viewed primarily as a foundation for the development of new nanoparticles with improved pharmaceutical and therapeutic features. In pursuit of this goal, future work on this area will be addressed to, among other things, compare different types of PLGA (e.g. 25/75, 30/70, 75/25) for their suitability in manufacturing ICG nanoparticles with enhanced entrapment efficiency and dye content. Another idea worthy of a future investigation is to test polymeric materials such as albumin, chitosan, and PEGs (including PEG 2000, 5000 and 20 000). In an effort to minimize the opsonization of the nanoparticles *in vivo* and, hence, to prolong the plasma half-life of ICG, the application of an external coating with a hydrophilic polymer may be warranted. Furthermore, to magnify the selectivity of the nanoparticles to particular target sites, one could explore the possibility of modifying the nanoparticle surface by the attachment of antibodies and other types of ligands with the ability to interact with specific types of tumors.

Another important aspect of nanotechnology applied to drug delivery using polymeric nanoparticles that will need to be considered is the scale-up of the production from the laboratory to an industrial scale, with particular attention to uniformity of particle size, reproducible solute entrapment efficiency and stability on storage under a variety of environmental conditions. Efforts will need to be directed to investigating the porosity characteristics of the nanoparticle surface (including pore size, pore shape and number of pores per surface area) and its relevance to solute release in a biological environment. In addition, to reduce the dose of ICG as ICG nanoparticles for applications like imaging and PDT, future developmental work on this type of formulation should concentrate in finding ways to enhance the fluorescence signal of a dye after undergoing intracellular uptake. The use of nanoparticles containing both silver ions and ICG is an attractive alternative that merits future consideration.

At the cellular level, a vast amount of work remains to be carried out with ICG nanoparticles using cell culture systems. In this regard, the use of new tumor cell lines will provide a better picture of the type of cancers that can be treated with ICG, especially cell lines of breast and skin cancers. The effectiveness of PDT for each of the cancer cell lines will only be established by evaluating the effects of critical factors such as light dose and ICG dose, which will eventually have to be optimized. A detailed investigation will have to be conducted to elucidate the mechanism of PDT activity on different tumor cell lines and the role of singlet oxygen in this process. The location of nanoparticles in the cell, their movement within the cells and the delivery of the nanoparticle contents to various cell organelles are also important subjects for future studies.

To more accurately define the biodistribution patterns and pharmacokinetic profiles of ICG delivered as nanoparticles, further investigation of this type of formulation could be done in higher animal models such as the rat and rabbit. Furthermore, testing the nanoparticles in tumor-bearing animal models will provide us with a clearer picture of the therapeutic and diagnostic effectiveness of the nanoparticles under more realistic conditions, particularly as it relates to tumor imaging

and PDT applications. Again, the results of these studies will be of great help in optimizing the test formulations.

## 12 Nanoparticles for Crossing Biological Membranes

*R. Pawar, A. Avramoff and A. J. Domb*

### 12.1 Introduction

Membrane transport plays an important role in cellular and subcellular pathways, including multidrug resistance (MDR), cellular signaling and cell–cell communication. Membrane transport mechanisms, such as the membrane permeability and extrusion machinery, lead to accumulation of specific intracellular substances and MDR. The introduction of the polymerase chain reaction resulted in the designing of new laboratory devices and analysis of amplified DNA fragments. In addition, a number of studies have been conducted related to mimicking living systems as well as developing nanodevices such as biomolecular sensors and artificial cells. The potential of nanotechnology has been studied in health care and medicine, including the development of nanoparticles for diagnostic and screening purposes [1].

New therapeutic agents are naturally occurring compounds like peptides, proteins, carbohydrates or oligonucleotides. The main problems faced in the utilization of these compounds are efficient and targeted drug delivery. Oral, nasal, transdermal and buccal routes are generally used for the administration of protein drug delivery. In such administration, the absorption of sufficient amount of drug through a particular barrier is expected in order to achieve a pharmacological response.

In therapeutic drug delivery, drugs generally should pass through barriers like the skin, blood–brain barrier (BBB) and gastrointestinal (GI) tract via cell membranes. These barriers can be overcome by using nanoparticle drug delivery. This chapter discusses general information on cell membranes and the problems encountered by drugs when trying to cross them. To circumvent such barriers in drug delivery, nanoparticulate drug delivery is preferred through the skin, BBB and orally.

In nanoparticle drug delivery through the skin the encapsulation of hydrophobic carriers with penetration enhancers is used to increase the hydrophobicity. Encapsulation involves the entrapment of a polypeptide drug within a polymeric, phospholipid or carbohydrate particulate delivery system such as nanoparticles, micro-

spheres and liposomes [2]. The BBB acts as an insurmountable barrier for a large number of drugs like central nervous system (CNS)-active drugs and antibiotics. It is also used as a major component in the regulation of the internal environment of the brain. A number of attempts have been made to overcome such a barrier, including the osmotic opening of tight junctions and the use of prodrugs or carrier system like nanoparticles/liposomes. Prodrugs can efficiently penetrate and transport across the lipophilic endothelial barrier or the efflux pump systems [3]. The best carriers for oral administration are nanoparticles and microspheres. A wide range of polymers of different sizes have been employed to investigate particle uptake. An encapsulation technique is used for the entrapment of hydrophilic or hydrophobic fluorochromes.

Nanoparticulate drug delivery has become a popular route of administration due to its penetrating and fast-acting capacity. Nanomaterials used in drug delivery created by nanotechnology research range from 1 to 100 nm in size. Nanomaterials have the potential to solve unique biological challenges such as dealing with inorganic materials, detecting electrical changes from biological molecules and treating disease.

## 12.2

### Cell Membranes

Cell membranes are composed of lipid bilayers, proteins and lipopolysaccharides attached to the membrane surface. Due to the amphipathic nature of the lipid molecules, the lipid bilayer has charged (phosphate) groups on the water-faced surface and hydrophilic carbon inside the chains. The membrane proteins are either partially or fully integrated into the membrane bilayer or attached to its surface. Protein-free lipid bilayers are freely permeable to water and small nonpolar molecules, such as  $O_2$  and  $N_2$ , but impermeable to ions. For this reason, cells have evolved special ways of transferring water-soluble molecules across the membranes [4].

Understanding membrane transport has been an important goal for more than a century because it governs many aspects of life. All membranes work as gatekeepers to cells. They are responsible for signaling in the nervous system, and for coordination of the contraction of skeletal muscle and the heart, forcing its muscle to function as a pump. Membranes contain receptors or effectors for many drugs and natural substances that control the life of cells. Some other important functions like energy storage and signal transduction are also mediated through biological pores via ion flow.

One major group of transport drugs is the ion channel proteins. The mechanism and properties of ion transport through these channel proteins are subjects of wide current interest [5–9]. These ion channels provide gates for ions like  $Na^+$ ,  $Cl^-$ ,  $K^+$  and  $Ca^{2+}$  to enter or leave the cell. The channel and carrier proteins allow solutes to cross the membrane passively in a so-called “facilitated diffusion”. These transport processes occur in the direction of a concentration gradient or according to

different transmembranal potentials [10] without requiring any cell energy. However, certain membrane proteins can also act as ion pumps, transporting ions actively against a concentration gradient using energy equivalents such as ATP. By regulating the passage through these gates, cells can maintain the desired internal ion concentrations (which are often quite different from their concentrations in the surrounding solutions).

Transport processes across membranes are experimentally studied with the patch-clamp recording technique, which has revolutionized research in this field. Transport through a single molecule of a channel protein can be studied in a small patch of membrane covering the mouth of a micropipette using this technique [4]. Patch-clamp recording enables us to observe the current flow through the channel depending on the applied voltage and voltage or transmitter-induced channel gating states.

Gap junctions are clusters of closely packed intercellular membrane channels embedded in the plasma membranes of two adjoining cells [11]. They are unique systems among ion channels because two hemi-channels are connected to span two cell membranes. They facilitate a form of intercellular communication by permitting the regulated passage of ions and small molecules from one cell to another. Intercellular communication through gap junction channels has functional roles in cell survival, development, differentiation, metabolism, morphogenesis and mutagenesis [12–15]. Gap junctions permit action potential propagation in electrically excitable synapses and help to maintain homeostasis in vascular systems, such as the lens and ovarian follicles [16]. The two hemi-channels are a structure of connexon hexamers, each consisting of six connexin proteins. They dock to form a sealed cell-to-cell passageway [17]. The interlocking of the two channels occurs extracellularly in a narrow 3.5 nm “gap” separating the junctional membranes. This channel–channel interaction is known to be selective between connexins [18]. So far, the secondary and tertiary structural organization of the connexins has been solved at 7–21 Å resolution [19]. The outer diameter of the connexon is about 70 Å and it narrows at the extracellular domains, creating a “waist” in the appearance of the intercellular channel in the gap region of an outer diameter of about 50 Å [11]. The channel pore narrows from an apparent 40 Å diameter at the cytoplasmic side to 15 Å at the extracellular side of the bilayer and then widens to 25 Å in the extracellular region. The gap junction channels can be opened and closed by various physiological stimuli and experimental treatments (gating processes). They are permeable to ions and neutral molecules up to a size of about 1 kDa or 1.5 nm diameter, including secondary messengers and metabolites. Trans-junctional voltages or those between the cytoplasm and exterior affect junctions the most [12, 16].

### 12.2.1

#### Functions of Biological Membranes

The main functions of biological membranes are to: (a) provide an enclosure for the cells, (b) allow the exchange of materials, (c) act as sites of biological reactions

Fig. 12.1. Schematic view of a typical cell membrane [20b].

including photosynthesis, electron transfer and oxidative phosphorylation, (d) facilitate cell motion, and (e) enable recognition and cell fusion.

The biological membrane has proved to be vital in countless mechanisms necessary for cell survival. The phospholipid bilayer performs the simpler functions of compartmentalization, protection and osmoregulation. The proteins perform a wider range of functions such as extracellular interactions and metabolic processes. The carbohydrates are found in conjunction with both the lipids and proteins, and therefore enhance the properties of both. This may vary from recognition to protection.

Overall, the biological membrane is an extensive, self-sealing, fluid, asymmetric, selectively permeable and compartmental barrier essential for the correct functioning of a cell or organelles, and for a cell survival [20a]. See Fig. 12.1 for a schematic view of a typical cell membrane.

### 12.2.2

#### Kinetic and Thermodynamic Aspects of Biological Membranes

Plasma membranes of eukaryotic cells show a pronounced asymmetry with respect to the distribution of the major lipid components between the two protein monolayers. The aminophospholipids phosphatidylserine (PS) and phosphatidylethanolamine (PE) are predominantly located on the cytoplasmic leaflet, whereas the phospholipids phosphatidylcholine (PC) and sphingomyelin (SM) are mainly found on the external leaflet. Evidence for the distribution of cholesterol as another membrane component is still contradictory. Some researchers found a preference for cholesterol for the cytoplasmic layer of the red blood cell membrane, whereas other results indicated a rather symmetrical distribution.

The asymmetrical distribution of the aminophospholipids may be understood by an ATP-dependent translocation of these components from the external to the

cytoplasmic layer. The response of the membrane to this directed transport will concern not only the counter-directed movement of PS and PE, but also a redistribution of PC, SM and cholesterol. Furthermore, a change in membrane curvature may occur because of geometrical restrictions and corresponding mechanical forces caused by the coupling of the monolayer surfaces. This reasoning shows that the membrane asymmetry is determined by a multitude of processes, depending on (a) the metabolic state of the cell, (b) the mechanism of active translocation, (c) the transmembrane concentration differences of lipids and (d) mechanical forces.

Studies have attempted to gain a complete understanding of the phenomena of transbilayer lipid movement by finding an appropriate phenomenological description of the lipid fluxes. The steady-state asymmetrical lipid distribution is governed by dynamic equations. A reference simulation with a minimal set of phenomenological parameters yields qualitative restrictions to the many possible translocation mechanisms. Relations between phenomenological and kinetic model parameters serve, furthermore, as guidelines for the selection of kinetic constants in a quantitative way. It can be shown how the mechanical driving forces of the phenomenological model are to be incorporated into a kinetic model of lipid translocation.

Active transport based on a kinetic scheme involving competitive binding of PS and PE has been developed. It is clear that besides the kinetic parameters of passive translocation, mechanical forces affect those of active transport. However, the presented mechanism of active transport is not sufficient to allow for a proper treatment of mechanical effects because ATP binding, ATP hydrolysis, ADP release and lipid translocation are lumped into single irreversible translocation steps for PS and PE. Despite this, the proposed equations for active translocation are compatible with present knowledge about the kinetic properties of active lipid translocation in erythrocytes. This is particularly noted in the competition of PS and PE for the same binding site with a 10-fold higher affinity of PS on the external monolayer. The latter property results in a pronounced difference in the time constants of active transport of these two lipids.
