In optical tweezers (OT) small particles are manipulated by optical traps [16.39]. Three-dimensional light intensity gradients of a focused laser beam are used to pull or push the particles against another one. Particle displacements can be followed with nanometer resolution. Movements of single molecular motors [16.40] and force-extension profiles of single extensible molecules such as titin [16.41] and DNA [16.42] were measured. Defined, force-controlled twisting of DNA using rotating, magnetically manipulated particles gave even further insights into DNA viscoelastic properties [16.43].

The atomic force microscope (AFM) is the force measuring method with the smallest-sized force sensor and therefore achieves the highest lateral resolution. Radii of commercially available AFM tips vary between 2 and 50 nm. In contrast, the sensing particles in SFD, BFP, and OT are in the 1 to 10 μm range, and the surfaces used in SFA exceed millimeter extensions. The small apex of the AFM tip allows for the probing of single biomolecules. Originally designed to explore the topography of rigorous surfaces with atomic resolution [16.1] in area scans, the AFM was used in biology to image the secondary structures of nucleotides [16.25], as well as polar lipid head groups and subunits of proteins embedded in membranes in liquid environments [16.27, 28].

The additional potential of the AFM to detect ultralow forces has been successfully applied to the detection of interaction forces of single receptor-ligand pairs [16.2–4]. These forces are measured in so called force-distance cycles using a ligand-carrying tip mounted to a cantilever and a probe surface with receptors firmly attached. A force-distance cycle, where a distensible tether was used to couple ligands to tips and receptors to surfaces is shown in Fig. 16.5 (from [16.4]). At a fixed lateral position the tip approaches the probe surface and is subsequently retracted, and the cantilever deflection Δx is measured in dependence of the tip-surface separation Δz. Cantilever deflections are detected by reflecting a laser beam off the back of the cantilever onto a split photodiode. Bending of the cantilever causes a change in the position where the laser beam strikes the photodiode and, therefore, a change in the output voltage of the photodiode.

The force F acting on the cantilever directly relates to the cantilever deflection Δx according to Hook's law $F = k\Delta x$, where k is the cantilever spring constant. During tip-surface approach (trace, and line 1 to 5), the cantilever deflection remains zero far away from the surface (1 to 4), because there is no detectable tip-surface interaction. Upon tip-surface contact (4), the cantilever bends upward (4 to 5), consistent with a repulsive force that increases linearly with z the harder the tip is pushed into the surface. Subsequent tip-surface retraction (retrace, 5 to 7) first leads to relaxation of the cantilever bending and the repulsive force drops back down to zero (5 to 4).

When ligand-receptor binding has occurred, the cantilever bends downward upon retraction, reflecting an attractive force (retrace, 4 to 7) that increases with increasing tip-surface separation. Since the cognitive molecules were tethered to the surfaces via flexible and distensible crosslinkers, the shape of the attractive force-distance profile is, in contrast to the repulsive force-distance profile of the contact region

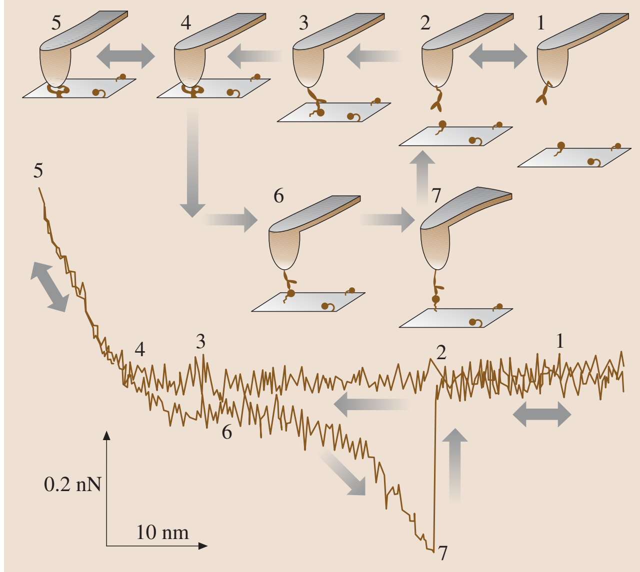

Fig. 16.5 Single-molecule recognition event detected with AFM. Raw data from a force-distance cycle with 100 nm z-amplitude at 1 Hz sweep frequency measured in PBS. Binding of the antibody on the tip to the antigen on the surface during approach (trace points 1 to 5) physically connects tip to probe. This causes a distinct force signal of distinct shape (points 6 to 7) during tip retraction, reflecting extension of the distensible crosslinker-antibody-antigen connection. The force increases until unbinding occurs at an unbinding force of 268 pN (points 7 to 2). (After [16.4])

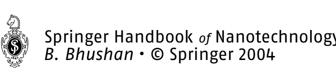
(4 to 7), nonlinear. Its shape is determined by the elastic properties of the flexible PEG crosslinker [16.17, 44] and shows parabolic-like characteristics, which reflects the increase of the spring constant of the crosslinker during extension. The force attractive profile contains the features of a single-molecule recognition event.

The physical connection between the tip and surface sustains the increasing force until the ligand-receptor complex dissociates at a certain critical force (unbinding force, 7), and the cantilever finally jumps back to the resting position (7 to 2). The quantitative force measure of the unbinding force f of a single receptor-ligand pair is directly given by the force at the moment of unbinding (7).

If the ligand on the tip does not form a specific bond with one of the receptors on the probe surface, the recognition event is missing and retrace looks like trace. Also, the specificity of the ligand-receptor binding is usually demonstrated in block experiments. Free ligands are injected in solution so as to block receptor sites on the surfaces. As a further consequence, recognition signals completely disappear, because the receptor sites on the surface are blocked by the ligand of the solution and, thus, prevent recognition by the ligand on the tip.

The force resolution of the AFM is limited by the thermal noise of the cantilever that is determined by its spring constant. According to the equipartition theorem, the cantilever has on average a thermal energy of $0.5\,k_{\mathrm{B}}T$, therefore, $0.5\,k\Delta z^2 = 0.5\,k_{\mathrm{B}}T$, where k_{B} is Boltzmann's constant and T the absolute temperature. Since $F = k\Delta x$, the force sensitivity is given by $\Delta F = (k_{\mathrm{B}}Tk)^{1/2}$ and is, therefore, better the softer the cantilever. The smallest force that can be detected with commercially available cantilevers is in the few picoNewton range. For thinner levers with low spring constants, the force resolution decreases by an order of magnitude [16.45]. Due to their smaller mass, they have a higher resonance frequency (30–100 kHz in liquid). When deflection is recorded at a typical bandwidth of 10 kHz, only a fraction of the thermal noise is included and fast movements of the tip can still be detected [16.45]. An alternative route for improving the force resolution was found by electronically increasing the apparent damping constant, which results in the reduction of thermal noise [16.46].

Besides the detection of intermolecular forces between receptors and ligands, the AFM also shows great potential in measuring intramolecular force profiles of single molecules. The molecule is clamped in between the tip and the probe surface and its visco-elastic properties are studied in force-distance cycles. The detailed force extension profile of the recognition event shown in Fig. 16.5 contains, for example, the elastic features of the crosslinker (PEG in this particular case) [16.44] with which the ligand is tethered to the tip of the AFM.



16.4 Principles of Molecular Recognition Force Spectroscopy

Specific interactions underlying molecular recognition are a distinct class of highly complementary, non-covalent bonds between biological macromolecules composed typically of a few tens of weak interactions such as electrostatic, polar, van der Waals, hydrophobic, and hydrogen bonds. The energy of each single bond is just slightly higher than the thermal energy $k_B T$. Due to the power law dependence of each weak interaction potential and the directionality of the hydrogen bonds, the attractive forces between the receptors and their cognitive ligands are extremely short-range. Therefore, a close geometrical and chemical fit within the binding pocket is a prerequisite for molecular recognition.

Conformational flexibility of at least one of the two binding partners is required for their structural adaptation. The weak interaction bonds are believed to be formed in a spatially and temporarily correlated fashion, thus creating a strong and highly specific molecular interaction. Recognition binding sites are structurally and chemically unique and selective for distinct receptor/ligand combinations. The overall affinity or binding energy of a receptor-ligand bond of a few tens of $k_B T$ is typically sufficient to effect chemical or physical changes of the binding partners, which often initiate biochemical reaction cascades or cellular metabolic pathways.

The binding energy E_B, given by the free energy difference between the bound and the free state, is the common parameter to describe the strength of a bond and can be determined in ensemble average calorimetric experiments. E_B determines the ratio of bound complexes, [RL], to the product of free reactants, [R] [L], at equilibrium in solution and is related to the equilibrium dissociation constant K_D, the affinity parameter, according to $E_B \alpha - \log(K_D)$. At thermodynamic equilibrium, the number of complexes that form per unit of time, k_{on} [R] [L], equals the number of complexes that dissociate per time unit, k_{off} [RL]. The empirical kinetic rate constants, on-rate k_{on} and off-rate k_{off}, are related to the equilibrium dissociation constant K_D through $K_D = k_{off}/k_{on}$.

In order to get an estimate for the interaction forces f from binding energies E_B, the dimension of the binding pocket may be used as the characteristic length dimension l; thus $f = E_B/l$. Typical values of $E_B = 20\,k_B T$ and $l = 0.5$ nm yields $f \sim 170$ pN as an order of magnitude feeling for the strength of a single receptor-ligand bond. Classical mechanics describes the force required to separate interacting molecules as the gradient in energy along the interaction potential. The complexed molecules would, therefore, dissociate when force exceeds the steepest gradient in energy. However, activation barriers, temperature, time scales, and the detailed characteristics of the energy landscape, all known to be essential for the understanding of receptor-ligand dissociation, are not considered in this purely mechanical picture.

Ligand-receptor binding is generally a reversible reaction. Viewed on the single-molecule level, the average lifetime of a ligand-receptor bond, $\tau(0)$, is given by the inverse of the kinetic off-rate, k_{off}, so $\tau(0) = k_{off}^{-1}$. Therefore, ligands will dissociate from receptors without any force applied to the bond at times larger than $\tau(0)$ (covering a range from milliseconds to days for different receptor-ligand combinations). In contrast, if molecules are pulled faster than $\tau(0)$, the bond will resist and require a force for detachment. The size of the unbinding force may vary over more than one order of magnitude, and even exceed the adiabatic limit given by the steepest energy gradient of the interaction potential if bond breakage occurs faster than diffusive relaxation (nanosecond range for biomolecules in viscous aqueous medium) and friction effects become dominant [16.47]. Therefore, unbinding forces do not resemble unitary values, and the dynamics of the experiment defines the physics underlying the unbinding process.

At the millisecond to second time scale of AFM experiments, thermal impulses govern the unbinding process. In the thermal activation model, the lifetime of a complex in solution is described by a Boltzmann ansatz, $\tau(0) = \tau_{osc} \exp(E_b/k_B T)$ [16.48], where τ_{osc} is the inverse of the natural oscillation frequency and E_b the energy barrier for dissociation. Hence, due to the thermal energy there is a finite probability of overcoming the energy barrier E_b, which leads to the separation of the receptor-ligand complex. The mean complex lifetime in solution is, therefore, determined by the ratio of E_b over the thermal energy.

A force acting on a binding complex deforms the interaction energy landscape and lowers the activation energy barrier, very similar to the mode of operation of an enzyme (Fig. 16.6). Thus the input of thermal energy by forces acting in this time regime reduces the bond lifetime. The lifetime $\tau(f)$ of a bond loaded with a constant force f is given as $\tau(f) = \tau_{osc} \exp[(E_b - x_\beta f)/k_B T]$ [16.48], x_β being interpreted as the distance of the energy barrier E_b from the energy minimum along the direction of the

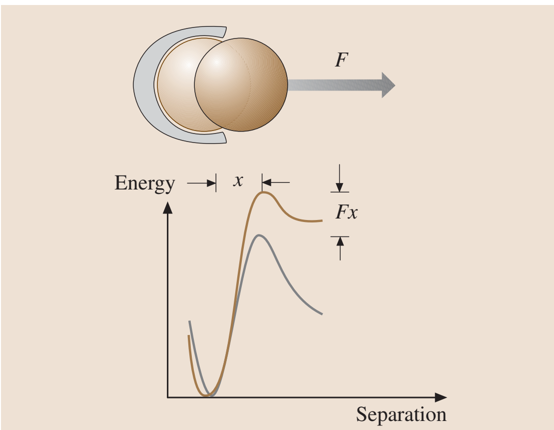

Fig. 16.6 Dissociation over a single sharp energy barrier. Under a constant force, the barrier is linearly decreased by the applied force F, giving rise to a characteristic length scale x that is interpreted as the distance of the energy barrier from the energy minimum along the projection of the force (after [16.50])

applied force. In this model, the energy barrier decreases linearly with the force applied. A detailed physical basis for Bell's theory has been derived in [16.49], where the strength of weak non-covalent bonds was studied in liquid using Kramer's theory for reaction kinetics in liquids under the influence of force.

The lifetime $\tau(f)$ under constant force f compares to the lifetime at zero force, $\tau(0)$, according to $\tau(f) = \tau(0)\exp(-x_\beta f/k_B T)$ [16.4] for a single sharp energy barrier for which a mono-exponential dependence is characteristic. Using AFM, receptor-ligand unbinding is commonly measured in force-distance cycles (cf. previous chapter), during which the applied force to the complex does not remain constant. Rather, it increases in a complex fashion at a nonlinear rate determined by the pulling velocity, the spring constant of the cantilever, and the force-distance profile of the complexed biomolecules. The main contribution of the thermal activation, however, comes from the part of the force curve, which is close to unbinding. Therefore, an effective force increase or loading rate r can be deduced from $r = \mathrm{d}f/\mathrm{d}t$ = pulling velocity times effective spring constant at the end of the force curve just before unbinding occurs. The approximation of a constant loading rate using force-distance cycles with AFM is sound with a properly defined effective loading rate [16.51].

The dependence of the unbinding force on a linear loading rate in the thermally activated regime was first derived in [16.49] and further described in [16.50]. Force-induced dissociation of receptor-ligand complexes using AFM or BFP can be regarded as an irreversible process, because the two binding partners are further separated after dissociation has occurred. Therefore, rebinding and back-reactions are negligible. The unbinding process itself is of a stochastic nature, and the likelihood of bond survival is expressed in the master equation as time-dependent probability $N(t)$ to be in the bound state under a linearly increasing force $f = rt$, thus $\mathrm{d}N(t) = -k_{\mathrm{off}}(rt)N(t)$ [16.50].

Rewriting Bell's formula using $\tau(f) = k_{\mathrm{off}}^{-1}(f)$ relates the kinetic off-rate at a given force f, $k_{\mathrm{off}}(f)$, to the off-rate at zero force, $k_{\mathrm{off}}(0)$: $k_{\mathrm{off}}(f) = k_{\mathrm{off}}(0)\exp(l_r f/k_B T)$. The master equation combined with Bell's formula results in a spectrum of Gaussian-like distributions of unbinding forces (frequency of occurrence versus force) parameterized by the loading rate r [16.50]. Thus the maximum of each force distribution, $f^*(r)$, reflects the most probable force of unbinding for the respective loading rate r. f^* is related to r through $f^* = f_\beta \log_e(rk_{\mathrm{off}}^{-1}/f_\beta)$, where the slope is governed by f_β, a force scale set by the ratio of the thermal energy $k_B T$ to the length scale x_β, which marks the thermally averaged position of the energy barrier along the direction of the force [16.49, 50]. Apparently, the unbinding force f^* scales linearly with the logarithm of the loading rate. For a single barrier, this would give rise to a simple, linear dependence of the force versus log loading rate. In cases where more barriers are involved along the escape path, the curve will follow a sequence of linear regimes, each of which marks a particular barrier [16.38]. Hence, transition from one regime to the other is associated with an abrupt change of slope determined by the characteristic barrier length scale.

In force spectroscopy experiments, the dynamics of pulling on specific receptor-ligand bonds is varied, which leads to detailed structural and kinetic information of the bond breakage, as discussed above and shown in the following chapter on explicit examples. Length scales of energy barriers are obtained from the slope of the spectroscopy plot (force versus loading rate) and their relative heights may be gained from the force shifts [16.38]. Extrapolation to zero forces yields the kinetic off-rate constant for the dissociation of the complex in solution [16.52].

16.5 Recognition Force Spectroscopy: From Isolated Molecules to Biological Membranes

In the early pioneering AFM studies receptor-ligand bond strengths were only measured at one loading rate. Therefore, only a single point in the spectrum of forces, that depend on the dynamics of the experiment, was determined. Avidin–biotin is often regarded as the prototype of receptor-ligand interaction due to its enormously high affinity ($K_D = 10^{-13}$ M) and long bond lifetime ($\tau(0) = 80$ days). Hence, it may not be too surprising that the first realizations of single-molecule recognition force detections were made with biotin and its cognitive receptors, streptavidin [16.2], the succinilated form of avidin, and avidin [16.3]. Unbinding forces of 250–300 pN and 160 pN were found for streptavidin and avidin, respectively. It was also shown [16.53] that the forces vary with the spring constant of the cantilever using the same pulling velocity, which is consistent with the loading rate dependency of the unbinding force discussed above. The recognition forces of various biotin analogs with avidin and streptavidin [16.53], as well as with site-directed streptavidin mutants [16.54] were related to their energies and found to be correlated with the equilibrium binding enthalpy [16.53] and the enthalpic activation barrier [16.54] but independent of free energy parameters. It was suggested that internal energies of the bond breakage, rather than entropic changes were probed by the force measurements [16.54].

16.5.1 Forces, Energies, and Kinetic Rates

In first measurements of inter- and intramolecular forces of the DNA double helix [16.6], complementary single-strand DNA oligonucleotides covalently attached to the AFM tip and the probe surface, respectively, were probed. The multimodal force distributions obtained (three distinct, separated force peaks) were associated with interchain interactions of single pairs of 12, 16, and 20 base sequence length. A long strain single-strand DNA with cohesive ends was sandwiched in between tip and substrate and its intramolecular force pattern revealed elastic properties comparable to polymeric molecules [16.6]. Single molecule interactions between all possible 16 combinations of the four bases were also studied [16.7] and yielded specific binding only when complemetary bases were present on the tip and the probe surface, indicating that AFM is capable of following Watson-Crick base pairing.

Antibody-antigen interactions are of key importance for the function of the immune system. Their affinities are known to vary over orders of magnitudes. For single-molecule recognition AFM studies, the molecules were surface-coupled via flexible and distensible crosslinkers [16.4, 10, 13, 14] to provide them with sufficient motional freedom, so that problems of misorientation and steric hindrance that can obscure specific recognition are avoided. In [16.4, 12], the tips were functionalized with a low antibody density, so that on the average only a single antibody on the tip end could access the antigens on the surface. Hence, isolated single molecular antibody-antigen complexes could be examined. It was observed that the interaction sites of the two Fab fragments of the antibody (the antibody consists of two antigen-active Fab-fragments and one Fc-portion) are able to bind simultaneously and independently with equal binding probability. Single antibody-antigen binding events were also studied with tip-bound antigens [16.10] using an antibody biosensor probe surface [16.13], or single chain antibody-fragments attached to gold via freely accessible sulfhidryl groups [16.14]. In the latter study, the unbinding forces of two mutant single-chain antibodies, varying by an order of magnitude in their affinity, were compared. The mutant of ten times lower affinity (consistent with 12% lower free energy due to the logarithmic dependence of the affinity on free energy) showed 20% lower unbinding force.

All these studies describe detection of intermolecular forces between single receptors and their cognitive ligands. However, the AFM can also be used to characterize single-molecule intramolecular forces, e.g., interactions responsible for stabilizing the conformations and tertiary structures of polymers and proteins. The force-extension profile (cf. also stretching of PEG in Fig. 16.5) of polysaccharide dextran revealed multiple elastic regimes dominated by entropic effects, internal bond angle twistings, and conformational changes [16.55, 56]. The complex quantities of elastic and viscous force contributions upon stretching a single dextran molecule were resolved by resonant energy tracking using dynamic force spectroscopy [16.57]. Titin, a fibrillose muscle protein, contains a large number of repetitive IgG domains that shows a characteristic sawtooth pattern in the force profile, reflecting their sequential unfolding (Fig. 16.7) [16.58]. Unfolding and refolding kinetics and energetics of proteins

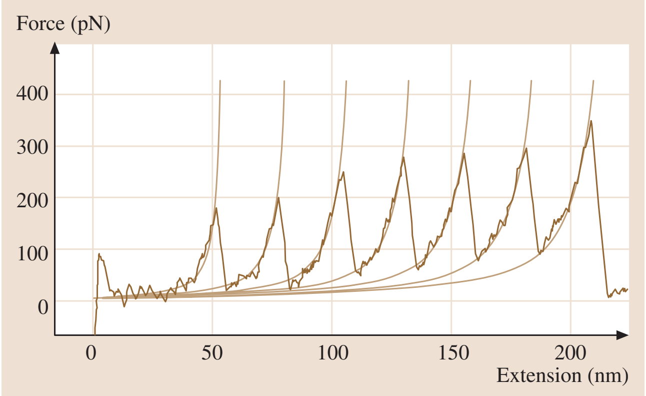

Fig. 16.7 Force extension profile of a single titin molecule. The periodic sawtooth-like pattern reflects domain unfolding in the peptide chain consistent with its modular construction and can be explained as a stepwise increase of the molecule's length upon each unfolding event (after [16.58])

were studied in pull-hold-release cycles [16.59] by carefully handling the molecule between tip and surface. These studies yield crucial information on the relation between structure and function of single molecules.

Besides the investigation of forces, single-molecule recognition force microscopy studies allow for the estimation of association and dissociation rates [16.4, 12, 22, 52, 60, 61], energies [16.38], and structural parameters of the binding pocket [16.4, 12, 15, 60, 61]. For single molecule studies, quantification of the on-rate constant k_{on} for the association of the ligand on the tip to a receptor on the surface requires determination of the interaction time $t_{0.5}$ needed for half-maximal probability of binding. This value is obtained from an experiment in which the encounter duration of the ligand-coated tip on the receptor-containing surface is varied until a range of the unbinding activity from zero to saturation is achieved [16.60]. With the knowledge of the effective ligand concentration c_{eff} on the tip available for receptor interaction, k_{on} is given by $k_{on} = t_{0.5}^{-1} c_{eff}^{-1}$. The effective concentration c_{eff} is described by the effective volume V_{eff} the tip-tethered ligand diffuses about the tip, which yields $c_{eff} = N_A^{-1} V_{eff}^{-1}$, where N_A is the Avogadro's number. V_{eff} is essentially a half-sphere with a radius of the effective tether length, and the kinetic on-rate can, therefore, be calculated from $k_{on} = t_{0.5}^{-1} N_A 2\pi/3r^3$. However, since k_{on} critically depends on the tether length r, only order of magnitude estimates are gained [16.60].

Additional information about the unbinding process is contained in the unbinding force distributions. Not only the maximum f^*, but also its intrinsic width σ increases with increasing loading rate [16.22, 38]. Apparently, at slower loading rates the systems adjust closer to equilibrium, which leads to smaller values of both the force f^* and its variation σ. This is another indication that dynamics is an important issue when studying recognition forces. An effective lifetime $\tau(f)$ of the bond under an applied force f was estimated by the time the cantilever spends in the force window spanned by the standard deviation σ of the f distribution [16.4]. The time the force increases from $f^* - \sigma$ to $f^* + \sigma$ is thus given by $\tau(f) \approx 2\sigma/\mathrm{d}f/\mathrm{d}t$ [16.4]. In an example of the Ni^{2+}-chelating ligand/receptor interaction nitrotrilacetate/hexa-histidin [16.22], the lifetime $\tau(f)$ decreased with increasing pulling force f from 17 ms at 150 pN to 2.5 ms at 194 pN. The data were fitted with Bell's formula, confirming the theoretically predicted exponential lifetime-force relation for the reduction of the lifetime $\tau(f)$ by the applied force f and, thus yielding a lifetime at zero force, $\tau_0 = 15$ s. Direct measurements of lifetimes are only possible by using a force clamp, where a constant adjustable force is applied to the complex via a feedback loop and the time duration of bond survival is detected. This configuration has been developed recently to study the force dependence of the unfolding probability of the filament muscle protein titin [16.62].

Theory predicts (cf. previous chapter) that the unbinding force of specific and reversible ligand-receptor bonds is dependent on the rate of the increasing force [16.47, 49, 63] during force-distance cycles. Indeed, in experiments unbinding forces were found to assume not a unitary value, but rather were dependent on both the pulling velocity [16.52, 60] and the cantilever spring constant [16.2]. The theoretical findings were confirmed by experimental studies and revealed a logarithmic dependence of the unbinding force on the loading rate [16.15, 22, 38, 52, 60, 61], consistent

with the exponential lifetime-force relation described above. On a half-logarithmic plot, a single linear slope is characteristic for a single energy barrier probed in the thermally activated regime [16.38]. The same relation was also found for unfolding forces of proteins [16.55]. The slope of the force spectroscopy curve contains the length scale of the energy barrier, which may be connected to the length dimension of the interaction binding pocket [16.60]. The kinetic off-rate k_{off} at zero force is gained from the extrapolation to zero force [16.52, 60]. Combining k_{off} with k_{on} leads to a value for the equilibrium dissociation constant K_{D}, according to $K_{\mathrm{D}} = k_{\mathrm{off}}/k_{\mathrm{on}}$.

A simple correlation between unbinding force and solution kinetics was found for nine different single-chain Fv fragments constructed from point mutations of three unrelated anti-fluorescein antibodies [16.61]. These molecules provide a good model system because they are monovalent and follow a 1:1 binding model without allosteric effects, and the ligand (fluoerscein) is inert and rigid. For each mutant, the affinity K_{D}, the kinetic rate constants k_{on} and k_{off}, and the temperature dependence of k_{off} yielding the activation barrier E_{b}, were determined in solution. In a series of single-molecule AFM recognition events, the loading rate (r) dependence of the unbinding forces (f) was measured. The maxima of the force distributions f^* scaled linearly with $\log r$. Therefore, unbinding was dictated by a single energy barrier along the reaction path (Fig. 16.8). Since the measured unbinding forces of all mutants precisely correlated with k_{off}, the unbinding path followed and the transition state crossed cannot be too dissimilar in spontaneous and forced unbinding. Interestingly, the distance of the energy barrier along the unbinding pathway determined from the force spectroscopy curve was found to be proportional to the barrier height and, thus, most likely includes elastic stretching of the antibody construct during the unbinding process.

16.5.2 Complex Bonds and Energy Landscapes

More complex force spectra were found from unbinding force measurements between complementary DNA strands of different lengths [16.15]. DNA duplexes with 10, 20, and 30 base pairs, were investigated to reveal unbinding forces from 20 to 50 pN of single duplexes, depending on the loading rate and sequence length. The unbinding force of the respective duplexes scaled

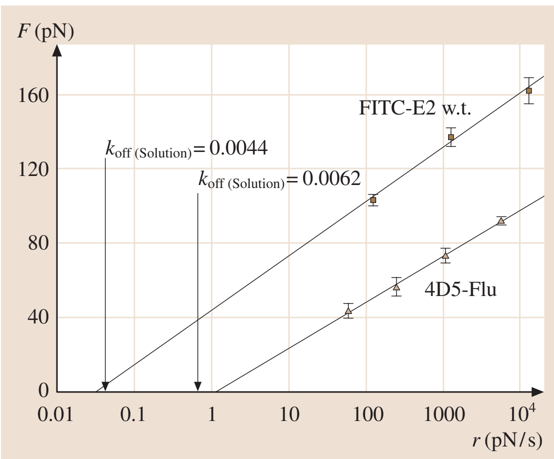

Fig. 16.8 Loading rate dependence of the unbinding force dependence of two anti-fluoresceins. For both FITC-E2 w.t. and 4D5-Flu, a strictly mono-logarithmic dependence was found in the range accessed, indicating that only a single energy barrier was probed. The same energy barrier dominates dissociation without forces applied, because extrapolation to zero force matches kinetic off-rates determined in solution (indicated by *arrow*) (after [16.61])

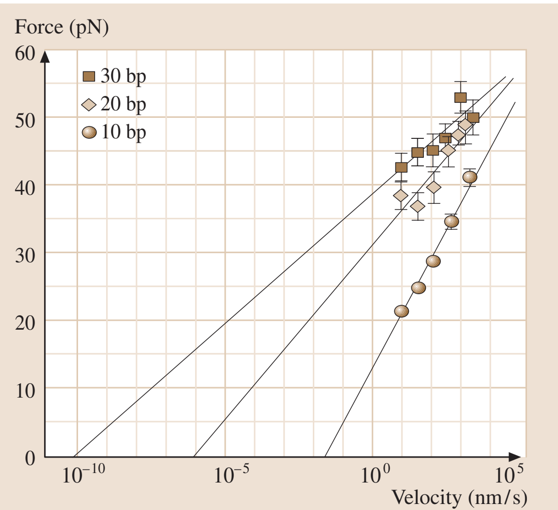

Fig. 16.9 Dependence of the unbinding force between DNA single-strand duplexes on the retract velocity. Besides the mono-logarithmic behavior, the unbinding force scales with the length of the strands, increasing from the 10- to 20- to 30-base-pair duplexes (after [16.15])

with the logarithm of the loading rate, however, each of them with a different slope (Fig. 16.9). The distance of the energy barrier along the separation path and the logarithm of the kinetic off-rate, both obtained from the force spectroscopy plot as parameters describing the energy landscape, were found to be proportional to the number of DNA complexes per duplex. This defined scaling leads to a model of fully cooperative bonds in a series for the unbinding of the base pairs in the duplex, described by one distinct length and time scale for each duplex length, where each single bond contributes a defined increment [16.15]. A temperature study revealed that entropic contributions also play a role in the unbinding between complementary DNA strands [16.64].

Energy landscapes of receptor-ligand bonds in biology can be rugged terrains with more than one prominent energy barrier. The inner barriers are undetectable in solution assays, but can become predominant for certain time scales in force-induced unbinding. Therefore, force spectroscopy appears to be a proper tool to discover hidden activation barriers and explore the energy landscape in greater detail. In initial AFM studies [16.53, 54], it was concluded that the interaction strength of biotin-streptavidin is in the range of 200–300 pN and the strength of biotin-avidin is somewhat lower ($\sim$ 150 pN). However, using BFP, the loading rate was varied over eight orders of magnitude (from 10^{-2} to 10^{6} pN/s) and gained a detailed picture of the force spectroscopy curve with forces increasing from 5 to 200 pN (Fig. 16.10) [16.38].

Distinct linear regimes that demonstrate the thermally activated nature of the bond breakage are visible, abrupt changes in slope imply a number of sharp barriers along the dissociation pathway. Above 85 pN, there is a common high strength regime for both biotin-streptavidin and biotin-avidin with a slope of $f_\beta = 34$ pN, locating a barrier deep in the binding pocket at $x_\beta = 0.12$ nm. Below 85 pN, the slopes for biotin-streptavidin and biotin-avidin are different. $f_\beta = 8$ pN for biotin-strepavidin marks a barrier at $x_\beta = 0.5$ nm, whereas the steeper slope $f_\beta = 13–14$ pN between 38 and 85 pN in the biotin-avidin spectrum indicates that its next barrier is located at 0.3 nm. Below 11 pN, the biotin-avidin spectrum exhibits a very low strength regime with a slope of $f_\beta = 1.4$ pN that maps to $x_\beta = 3$ nm. In addition to the map of barrier locations, the logarithmic intercepts found by extrapolation of each linear regime to zero force also yield estimates of the energy differences between the activation barriers (Fig. 16.10).

A meticulous picture of the biotin-avidin bond rupture process with amino acid resolution was obtained

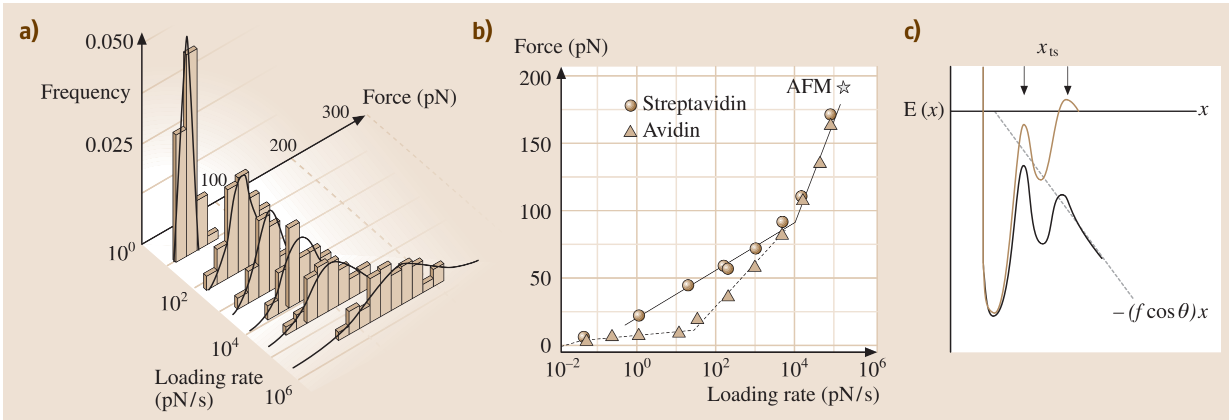

Fig. 16.10a–c Unbinding force distributions and energy landscape of a complex molecular bond. **(a)** Force histograms of single biotin-streptavidin bonds recorded at different loading rates. The shift in peak location and the increase in width with increasing loading rate is clearly demonstrated. **(b)** Dynamic force spectra for biotin-streptavidin (*circles*) and biotin-avidin (*triangles*). The slopes of the linear regimes mark distinct activation barriers along the direction of force. **(c)** Conceptual energy landscape traversed along a reaction coordinate under force under an angle θ to the molecular coordinate. The external force f adds a mechanical potential that tilts the energy landscape and lowers the barriers. The inner barrier starts to dominate when the outer has fallen below it due to the applied force (after [16.38])

with molecular dynamics simulation (MDS) [16.47,63]. Although the time scales of MDS for AFM pulling experiments are orders of magnitudes faster, forces in laboratory speeds were approximated. By reconstructing the interaction potential, the experimentally found transition states were readily identified. Simulations of antibody-antigen unbinding, however, revealed a large heterogeneity of enforced unbinding pathways and a correspondingly large flexibility of the binding pocket region, which exhibited significant induced fit motions [16.65].

The velocity dependence of rupture forces and adhesion probability of the receptor/ligand system P-selectin/P-selectin glycoprotein ligand-1 (PSGL-1) and their relation to kinetic and thermodynamic parameters obtained in ensemble average assays were analyzed in detail in [16.52]. The adhesive interactions of this system play a central immunogenic role in directing the PSGLT-1-containing leukocytes out of the blood stream and into sites of inflammation on cell layers via P-selectin. The high molecular elasticity of the P-selectin/PSGL-1 complex was determined from the force extension profile gained in force-distance cycles and described by the freely jointed chain, a polymer model that yields the Contour length (overall maximum extension), the persistence length (effective segment dimension), and the molecular spring constant. Rupture forces of single complex unbinding increased logarithmically with the loading rate (spring constant times pulling velocity), as expected from theory, and yielded $k_{\mathrm{off}} = 0.02\,\mathrm{s}^{-1}$ and $l = 0.25\,\mathrm{nm}$.

Another characteristic of the P-selectin/PSGL-1 relevant to its biological function was found by investigating the adhesion probability, defined as the ratio between the force-distance cycles showing an adhesion event and the total number of cycles, on the pulling velocity. Counterintuitively and in contrast to experiments with antibody-antigen [16.4], cell adhesion proteins [16.9] and cadherins [16.60], the adhesion probability increased with increasing velocities [16.52]. Since the adhesion probability approaches 1.0 at fast velocities, P-selectin/PSGL-1 complex formation must occur as soon as the tip reaches the surface, thus reflecting a fast kinetic on-rate. Upon the increase in force during pulling, the complexes only dissociate under a measurable force when pulled at fast velocities. No force will be detected at low velocities because the complex has already dissociated by the pure thermal energy and/or a force beneath the noise limit. A quantitative analysis revealed a fast kinetic off-rate of $k_{\mathrm{off}} = 15 \pm 2\,\mathrm{s}^{-1}$. The fast kinetic rates and high chain-like elasticity of the PSGL-1 system guarantee a rapid exchange of the leukocytes on endothelial cell surfaces and therefore provide the basis of the physiological leukocyte *roling* process [16.52].

PSGL-1 recognition to another member of the selectin family, L-selectin, was studied using BFP [16.66]. The loading rate was varied over three orders of magnitude, thereby gaining rupture forces from a few to 200 pN. Plotted on a logarithmic scale of loading rates, the rupture forces reveal two prominent energy barriers along the unbinding pathway. Strengths above 75 pN arise from rapid detachment ($< 0.01\,\mathrm{s}$) impeded by an inner barrier that requires Ca^{2+}, whereas strengths below 75 pN occur under slow detachment ($> 0.01\,\mathrm{s}$) impeded by an outer barrier, most likely constituted by an array of weak hydrogen bonds. It was speculated that a complex hierarchy of inner and outer barriers is significant in selectin-mediated function [16.66].

Single molecule recognition was also used to investigate the mechanism of the cadherin-mediated adhesion process of vascular endothelial cells. A monolayer of these cells constitutes the major barrier of the body that separates the blood compartment from the extracellular space of tissues. Homophilic cadherin adhesion acting within the cell junctions allows fast dynamic cellular remodeling to change the barrier properties of the cell layers. Recordings of force-distance cycles showed specific recognition events between tip- and surface-bound chimeric VE-cadherin dimers. Measuring the binding activity in dependence of the free Ca^{2+} concentration [16.60] revealed an apparent K_{D} of 1.15 mM with a Hill coefficient of $n_{\mathrm{H}} = 5.04$, indicating high cooperativity and steep dependency. It might be of physiological relevance that a local drop of free Ca^{2+} in the narrow intercellular cleft weakens intercellular adhesion and is, therefore, involved in facilitating cellular remodeling.

The rather low trans-interaction force of a single bond between two cadherin strand dimers was found to be amplified by complexes of cumulative binding strength, visible as distinct force quanta in the adhesion force distributions. These associates were formed by time-controlled lateral and trans-oligomerization, suggesting that cadherins from opposing cells associate to form complexes and, thus, increase the intercellular binding strength. The rather low values for the kinetic rates and the adhesive binding activity determined as described above, make cadherins ideal candidates for adhesion regulation by cytoskeletal tethering, thereby setting the kinetic rate of lateral self-association [16.60].

16.5.3 Live Cells and Membranes

So far, there have been only a few attempts to apply recognition force microscopy to living cells. Recently, *Lehenkari* et al. [16.67] measured the binding forces between integrin receptors in intact cells and Arg-Gly-Asp (RGD) amino acid sequence containing extracellular matrix protein ligands. Ligands, which had a higher predicted affinity for the receptor, gave greater unbinding forces, and the amino acid sequence/pH/divalent cation dependency of the receptor-ligand interaction examined by AFM was similar to the one observed under bulk measurement conditions using other techniques. In another study [16.68], the AFM was used to detect the adhesive strength between concavalin A (con A) coupled to an AFM tip and Con A receptors on the surface of NIH3T3 fibroblast cells. Crosslinking of receptors led to an increase in adhesion that could be attributed to enhanced cooperativity among adhesion complexes, which has been proposed as a physiological mechanism for modulating cell adhesion.

The sidedness and accessability of protein epitopes of the Na^{2+}/D-glucose co-transporter in intact brush border membrane vesicles was sensed with an AFM tip containing an antibody directed against an a sequence close to the glucose binding site [16.35]. Orientations and conformations of the transporter molecule were found to change during glucose binding and transmembrane transport, as evident from the observation of three distinct states discernable in interaction strength and binding activity. Force spectroscopy experiments between leukocyte function-associated antigen-1 (LFA-1) on the tip and intercellular adhesion molecule-1 (ICAM-1) expressed on cell surfaces [16.69] revealed a bilinear behavior in the force vs. log loading rate curve, marking a steep inner activation barrier and a wide outer activation barrier. Since addition of Mg^{2+}, a co-factor that stabilizes the LFA-1/ICAM-1 interaction, elevated the unbinding force of the complex in the slow loading regime and EDTA suppressed the inner barrier, it was suggested that the equilibrium dissociation constant is regulated by the energetics of the outer barrier, whereas the inner barrier determines the ability to resist an external force.

Forces about ten times higher (3 nN) were achieved when whole cells were used to modify the tip instead of single molecules, as shown in measurements of inter-cell force detections between trophoplasts and uterine pithelium cells [16.70]. In a similar configuration but with defined control of the interaction, de-adhesion forces at the resolution of individual cell adhesion molecules in cell membranes were detected and the expression of a gene was quantitatively linked to the function of its product in cell adhesion [16.71].

16.6 Recognition Imaging

Besides studying ligand-receptor recognition processes, the identification and localization of receptor binding sites on bio-surfaces such as cells and membranes are of particular interest. For this, high resolution imaging must by combined with force detection, so that binding sites can be assigned to structures.

A method for imaging functional groups using chemical force microscopy was developed in [16.72]. Both tip and surface were chemically modified, and the adhesive interactions between tip and surface directly correlated with friction images of the patterned sample surfaces. Simultaneous information for topography and recognition forces on a μm-sized streptavidin pattern was obtained by lateral force mapping on a μm-sized streptavidin pattern with a biotinylated AFM tip. An approach-retract cycle was performed in every pixel of the image, and the information for topography was gained from the contact region, whereas a recognition image was constructed from the recognition forces of the force curve [16.72]. This method was also used to map functional receptors on living cells [16.73] and differentiate red blood cells of different blood groups within a mixed population using AFM tips conjugated with a blood group A specific lectin [16.74].

A first identification and localization of single-molecule antigenic sites was realized by laterally scanning an AFM tip containing antibodies in one dimension across a surface containing a low density of antigens during recording force-distance cycles. The binding probability was determined in dependence of the lateral position, resulting in Gaussian-like profiles [16.4, 12]. The position of the antigen could be determined from the position of the maximum, yielding a positional accuracy of 1.5 nm. The width of the binding profile of 6 nm reflects the dynamical reach of the antibody on the tip, provided by the crosslinker used for coupling the antibody to the tip, and can be considered the lateral resolution obtained by this tech-

nique [16.4]. With a similar configuration, height and adhesion force images were simultaneously obtained with resolution approaching the single-molecule level as well [16.75].

The strategies of force mapping, however, lack high lateral resolution [16.72] and/or are much slower in data acquisition [16.4, 12, 75] than topography imaging, since the frequency of the retract-approach cycles performed in every pixel is limited by hydrodynamic forces in the aqueous solution. In addition, obtaining the force image requires the ligand to be disrupted from the receptor in each retract-approach cycle. For this, the z-amplitude of the retract-approach cycle must be at least 50 nm and, therefore, the ligand on the tip is without access to the receptor on the surface for most of the experiment. The development of shorter cantilevers [16.45], however, increases the speed for force mapping, because the hydrodynamic forces are significantly reduced and the resonance frequency is higher than that of commercially available cantilevers. The short cantilevers were also recently applied to follow the association and dissociation of individual chaperonin proteins GroES to GroEL in real time using dynamic force microscopy topography imaging [16.76].

An imaging method for the mapping of antigenic sites on surfaces was recently developed [16.20] by combining molecular recognition force spectroscopy [16.4] with dynamic force microscopy (DFM) [16.25, 77]. In DFM, the AFM tip is oscillated across a surface and the amplitude reduction arising from tip-surface interactions is held constant by a feedback loop that lifts or lowers the tip according to the detected amplitude signal. Since the tip only intermittently contacts the surface, this technique provides very gentle tip-surface interactions, and the specific interaction of the antibody on the tip with the antigen on the surface can be used to localize antigenic sites for recording recognition images. The principles of this method are described in detail below and in Fig. 16.11. A magnetically coated tip is oscillated by an alternating magnetic field at an ampli-

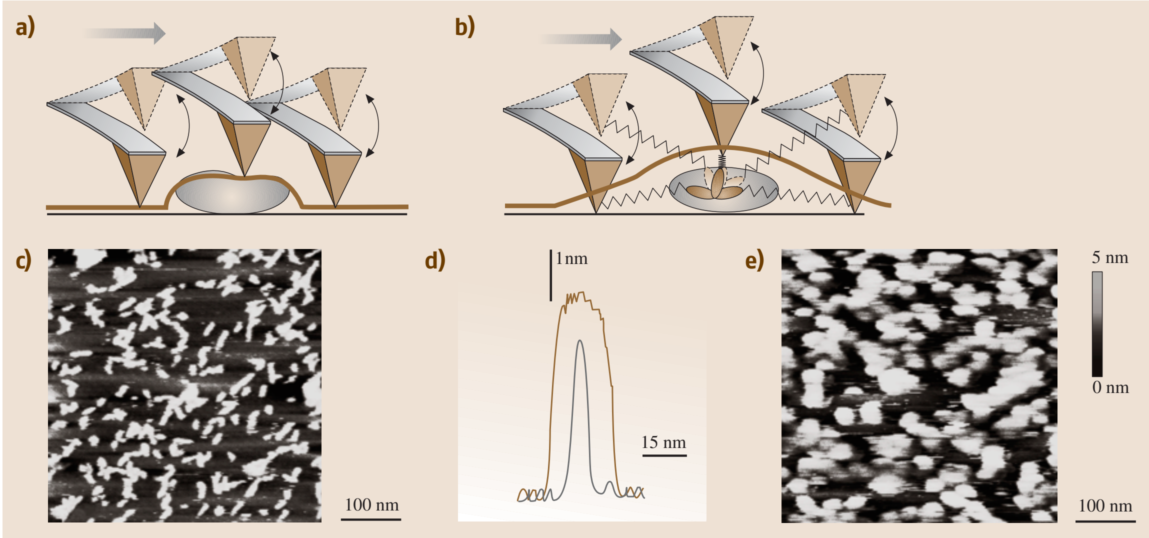

Fig. 16.11a–e Topography and recognition image. **(a)** AFM tip-lysozyme interaction during topography imaging. The *brown line* indicates the height profile obtained from a single lysozyme molecule with the AFM using a bare tip. **(b)** AFM tip-lysozyme interaction during recognition imaging. Half-antibodies are bound to the AFM tip via a flexible tether (*jagged line*) for the recognition of lysozyme on the surface. Imaging results in a height profile, as indicated (*brown line*). **(c)** Topography image. Single lysozyme molecules can be clearly resolved. Sometimes small lysozyme aggregates are observed. Image size was 500 nm. False color bar for heights from 0 (*dark*) to 5 (*bright*) nm. **(d)** Height profiles. Cross-sectional profiles of single lysozyme molecules obtained from the topography (*black line*) and the recognition (*brown line*) image. **(e)** Recognition image. The *bright dots* represent recognition profiles of single lysozyme molecules. Imaging was performed using an AFM tip carrying one half-antibody with access to the antigens on the surface. Conditions were exactly the same as in **(c)**. (After [16.20])

tude of 5 nm while being scanned along the surface. Since the tether has a length of 8 nm, the antibody on the tip always has a chance of recognition when passing an antigenic site, which increases the binding probability enormously. Since the oscillation frequency is more than 100 times faster than typical frequencies in conventional force mapping, the data acquisition rate is much higher.

Half-antibodies were used to provide a monovalent ligand on the tip. The antigen, lysozyme, was tightly adsorbed to mica in conditions that yielded a low surface coverage (for details see [16.20]). A topographic image of this preparation was first recorded in buffer using a bare AFM tip as a control (Fig. 16.11c). Single lysozyme molecules were clearly resolved (Fig. 16.11c). A cross-sectional analysis (Fig. 16.11d, profile in black) reveals that the molecules appear 8 to 12 nm in diameter and 2.0 to 2.5 nm in height. Imaging with a half-antibody tethered to the tip in conditions identical to those used to obtain the topographical image gave strikingly different images (Fig. 16.11e). They differ significantly both in height and diameter compared to the topography image (Fig. 16.11c). Cross-sectional analysis (Fig. 16.11d, trace in red) reveals a height of 3.0 to 3.5 nm and a diameter of 20 to 25 nm. Therefore, profiles obtained from the recognition image appear at least 1 nm higher and 10 nm broader than profiles from the topography image.

The antibody-antigen recognition process during imaging is depicted in Fig. 16.11b. Approaching the antigen in a lateral scan from the left, the antibody on the tip binds to the antigen about 10 nm before the tip end is above the antigenic site (Fig. 16.11b, left tip), due to the flexible tethering provided by the crosslinker. In the bound state, the z-oscillation of the cantilever is further reduced by the attractive force of the crosslinker-antibody-antigen connection, which is acting as a nonlinear spring. Since the AFM detects the z-projection of the force, the amount of the attractive force measured increases when the tip moves further to the right and reaches its maximum just above the position of the antigenic site (Fig. 16.11b, tip in middle). At lateral distances comparable to the length of the antibody-crosslinker connection, the antibody on the tip dissociates from the antibody on the surface and the attractive force goes to zero.

The diameter of cross-sectional profiles obtained from the recognition image (Fig. 16.11d, brown trace) corresponds to about twice the length of the crosslinker (6 nm) plus antibody (6 nm). Increased heights detected in comparison to profiles of the topography image (Fig. 16.11d, black trace) reflect the amplitude reduction owing to antibody-antigen recognition. The maxima of the cross-sectional profiles of the recognition image, as shown in Fig. 16.11d (brown trace), indicate the position of the antigenic site. The accuracy of maximum determination, which in turn reflects the positional accuracy of determining the position of the antigenic site, was 3 nm. The specific nature of the antibody-antigen interaction was tested by injecting free antibody into the liquid cell, so as to block the antigenic sites on the surface, and subsequent images showed a reduction in apparent height.

With this methodology, topography and recognition images can be obtained at the same time and distinct receptor sites in the recognition image can be assigned to structures from the topography image. The described methodology [16.20] is applicable to any ligand and, therefore, it should prove possible to recognize many types of proteins or protein layers and carry out epitope mapping on a nanometer scale on membranes and cells.

16.7 Concluding Remarks

Atomic force microscopy has evolved into the imaging method that yields the greatest structural details on live, biological samples like proteins, nucleotides, membranes and cells in their native, aqueous environment at ambient conditions. Due to its high lateral resolution and sensitive force detection capability, the exciting possibility of measuring inter- and intramolecular forces of biomolecules on the single-molecule level has become possible. The proof-of-principle stage of the pioneering experiments has already developed into a high-end analysis method for exploring kinetic and structural details of interactions underlying protein folding and molecular recognition by taking the advantages of single molecule studies. The information obtained from force spectroscopy includes physical parameters unachievable by other methods and opens new perspectives in exploring the regulation of the dynamics of biological processes such as molecular recognition. With ongoing instrumental developments to increase sensitivity and speed, exciting new fields may also open up in drug and cell screening technologies.

17. Micro/Nanotribology and Materials Characterization Studies Using Scanning Probe Microscopy

A sharp AFM/FFM tip sliding on a surface simulates just one asperity contact. However, asperities come in all shapes and sizes. The effect of radius of a single asperity (tip) on the friction/adhesion performance can be studied using tips of different radii. AFM/FFM are used to study the various tribological phenomena, which include surface/roughness, adhesion, friction, scratching, wear, indentation, detection of material transfer, and boundary lubrication.

Directionality in the friction is observed on both micro- and macroscales and results from the surface roughness and surface preparation. Microscale friction is generally found to be smaller than the macrofriction, as there is less plowing contribution in microscale measurements. The mechanism of material removal on the microscale is studied. Evolution of wear has also been studied using AFM. Wear is found to be initiated at nanoscratches. For a sliding interface requiring near-zero friction and wear, contact stresses should be below the hardness of the softer material to minimize plastic deformation, and surfaces should be free of nanoscratches. Wear precursors can be detected at early stages of wear by using surface potential measurements. Detection of material transfer on a nanoscale is possible with AFM. In situ surface characterization of local deformation of materials and thin coatings can be carried out using a tensile stage inside an AFM.

Boundary lubrication studies can be conducted using AFM. Chemically bonded lubricant films and self-assembled monolayers are superior in friction and wear resistance. For chemically bonded lubricant films, the adsorption of water, the formation of meniscus and its change during sliding, viscosity, and surface properties play an important role on the friction, adhesion, and durability of these films. For SAMs, their friction mechanism is explained by a so-called "molecular spring" model.

The mechanisms and dynamics of the interactions of two contacting solids during relative motion ranging from atomic- to microscale need to be understood in order to develop a fundamental understanding of adhesion, friction, wear, indentation, and lubrication processes. At most solid-solid interfaces of technological relevance contact occurs at many asperities. Consequently, the importance of investigating single asperity contacts in studies of the fundamental micro/nanomechanical and micro/nanotribological properties of surfaces and interfaces has long been recognized. The recent emergence and proliferation of proximal probes, including scanning probe microscopies (the scanning tunneling microscope and the atomic force microscope), the surface force apparatus, and computational techniques for simulating tip-surface interactions and interfacial properties, have allowed systematic investigations of interfacial problems with high resolution, as well as ways and means of modifying and manipulating nanoscale structures. These advances have led to the appearance of the new field of micro/nanotribology, which pertains to experimental and theoretical investigations of interfacial processes on scales ranging from the atomic- and molecular- to the microscale, occurring during adhesion, friction, scratching, wear, indentation, and thin-film lubrication at sliding surfaces [17.1–12].

Micro/nanotribological studies are needed to develop a fundamental understanding of interfacial phenomena on a small scale and study interfacial phenomena in micro/nanostructures used in magnetic storage systems, micro/nanoelectromechanical systems (MEMS/NEMS), and other applications [17.3, 7–9, 13, 14]. Friction and wear of lightly loaded micro/nanocomponents are highly dependent on the surface interactions (few atomic layers). These structures are generally lubricated with molecularly thin films. Micro/nanotribological studies are also valuable in understanding interfacial phenomena in macrostructures and provide a bridge between science and engineering.

The surface force apparatus (SFA), the scanning tunneling microscopes (STM), atomic force and friction force microscopes (AFM and FFM) are widely used in micro/nanotribological studies. Typical operating parameters are compared in Table 17.1. The SFA was developed in 1968 and is commonly employed to study both static and dynamic properties of molecularly thin films sandwiched between two molecularly smooth surfaces. The STM, developed in 1981, allows imaging of electrically conducting surfaces with atomic resolution and has been used for the imaging of clean surfaces, as well as of lubricant molecules. The introduction of the atomic force microscope in 1985 provided a method for measuring ultra-small forces between a probe tip and an engineering (electrically conducting or insulating) surface and has been used for topographical measurements of surfaces on the nanoscale, as well as for adhesion and electrostatic force measurements. Subsequent modifications of the AFM led to the development of the friction

Table 17.1 Comparison of typical operating parameters in SFA, STM, and AFM/FFM used for micro/nanotribological studies

Operating parameter	SFA	STM[a]	AFM/FFM
Radius of mating surface/tip	~ 10 mm	5–100 nm	5–100 nm
Radius of contact area	10–40 μm	N/A	0.05–0.5 nm
Normal load	10–100 mN	N/A	< 0.1 nN – 500 nN
Sliding velocity	0.001–100 μm/s	0.02–200 μm/s (scan size ~ 1 nm ×1 nm to 125 μm ×125 μm; scan rate < 1–122 Hz)	0.02–200 μm/s (scan size ~ 1 nm ×1 nm to 125 μm ×125 μm; scan rate < 1–122 Hz)
Sample limitations	Typically atomically smooth, optically transparent mica; opaque ceramic, smooth surfaces can also be used	Electrically conducting samples	None

[a] Can only be used for atomic-scale imaging

force microscope (FFM), designed for atomic-scale and microscale studies of friction. This instrument measures forces in the scanning direction. The AFM is also used in investigations of scratching, wear, indentation, detection of transfer of material, boundary lubrication, and fabrication and machining. Meanwhile, significant progress in understanding the fundamental nature of bonding and interactions in materials, combined with advances in computer-based modeling and simulation methods, have allowed theoretical studies of complex interfacial phenomena with high resolution in space and time. Such simulations provide insights into atomic-scale energetics, structure, dynamics, thermodynamics, transport and rheological aspects of tribological processes.

The nature of interactions between two surfaces brought close together and those between two surfaces in contact as they are separated have been studied experimentally with the surface force apparatus. This has led to a basic understanding of the normal forces between surfaces and the way in which these are modified by the presence of a thin liquid or a polymer film. The frictional properties of such systems have been studied by moving the surfaces laterally, and such experiments have provided insights into the molecular-scale operation of lubricants such as thin liquid or polymer films. Complementary to these studies are those in which the AFM or FFM is used to provide a model asperity in contact with a solid or lubricated surface, Fig. 17.1. These experiments have demonstrated that the relationship between friction and surface roughness is not always simple or obvious. AFM studies have also revealed much about the nanoscale nature of intimate contact during wear and indentation.

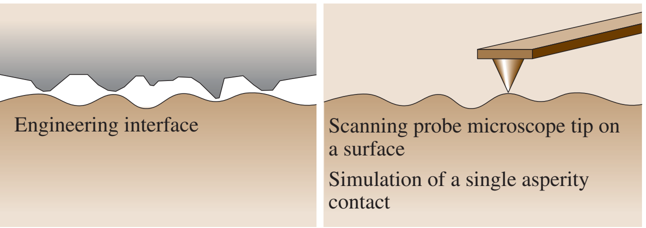

Fig. 17.1 Schematics of an engineering interface and scanning probe microscope tip in contact with an engineering interface

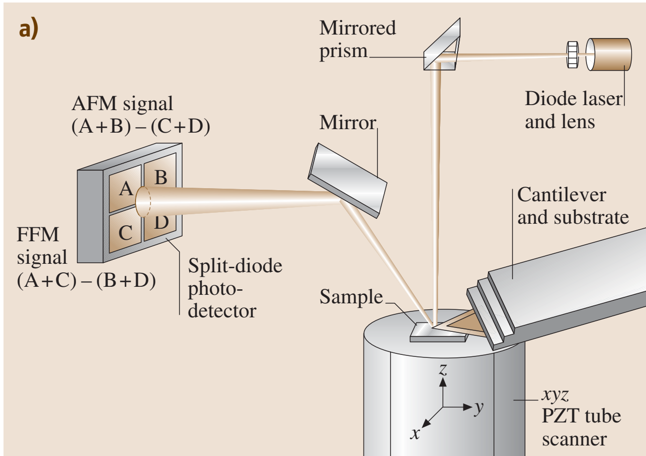
In this chapter, we present a review of significant aspects of micro/nanotribological studies conducted using AFM/FFM.

17.1 Description of AFM/FFM and Various Measurement Techniques

An atomic force microscope (AFM) was developed by *Binnig* et al. in 1985. It is capable of investigating surfaces of scientific and engineering interest on an atomic scale [17.15, 16]. The AFM relies on a scanning technique to produce very high resolution, 3-D images of sample surfaces. It measures ultrasmall forces (less than 1 nN) present between the AFM tip surface mounted on a flexible cantilever beam and a sample surface. These small forces are determined by measuring the motion of a very flexible cantilever beam with an ultra-small mass by a variety of measurement techniques including optical deflection, optical interference, capacitance, and tunneling current. The deflection can be measured to within 0.02 nm, so for a typical cantilever spring constant of 10 N/m, a force as low as 0.2 nN can be detected. To put these numbers in perspective, individual atoms and human hair are typically a fraction of a nanometer and about 75 μm in diameter, respectively, and a drop of water and an eyelash have a mass of about 10 μN and 100 nN, respectively. In the operation of high resolution AFM, the sample is generally scanned, rather than the tip, because any cantilever movement would add vibrations. AFMs are available for measurement of large samples where the tip is scanned and the sample is stationary. To obtain atomic resolution with the AFM, the spring constant of the cantilever should be weaker than the equivalent spring between atoms. A cantilever beam with a spring constant of about 1 N/m or lower is desirable. For high lateral resolution, tips should be as sharp as possible. Tips with a radius ranging from 10–100 nm are commonly available.

A modification to AFM, providing a sensor to measure the lateral force, led to the development of the friction force microscope (FFM), or the lateral force microscope (LFM), designed for atomic-scale and microscale studies of friction [17.3–5, 7, 8, 11, 17–25] and lubrication [17.26–30]. This instrument measures lateral or friction forces (in the plane of sample surface and in the scanning direction). By using a standard or a sharp diamond tip mounted on a stiff cantilever beam, AFM is also used in investigations of scratching and wear [17.6, 9, 11, 22, 31–33], indentation [17.6, 9, 11, 22, 34, 35], and fabrication/machining [17.4, 11, 22].



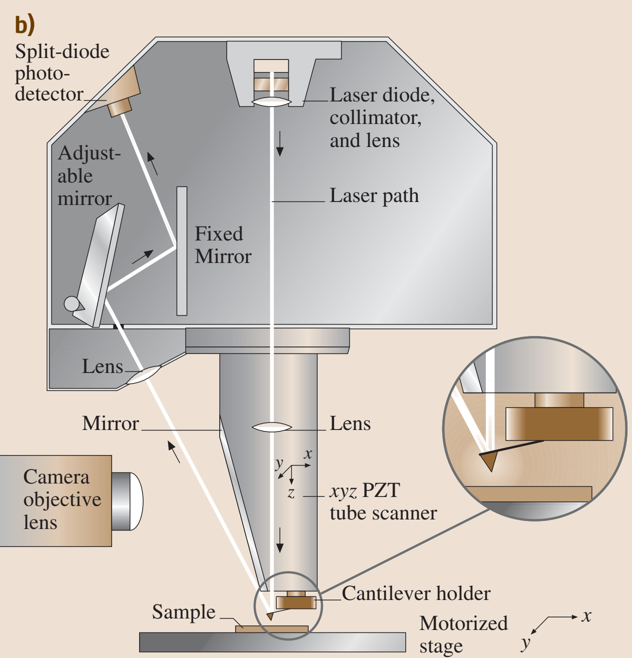


Fig. 17.2a,b Schematics **(a)** of a commercial small sample atomic force microscope/friction force microscope (AFM/FFM) and **(b)** a large sample AFM/FFM

Surface roughness, including atomic-scale imaging, is routinely measured using the AFM, Fig. 17.2. Adhesion, friction, wear, and boundary lubrication at the interface between two solids with and without liquid films are studied using AFM and FFM. Nanomechanical properties are also measured using an AFM. In situ surface characterization of local deformation of materials and thin coatings has been carried out by imaging the sample surfaces using an AFM during tensile deformation using a tensile stage.

17.1.1 Surface Roughness and Friction Force Measurements

Simultaneous measurements of surface roughness and friction force can be made with a commercial AFM/FFM. These instruments are available for the measurement of small samples and large samples. In a small sample AFM, shown in Fig. 17.2a, the sample, generally no larger than 10 mm × 10 mm, is mounted on a PZT tube scanner that consists of separate electrodes to scan precisely the sample in the x-y plane in a raster pattern and move it in the vertical (z) direction. A sharp tip at the free end of a flexible cantilever is brought in contact with the sample. Normal and frictional forces being applied at the tip-sample interface are measured using a laser beam deflection technique. A laser beam from a diode laser is directed by a prism onto the back of a cantilever near its free end, which is tilted downward at about 10° with respect to the horizontal plane. The reflected beam from the vertex of the cantilever is directed through a mirror onto a quad photodetector (split photodetector with four quadrants). The differential signal from the top and bottom photodiodes provides the AFM signal, which is a sensitive measure of the cantilever vertical deflection. Topographic features of the sample cause the tip to deflect in the vertical direction as the sample is scanned under the tip. This tip deflection will change the direction of the reflected laser beam, changing the intensity difference between the top and bottom sets of photodetectors (AFM signal). In the AFM operating mode, called the height mode, for topographic imaging, or for any other operation in which the applied normal force is to be kept a constant, a feedback circuit is used to modulate the voltage applied to the PZT scanner to adjust the height of the PZT, so that the cantilever vertical deflection (given by the intensity difference between the top and bottom detector) will remain constant during scanning. The PZT height variation is thus a direct measure of the surface roughness of the sample.

In a large sample AFM both force sensors using optical deflection method and scanning unit are mounted on the microscope head, Fig. 17.2b. Because of vibrations added by cantilever movement, lateral resolution of this design is somewhat poorer than the design in Fig. 17.2a in which the sample is scanned instead of cantilever

beam. The advantage of the large sample AFM is that large samples can be measured readily.

Most AFMs can be used for topography measurements in the so-called tapping mode (intermittent contact mode), also referred to as dynamic force microscopy. In the tapping mode, during scanning over the surface, the cantilever/tip assembly is sinusoidally vibrated by a piezo mounted above it, and the oscillating tip slightly taps the surface at the resonant frequency of the cantilever (70–400 Hz) with a constant (20–100 nm) oscillating amplitude introduced in the vertical direction with a feedback loop keeping the average normal force constant, Fig. 17.3. The oscillating amplitude is kept large enough so that the tip does not get stuck to the sample because of adhesive attractions. The tapping mode is used in topography measurements to minimize the effects of friction and other lateral forces and to measure topography of soft surfaces.

For measurement of friction force being applied at the tip surface during sliding, left-hand and right-hand sets of quadrants of the photodetector are used. In the so-called friction mode, the sample is scanned back and forth in a direction orthogonal to the long axis of the cantilever beam. A friction force between the sample and the tip will produce a twisting of the cantilever. As a result, the laser beam will be reflected out of the plane defined by the incident beam and the beam reflected vertically from an untwisted cantilever. This produces an intensity difference of the laser beam received in the left-hand and right-hand sets of quadrants of the photodetector. The intensity difference between the two sets of detectors (FFM signal) is directly related to the degree of twisting and, hence, to the magnitude of the friction force. One problem associated with this method is that any misalignment between the laser beam and the photodetector axis would introduce error in the measurement. However, by following the procedures developed by *Ruan* and *Bhushan* [17.19], in which the average FFM signal for the sample scanned in two opposite directions is subtracted from the friction profiles of each of the two scans, the misalignment effect is eliminated. This method provides three-dimensional maps of friction force. By following the friction force calibration procedures developed by *Ruan* and *Bhushan* [17.19], voltages corresponding to friction forces can be converted to force units. The coefficient of friction is obtained from the slope of friction force data measured as a function of normal loads typically ranging from 10–150 nN. This approach eliminates any contributions due to the adhesive forces [17.22]. For calculation of the coefficient of friction based on a single point measurement, friction force should be divided by the sum of applied normal load and intrinsic adhesive force. Furthermore, it should be pointed out that for a single asperity contact, the coefficient of friction is not independent of load. This will be discussed in greater detail later in the chapter.

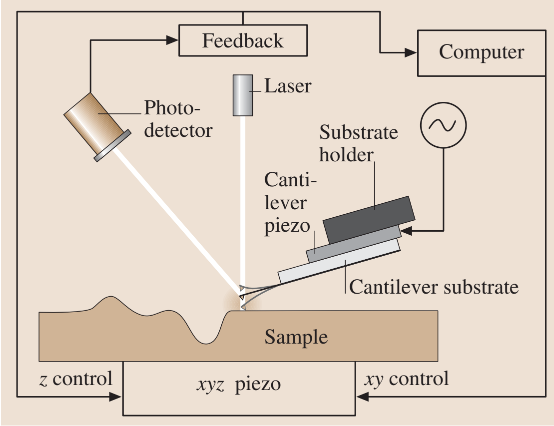

Fig. 17.3 Schematic of tapping mode used for surface topography measurements

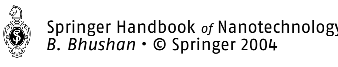
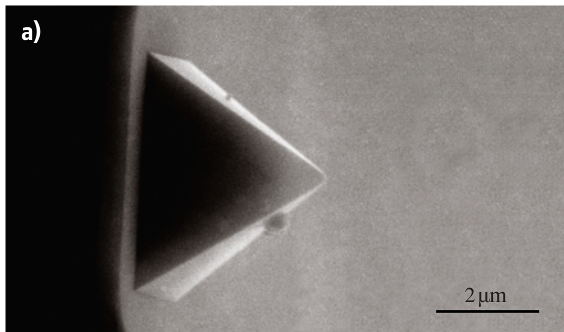
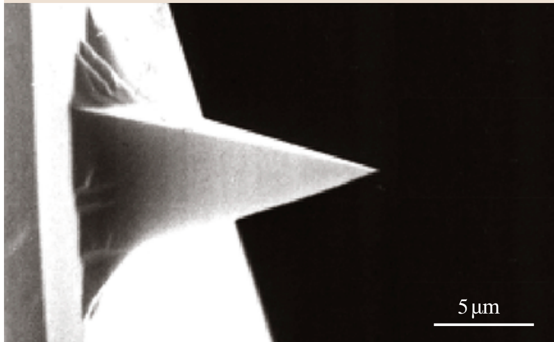
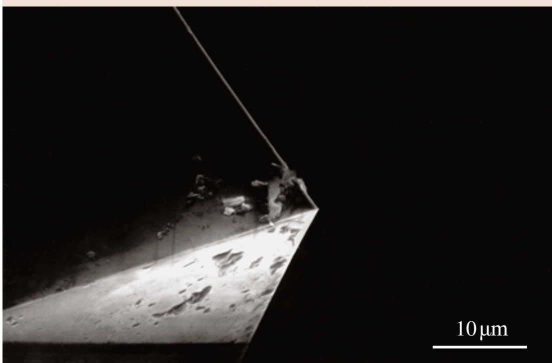
Topographic measurements in the contact mode are typically made using a sharp, microfabricated square-pyramidal Si_3N_4 tip with a radius of 30–50 nm on a triangular cantilever beam (Fig. 17.4a) with normal stiffness on the order of 0.5 N/m at a normal load of about 10 nN, and friction measurements are carried out in the load range of 10–150 nN. Topography measurements in the tapping mode utilize a stiff cantilever with high resonant frequency; typically, a square-pyramidal, etched, single-crystal silicon tip with a tip radius of 5–10 nm mounted on a stiff rectangular silicon cantilever beam (Fig. 17.4a) with a normal stiffness on the order of 50 N/m is used. Carbon nanotube tips with small diameters (few nm) and high aspect ratios attached on the single-crystal silicon, square pyramidal tips are used for high resolution imaging of surfaces and deep trenches in the tapping mode or noncontact mode (Fig. 17.4b). To study the effect of the radius of a single asperity (tip) on adhesion and friction, microspheres of silica with radii ranging from about 4–15 µm are attached with epoxy at the ends of tips of Si_3N_4 cantilever beams. Optical micrographs of two of the microspheres mounted at the ends of triangular cantilever beams are shown in Fig. 17.4c.

The tip is scanned in such a way that its trajectory on the sample forms a triangular pattern, Fig. 17.5.









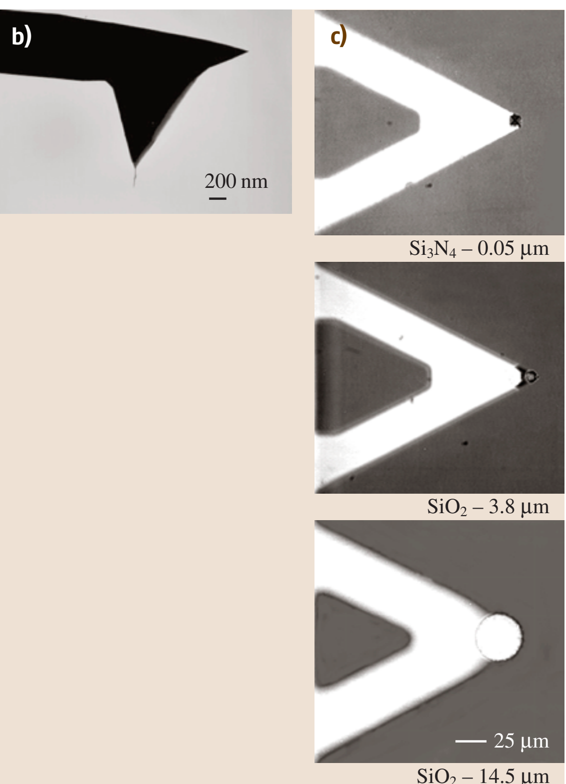


Fig. 17.4 **(a)** SEM micrographs of a square-pyramidal PECVD Si_3N_4 tip with a triangular cantilever beam (*top*), a square-pyramidal etched single-crystal silicon tip with a rectangular silicon cantilever beam (*middle*), and a three-sided pyramidal natural diamond tip with a square stainless steel cantilever beam (*bottom*), **(b)** SEM micrograph of a multiwalled carbon nanotube (MWNT) physically attached on the single-crystal silicon, square-pyramidal tip, and **(c)** optical micrographs of a commercial Si_3N_4 tip and two modified tips showing SiO_2 spheres mounted over the sharp tip and at the end of the triangular Si_3N_4 cantilever beams. (Radii of the tips are given in the figure)

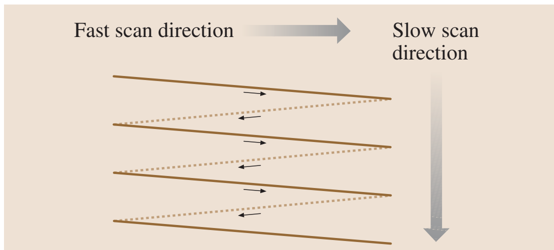

Fig. 17.5 Schematic of triangular pattern trajectory of the tip as the sample (or the tip) is scanned in two dimensions. During scanning, data are recorded only during scans along the solid scan lines

Scanning speeds in the fast and slow scan directions depend on the scan area and scan frequency. Scan sizes ranging from less than 1 nm × 1 nm to 125 µm × 125 µm and scan rates from less than 0.5 to 122 Hz typically can be used. Higher scan rates are used for smaller scan lengths. For example, scan rates in the fast and slow scan directions for an area of 10 µm × 10 µm scanned at 0.5 Hz are 10 µm/s and 20 nm/s, respectively.

17.1.2 Adhesion Measurements

Adhesive force measurements are performed in the so-called force calibration mode. In this mode, force-distance curves are obtained, for an example, see Fig. 17.6. The horizontal axis gives the distance the piezo (and hence the sample) travels, and the vertical axis gives the tip deflection. As the piezo extends, it approaches the tip, which is at this point in free air and hence shows no deflection. This is indicated by the flat portion of the curve. As the tip approaches within a few nanometers of the sample (point A), an attractive force exists between the atoms of the tip surface and the atoms of the sample surface. The tip is pulled toward the sample and contact occurs at point B on the graph. From this point on, the tip is in contact with the surface, and as the piezo extends farther, the tip gets deflected farther. This is represented by the sloped portion of the curve. As the piezo retracts, the tip goes beyond the zero deflection (flat) line, due to attractive forces (van der Waals forces and long-range meniscus forces), into the adhesive regime. At point C in the graph, the tip snaps free of the adhesive forces and is again in free air. The horizontal distance between points B and C along the retrace line gives the distance the tip moved in the adhesive regime. This distance multiplied by the stiffness of the cantilever gives the adhesive force. Incidentally, the horizontal shift between the loading and unloading curves results from the hysteresis in the PZT tube [17.4, 36].

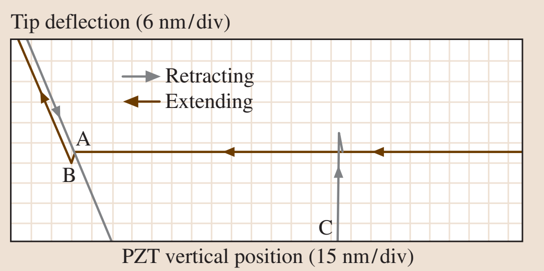

Fig. 17.6 Typical force-distance curve for a contact between Si_3N_4 tip and single-crystal silicon surface in measurements made in the ambient environment. Contact between the tip and silicon occurs at point B; tip breaks free of adhesive forces at point C as the sample moves away from the tip

17.1.3 Scratching, Wear and Fabrication/Machining

For microscale scratching, microscale wear, nanofabrication/nanomachining, and nanoindentation hardness measurements, an extremely hard tip is required. A three-sided pyramidal single-crystal natural diamond tip with an apex angle of 80° and a radius of about 100 nm mounted on a stainless steel cantilever beam with normal stiffness of about 25 N/m is used at relatively higher loads (1–150 μN), Fig. 17.4a. For scratching and wear studies, the sample is generally scanned in a direction orthogonal to the long axis of the cantilever beam (typically at a rate of 0.5 Hz), so that friction can be measured during scratching and wear. The tip is mounted on the cantilever such that one of its edges is orthogonal to the long axis of the beam. Therefore, wear during scanning along the beam axis is higher (about two to three times) than during scanning orthogonal to the beam axis. For wear studies, an area on the order of 2 μm × 2 μm is scanned at various normal loads (ranging from 1 to 100 μN) for a selected number of cycles [17.4, 22].

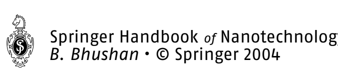
Scratching can also be performed at ramped loads and the coefficient of friction can be measured during scratching [17.33]. A linear increase in the normal load approximated by a large number of normal load increments of small magnitude is applied using a software interface (lithography module in Nanoscope III) that allows the user to generate controlled movement of the tip with respect to the sample. The friction signal is tapped out of the AFM and is recorded on a computer. A scratch length on the order of 25 μm and a velocity on the order of 0.5 μm/s are used and the number of loading steps is usually 50.

Nanofabrication/nanomachining is conducted by scratching the sample surface with a diamond tip at specified locations and scratching angles. The normal load used for scratching (writing) is on the order of 1–100 μN with a writing speed on the order of 0.1–200 μm/s [17.4, 5, 11, 22, 37].

17.1.4 Surface Potential Measurements

To detect wear precursors and study the early stages of localized wear, the multimode AFM can be used to measure the potential difference between the tip and the sample by applying a DC bias potential and an oscillating (AC) potential to a conducting tip over a grounded substrate in a Kelvin probe microscopy, or so-called "nano-Kelvin probe" technique [17.38–40].

Mapping of the surface potential is made in the so-called "lift mode" (Fig. 17.7). These measurements are made simultaneously with the topography scan in the



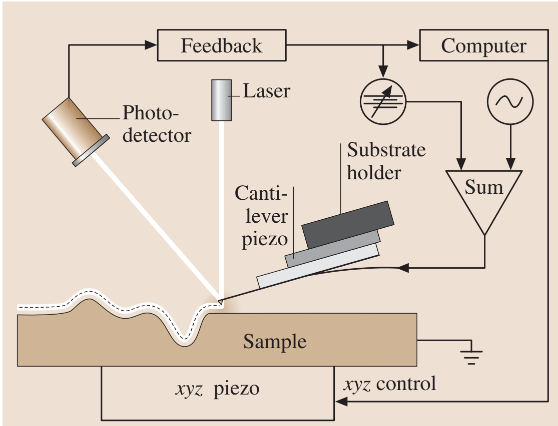


Fig. 17.7 Schematic of lift mode used to make surface potential measurement. The topography is collected in tapping mode in the primary scan. The cantilever piezo is deactivated. Using topography information of the primary scan, the cantilever is scanned across the surface at a constant height above the sample. An oscillating voltage at the resonant frequency is applied to the tip and a feedback loop adjusts the DC bias of the tip to maintain the cantilever amplitude at zero. The output of the feedback loop is recorded by the computer and becomes the surface potential map [17.4]

tapping mode using an electrically conducting (nickel-coated single-crystal silicon) tip. After each line of the topography scan is completed, the feedback loop controlling the vertical piezo is turned off, and the tip is lifted from the surface and traced over the same topography at a constant distance of 100 nm. During the lift mode, a DC bias potential and an oscillating potential (3–7 V) is applied to the tip. The frequency of oscillation is chosen to be equal to the resonant frequency of the cantilever ($\sim$ 80 kHz). When a DC bias potential equal to the negative value of surface potential of the sample (on the order of $\pm$2 V) is applied to the tip, it does not vibrate. During scanning, a difference between the DC bias potential applied to the tip and the potential of the surface will create DC electric fields that interact with the oscillating charges (as a result of the AC potential), causing the cantilever to oscillate at its resonant frequency, as in tapping mode. However, a feedback loop is used to adjust the DC bias on the tip to exactly nullify the electric field and, thus, the vibrations of the cantilever. The required bias voltage follows the localized potential of the surface. The surface potential was obtained by reversing the sign of the bias potential provided by the electronics [17.39, 40]. Surface and subsurface changes of structure and/or chemistry can cause changes in the measured potential of a surface. Thus, the mapping of the surface potential after sliding can be used for detecting wear precursors and studying the early stages of localized wear.

17.1.5 In Situ Characterization of Local Deformation Studies

In situ characterization of local deformation of materials can be carried out by performing tensile, bending, or compression experiments inside an AFM and by observing nanoscale changes during the deformation experiment [17.6]. In these experiments, small deformation stages are used to deform the samples inside an AFM. In tensile testing of the polymeric films carried out by *Bobji* and *Bhushan* [17.41, 42], a tensile stage was used (Fig. 17.8). The stage with a left-right combination lead screw (which helps to move the slider in the opposite direction) was used to stretch the sample and minimize the movement of the scanning area, which was kept close to the center of the tensile specimen. One end of the sample was mounted on the slider via a force sensor to monitor the tensile load. The samples were stretched for various strains using a stepper motor, and the same control area at different strains was imaged. In order to better locate the control area for imaging, a set of four markers was created at the corners of a 30 μm × 30 μm square at the center of the sample by scratching the sample with a sharp silicon tip. The scratching depth was controlled such that it did not affect cracking behavior of the coating. A minimum displacement of 1.6 μm could be obtained. This corresponded to a strain increment of 8×10^{-3}% for a sample length of 38 mm. The maximum travel was about 100 mm. The resolution of the force sensor was 10 mN with a capacity of 45 N. During stretching, a stress-strain curve was obtained during the experiment to study any correlation between the degree of plastic strain and propensity of cracks.

17.1.6 Nanoindentation Measurements

For nanoindentation hardness measurements, the scan size is set to zero, and a normal load is then applied to make the indents using the diamond tip. During this procedure, the tip is continuously pressed against the sample surface for about two seconds at various indentation loads. The sample surface is scanned before and after the scratching, wear, or indentation to obtain the

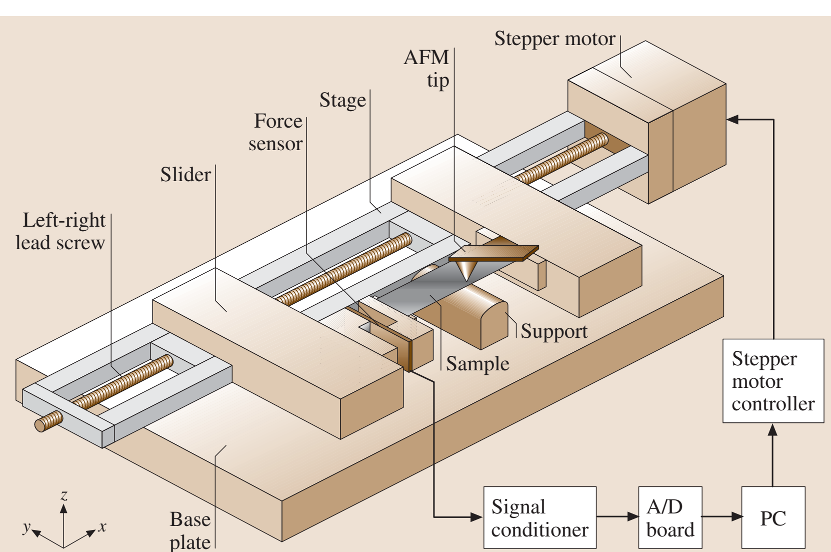

Fig. 17.8 Schematic of the tensile stage to conduct in situ tensile testing of the polymeric films in AFM [17.42]

initial and final surface topographies at a low normal load of about 0.3 μN using the same diamond tip. An area larger than the indentation region is scanned to observe the indentation marks. Nanohardness is calculated by dividing the indentation load by the projected residual area of the indents [17.34].

Direct imaging of the indent allows one to quantify piling up of ductile material around the indenter. However, it becomes difficult to identify the boundary of the indentation mark with great accuracy. This makes the direct measurement of contact area somewhat inaccurate. A technique with the dual capability of depth-sensing, as well as in situ imaging, which is most appropriate in nanomechanical property studies, is used for accurate measurement of hardness with shallow depths [17.4, 35]. This indentation system is used to make load-displacement measurement and, subsequently, carry out in situ imaging of the indent, if required. The indentation system consists of a three-plate transducer with electrostatic actuation hardware used for direct application of normal load and a capacitive sensor used for measurement of vertical displacement. The AFM head is replaced with this transducer assembly while the specimen is mounted on the PZT scanner, which remains stationary during indentation experiments. Indent area and, consequently, hardness value can be obtained from the load-displacement data. The Young's modulus of elasticity is obtained from the slope of the unloading curve.

17.1.7 Localized Surface Elasticity and Viscoelasticity Mapping

Indentation experiments provide a single-point measurement of the Young's modulus of elasticity calculated from the slope of the indentation curve during unloading. Localized surface elasticity maps can be obtained using dynamic force microscopy in which an oscillating tip is scanned over the sample surface in contact under steady and oscillating load. Lower frequency operation mode in the kHz range such as force modulation microscopy [17.43–45] and pulsed force microscopy [17.46] are well suited for soft samples such as polymers. However, if the tip-sample contact stiffness becomes significantly higher than the cantilever stiffness, the sensitivity of these techniques strongly decreases. In this case, sensitivity of the measurement of stiff materials can be improved by using high-frequency operation modes in the MHz range such as acoustic (ultrasonic) force microscopy [17.47]. We only describe here the force modulation technique.

In the force modulation technique, the oscillation is applied to the cantilever substrate with a cantilever piezo (bimorph), Fig. 17.9a. For measurements, an etched silicon tip is first brought in contact with a sample under a static load of 50–300 nN. In addition to the static load applied by the sample piezo, a small oscillating (modulating) load is applied by a bimorph, generally at a frequency (about 8 kHz) far below that of the natural resonance of the cantilever (70–400 kHz). When the

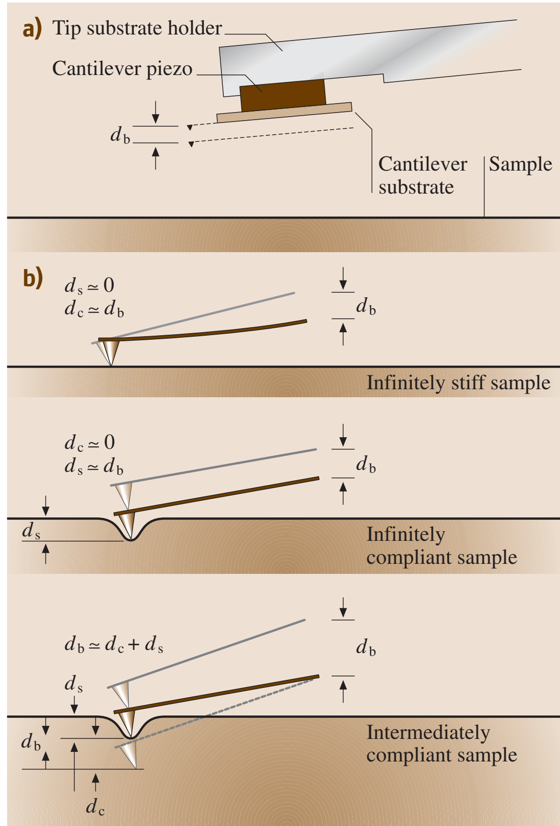

Fig. 17.9a,b Schematics **(a)** of the bimorph assembly and **(b)** of the motion of the cantilever and tip as a result of the oscillations of the bimorph for an infinitely stiff sample, an infinitely compliant sample, and an intermediate sample. The *thin line* represents the cantilever at the top cycle, and the *thick line* corresponds to the bottom of the cycle. The *dashed line* represents the position of the tip if the sample was not present or was infinitely compliant. d_c, d_s and d_b are the oscillating (AC) deflection amplitude of the cantilever, penetration depth, and oscillating (AC) amplitude of the bimorph, respectively [17.44]

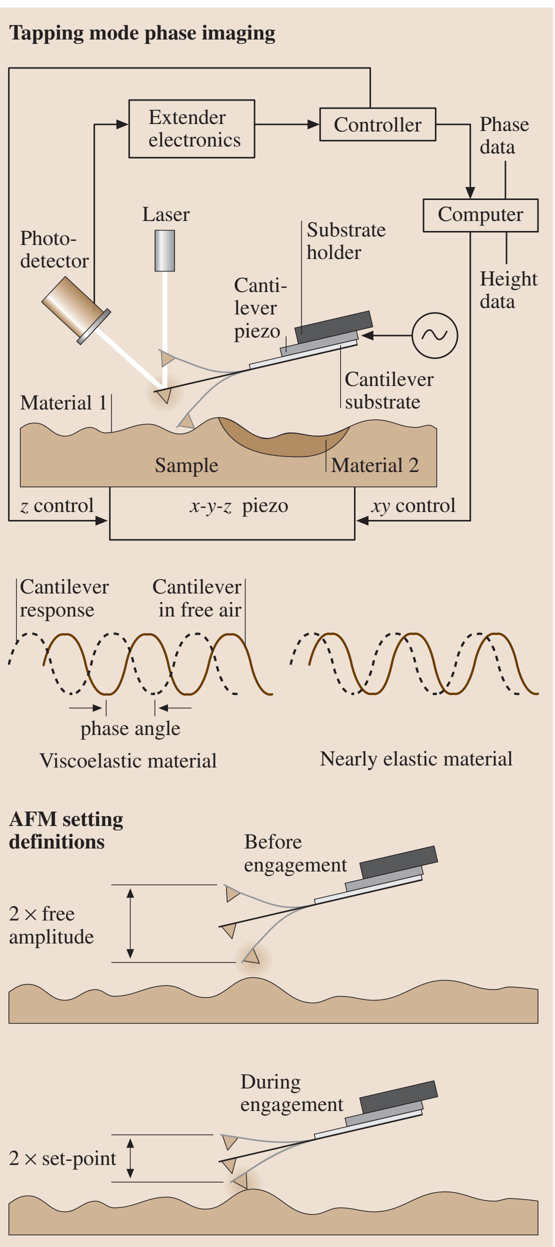

Fig. 17.10 Schematic of tapping mode used to obtain height and phase data and definitions of tapping amplitude and set point. During scanning the cantilever is vibrated at its resonant frequency and the sample x-y-z piezo is adjusted by feedback control in the z-direction to maintain a constant set point. The computer records height and phase angle (which is a function of the viscoelastic properties of the sample materials) data

tip is brought into contact with the sample, the surface resists the oscillations of the tip, and the cantilever deflects. Under the same applied load, a stiff area on the sample would deform less than a soft one; i. e., stiffer areas cause greater deflection amplitudes of the cantilever, Fig. 17.9b. The variations in the deflection amplitudes provide a measure of the relative stiffness of the surface. Contact analyses can be used to obtain a quantitative measure of localized elasticity of soft surfaces [17.44]. The elasticity data are collected simultaneously with

the surface height data using a so-called negative lift mode technique. In this mode, each scan line of each topography image (obtained in tapping mode) is replaced with the tapping action disabled and the tip lowered into steady contact with the surface.

Another form of dynamic force microscopy, phase contrast microscopy, is used to detect the contrast in viscoelastic (viscous energy dissipation) properties of the different materials across the surface [17.48–52]. In this technique, both deflection amplitude and phase angle contrasts are measured, which are the measures of the relative stiffness and viscoelastic properties, respectively. Tapping mode is utilized. For tapping mode during scanning, the cantilever/tip assembly is sinusoidally vibrated at its resonant frequency, and the sample X-Y-Z piezo is adjusted using feedback control in the z-direction to maintain a constant set point. As shown in Fig. 17.10, the cantilever/tip assembly is vibrated at some amplitude, here referred to as the tapping amplitude, by a cantilever piezo before the tip engages the sample. The tip engages the sample at some set point, which may be thought of as the amplitude of the cantilever as influenced by contact with the sample. A lower set point gives a reduced amplitude and closer mean tip-to-sample distance. This is also depicted in Fig. 17.10. The feedback signal to the z-direction sample piezo (to keep the set point constant) is a measure of topography. This height data is recorded on a computer. The extender electronics is used to measure the phase angle lag between the cantilever piezo drive signal and the cantilever response during sample engagement. As illustrated in Fig. 17.10, the phase angle lag is (at least partially) a function of the viscoelastic properties of the sample material. A range of tapping amplitudes and set points can be used for measurements. A commercially etched single-crystal silicon tip (DI TESP) used for tapping mode, with a radius of 5–10 nm, a stiffness of 20–100 N/m, and a natural frequency of 350–400 kHz is normally used. Scanning is normally set to a rate of 1 Hz along the fast axis.

17.1.8 Boundary Lubrication Measurements

To study nanoscale boundary lubrication, adhesive forces are measured in the force calibration mode, as previously described. The adhesive forces are also calculated from the horizontal intercept of friction versus normal load curves at a zero value of friction force. For friction measurements, the samples are typically scanned using an Si_3N_4 tip over an area of 2×2 μm at the normal load ranging from 5 to 130 nN. The samples are generally scanned with a scan rate of 0.5 Hz resulting in a scanning speed of 2 μm/s. Velocity effects on friction are studied by changing the scan frequency from 0.1 to 60 Hz while the scan size is maintained at 2×2 μm, which allows the velocity to vary from 0.4 to 240 μm/s. To study the durability properties, the friction force and coefficient of friction are monitored during scanning at a normal load of 70 nN and a scanning speed of 0.8 μm/s for a desired number of cycles [17.27, 28, 30].

17.2 Friction and Adhesion

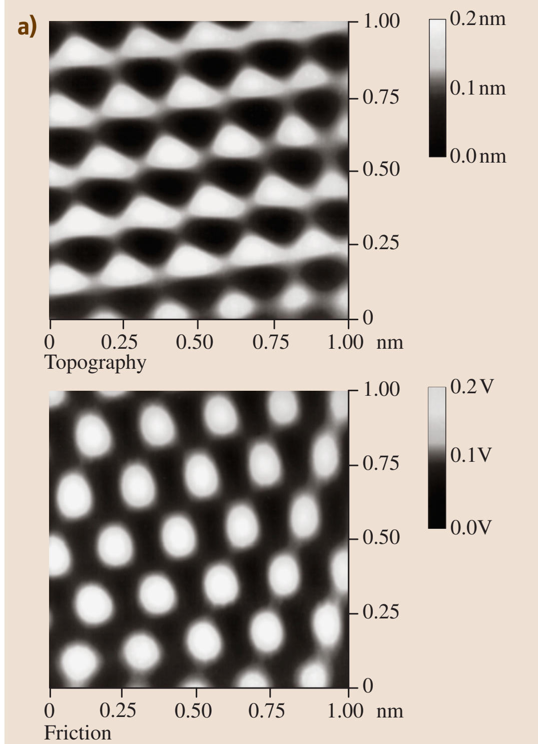
17.2.1 Atomic-Scale Friction

To study friction mechanisms on an atomic scale, a well characterized, freshly cleaved surface of highly oriented pyrolytic graphite (HOPG) has been used by *Mate* et al. [17.17] and *Ruan* and *Bhushan* [17.20].

The atomic-scale friction force of HOPG exhibited the same periodicity as that of the corresponding topography (Fig. 17.11a), but the peaks in friction and those in topography are displaced relative to each other (Fig. 17.11b). A Fourier expansion of the interatomic potential was used to calculate the conservative interatomic forces between atoms of the FFM tip and those of the graphite surface. Maxima in the interatomic forces in the normal and lateral directions do not occur at the same location, which explains the observed shift between the peaks in the lateral force and those in the corresponding topography. Furthermore, the observed local variations in friction force were explained by variation in the intrinsic lateral force between the sample and the FFM tip resulting from an atomic-scale stick-slip process [17.17, 20].

17.2.2 Microscale Friction

Local variations in the microscale friction of cleaved graphite have been observed (Fig. 17.12). These arise from structural changes that occur during the cleaving process [17.21]. The cleaved HOPG surface is largely atomically smooth, but exhibits line-shaped regions in which the coefficient of friction is more than an order of magnitude larger. Transmission electron microscopy indicates that the line-shaped regions consist of graphite planes of different orientation, as well as of amorphous



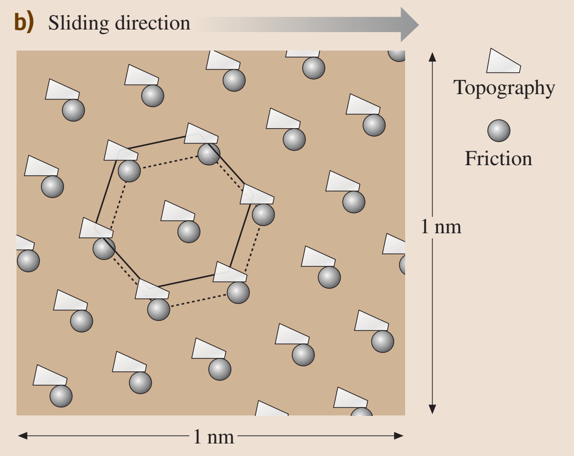


Fig. 17.11 **(a)** Gray-scale plots of surface topography and friction force maps of a 1 nm × 1 nm area of freshly cleaved HOPG showing the atomic-scale variation of topography and friction and **(b)** schematic of superimposed topography and friction maps from **(a)**; the symbols correspond to maxima. Note the spatial shift between the two plots [17.20]

carbon. Differences in friction have also been observed for multiphase ceramic materials [17.53]. Figure 17.13 shows the surface roughness and friction force maps of Al_2O_3-TiC (70–30 wt%). TiC grains have a Knoop hardness of about 2,800 kg/mm^2. Therefore, they do not polish as much and result in a slightly higher elevation (about 2–3 nm higher than that of Al_2O_3 grains). TiC grains exhibit higher friction force than Al_2O_3 grains. The coefficients of friction of TiC and Al_2O_3 grains are 0.034 and 0.026, respectively, and the coefficient of friction of Al_2O_3-TiC composite is 0.03. Local variation in friction force also arises from the scratches present on the Al_2O_3-TiC surface. *Meyer* et al. [17.54] also used FFM to measure structural variations of organic mono- and multilayer films. All of these measurements suggest that the FFM can be used for structural mapping of the

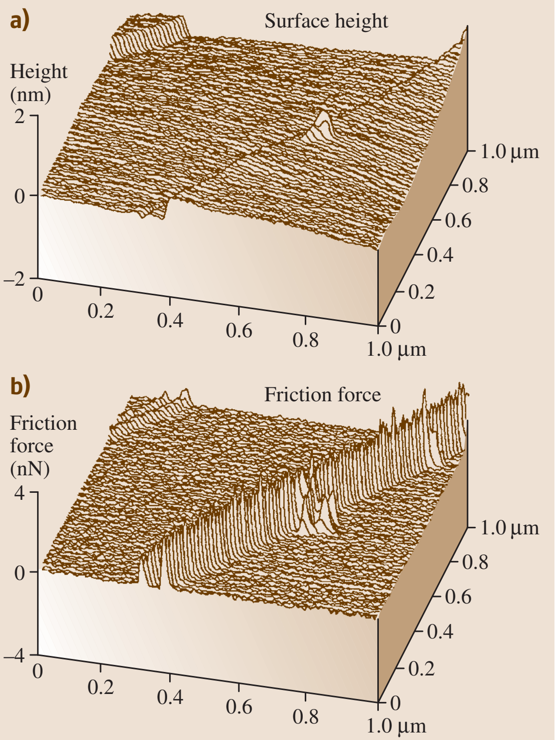

Fig. 17.12 **(a)** Surface roughness and **(b)** friction force maps at a normal load of 42 nN of freshly cleaved HOPG surface against an Si_3N_4 FFM tip. Friction in the *line-shaped region* is over an order of magnitude larger than the *smooth areas* [17.20]

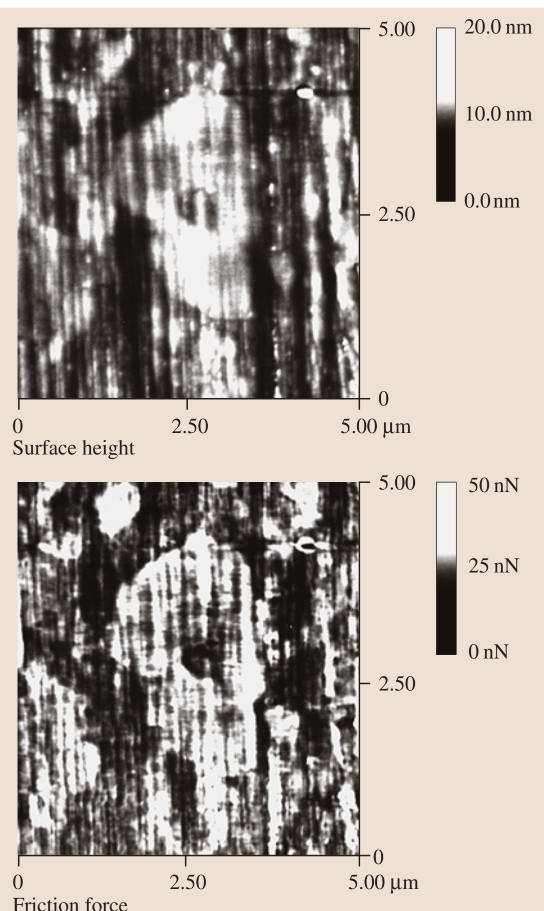

Fig. 17.13 Gray-scale surface roughness ($\sigma = 0.80$ nm) and friction force maps (mean $= 7.0$ nN, $\sigma = 0.90$ nN) for Al_2O_3-TiC (70–30 wt%) at a normal load of 138 nN [17.53]

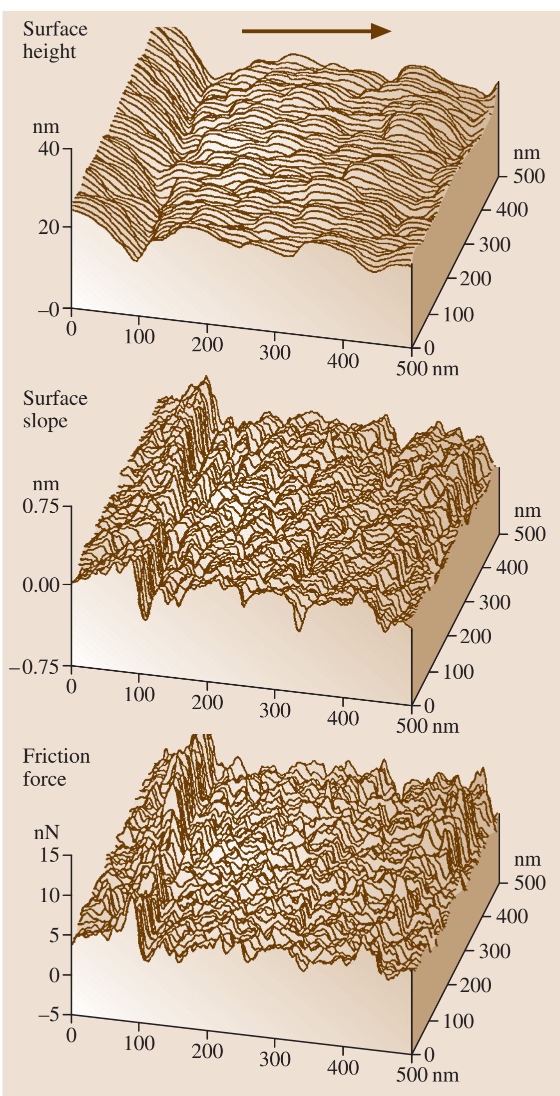

Fig. 17.14 Surface roughness map ($\sigma = 4.4$ nm); surface slope map taken in the sample sliding direction, the horizontal axis, (mean $= 0.023$, $\sigma = 0.197$); and friction force map (mean $= 6.2$ nN, $\sigma = 2.1$ nN) for a lubricated thin-film magnetic rigid disk for a normal load of 160 nN [17.22]

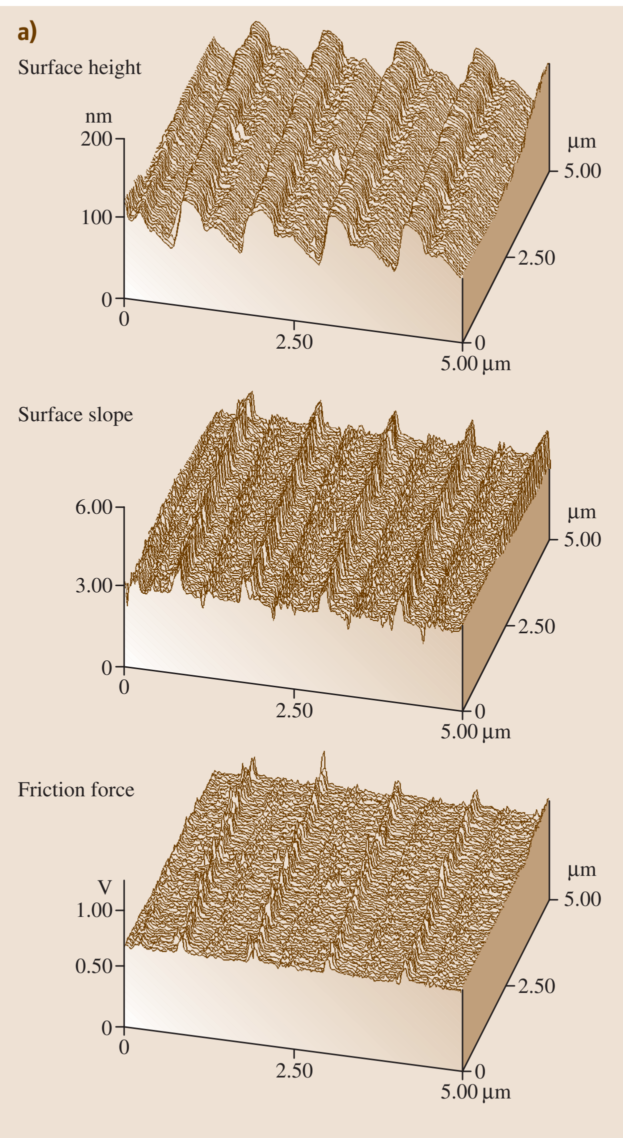
surfaces. FFM measurements can be used to map chemical variations, as indicated by the use of the FFM with a modified probe tip to map the spatial arrangement of chemical functional groups in mixed organic monolayer films [17.55]. Here, sample regions that had stronger interactions with the functionalized probe tip exhibited larger friction.

Local variations in the microscale friction of nominally rough, homogeneous surfaces can be significant and are seen to depend on the local surface slope, rather than the surface height distribution, Fig. 17.14. This dependence was first reported by *Bhushan* and *Ruan* [17.18], *Bhushan* et al. [17.22], and *Bhushan* [17.37] and later discussed in more detail in [17.56] and [17.57]. In order to show elegantly any correlation between local values of friction and surface roughness, surface roughness and friction force maps of a gold-coated ruling with somewhat rectangular grids and a silicon grid with square pits were obtained, see Fig. 17.15 [17.57]. Figures 17.14 and 17.15 show the



surface roughness map, the slopes of the roughness map taken along the sliding direction (surface slope map), and the friction force map for various samples. There is a strong correlation between the surface slopes and friction forces. For example, in Fig. 17.15, friction force is high locally at the edge of the grids and pits with a positive slope and is low at the edges with a negative slope.

We now examine the mechanism of microscale friction, which may explain the resemblance between the slope of surface roughness maps and the corresponding friction force maps [17.4, 5, 18, 20–22, 56, 57]. There are three dominant mechanisms of friction: adhesive, adhesive and roughness (ratchet), and plowing [17.10, 57]. First, we may assume these to be additive. The adhesive mechanism cannot explain the local variation in friction. Next, we consider the ratchet mechanism. We consider a small tip sliding over an asperity making an angle θ with the horizontal plane, Fig. 17.16. The normal force W (normal to the general surface) applied by the tip to the sample surface is constant. The friction force F on the sample would be a constant for a smooth surface if the friction mechanism does not change. For a rough surface, as shown in Fig. 17.16, if the adhesive mechanism does not change during sliding, the local value of coefficient of friction remains constant,

$$\mu_0 = S/N \,, \tag{17.1}$$

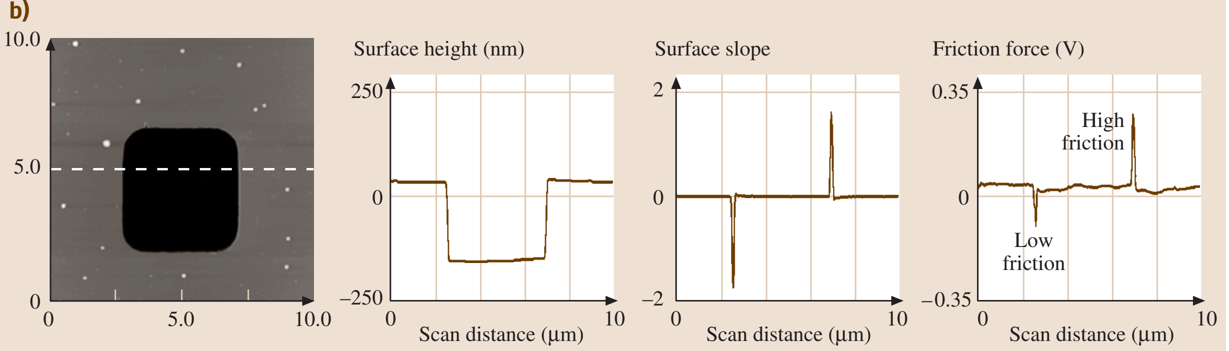


Fig. 17.15a,b Surface roughness map, surface slope map taken in the sample sliding direction (the horizontal axis), and friction force map for **(a)** a gold-coated ruling (with somewhat rectangular grids with a pitch of 1 µm and a ruling step height of about 70 nm) at a normal load of 25 nN and **(b)** a silicon grid (with 5 µm square pits of 180-nm depth and a pitch of 10 µm) [17.57]

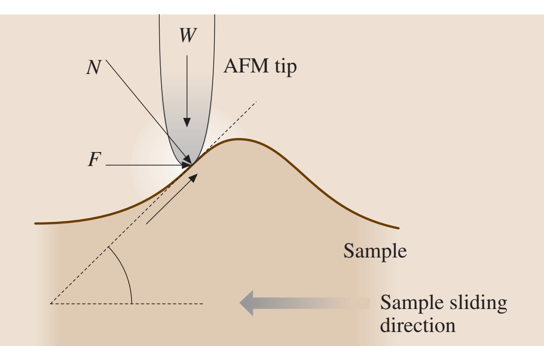

Fig. 17.16 Schematic illustration showing the effect of an asperity (making an angle θ with the horizontal plane) on the surface in contact with the tip on local friction in the presence of adhesive friction mechanism. W and F are the normal and friction forces, respectively, and S and N are the force components along and perpendicular to the local surface of the sample at the contact point, respectively

where S is the local friction force and N is the local normal force. However, the friction and normal forces are measured with respect to global horizontal and normal axes, respectively. The measured local coefficient of friction μ_1 in the ascending part is

$$\mu_1 = F/W = (\mu_0 + \tan\theta) / (1 - \mu_0 \tan\theta) \sim \mu_0 + \tan\theta \,, \quad \text{for small } \mu_0 \tan\theta \,, \tag{17.2}$$

indicating that in ascending part of the asperity one may simply add the friction force and the asperity slope to one another. Similarly, on the right-hand side (descending part) of the asperity,

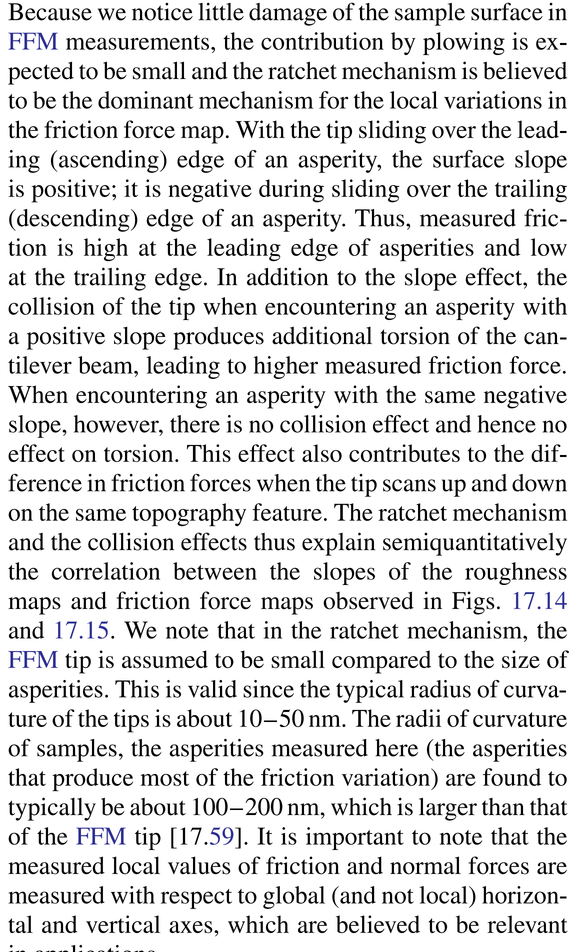
$$\mu_2 = (\mu_0 - \tan\theta) / (1 + \mu_0 \tan\theta) \sim \mu_0 - \tan\theta \,, \quad \text{for small } \mu_0 \tan\theta \,. \tag{17.3}$$

For a symmetrical asperity, the average coefficient of friction experienced by the FFM tip traveling across the whole asperity is

$$\mu_{\text{ave}} = (\mu_1 + \mu_2)/2 = \mu_0 \left(1 + \tan^2\theta\right) / \left(1 - \mu_0^2 \tan^2\theta\right) \sim \mu_0 \left(1 + \tan^2\theta\right) \,, \quad \text{for small } \mu_0 \tan\theta \,. \tag{17.4}$$

Finally, we consider the plowing component of friction with tip sliding in either direction, which is [17.10, 58]

$$\mu_p \sim \tan\theta \,. \tag{17.5}$$



Because we notice little damage of the sample surface in FFM measurements, the contribution by plowing is expected to be small and the ratchet mechanism is believed to be the dominant mechanism for the local variations in the friction force map. With the tip sliding over the leading (ascending) edge of an asperity, the surface slope is positive; it is negative during sliding over the trailing (descending) edge of an asperity. Thus, measured friction is high at the leading edge of asperities and low at the trailing edge. In addition to the slope effect, the collision of the tip when encountering an asperity with a positive slope produces additional torsion of the cantilever beam, leading to higher measured friction force. When encountering an asperity with the same negative slope, however, there is no collision effect and hence no effect on torsion. This effect also contributes to the difference in friction forces when the tip scans up and down on the same topography feature. The ratchet mechanism and the collision effects thus explain semiquantitatively the correlation between the slopes of the roughness maps and friction force maps observed in Figs. 17.14 and 17.15. We note that in the ratchet mechanism, the FFM tip is assumed to be small compared to the size of asperities. This is valid since the typical radius of curvature of the tips is about 10–50 nm. The radii of curvature of samples, the asperities measured here (the asperities that produce most of the friction variation) are found to typically be about 100–200 nm, which is larger than that of the FFM tip [17.59]. It is important to note that the measured local values of friction and normal forces are measured with respect to global (and not local) horizontal and vertical axes, which are believed to be relevant in applications.

17.2.3 Directionality Effect on Microfriction

During friction measurements, the friction force data from both the forward (trace) and backward (retrace) scans are useful in understanding the origins of the observed friction forces. Magnitudes of material-induced effects are independent of the scanning direction, whereas topography-induced effects are different between forward and backward scanning directions. Since the sign of the friction force changes as the scanning direction is reversed (because of the reversal of torque applied to the end of the tip), addition of the friction force data of the forward and backward scan eliminates the material-induced effects, while topography-induced effects still remain. Subtraction of the data between forward and backward scans does not eliminate either effect, see Fig. 17.17 [17.57].

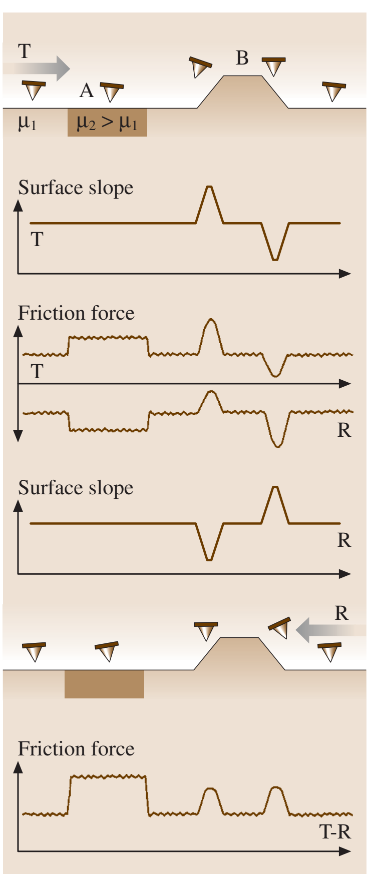


Fig. 17.17 Schematic of friction forces expected when a tip traverses a sample that is composed of different materials and sharp changes in topography. A schematic of surface slope is also shown (T = Trace, R = Retrace)

Owing to the reversal of the sign of the retrace (R) friction force with respect to the trace (T) data, the friction force variations due to topography are in the same direction (peaks in trace correspond to peaks in retrace). However, the magnitudes of the peaks in trace and retrace at a given location are different. An increase in the friction force experienced by the tip when scanning up a sharp change in topography is more than the decrease in the friction force experienced when scanning down the same topography change, partly due to the collision effects discussed earlier. Asperities on engineering surfaces are asymmetrical, which also affect the magnitude of friction force in the two directions. In addition, asymmetry in tip shape may have an effect on the directionality effect of friction. We will later note that the magnitude of surface slopes are virtually identical. Therefore, the tip shape asymmetry should not have much effect.

Figure 17.18 shows surface height and friction force data for gold ruler and a silicon grid in the trace and retrace directions. Subtraction of two friction data yields a residual peak, because of the differences in the magnitudes of friction forces in the two directions. This effect is observed at all locations of significant changes in topography.

In order to facilitate comparison of directionality effect on friction, it is important to take into account the sign change of the surface slope and friction force in

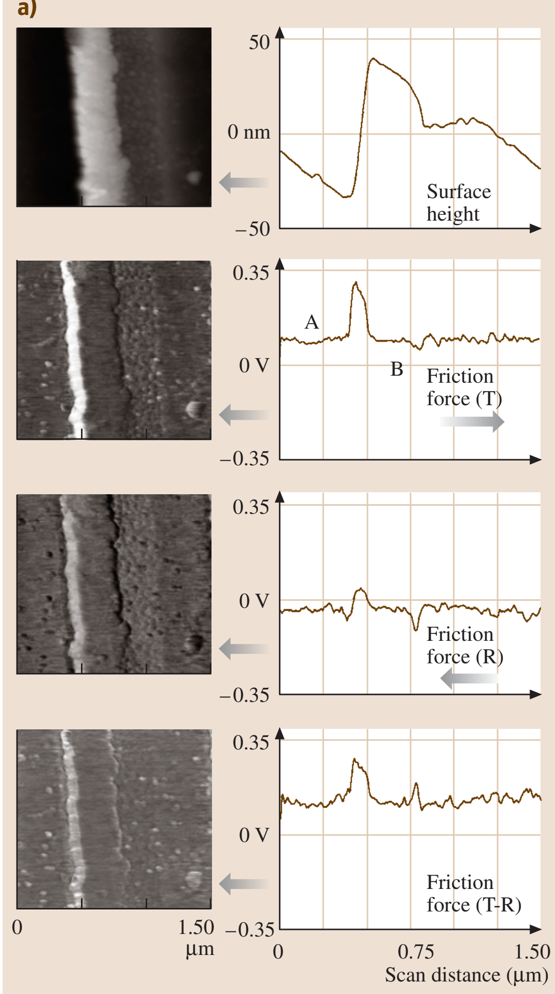

Fig. 17.18 **(a)** Gray-scale images and two-dimensional profiles of surface height and friction forces across a single ruling of the gold-coated ruling and **(b)** (*see next page*) two-dimensional profiles of surface height and friction forces across a silicon grid pit. Friction force data in trace (T) and retrace (R) directions and substrated force data are presented

the trace and retrace directions. Figure 17.19 shows surface height, surface slope, and friction force data for the two samples in the trace and retrace directions. The correlation between surface slope and friction forces is clear. The third column in the figures shows retrace slope and friction data with an inverted sign (−retrace). Now we can compare trace data with −retrace data. It is clear that the friction experienced by the tip is dependent upon the scanning direction because of surface topography. In addition to the effect of topographical changes discussed earlier, during surface-finishing processes, material can be transferred preferentially onto one side of the asperities, which also causes asymmetry and direction dependence. Reduction in local variations and in directionality of friction properties requires careful optimization of surface roughness distributions and of surface-finishing processes.

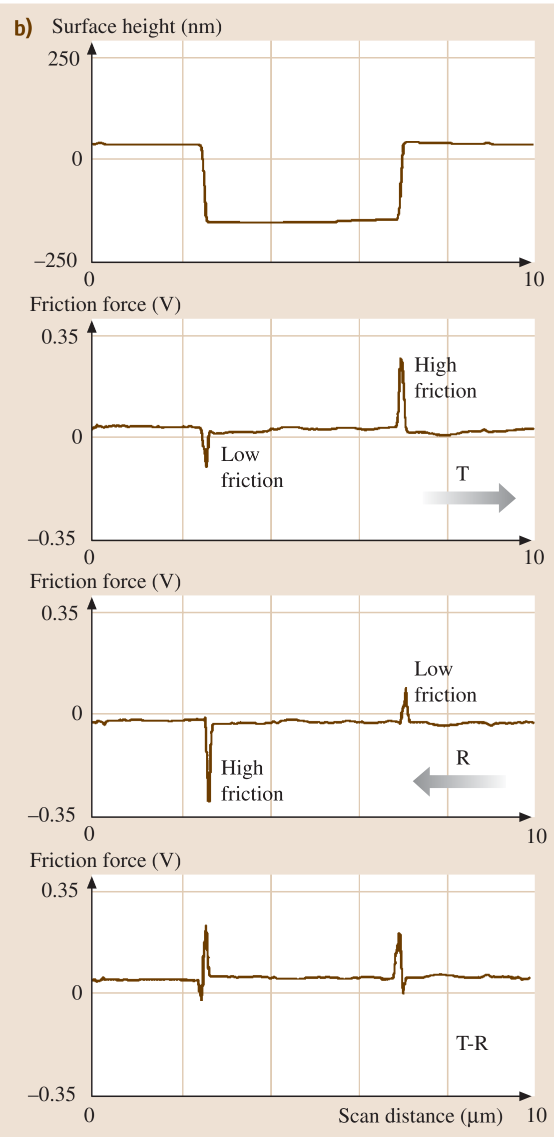

Fig. 17.18 b

The directionality as a result of surface asperities effect will also be manifested in macroscopic friction data, i. e., the coefficient of friction may be different in one sliding direction than in the other direction. Asymmetrical shape of asperities accentuates this effect. The frictional directionality can also exist in materials with particles with a preferred orientation. The directionality effect in friction on a macroscale is observed in some magnetic tapes. In a macroscale test, a 12.7-mm wide polymeric magnetic tape was wrapped over an aluminum drum and slid in a reciprocating motion with a normal load of 0.5 N and a sliding speed of about 60 mm/s [17.3]. The coefficient of friction as a function of sliding distance in either direction is shown in Fig. 17.20. We note that the coefficient of friction on a macroscale for this tape varies in different directions. Directionality in friction is sometimes observed on the macroscale; on the microscale this is the norm [17.4, 13]. On the macroscale, the effect of surface asperities is normally averaged out over a large number of contacting asperities.

17.2.4 Velocity Dependence on Microfriction

AFM/FFM experiments are generally conducted at relative velocities as high as a few tens of µm/s. To simulate applications, it is of interest to conduct friction experiments at higher velocities. High velocities can be achieved by mounting either the sample or the cantilever beam on a shear wave transducer (ultrasonic transducer) to produce surface oscillations at MHz frequencies [17.24, 25, 60]. The velocities on the order of a few mm/s can thus be achieved. The effect of in-plane and out-of-plane sample vibration amplitude on the coefficient of friction is shown in Fig. 17.21. Vibration of a sample at ultrasonic frequencies (> 20 kHz) can substantially reduce the coefficient of friction, known as ultrasonic lubrication or sonolubrication. When the surface is vibrated in-plane, classical hydrodynamic lubrication develops hydrodynamic pressure, which supports the tip and reduces friction. When the surface is vibrated out-of-plane, a lift-off caused by the squeeze-film lubrication (a form of hydrodynamic lubrication), reduces friction.

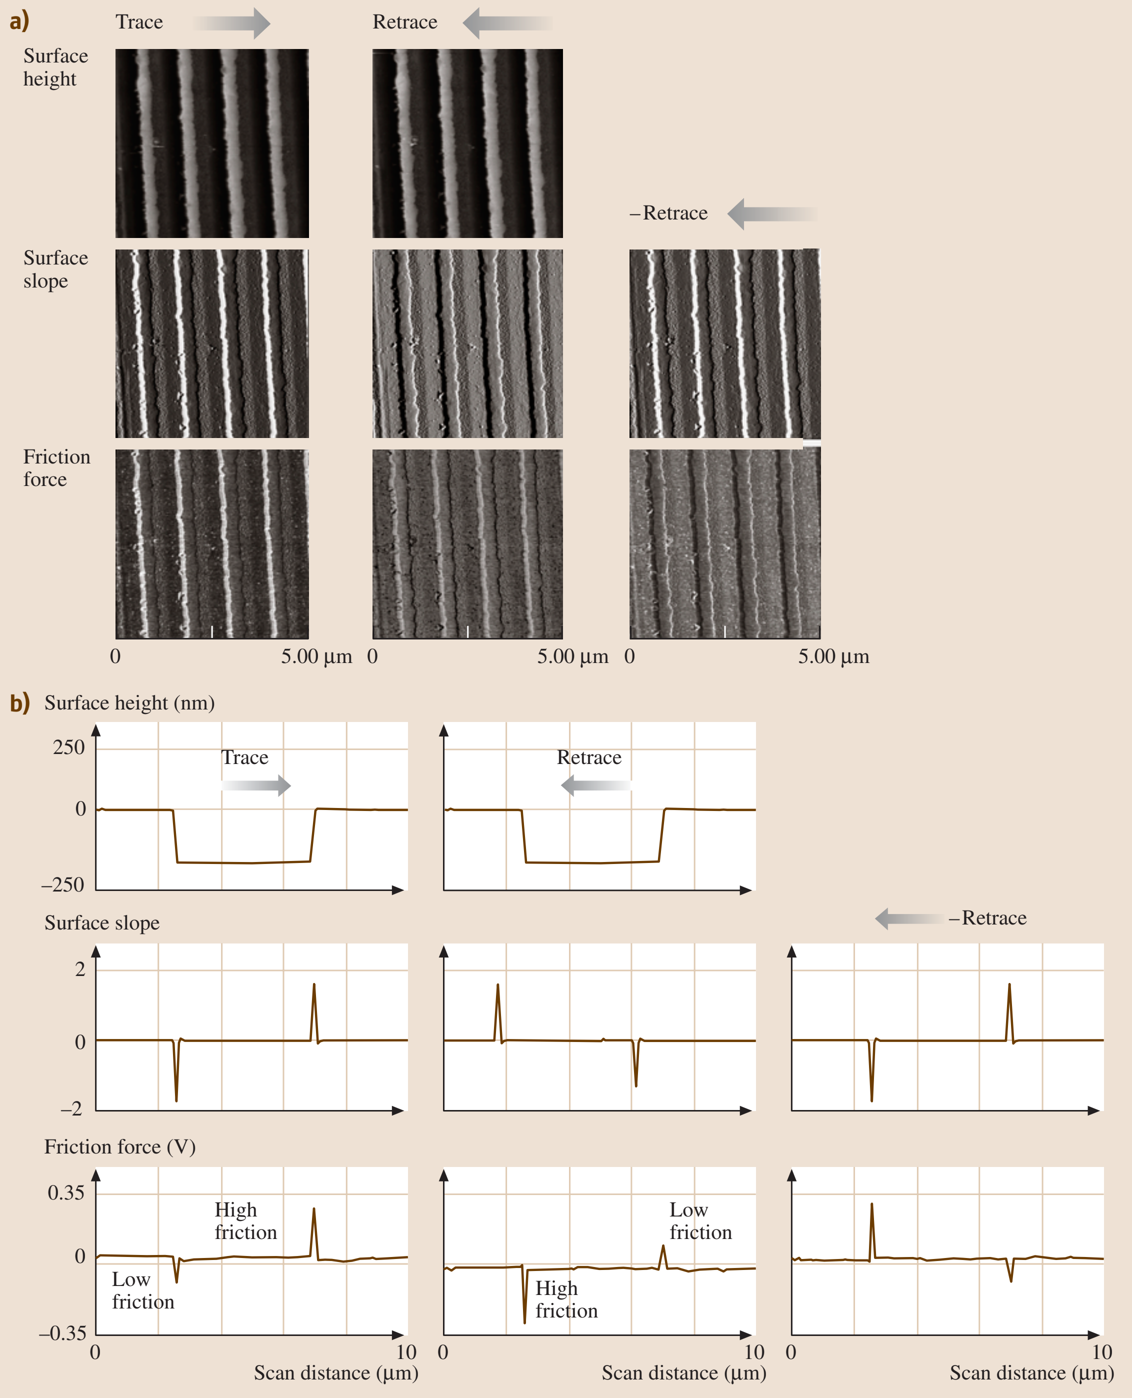

Fig. 17.19 **(a)** Gray-scale images of surface heights, surface slopes, and friction forces for scans across a gold-coated ruling, and **(b)** two-dimensional profiles of surface heights, surface slopes, and friction forces for scans across the silicon grid pit. *Arrows* indicate the tip sliding direction [17.57]

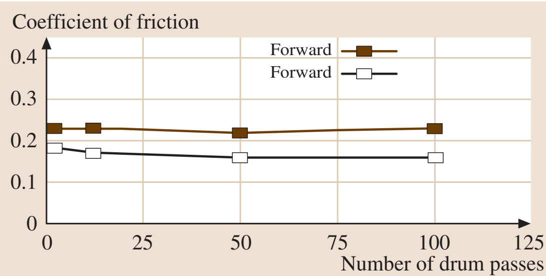

Fig. 17.20 Coefficient of macroscale friction as a function of drum passes for a polymeric magnetic tape sliding over an aluminum drum in a reciprocating mode in both directions. Normal load = 0.5 N over 12.7-mm wide tape, sliding speed = 60 mm/s [17.37]

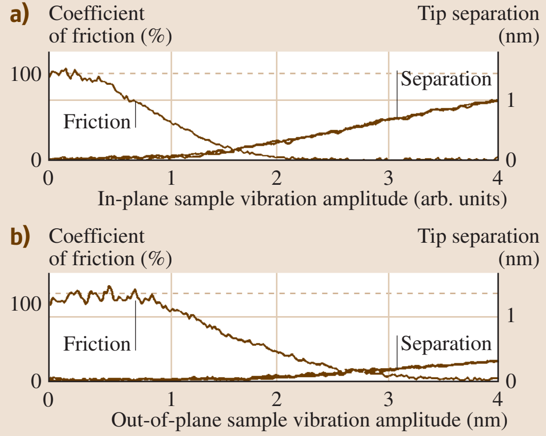

Fig. 17.21a,b Reduction of coefficient of friction measured at a normal load of 100 nN and average tip separation as a function of surface amplitude on a single-crystal silicon subjected to **(a)** in-plane and **(b)** out-of-plane vibrations at about 1 MHz against a silicon nitride tip [17.24]

17.2.5 Effect of Tip Radii and Humidity on Adhesion and Friction

The tip radius and relative humidity affect adhesion and friction for dry and lubricated surfaces [17.23, 36].

Experimental Observations

Figure 17.22 shows the variation of single-point adhesive-force measurements as a function of tip radius on a Si(100) sample for several humidities. The adhesive force data are also plotted as a function of relative humidity for several tip radii. The general trend at humidities up to the ambient is that a 50-nm radius Si_3N_4 tip exhibits a slightly lower adhesive force compared to the other microtips of larger radii; in the latter case, values are similar. Thus, for the microtips there is no appreciable variation in adhesive force with tip radius at a given humidity up to the ambient. The adhesive force increases as relative humidity increases for all tips.

Sources of adhesive force between a tip and a sample surface are van der Waals attraction and meniscus formation [17.10, 58]. Relative magnitudes of the forces from the two sources are dependent upon various factors, including the distance between the tip and the sample surface, their surface roughness, their hydrophobicity, and relative humidity [17.61]. For most rough surfaces, meniscus contribution dominates at moderate to high humidities, which arise from capillary condensation of water vapor from the environment. If enough liquid is present to form a meniscus bridge, the meniscus force should increase with an increase in tip radius (proportional to tip radius for a spherical tip). In addition, an increase in tip radius results in increased contact area leading to higher values of van der Waals forces. However, if nanoasperities on the tip and the sample are considered, then the number of contacting and near-contacting asperities forming meniscus bridges increases with an increase of humidity leading to an increase in meniscus forces. These explain the trends observed in Fig. 17.22. From the data, the tip radius has little effect on the adhesive forces at low humidities, but increases with tip radius at high humidity. Adhesive force also increases with an increase in humidity for all tips. This observation suggests that thickness of the liquid film at low humidities is insufficient to form continuous meniscus bridges to affect adhesive forces in the case of all tips.

Figure 17.22 also shows the variation in coefficient of friction as a function of tip radius at a given humidity and as a function of relative humidity for a given tip radius for Si(100). It can be observed that for 0% RH, the coefficient of friction is about the same for the tip radii except for the largest tip, which shows a higher value. At all other humidities, the trend consistently shows that the coefficient of friction increases with tip radius. An increase in friction with tip radius at low to moderate humidities arises from increased contact area (higher van der Waals forces) and higher values of shear forces required for larger contact area. At high humidities, similar to adhesive force data, an increase with tip radius occurs due to both contact area and meniscus effects. Although AFM/FFM measurements are able to measure the combined effect of the contribution of van der Waals

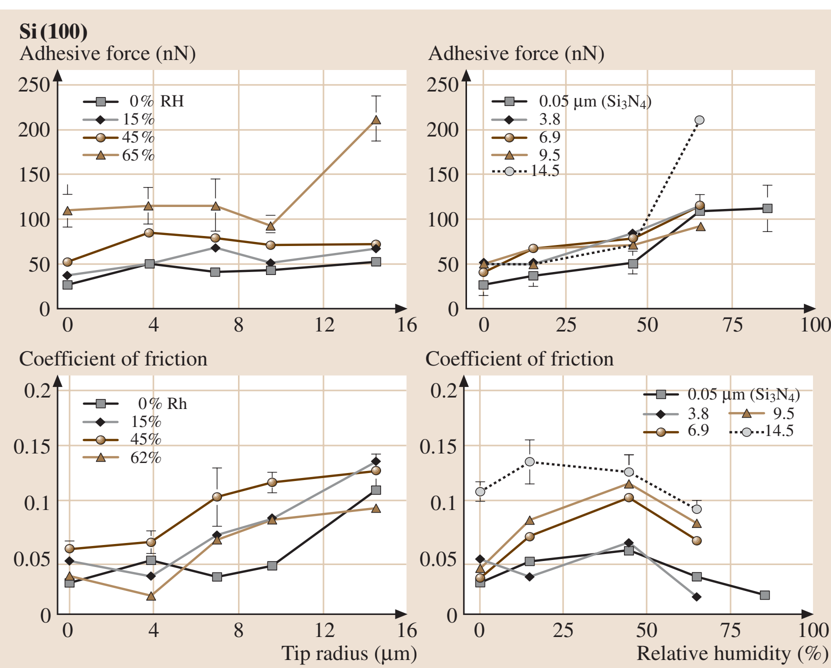

Fig. 17.22 Adhesive force and coefficient of friction as a function of tip radius at several humidities and as a function of relative humidity (RH) at several tip radii on Si(100) [17.23]

and meniscus forces toward friction force or adhesive force, it is difficult to measure their individual contributions separately. It can be seen that for all tips, the coefficient of friction increases with humidity to about ambient, beyond which it starts to decrease. The initial increase in the coefficient of friction with humidity arises from the fact that the thickness of the water film increases with an increase in the humidity, which results in a larger number of nanoasperities forming meniscus bridges and leads to higher friction (larger shear force). The same trend is expected with the microtips beyond 65% RH. This is attributed to the fact that at higher humidities, the adsorbed water film on the surface acts as a lubricant between the two surfaces. Thus the interface is changed at higher humidities, resulting in lower shear strength and, hence, lower friction force and coefficient of friction.

Adhesion and Friction Force Expressions for a Single-Asperity Contact

We now obtain the expressions for the adhesive force and coefficient of friction for a single-asperity contact with a meniscus formed at the interface. For a spherical asperity of radius R in contact with a flat and smooth surface with the composite modulus of elasticity E^* and with a concave meniscus, the attractive meniscus force (adhesive force) W_{ad} is given as [17.10, 58]

$$W_{ad} = 2\pi R \gamma_1 (\cos\theta_1 + \cos\theta_2) \; . \tag{17.6}$$

For an elastic contact for both extrinsic (W) and intrinsic (W_{ad}) normal load, the friction force is given as

$$F_e = \pi\tau \left(\frac{3(W + W_{ad})R}{4E^*} \right)^{2/3} \; , \tag{17.7}$$

where γ_1 is the surface tension of the liquid in air, θ_1 and θ_2 are the contact angles between the liquid and the two surfaces, W is the external load, and τ is the average shear strength of the contacts. (Surface energy effects are not considered here.) Note that adhesive force increases linearly with an increase in the tip radius, and the friction force increases with an increase in tip radius as $R^{2/3}$ and with normal load as $(W + W_{ad})^{2/3}$. The experimental data in support of $W^{2/3}$ dependence on the friction force can be found in various references (see, for example, [17.62]). The coefficient of friction μ_e is obtained from (17.7) as

$$\mu_e = \frac{F_e}{(W + W_{ad})} = \pi\tau \left(\frac{3R}{4E^*} \right)^{2/3} \frac{1}{(W + W_{ad})^{1/3}} \; . \tag{17.8}$$

In the plastic contact regime [17.58], the coefficient of friction μ_p is obtained as

$$\mu_p = \frac{F_p}{(W + W_{ad})} = \frac{\tau}{H_s}\,, \quad (17.9)$$

where H_s is the hardness of the softer material. Note that in the plastic contact regime, the coefficient of friction is independent of external load, adhesive contributions, and surface geometry.

In comparison, for multiple-asperity contacts in the elastic contact regime, the total adhesive force W_{ad} is the summation of adhesive forces at n individual contacts,

$$W_{ad} = \sum_{i=1}^{n} (W_{ad})_i \quad \text{and}$$

$$\mu_e \approx \frac{3.2\tau}{E^* \left(\sigma_p / R_p\right)^{1/2} + W_{ad}/W}\,, \quad (17.10)$$

where σ_p and R_p are the standard deviation of summit heights and average summit radius, respectively. Note that the coefficient of friction depends upon the surface roughness. In the plastic contact regime, the expression for μ_p in (17.9) does not change.

The source of the adhesive force, in a wet contact in the AFM experiments being performed in an ambient environment, includes mainly attractive meniscus force due to capillary condensation of water vapor from the environment. The meniscus force for a single contact increases with an increase in tip radius. A sharp AFM tip in contact with a smooth surface at low loads (on the order of a few nN) for most materials can be simulated as a single-asperity contact. At higher loads, for rough and soft surfaces, multiple contacts would occur. Furthermore, at low loads (nN range) for most materials, the local deformation would be primarily elastic. Assuming that shear strength of contacts does not change, the adhesive force for smooth and hard surfaces at low normal load (on the order of few nN) (for a single-asperity contact in the elastic contact regime) would increase with an increase in tip radius, and the coefficient of friction would decrease with an increase in total normal load as $(W + W_{ad})^{-1/3}$ and would increase with an increase of tip radius as $R^{2/3}$. In this case, the Amontons law of friction, which states that the coefficient of friction is independent of normal load and is independent of apparent area of contact, does not hold. For a single-asperity plastic contact and multiple-asperity plastic contacts, neither the normal load nor tip radius come into play in the calculation of the coefficient of friction. In the case of multiple-asperity contacts, the number of contacts increase with an increase of normal load. Therefore, adhesive force increases with an increase in load.

In the data presented earlier in this section, the effect of tip radius and humidity on the adhesive forces and coefficient of friction is investigated for experiments with Si(100) surface at loads in the range of 10–100 nN. The multiple-asperity elastic contact regime is relevant for this study. An increase in humidity generally results in an increase in the number of meniscus bridges that would increase the adhesive force. As suggested earlier, that increase in humidity may also decrease the shear strength of contacts. A combination of an increase in adhesive

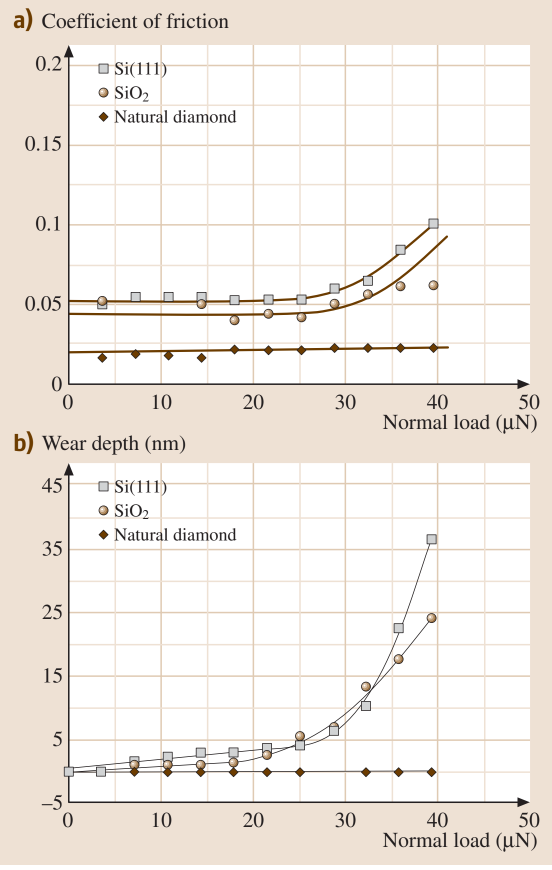

Fig. 17.23 **(a)** Coefficient of friction as a function of normal load and **(b)** corresponding wear depth as a function of normal load for silicon, SiO_2 coating, and natural diamond. Inflections in the curves for silicon and SiO_2 correspond to the contact stresses equal to the hardnesses of these materials [17.63]

Table 17.2 Surface roughness (standard deviation of surface heights or σ) and coefficients of friction on nano- and macroscales of various samples in air

Material	σ (nm)	Coefficient of nanoscale friction versus Si_3N_4 tip[a]	Coefficient of macroscale friction versus Si_3N_4 ball[b]
Graphite (HOPG)	0.09	0.006	0.1
Natural diamond	2.3	0.04	0.2
Si(100)	0.14	0.07	0.4

[a] Tip radius of about 50 nm in the load range of 10–150 nN (2.5–6.1 GPa) and a scanning speed of 0.5 nm/s and scan area of 1 nm × 1 nm for HOPG and a scanning speed of 4 µm/s and scan area of 1 µm × 1 µm for diamond and Si(100)

[b] Ball radius of 3 mm at a normal load of 1 N (0.6 GPa) and average sliding speed of 0.8 mm/s

force and a decrease in shear strength would affect the coefficient of friction. An increase in tip radius would increase the meniscus force (adhesive force). A substantial increase in the tip radius may also increase interatomic forces. These effects influence the coefficient of friction with an increase in the tip radius.

17.2.6 Scale Dependence on Friction

Table 17.2 shows the coefficient of friction measured for various materials on nano- and macroscales [17.19]. It is clearly observed that friction values are scale-dependent. The values on the nano/microscale are much lower than those on the macroscale. There can be the following four, and possibly more, differences in the operating conditions responsible for these differences. First, the contact stresses at AFM conditions, in spite of small tip radii, generally do not exceed the sample hardness that minimizes plastic deformation. Average contact stresses in macrocontacts are generally lower than in AFM contacts, however, a large number of asperities come into contact that go through some plastic deformation. Second, when measured for the small contact areas and very low loads used in microscale studies, indentation hardness is higher than at the macroscale, as will be discussed later [17.11, 34, 35]. Lack of plastic deformation and improved mechanical properties reduce the degree of wear and friction. Third, the small apparent area of contact reduces the number of particles trapped at the interface, and thus minimizes the third-body plowing contribution to the friction force [17.11]. As a fourth and final difference, we have seen in the previous section that coefficient of friction increases with an increase in the AFM tip radius. AFM data are taken with a sharp tip, whereas asperities coming in contact in macroscale tests range from nanoasperities to much larger asperities, which may be responsible for larger values of friction force on the macroscale.

To demonstrate the load dependence on the coefficient of friction, stiff cantilevers were used to conduct friction experiments at high loads, see Fig. 17.23 [17.63]. At higher loads (with contact stresses exceeding the hardness of the softer material), as anticipated, the coefficient of friction for microscale measurements increases toward values comparable to those obtained from macroscale measurements, and surface damage also increases. At high loads, plowing is a dominant contributor to the friction force. Based on these results, Amontons rule of friction, which states that the coefficient of friction is independent of apparent area and normal load, does not hold for microscale measurements. These findings also suggest that microcomponents sliding under lightly loaded conditions should experience ultralow friction and near-zero wear [17.11].

17.3 Scratching, Wear, Local Deformation, and Fabrication/Machining

17.3.1 Nanoscale Wear

Bhushan and *Ruan* [17.18] conducted nanoscale wear tests on polymeric magnetic tapes using conventional silicon nitride tips at two different loads of 10 and 100 nN (Fig. 17.24). For a low normal load of 10 nN, measurements were made twice. There was no discernible difference between consecutive measurements for this load. However, as the load was increased from 10 nN to 100 nN, topographical changes were ob-

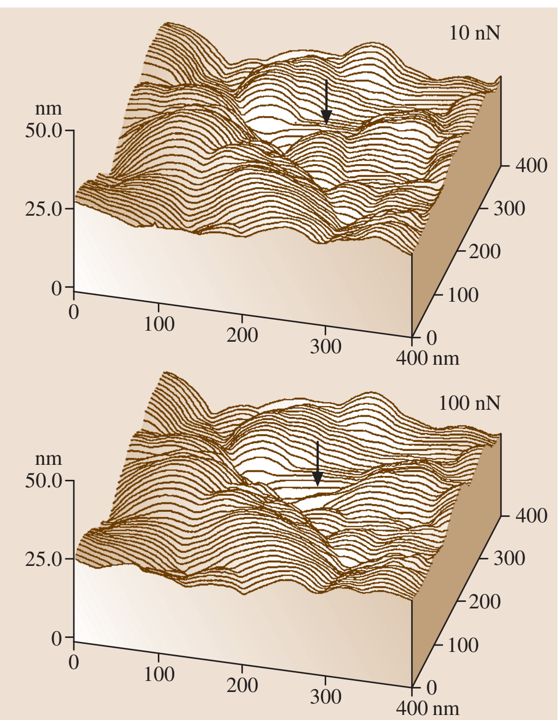

Fig. 17.24 Surface roughness maps of a polymeric magnetic tape at the applied normal load of 10 nN and 100 nN. Location of the change in surface topography as a result of nanowear is indicated by *arrows* [17.18]

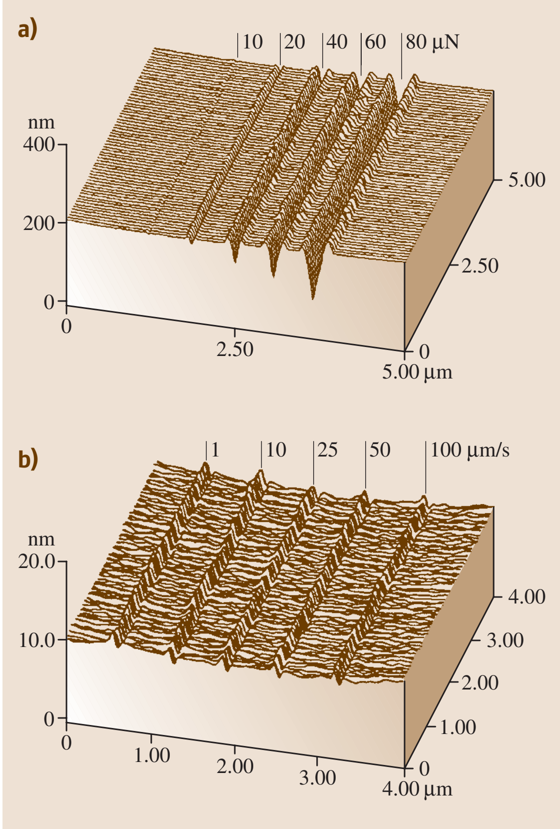

Fig. 17.25a,b Surface plots of **(a)** Si(111) scratched for 10 cycles at various loads and a scanning velocity of 2 µm/s. Note that x and y axes are in µm and z axis is in nm. **(b)** Si(100) scratched in one unidirectional scan cycle at a normal force of 80 µN and different scanning velocities

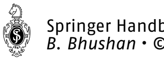
served during subsequent scanning at a normal load of 10 nN; material was pushed in the sliding direction of the AFM tip relative to the sample. The material movement is believed to occur as a result of plastic deformation of the tape surface. Thus, deformation and movement of the soft materials on a nanoscale can be observed.

17.3.2 Microscale Scratching

The AFM can be used to investigate how surface materials can be moved or removed on micro- to nanoscales, for example, in scratching and wear [17.4] (where these things are undesirable), and nanofabrication/nanomachining (where they are desirable). Figure 17.25a shows microscratches made on Si(111) at various loads and scanning velocity of 2 µm/s after 10 cycles [17.22]. As expected, the scratch depth increases linearly with load. Such microscratching measurements can be used to study failure mechanisms on the microscale and evaluate the mechanical integrity (scratch resistance) of ultrathin films at low loads.

To study the effect of scanning velocity, unidirectional scratches, 5 µm in length, were generated at scanning velocities ranging from 1–100 µm/s at various normal loads ranging from 40–140 µN. There is no effect of scanning velocity obtained at a given normal load. (For representative scratch profiles at 80 µN, see Fig. 17.25b.) This may be because of a small effect of frictional heating with the change in scanning velocity used here. Furthermore, for a small change in interface temperature, there is a large underlying volume to dissipate the heat generated during scratching.

Scratching can be performed under ramped loading to determine the scratch resistance of materials and



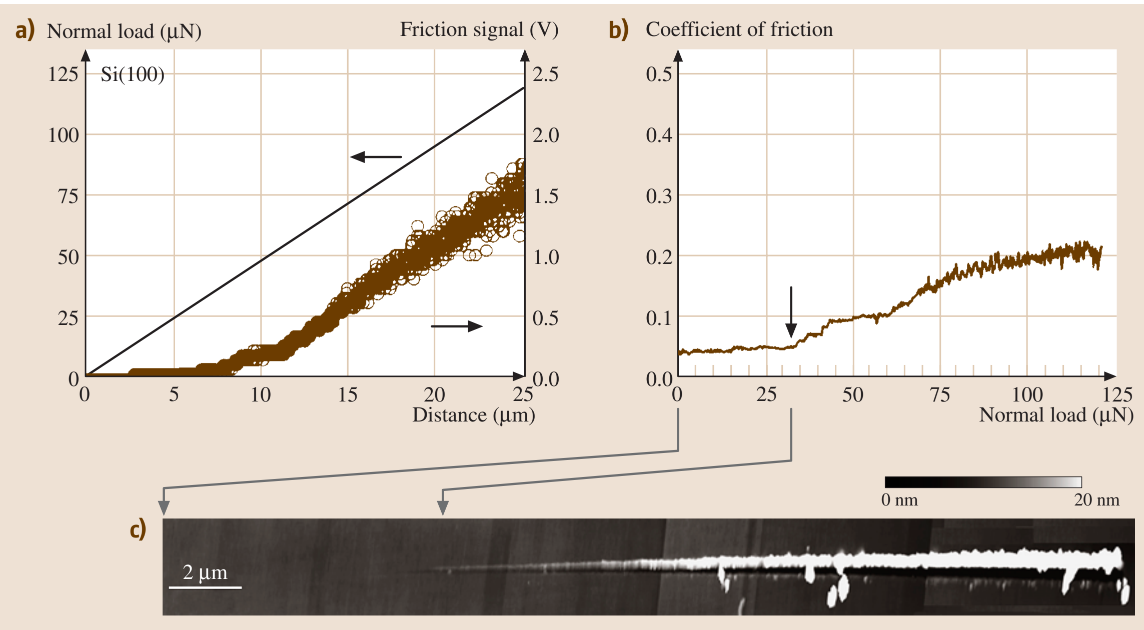


Fig. 17.26 **(a)** Applied normal load and friction signal measured during the microscratch experiment on Si(100) as a function of scratch distance, **(b)** friction data plotted in the form of coefficient of friction as a function of normal load, and **(c)** AFM surface height image of scratch obtained in tapping mode [17.33]

coatings. The coefficient of friction is measured during scratching, and the load at which the coefficient of friction increases rapidly is known as the "critical load", which is a measure of scratch resistance. In addition, post-scratch imaging can be performed in situ with the AFM in tapping mode to study failure mechanisms. Figure 17.26 shows data from a scratch test on Si(100) with a scratch length of 25 μm and a scratching velocity of 0.5 μm/s. At the beginning of the scratch, the coefficient of friction is 0.04, which indicates a typical value for silicon. At about 35 μN (indicated by the arrow in the figure), there is a sharp increase in the coefficient of friction, which indicates the critical load. Beyond the critical load, the coefficient of friction continues to increase steadily. In the post-scratch image, we note that at the critical load, a clear groove starts to form. This implies that Si(100) was damaged by plowing at the critical load, associated with the plastic flow of the material. At and after the critical load, small and uniform debris is observed and the amount of debris increases with increasing normal load. *Sundararajan* and *Bhushan* [17.33] have also used this technique to measure the scratch resistance of diamond-like carbon coatings ranging in thickness from 3.5–20 nm.

17.3.3 Microscale Wear

By scanning the sample in two dimensions with the AFM, wear scars are generated on the surface. Figure 17.27 shows the effect of normal load on wear depth. We note that wear depth is very small below 20 μN of normal load [17.64, 65]. A normal load of 20 μN corresponds to contact stresses comparable

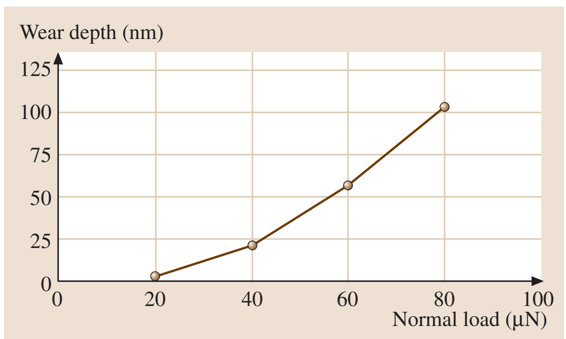

Fig. 17.27 Wear depth as a function of normal load for Si(100) after one cycle [17.65]

to the hardness of the silicon. Elastic deformation at loads below 20 μN is primarily responsible for low wear [17.63].

A typical wear mark, of the size 2 μm × 2 μm, generated at a normal load of 40 μN for one scan cycle and imaged using AFM with scan size of 4 μm × 4 μm at 300 nN load is shown in Fig. 17.28a [17.64]. The inverted map of wear marks shown in Fig. 17.28b indicates the uniform material removal at the bottom of the wear mark. An AFM image of the wear mark shows small debris at the edges, swiped during AFM scanning. Thus, the debris is loose (not sticky) and can be removed during the AFM scanning.

Next, we examine the mechanism of material removal on a microscale in AFM wear experiments [17.23, 64, 65]. Figure 17.29 shows a secondary electron image of the wear mark and associated wear particles. The specimen used for the scanning electron microscope (SEM) was not scanned with the AFM after initial wear, in order to retain wear debris in the wear region. Wear debris is clearly observed. In the SEM micrographs, the wear debris appear to be agglomerated because of high surface energy of the fine particles. Particles appear to be a mixture of rounded and so-called cutting type (feather-like or ribbon-like material). *Zhao* and *Bhushan* [17.65] reported an increase in the number and size of cutting-type particles with the normal load. The presence of cutting-type particles indicates that the material is removed primarily by plastic deformation.

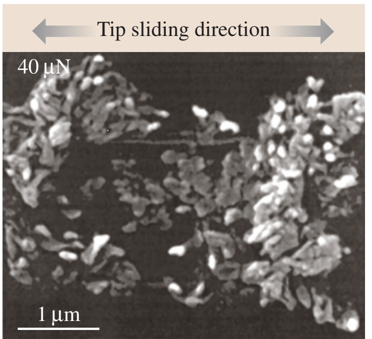

Fig. 17.29 Secondary electron image of wear mark and debris for Si(100) produced at a normal load of 40 μN and one scan cycle

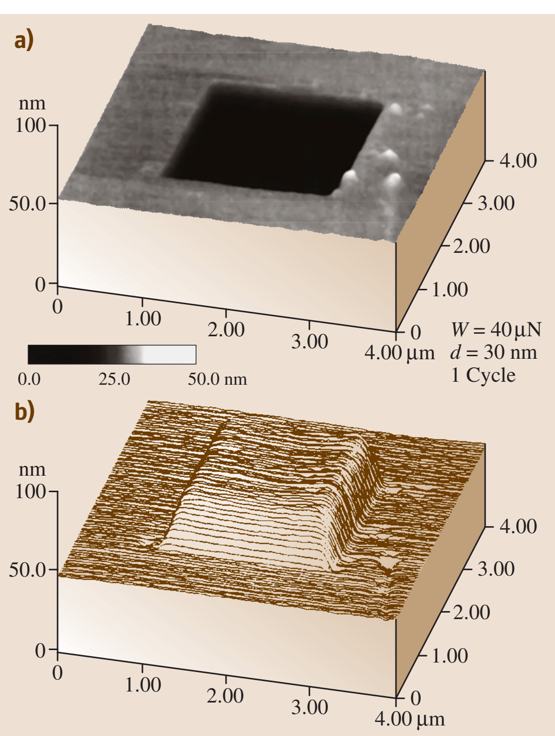

Fig. 17.28 **(a)** Typical gray-scale and **(b)** inverted AFM images of wear mark created using a diamond tip at a normal load of 40 μN and one scan cycle on Si(100) surface

To better understand the material removal mechanisms, transmission electron microscopy (TEM) has been used. The TEM micrograph of the worn region and associated diffraction pattern are shown in Fig. 17.30a,b. The bend contours are observed to pass through the wear mark in the micrograph. The bend contours around and inside the wear mark are indicative of a strain field, which, in the absence of applied stresses, can be interpreted as plastic deformation and/or elastic residual stresses. Often, localized plastic deformation during loading would lead to residual stresses during unloading; therefore, bend contours reflect a mix of elastic and plastic strains. The wear debris is observed outside the wear mark. The enlarged view of the wear debris in Fig. 17.30c shows that much of the debris is ribbon-like, indicating that material is removed by a cutting process via plastic deformation, which is consistent with the SEM observations. The diffraction pattern from inside the wear mark is similar to that of virgin silicon, showing no evidence of any phase transformation (amorphization) during wear. A selected area diffraction pattern of the wear debris shows some diffuse rings, which indicates the existence of amorphous

material in the wear debris, confirmed as silicon oxide products from chemical analysis. It is known that plastic deformation occurs by generation and propagation of dislocations. No dislocation activity or cracking was observed at 40 µN. However, dislocation arrays could be observed at 80 µN. Figure 17.31 shows the TEM micrographs of the worn region at 80 µN; for better observation of the worn surface, wear debris was moved out of the wear mark using AFM with a large area scan at 300 nN after the wear test. The existence of dislocation arrays confirms that material removal occurs by plastic deformation. This corroborates the observations made in scratch tests at ramped load in the previous section. It is concluded that the material on microscale at high loads is removed by plastic deformation with a small contribution from elastic fracture [17.65].

To understand wear mechanisms, evolution of wear can be studied using AFM. Figure 17.32 shows evolution of wear marks of a DLC-coated disk sample. The data illustrate how the microwear profile for a load of 20 µN develops as a function of the number of scanning cycles [17.22]. Wear is not uniform, but is initiated at the nanoscratches. Surface defects (with high surface energy) present at nanoscratches act as initiation sites for wear. Coating deposition also may not be uniform on and near nanoscratches, which may lead to coating delamination. Thus, scratch-free surfaces will be relatively resistant to wear.

Wear precursors (precursors to measurable wear) can be studied by making surface potential measurements [17.38–40]. The contact potential difference, or simply surface potential between two surfaces, depends on a variety of parameters such as electronic work function, adsorption, and oxide layers. The surface potential map of an interface gives a measure of changes in the work function, which is sensitive to both physical and chemical conditions of the surfaces, including structural and chemical changes. Before material is actually removed in a wear process, the surface experiences stresses that result in surface and subsurface changes of structure and/or chemistry. These can cause changes in the measured potential of a surface. An AFM tip allows mapping of surface potential with nanoscale resolution. Surface height and change in surface potential maps of a polished single-crystal aluminum (100) sample abraded using a diamond tip at loads of 1 µN and 9 µN are shown in Fig. 17.33a. (Note that the sign of the change in surface potential is reversed here from that in [17.38].) It is evident that both abraded regions show a large potential contrast (∼ 0.17 V) with respect

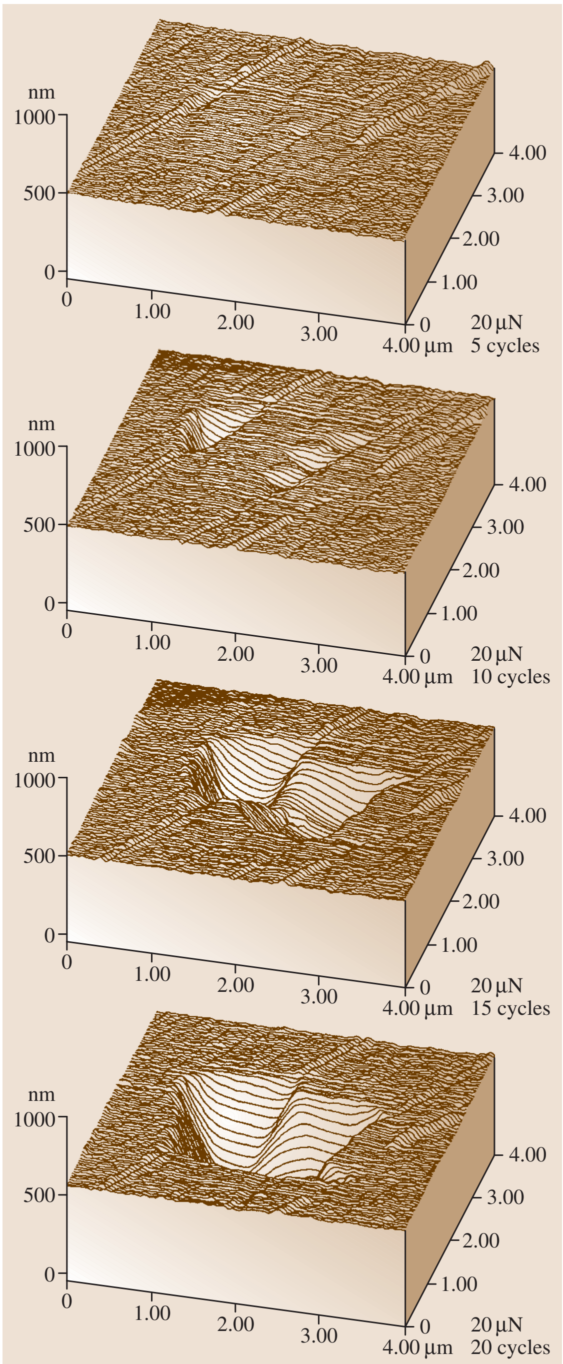

Fig. 17.32 Surface plots of diamond-like carbon-coated thin-film disk showing the worn region; the normal load and number of test cycles are indicated [17.22]

to the non-abraded area. The black region in the lower right-hand part of the topography scan shows a step that was created during the polishing phase. There is no potential contrast between the high region and the low region of the sample, indicating that the technique is independent of surface height. Figure 17.33b shows a close-up scan of the upper (low load) wear region in Fig. 17.33a. Notice that while there is no detectable change in the surface topography, there is, nonetheless, a large change in the potential of the surface in the worn region. Indeed, the wear mark of Fig. 17.33b might not have been visible at all in the topography map were it not for the noted absence of wear debris generated nearby and then swept off during the low load scan. Thus, even in the case of zero wear (no mea-

surable deformation of the surface using AFM), there can be a significant change in the surface potential inside the wear mark, which is useful for the study of wear precursors. It is believed that the removal of the thin contaminant layer including the natural oxide layer gives rise to the initial change in surface potential. The structural changes, which precede generation of wear debris and/or measurable wear scars, occur under ultralow loads in the top few nanometers of the sample and are primarily responsible for the subsequent changes in surface potential.

17.3.4 In Situ Characterization of Local Deformation

In situ surface characterization of local deformation of materials and thin films is carried out using a tensile stage inside an AFM. Failure mechanisms

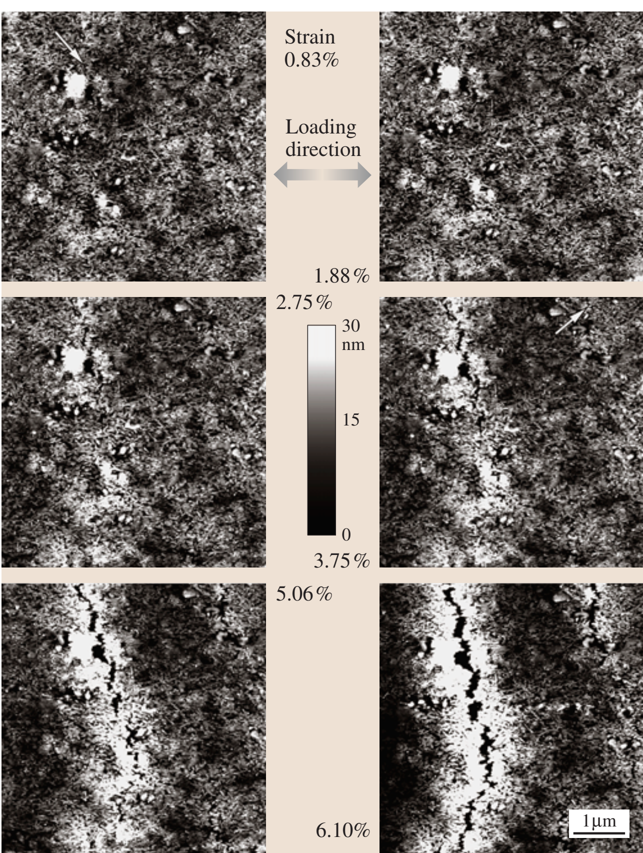

Fig. 17.34 Topographical images of the MP magnetic tape at different strains [17.41]

of polymeric thin films were studied by *Bobji* and *Bhushan* [17.41, 42]. The specimens were strained at a rate of 4×10^{-3}% per second, and AFM images were captured at different strains up to about 10% to monitor generation and propagation of cracks and deformation bands.

Bobji and *Bhushan* [17.41, 42] studied three magnetic tapes with thickness ranging from 7 to 8.5 µm. One of these was with acicular-shaped metal particle (MP) coating, and the other two with metal-evaporated (ME) coating and with and without a thin diamond-like carbon (DLC) overcoat, both on a polymeric substrate and all with particulate back coating [17.13]. They also studied the polyethylene terephthalate (PET) substrate with 6 µm thickness. They reported that cracking of the coatings started at about 1% strain for all tapes, much before the substrate starts to yield at about 2% strain. Figure 17.34 shows the topographical images of the MP tape at different strains. At 0.83% strain, a crack can be seen originating at the marked point. As the tape is further stretched along the direction, as shown in Fig. 17.34, the crack propagates along the shorter boundary of the ellipsoidal particle. However, the general direction of the crack propagation remains perpendicular to the direction of the stretching. The length, width, and depth of the cracks increase with strain, and at the same time, newer cracks keep on nucleating and propagating with reduced crack spacing. At 3.75% strain, another crack can be seen nucleating. This crack continues to grow parallel to the first. When the tape is unloaded after stretching up to a strain of about 2%, i. e., within the elastic limit of the substrate, the cracks rejoin perfectly and it is impossible to determine the difference from the unstrained tape.

Figure 17.35 shows topographical images of the three magnetic tapes and the PET substrate after being strained to 3.75%, which is well beyond the elastic limit of the substrate. MP tape develops short and numerous cracks perpendicular to the direction of loading. In tapes with metallic coating, the cracks extend throughout the tape width. In ME tape with DLC coating, there is a bulge in the coating around the primary cracks that are initiated when the substrate is still elastic, like crack A in the figure. The white band on the right-hand side of the figure is the bulge of another crack. The secondary cracks like B and C are generated at higher strains and are straighter compared to the primary cracks. In ME tape, which has a Co-O film on PET substrate, with a thickness ratio of 0.03, both with and without DLC coating, no difference is observed in the rate of growth between primary and secondary cracks. The failure is cohesive with no

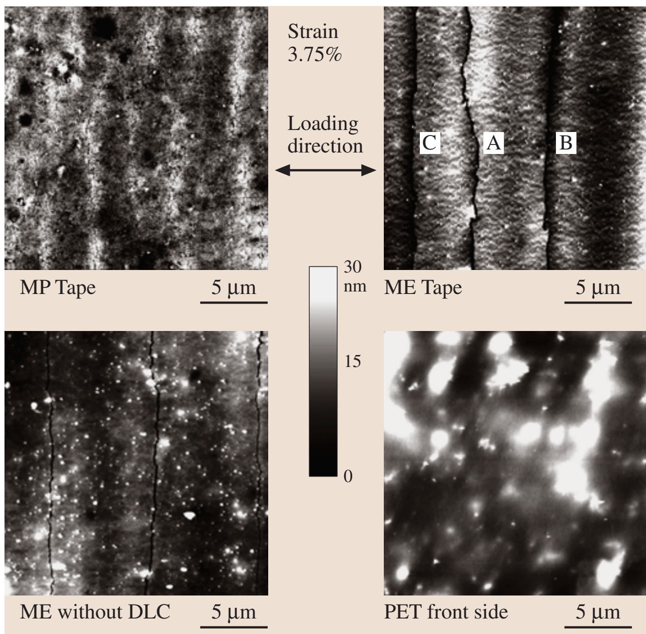

Fig. 17.35 Comparison of crack morphologies at 3.75% strain in three magnetic tapes and PET substrate. Cracks B and C, nucleated at higher strains, are more linear than crack A [17.42]

bulging of the coating. This seems to suggest that the DLC coating has residual stresses that relax when the coating cracks, causing delamination. Since the stresses are already relaxed, the secondary crack does not result in delamination. The presence of the residual stress is confirmed by the fact that a freestanding ME tape curls up (in a cylindrical form with its axis perpendicular to the tape length) with a radius of curvature of about 6 mm; the ME tape without the DLC does not curl. The magnetic coating side of PET substrate is much smoother at smaller scan lengths. However, in 20 µm scans it has a lot of bulging out, which appears as white spots in the figure. These spots change shape even while scanning the samples in tapping mode at very low contact forces.

The variation of average crack width and average crack spacing with strain is plotted in Fig. 17.36. The crack width is measured at a spot along a given crack over a distance of 1 µm in the 5 µm scan image at different strains. The crack spacing is obtained by averaging the inter-crack distance measured in five separate 50 µm scans at each strain. It can be seen that the cracks nucleate at a strain of about 0.7–1.0%, well within the elastic limit of the substrate. There is a definite change in the slope of the load-displacement curve at the strain where cracks nucleate, and the slope after that is closer to the slope of the elastic portion of the substrate. This would mean that most of the load is supported by the substrate once the coating fails by cracking.

In situ surface characterization of unstretched and stretched films has been used to measure Poisson's ratio of polymeric thin films [17.66]. Uniaxial tension is applied by the tensile stage. Surface height profiles obtained from the AFM images of unstretched and stretched samples are used to monitor simultaneously the changes in displacements of the polymer films in the longitudinal and lateral directions.

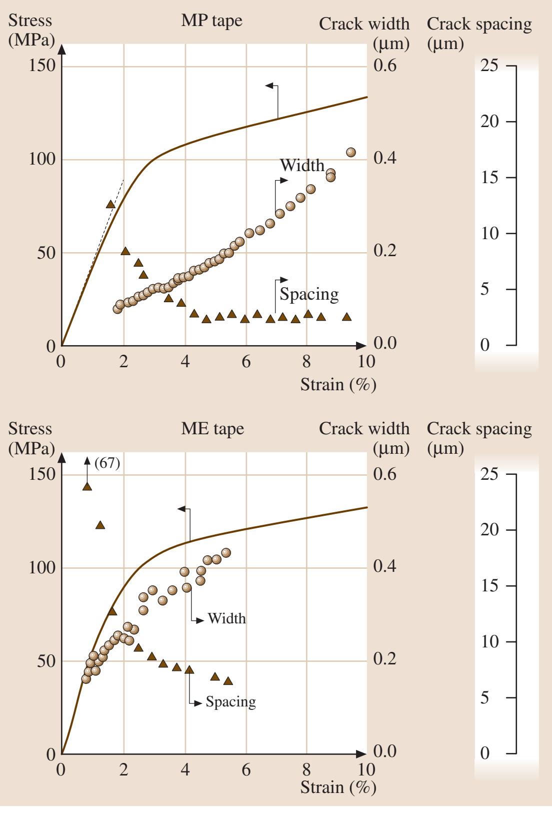

Fig. 17.36 Variation of stress, crack width, and crack spacing with strain in three magnetic tapes and PET substrate [17.41]

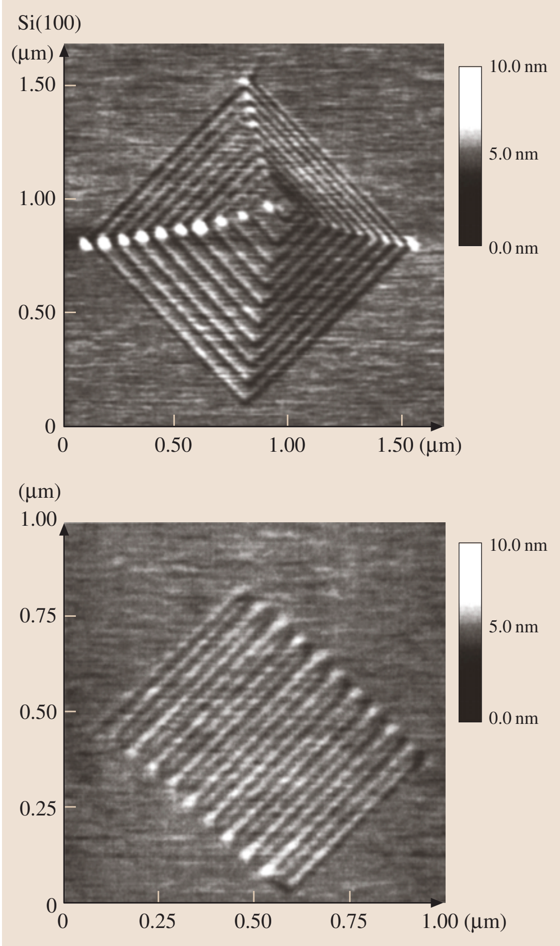

Fig. 17.37 **(a)** Trim and **(b)** spiral patterns generated by scratching a Si(100) surface using a diamond tip at a normal load of 15 µN and writing speed of 0.5 µm/s

17.3.5 Nanofabrication/Nanomachining

An AFM can be used for nanofabrication/nanomachining by extending the microscale scratching operation [17.4, 11,22,37]. Figure 17.37 shows two examples of nanofabrication. The patterns were created on a single-crystal silicon (100) wafer by scratching the sample surface with a diamond tip at specified locations and scratching angles. Each line is scribed manually at a normal load of 15 µN and a writing speed of 0.5 µm/s. The separation between lines is about 50 nm, and the variation in line width is due to the tip asymmetry. Nanofabrication parameters – normal load, scanning speed, and tip geometry – can be controlled precisely to control the depth and length of the devices.

Nanofabrication using mechanical scratching has several advantages over other techniques. Better control over the applied normal load, scan size, and scanning speed can be used for nanofabrication of devices. Using the technique, nanofabrication can be performed on any engineering surface. Use of chemical etching or reactions is not required, and this dry nanofabrication process can be used where use of chemicals and electric field is prohibited. One disadvantage of this technique is the formation of debris during scratching. At light loads, debris formation is not a problem compared to high-load scratching. However, debris can be removed easily from the scan area at light loads during scanning.

17.4 Indentation

Mechanical properties such as hardness and Young's modulus of elasticity can be determined on micro- to picoscales using the AFM [17.18,22,31,34] and a depth-sensing indentation system used in conjunction with an AFM [17.35, 67–69].

17.4.1 Picoindentation

Indentability on the scale of subnanometers of soft samples can be studied in the force calibration mode (Fig. 17.6) by monitoring the slope of cantilever deflection as a function of sample traveling distance after the tip is engaged and the sample is pushed against the tip. For a rigid sample, cantilever deflection equals the sample traveling distance, but the former quantity is smaller if the tip indents the sample. In an example of a polymeric magnetic tape shown in Fig. 17.38, the line in the left portion of the figure is curved with a slope of less than 1 shortly after the sample touches the tip, which suggests that the tip has indented the sample [17.18]. Later, the slope is equal to 1, suggesting that the tip no longer indents the sample. This observation indicates that the tape surface is soft locally (polymer-rich) but hard (as a result of magnetic particles) underneath. Since

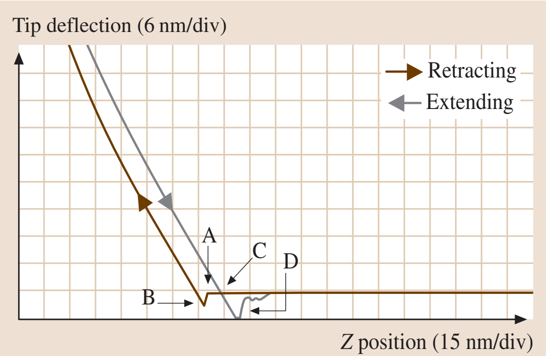

Fig. 17.38 Tip deflection (normal load) as a function of the Z (separation distance) curve for a polymeric magnetic tape [17.18]

the curves in extending and retracting modes are identical, the indentation is elastic up to a maximum load of about 22 nN used in the measurements.

Detection of transfer of material on a nanoscale is possible with the AFM. Indentation of C_{60}-rich fullerene films with an AFM tip has been shown [17.70] to result in the transfer of fullerene molecules to the AFM tip, as indicated by discontinuities in the cantilever deflection as a function of sample traveling distance in subsequent indentation studies.

17.4.2 Nanoscale Indentation

The indentation hardness of surface films with an indentation depth as small as about 1 nm can be measured using an AFM [17.11, 34, 35]. Figure 17.39 shows the gray-scale plots of indentation marks made on Si(111) at normal loads of 60, 65, 70, and 100 μN. Triangular indents can be clearly observed with very shallow depths. At a normal load of 60 μN, indents are observed and the depth of penetration is about 1 nm. As the normal load is increased, the indents become clearer and indentation depth increases. For the case of hardness measurements at shallow depths on the same order as variations in surface roughness, it is desirable to subtract the original (unindented) map from the indent map for accurate measurement of the indentation size and depth [17.22].

To make accurate measurements of hardness at shallow depths, a depth-sensing indentation system is used [17.35]. Figure 17.40 shows the load-displacement curves at different peak loads for Si(100). Loading/unloading curves often exhibit sharp discontinuities,

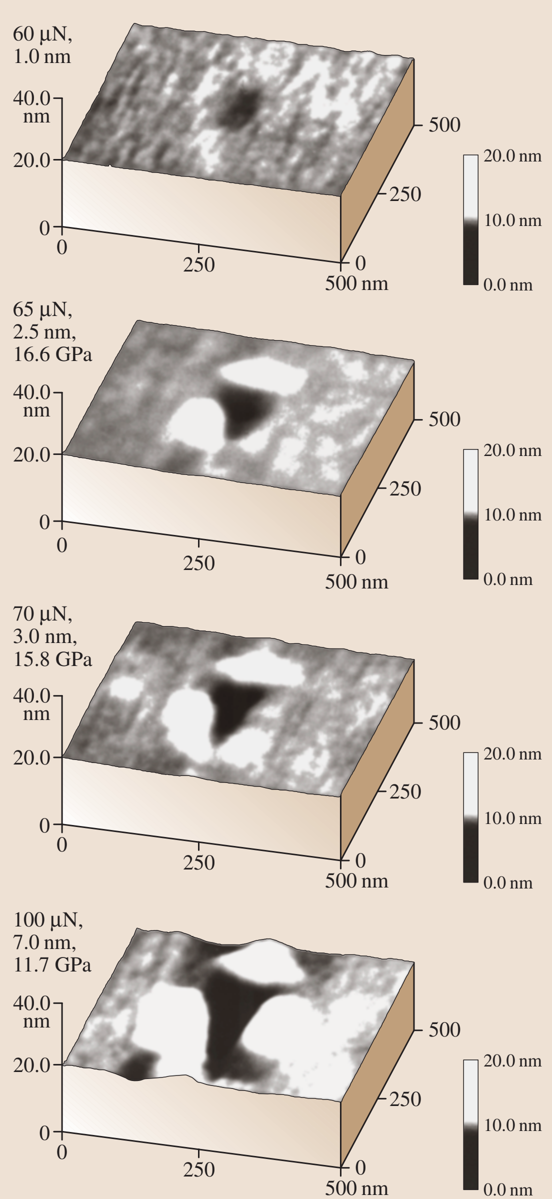

Fig. 17.39 Gray-scale plots of indentation marks on the Si(111) sample at various indentation loads. Loads, indentation depths, and hardness values are listed in the figure [17.34]

particularly at high loads. Discontinuities, referred to as pop-ins, during the initial loading part of the curve mark a sharp transition from pure elastic loading to a plastic deformation of the specimen surface, thus correspond-

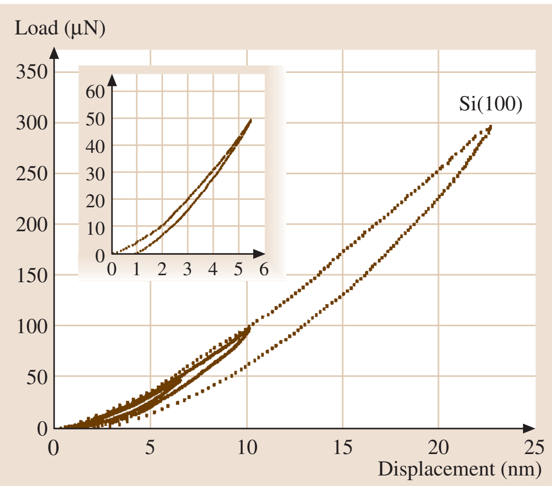

Fig. 17.40 Load-displacement curves at various peak loads for Si(100) [17.35]

ing to an initial yield point. The sharp discontinuities in the unloading part of the curves are believed to be due to the formation of lateral cracks that form at the base of the median crack, which results in the surface of the specimen being thrust upward. Load-displacement data at residual depths as low as about 1 nm can be obtained, and the indentation hardness of surface films has been measured for Si(100) [17.35, 67–69]. The hardness of silicon on a nanoscale is found to be higher than on a microscale (Fig. 17.41). Microhardness has also been reported to be higher than on the millimeter scale by several investigators. The data reported to date show that hardness exhibits size effect. According to the strain gradient plasticity theory advanced by *Fleck* et al. [17.71], large strain gradients inherent in small indentations lead to the accumulation of geometrically necessary dislocations for strain compatibility reasons that cause enhanced hardening. In addition, the decrease in hardness with an increase in indentation depth can possibly be rationalized on the basis that as the volume of deformed material increases, there is a higher probability of encountering material defects.

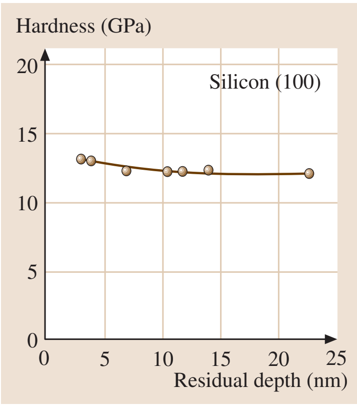

Fig. 17.41 Indentation hardness as a function of residual indentation depth for Si(100) [17.35]

Bhushan and *Koinkar* [17.31] have used AFM measurements to show that ion implantation of silicon surfaces increases their hardness and thus their wear resistance. Formation of surface alloy films with improved mechanical properties by ion implantation is of growing technological importance as a means of improving the mechanical properties of materials. Hardness of 20 nm-thick diamond-like carbon films has been measured by *Kulkarni* and *Bhushan* [17.69].

The creep and strain-rate effects (viscoelastic effects) of ceramics can be studied using a depth-sensing indentation system. *Bhushan* et al. [17.35] and *Kulkarni* and *Bhushan* [17.67–69] have reported that ceramics exhibit significant plasticity and creep on a nanoscale. Figure 17.42a shows the load-displacement curves for single-crystal silicon at various peak loads held at 180 s. To demonstrate the creep effects, the load-displacement curves for a 500 µN peak load held at 0 and 30 s are also shown as an inset. Note that significant creep occurs at room temperature. Nanoindenter experiments conducted by *Li* et al. [17.72] exhibited significant creep only at high temperatures (greater than or equal to 0.25 times the melting point of silicon). The mechanism of dislocation glide plasticity is believed to dominate the indentation creep process on the macroscale. To study the strain-rate sensitivity of silicon, data at two different (constant) rates of loading are presented in Fig. 17.42b. Note that a change in the loading rate by a factor of about five results in a significant change in the load-displacement data. The viscoelastic effects observed here for silicon at ambient temperature could arise from size effects mentioned earlier. Most likely, creep and strain rate experiments are being conducted on the hydrated films present on the silicon surface in ambient environment, and these films are expected to be viscoelastic.

17.4.3 Localized Surface Elasticity and Viscoelasticity Mapping

The Young's modulus of elasticity is calculated from the slope of the indentation curve during unloading. However, these measurements provide a single-point measurement. By using the force modulation technique, it is possible to get localized elasticity maps of soft and

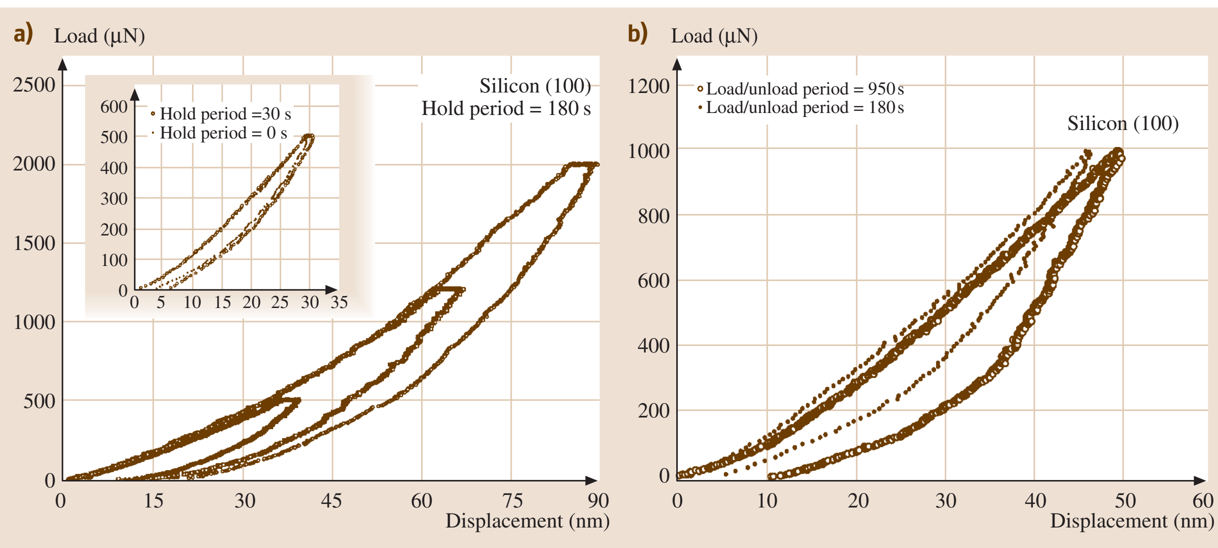

Fig. 17.42 **(a)** Creep behavior and **(b)** strain-rate sensitivity of Si(100) [17.35]

compliant materials with penetration depths of less than 100 nm. This technique has been successfully used for polymeric magnetic tapes, which consist of magnetic and nonmagnetic ceramic particles in a polymeric matrix. Elasticity maps of a tape can be used to identify relative distribution of hard magnetic and nonmagnetic ceramic particles on the tape surface, which has an effect on friction and stiction at the head-tape interface [17.13]. Figure 17.43 shows surface height and elasticity maps on a polymeric magnetic tape [17.44]. The elasticity image reveals sharp variations in surface elasticity due to the composite nature of the film. As can be clearly seen, regions of high elasticity do not always correspond to high or low topography. Based on a Hertzian elastic-contact analysis, the static indentation depth of these samples during the force modulation scan is estimated to be about 1 nm. We conclude that the contrast seen is influenced most strongly by material properties in the top few nanometers, independent of the composite structure beneath the surface layer.

By using phase contrast microscopy, it is possible to get phase contrast maps or the contrast in viscoelastic properties of near surface regions. This technique has been used successfully for polymeric films and magnetic tapes that consist of ceramic particles in a polymeric matrix [17.51, 52]. Figure 17.44 shows topography, phase angle, and friction force images for polyethylene terephthalate (PET) film. Three particles, which show up as approximately circular, lightly shaded (high points) regions, are seen in the topography image. In the phase angle images, the particles show up dark against the film background. A combination of high tapping amplitude and low set point was found to maximize contrast in phase images. This result may be explained by the degree to which the tip is able to penetrate and thus deform the sample. A high tapping amplitude and low set point should maximize the force with which the tip strikes the sample. This should give more penetration. So the mater-

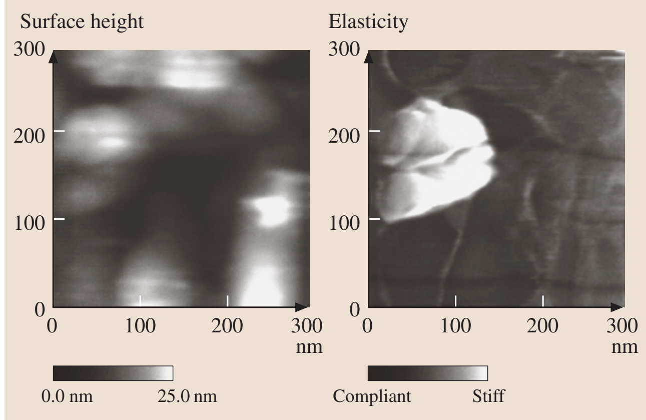

Fig. 17.43 Surface height and elasticity maps on a polymeric magnetic tape ($\sigma = 6.72$ nm and P-V = 31.7 nm; σ and P-V refer to standard deviation of surface heights and peak-to-valley distance, respectively). The gray scale on the elasticity map is arbitrary [17.44]

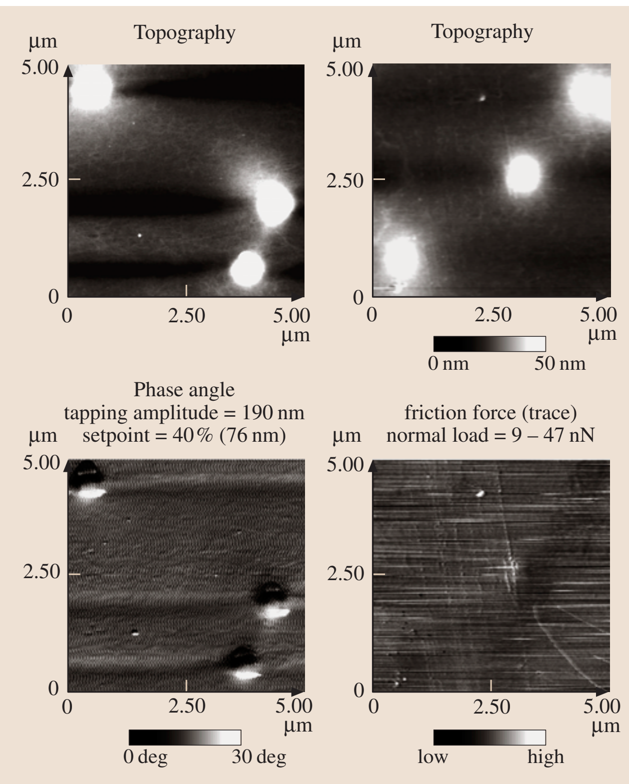

Fig. 17.44 Tapping mode height and phase angle images acquired using a TESP tip at a tapping amplitude of 190 nm and a setpoint of 40% (74 nm), and contact mode height and friction force (trace) images using an MESP tip with a normal load between 9 and 47 nN for PET film with embedded ceramic particles [17.51]

ial or viscoelastic contribution, as opposed to the surface force and adhesion hysteresis contributions, should be more dominant for this tapping condition. The phase angle image shown in Fig. 17.44 was acquired using tapping mode with a relatively high tapping amplitude of 190 nm and a relatively low set point of 40% (of the tapping amplitude) to emphasize viscoelastic properties. Very little correlation is found between the phase angle and friction force images. Friction force images were obtained using an etched single-crystal silicon tip (DI MESP) with a radius of 20–50 nm, a stiffness of 1–5 N/m, and a natural frequency of 60–70 kHz. A lack of correlation may be a further indication that something other than adhesion, which should correlate to friction force, causes the phase angle contrast; this may imply that viscoelastic properties may be dominant. These results also indicate that phase angle imaging yields information that cannot be obtained using other, more conventional AFM modes.

17.5 Boundary Lubrication

17.5.1 Perfluoropolyether Lubricants

The classical approach to lubrication uses freely supported multimolecular layers of liquid lubricants [17.10, 13, 58, 73]. The liquid lubricants are sometimes chemically bonded to improve their wear resistance [17.10, 13, 58]. Partially chemically bonded, molecularly thick perfluoropolyether (PFPE) films are used for lubrication of magnetic storage media [17.13]. These are considered potential candidate lubricants for micro/nanoelectromechanical systems (MEMS/NEMS). Molecularly thick PFPEs are well suited because of the following properties: low surface tension and low contact angle, which allow easy spreading on surfaces and provide hydrophobic properties; chemical and thermal stability, which minimize degradation under use; low vapor pressure, which provides low out-gassing; high adhesion to substrate via organic functional bonds; and good lubricity, which reduces contact surface wear.

For boundary lubrication studies, friction, adhesion, and durability experiments have been performed on virgin Si(100) surfaces and silicon surfaces lubricated with two PFPE lubricants – Z-15 (with $-CF_3$ nonpolar end groups) and Z-DOL (with −OH polar end groups) [17.27, 28, 30]. Z-DOL film was thermally bonded at 150 °C for 30 minutes and an unbonded fraction was removed by a solvent (BW) [17.13]. The thicknesses of Z-15 and Z-DOL films were 2.8 nm and 2.3 nm, respectively.

The adhesive forces of Si(100), Z-15, and Z-DOL (BW) measured by force calibration plot and friction force versus normal load plot are summarized in Fig. 17.45. The results measured by these two methods are in good agreement. Figure 17.45 shows that the presence of mobile Z-15 lubricant film increases the adhesive force as compared to that of Si(100) by meniscus formation. The presence of solid phase Z-DOL (BW) film reduces the adhesive force as compared to that of

Si(100) because of the absence of mobile liquid. The schematic (bottom) in Fig. 17.45 shows relative size and sources of meniscus. It is well-known that the native oxide layer (SiO_2) on the top of a Si(100) wafer exhibits hydrophilic properties, and some water molecules can be adsorbed on this surface. The condensed water will form meniscus as the tip approaches the sample surface. The larger adhesive force in Z-15 is not only caused by the Z-15 meniscus; the nonpolarized Z-15 liquid does not have good wettability and strong bonding with Si(100). In the ambient environment, the condensed water molecules from the environment will permeate through the liquid Z-15 lubricant film and compete with the lubricant molecules present on the substrate. The interaction of the liquid lubricant with the substrate is weakened, and a boundary layer of the liquid lubricant forms puddles [17.27, 28]. This de-wetting allows water molecules to be adsorbed on the Si(100) surface as aggregates along with Z-15 molecules. And both of them can form meniscus while the tip approaches the surface. Thus, the de-wetting of liquid Z-15 film results in higher adhesive force and poorer lubrication performance. In addition, as the Z-15 film is pretty soft compared to the solid Si(100) surface, and penetration of the tip in the film occurs while pushing the tip down. This leads the large area of the tip involved to form the meniscus at the tip-liquid (mixture of Z-15 and water) interface. It should also be noted that Z-15 has a higher viscosity compared to water and, therefore, Z-15 film provides higher resistance to motion and coefficient of friction. In the case of Z-DOL (BW) film, both of the active groups of Z-DOL molecules are mostly bonded on Si(100) substrate. Thus, the Z-DOL (BW) film has low free surface energy and cannot be displaced readily by water molecules or readily adsorb water molecules. Therefore, the use of Z-DOL (BW) can reduce the adhesive force.

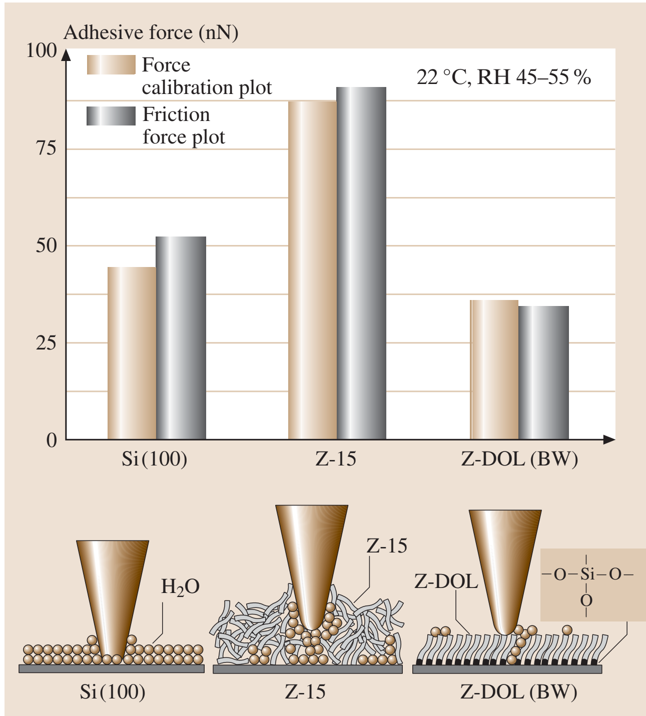

Fig. 17.45 Summary of the adhesive forces of Si(100) and Z-15 and Z-DOL (BW) films measured by force calibration plots and friction force versus normal load plots in ambient air. The schematic (*bottom*) showing the effect of meniscus formed between the AFM tip and surface sample on the adhesive and friction forces [17.30]

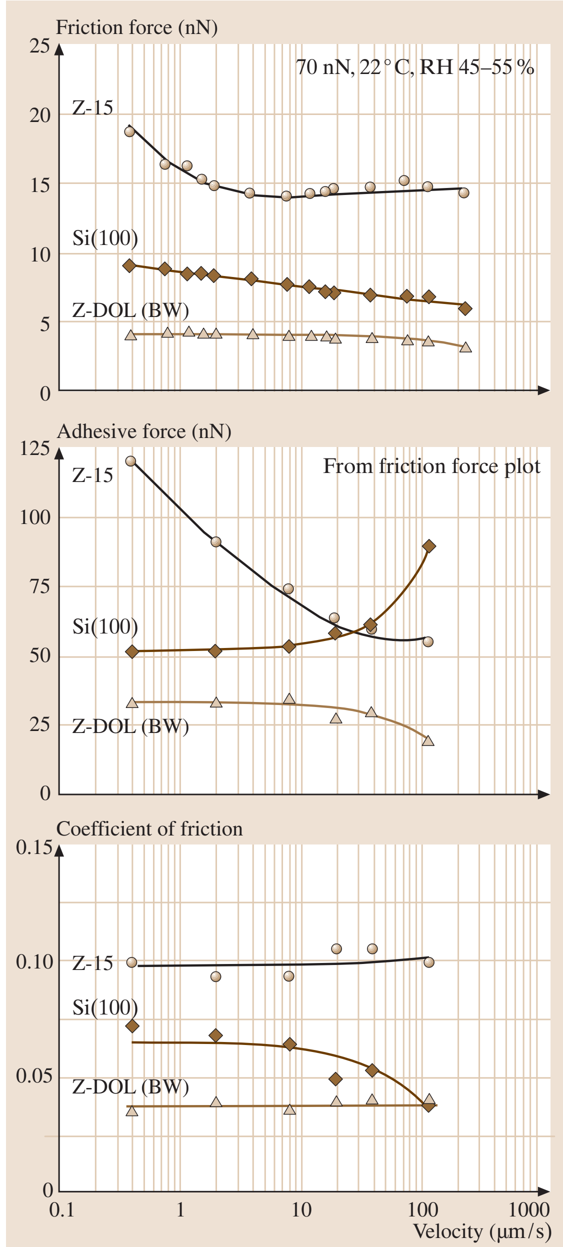
To study the velocity effect on friction and adhesion, the variation of friction force, adhesive force, and coefficient of friction of Si(100), Z-15 and Z-DOL (BW) as a function of velocity are summarized in Fig. 17.46. It indicates that for silicon wafer the friction force decreases logarithmically with increasing velocity. For Z-15, the friction force decreases with increasing velocity up to 10 μm/s, after which it remains almost constant. The velocity has very small effect on the friction force of Z-DOL (BW): It reduced slightly only at very high velocity. Figure 17.46 also indicates that the adhesive force of Si(100) increases when the velocity is higher than 10 μm/s. The adhesive force of Z-15 is reduced dramatically with a velocity increase up to 20 μm/s, after which it is reduced slightly. And the adhesive force of Z-DOL (BW) also decreases at high velocity. In the testing range of velocity, only the coefficient of friction of Si(100) decreases with velocity, but the coefficients of friction of Z-15 and Z-DOL (BW) almost remain constant. This implies that the friction mechanisms of Z-15 and Z-DOL (BW) do not change with the variation of velocity.

The mechanisms of the effect of velocity on the adhesion and friction are explained based on schematics shown in Fig. 17.46 (right). For Si(100), tribochemical reaction plays a major role. Although at high velocity the meniscus is broken and does not have enough time to rebuild, the contact stresses and high velocity lead to tribochemical reactions of Si(100) wafer (which has native oxide (SiO_2)) and a Si_3N_4 tip with water molecules and form $Si(OH)_4$. The $Si(OH)_4$ is removed and continuously replenished during sliding. The $Si(OH)_4$ layer between the tip and Si(100) surface is known to be of low shear strength and causes a decrease in friction force and



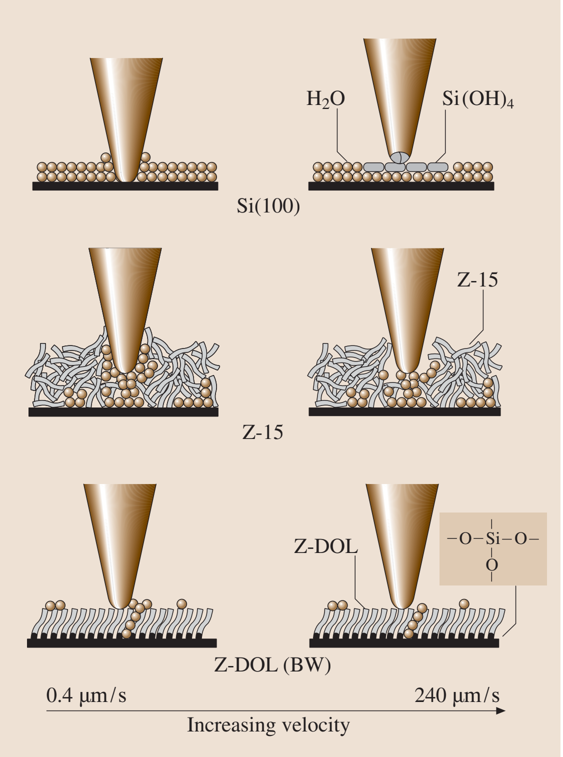


Fig. 17.46 The influence of velocity on the friction force, adhesive force, and coefficient of friction of Si(100) and Z-15 and Z-DOL (BW) films at 70 nN, in ambient air. The schematic (*right*) shows the change of surface composition (by tribochemical reaction) and formation of meniscus while increasing the velocity [17.30]

coefficient of friction [17.10, 58]. The chemical bonds of Si−OH between the tip and Si(100) surface induce large adhesive force. For Z-15 film, at high velocity the meniscus formed by condensed water and Z-15 molecules is broken and does not have enough time to rebuild. Therefore, the adhesive force and, consequently, friction force are reduced. The friction mechanism for Z-15 film still is shearing the same viscous liquid even at high velocity range, thus, the coefficient of friction of Z-15 does not change with velocity. For Z-DOL (BW) film, the surface can adsorb few water molecules in ambient condition, and at high velocity these molecules are displaced, which causes a slight decrease in friction and adhesive forces. *Koinkar* and *Bhushan* [17.27, 28] have suggested that in the case of samples with mobile films such as condensed water and Z-15 films, alignment of liquid molecules (shear thinning) is responsible for the drop in friction force with an increase in scanning velocity. This could be another reason for the decrease in friction force for Si(100) and Z-15 film with velocity in this study.

To study the relative humidity effect on friction and adhesion, the variations of friction force, adhesive force,

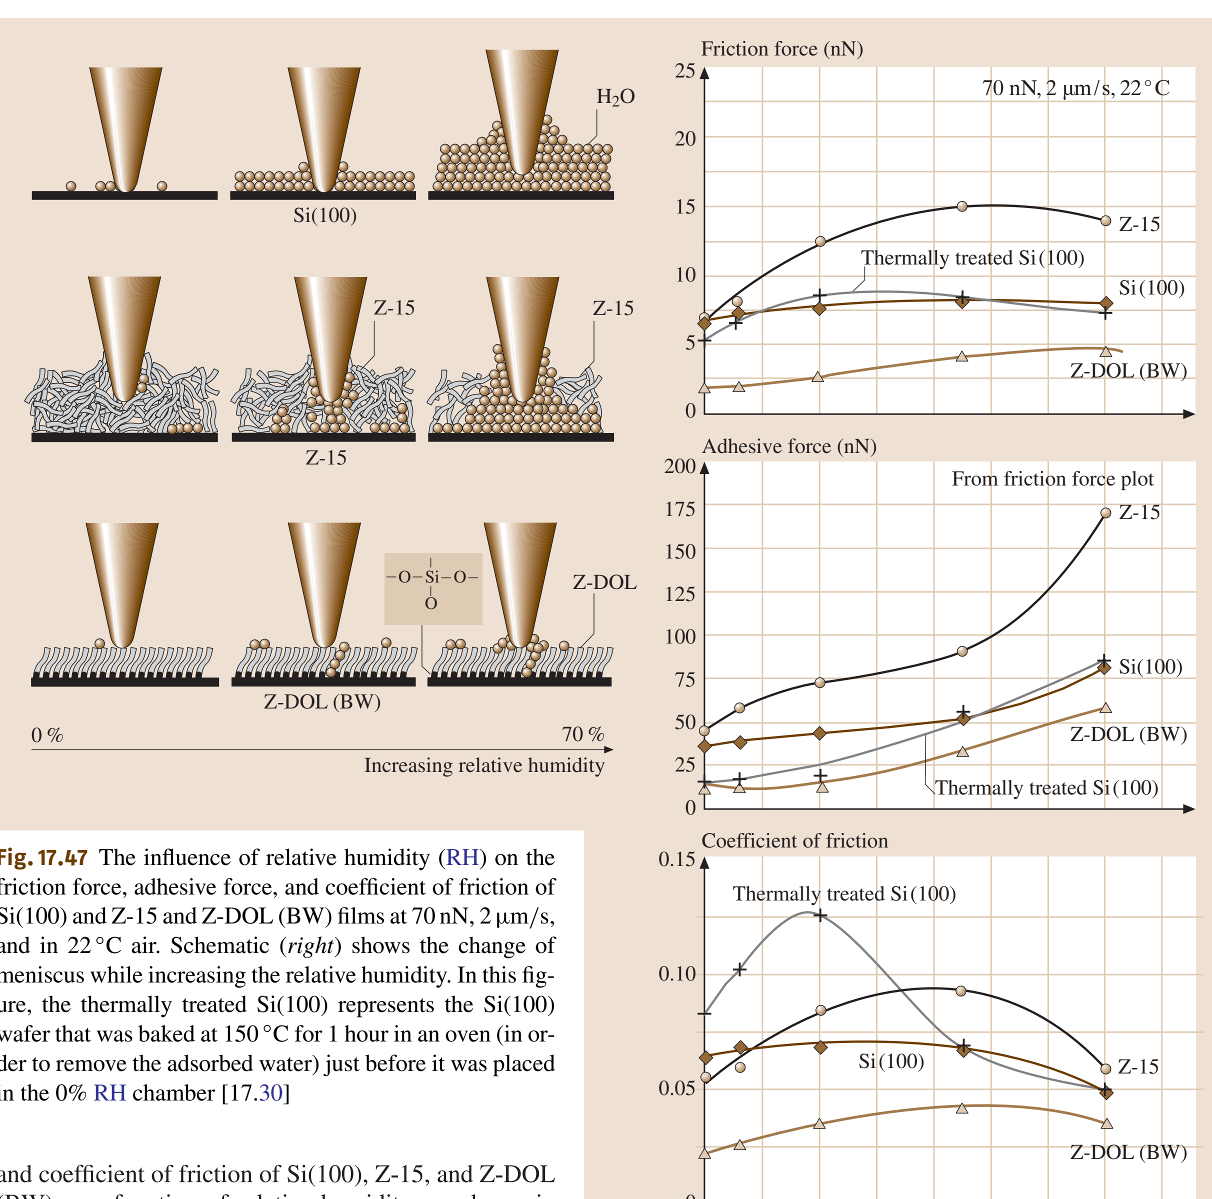

Fig. 17.47 The influence of relative humidity (RH) on the friction force, adhesive force, and coefficient of friction of Si(100) and Z-15 and Z-DOL (BW) films at 70 nN, 2 µm/s, and in 22 °C air. Schematic (*right*) shows the change of meniscus while increasing the relative humidity. In this figure, the thermally treated Si(100) represents the Si(100) wafer that was baked at 150 °C for 1 hour in an oven (in order to remove the adsorbed water) just before it was placed in the 0% RH chamber [17.30]

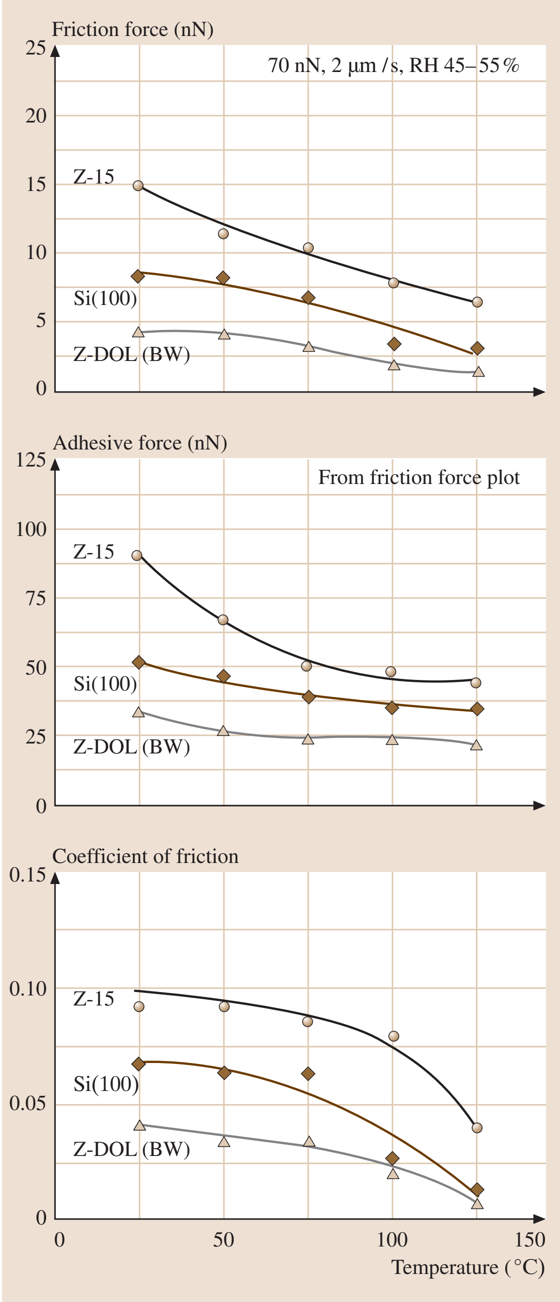
and coefficient of friction of Si(100), Z-15, and Z-DOL (BW) as a function of relative humidity are shown in Fig. 17.47. It shows that for Si(100) and Z-15 film, the friction force increases with a relative humidity increase of up to 45%, and then slightly decreases with a further increase in the relative humidity. Z-DOL (BW) has a smaller friction force than Si(100) and Z-15 in the whole testing range. And its friction force shows a relative apparent increase when the relative humidity is higher than 45%. For Si(100), Z-15, and Z-DOL (BW), their adhesive forces increase with relative humidity, and their coefficients of friction increase with relative humidity up to 45%, after which they decrease with further increasing of the relative humidity. It is also observed that the humidity effect on Si(100) really depends on the history of the Si(100) sample. As the surface of Si(100) wafer readily adsorbs water in air, without any pre-treatment the Si(100) used in our study almost



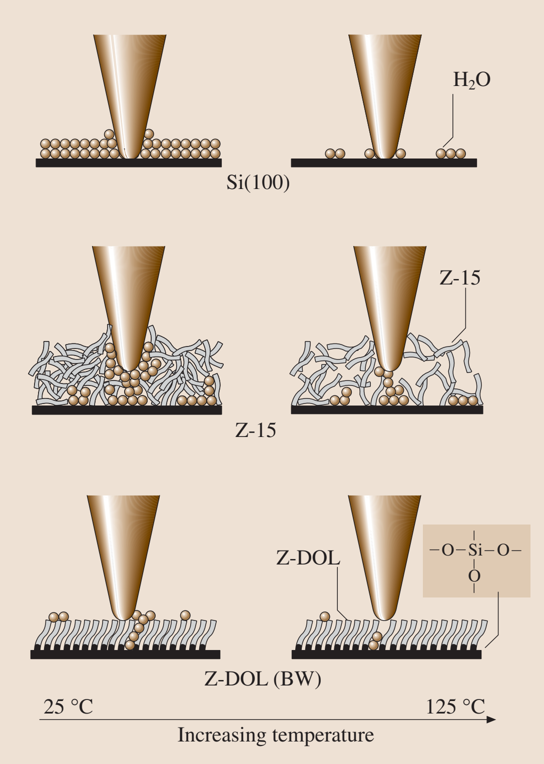


Fig. 17.48 The influence of temperature on the friction force, adhesive force, and coefficient of friction of Si(100) and Z-15 and Z-DOL (BW) films at 70 nN, at 2 µm/s, and in RH 40–50% air. The schematic (*right*) shows that at high temperature desorption of water decreases the adhesive forces. And the reduced viscosity of Z-15 leads to the decrease of the coefficient of friction. High temperature facilitates orientation of molecules in Z-DOL (BW) film, which results in lower coefficient of friction [17.30]

reaches to its saturate stage of adsorbed water and is responsible for less effect during increasing relative humidity. However, once the Si(100) wafer was thermally treated by baking at 150 °C for 1 hour, a bigger effect was observed.

The schematic in Fig. 17.47 (right) shows that Si(100), because its high free surface energy, can adsorb more water molecules with increasing relative humidity. As discussed earlier, for Z-15 film in the humid environment, the condensed water from the humid environment competes with the lubricant film present on the sample surface, interaction of the liquid lubricant film with the silicon substrate is weakened, and a boundary layer of the liquid lubricant forms puddles. This dewetting allows water molecules to be adsorbed on the Si(100) substrate mixed with Z-15 molecules [17.27, 28]. Obviously, more water molecules can be adsorbed on Z-15 surface while increasing relative humidity. The more ad-

sorbed water molecules in the case of Si(100), along with lubricant molecules in Z-15 film case, form bigger water meniscus which leads to an increase of friction force, adhesive force, and coefficient of friction of Si(100) and Z-15 with humidity. But at a very high humidity of 70%, large quantities of adsorbed water can form a water layer that separates the tip and sample surface and act as a kind of lubricant, which causes a decrease in the friction force and coefficient of friction. For Z-DOL (BW) film, because of its hydrophobic surface properties, water molecules can be adsorbed at a humidity higher than 45% and causes an increase in the adhesive and friction forces.

To study the temperature effect on friction and adhesion, the variations of friction force, adhesive force, and coefficient of friction of Si(100), Z-15, and Z-DOL (BW) as a function of temperature are summarized in Fig. 17.48. It shows that the increasing temperature causes a decrease in friction force, adhesive force, and coefficient of friction of Si(100), Z-15, and Z-DOL (BW). The schematic (right) in Fig. 17.48 indicates that at high temperature, desorption of water leads to the decrease of friction force, adhesive forces, and coefficient of friction for all of the samples. For Z-15 film, the reduction of viscosity at high temperature also contributes to the decrease of friction force and coefficient of friction. In the case of Z-DOL (BW) film, molecules are more easily oriented at high temperature, which may be partly responsible for the low friction force and coefficient of friction.

To study the durability of lubricant films at the nanoscale, the friction of Si(100), Z-15, and Z-DOL (BW) as a function of the number of scanning cycles is shown in Fig. 17.49. As observed earlier, friction force and coefficient of friction of Z-15 is higher than that of Si(100) with the lowest values for Z-DOL (BW). During cycling, friction force and coefficient of friction of Si(100) show a slight decrease during the initial few cycles then remain constant. This is related to the removal of the top adsorbed layer. In the case of Z-15 film, the friction force and coefficient of friction show an increase during the initial few cycles, and then approach higher and stable values. This is believed to be caused by the attachment of the Z-15 molecules to the tip. The molecular interaction between these attached molecules to the tip and molecules on the film surface is responsible for an increase in friction. But after several scans, this molecular interaction reaches the equilibrium, and after that, friction force and coefficient of friction remain constant. In the case of Z-DOL (BW) film, the friction force and coefficient of friction start out low and remain

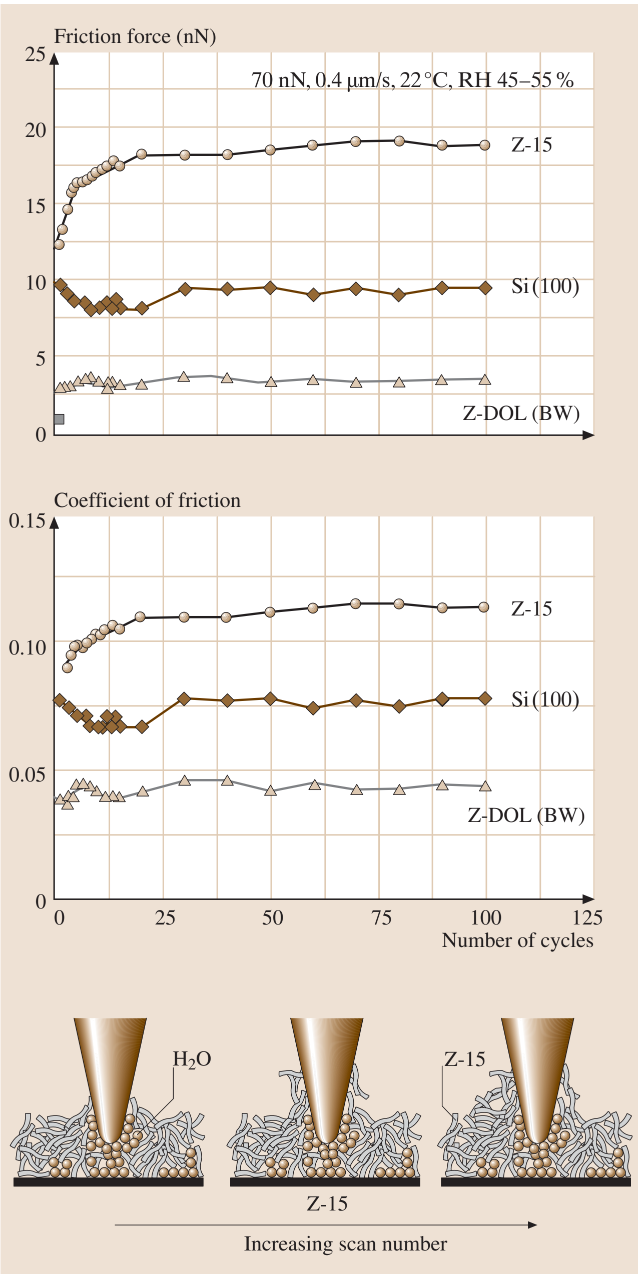

Fig. 17.49 Friction force and coefficient of friction versus number of sliding cycles for Si(100) and Z-15 and Z-DOL (BW) films at 70 nN, 0.8 µm/s, and in ambient air. Schematic (*bottom*) shows that some liquid Z-15 molecules can be attached to the tip. The molecular interaction between the attached molecules to the tip with the Z-15 molecules in the film results in an increase of the friction force with multiple scanning [17.30]

low during the entire test for 100 cycles, suggesting that Z-DOL (BW) molecules do not get attached or displaced as readily as Z-15 molecules.

As a brief summary, the influence of velocity, relative humidity, and temperature on the friction force of mobile Z-15 film is presented in Fig. 17.50. The changing trends are also addressed in this figure.

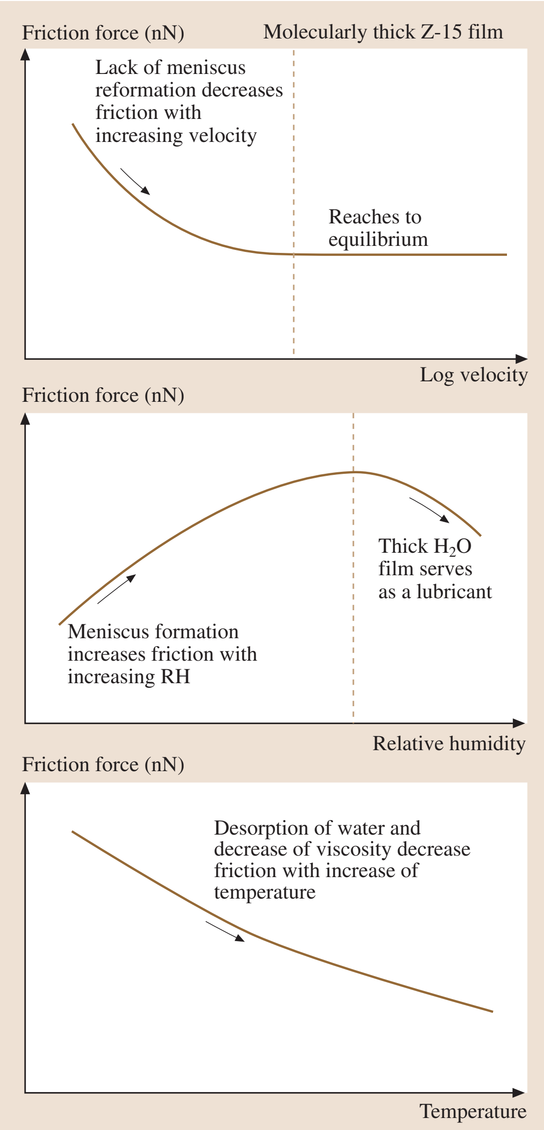

Fig. 17.50 Schematic shows the change of friction force of molecularly thick Z-15 films with log velocity, relative humidity, and temperature. The changing trends are also addressed in this figure [17.30]

17.5.2 Self-Assembled Monolayers

For lubrication of MEMS/NEMS, another effective approach involves the deposition of organized and dense molecular layers of long-chain molecules. Two common methods to produce monolayers and thin films are the Langmuir–Blodgett (L-B) deposition and self-assembled monolayers (SAMs) by chemical grafting of molecules. L-B films are physically bonded to the substrate by weak van der Waals attraction, while SAMs are chemically bonded via covalent bonds to the substrate. Because of the choice of chain length and terminal linking group that SAMs offer, they hold great promise for boundary lubrication of MEMS/NEMS. A number of studies have been conducted to study tribological properties of various SAMs [17.26, 29, 74–76]. It has been reported that SAMs with high-compliance long carbon chains exhibit low friction; chain compliance is desirable for low friction. Based on [17.29], the friction mechanism of SAMs is explained by a so-called "molecular spring" model (Fig. 17.51). According to this model, the chemically adsorbed self-assembled molecules on a substrate are just like assembled molecular springs anchored to the substrate. An asperity sliding on the surface of SAMs is like a tip sliding on the top of "molecular springs or brush". The molecular spring assembly has compliant features and can experience orientation and compression under load. The orientation of the molecular springs or brush under normal load reduces the shearing force at the interface, which, in turn, reduces the friction force.

The SAMs with high-compliance long carbon chains also exhibit the best wear resistance [17.29, 75]. In wear experiments, the wear depth as a function of normal load curves shows critical normal loads (Fig. 17.52). Below the critical normal load SAMs undergo orien-

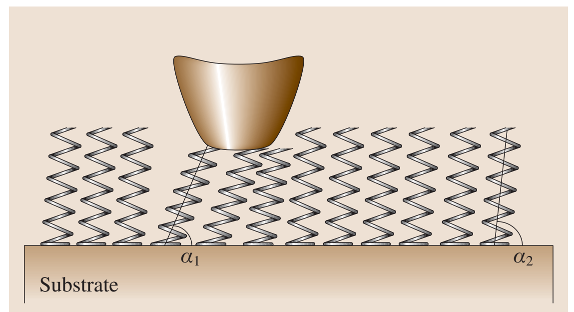

Fig. 17.51 Molecular spring model of SAMs. In this figure, $\alpha_1 < \alpha_2$, which is caused by the further orientation under the normal load applied by an asperity tip [17.29]

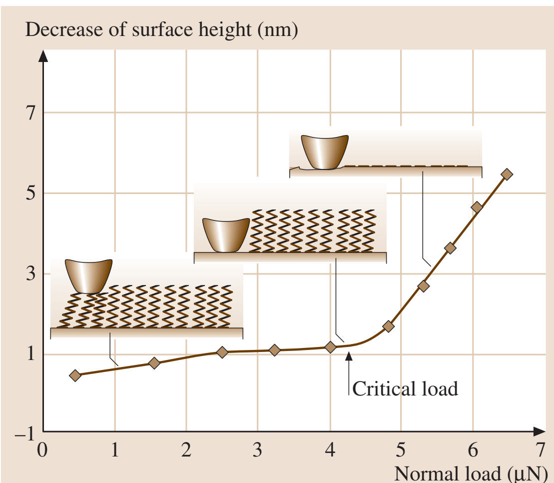

Fig. 17.52 Illustration of the wear mechanism of SAMs with increasing normal load [17.75]

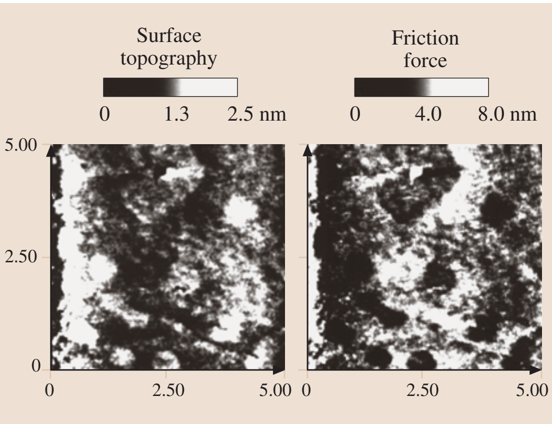

Fig. 17.53 Gray-scale plots of the surface topography and friction force obtained simultaneously for unbonded Demnum-type perfluoropolyether lubricant film on silicon [17.27]

tation, at the critical load SAMs wear away from the substrate due to weak interface bond strengths, while above the critical normal load severe wear takes place on the substrate.

17.5.3 Liquid Film Thickness Measurements

Liquid film thickness measurement of thin lubricant films (on the order of 10 nm or thicker) with nanometer lateral resolution can be made with the AFM [17.4, 59]. The lubricant thickness is obtained by measuring the force on the tip as it approaches, contacts, and pushes through the liquid film and ultimately contacts the substrate. The distance between the sharp snap-in (owing to the formation of a liquid meniscus between the film and the tip) at the liquid surface and the hard repulsion at the substrate surface is a measure of the liquid film thickness.

Lubricant film thickness mapping of ultrathin films (on the order of 2 nm) can be obtained using friction force microscopy [17.27] and adhesive force mapping [17.36]. Figure 17.53 shows gray-scale plots of the surface topography and friction force obtained simultaneously for unbonded Demnum-type PFPE lubricant film on silicon. The friction force plot shows well distinguished low and high friction regions roughly corresponding to high and low regions in surface topography (thick and thin lubricant regions). A uniformly lubricated sample does not show such a variation in the friction. Friction force imaging can thus be used to measure the lubricant uniformity on the sample surface, which cannot be identified by surface topography alone. Figure 17.54 shows the gray-scale plots of the adhesive force distribution for silicon samples coated uniformly and nonuniformly with Z-DOL type PFPE lubricant. It can be clearly seen that a region exists that has an adhesive force distinctly different from the other region for the nonuniformly coated sample. This implies that the liquid film thickness is nonuniform, giving rise to a difference in the meniscus forces.

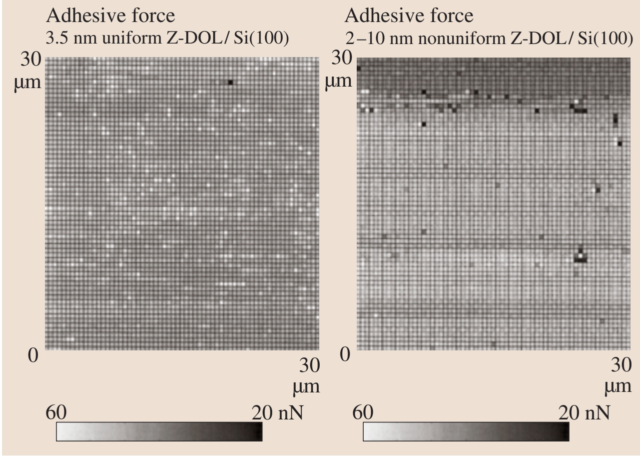

Fig. 17.54 Gray-scale plots of the adhesive force distribution of a uniformly coated, 3.5-nm thick unbonded Z-DOL film on silicon and 3- to 10-nm thick unbonded Z-DOL film on silicon that was deliberately coated nonuniformly by vibrating the sample during the coating process [17.36]

17.6 Closure

At most solid-solid interfaces of technological relevance, contact occurs at many asperities. A sharp AFM/FFM tip sliding on a surface simulates just one such contact. However, asperities come in all shapes and sizes. The effect of radius of a single asperity (tip) on the friction/adhesion performance can be studied using tips of different radii. AFM/FFM are used to study various tribological phenomena, including surface roughness, adhesion, friction, scratching, wear, indentation, detection of material transfer, and boundary lubrication. Measurement of atomic-scale friction of a freshly cleaved, highly oriented pyrolytic graphite exhibits the same periodicity as that of the corresponding topography. However, the peaks in friction and those in the corresponding topography are displaced relative to one another. Variations in atomic-scale friction and the observed displacement can be explained by the variation in interatomic forces in the normal and lateral directions. Local variations in microscale friction occur and are found to correspond to the local slopes, suggesting that a ratchet mechanism and collision effects are responsible for this variation. Directionality in the friction is observed on both micro- and macroscales, resulting from the surface roughness and surface preparation. Anisotropy in surface roughness accentuates this effect. Microscale friction is generally found to be smaller than the macrofriction, as there is less plowing contribution in microscale measurements. Microscale friction is load-dependent, and friction values increase with an increase in the normal load, approaching the macrofriction at contact stresses higher than the hardness of the softer material. The tip radius also affects adhesion and friction.

Mechanism of material removal on the microscale is studied. Wear rate for single-crystal silicon is negligible below 20 μN and is much higher and remains approximately constant at higher loads. Elastic deformation at low loads is responsible for negligible wear. Most of the wear debris is loose. SEM and TEM studies of the wear region suggest that the material on the microscale is removed by plastic deformation with a small contribution from elastic fracture; this observation corroborates the scratch data. Evolution of wear has also been studied using AFM. Wear is found to be initiated at nanoscratches. For a sliding interface requiring near-zero friction and wear, contact stresses should be below the hardness of the softer material to minimize plastic deformation, and surfaces should be free of nanoscratches. Furthermore, wear precursors can be detected at early stages of wear by using surface potential measurements. It is found that even in the case of zero wear (no measurable deformation of the surface using AFM), there can be a significant change in the surface potential inside the wear mark, which is useful for study of wear precursors. Detection of material transfer on a nanoscale is possible with AFM.

In situ surface characterization of local deformation of materials and thin coatings can be carried out using a tensile stage inside an AFM. An AFM can also be used for nanofabrication/nanomachining.

By using the force modulation technique, localized surface elasticity maps of composite materials with penetrating depths of less than 100 nm can be obtained. It is possible using phase contrast microscopy to get phase contrast maps or the contrast in viscoelastic properties of near surface regions. Scratching and indentation on nanoscales are powerful ways to screen for adhesion and resistance to deformation of ultrathin films. Modified AFM can be used to obtain load-displacement curves and for measurement of nanoindentation hardness and Young's modulus of elasticity, with depth of indentation as low as 1 nm. Hardness of ceramics on the nanoscale is found to be higher than that on the microscale. Ceramics exhibit significant plasticity and creep on a nanoscale.

Boundary lubrication studies and measurement of lubricant-film thickness with a lateral resolution on a nanoscale can be conducted using AFM. Chemically bonded lubricant films and self-assembled monolayers are superior in friction and wear resistance. For chemically bonded lubricant films, the adsorption of water, the formation of meniscus, and its change during sliding, viscosity, and surface properties play an important role on the friction, adhesion, and durability of these films. For SAMs, their friction mechanism is explained by a so-called "molecular spring" model. The films with high-compliance long carbon chains exhibit low friction and wear.

Investigations of wear, scratching, and indentation on the nanoscale using the AFM can provide insights into failure mechanisms of materials. Coefficients of friction, wear rates, and mechanical properties such as hardness have been found to be different on the nanoscale than on the macroscale; generally, coefficients of friction and wear rates on micro- and nanoscales are smaller, whereas hardness is greater. Therefore, micro/nanotribological studies may help define the regimes for ultralow friction and near-zero wear. These studies also provide insight into the atomic origins of adhesion, friction, wear, and lubrication mechanisms.

18. Surface Forces and Nanorheology of Molecularly Thin Films

In this chapter, we describe the static and dynamic normal forces that occur between surfaces in vacuum or liquids and the different modes of friction that can be observed between (i) bare surfaces in contact (dry or interfacial friction), (ii) surfaces separated by a thin liquid film (lubricated friction), and (iii) surfaces coated with organic monolayers (boundary friction).

Experimental methods suitable for measuring normal surface forces, adhesion and friction (lateral or shear) forces of different magnitude at the molecular level are described. We explain the molecular origin of van der Waals, electrostatic, solvation and polymer mediated interactions, and basic models for the contact mechanics of adhesive and nonadhesive elastically deforming bodies. The effects of interaction forces, molecular shape, surface structure and roughness on adhesion and friction are discussed.

Simple models for the contributions of the adhesion force and external load to interfacial friction are illustrated with experimental data on both unlubricated and lubricated systems, as measured with the surface forces apparatus. We discuss rate-dependent adhesion (adhesion hysteresis) and how this is related to friction. Some examples of the transition from wearless friction to friction with wear are shown.

Lubrication in different lubricant thickness regimes is described together with explanations of nanorheological concepts. The occurrence of and transitions between smooth and stick–slip sliding in various types of dry (unlubricated and solid boundary lubricated) and liquid lubricated systems are discussed based on recent experimental results and models for stick–slip involving memory distance and dilatency.

18.1 Introduction: Types of Surface Forces

In this chapter, we discuss the most important types of surface forces and the relevant equations for the force and friction laws. Several different attractive and repulsive forces operate between surfaces and particles. Some forces occur in vacuum, for example, attractive van der Waals and repulsive hard-core interactions. Other types of forces can arise only when the interacting surfaces are separated by another condensed phase, which is usually a liquid. The most common types of surface forces and their main characteristics are listed in Table 18.1.

In *vacuum*, the two main long-range interactions are the attractive van der Waals and electrostatic (Coulomb) forces. At smaller surface separations (corresponding to molecular contact at surface separations of $D \approx 0.2$ nm), additional attractive interactions can be found such as covalent or metallic bonding forces. These attractive forces are stabilized by the hard-core repulsion. Together they determine the surface and interfacial energies of planar surfaces, as well as the strengths of materials and adhesive junctions. Adhesion forces are often strong enough to elastically or plastically deform bodies or particles when they come into contact.

In *vapors* (e.g., atmospheric air containing water and organic molecules), solid surfaces in or close to contact will generally have a surface layer of chemisorbed or physisorbed molecules, or a capillary condensed liquid bridge between them. A surface layer usually causes the adhesion to decrease, but in the case of capillary condensation, the additional Laplace pressure or attractive "capillary" force may make the adhesion between the surfaces stronger than in inert gas or vacuum.

When totally immersed in a *liquid*, the force between particles or surfaces is completely modified from that in vacuum or air (vapor). The van der Waals attraction is generally reduced, but other forces can now arise that can qualitatively change both the range and even the sign of the interaction. The attractive force in such a system can be either stronger or weaker than in the absence of the intervening liquid. For example, the overall attraction can be stronger in the case of two hydrophobic surfaces separated by water, but weaker for two hydrophilic surfaces. Depending on the different forces that may be operating simultaneously in solution, the overall force law is not generally monotonically attractive even at long range; it can be repulsive, or the force can change sign at some finite surface separation. In such cases, the potential energy minimum, which determines the adhesion force or energy, occurs not at true molecular contact between the surfaces, but at some small distance farther out.

The forces between surfaces in a liquid medium can be particularly complex at *short range*, i. e., at surface separations below a few nanometers or 4–10 molecular diameters. This is partly because with increasing confinement, a liquid ceases to behave as a structureless continuum with bulk properties; instead, the size and shape of its molecules begin to determine the overall interaction. In addition, the surfaces themselves can no longer be treated as inert and structureless walls (i. e., mathematically flat) and their physical and chemical properties at the atomic scale must now be taken into account. The force laws will then depend on whether the surfaces are amorphous or crystalline (and whether the lattices of crystalline surfaces are matched or not), rough or smooth, rigid or soft (fluid-like), and hydrophobic or hydrophilic.

It is also important to distinguish between *static* (i. e., equilibrium) interactions and *dynamic* (i. e., nonequilibrium) forces such as viscous and friction forces. For example, certain liquid films confined between two contacting surfaces may take a surprisingly long time to equilibrate, as may the surfaces themselves, so that the short-range and adhesion forces appear to be time-dependent, resulting in "aging" effects.

Table 18.1 Types of surface forces in vacuum vs. in liquid (colloidal forces)

Type of force	Subclasses or alternative names	Main characteristics
	Attractive forces	
van der Waals	Debye induced dipole force (v & s) London dispersion force (v & s) Casimir force (v & s)	Ubiquitous, occurs both in vacuum and in liquids
Electrostatic	Ionic bond (v) Coulombic force (v & s) Hydrogen bond (v) Charge-exchange interaction (v & s) Acid–base interaction (s) "Harpooning" interaction (v)	Strong, long-range, arises in polar solvents; requires surface charging or charge-separation mechanism
Ion correlation	van der Waals force of polarizable ions (s)	Requires mobile charges on surfaces in a polar solvent
Quantum mechanical	Covalent bond (v) Metallic bond (v) Exchange interaction (v)	Strong, short-range, responsible for contact binding of crystalline surfaces
Solvation	Oscillatory force (s) Depletion force (s)	Mainly entropic in origin, the oscillatory force alternates between attraction and repulsion
Hydrophobic	Attractive hydration force (s)	Strong, apparently long-range; origin not yet understood
Specific binding	"Lock-and-key" or complementary binding (v & s) Receptor–ligand interaction (s) Antibody–antigen interaction (s)	Subtle combination of different non-covalent forces giving rise to highly specific binding; main recognition mechanism of biological systems
	Repulsive forces	
van der Waals	van der Waals disjoining pressure (s)	Arises only between dissimilar bodies interacting in a medium
Electrostatic	Coulombic force (v & s)	Arises only for certain constrained surface charge distributions
Quantum mechanical	Hard-core or steric repulsion (v) Born repulsion (v)	Short-range, stabilizing attractive covalent and ionic binding forces, effectively determine molecular size and shape
Solvation	Oscillatory solvation force (s) Structural force (s) Hydration force (s)	Monotonically repulsive forces, believed to arise when solvent molecules bind strongly to surfaces
Entropic	Osmotic repulsion (s) Double-layer force (s) Thermal fluctuation force (s) Steric polymer repulsion (s) Undulation force (s) Protrusion force (s)	Due to confinement of molecular or ionic species; requires mechanism that keeps trapped species between the surfaces
	Dynamic interactions	
Non-equilibrium	Hydrodynamic forces (s) Viscous forces (s) Friction forces (v & s) Lubrication forces (s)	Energy-dissipating forces occurring during relative motion of surfaces or bodies

Note: (v) applies only to interactions in vacuum, (s) applies only to interactions in solution (or to surfaces separated by a liquid), and (v & s) applies to interactions occurring both in vacuum and in solution.

18.2 Methods Used to Study Surface Forces

18.2.1 Force Laws

The full force law $F(D)$ between two surfaces, i.e., the force F as a function of surface separation D, can be measured in a number of ways [18.2–6]. The simplest is to move the base of a spring by a known amount, ΔD_0. Figure 18.1 illustrates this method when applied to the interaction of two magnets. However, the method is applicable also at the microscopic or molecular level, and it forms the basis of all direct force-measuring apparatuses such as the surface forces apparatus (SFA; [18.3, 7]) and the atomic force microscope (AFM; [18.8–10]). If there is a detectable force between the surfaces, this will cause the force-measuring spring to deflect by ΔD_s, while the surface separation changes by ΔD. These three displacements are related by

$$\Delta D_s = \Delta D_0 - \Delta D \, . \tag{18.1}$$

The difference in force, ΔF, between the initial and final separations is given by

$$\Delta F = k_s \Delta D_s \, , \tag{18.2}$$

where k_s is the spring constant. The equations above provide the basis for measurements of the force difference between any two surface separations. For example, if a force-measuring apparatus with a known k_s can measure D (and thus ΔD), ΔD_0, and ΔD_s, the force difference ΔF can be measured between a large initial or reference separation D, where the force is zero ($F = 0$), and another separation $D - \Delta D$. By working one's way in increasing increments of $\Delta D = \Delta D_0 - \Delta D_s$, the full force law $F(D)$ can be constructed over any desired distance regime.

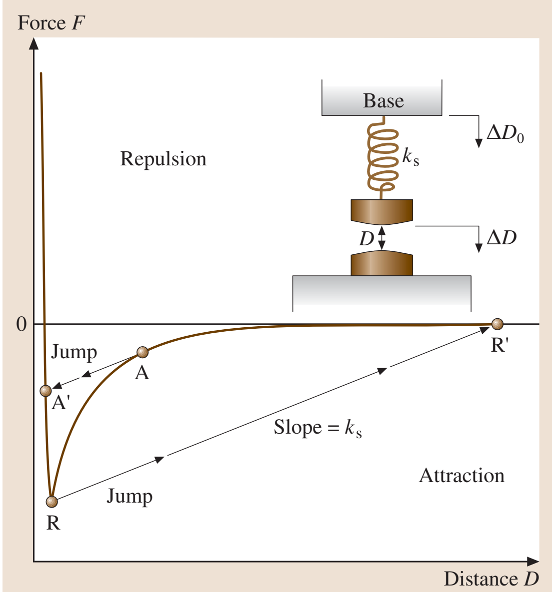

Fig. 18.1 Schematic attractive force law between two macroscopic objects such as two magnets, or between two microscopic objects such as the van der Waals force between a metal tip and a surface. On lowering the base supporting the spring, the latter will expand or contract such that at any equilibrium separation D the attractive force balances the elastic spring restoring force. If the gradient of the attractive force $\mathrm{d}F/\mathrm{d}D$ exceeds the gradient of the spring's restoring force (defined by the spring constant k_s), the upper surface will jump from A into contact at A′ (A for "advancing"). On separating the surfaces by raising the base, the two surfaces will jump apart from R to R′ (R for "receding"). The distance R–R′ multiplied by k_s gives the adhesion force, i.e., the value of F at the point R (after [18.1] with permission)

In order to measure an equilibrium force law, it is essential to establish that the two surfaces have stopped moving before the displacements are measured. When displacements are measured while two surfaces are still in relative motion, one also measures a viscous or frictional contribution to the total force. Such dynamic force measurements have enabled the viscosities of liquids near surfaces and in thin films to be accurately determined [18.11–13].

In practice, it is difficult to measure the forces between two perfectly flat surfaces, because of the stringent requirement of perfect alignment for making reliable measurements at distances of a few tenths of a nanometer. It is far easier to measure the forces between curved surfaces, e.g., two spheres, a sphere and a flat surface, or two crossed cylinders. Furthermore, the force $F(D)$ measured between two curved surfaces can be directly related to the energy per unit area $E(D)$ between two flat surfaces at the same separation, D, by the so-called Derjaguin approximation [18.14]:

$$E(D) = \frac{F(D)}{2\pi R} \, , \tag{18.3}$$

where R is the radius of the sphere (for a sphere and a flat surface) or the radii of the cylinders (for two crossed cylinders).

18.2.2 Adhesion Forces

The most direct way to measure the adhesion of two solid surfaces (such as two spheres or a sphere on a flat) is to suspend one of them on a spring and measure the adhesion or "pull-off" force needed to separate the two bodies from its deflection. If k_s is the stiffness of the force-measuring spring and ΔD the distance the two surfaces jump apart when they separate, then the adhesion force F_s is given by

$$F_s = F_{max} = k_s \Delta D , \tag{18.4}$$

where we note that in liquids, the maximum or minimum in the force may occur at some nonzero surface separation (see Fig. 18.7). From F_s and a known surface geometry, and assuming that the surfaces were everywhere in molecular contact, one may also calculate the surface or interfacial energy γ. For an elastically deformable sphere of radius R on a flat surface, or for two crossed cylinders of radius R, we have [18.3, 15]

$$\gamma = \frac{F_s}{3\pi R} , \tag{18.5}$$

while for two spheres of radii R_1 and R_2

$$\gamma = \frac{F_s}{3\pi}\left(\frac{1}{R_1}+\frac{1}{R_2}\right) , \tag{18.6}$$

where γ is in units of $J\,m^{-2}$ (see Sect. 18.5.2).

18.2.3 The SFA and AFM

In a typical force-measuring experiment, at least two of the above displacement parameters – ΔD_0, ΔD, and ΔD_s – are directly or indirectly measured, and from these the third displacement and the resulting force law $F(D)$ are deduced using (18.1) and (18.2) together with a measured value of k_s. For example, in SFA experiments, ΔD_0 is changed by expanding or contracting a piezoelectric crystal by a known amount or by moving the base of the spring with sensitive motor-driven mechanical stages. The resulting change in surface separation ΔD is measured optically, and the spring deflection ΔD_s can then be obtained according to (18.1). In AFM experiments, ΔD_0 and ΔD_s are measured using a combination of piezoelectric, optical, capacitance or magnetic techniques, from which the change in surface separation ΔD is deduced. Once a force law is established, the geometry of the two surfaces (e.g., their radii) must also be known before the results can be compared with theory or with other experiments.

The SFA (Fig. 18.2) is used for measurements of adhesion and force laws between two curved molecularly smooth surfaces immersed in liquids or controlled vapors [18.3, 7, 16]. The surface separation is measured by multiple beam interferometry with an accuracy of ± 0.1 nm. From the shape of the interference fringes one also obtains the radius of the surfaces, R, and any surface deformation that arises during an interaction [18.17–19]. The resolution in the lateral direction is about 1 μm. The surface separation can be independently controlled to within 0.1 nm, and the force sensitivity is about 10^{-8} N. For a typical surface radius of $R \approx 1$ cm, γ values can be measured to an accuracy of about 10^{-3} mJ m^{-2}.

Several different materials have been used to form the surfaces in the SFA, including mica [18.20, 21], silica [18.22], sapphire [18.23], and polymer sheets [18.24]. These materials can also be used as supporting substrates in experiments on the forces between adsorbed or chemically bound polymer layers [18.13, 25–30], surfactant and lipid monolayers and bilayers [18.31–34], and metal and metal oxide layers [18.35–42]. The range of liquids and vapors that can be used is almost endless, and have thus far included aqueous solutions, organic liquids and solvents, polymer melts, various petroleum oils and lubricant liquids, and liquid crystals.

Friction attachments for the SFA [18.43–47] allow for the two surfaces to be sheared laterally past each other at varying sliding speeds or oscillating frequencies, while simultaneously measuring both the transverse (frictional or shear) force and the normal force (load) between them. The ranges of friction forces and sliding speeds that can be studied with such methods are currently 10^{-7}–10^{-1} N and 10^{-13}–10^{-2} m s^{-1}, respectively [18.48]. The externally applied load, L, can be varied continuously, and both positive and negative loads can be applied. The distance between the surfaces, D, their true molecular contact area, their elastic (or viscoelastic or elastohydrodynamic) deformation, and their lateral motion can all be monitored simultaneously by recording the moving interference fringe pattern.

In the atomic force microscope (Fig. 18.3), the force is measured by monitoring the deflection of a soft cantilever supporting a sub-microscopic tip ($R \approx 10$–200 nm) as this is interacting with a flat, macroscopic surface [18.8, 49, 50]. The measurements can be done in a vapor or liquid. The normal (bending) spring stiffness of the cantilever can be as small as 0.01 N m^{-1}, allowing measurements of normal forces as small as 1 pN (10^{-12} N), which corresponds to the bond strength

Fig. 18.2 A surface forces apparatus (SFA) where the intermolecular forces between two macroscopic, cylindrical surfaces of local radius R can be directly measured as a function of surface separation over a large distance regime from tenths of a nanometer to micrometers. Local or transient surface deformations can be detected optically. Various attachments for moving one surface laterally with respect to the other have been developed for friction measurements in different regimes of sliding velocity and sliding distance (after [18.16] with permission)

of single molecules [18.51, 52]. Distances can be inferred with an accuracy of about 1 nm, and changes in distance can be measured to about 0.1 nm. Since the contact area is small, different interaction regimes can be resolved on samples with a heterogeneous composition on lateral scales of about ten nanometers. Height differences and the roughness of the sample can be measured directly from the cantilever deflection or, alternatively, by using a feedback system to raise or lower the sample so that the deflection (the normal force) is kept constant during a scan over the area of interest. Weak interaction forces and larger (microscopic) interaction areas can be investigated by replacing the tip with a micrometer-sized sphere to form a "colloidal probe" [18.9].

The atomic force microscope can also be used for friction measurements (lateral force microscopy, LFM) by monitoring the torsion of the cantilever as the sample is scanned in the direction perpendicular to the long axis of the cantilever [18.10, 50, 53, 54]. Typically, the stiffness of the cantilever to lateral bending is much larger than to bending in the normal direction and to torsion, so that these signals are decoupled and height and friction can be detected simultaneously. The torsional spring constant can be as low as $0.1\,\mathrm{N\,m^{-1}}$, giving a lateral (friction) force sensitivity of 10^{-11} N.

Rapid technical developments have facilitated the calibrations of the normal [18.55, 56] and lateral spring constants [18.54, 57], as well as in situ measurements of

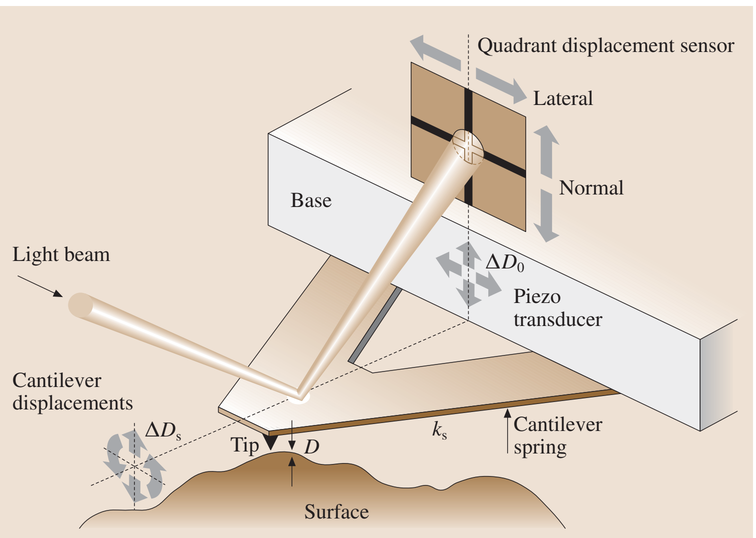

Fig. 18.3 Schematic drawing of an atomic force microscope (AFM) tip supported on a triangular cantilever interacting with an arbitrary solid surface. The normal force and topology are measured by monitoring the calibrated deflection of the cantilever as the tip is moved across the surface by means of a piezoelectric transducer. Various designs have been developed that move either the sample or the cantilever during the scan. Friction forces can be measured from the torsion of the cantilever when the scanning is in the direction perpendicular to its long axis (after [18.62] with permission)

the macroscopic tip radius [18.58]. Cantilevers of different shapes with a large range of spring constants, tip radii, and surface treatments (inorganic or organic coatings) are commercially available. The flat surface, and also the particle in the colloidal probe technique, can be any material of interest. However, remaining difficulties with this technique are that the distance between the tip and the substrate, D, and the deformations of the tip and sample are not directly measurable. Another important difference between the AFM/LFM and SFA techniques is the different size of the contact area, and the related observation that even when a cantilever with a very low spring constant is used in the AFM, the pressure in the contact zone is typically much higher than in the SFA. Hydrodynamic effects in liquids also affect the measurements of normal forces differently on certain time scales [18.59–61].

18.2.4 Some Other Force-Measuring Techniques

A large number of other techniques are available for the measurements of the normal forces between solid or fluid surfaces (see [18.5, 62]). The techniques discussed in this section are not used for lateral (friction) force measurements, but are commonly used to study normal forces, particularly in biological systems.

Micropipette aspiration is used to measure the forces between cells or vesicles, or between a cell or vesicle and another surface [18.63–65]. The cell or vesicle is held by suction at the tip of a glass micropipette and deforms elastically in response to the net interactions with another surface and to the applied suction. The shape of the deformed surface (cell membrane) is measured and used to deduce the force between the surfaces and the membrane tension [18.64]. The membrane tension, and thus the stiffness of the cell or vesicle, is regulated by applying different hydrostatic pressures. Forces can be measured in the range of 0.1 pN to 1 nN, and the distance resolution is a few nanometers. The interactions between a colloidal particle and another surface can be studied by attaching the particle to the cell membrane [18.66].

In the osmotic stress technique, pressures are measured between colloidal particles in aqueous solution, membranes or bilayers, or other ordered colloidal structures (viruses, DNA). The separation between the particle surfaces and the magnitude of membrane undulations are measured by X-ray or neutron scattering techniques. This is combined with a measurement of the osmotic pressure of the solution [18.67–70]. The technique has been used to measure repulsive forces, such as DLVO interactions, steric forces, and hydration forces [18.71]. The sensitivity in pressure is 0.1 mN m^{-2}, and distances can be resolved to 0.1 nm.

The optical tweezers technique is based on the trapping of dielectric particles at the center of a focused laser beam by restoring forces arising from radiation pressure and light intensity gradients [18.72, 73]. The forces experienced by particles as they are moved toward or away from one another can be measured with a sensitivity in the pN range. Small biological molecules are typically attached to a larger bead of a material

with suitable refractive properties. Recent development allows determinations of position with nanometer resolution [18.74], which makes this technique useful for studying the forces during extension of single molecules.

In total internal reflection microscopy (TIRM), the potential energy between a micrometer-sized colloidal particle and flat surface in aqueous solution is deduced from the average equilibrium height of the particle above the surface, measured from the intensity of scattered light. The average height ($D \approx 10-100$ nm) results from a balance of gravitational force, radiation pressure from a laser beam focused at the particle from below, and intermolecular forces [18.75]. The technique is particularly suitable for measuring weak forces (sensitivity ca. 10^{-14} N), but is more difficult to use for systems with strong interactions. A related technique is reflection interference contrast microscopy (RICM), where optical interference is used to also monitor changes in the shape of the approaching colloidal particle or vesicle [18.76].

An estimate of bond strengths can be obtained from the hydrodynamic shear force exerted by a fluid on particles or cells attached to a substrate [18.77, 78]. At a critical force, the bonds are broken and the particle or cell will be detached and move with the velocity of the fluid. This method requires knowledge of the contact area and the flow velocity profile of the fluid. Furthermore, a uniform stress distribution in the contact area is generally assumed. At low bond density, this technique can be used to determine the strength of single bonds (1 pN).

18.3 Normal Forces Between Dry (Unlubricated) Surfaces

18.3.1 Van der Waals Forces in Vacuum and Inert Vapors

Forces between macroscopic bodies (such as colloidal particles) across vacuum arise from interactions between the constituent atoms or molecules of each body across the gap separating them. These intermolecular interactions are electromagnetic forces between permanent or induced dipoles (van der Waals forces), and between ions (electrostatic forces). In this section, we describe the van der Waals forces, which occur between all atoms and molecules and between all macroscopic bodies (see [18.3]).

The interaction between two permanent dipoles with a fixed relative orientation can be attractive or repulsive. For the specific case of two freely rotating permanent dipoles in a liquid or vapor (orientational or Keesom interaction), and for a permanent dipole and an induced dipole in an atom or polar or nonpolar molecule (induction or Debye interaction), the interaction is on average always attractive. The third type of van der Waals interaction, the fluctuation or London dispersion interaction, arises from instantaneous polarization of one nonpolar or polar molecule due to fluctuations in the charge distribution of a neighboring nonpolar or polar molecule (Fig. 18.4a). Correlation between these fluctuating induced dipole moments gives an attraction that is present between any two molecules or surfaces across vacuum. At very small separations, the interaction will ultimately be repulsive as the electron clouds of atoms and molecules begin to overlap. The total interaction is thus a combination of a short-range repulsion and a relatively long-range attraction.

Except for in highly polar materials such as water, London dispersion interactions give the largest contribution (70–100 %) to the van der Waals attraction. The interaction energy of the van der Waals force between atoms or molecules depends on the separation r as

$$E(D) = \frac{-C_{\mathrm{vdW}}}{r^6}\,, \tag{18.7}$$

where the constant C_{vdW} depends on the dipole moments and polarizabilities of the molecules. At large separations (> 10 nm), the London interaction is weakened by a randomizing effect caused by the rapid fluctuations. That is, the induced temporary dipole moment of one molecule may have changed during the time needed for the transmission of the electromagnetic wave (photon) generated by its fluctuating charge density to another molecule and the return of the photon generated by the induced fluctuation in this second molecule. This phenomenon is called retardation and causes the interaction energy to decay as r^{-7} at large separations [18.79].

Dispersion interactions are to a first approximation additive, and their contribution to the interaction energy between two macroscopic bodies (such as colloidal particles) across vacuum can be found by summing the

pair-wise interactions [18.80]. The interaction is generally described in terms of the Hamaker constant, A_H. Another approach is to treat the interacting bodies and an intervening medium as continuous phases and determine the strength of the interaction from bulk dielectric properties of the materials [18.81, 82]. Unlike the pair-wise summation, this method takes into account the screening of the interactions between molecules inside the bodies by the molecules closer to the surfaces and the effects of the intervening medium. For the interaction between material 1 and material 3 across material 2, the non-retarded Hamaker constant given by the Lifshitz theory

Table 18.2 Van der Waals interaction energy and force between macroscopic bodies of different geometries

Geometry of bodies with surfaces D apart ($D \ll R$)			van der Waals interaction Energy, E	Force, F
Two atoms or small molecules	r, σ	$r \gg \sigma$	$\frac{-C_{vdW}}{r^6}$	$\frac{-6C_{vdW}}{r^7}$
Two flat surfaces (per unit area)	r, Area $= \pi r^2$, D	$r \gg D$	$\frac{-A_H}{12\pi D^2}$	$\frac{-A_H}{6\pi D^3}$
Two spheres or macromolecules of radii R_1 and R_2	R_1, R_2, D	$R_1, R_2 \gg D$	$\frac{-A_H}{6D}\left(\frac{R_1 R_2}{R_1+R_2}\right)$	$\frac{-A_H}{6D^2}\left(\frac{R_1 R_2}{R_1+R_2}\right)$
Sphere or macromolecule of radius R near a flat surface	R, D	$R \gg D$	$\frac{-A_H R}{6D}$	$\frac{-A_H R}{6D^2}$
Two parallel cylinders or rods of radii R_1 and R_2 (per unit length)	R_1, R_2, Length	$R_1, R_2 \gg D$	$\frac{-A_H}{12\sqrt{2}\,D^{3/2}}\left(\frac{R_1 R_2}{R_1+R_2}\right)^{1/2}$	$\frac{-A_H}{8\sqrt{2}\,D^{5/2}}\left(\frac{R_1 R_2}{R_1+R_2}\right)^{1/2}$
Cylinder of radius R near a flat surface (per unit length)	R, D	$R \gg D$	$\frac{-A_H\sqrt{R}}{12\sqrt{2}\,D^{3/2}}$	$\frac{-A_H\sqrt{R}}{8\sqrt{2}\,D^{5/2}}$
Two cylinders or filaments of radii R_1 and R_2 crossed at 90°	R_1, R_2, D	$R_1, R_2 \gg D$	$\frac{-A_H\sqrt{R_1 R_2}}{6D}$	$\frac{-A_H\sqrt{R_1 R_2}}{6D^2}$

A negative force (A_H positive) implies attraction, a positive force means repulsion (A_H negative) (after [18.62] with permission)

is approximately [18.3]:

$$\begin{aligned} A_{\mathrm{H},123} &= A_{\mathrm{H},\nu=0} + A_{\mathrm{H},\nu>0} \\ &\approx \frac{3}{4}k_{\mathrm{B}}T\left(\frac{\varepsilon_1-\varepsilon_2}{\varepsilon_1+\varepsilon_2}\right)\left(\frac{\varepsilon_3-\varepsilon_2}{\varepsilon_3+\varepsilon_2}\right) \\ &+ \frac{3h\nu_{\mathrm{e}}}{8\sqrt{2}} \frac{(n_1^2-n_2^2)(n_3^2-n_2^2)}{\sqrt{(n_1^2+n_2^2)}\sqrt{(n_3^2+n_2^2)}\left(\sqrt{(n_1^2+n_2^2)}+\sqrt{(n_3^2+n_2^2)}\right)}\,, \end{aligned} \quad (18.8)$$

where the first term ($\nu = 0$) represents the permanent dipole and dipole–induced dipole interactions and the second ($\nu > 0$) the London (dispersion) interaction. ε_i and n_i are the static dielectric constants and refractive indexes of the materials, respectively. ν_{e} is the frequency of the lowest electron transition (around $3\times10^{15}\,\mathrm{s}^{-1}$). Either one of the materials 1, 2, or 3 in (18.8) can be vacuum or air ($\varepsilon = n = 1$). A_{H} is typically 10^{-20}–10^{-19} J (the higher values are found for metals) for interactions between solids and liquids across vacuum or air.

The interaction energy between two macroscopic bodies is dependent on the geometry and is always attractive between two bodies of the same material [A_{H} positive, see (18.8)]. The van der Waals interaction energy and force laws ($F = -\mathrm{d}E(D)/\mathrm{d}D$) for some common geometries are given in Table 18.2. Because of the retardation effect, the equations in Table 18.2 will lead to an overestimation of the dispersion force at large separations. It is, however, apparent that the interaction energy between macroscopic bodies decays more slowly with separation (i. e., has a longer range) than between two molecules.

For inert nonpolar surfaces, e.g., consisting of hydrocarbons or van der Waals solids and liquids, the Lifshitz theory has been found to apply even at molecular contact, where it can be used to predict the surface energies (surface tensions) of such solids and liquids. For example, for hydrocarbon surfaces, $A_{\mathrm{H}} = 5\times10^{-20}$ J. Inserting this value into the equation for two flat surfaces (Table 18.2) and using a "cut-off" distance of $D_0 \approx 0.165$ nm as an effective separation when the surfaces are in contact [18.3], we obtain for the surface energy γ (which is defined as half the interaction energy)

$$\gamma = \frac{E}{2} = \frac{A_{\mathrm{H}}}{24\pi D_0^2} \approx 24\,\mathrm{mJ\,m^{-2}}\,, \quad (18.9)$$

a value that is typical for hydrocarbon solids and liquids [18.83].

If the adhesion force is measured between a spherical surface of radius $R = 1$ cm and a flat surface using an SFA, we expect the adhesion force to be (see Table 18.2) $F = A_{\mathrm{H}}R/(6D_0^2) = 4\pi R\gamma \approx 3.0$ mN. Using a spring constant of $k_{\mathrm{s}} = 100\,\mathrm{N\,m^{-1}}$, such an adhesive force will cause the two surfaces to jump apart by $\Delta D = F/k_{\mathrm{s}} = 30\,\mu\mathrm{m}$, which can be accurately measured. (For elastic bodies that deform in adhesive contact, R changes during the interaction and the measured adhesion force is 25% lower, see Sect. 18.5.2). Surface energies of solids can thus be directly measured with the SFA and, in principle, with the AFM if the contact geometry can be quantified. The measured values are in good agreement with calculated values based on the known surface energies γ of the materials, and for nonpolar low-energy solids they are well accounted for by the Lifshitz theory [18.3].

18.3.2 Charge Exchange Interactions

Electrostatic interactions are present between ions (Coulomb interactions), between ions and permanent dipoles, and between ions and nonpolar molecules in which a charge induces a dipole moment. The interaction energy between ions or between a charge and a fixed permanent dipole can be attractive or repulsive. For an induced dipole or a freely rotating permanent dipole in vacuum or air, the interaction energy with a charge is always attractive.

Spontaneous charge transfer may occur between two dissimilar materials in contact [18.84]. The phenomenon is especially prominent in contacts between a metal, for example, mercury, and a material with low conductivity, but is also observed, for example, between two different polymer layers. During separation, rolling or sliding of one body over the other, the surfaces experience both charge transition from one surface to the other and charge transfer (conductance) along each surface (Fig. 18.4b). The latter process is typically slower, and, as a result, charges remain on the surfaces as they are separated in vacuum or dry nitrogen gas. The charging gives rise to a strong adhesion with adhesion energies of over 1,000 $\mathrm{mJ\,m^{-2}}$, similar to fracture or cohesion energies of the solid bodies themselves [18.84, 85]. Upon separating the surfaces farther apart, a strong, long-range electrostatic attraction is observed. The charging can be decreased through discharges across the gap between the surfaces (which requires a high charging) or through conducting in the solids. It has been suggested that charge exchange interactions are particularly important in rolling friction between dry surfaces (which can simplistically be thought of as an adhesion–separation process), where the distance dependence of forces acting normally to the surfaces plays a larger role than

in sliding friction. Recent experiments on the sliding friction between metal–insulator surfaces indicate that stick–slip would be accompanied by charge transfer events [18.86].

Photo-induced charge transfer, or harpooning, involves the transfer of an electron between an atom in a molecular beam or at a solid surface (typically alkali or transition metal) to an atom or molecule in a gas (typically halides) to form a negatively charged molecular ion in a highly excited vibrational state. This transfer process can occur at atomic distances of 0.5–0.7 nm, which is far from molecular contact. The formed molecular ion is attracted to the surface and chemisorbs onto it. Photo-induced charge transfer processes also occur in the photosynthesis in green plants and in photoelectrochemical cells (solar cells) at the junction between two semiconductors or between a semiconductor and an electrolyte solution [18.87].

18.3.3 Sintering and Cold Welding

When macroscopic particles in a powder or in a suspension come into molecular contact, they can bond together to form a network or solid body with very different density and shear strength compared to the powder (a typical example is porcelain). The rate of bonding is dependent on the surface energy (causing a stress at the edge of the contact) and the atomic mobility (diffusion rate) of the contacting materials. To increase the diffusion rate, objects formed from powders are heated to about one-half of the melting temperature of the components in a process called sintering, which can be done in different atmospheres or in a liquid.

In the sintering process, the surface energy of the system is lowered due to the reduction of total surface area (Fig. 18.4c). In metal and ceramic systems, the most important mechanism is solid-state diffusion, initially surface diffusion. As the surface area decreases and the grain boundaries increase at the contacts, grain boundary diffusion and diffusion through the crystal lattice become more important. The grain boundaries will eventually migrate, so that larger particles are formed (coarsening). Mass can also be transferred through evaporation and condensation, and through viscous and plastic flow. In liquid-phase sintering, the materials can melt, which increases the mass transport. Amorphous materials like polymers and glasses do not have real grain boundaries and sinter by viscous flow [18.88].

Some of these mechanisms (surface diffusion and evaporation–condensation) reduce the surface area and increase the grain size (coarsening) without densification, in contrast to bulk transport mechanisms like grain boundary diffusion and plastic and viscous flow. As the material becomes denser, elongated pores collapse to form smaller, spherical pores with a lower surface energy. Models for sintering typically consider the size and growth rate of the grain boundary (the "neck") formed between two spherical particles. At a high stage of densification, the sintering stress σ at the curved neck between two particles is given by [18.88]

$$\sigma = \frac{2\gamma_{SS}}{G} + \frac{2\gamma_{SV}}{r_p} , \quad (18.10)$$

where γ_{SS} is the solid–solid grain boundary energy, γ_{SV} is the solid–vapor surface energy, G is the grain size, and r_p is the radius of the pore.

A related phenomenon is cold welding, which is the spontaneous formation of strong junctions between clean (unoxidized) metal surfaces with a mutual solubility when they are brought in contact with or without an applied pressure. The plastic deformations accompanying the formation and breaking of such contacts on a molecular scale during motion of one surface normally (see Fig. 18.10c,d) or laterally (shearing) with respect to the other have been studied both experimentally [18.89] and theoretically [18.90–95]. The breaking of a cold welded contact is generally associated with damage or deformation of the surface structure.

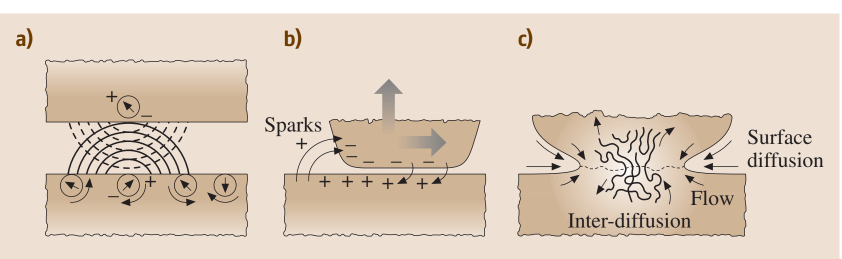

Fig. 18.4a–c Schematic representation of **(a)** van der Waals interaction (dipole–induced dipole interaction), **(b)** charge exchange, which acts to increase adhesion and friction forces, and **(c)** sintering between two surfaces

18.4 Normal Forces Between Surfaces in Liquids

18.4.1 Van der Waals Forces in Liquids

The dispersion interaction in a medium will be significantly lower than in vacuum, since the attractive interaction between two solute molecules in a medium (solvent) involves displacement and reorientation of the nearest-neighbor solvent molecules. Even though the surrounding medium may change the dipole moment and polarizability from that in vacuum, the interaction between two identical molecules remains attractive in a binary mixture. The extension of the interactions to the case of two macroscopic bodies is the same as described in Sect. 18.3.1. Typically, the Hamaker constants for interactions in a medium are an order of magnitude lower than in vacuum. Between macroscopic surfaces in liquids, van der Waals forces become important at distances below 10–15 nm and may at these distances start to dominate interactions of different origin that have been observed at larger separations.

Figure 18.5 shows the measured van der Waals forces between two crossed cylindrical mica surfaces in water and various salt solutions. Good agreement is obtained between experiment and theory. At larger surface separations, above about 5 nm, the measured forces fall off more rapidly than as D^{-2}. This retardation effect (see Sect. 18.3.1) is also predicted by Lifshitz theory and is due to the time needed for propagation of the induced dipole moments over large distances.

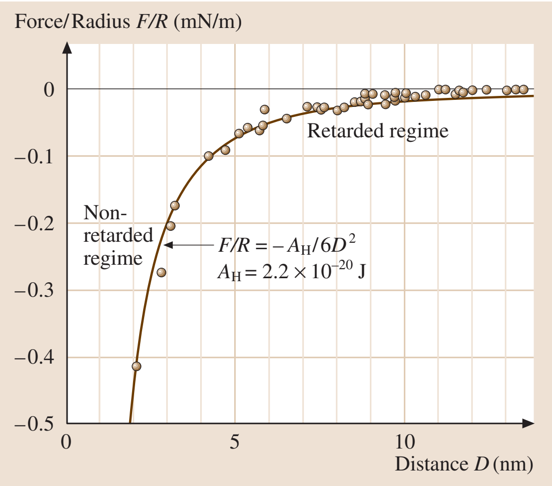

Fig. 18.5 Attractive van der Waals force F between two curved mica surfaces of radius $R \approx 1$ cm measured in water and various aqueous electrolyte solutions. The electrostatic interaction has been subtracted from the total measured force. The measured non-retarded Hamaker constant is $A_H = 2.2 \times 10^{-20}$ J. Retardation effects are apparent at distances larger than 5 nm, as expected theoretically. (After [18.3]. Copyright 1991, with permission from Elsevier Science)

From Fig. 18.5, we may conclude that at separations above about 2 nm, or 8 molecular diameters of water, the *continuum* Lifshitz theory is valid. This would mean that water films as thin as 2 nm may be expected to have bulk-like properties, at least as far as their interaction forces are concerned. Similar results have been obtained with other liquids, where in general continuum properties are manifested, both as regards their interactions and other properties such as viscosity, at a film thickness larger than 5 or 10 molecular diameters. In the absence of a solvent (in vacuum), the agreement of measured van der Waals forces with the continuum Lifshitz theory is generally good at all separations down to molecular contact ($D = D_0$).

Van der Waals interactions in a system of three or more different materials (see (18.8)) can be attractive or repulsive, depending on their dielectric properties. Numerous experimental studies show the attractive van der Waals forces in various systems [18.3], and also repulsive van der Waals forces have been measured directly [18.96]. A practical consequence of the repulsive interaction obtained across a medium with intermediate dielectric properties is that the van der Waals forces will give rise to preferential, nonspecific adsorption of molecules with an intermediate dielectric constant. This is commonly seen as adsorption of vapors or solutes to a solid surface. It is also possible to diminish the attractive interaction between dispersed colloidal particles by adsorption of a thin layer of material with dielectric properties close to those of the surrounding medium (matching of refractive index), or by adsorption of a polymer that gives a steric repulsive force that keeps the particles separated at a distance where the magnitude of the van der Waals attraction is negligible. Thermal motion will then keep the particles dispersed.

18.4.2 Electrostatic and Ion Correlation Forces

Most surfaces in contact with a highly polar liquid (such as water) acquire a surface charge, either by dissociation of ions from the surface into the solution or by preferential adsorption of certain ions from the solution.

The surface charge is balanced by a layer of oppositely charged ions (counterions) in the solution at some small distance from the surface (see [18.3]). In dilute solution, this distance is the Debye length, κ^{-1}, which is purely a property of the electrolyte *solution*. The Debye length falls with increasing ionic strength (i. e., with the molar concentration M_i and valency z_i) of the ions in solution:

$$\kappa^{-1} = \left(\frac{\varepsilon\varepsilon_0 k_B T}{e^2 N_A \sum_i z_i^2 M_i} \right)^{1/2} , \quad (18.11)$$

where e is the electronic charge. For example, for 1:1 electrolytes at 25 °C, $\kappa^{-1} = 0.304\,\text{nm}/\sqrt{M_{1:1}}$, where M_i is given in M ($\text{mol}\,\text{dm}^{-3}$). κ^{-1} is thus ca. 10 nm in a 1 mM NaCl solution and 0.3 nm in a 1 M solution. In totally pure water at pH 7, where $M_i = 10^{-7}$ M, κ^{-1} is 960 nm, or about 1 µm. The Debye length also relates the surface charge density σ of a surface to the electrostatic surface potential ψ_0 via the Grahame equation, which for 1:1 electrolytes can be expressed as:

$$\sigma = \sqrt{8\varepsilon\varepsilon_0 k_B T} \sinh(e\psi_0/2k_B T) \times \sqrt{M_{1:1}} . \quad (18.12)$$

Since the Debye length is a measure of the thickness of the diffuse atmosphere of counterions near a charged surface, it also determines the range of the electrostatic "double-layer" interaction between two charged surfaces. The electrostatic double-layer interaction is an entropic effect that arises upon decreasing the thickness of the liquid film containing the dissolved ions. Because of the attractive force between the dissolved ions and opposite charges on the surfaces, the ions stay between the surfaces, but an osmotic repulsion arises as their concentration increases. The long-range electrostatic interaction energy at large separations (weak overlap) between two similarly charged molecules or surfaces is typically repulsive and is roughly an exponentially decaying function of D:

$$E(D) \approx +C_{ES}\,e^{-\kappa D} , \quad (18.13)$$

where C_{ES} is a constant that depends on the geometry of the interacting surfaces, on their surface charge density, and the solution conditions (Table 18.3). We see that the Debye length is the decay length of the interaction energy between two surfaces (and of the mean potential away from one surface). C_{ES} can be determined by solving the so-called Poisson–Boltzmann equation or by using other theories [18.97, 98]. The equations in Table 18.3 are expressed in terms of a constant, Z, defined as

$$Z = 64\pi\varepsilon\varepsilon_0 (k_B T/e)^2 \tanh^2 [ze\psi_0/(4k_B T)] , \quad (18.14)$$

which depends only on the properties of the *surfaces*.

The above approximate expressions are accurate only for surface separations larger than about one Debye length. At smaller separations one must use numerical solutions of the Poisson–Boltzmann equation to obtain the exact interaction potential, for which there are no simple expressions. In the limit of small D, it can be shown that the interaction energy depends on whether the surfaces remain at constant potential ψ_0 (as assumed in the above equations) or at constant charge σ (when the repulsion exceeds that predicted by the above equations), or somewhere between these limits. In the "constant charge limit" the total *number* of counterions in the compressed film does not change as D is decreased, whereas at constant potential, the *concentration* of counterions is constant.The limiting pressure (or force per unit area) at constant charge is the osmotic pressure of the confined ions:

$$\begin{aligned} F &= k_B T \times \text{ion number density} \\ &= 2\sigma k_B T/(zeD), \quad \text{for } D \ll \kappa^{-1} . \end{aligned} \quad (18.15)$$

That is, as $D \to 0$ the double-layer pressure at constant surface charge becomes infinitely repulsive and independent of the salt concentration (at constant potential the force instead becomes a constant at small D). However, at small separations, the van der Waals attraction (which goes as D^{-2} between two spheres or as D^{-3} between two planar surfaces, see Table 18.2) wins out over the double-layer repulsion, unless some other short-range interaction becomes dominant (see Sect. 18.4.4). This is the theoretical prediction that forms the basis of the so-called Derjaguin–Landau–Verwey–Overbeek (DLVO) theory [18.97, 99], illustrated in Fig. 18.6.

Because of the different distance dependence of the van der Waals and electrostatic interactions, the total force law, as described by the DLVO theory, can show several minima and maxima. Typically, the depth of the outer (secondary) minimum is a few $k_B T$, enough to cause reversible flocculation of particles from an aqueous dispersion. If the force barrier between the secondary and primary minimum is lowered, for example, by increasing the electrolyte concentration, particles can be irreversibly coagulated in the primary minimum. In practice, other forces (described

Table 18.3 Electrical "double-layer" interaction energy $E(D)$ and force ($F = -\mathrm{d}E/\mathrm{d}D$) between macroscopic bodies

Geometry of bodies with surfaces D apart ($D \ll R$)		Electric "double-layer" interaction Energy, E	Force, F
Two ions or small molecules	$r > \sigma$	$\dfrac{+z_1 z_2 e^2}{4\pi\varepsilon\varepsilon_0 r}\,\dfrac{\mathrm{e}^{-\kappa(r-\sigma)}}{(1+\kappa\sigma)}$	$\dfrac{+z_1 z_2 e^2}{4\pi\varepsilon\varepsilon_0 r^2}\,\dfrac{(1+\kappa r)}{(1+\kappa\sigma)}\,\mathrm{e}^{-\kappa(r-\sigma)}$
Two flat surfaces (per unit area)	$r \gg D$	$(\kappa/2\pi)\,Z\mathrm{e}^{-\kappa D}$	$\left(\kappa^2/2\pi\right)Z\mathrm{e}^{-\kappa D}$
Two spheres or macromolecules of radii R_1 and R_2	$R_1, R_2 \gg D$	$\left(\dfrac{R_1 R_2}{R_1+R_2}\right)Z\mathrm{e}^{-\kappa D}$	$\kappa\left(\dfrac{R_1 R_2}{R_1+R_2}\right)Z\mathrm{e}^{-\kappa D}$
Sphere or macromolecule of radius R near a flat surface	$R \gg D$	$RZ\mathrm{e}^{-\kappa D}$	$\kappa RZ\mathrm{e}^{-\kappa D}$

Two cylinders or filaments of radii R_1 and R_2 crossed at 90°	$R_1, R_2 \gg D$	$\sqrt{R_1 R_2}\,Z\mathrm{e}^{-\kappa D}$	$\kappa\sqrt{R_1 R_2}\,Z\mathrm{e}^{-\kappa D}$

The interaction energy and force for bodies of different geometries is based on the Poisson–Boltzmann equation (a continuum, mean-field theory). Equation (18.14) gives the interaction constant Z (in terms of surface potential ψ_0) for the interaction between similarly charged (ionized) surfaces in aqueous solutions of monovalent electrolyte. It can also be expressed in terms of the surface charge density σ by applying the Grahame equation (18.12) (after [18.62] with permission)

in the following sections) often appear at very small separations, so that the full force law between two surfaces or colloidal particles in solution can be more complex than might be expected from the DLVO theory.

There are situations when the double-layer interaction can be attractive at short range even between surfaces of similar charge, especially in systems with charge regulation due to dissociation of chargeable groups on the surfaces [18.100]; ion condensa-

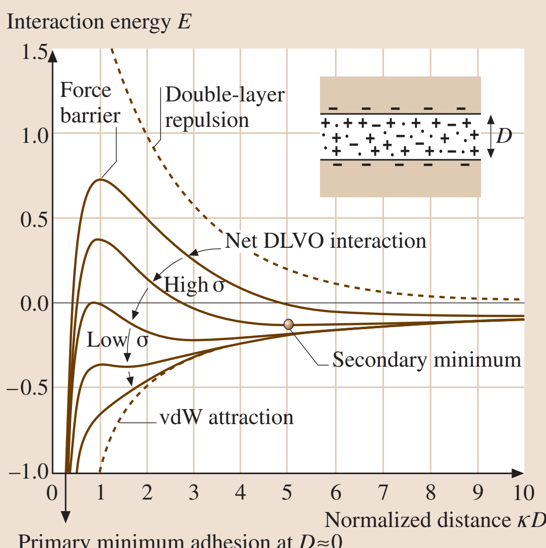

Fig. 18.6 Schematic plots of the DLVO interaction potential energy E between two flat, charged surfaces (or, according to the Derjaguin approximation, (18.3), the force F between two curved surfaces) as a function of the surface separation normalized by the Debye length, κ^{-1}. The van der Waals attraction (inverse power-law dependence on D) together with the repulsive electrostatic "double-layer" force (roughly exponential) at different surface charge σ (or potential, see (18.12)) determine the net interaction potential in aqueous electrolyte solution (after [18.62] with permission)

tion [18.101], which may lower the effective surface charge density in systems containing di-and trivalent counterions; or ion correlation, which is an additional van der Waals-like attraction due to mobile and therefore highly polarizable counterions located at the surface [18.102]. The ion correlation (or charge fluctuation) force becomes significant at separations below 4 nm and increases with the surface charge density σ and the valency z of the counterions. Computer simulations have shown that at high charge density and monovalent counterions, the ion correlation force can reduce the effective double-layer repulsion by 10–15 %. With divalent counterions, the ion correlation force was found to exceed the double-layer repulsion and the total force then became attractive at a separation below 2 nm even in dilute electrolyte solution [18.103]. Experimentally, such short-range attractive forces have been found in charged bilayer systems [18.104, 105].

18.4.3 Solvation and Structural Forces

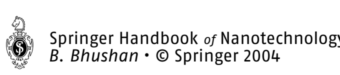
When a liquid is confined within a restricted space, for example, a very thin film between two surfaces, it ceases to behave as a structureless continuum. At small surface separations (below about 10 molecular diameters), the van der Waals force between two surfaces or even two solute molecules in a liquid (solvent) is no longer a smoothly varying attraction. Instead, there arises an additional "solvation" force that generally oscillates between attraction and repulsion with distance, with a periodicity equal to some mean dimension σ of the liquid molecules [18.106]. Figure 18.7a shows the force law between two smooth mica surfaces across the hydrocarbon liquid tetradecane, whose inert, chain-like molecules have a width of $\sigma \approx 0.4$ nm.

The short-range oscillatory force law is related to the "density distribution function" and "potential of mean force" characteristic of intermolecular interactions in liquids. These forces arise from the confining effects two surfaces have on liquid molecules, forcing them to order into quasi-discrete layers. Such layers are energetically or entropically favored and correspond to the minima in the free energy, whereas fractional layers are disfavored (energy maxima). This effect is quite general and arises in all simple liquids when they are confined between two smooth, rigid surfaces, both flat and curved. Oscillatory forces do not require any attractive liquid–liquid or liquid–wall interaction, only two hard walls confining molecules whose shape is not too irregular and that are free to exchange with molecules in a bulk liquid reservoir. In the absence of any attractive pressure between the molecules, the bulk liquid density could be maintained by an external hydrostatic pressure – in real liquids attractive van der Waals forces play the role of such an external pressure.

Oscillatory forces are now well understood theoretically, at least for simple liquids, and a number of theoretical studies and computer simulations of various confined liquids (including water) that interact via some form of Lennard-Jones potential have invariably led to an oscillatory solvation force at surface separations below a few molecular diameters [18.107–114]. In a first approximation, the oscillatory force law may be described by an exponentially decaying cosine function of the form

$$E \approx E_0 \cos(2\pi D/\sigma)\,\mathrm{e}^{-D/\sigma} , \quad (18.16)$$

where both theory and experiments show that the oscillatory period and the characteristic decay length of the envelope are close to σ.



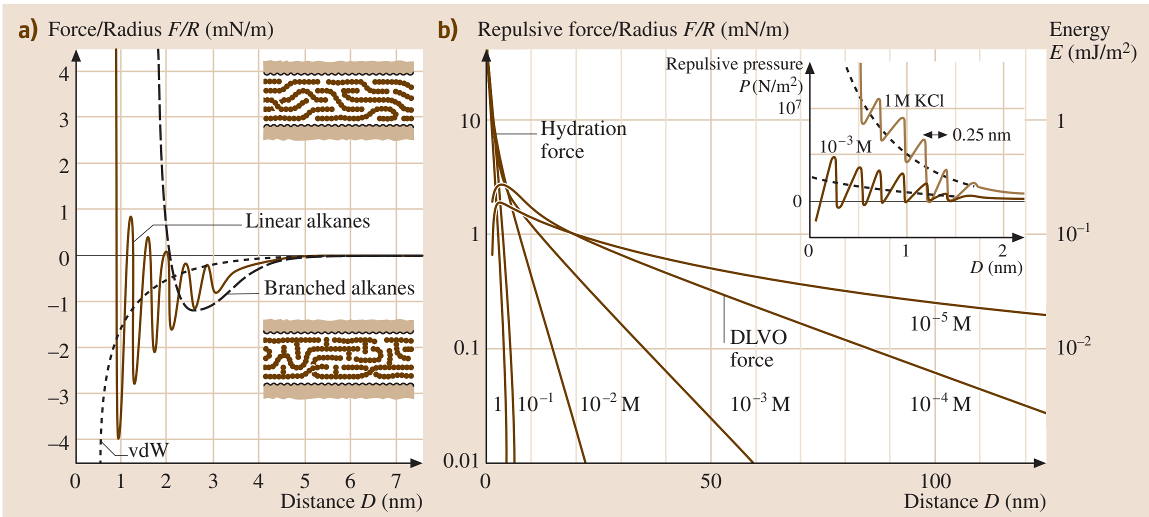


Fig. 18.7 **(a)** *Solid curve:* Forces measured between two mica surfaces across saturated linear chain alkanes such as n-tetradecane and n-hexadecane [18.115, 116]. The 0.4 nm periodicity of the oscillations indicates that the molecules are preferentially oriented parallel to the surfaces, as shown schematically in the *upper insert*. The theoretical continuum van der Waals attraction is shown as a *dotted curve*. *Dashed curve:* Smooth, non-oscillatory force law exhibited by irregularly shaped alkanes (such as 2-methyloctadecane) that cannot order into well-defined layers (*lower insert*) [18.116, 117]. Similar non-oscillatory forces are also observed between "rough" surfaces, even when these interact across a saturated linear chain liquid. This is because the irregularly shaped surfaces (rather than the liquid) now prevent the liquid molecules from ordering in the gap. **(b)** Forces measured between charged mica surfaces in KCl solutions of varying concentrations [18.20]. In dilute solutions (10^{-5} and 10^{-4} M), the measured forces are excellently described by the DLVO theory, based on exact solutions to the nonlinear Poisson–Boltzmann equation for the electrostatic forces and the Lifshitz theory for the van der Waals forces (using a Hamaker constant of $A_{\mathrm{H}} = 2.2 \times 10^{-20}$ J). At higher concentrations, as more hydrated K^+ cations adsorb onto the negatively charged surfaces, an additional hydration force appears superimposed on the DLVO interaction at distances below 3–4 nm. This force has both an oscillatory and a monotonic component. *Insert:* Short-range hydration forces between mica surfaces shown as pressure versus distance. The lower and upper curves show surfaces 40% and 95% saturated with K^+ ions. At larger separations, the forces are in good agreement with the DLVO theory. (After [18.3]. Copyright 1991, with permission from Elsevier Science)

Once the solvation zones of the two surfaces overlap, the mean liquid density in the gap is no longer the same as in the bulk liquid. Since the van der Waals interaction depends on the optical properties of the liquid, which in turn depends on the density, the van der Waals and the oscillatory solvation forces are not strictly additive. It is more correct to think of the solvation force as *the* van der Waals force at small separations with the molecular properties and density variations of the medium taken into account. It is also important to appreciate that solvation forces do not arise simply because liquid molecules tend to structure into semi-ordered layers at surfaces. They arise because of the disruption or *change* of this ordering during the approach of a second surface. The two effects are related; the greater the tendency toward structuring at an isolated surface the greater the solvation force between two such surfaces, but there is a real distinction between the two phenomena that should be borne in mind.

Oscillatory forces lead to different adhesion values depending on the energy minimum from which two surfaces are being separated. For an interaction energy described by (18.16), "quantized" adhesion energies will be E_0 at $D = 0$ (primary minimum), E_0/e at $D = \sigma$, E_0/e^2 at $D = 2\sigma$, etc. E_0 can be thought of as a depletion force (see Sect. 18.4.5) that is approximately given by the osmotic limit $E_0 \approx -k_{\mathrm{B}}T/\sigma^2$, which can exceed the contribution to the adhesion energy in contact from the van der Waals forces (at $D_0 \approx 0.15$–0.20 nm, as discussed in Sect. 18.3.1, keeping in mind that the

Lifshitz theory fails to describe the force law at *intermediate* distances). Such multivalued adhesion forces have been observed in a number of systems, including the interactions of fibers.

Measurements of oscillatory forces between different surfaces across both aqueous and nonaqueous liquids have revealed their richness of properties [18.118–121], for example, their great sensitivity to the shape and rigidity of the solvent molecules, to the presence of other components, and to the structure of the confining surfaces (see Sects. 18.5.3 and 18.9). In particular, the oscillations can be smeared out if the molecules are irregularly shaped (e.g., branched) and therefore unable to pack into ordered layers, or when the interacting surfaces are rough or fluid-like (see Sect. 18.4.6).

It is easy to understand how oscillatory forces arise between two flat, plane parallel surfaces. Between two curved surfaces, e.g., two spheres, one might imagine the molecular ordering and oscillatory forces to be smeared out in the same way that they are smeared out between two randomly rough surfaces (see Sect. 18.5.3); however, this is not the case. Ordering can occur so long as the curvature or roughness is itself regular or uniform, i. e., not random. This is due to the Derjaguin approximation (18.3). If the energy between two flat surfaces is given by a decaying oscillatory function (for example, a cosine function as in (18.16)), then the force (and energy) between two curved surfaces will also be an oscillatory function of distance with some phase shift. Likewise, two surfaces with regularly curved regions will also retain their oscillatory force profile, albeit modified, as long as the corrugations are truly regular, i. e., periodic. On the other hand, surface roughness, even on the nanometer scale, can smear out oscillations if the roughness is random and the confined molecules are smaller than the size of the surface asperities [18.122, 123]. If an organic liquid contains small amounts of water, the expected oscillatory force can be replaced by a strongly attractive capillary force (see Sect. 18.5.1).

18.4.4 Hydration and Hydrophobic Forces

The forces occurring in water and electrolyte solutions are more complex than those occurring in nonpolar liquids. According to continuum theories, the attractive van der Waals force is always expected to win over the repulsive electrostatic "double-layer" force at small surface separations (Fig. 18.6). However, certain surfaces (usually oxide or hydroxide surfaces such as clays or silica) swell spontaneously or repel each other in aqueous solution, even at high salt concentrations. Yet in all these systems one would expect the surfaces or particles to remain in strong adhesive contact or coagulate in a primary minimum if the only forces operating were DLVO forces.

There are many other aqueous systems in which the DLVO theory fails and where there is an additional short-range force that is not oscillatory but monotonic. Between hydrophilic surfaces this force is exponentially repulsive and is commonly referred to as the *hydration*, or *structural*, force. The origin and nature of this force has long been controversial, especially in the colloidal and biological literature. Repulsive hydration forces are believed to arise from strongly hydrogen-bonding surface groups, such as hydrated ions or hydroxyl (−OH) groups, which modify the hydrogen-bonding network of liquid water adjacent to them. Because this network is quite extensive in range [18.124], the resulting interaction force is also of relatively long range.

Repulsive hydration forces were first extensively studied between clay surfaces [18.125]. More recently, they have been measured in detail between mica and silica surfaces [18.20–22], where they have been found to decay exponentially with decay lengths of about 1 nm. Their effective range is about 3 to 5 nm, which is about twice the range of the oscillatory solvation force in water. Empirically, the hydration repulsion between two hydrophilic surfaces appears to follow the simple equation

$$E = E_0 \mathrm{e}^{-D/\lambda_0} \,, \qquad (18.17)$$

where $\lambda_0 \approx 0.6{-}1.1$ nm for 1:1 electrolytes and $E_0 = 3{-}30\,\mathrm{mJ\,m^{-2}}$ depending on the hydration (hydrophilicity) of the surfaces, higher E_0 values generally being associated with lower λ_0 values.

The interactions between molecularly smooth mica surfaces in dilute electrolyte solutions obey the DLVO theory (Fig. 18.7b). However, at higher salt concentrations, specific to each electrolyte, hydrated cations bind to the negatively charged surfaces and give rise to a repulsive hydration force [18.20, 21]. This is believed to be due to the energy needed to dehydrate the bound cations, which presumably retain some of their water of hydration on binding. This conclusion was arrived at after noting that the strength and range of the hydration forces increase with the known hydration numbers of the electrolyte cations in the order: $Mg^{2+} > Ca^{2+} > Li^{+} \sim Na^{+} > K^{+} > Cs^{+}$. Similar trends are observed with other negatively charged colloidal surfaces.

While the hydration force between two mica surfaces is overall repulsive below a distance of 4 nm, it is not always monotonic below about 1.5 nm but exhibits oscillations of mean periodicity of 0.25 ± 0.03 nm, roughly equal to the diameter of the water molecule. This is shown in the insert in Fig. 18.7b, where we may note that the first three minima at $D = 0$, 0.28, and 0.56 nm occur at negative energies, a result that rationalizes observations on certain colloidal systems. For example, clay platelets such as montmorillonite often repel each other increasingly strongly as they come closer together, but they are also known to stack into stable aggregates with water interlayers of typical thickness 0.25 and 0.55 nm between them [18.126, 127], suggestive of a turnabout in the force law from a monotonic repulsion to discretized attraction. In chemistry we would refer to such structures as stable hydrates of fixed stoichiometry, whereas in physics we may think of them as experiencing an oscillatory force.

Both surface force and clay swelling experiments have shown that hydration forces can be modified or "regulated" by exchanging ions of different hydration on surfaces, an effect that has important practical applications in controlling the stability of colloidal dispersions. It has long been known that colloidal particles can be precipitated (coagulated or flocculated) by increasing the electrolyte concentration, an effect that was traditionally attributed to the reduced screening of the electrostatic double-layer repulsion between the particles due to the reduced Debye length. However, there are many examples where colloids are stabilized at high salt concentrations, not at low concentrations. This effect is now recognized as being due to the increased hydration repulsion experienced by certain surfaces when they bind highly hydrated ions at higher salt concentrations. Hydration regulation of adhesion and interparticle forces is an important practical method for controlling various processes such as clay swelling [18.126, 127], ceramic processing and rheology [18.128, 129], material fracture [18.128], and colloidal particle and bubble coalescence [18.130].

Water appears to be unique in having a solvation (hydration) force that exhibits both a monotonic and an oscillatory component. Between hydrophilic surfaces the monotonic component is repulsive (Fig. 18.7b), but between hydrophobic surfaces it is attractive and the final adhesion is much greater than expected from the Lifshitz theory.

A hydrophobic surface is one that is inert to water in the sense that it cannot bind to water molecules via ionic or hydrogen bonds. Hydrocarbons and fluorocarbons are hydrophobic, as is air, and the strongly attractive hydrophobic force has many important manifestations and consequences such as the low solubility or miscibility of water and oil molecules, micellization, protein folding, strong adhesion and rapid coagulation of hydrophobic surfaces, non-wetting of water on hydrophobic surfaces, and hydrophobic particle attachment to rising air bubbles (the basic principle of froth flotation).

In recent years, there has been a steady accumulation of experimental data on the force laws between various hydrophobic surfaces in aqueous solution [18.131–143]. These studies have found that the hydrophobic force law between two macroscopic surfaces is of surprisingly long range, decaying exponentially with a characteristic decay length of 1 to 2 nm in the separation range of 0 to 10 nm, and then more gradually further out. The hydrophobic force can be far stronger than the van der Waals attraction, especially between hydrocarbon surfaces in water, for which the Hamaker constant is quite small. The magnitude of the hydrophobic attraction has been found to decrease with the decreasing hydrophobicity (increasing hydrophilicity) of lecithin lipid bilayer surfaces [18.31] and silanated surfaces [18.139], whereas examples of the opposite trend have been shown for some Langmuir–Blodgett-deposited monolayers [18.144].

For two surfaces in water the purely hydrophobic interaction energy (ignoring DLVO and oscillatory forces) in the range of 0 to 10 nm is given by

$$E = -2\gamma\, e^{-D/\lambda_0} , \tag{18.18}$$

where typically $\lambda_0 = 1$–2 nm, and $\gamma = 10$–$50\ \mathrm{mJ\,m^{-2}}$. The higher value corresponds to the interfacial energy of a pure hydrocarbon–water interface.

At a separation below 10 nm, the hydrophobic force appears to be insensitive or only weakly sensitive to changes in the type and concentration of electrolyte ions in the solution. The absence of a "screening" effect by ions attests to the non-electrostatic origin of this interaction. In contrast, some experiments have shown that at separations greater than 10 nm, the attraction does depend on the intervening electrolyte, and that in dilute solutions, or solutions containing divalent ions, it can continue to exceed the van der Waals attraction out to separations of 80 nm [18.136, 145].

The long-range nature of the hydrophobic interaction has a number of important consequences. It accounts for the rapid coagulation of hydrophobic particles in water and may also account for the rapid folding of proteins. It also explains the ease with which water films rupture on hydrophobic surfaces. In this case, the

van der Waals force across the water film is repulsive and therefore favors wetting, but this is more than offset by the attractive hydrophobic interaction acting between the two hydrophobic phases across water. Hydrophobic forces are increasingly being implicated in the adhesion and fusion of biological membranes and cells. It is known that both osmotic and electric field stresses enhance membrane fusion, an effect that may be due to the concomitant increase in the hydrophobic area exposed between two adjacent surfaces.

From the previous discussion we can infer that hydration and hydrophobic forces are not of a simple nature. These interactions are probably the most important, yet the least understood of all the forces in aqueous solutions. The unusual properties of water and the nature of the surfaces (including their homogeneity and stability) appear to be equally important. Some particle surfaces can have their hydration forces regulated, for example, by ion exchange. Others appear to be intrinsically hydrophilic (e.g., silica) and cannot be coagulated by changing the ionic condition, but can be rendered hydrophobic by chemically modifying their surface groups. For example, on heating silica to above 600 °C, two adjacent surface silanol (−OH) groups release a water molecule and form a hydrophobic siloxane (−O−) group, whence the repulsive hydration force changes into an attractive hydrophobic force.

How do these exponentially decaying repulsive or attractive forces arise? Theoretical work and computer simulations [18.109, 111, 146, 147] suggest that the solvation forces in water should be purely oscillatory, whereas other theoretical studies [18.148–153] suggest a monotonically exponential repulsion or attraction, possibly superimposed on an oscillatory force. The latter is consistent with experimental findings, as shown in the inset to Fig. 18.7b, where it appears that the oscillatory force is simply additive with the monotonic hydration and DLVO forces, suggesting that these arise from essentially different mechanisms.

It is probable that the short-range hydration force between all smooth, rigid, or crystalline surfaces (e.g., mineral surfaces such as mica) has an oscillatory component. This may or may not be superimposed on a monotonic force due to image interactions [18.150] and/or structural or hydrogen bonding interactions [18.148, 149].

Like the repulsive hydration force, the origin of the hydrophobic force is still unknown. *Luzar* et al. [18.152] carried out a Monte Carlo simulation of the interaction between two hydrophobic surfaces across water at separations below 1.5 nm. They obtained a decaying oscillatory force superimposed on a monotonically attractive curve. In more recent work [18.154, 155], it has been suggested that hydrophobic surfaces generate a depleted region of water around them, and that a long-range attractive force due to depletion arises between two such surfaces.

It is questionable whether the hydration or hydrophobic force should be viewed as an ordinary type of solvation or structural force that is reflecting the packing of water molecules. The energy (or entropy) associated with the hydrogen bonding network, which extends over a much larger region of space than the molecular correlations, is probably at the root of the long-range interactions of water. The situation in water appears to be governed by much more than the molecular packing effects that dominate the interactions in simpler liquids.

18.4.5 Polymer-Mediated Forces

Polymers or macromolecules are chain-like molecules consisting of many identical segments (monomers or repeating units) held together by covalent bonds. The size of a polymer coil in solution or in the melt is determined by a balance between van der Waals attraction (and hydrogen bonding, if present) between polymer segments, and the entropy of mixing, which causes the polymer coil to expand. In polymer melts above the glass transition temperature, and at certain conditions in solution, the attraction between polymer segments is exactly balanced by the entropy effect. The polymer solution will then behave virtually ideally, and the density distribution of segments in the coil is Gaussian. This is called the theta (θ) condition, and it occurs at the theta or Flory temperature for a particular combination of polymer and solvent or solvent mixture. At lower temperatures (in a poor or bad solvent), the polymer–polymer interactions dominate over the entropic, and the coil will shrink or precipitate. At higher temperatures (good solvent conditions), the polymer coil will be expanded.

High molecular weight polymers form large coils, which significantly affect the properties of a solution even when the total mass of polymer is very low. The radius of the polymer coil is proportional to the segment length, a, and the number of segments, n. At theta conditions, the hydrodynamic radius of the polymer coil (the root-mean-square separation of the ends of one polymer chain) is theoretically given by $R_{\mathrm{h}} = a\,n^{1/2}$, and the unperturbed radius of gyration (the average root-mean-square distance of a segment from the center of mass of the molecule) is $R_{\mathrm{g}} = a\ (n/6)^{1/2}$. In a good sol-

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

vent the perturbed size of the polymer coil, the Flory radius R_F, is proportional to $n^{3/5}$.

Polymers interact with surfaces mainly through van der Waals and electrostatic interactions. The physisorption of polymers containing only one type of segment is reversible and highly dynamic, but the rate of exchange of adsorbed chains with free chains in the solution is low, since the polymer remains bound to the surface as long as one segment along the chain is adsorbed. The adsorption energy per segment is on the order of $k_B T$. In a good solvent, the conformation of a polymer on a surface is very different from the coil conformation in bulk solution. Polymers adsorb in "trains", separated by "loops" extending into solution and dangling "tails" (the ends of the chain). Compared to adsorption at lower temperatures, good solvent conditions favor more of the polymer chain being in the solvent, where it can attain its optimum conformation. As a result, the extension of the polymer is longer, even though the total amount of adsorbed polymer is lower. In a good solvent, the polymer chains can also be effectively repelled from a surface, if the loss in conformational entropy close to the surface is not compensated for by a gain in enthalpy from adsorption of segments. In this case, there will be a layer of solution (thickness $\approx R_g$) close to the surfaces that is depleted of polymer.

The interaction forces between two surfaces across a polymer solution will depend on whether the polymer is adsorbing onto the surfaces or is repelled from them, and also on whether the interaction occurs at "true" or "restricted" thermodynamic equilibrium. At true or full equilibrium, the polymer between the surfaces can equilibrate (exchange) with polymer in the bulk solution at all surface separations. Some theories [18.156, 157] predict that at full equilibrium, the polymer chains would move from the confined gap into the bulk solution where they could attain entropically more favorable conformations, and that a monotonic attraction at all distances would result from bridging and depletion interactions (which will be discussed below). Other theories suggest that the interaction at small separations would be ultimately repulsive, since some polymer chains would remain in the gap due to their attractive interactions with many sites on the surface (enthalpic) – more sites would be available to the remaining polymer chains if some others desorbed and diffused out from the gap [18.64, 158, 159].

At restricted equilibrium, the polymer is kinetically trapped, and the adsorbed amount is thus constant as the surfaces are brought toward each other, but the chains can still rearrange on the surfaces and in the gap. Experimentally, the true equilibrium situation is very difficult to attain, and most experiments are done at restricted equilibrium conditions. Even the equilibration of conformations assumed in theoretical models for restricted equilibrium conditions can be so slow that this condition is difficult to reach.

In systems of adsorbing polymer, bridging of chains from one surface to the other can give rise to a long-range attraction, since the bridging chains would gain conformational entropy if the surfaces were closer together. In poor solvents, both bridging and intersegment interactions contribute to an attraction [18.26]. However, regardless of solvent and equilibrium conditions, a strong repulsion due to the osmotic interactions is seen as small surface separations in systems of adsorbing polymers at restricted equilibrium.

In systems containing high concentrations of non-adsorbing polymer, the difference in solute concentration in the bulk and between the surfaces at separations smaller than the approximate polymer coil diameter ($2R_g$, i. e., when the polymer has been squeezed out from the gap between the surfaces) may give rise to an attractive osmotic force ("depletion attraction") [18.160–164]. In addition, if the polymer coils become initially compressed as the surfaces approach each other, this can give rise to a repulsion ("depletion stabilization") at large separations [18.163]. For a system of two cylindrical surfaces or radius R, the maximum depletion force, F_{dep}, is expected to occur when the surfaces are in contact and is given by multiplying the depletion (osmotic) pressure, $P_{dep} = \rho k_B T$, by the contact area πr^2, where r is given by the chord theorem: $r^2 = (2R - R_g)R_g \approx 2RR_g$ [18.3]:

$$F_{dep}/R = -2\pi R_g \rho k_B T \;, \qquad (18.19)$$

where ρ is the number density of the polymer in the bulk solution.

If a part of the polymer (typically an end group) is different from the rest of the chain, this part may preferentially adsorb to the surface. End-adsorbed polymer is attached to the surface at only one point, and the extension of the chain is dependent on the grafting density, i. e., the average distance, s, between adsorbed end groups on the surface (Fig. 18.8). One distinguishes between different regions of increasing overlap of the chains (stretching) called pancake, mushroom, and brush regimes [18.165]. In the mushroom regime, where the coverage is sufficiently low so that there is no overlap between neighboring chains, the thickness of the adsorbed layer is proportional to $n^{1/2}$ (i. e., to R_g) at theta conditions and to $n^{3/5}$ in a good solvent.

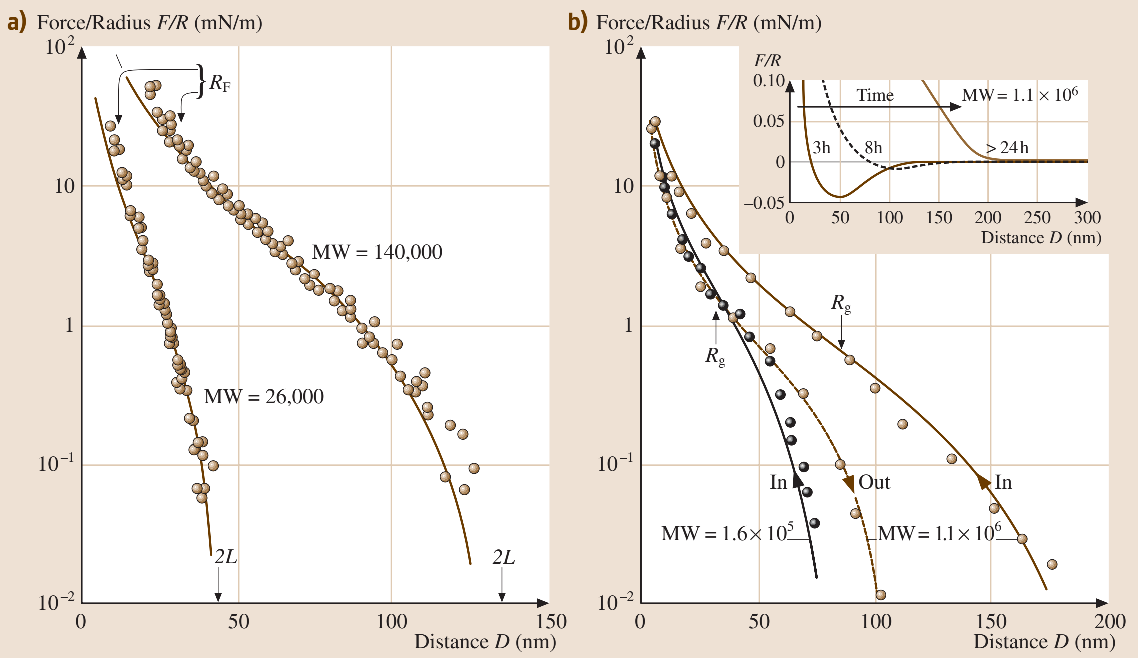

Fig. 18.8a,b Experimentally determined forces in systems of two interacting polymer brushes: **(a)** Polystyrene brush layers grafted via an adsorbing chain-end group onto mica surfaces in toluene (a good solvent for polystyrene). *Left curve:* MW = 26,000 g/mol, $R_F = 12$ nm. *Right curve*: MW = 140,000 g/mol, $R_F = 32$ nm. Both force curves were reversible on approach and separation. The *solid curves* are theoretical fits using the Alexander–de Gennes theory with the following measured parameters: spacing between attachments sites: $s = 8.5$ nm, brush thickness: $L = 22.5$ nm and 65 nm, respectively. (Adapted from [18.171]). **(b)** Polyethylene oxide layers physisorbed onto mica from 150 μg/ml solution in aqueous 0.1 M KNO_3 (a good solvent for polyethylene oxide). *Main figure:* Equilibrium forces at full coverage after ∼ 16 h adsorption time. *Left curve:* MW = 160,000 g/mol, $R_g = 32$ nm. *Right curve:* MW = 1,100,000 g/mol, $R_g = 86$ nm. Note the hysteresis (irreversibility) on approach and separation for this *physisorbed* layer, in contrast to the absence of hysteresis with *grafted* chains in case **(a)**. The *solid curves* are based on a modified form of the Alexander–de Gennes theory. *Inset* in **(b)**: Evolution of the forces with the time allowed for the higher MW polymer to adsorb from solution. Note the gradual reduction in the attractive bridging component. (Adapted from [18.172–174]. After [18.3]. Copyright 1991, with permission from Elsevier Science)

Several models [18.165–170] have been developed for the extension and interactions between two brushes (strongly stretched grafted chains). They are based on a balance between osmotic pressure within the brush layers (uncompressed and compressed) and elastic energy of the chains and differ mainly in the assumptions of the segment density profile, which can be a step function or parabolic. At high coverage (in the brush regime),where the chains will avoid overlapping each other, the thickness of the layer is proportional to n.

Experimental work on both monodisperse [18.27, 28, 171, 175] and polydisperse [18.30] systems at different solvent conditions has confirmed the expected range and magnitude of the repulsive interactions resulting from compression of densely packed grafted layers.

18.4.6 Thermal Fluctuation Forces

If a surface is not rigid but very soft or even fluid-like, this can act to smear out any oscillatory solvation force. This is because the thermal fluctuations of such interfaces make them dynamically "rough" at any instant, even though they may be perfectly smooth on a time average. The types of surfaces that fall into this category are fluid-like amphiphilic surfaces of micelles, bilayers, emulsions, soap films, etc., but also solid colloidal par-

ticle surfaces that are coated with surfactant monolayers, as occurs in lubricating oils, paints, toners, etc.

These thermal fluctuation forces (also called entropic or steric forces) are usually short-range and repulsive and are very effective at stabilizing the attractive van der Waals forces at some small but finite separation. This can reduce the adhesion energy or force by up to three orders of magnitude. It is mainly for this reason that fluid-like micelles and bilayers, biological membranes, emulsion droplets, or gas bubbles adhere to each other only very weakly.

Because of their short range it was, and still is, commonly believed that these forces arise from water ordering or "structuring" effects at surfaces, and that they reflect some unique or characteristic property of water. However, it is now known that these repulsive forces also exist in other liquids. Moreover, they appear to become stronger with increasing temperature, which is unlikely if the force would originate from molecular ordering effects at surfaces. Recent experiments, theory, and computer simulations [18.176–178] have shown that these repulsive forces have an entropic origin arising from the osmotic repulsion between exposed thermally mobile surface groups once these overlap in a liquid. These phenomena include undulating and peristaltic forces between membranes or bilayers, and, on the molecular scale, protrusion and head group overlap forces where the interactions also are influenced by hydration forces.

18.5 Adhesion and Capillary Forces

18.5.1 Capillary Forces

When considering the adhesion of two solid surfaces or particles in air or in a liquid, it is easy to overlook or underestimate the important role of capillary forces, i.e., forces arising from the Laplace pressure of curved menisci formed by condensation of a liquid between and around two adhering surfaces (Fig. 18.9).

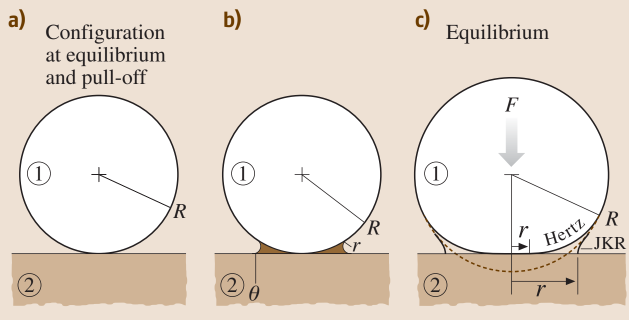

Fig. 18.9a–c Adhesion and capillary forces: **(a)** a non-deforming sphere on a rigid, flat surface in an inert atmosphere and **(b)** in a vapor that can "capillary condense" around the contact zone. At equilibrium, the concave radius, r, of the liquid meniscus is given by the Kelvin equation. For a concave meniscus to form, the contact angle θ has to be less than 90°. In the case of hydrophobic surfaces surrounded by water, a vapor cavity can form between the surfaces. As long as the surfaces are perfectly smooth, the contribution of the meniscus to the adhesion force is independent of r. (After [18.1] with permission.) **(c)** Elastically deformable sphere on a rigid flat surface in the absence (Hertz) and presence (JKR) of adhesion [**(a)** and **(c)** after [18.3]. The adhesion force between a non-deformable spherical particle of radius R and a flat surface in an inert atmosphere (Fig. 18.9a) is

$$F_s = 4\pi R \gamma_{SV} \,. \tag{18.20}$$

But in an atmosphere containing a condensable vapor, the expression above is replaced by

$$F_s = 4\pi R(\gamma_{LV} \cos\theta + \gamma_{SL}) \,, \tag{18.21}$$

where the first term is due to the Laplace pressure of the meniscus and the second is due to the direct adhesion of the two contacting solids within the liquid. Note that the above equation does not contain the radius of curvature, r, of the liquid meniscus (see Fig. 18.9b). This is because for smaller r the Laplace pressure γ_{LV}/r increases, but the area over which it acts decreases by the same amount, so the two effects cancel out. Experiments with inert liquids, such as hydrocarbons, condensing between two mica surfaces indicate that (18.21) is valid for values of r as small as 1–2 nm, corresponding to vapor pressures as low as 40% of saturation [18.121, 179, 180]. Capillary condensation also occurs in binary liquid systems, e.g., when water dissolved in hydrocarbon liquids condense around two contacting hydrophilic surfaces or when a vapor cavity forms in water around two hydrophobic surfaces. In the case of water condensing from vapor or from oil, it also appears that the bulk value of γ_{LV} is applicable for meniscus radii as small as 2 nm.

The capillary condensation of liquids, especially water, from vapor can have additional effects on the

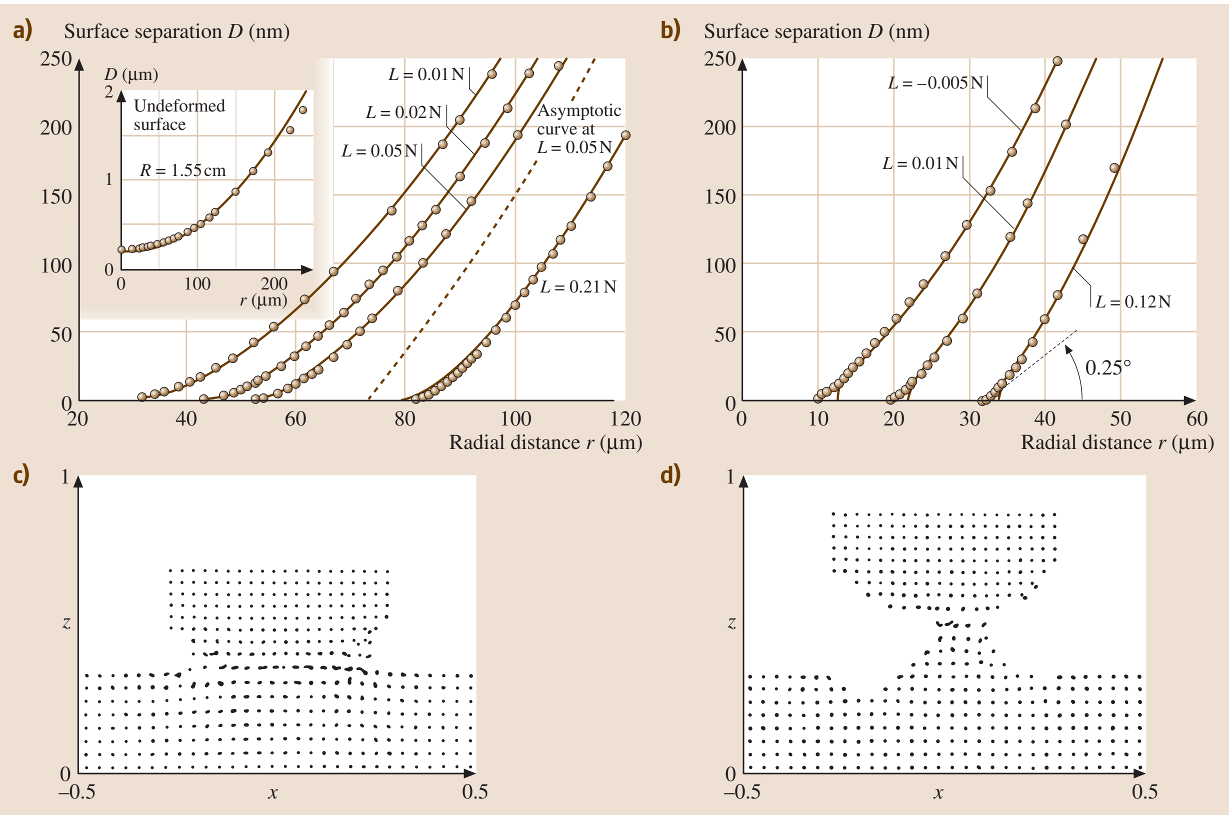

Fig. 18.10a–d Experimental and computer simulation data on contact mechanics for ideal Hertz and JKR contacts. **(a)** Measured profiles of surfaces in nonadhesive contact (*circles*) compared with Hertz profiles (*continuous curves*). The system was mica surfaces in a concentrated KCl solution in which they do not adhere. When not in contact, the surface shape is accurately described by a sphere of radius $R = 1.55$ cm (*inset*). The applied loads were 0.01, 0.02, 0.05, and 0.21 N. The last profile was measured in a different region of the surfaces where the local radius of curvature was 1.45 cm. The Hertz profiles correspond to central displacements of $\delta = 66.5$, 124, 173, and 441 nm. The *dashed line* shows the shape of the undeformed sphere corresponding to the curve at a load of 0.05 N; it fits the experimental points at larger distances (not shown). **(b)** Surface profiles measured with adhesive contact (mica surfaces adhering in dry nitrogen gas) at applied loads of -0.005, 0.01, and 0.12 N. The continuous lines are JKR profiles obtained by adjusting the central displacement in each case to get the best fit to points at larger distances. The values are $\delta = -4.2$, 75.6, and 256 nm. Note that the scales of this figure exaggerate the apparent angle at the junction of the surfaces. This angle, which is insensitive to load, is only about 0.25°. **(c)** and **(d)** Molecular dynamics simulation illustrating the formation of a connective neck between an Ni tip (topmost eight layers) and an Au substrate. The figures show the atomic configuration in a slice through the system at indentation **(c)** and during separation **(d)**. Note the crystalline structure of the neck. Distances are given in units of x and z, where $x = 1$ and $z = 1$ correspond to 6.12 nm. [**(a)** and **(b)** after [18.181]. physical state of the contact zone. For example, if the surfaces contain ions, these will diffuse and build up within the liquid bridge, thereby changing the chemical composition of the contact zone, as well as influencing the adhesion. In the case of surfaces covered with surfactant or polymer molecules (amphiphilic surfaces), the molecules can overturn on exposure to humid air, so that the surface nonpolar groups become replaced by polar groups, which renders the surfaces hydrophilic. When two such surfaces come into contact, water will condense around the contact zone and the adhesion force will also be affected – generally increasing well above

the value expected for inert hydrophobic surfaces. It is apparent that the adhesion in vapor or a solvent is often largely determined by capillary forces arising from the condensation of liquid that may be present only in very small quantities, e.g., 10–20 % of saturation in the vapor, or 20 ppm in the solvent.

18.5.2 Adhesion Mechanics

Two bodies in contact deform as a result of surface forces and/or applied normal forces. For the simplest case of two interacting elastic spheres (a model that is easily extended to an elastic sphere interacting with an undeformable surface (or vice versa)) and in the absence of attractive surface forces, the vertical central displacement (compression) was derived by *Hertz* [18.182]. In this model, the displacement and the contact area are equal to zero when no external force (load) is applied, i. e., at the points of contact and of separation.

In systems where attractive surface forces are present between the surfaces, the deformations are more complicated. Modern theories of the adhesion mechanics of two contacting solid surfaces are based on the Johnson–Kendall–Roberts (JKR) theory [18.15, 183], or on the Derjaguin–Muller–Toporov (DMT) theory [18.184–186]. The JKR theory is applicable to easily deformable, large bodies with high surface energy, whereas the DMT theory better describes very small and hard bodies with low surface energy [18.187].

In the JKR theory, two spheres of radii R_1 and R_2, bulk elastic modulus K, and surface energy γ will flatten due to attractive surface forces when in contact at no external load. The contact area will increase under an external load or normal force F, such that at mechanical equilibrium the radius of the contact area, r, is given by

$$r^3 = \frac{R}{K}\left[F + 6\pi R\gamma + \sqrt{12\pi R\gamma F + (6\pi R\gamma)^2}\right] , \qquad (18.22)$$

where $R = R_1 R_2/(R_1 + R_2)$. In the absence of surface energy, γ, equation (18.22) is reduced to the expression for the radius of the contact area in the Hertz model. Another important result of the JKR theory gives the adhesion force or "pull-off" force:

$$F_S = -3\pi R\gamma_S , \qquad (18.23)$$

where the surface energy, γ_S, is defined as $W = 2\gamma_S$, where W is the reversible work of adhesion. Note that according to the JKR theory a finite elastic modulus, K, while having an effect on the load–area curve, has no effect on the adhesion force, an interesting and unexpected result that has nevertheless been verified experimentally [18.15, 181, 188, 189].

Equation (18.22) and (18.23) provide the framework for analyzing results of adhesion measurements of contacting solids, known as contact mechanics [18.183, 190], and for studying the effects of surface conditions and time on adhesion energy hysteresis (see Sect. 18.5.4).

18.5.3 Effects of Surface Structure, Roughness, and Lattice Mismatch

In a contact between two rough surfaces, the real area of contact varies with the applied load in a different manner than between smooth surfaces [18.191, 192]. For a Hertzian contact, it has been shown that the contact area for rough surfaces increases approximately linearly with the applied normal force (load), F, instead of as $F^{2/3}$ for smooth surfaces. In systems with attractive surface forces, there is a competition between this attraction and repulsive forces arising from compression of high asperities. As a result, the adhesion in such systems can be very low, especially if the surfaces are not easily deformed [18.193–195]. The opposite is possible for soft (viscoelastic) surfaces where the real (molecular) contact area might be larger than for two perfectly smooth surfaces.

Adhesion forces may also vary depending on the commensurability of the crystallographic lattices of the interacting surfaces. *McGuiggan* and *Israelachvili* [18.196] measured the adhesion between two mica surfaces as a function of the orientation (twist angle) of their surface lattices. The forces were measured in air, water, and an aqueous salt solution where oscillatory structural forces were present. In humid air, the adhesion was found to be relatively independent of the twist angle θ due to the adsorption of a 0.4-nm-thick amorphous layer of organics and water at the interface. In contrast, in water, sharp adhesion peaks (energy minima) occurred at $\theta = 0°, \pm 60°, \pm 120°$ and 180°, corresponding to the "coincidence" angles of the surface lattices (Fig. 18.11). As little as $\pm 1°$ away from these peaks, the energy decreased by 50%. In aqueous KCl solution, due to potassium ion adsorption the water between the surfaces becomes ordered, resulting in an oscillatory force profile where the adhesive minima occur at discrete separations of about 0.25 nm, corresponding to integral numbers of water layers. The whole interaction potential was now found to depend on the orientation of

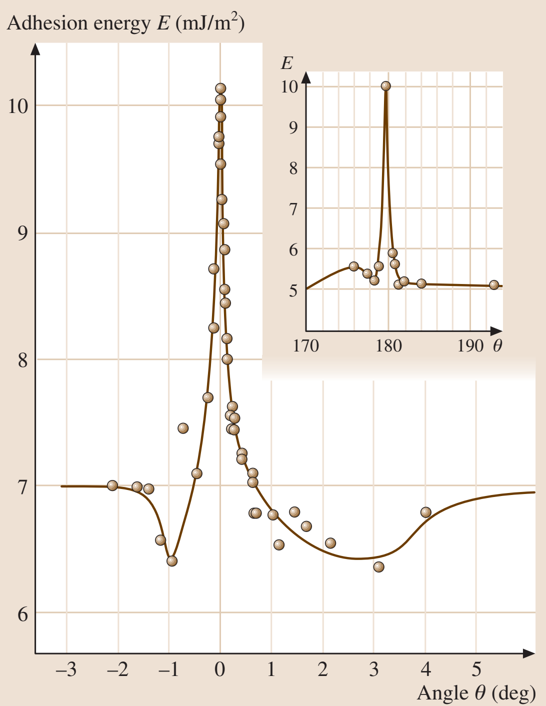

Fig. 18.11 Adhesion energy for two mica surfaces in contact in water (in the primary minimum of an oscillatory force curve) as a function of the mismatch angle θ about $\theta = 0°$ and 180° between the mica surface lattices. (After [18.197] with permission)

the surface lattices, and the effect extended at least four molecular layers.

It has also been appreciated that the structure of the confining surfaces is just as important as the nature of the liquid for determining the solvation forces [18.90, 122, 123, 198–202]. Between two surfaces that are completely flat but "unstructured", the liquid molecules will order into layers, but there will be no lateral ordering within the layers. In other words, there will be positional ordering normal but not parallel to the surfaces. If the surfaces have a crystalline (periodic) lattice, this may induce ordering parallel to the surfaces, as well, and the oscillatory force then also depends on the structure of the surface lattices. Further, if the two lattices have different dimensions ("mismatched" or "incommensurate" lattices), or if the lattices are similar but are not in register relative to each other, the oscillatory force law is further modified [18.196, 203] and the tribological properties of the film are also influenced, as discussed in Sect. 18.9 [18.203, 204].

As shown by the experiments, these effects can alter the magnitude of the adhesive minima found at a given separation within the last one or two nanometers of a thin film by a factor of two. The force barriers (maxima) may also depend on orientation. This could be even more important than the effects on the minima. A high barrier could prevent two surfaces from coming closer together into a much deeper adhesive well. Thus the maxima can effectively contribute to determining not only the final separation of two surfaces, but also their final adhesion. Such considerations should be particularly important for determining the thickness and strength of intergranular spaces in ceramics, the adhesion forces between colloidal particles in concentrated electrolyte solution, and the forces between two surfaces in a crack containing capillary condensed water.

For surfaces that are *randomly* rough, oscillatory forces become smoothed out and disappear altogether, to be replaced by a purely monotonic solvation force [18.116, 122, 123]. This occurs even if the liquid molecules themselves are perfectly capable of ordering into layers. The situation of *symmetric* liquid molecules confined between *rough* surfaces is therefore not unlike that of *asymmetric* molecules between *smooth* surfaces (see Sect. 18.4.3 and Fig. 18.7a). To summarize, for there to be an oscillatory solvation force, the liquid molecules must be able to be correlated over a reasonably long range. This requires that both the liquid molecules and the surfaces have a high degree of order or symmetry. If either is missing, so will the oscillations. A roughness of only a few tenths of a nanometer is often sufficient to eliminate any oscillatory component of the force law.

18.5.4 Nonequilibrium and Rate-Dependent Interactions: Adhesion Hysteresis

Under ideal conditions the adhesion energy is a well-defined thermodynamic quantity. It is normally denoted by E or W (the work of adhesion) or γ (the surface tension, where $W = 2\gamma$) and gives the reversible work done on bringing two surfaces together or the work needed to separate two surfaces from contact. Under ideal, equilibrium conditions these two quantities are the same, but under most realistic conditions they are not: The work needed to separate two surfaces is always greater than that originally gained by bringing them together. An understanding of the molecular mechanisms underlying this phenomenon is essential for understanding many adhesion phenomena, energy dissipation during loading–unloading cycles, contact angle hysteresis, and

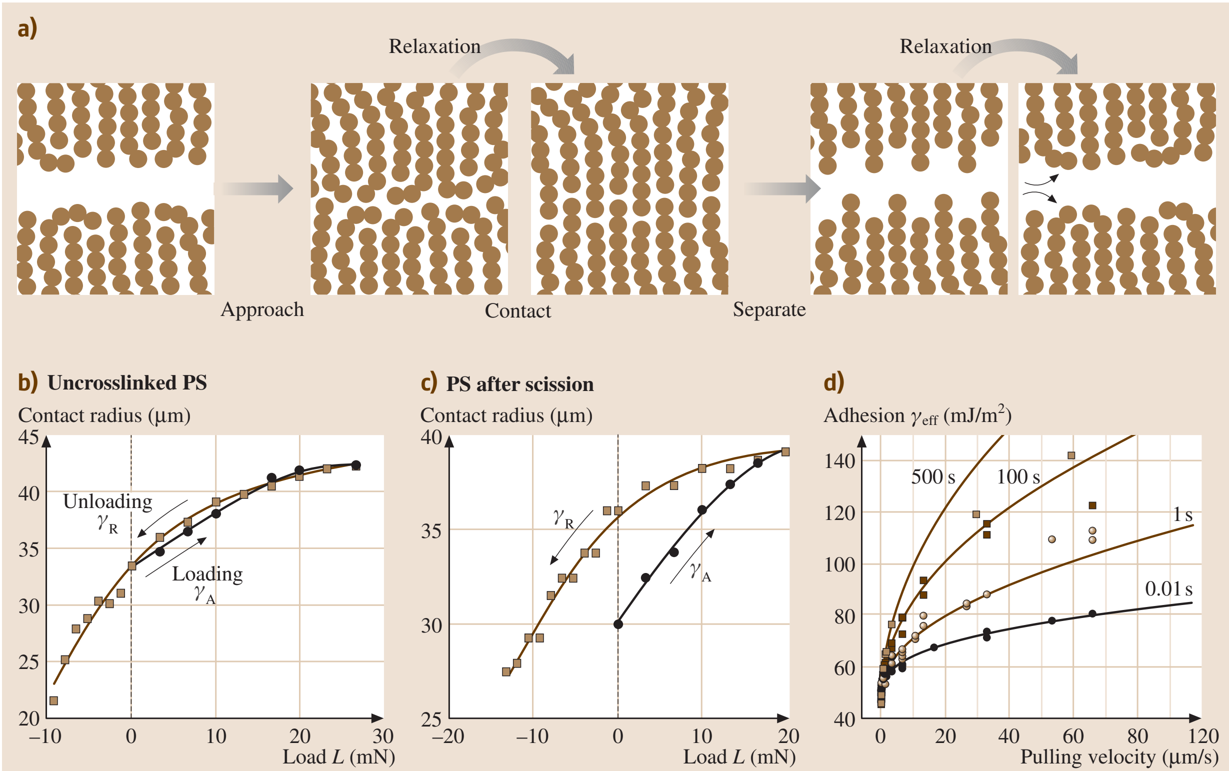

Fig. 18.12 **(a)** Schematic representation of interpenetrating chains. **(b)** and **(c)**: JKR plots (contact radius r as a function of applied load L) showing small adhesion hysteresis for uncrosslinked polystyrene and larger adhesion hysteresis after chain scission at the surfaces after 18 h irradiation with ultraviolet light in an oxygen atmosphere. The adhesion hysteresis continues to increase with the irradiation time. **(d)** Rate-dependent adhesion of CTAB surfactant monolayers. The *solid curves* [18.205] are fits to experimental data on CTAB adhesion after different contact times [18.206] using an approximate analytical solution for a JKR model, including crack tip dissipation. Due to the limited range of validity of the approximation, the fits rely on the low effective adhesion energy part of the experimental data only. From the fits one can determine the thermodynamic adhesion energy, the characteristic dissipation velocity, and the intrinsic dissipation exponent of the model. [**(a)** after [18.207]. the molecular mechanisms associated with many frictional processes.

It is wrong to think that hysteresis arises because of some imperfection in the system such as rough or chemically heterogeneous surfaces, or because the supporting material is viscoelastic. Adhesion hysteresis can arise even between perfectly smooth and chemically homogenous surfaces supported by perfectly elastic materials. It can be responsible for such phenomena as rolling friction and elastoplastic adhesive contacts [18.190, 209–212] during loading–unloading and adhesion–decohesion cycles.

Adhesion hysteresis may be thought of as being due to mechanical effects such as instabilities, or chemical effects such as interdiffusion, interdigitation, molecular reorientations and exchange processes occurring at an interface after contact, as illustrated in Fig. 18.12. Such processes induce roughness and chemical heterogeneity even though initially (and after separation and re-equilibration) both surfaces are perfectly smooth and chemically homogeneous. In general, if the energy change, or work done, on separating two surfaces from adhesive contact is not fully recoverable on bringing the two surfaces back into contact again, the adhesion

hysteresis may be expressed as

$$\underset{\text{Receding}}{W_R} > \underset{\text{Advancing}}{W_A}$$

or

$$\Delta W = (W_R - W_A) > 0 , \quad (18.24)$$

where W_R and W_A are the adhesion or surface energies for receding (separating) and advancing (approaching) two solid surfaces, respectively.

Hysteresis effects are also commonly observed in wetting/dewetting phenomena [18.213]. For example, when a liquid spreads and then retracts from a surface the advancing contact angle θ_A is generally larger than the receding angle θ_R. Since the contact angle, θ, is related to the liquid–vapor surface tension, γ_L, and the solid–liquid adhesion energy, W, by the Dupré equation,

$$(1 + \cos\theta)\gamma_L = W , \quad (18.25)$$

we see that *wetting hysteresis* or *contact angle hysteresis* ($\theta_A > \theta_R$) actually implies adhesion hysteresis, $W_R > W_A$, as given by (18.24).

Energy dissipating processes such as adhesion and contact angle hysteresis arise because of practical constraints of the *finite time* of measurements and the *finite elasticity* of materials. This prevents many loading–unloading or approach–separation cycles from being thermodynamically reversible, even though if carried out infinitely slowly they would be. By thermodynamically irreversible one simply means that one cannot go through the approach–separation cycle via a continuous series of equilibrium states, because some of these are connected via spontaneous – and therefore thermodynamically irreversible – instabilities or transitions where energy is liberated and therefore "lost" via heat or phonon release [18.214]. This is an area of much current interest and activity, especially regarding the fundamental molecular origins of adhesion and friction in polymer and surfactant systems, and the relationships between them [18.190, 205, 206, 208, 210, 215–218].

18.6 Introduction: Different Modes of Friction and the Limits of Continuum Models

Most frictional processes occur with the sliding surfaces becoming damaged in one form or another [18.209]. This may be referred to as "normal" friction. In the case of brittle materials, the damaged surfaces slide past each other while separated by relatively large, micron-sized wear particles. With more ductile surfaces, the damage remains localized to nanometer-sized, plastically deformed asperities. Some features of the friction between damaged surfaces will be described in Sect. 18.7.4.

There are also situations in which sliding can occur between two perfectly smooth, undamaged surfaces. This may be referred to as "interfacial" sliding or

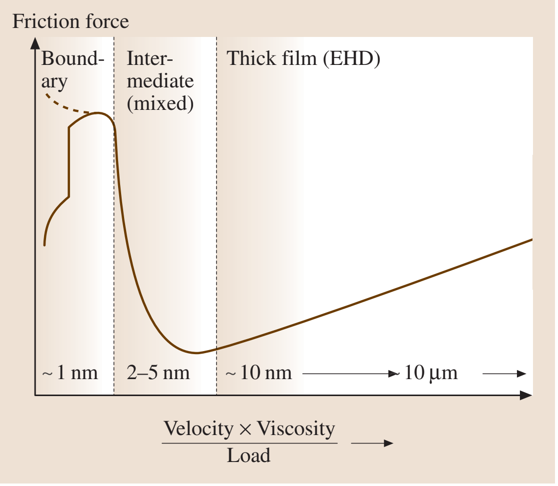

Fig. 18.13 Stribeck curve: an empirical curve giving the trend generally observed in the friction forces or friction coefficients as a function of sliding velocity, the bulk viscosity of the lubricating fluid, and the applied load. The three friction/lubrication regimes are known as the boundary lubrication regime (see Sect. 18.7), the intermediate or mixed lubrication regime (Sect. 18.8.2), and thick film or elastohydrodynamic (EHD) lubrication regime (Sect. 18.8.1). The film thicknesses believed to correspond to each of these regimes are also shown. For thick films, the "friction" force is purely viscous, e.g., Couette flow at low shear rates, but may become complicated at higher shear rates where EHD deformations of surfaces can occur during sliding. (After [18.1] with permission)

Table 18.4 The three main tribological regimes characterizing the changing properties of liquids subjected to an increasing confinement between two solid surfaces[a]

Regime	Conditions for getting into this regime	Static/equilibrium properties[b]	Dynamic properties[c]
Bulk	• Thick films (> 10 molecular diameters, $\gg R_g$ for polymers) • Low or zero loads • High shear rates	Bulk (continuum) properties: • Bulk liquid density • No long-range order	Bulk (continuum) properties: • Newtonian viscosity • Fast relaxation times • No glass temperature • No yield point • Elastohydrodynamic lubrication
Intermediate mixed	• Intermediately thick films (4–10 molecular diameters, $\sim R_g$ for polymers) • Low loads or pressure	Modified fluid properties include: • Modified positional and orientational order[a] • Medium to long-range molecular correlations • Highly entangled states	Modified rheological properties include: • Non-Newtonian flow • Glassy states • Long relaxation times • Mixed lubrication
Boundary	• Molecularly thin films (< 4 molecular diameters) • High loads or pressure • Low shear rates • Smooth surfaces or asperities	Onset of non-fluidlike properties: • Liquid-like to solid-like phase transitions • Appearance of new liquid-crystalline states • Epitaxially induced long-range ordering	Onset of tribological properties: • No flow until yield point or critical shear stress reached • Solid-like film behavior characterized by defect diffusion, dislocation motion, shear melting • Boundary lubrication

Based on work by *Granick* [18.219], *Hu* and *Granick* [18.220], and others [18.38, 207, 221] on the dynamic properties of short chain molecules such as alkanes and polymer melts confined between surfaces

[a] Confinement can lead to an increased or decreased order in a film, depending both on the surface lattice structure and the geometry of the confining cavity

[b] In each regime both the static and dynamic properties change. The static properties include the film density, the density distribution function, the potential of mean force, and various positional and orientational order parameters

[c] Dynamic properties include viscosity, viscoelastic constants, and tribological yield points such as the friction coefficient and critical shear stress

"boundary" friction and is the focus of the following sections. The term "boundary lubrication" is more commonly used to denote the friction of surfaces that contain a thin protective lubricating layer such as a surfactant monolayer, but here we shall use the term more broadly to include any molecularly thin solid, liquid, surfactant, or polymer film.

Experiments have shown that as a liquid film becomes progressively thinner, its physical properties change, at first quantitatively and then qualitatively [18.44, 47, 219, 220, 222, 223]. The quantitative changes are manifested by an increased viscosity, non-Newtonian flow behavior, and the replacement of normal melting by a glass transition, but the film remains recognizable as a liquid (Fig. 18.13). In tribology, this regime is commonly known as the "mixed lubrication" regime, where the rheological properties of a film are intermediate between the bulk and boundary properties. One may also refer to it as the "intermediate" regime (Table 18.4).

For even thinner films, the changes in behavior are more dramatic, resulting in a qualitative change in properties. Thus first-order phase transitions can now occur to solid or liquid-crystalline phases [18.46,201,207,221, 224–227], whose properties can no longer be characterized even qualitatively in terms of bulk or continuum liquid properties such as viscosity. These films now exhibit yield points (characteristic of fracture in solids) and their molecular diffusion and relaxation times can be ten orders of magnitude longer than in the bulk liquid or even in films that are just slightly thicker. The three friction regimes are summarized in Table 18.4.

18.7 Relationship Between Adhesion and Friction Between Dry (Unlubricated and Solid Boundary Lubricated) Surfaces

18.7.1 Amontons' Law and Deviations from It Due to Adhesion: The Cobblestone Model

Early theories and mechanisms for the dependence of friction on the applied normal force or load, L, were developed by *da Vinci*, *Amontons*, *Coulomb* and *Euler* [18.228]. For the macroscopic objects investigated, the friction was found to be directly proportional to the load, with no dependence on the contact area. This is described by the so-called Amontons' law:

$$F = \mu L \;, \tag{18.26}$$

where F is the shear or friction force and μ is a constant defined as the coefficient of friction. This friction law has a broad range of applicability and is still the principal means of quantitatively describing the friction between surfaces. However, particularly in the case of adhering surfaces, Amontons' law does not adequately describe the friction behavior with load, because of the finite friction force measured at zero and even negative applied loads.

When a lateral force, or shear stress, is applied to two surfaces in adhesive contact, the surfaces initially remain "pinned" to each other until some critical shear force is reached. At this point, the surfaces begin to slide past each other either smoothly or in jerks. The frictional force needed to initiate sliding from rest is known as the *static* friction force, denoted by F_s, while the force needed to maintain smooth sliding is referred to as the *kinetic* or *dynamic* friction force, denoted by F_k. In general, $F_s > F_k$. Two sliding surfaces may also move in regular jerks, known as stick–slip sliding, which is discussed in more detail in Sect. 18.8.3. Such friction forces cannot be described by models used for thick films that are viscous (see Sect. 18.8.1) and, therefore, shear as soon as the smallest shear force is applied.

Experimentally, it has been found that during both smooth and stick–slip sliding the local geometry of the contact zone remains largely unchanged from the static geometry. In an adhesive contact, the contact area as a function of load is thus generally well described by the JKR equation, (18.22). The friction force between two molecularly smooth surfaces sliding in adhesive contact is not simply proportional to the applied load, L, as might be expected from Amontons' law. There is an additional adhesion contribution that is proportional to the area of contact, A. Thus, in general, the interfacial friction force of dry, unlubricated surfaces sliding smoothly past each other in adhesive contact is given by

$$F = F_k = S_c A + \mu L \;, \tag{18.27}$$

where S_c is the "critical shear stress" (assumed to be constant), $A = \pi r^2$ is the contact area of radius r given by (18.22), and μ is the coefficient of friction. For low loads we have:

$$\begin{aligned} F &= S_c A = S_c \pi r^2 \\ &= S_c \pi \left[\frac{R}{K} \left(L + 6\pi R\gamma + \sqrt{12\pi R\gamma L + (6\pi R\gamma)^2} \right) \right]^{2/3} ; \end{aligned} \tag{18.28}$$

whereas for high loads (or high μ), (18.27) reduces to Amontons' law: $F = \mu L$. Depending on whether the friction force in (18.27) is dominated by the first or second term, one may refer to the friction as *adhesion-controlled* or *load-controlled*, respectively.

The following friction model, first proposed by *Tabor* [18.229] and developed further by *Sutcliffe* et al. [18.230], *McClelland* [18.231], and *Homola* et al. [18.45], has been quite successful at explaining the interfacial and boundary friction of two solid crystalline surfaces sliding past each other in the absence of wear. The surfaces may be unlubricated, or they may be

separated by a monolayer or more of some boundary lubricant or liquid molecules. In this model, the values of the critical shear stress S_c, and coefficient of friction μ, of (18.27) are calculated in terms of the energy needed to overcome the attractive intermolecular forces and compressive externally applied load as one surface is raised and then slid across the molecular-sized asperities of the other.

This model (variously referred to as the *interlocking asperity model*, *Coulomb friction*, or the *cobblestone model*) is similar to pushing a cart over a road of cobblestones where the cartwheels (which represent the molecules of the upper surface or film) must be made to roll over the cobblestones (representing the molecules of the lower surface) before the cart can move. In the case of the cart, the downward force of gravity replaces the attractive intermolecular forces between two material surfaces. When at rest, the cartwheels find grooves between the cobblestones where they sit in potential energy minima, and so the cart is at some stable mechanical equilibrium. A certain lateral force (the "push") is required to raise the cartwheels against the force of gravity in order to initiate motion. Motion will continue as long as the cart is pushed, and rapidly stops once it is no longer pushed. Energy is dissipated by the liberation of heat (phonons, acoustic waves, etc.) every time a wheel hits the next cobblestone. The cobblestone model is not unlike the *Coulomb* and *interlocking asperity* models of friction [18.228] except that it is being applied at the molecular level and for a situation where the external load is augmented by attractive intermolecular forces.

There are thus two contributions to the force pulling two surfaces together: the externally applied load or pressure, and the (internal) attractive intermolecular forces that determine the adhesion between the two surfaces. Each of these contributions affects the friction force in a different way, which we will discuss in more detail below.

18.7.2 Adhesion Force and Load Contribution to Interfacial Friction

Adhesion Force Contribution

Consider the case of two surfaces sliding past each other, as shown in Fig. 18.14. When the two surfaces are initially in adhesive contact, the surface molecules will adjust themselves to fit snugly together [18.233], in an analogous manner to the self-positioning of the cartwheels on the cobblestone road. A small tangential force applied to one surface will therefore not result in

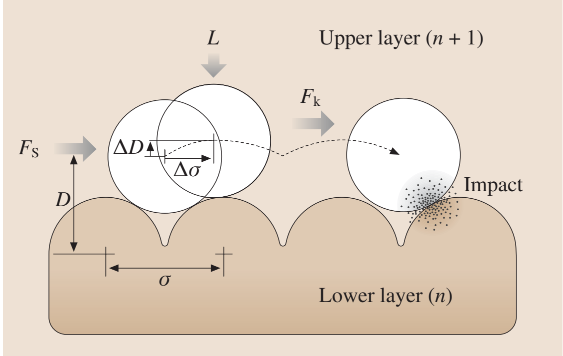

Fig. 18.14 Schematic illustration of how one molecularly smooth surface moves over another when a lateral force F is applied (the "cobblestone model"). As the upper surface moves laterally by some fraction of the lattice dimension $\Delta\sigma$, it must also move up by some fraction of an atomic or molecular dimension ΔD before it can slide across the lower surface. On impact, some fraction ε of the kinetic energy is "transmitted" to the lower surface, the rest being "reflected" back to the colliding molecule (upper surface). (After [18.232] with permission)

the sliding of that surface relative to the other. The attractive van der Waals forces between the surfaces must first be overcome by having the surfaces separate by a small amount. To initiate motion, let the separation between the two surfaces increase by a small amount ΔD, while the lateral distance moved is $\Delta\sigma$. These two values will be related via the geometry of the two surface lattices. The energy put into the system by the force F acting over a lateral distance $\Delta\sigma$ is

$$\text{Input energy: } F \times \Delta\sigma \,. \tag{18.29}$$

This energy may be equated with the change in interfacial or surface energy associated with separating the surfaces by ΔD, i. e., from the equilibrium separation $D = D_0$ to $D = (D_0 + \Delta D)$. Since $\gamma \propto D^{-2}$ for two flat surfaces, the energy cost may be approximated by:

$$\text{Surface energy change} \times \text{area:}$$
$$2\gamma A\left[1 - D_0^2/(D_0 + \Delta D)^2\right] \approx 4\gamma A(\Delta D/D_0) \,, \tag{18.30}$$

where γ is the surface energy, A the contact area, and D_0 the surface separation at equilibrium. During steady state sliding (kinetic friction), not all of this energy will be "lost" or absorbed by the lattice every time the surface molecules move by one lattice spacing: Some fraction will be reflected during each impact of the "cartwheel"

molecules [18.231]. Assuming that a fraction ε of the above surface energy is "lost" every time the surfaces move across the characteristic length $\Delta\sigma$ (Fig. 18.14), we obtain after equating (18.29) and (18.30)

$$S_c = \frac{F}{A} = \frac{4\gamma\varepsilon\Delta D}{D_0\Delta\sigma} . \quad (18.31)$$

For a typical hydrocarbon or a van der Waals surface, $\gamma \approx 25\,\mathrm{mJ\,m^{-2}}$. Other typical values would be: $\Delta D \approx 0.05\,\mathrm{nm}$, $D_0 \approx 0.2\,\mathrm{nm}$, $\Delta\sigma \approx 0.1\,\mathrm{nm}$, and $\varepsilon \approx 0.1$–0.5. Using the above parameters, (18.31) predicts $S_c \approx (2.5\text{–}12.5)\times 10^7\,\mathrm{N\,m^{-2}}$ for van der Waals surfaces. This range of values compares very well with typical experimental values of $2\times 10^7\,\mathrm{N\,m^{-2}}$ for hydrocarbon or mica surfaces sliding in air (see Fig. 18.16) or separated by one molecular layer of cyclohexane [18.45].

The above model suggests that all interfaces, whether dry or lubricated, dilate just before they shear or slip. This is a small but important effect: The dilation provides the crucial extra space needed for the molecules to slide across each other or flow. This dilation has been computed by *Thompson* and *Robbins* [18.201] and *Zaloj* et al. [18.234] and measured by *Dhinojwala* et al. [18.235].

This model may be extended, at least semi-quantitatively, to lubricated sliding, where a thin liquid film is present between the surfaces. With an increase in the number of liquid layers between the surfaces, D_0 increases while ΔD decreases, hence the lower the friction force. This is precisely what is observed, but with more than one liquid layer between two surfaces the situation becomes too complex to analyze analytically (actually, even with one or no interfacial layers, the calculation of the fraction of energy dissipated per molecular collision ε is not a simple matter). Furthermore, even in systems as simple as linear alkanes, interdigitation and interdiffusion have been found to contribute strongly to the properties of the system [18.114, 236]. Sophisticated modeling based on computer simulations is now required, as described in the following section.

Relation Between Boundary Friction and Adhesion Energy Hysteresis

While the above equations suggest that there is a direct correlation between friction and adhesion, this is not the case. The correlation is really between friction and adhesion hysteresis, described in Sect. 18.5.4. In the case of friction, this subtle point is hidden in the factor ε, which is a measure of the amount of energy absorbed (dissipated, transferred, or "lost") by the lower surface when it is impacted by a molecule from the upper surface. If $\varepsilon = 0$, all the energy is reflected, and there will be no kinetic friction force nor any adhesion hysteresis, but the absolute magnitude of the adhesion force or energy will remain finite and unchanged. This is illustrated in Figs. 18.17 and 18.19.

The following simple model shows how adhesion hysteresis and friction may be quantitatively related. Let $\Delta\gamma = \gamma_R - \gamma_A$ be the adhesion energy hysteresis per unit area, as measured during a typical loading–unloading cycle (see Figs. 18.17a and 18.19c,d). Now consider the same two surfaces sliding past each other and assume that frictional energy dissipation occurs through the same mechanism as adhesion energy dissipation, and that both occur over the same characteristic molecular length scale σ. Thus, when the two surfaces (of contact area $A = \pi r^2$) move a distance σ, equating the frictional energy $(F\times\sigma)$ to the dissipated adhesion energy $(A\times\Delta\gamma)$, we obtain

$$\text{Friction force: } F = \frac{A\times\Delta\gamma}{\sigma} = \frac{\pi r^2}{\sigma}(\gamma_R - \gamma_A) , \quad (18.32)$$

$$\text{or} \quad \text{Critical shear stress: } S_c = F/A = \Delta\gamma/\sigma , \quad (18.33)$$

which is the desired expression and has been found to give order of magnitude agreement between measured friction forces and adhesion energy hysteresis [18.207]. If we equate (18.33) with (18.31), since $4\Delta D/(D_0\Delta\sigma) \approx 1/\sigma$, we obtain the intuitive relation

$$\varepsilon = \frac{\Delta\gamma}{\gamma} . \quad (18.34)$$

External Load Contribution to Interfacial Friction

When there is no interfacial adhesion, S_c is zero. Thus, in the absence of any adhesive forces between two surfaces, the only "attractive" force that needs to be overcome for sliding to occur is the externally applied load or pressure.

For a preliminary discussion of this question, it is instructive to compare the magnitudes of the *externally* applied pressure to the *internal* van der Waals pressure between two smooth surfaces. The internal van der Waals pressure between two flat surfaces is given (see Table 18.2) by $P = A_H/6\pi D_0^3 \approx 1\,\mathrm{GPa}$ (10^4 atm), using a typical Hamaker constant of $A_H = 10^{-19}\,\mathrm{J}$, and assuming $D_0 \approx 2\,\mathrm{nm}$ for the equilibrium interatomic spacing. This implies that we should not expect the externally

applied load to affect the interfacial friction force F, as defined by (18.27), until the externally applied pressure L/A begins to exceed $\sim 100\,\mathrm{MPa}$ (10^3 atm). This is in agreement with experimental data [18.237] where the effect of load became dominant at pressures in excess of 10^3 atm.

For a more general semiquantitative analysis, again consider the cobblestone model used to derive (18.31), but now include an additional contribution to the surface energy change of (18.30) due to the work done against the external load or pressure, $L\Delta D = P_{\mathrm{ext}}A\Delta D$ (this is equivalent to the work done against gravity in the case of a cart being pushed over cobblestones). Thus:

$$S_{\mathrm{c}} = \frac{F}{A} = \frac{4\gamma\varepsilon\Delta D}{D_0\Delta\sigma} + \frac{P_{\mathrm{ext}}\varepsilon\Delta D}{\Delta\sigma}\,, \qquad (18.35)$$

which gives the more general relation

$$S_{\mathrm{c}} = F/A = C_1 + C_2 P_{\mathrm{ext}}\,, \qquad (18.36)$$

where $P_{\mathrm{ext}} = L/A$ and C_1 and C_2 are constants characteristic of the surfaces and sliding conditions. The constant $C_1 = 4\gamma\varepsilon\Delta D/(D_0\Delta\sigma)$ depends on the mutual adhesion of the two surfaces, while both C_1 and $C_2 = \varepsilon\Delta D/\Delta\sigma$ depend on the topography or atomic bumpiness of the surface groups (Fig. 18.14). The smoother the surface groups the smaller the ratio $\Delta D/\Delta\sigma$ and hence the lower the value of C_2. In addition, both C_1 and C_2 depend on ε (the fraction of energy dissipated per collision), which depends on the relative masses of the shearing molecules, the sliding velocity, the temperature, and the characteristic molecular relaxation processes of the surfaces. This is by far the most difficult parameter to compute, and yet it is the most important since it represents the energy transfer mechanism in any friction process, and since ε can vary between 1 and 0, it determines whether a particular friction force will be large or close to zero. Molecular simulations offer the best way to understand and predict the magnitude of ε, but the complex multi-body nature of the problem makes simple conclusions difficult to draw [18.239–241]. Some of the basic physics of the energy transfer and dissipation of the molecular collisions can be drawn from simplified models such as a 1-D three-body system [18.214].

Finally, the above equation may also be expressed in terms of the friction force F:

$$F = S_{\mathrm{c}}A = C_1 A + C_2 L\,. \qquad (18.37)$$

Equations similar to (18.36) and (18.37) were previously derived by *Derjaguin* [18.242,243] and by *Briscoe*

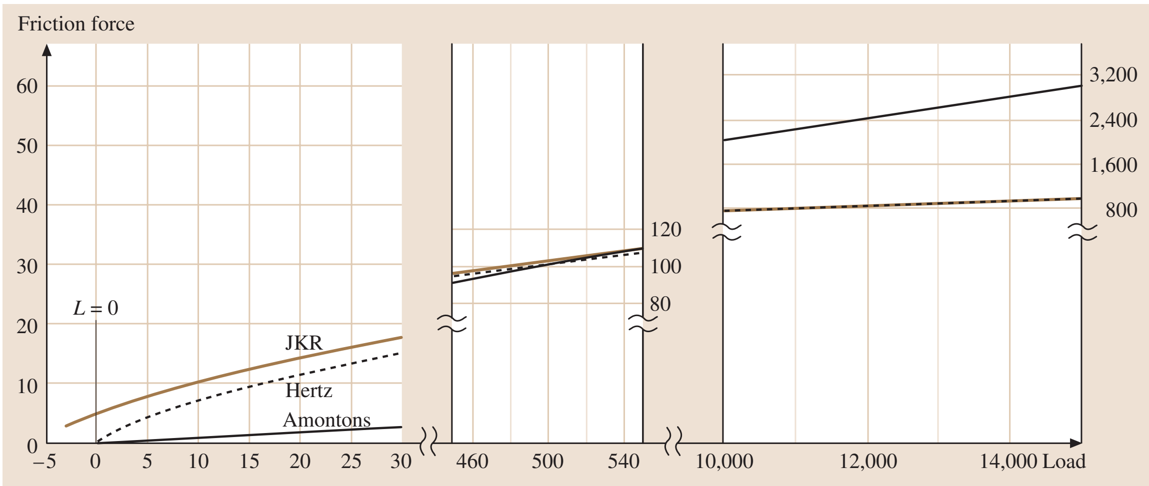

Fig. 18.15 Friction as a function of load for smooth surfaces. At low loads, the friction is dominated by the C_1A term of (18.37). The adhesion contribution (JKR curve) is most prominent near zero load where the Hertzian and Amontons' contributions to the friction are minimal. As the load increases, the adhesion contribution becomes smaller as the JKR and Hertz curves converge. In this range of loads, the linear C_2L contribution surpasses the area contribution to the friction. At much higher loads the explicit load dependence of the friction dominates the interactions, and the observed behavior approaches Amontons' law. It is interesting to note that for smooth surfaces the pressure over the contact area does not increase as rapidly as the load. This is because as the load is increased, the surfaces deform to increase the surface area and thus moderate the contact pressure. (After [18.238] with permission of Kluwer Academic Publishers)

and *Evans* [18.244], where the constants C_1 and C_2 were interpreted somewhat differently than in this model.

In the absence of any attractive interfacial force, we have $C_1 \approx 0$, and the second term in (18.36) and (18.37) should dominate (Fig. 18.15). Such situations typically arise when surfaces repel each other across the lubricating liquid film. In such cases, the total frictional force should be low and should increase *linearly* with the external load according to

$$F = C_2 L \,. \tag{18.38}$$

An example of such lubricated sliding occurs when two mica surfaces slide in water or in salt solution (see Fig. 18.20), where the short-range "hydration" forces between the surfaces are repulsive. Thus, for sliding in 0.5 M KCl it was found that $C_2 = 0.015$ [18.245]. Another case where repulsive surfaces eliminate the adhesive contribution to friction is for polymer chains attached to surfaces at one end and swollen by a good solvent [18.175]. For this class of systems, $C_2 < 0.001$ for a finite range of polymer layer compressions (normal loads, L). The low friction between the surfaces in this regime is attributed to the entropic repulsion between the opposing brush layers with a minimum of entanglement between the two layers. However, with higher normal loads, the brush layers become compressed and begin to entangle, which results in higher friction (see [18.246]).

It is important to note that (18.38) has exactly the same form as Amontons' Law

$$F = \mu L \,, \tag{18.39}$$

where μ is the coefficient of friction.

At the molecular level a thermodynamic analog of the Coulomb or cobblestone models (see Sect. 18.7.1) based on the "contact value theorem" [18.3, 238, 245] can explain why $F \propto L$ also holds at the microscopic or molecular level. In this analysis we consider the surface molecular groups as being momentarily compressed and decompressed as the surfaces move along. Under irreversible conditions, which always occur when a cycle is completed in a finite amount of time, the energy "lost" in the compression–decompression cycle is dissipated as heat. For two non-adhering surfaces, the stabilizing pressure P_i acting locally between any two elemental contact points i of the surfaces may be expressed by the contact value theorem [18.3]:

$$P_i = \rho_i k_B T = k_B T / V_i \,, \tag{18.40}$$

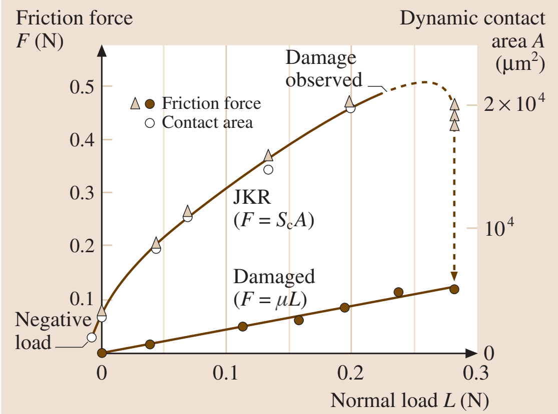

Fig. 18.16 Friction force F and contact area A vs. load L for two mica surfaces sliding in adhesive contact in dry air. The contact area is well described by the JKR theory, (18.22), even during sliding, and the friction force is found to be directly proportional to this area, (18.28). The *vertical dashed line* and *arrow* show the transition from interfacial to normal friction with the onset of wear (*lower curve*). Sliding velocity is $0.2\,\mu m\,s^{-1}$. (After [18.45] with permission, copyright 1989 American Society of Mechanical Engineers)

where $\rho_i = V_i^{-1}$ is the local number density (per unit volume) or activity of the interacting entities, be they molecules, atoms, ions or the electron clouds of atoms. This equation is essentially the osmotic or entropic pressure of a gas of confined molecules. As one surface moves across the other, local regions become compressed and decompressed by a volume ΔV_i. The work done per cycle can be written as $\varepsilon P_i \Delta V_i$, where ε ($\varepsilon \le 1$) is the fraction of energy per cycle "lost" as heat, as defined earlier. The energy balance shows that for each compression–decompression cycle, the dissipated energy is related to the friction force by

$$F_i x_i = \varepsilon P_i \Delta V_i \,, \tag{18.41}$$

where x_i is the lateral distance moved per cycle, which can be the distance between asperities or the distance between surface lattice sites. The pressure at each contact junction can be expressed in terms of the local normal load L_i and local area of contact A_i as $P_i = L_i / A_i$. The volume change over a cycle can thus be expressed as $\Delta V_i = A_i z_i$, where z_i is the vertical distance of confinement. Inserting these into (18.41), we get

$$F_i = \varepsilon L_i (z_i / x_i) \,, \tag{18.42}$$

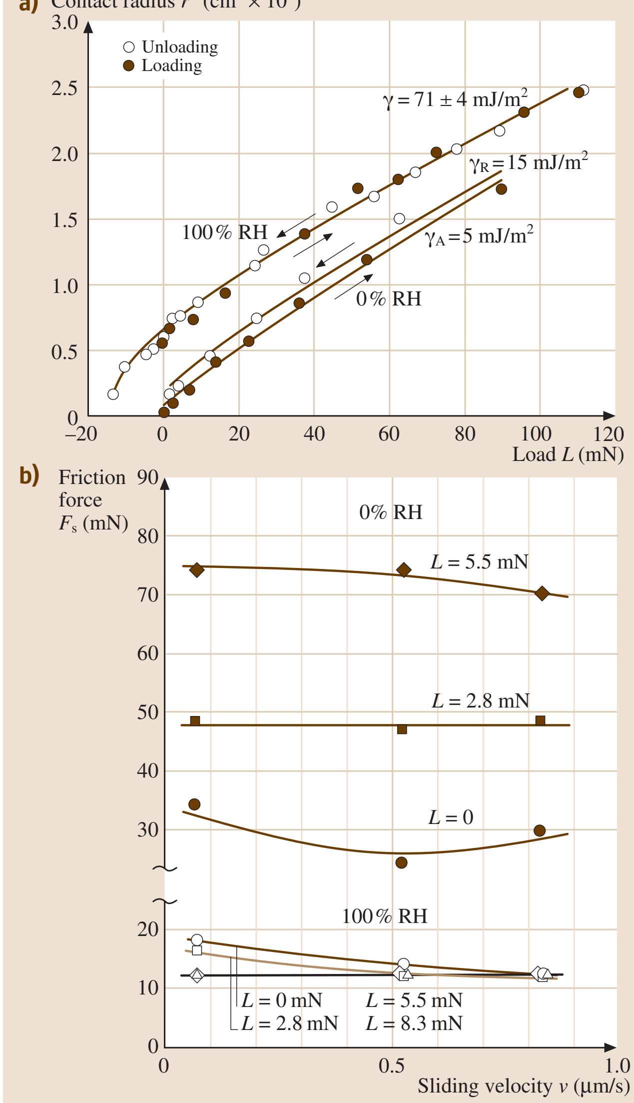

Fig. 18.17 **(a)** Contact radius r versus externally applied load L for loading and unloading of two hydrophilic silica surfaces exposed to dry and humid atmospheres. Note that while the adhesion is higher in humid air, the *hysteresis* in the adhesion is higher in dry air. **(b)** Effect of velocity on the static friction force F_s for hydrophobic (heat-treated electron beam evaporated) silica in dry and humid air. The effects of humidity, load, and sliding velocity on the friction forces, as well as the stick–slip friction of the hydrophobic surfaces, are qualitatively consistent with a "friction" phase diagram representation as in Fig. 18.28. (After [18.41]. Copyright 1994, with permission from Elsevier Science)

which is independent of the local contact area A_i. The total friction force is thus

$$F = \sum F_i = \sum \varepsilon L_i (z_i/x_i) = \varepsilon \langle z_i/x_i \rangle \sum L_i = \mu L \,, \quad (18.43)$$

where it is assumed that on average the local values of L_i and P_i are independent of the local "slope" z_i/x_i. Therefore, the friction coefficient μ is a function only of the average surface topography and the sliding velocity, but is independent of the local (real) or macroscopic (apparent) contact areas.

While this analysis explains non-adhering surfaces, there is still an additional explicit contact area contribution for the case of adhering surfaces, as in (18.37). The distinction between the two cases arises because the initial assumption of the contact value theorem, (18.40), is incomplete for adhering systems. A more appropriate starting equation would reflect the full intermolecular interaction potential, including the attractive interactions, in addition to the purely repulsive contributions of (18.40), much as the van der Waals equation of state modifies the ideal gas law.

18.7.3 Examples of Experimentally Observed Friction of Dry Surfaces

Numerous model systems have been studied with a surface forces apparatus (SFA) modified for friction experiments (see Sect. 18.2.3). The apparatus allows for control of load (normal force) and sliding speed, and simultaneous measurement of surface separation, surface shape, true (molecular) area of contact between smooth surfaces, and friction forces. A variety of both unlubricated and solid and liquid lubricated surfaces have been studied both as smooth single-asperity contacts and after they have been roughened by shear-induced damage.

Figure 18.16 shows the contact area, A, and friction force, F, both plotted against the applied load, L, in an experiment in which two molecularly smooth surfaces of mica in adhesive contact were slid past each other in an atmosphere of dry nitrogen gas. This is an example of the low load, adhesion controlled limit, which is excellently described by (18.28). In a number of different experiments, S_c was measured to be 2.5×10^7 N m^{-2} and to be independent of the sliding velocity [18.45, 247]. Note that there is a friction force even at negative loads, where the surfaces are still sliding in adhesive contact.

Figure 18.17 shows the correlation between adhesion hysteresis and friction for two surfaces consisting of silica films deposited on mica substrates [18.41].

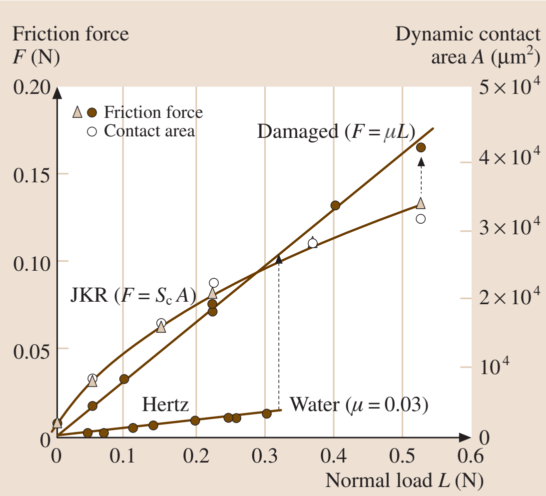

Fig. 18.18 Sliding of mica surfaces, each coated with a 2.5-nm-thick monolayer of calcium stearate surfactant, in the absence of damage (obeying JKR type boundary friction) and in the presence of damage (obeying Amontons' type normal friction). Note that both for this system and for the bare mica in Figs. 18.16 and 18.20, the friction force obeys Amontons' law with a friction coefficient of $\mu \approx 0.3$ after damage occurs. At much higher applied loads, the undamaged surfaces also follow Amontons' type sliding, but for a different reason: The dependence on adhesion becomes smaller. *Lower line:* Interfacial sliding with a monolayer of water between the mica surfaces, shown for comparison. (After [18.247]. Copyright 1990, with permission from Elsevier Science)

The friction between undamaged hydrophobic silica surfaces showed stick–slip both at dry conditions and at 100% relative humidity. Similar to the mica surfaces in Figs. 18.16, 18.18, and 18.20, the friction of damaged silica surfaces obeyed Amontons' law with a friction coefficient of 0.25 both at dry conditions and at 55% relative humidity.

The high friction force of unlubricated sliding can often be reduced by treating the solid surface with a boundary layer of some other solid material that exhibits lower friction such as a surfactant monolayer, or by ensuring that during sliding, a thin liquid film remains between the surfaces (as will be discussed in Sect. 18.8). The effectiveness of a solid boundary lubricant layer on reducing the forces of friction is illustrated in Fig. 18.18. Comparing this with the friction of the unlubricated/untreated surfaces (Fig. 18.16) shows that the critical shear stress has been reduced by a factor of about ten: from 2.5×10^7 to $3.5\times10^6\,\mathrm{N\,m^{-2}}$. At much higher applied loads or pressures, the friction force is proportional to the load, rather than the area of contact [18.237], as expected from (18.27).

Yamada and *Israelachvili* [18.248] studied the adhesion and friction of fluorocarbon surfaces (surfactant-coated boundary lubricant layers), which were compared to those of hydrocarbon surfaces. They concluded that well-ordered fluorocarbon surfaces have a high friction, in spite of their lower adhesion energy (in agreement with previous findings). The low friction coefficient of PTFE (Teflon) must, therefore, be due to some effect other than a low adhesion. For example, the softness of PTFE, which allows material to flow at the interface, which thus behaves like a fluid lubricant. On a related issue, *Luengo* et al. [18.249] found that C_{60} surfaces also exhibited low adhesion but high friction. In both cases the high friction appears to arise from the bulky surface groups – fluorocarbon compared to hydrocarbon groups in the former, large fullerene spheres in the latter. Apparently, the fact that C_{60} molecules rotate *in their lattice* does not make them a good lubricant: The molecules of the opposing surface must still climb over them in order to slide, and this requires energy that is independent of whether the surface molecules are fixed or freely rotating. Larger particles such as ~25 nm-sized nanoparticles (also known as "inorganic fullerenes") do appear to produce low friction by behaving like molecular ball bearings, but the potential of this promising new class of solid lubricant has still to be explored [18.250].

Figure 18.19 illustrates the relationship between adhesion hysteresis and friction for surfactant-coated surfaces under different conditions. This effect, however, is much more general and has been shown to hold for other surfaces as well [18.41, 232, 251].

Direct comparisons between absolute adhesion energies and friction forces show little correlation. In some cases, higher adhesion energies for the same system under different conditions correspond with lower friction forces. For example, for hydrophilic silica surfaces (Fig. 18.17) it was found that with increasing relative humidity the adhesion energy *increases*, but the adhesion energy hysteresis measured in a loading–unloading cycle *decreases*, as does the friction force [18.41]. For hydrophobic silica surfaces under dry conditions, the friction at load $L = 5.5\,\mathrm{mN}$ was $F = 75\,\mathrm{mN}$. For the same sample, the adhesion energy hysteresis was $\Delta\gamma = 10\,\mathrm{mJ\,m^{-2}}$, with a contact area of $A \approx 10^{-8}\,\mathrm{m^2}$ at the same load. Assuming a value for the characteristic distance σ on the order of one lattice spacing, $\sigma \approx 1\,\mathrm{nm}$, and inserting these values into (18.32), the friction force

is predicted to be $F \approx 100\,\mathrm{mN}$ for the kinetic friction force, which is close to the measured value of 75 mN. Alternatively, we may conclude that the dissipation factor is $\varepsilon = 0.75$, i. e., that almost all the energy is dissipated as heat at each molecular collision.

A liquid lubricant film (Sect. 18.8.3) is usually much more effective at lowering the friction of two surfaces than a solid boundary lubricant layer. However, to successfully use a liquid lubricant, it must "wet" the surfaces, that is, it should have a high affinity for the surfaces, so that not all the liquid molecules become squeezed out when the surfaces come close together, even under a large compressive load. Another important requirement is that the liquid film remains a liquid under tribological conditions, i. e., that it does not epitaxially solidify between the surfaces.

Effective lubrication usually requires that the lubricant be injected between the surfaces, but in some cases the liquid can be made to condense from the vapor. This is illustrated in Fig. 18.20 for two untreated mica surfaces sliding with a thin layer of water between them. A monomolecular film of water (of thickness 0.25 nm per surface) has reduced S_c from its value for dry surfaces (Fig. 18.16) by a factor of more than 30, which

Fig. 18.19a–d *Top:* Friction traces for two fluid-like calcium alkylbenzene sulfonate monolayer-coated surfaces at 25 °C showing that the friction force is much higher between dry monolayers **(a)** than between monolayers whose fluidity has been enhanced by hydrocarbon penetration from vapor **(b)**. *Bottom:* Contact radius vs. load (r^3 vs. L) data measured for the same two surfaces as above and fitted to the JKR equation (18.22), shown by the *solid curves*. For dry monolayers **(c)** the adhesion energy on unloading ($\gamma_R = 40\,\mathrm{mJ\,m^{-2}}$) is greater than that on loading ($\gamma_R = 28\,\mathrm{mJ\,m^{-2}}$), indicative of an adhesion energy hysteresis of $\Delta\gamma = \gamma_R - \gamma_A = 12\,\mathrm{mJ\,m^{-2}}$. For monolayers exposed to saturated decane vapor **(d)** their adhesion hysteresis is zero ($\gamma_A = \gamma_R$), and both the loading and unloading data are well fitted by the thermodynamic value of the surface energy of fluid hydrocarbon chains, $\gamma = 24\,\mathrm{mJ\,m^{-2}}$. (After [18.207] with permission. Copyright 1993 American Chemical Society)

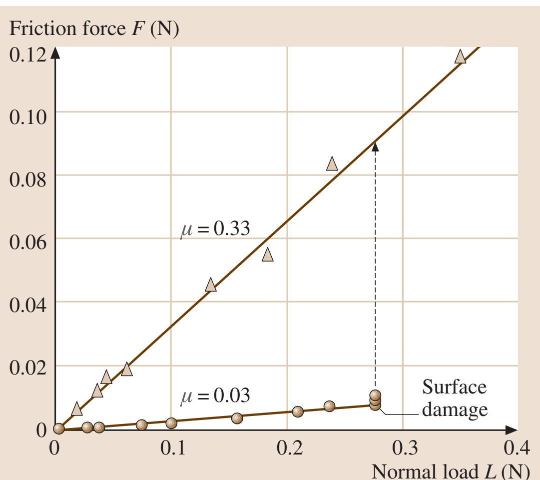

Fig. 18.20 Two mica surfaces sliding past each other while immersed in a 0.01 M KCl salt solution (nonadhesive conditions). The water film is molecularly thin, 0.25 to 0.5 nm thick, and the interfacial friction force is very low: $S_c \approx 5\times10^5\,N\,m^{-2}$, $\mu \approx 0.03$ (before damage occurs). After the surfaces have become damaged, the friction coefficient is ca. 0.3. (After [18.247]. Copyright 1990, with permission from Elsevier Science)

may be compared with the factor of ten attained with the boundary lubricant layer (of thickness 2.5 nm per surface) in Fig. 18.18. Water appears to have unusual lubricating properties and usually gives wearless friction with no stick–slip.

The effectiveness of a water film only 0.25 nm thick to lower the friction force by more than an order of magnitude is attributed to the "hydrophilicity" of the mica surface (mica is "wetted" by water) and to the existence of a strongly repulsive short-range hydration force between such surfaces in aqueous solutions, which effectively removes the adhesion-controlled contribution to the friction force [18.245]. It is also interesting that a 0.25-nm-thick water film between two mica surfaces is sufficient to bring the coefficient of friction down to 0.01–0.02, a value that corresponds to the unusually low friction of ice. Clearly, a single monolayer of water can be a very good lubricant – much better than most other monomolecular liquid films – for reasons that will be discussed in Sect. 18.9.

Dry polymer layers (Fig. 18.21) typically show a high initial static friction ("stiction") as sliding commences from rest in adhesive contact. The development of the friction force after a change in sliding direction, a gradual transition from stick–slip to smooth sliding, is shown in Fig. 18.21. A correlation between adhesion hysteresis and friction similar to the one observed for silica surfaces in Fig. 18.17 can be seen for dry polymer layers below their glass transition temperature. As shown in Fig. 18.12b,c, the adhesion hysteresis for polystyrene surfaces can be increased by irradiation to induce scission of chains, and it has been found that the steady state friction force (kinetic friction) shows a similar increase with irradiation time [18.208].

Figure 18.22 shows an example of a computer simulation of the sliding of two unlubricated silicon surfaces (modeled as a tip sliding over a planar surface) [18.91]. The sliding proceeds through a series of stick–slip events, and information on the friction force and the local order of the initially crystalline surfaces can be obtained. Similar studies for cold welding systems [18.91] have demonstrated the occurrence of shear or friction damage within the sliding surface (tip) as the lowest layer of it adheres to the bottom surface.

18.7.4 Transition from Interfacial to Normal Friction with Wear

Frictional damage can have many causes such as adhesive tearing at high loads or overheating at high sliding speeds. Once damage occurs, there is a transition from "interfacial" to "normal" or load-controlled friction as the surfaces become forced apart by the torn-out as-

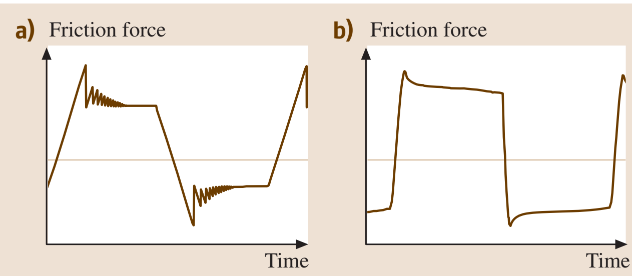

Fig. 18.21a,b Typical friction traces showing how the friction force varies with the sliding time for two symmetric, glassy polymer films at dry conditions. Qualitative features that are common to both polystyrene and polyvinyl benzyl chloride: **(a)** Decaying stick–slip motion is observed until smooth sliding is attained if the motion continues for a sufficiently long distance. **(b)** Smooth sliding observed at sufficiently high speeds. Similar observations have been made by *Berthoud* et al. [18.252] in measurements on polymethyl methacrylate. (After [18.208] with permission. Copyright 2002 American Association for the Advancement of Science)

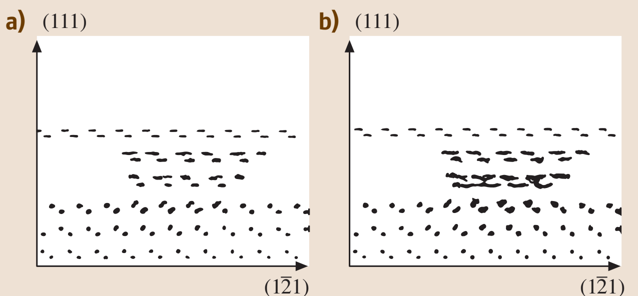

Fig. 18.22a,b Computer simulation of the sliding of two contacting Si surfaces (a tip and a flat surface). Shown are particle trajectories in a constant-force simulation, $F_{z,\text{external}} = -2.15 \times 10^{-8}$ N, viewed along the (10$\bar{1}$) direction just before **(a)** and after **(b)** a stick–slip event for a large, initally ordered, dynamic tip. (After [18.91] with permission of Kluwer Academic Publishers)

perities (wear particles). For low loads, the friction changes from obeying $F = S_c A$ to obeying Amontons' law, $F = \mu L$, as shown in Figs. 18.16 and 18.18, and sliding now proceeds smoothly with the surfaces separated by a 10–100 nm forest of wear debris (in this case, mica flakes). The wear particles keep the surfaces apart over an area that is much greater than their size, so that even one submicroscopic particle or asperity can cause a significant reduction in the area of contact and, therefore, in the friction [18.247]. For this type of frictional sliding, one can no longer talk of the molecular contact area of the two surfaces, although the macroscopic or "apparent" area is still a useful parameter.

One remarkable feature of the transition from interfacial to normal friction of brittle surfaces is that while the strength of interfacial friction, as reflected in the values of S_c, is very dependent on the type of surface and on the liquid film between the surfaces, this is not the case once the transition to normal friction has occurred. At the onset of damage, the material properties of the underlying substrates control the friction. In Figs. 18.16, 18.18, and 18.20 the friction for the damaged surfaces is that of any damaged mica–mica system, $\mu \approx 0.3$, *independent of the initial surface coatings or liquid films between the surfaces*. A similar friction coefficient was found for damaged silica surfaces [18.41].

In order to practically modify the frictional behavior of such brittle materials, it is important to use coatings that will both alter the interfacial tribological character and remain intact and protect the surfaces from damage during sliding. *Berman* et al. [18.253] found that the friction of a strongly bound octadecyl phosphonic acid monolayer on alumina surfaces was higher than for untreated, undamaged α-alumina surfaces, but the bare surfaces easily became damaged upon sliding, resulting in an ultimately higher friction system with greater wear rates than the more robust monolayer-coated surfaces.

Clearly, the mechanism and factors that determine *normal* friction are quite different from those that govern *interfacial* friction (Sects. 18.7.1–18.7.2). This effect is not general and may only apply to brittle materials. For example, the friction of ductile surfaces is totally different and involves the continuous plastic deformation of contacting surface asperities during sliding, rather than the rolling of two surfaces on hard wear particles [18.209]. Furthermore, in the case of ductile surfaces, water and other surface-active components do have an effect on the friction coefficients under "normal" sliding conditions.

18.8 Liquid Lubricated Surfaces

18.8.1 Viscous Forces and Friction of Thick Films: Continuum Regime

Experimentally, it is usually difficult to unambiguously establish which type of sliding mode is occurring, but an empirical criterion, based on the Stribeck curve (Fig. 18.13), is often used as an indicator. This curve shows how the friction force or the coefficient of friction is expected to vary with sliding speed, depending on which type of friction regime is operating. For thick liquid lubricant films whose behavior can be described by bulk (continuum) properties, the friction forces are essentially the hydrodynamic or viscous drag forces. For example, for two plane parallel surfaces of area A separated by a distance D and moving laterally relative to each other with velocity v, if the intervening liquid is *Newtonian*, i. e., if its viscosity η is independent of the shear rate, the frictional force experienced by the surfaces is given by

$$F = \frac{\eta A v}{D}\,, \tag{18.44}$$

where the shear rate $\dot{\gamma}$ is defined by

$$\dot{\gamma} = \frac{v}{D} . \quad (18.45)$$

At higher shear rates, two additional effects often come into play. First, certain properties of liquids may change at high $\dot{\gamma}$ values. In particular, the effective viscosity may become non-Newtonian, one form given by

$$\eta = \dot{\gamma}^n , \quad (18.46)$$

where $n = 0$ (i. e., $\eta_{eff} =$ constant) for Newtonian fluids, $n > 0$ for shear thickening (dilatent) fluids, and $n < 0$ for shear thinning (pseudoplastic) fluids (the latter become less viscous, i. e., flow more easily, with increasing shear rate). An additional effect on η can arise from the higher local stresses (pressures) experienced by the liquid film as $\dot{\gamma}$ increases. Since the viscosity is generally also sensitive to the pressure (usually increasing with P), this effect also acts to increase η_{eff} and thus the friction force.

A second effect that occurs at high shear rates is surface deformation, arising from the large hydrodynamic forces acting on the sliding surfaces. For example, Fig. 18.23 shows how two surfaces deform elastically when the sliding speed increases to a high value. These deformations alter the hydrodynamic friction forces, and this type of friction is often referred to as *elastohydrodynamic lubrication* (EHD or EHL), as mentioned in Table 18.4.

How thin can a liquid film be before its dynamic, e.g., viscous flow, behavior ceases to be described by bulk properties and continuum models? Concerning the static properties, we have already seen in Sect. 18.4.3 that films composed of simple liquids display continuum behavior down to thicknesses of 4–10 molecular diameters. Similar effects have been found to apply to the dynamic properties, such as the viscosity, of simple liquids in thin films. Concerning viscosity measurements, a number of dynamic techniques were recently developed [18.11–13, 43, 254, 255] for directly measuring the viscosity as a function of film thickness and shear rate across very thin liquid films between two surfaces. By comparing the results with theoretical predictions of fluid flow in thin films, one can determine the effective positions of the shear planes and the onset of non-Newtonian behavior in very thin films.

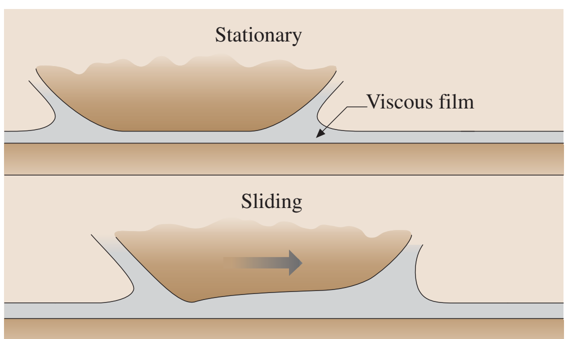

Fig. 18.23 *Top:* Stationary surfaces (one more deformable and one rigid) separated by a thick liquid film. *Bottom:* Elastohydrodynamic deformation of the upper surface during sliding. (After [18.1] with permission)

The results show that for simple liquids, including linear chain molecules such as alkanes, the viscosity in thin films is the same, within 10%, as the bulk even for films as thin as 10 molecular diameters (or segment widths) [18.11–13, 254, 255]. This implies that the shear plane is effectively located within one molecular diameter of the solid–liquid interface, and these conclusions were found to remain valid even at the highest shear rates studied (of $\sim 2 \times 10^5\ \mathrm{s}^{-1}$). With water between two mica or silica surfaces [18.22, 254–256] this has been found to be the case (to within ±10%) down to surface separations as small as 2 nm, implying that the shear planes must also be within a few tenths of a nanometer of the solid–liquid interfaces. These results appear to be independent of the existence of electrostatic "double-layer" or "hydration" forces. For the case of the simple liquid toluene confined between surfaces with adsorbed layers of C_{60} molecules, this type of viscosity measurement has shown that the traditional no-slip assumption for flow at a solid interface does not always hold [18.257]. The C_{60} layer at the mica–toluene interface results in a "full slip" boundary, which dramatically lowers the viscous drag or effective viscosity for regular Couette or Poiseuille flow.

With polymeric liquids (polymer melts) such as polydimethylsiloxanes (PDMS) and polybutadienes (PBD), or with polystyrene (PS) adsorbed onto surfaces from solution, the far-field viscosity is again equal to the bulk value, but with the non-slip plane (hydrodynamic layer thickness) being located at $D = 1$–$2R_g$ away from each surface [18.11, 47], or at $D = L$ or less for polymer brush layers of thickness L per surface [18.13, 258]. In contrast, the same technique was used to show that for non-adsorbing polymers in solution, there is actually a depletion layer of nearly pure solvent that exists at the surfaces that affects the confined solution flow properties [18.256]. These effects are observed from near contact to surface separations in excess of 200 nm.

Further experiments with surfaces closer than a few molecular diameters ($D < 2{-}4$ nm for simple liquids, or $D < 2{-}4R_g$ for polymer fluids) indicate that large deviations occur for thinner films, described below. One important conclusion from these studies is, therefore, that the dynamic properties of simple liquids, including water, near an *isolated* surface are similar to those of the bulk liquid *already within the first layer of molecules adjacent to the surface*, only changing when another surface approaches the first. In other words, the viscosity and position of the shear plane near a surface are not simply a property of that surface, but of how far that surface is from another surface. The reason for this is because when two surfaces are close together, the constraining effects on the liquid molecules between them are much more severe than when there is only one surface. Another obvious consequence of the above is that one should not make measurements on a single, isolated solid–liquid interface and then draw conclusions about the state of the liquid or its interactions in a thin film *between* two surfaces.

18.8.2 Friction of Intermediate Thickness Films

For liquid films in the thickness range between 4 and 10 molecular diameters, the properties can be significantly different from those of bulk films. Still, the fluids remain recognizable as fluids; in other words, they do not undergo a phase transition into a solid

◀ **Fig. 18.24a–d** Typical rheological behavior of liquid films in the mixed lubrication regime. **(a)** Increase in effective viscosity of dodecane film between two mica surfaces with decreasing film thickness. At distances larger than 4–5 nm, the effective viscosity η_{eff} approaches the bulk value η_{bulk} and does not depend on the shear rate $\dot{\gamma}$. (After [18.219]. Copyright 1991 American Association for the Advancement of Science.) **(b)** Non-Newtonian variation of η_{eff} with shear rate of a 2.7-nm-thick dodecane film at a net normal pressure of 0.12 MPa and at 28 °C. The effective viscosity decays as a power law, as in (18.46). In this example, $n = 0$ at the lowest $\dot{\gamma}$ and changes to $n = -2/3$ and -1 at higher $\dot{\gamma}$. For films of bulk thickness, dodecane is a low viscosity Newtonian fluid ($n = 0$). **(c)** Proposed general friction map of effective viscosity η_{eff} (arbitrary units) as a function of effective shear rate $\dot{\gamma}$ (arbitrary units) on logarithmic scales. Three main classes of behavior emerge: (i) Thick films: elastohydrodynamic sliding. At $L = 0$, approximating bulk conditions, η_{eff} is independent of shear rate except when shear thinning might occur at sufficiently large $\dot{\gamma}$. (ii) Boundary layer films, intermediate regime. A Newtonian regime is again observed [η_{eff} = constant, $n = 0$ in (18.46)] at low loads and low shear rates, but η_{eff} is much higher than the bulk value. As the shear rate $\dot{\gamma}$ increases beyond $\dot{\gamma}_{min}$, the effective viscosity starts to drop with a power-law dependence on the shear rate [see panel **(b)**], with n in the range $-1/2$ to -1 most commonly observed. As the shear rate $\dot{\gamma}$ increases still more, beyond $\dot{\gamma}_{max}$, a second Newtonian plateau is encountered. (iii) Boundary layer films, high load. The η_{eff} continues to grow with load and to be Newtonian provided that the shear rate is sufficiently low. Transition to sliding at high velocity is discontinuous ($n < -1$) and usually of the stick–slip variety. **(d)** Proposed friction map of friction force as a function of sliding velocity in various tribological regimes. With increasing load, Newtonian flow in the elastohydrodynamic (EHD) regimes crosses into the boundary regime of lubrication. Note that even EHD lubrication changes, at the highest velocities, to limiting shear stress response. At the highest loads (L) and smallest film thickness (D), the friction force goes through a maximum (the static friction, F_s), followed by a regime where the friction coefficient (μ) is roughly constant with increasing velocity (meaning that the kinetic friction, F_k, is roughly constant). Non-Newtonian shear thinning is observed at somewhat smaller load and larger film thickness; the friction force passes through a maximum at the point where $De = 1$. De, the Deborah number, is the point at which the applied shear rate exceeds the natural relaxation time of the boundary layer film. The velocity axis from 10^{-10} to 10^{10} (arbitrary units) indicates a large span. (Panels **(b)–(d)** after [18.259]. Copyright 1996, with permission from Elsevier Science)

or liquid-crystalline phase. This regime has recently been studied by *Granick* et al. [18.44, 219, 220, 222, 223], who used a friction attachment [18.43, 44] to the SFA where a sinusoidal input signal to a piezoelectric device makes the two surfaces slide back and forth laterally past each other at small amplitudes. This method provides information on the real and imaginary parts (elastic and dissipative components, respectively) of the shear modulus of thin films at different shear rates and film thickness. *Granick* [18.219] and *Hu* et al. [18.223] found that films of simple liquids become non-Newtonian in the 2.5–5 nm regime (about 10 molecular diameters, see Fig. 18.24). Polymer melts become non-Newtonian at much larger film thicknesses, depending on their molecular weight [18.47].

Klein and *Kumacheva* [18.46, 226, 260] studied the interaction forces and friction of small quasi-spherical liquid molecules such as cyclohexane between molecularly smooth mica surfaces. They concluded that surface epitaxial effects can cause the liquid film to already solidify at 6 molecular diameters, resulting in a sudden (discontinuous) jump to high friction at low shear rates. Such dynamic first-order transitions, however, may depend on the shear rate.

A generalized friction map (Fig. 18.24c,d) has been proposed by *Luengo* et al. [18.259] that illustrates the changes in η_{eff} from bulk Newtonian behavior ($n = 0$, $\eta_{eff} = \eta_{bulk}$) through the transition regime where n reaches a minimum of -1 with decreasing shear rate to the solid-like creep regime at very low $\dot{\gamma}$ where n returns to 0. A number of results from experimental, theoretical, and computer simulation work have shown values of n from $-1/2$ to -1 for this transition regime for a variety of systems and assumptions [18.219, 220, 239, 261–267].

The intermediate regime appears to extend over a narrow range of film thickness, from about 4 to 10 molecular diameters or polymer radii of gyration. Thinner films begin to adopt "boundary" or "interfacial" friction properties (described below, see also Table 18.5). Note that the intermediate regime is actually a very narrow one when defined in terms of film thickness, for example, varying from about $D = 2$ to 4 nm for hexadecane films [18.219].

A fluid's effective viscosity η_{eff} in the intermediate regime is usually higher than in the bulk, but η_{eff} usu-

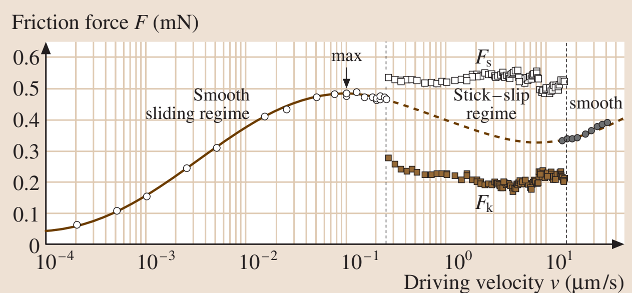

Fig. 18.25 Transition from smooth sliding to "inverted" stick–slip and to a second smooth sliding regime with increasing driving velocity during shear of two adsorbed surfactant monolayers in aqueous solution at a load of $L = 4.5$ mN and $T = 20\,°$C. The smooth sliding (*open circles*) to inverted stick–slip (*squares*) transition occurs at $v_c \sim 0.3\,\mu$m/s. Prior to the transition, the kinetic stress levels off at after a logarithmic dependence on velocity. The quasi-smooth regime persists up to the transition at v_c. At high driving velocities (*filled circles*), a new transition to a smooth sliding regime is observed between 14 and 17 μm/s. (After [18.268] with permission)

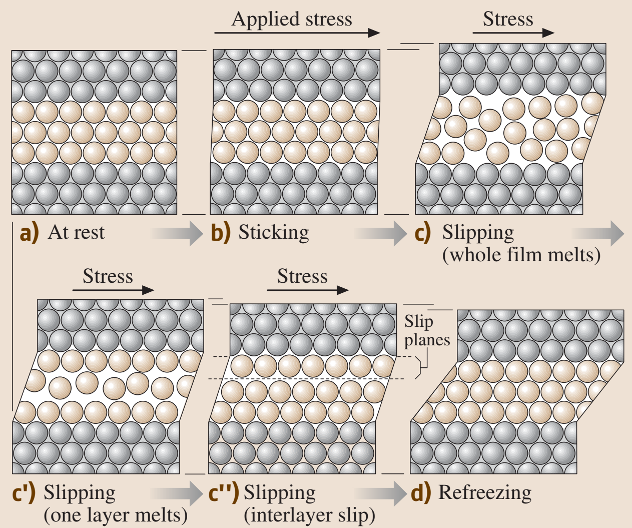

Fig. 18.26a–d Idealized schematic illustration of molecular rearrangements occurring in a molecularly thin film of spherical or simple chain molecules between two solid surfaces during shear. Depending on the system, a number of different molecular configurations within the film are possible during slipping and sliding, shown here as stages (c): total disorder as the whole film melts; (c′): partial disorder; and (c″): order persists even during sliding with slip occurring at a single slip plane either within the film or at the walls. A dilation is predicted in the direction normal to the surfaces. (After [18.224] with permission)

ally *decreases* with increasing sliding velocity, v (known as *shear thinning*). When two surfaces slide in the intermediate regime, the motion tends to thicken the film (dilatancy). This sends the system into the bulk EHL regime where, as indicated by (18.44), the friction force now *increases* with velocity. This initial decrease, followed by an increase, in the frictional forces of many lubricant systems is the basis for the empirical Stribeck curve of Fig. 18.13. In the transition from bulk to boundary behavior there is first a quantitative change in the material properties (viscosity and elasticity), which can be continuous, to discontinuous qualitative changes that result in yield stresses and non-liquidlike behavior.

The rest of this section is devoted to friction in the boundary regime. Boundary friction may be thought of as applying to the case where a lubricant film is present, but where this film is of molecular dimensions – a few molecular layers or less.

18.8.3 Boundary Lubrication of Molecularly Thin Films: Nanorheology

When a liquid is confined between two surfaces or within any narrow space whose dimensions are less than 4 to 10 molecular diameters, both the static (equilibrium) and dynamic properties of the liquid, such as its compressibility and viscosity, can no longer be described even qualitatively in terms of the bulk properties. The molecules confined within such molecularly thin films become ordered into layers ("out-of-plane" ordering), and within each layer they can also have lateral order ("in-plane" ordering). Such films may be thought of as behaving more like a liquid crystal or a solid than a liquid.

As described in Sect. 18.4.3, the measured *normal* forces between two solid surfaces across molecularly thin films exhibit exponentially decaying oscillations, varying between attraction and repulsion with a periodicity equal to some molecular dimension of the solvent molecules. Thus most liquid films can sustain a finite normal stress, and the adhesion force between two surfaces across such films is "quantized", depending on the thickness (or number of liquid layers) between the surfaces. The structuring of molecules in thin films and the oscillatory forces it gives rise to are now reasonably well understood, both experimentally and theoretically, at least for simple liquids.

Work has also recently been done on the dynamic, e.g., viscous or shear, forces associated with molecularly thin films. Both experiments [18.38, 46, 203, 221,

226,227,269,270] and theory [18.200,201,261,271] indicate that even when two surfaces are in steady state sliding they still prefer to remain in one of their stable potential energy minima, i. e., a sheared film of liquid can retain its basic layered structure. Thus even during motion the film does not become totally liquid-like. Indeed, if there is some "in-plane" ordering within a film, it will exhibit a yield-point before it begins to flow. Such films can therefore sustain a finite shear stress, in addition to a finite normal stress. The value of the yield stress depends on the number of layers comprising the film and represents another "quantized" property of molecularly thin films [18.200].

The dynamic properties of a liquid film undergoing shear are very complex. Depending on whether the film is more liquid-like or solid-like, the motion will be smooth or of the stick–slip type. During sliding, transitions can occur between n layers and $(n-1)$ or $(n+1)$ layers (see Fig. 18.27). The details of the motion depend critically on the externally applied load, the temperature, the sliding velocity, the twist angle between the two surface lattices, and the sliding direction relative to the lattices.

Smooth and Stick–Slip Sliding

Recent advances in friction-measuring techniques have enabled the interfacial friction of molecularly thin films to be measured with great accuracy. Some of these advances have involved the surface forces apparatus technique [18.38, 45, 47, 221, 247, 269, 270], while others have involved the atomic force microscope [18.10, 53, 231, 272]. In addition, computer simulations [18.90,200,201,271,273,274] have become sufficiently sophisticated to enable fairly complex tribological systems to be studied. All these advances are necessary if one is to probe such subtle effects as smooth or stick–slip friction, transient and memory effects, and ultralow friction mechanisms at the molecular level.

The theoretical models presented in this section will be concerned with a situation commonly observed experimentally: Stick–slip occurs between a static state with high friction and a low-friction kinetic state, and a transition from this sliding regime to smooth sliding can be induced by an increase in velocity. Experimental data on various systems showing this behavior are shown in Figs. 18.27, 18.30b, and 18.31a. Recent studies on adhesive systems have revealed the possibility of other dynamic responses such as "inverted" stick–slip between two kinetic states of higher and lower friction and with a transition from smooth sliding to stick–slip with increasing velocity, as shown in Fig. 18.25 [18.268].

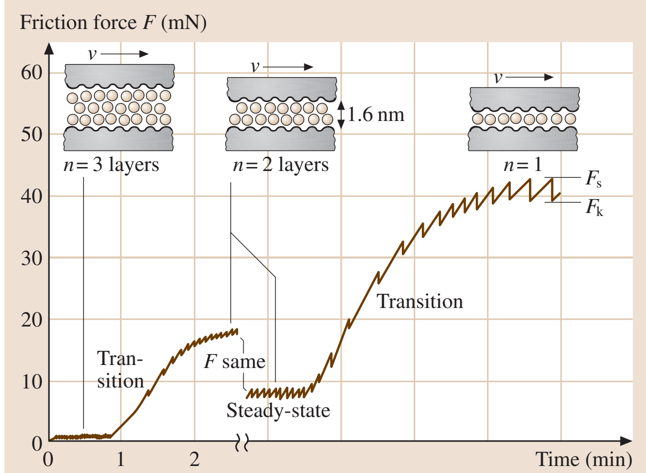

Fig. 18.27 Measured change in friction during interlayer transitions of the silicone liquid octamethylcyclotetrasiloxane (OMCTS), an inert liquid whose quasispherical molecules have a diameter of 0.8 nm. In this system, the shear stress $S_c = F/A$ was found to be constant as long as the number of layers, n, remained constant. Qualitatively similar results have been obtained with other quasi-spherical molecules such as cyclohexane [18.269]. The shear stresses are only weakly dependent on the sliding velocity v. However, for sliding velocities above some critical value, v_c, the stick–slip disappears and sliding proceeds smoothly at the kinetic value. (After [18.221] with permission)

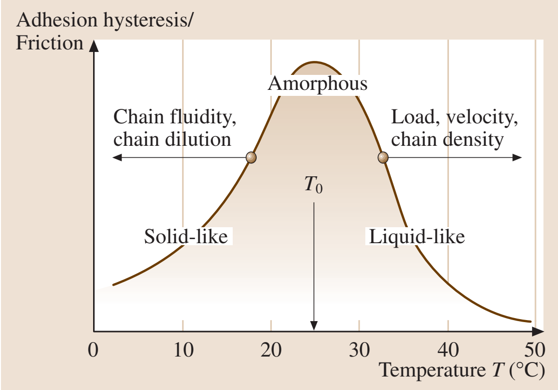

Fig. 18.28 Schematic friction phase diagram representing the trends observed in the boundary friction of a variety of different surfactant monolayers. The characteristic bell-shaped curve also correlates with the adhesion energy hysteresis of the monolayers. The *arrows* indicate the direction in which the whole curve is dragged when the load, velocity, etc., is increased. (After [18.232] with permission)

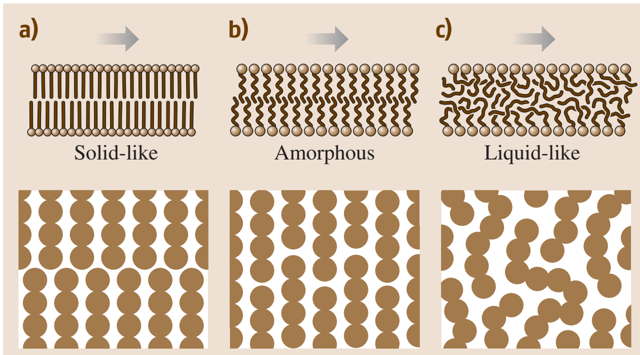

Fig. 18.29a–c Different dynamic phase states of boundary monolayers during adhesive contact and/or frictional sliding. Solid-like **(a)** and liquid-like monolayers **(c)** exhibit low adhesion hysteresis and friction. Increasing the temperature generally shifts a system from the left to the right. Changing the load, sliding velocity, or other experimental conditions can also change the dynamic phase state of surface layers, as shown in Fig. 18.28. (After [18.232] with permission)

With the added insights provided by computer simulations, a number of distinct molecular processes have been identified during smooth and stick–slip sliding in model systems for the more familiar static-to-kinetic stick–slip and transition from stick–slip to smooth sliding. These are shown schematically in Fig. 18.26 for the case of spherical liquid molecules between two solid crystalline surfaces. The following regimes may be identified:

Surfaces at rest (Fig. 18.26a): Even with no externally applied load, solvent–surface epitaxial interactions can cause the liquid molecules in the film to attain a solid-like state. Thus at rest the surfaces are stuck to each other through the film.

Sticking regime (frozen, solid-like film) (Fig. 18.26b): A progressively increasing lateral shear stress is applied. The solid-like film responds elastically with a small lateral displacement and a small increase or "dilatancy" in film thickness (less than a lattice spacing or molecular dimension, σ). In this regime the film retains its frozen, solid-like state: All the strains are elastic and reversible, and the surfaces remain effectively stuck to each other. However, slow creep may occur over long time periods.

Slipping and sliding regimes (molten, liquid-like film) (Fig. 18.26c,c′,c″): When the applied shear stress or force has reached a certain critical value, the *static* friction force, F_s, the film suddenly melts (known as "shear melting") or rearranges to allow for wall-slip or slip within the film to occur at which point the two surfaces begin to slip rapidly past each other. If the applied stress is kept at a high value, the upper surface will continue to slide indefinitely.

Refreezing regime (resolidification of film) (Fig. 18.26d): In many practical cases, the rapid slip of the upper surface relieves some of the applied force, which eventually falls below another critical value, the *kinetic* friction force F_k, at which point the film resolidifies and the whole stick–slip cycle is repeated. On the other hand, if the slip rate is smaller than the rate at which the external stress is applied, the surfaces will continue to slide smoothly in the kinetic state and there will be no more stick–slip. The critical velocity at which stick–slip disappears is discussed in more detail in Sect. 18.8.3.

Experiments with linear chain (alkane) molecules show that the film thickness remains quantized during sliding, so that the structure of such films is probably more like that of a nematic liquid crystal where the liquid molecules have become shear aligned in some direction, enabling shear motion to occur while retaining some order within the film. Experiments on the friction of two molecularly smooth mica surfaces separated by three molecular layers of the liquid OMCTS (Fig. 18.27) show how the friction increases to higher values in a quantized way when the number of layers falls from $n = 3$ to $n = 2$ and then to $n = 1$.

Computer simulations for simple spherical molecules [18.201] further indicate that during the slip the film thickness is roughly 15% higher than at rest (i. e., the film density falls), and that the order parameter within the film drops from 0.85 to about 0.25. Such dilatancy has been investigated both experimentally [18.235] and in further computer simulations [18.234]. The changes in thickness and in order parameter are consistent with a disorganized state for the whole film during the slip [18.271], as illustrated schematically in Fig. 18.26c. At this stage, we can only speculate on other possible configurations of molecules in the slipping and sliding regimes. This probably depends on the shapes of the molecules (e.g., whether spherical or linear or branched), on the atomic structure of the surfaces, on the sliding velocity, etc. [18.275]. Figure 18.26c,c′,c″ shows three possible sliding modes wherein the shearing film either totally melts, or where the molecules retain their layered structure and where slip occurs between two or more layers. Other sliding modes, for example, involving the movement of dislocations or disclinations are also possible, and it is unlikely that one single mechanism applies in all cases.

Both friction and adhesion hysteresis vary nonlinearly with temperature, often peaking at some

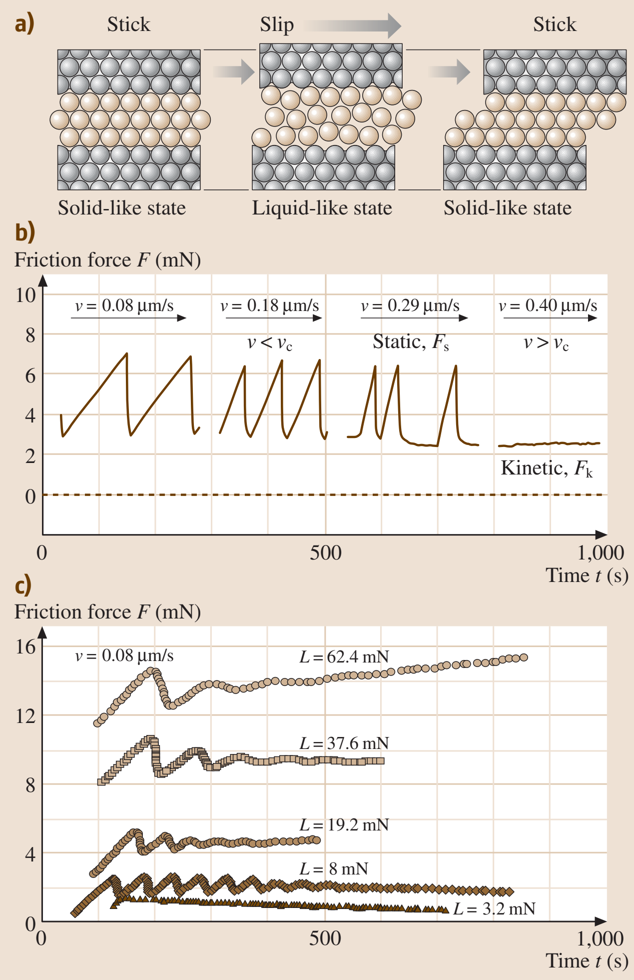

Fig. 18.30 **(a)** "Phase transitions" model of stick–slip where a thin liquid film alternately freezes and melts as it shears, shown here for 22 spherical molecules confined between two solid crystalline surfaces. In contrast to the velocity-dependent friction model, the intrinsic friction force is assumed to change abruptly (at the transitions), rather than smooth or continuously. The resulting stick–slip is also different, for example, the peaks are sharper and the stick–slip disappears above some critical velocity v_c. Note that while the slip displacement is here shown to be only two lattice spacings, in most practical situations it is much larger, and that freezing and melting transitions at surfaces or in thin films may not be the same as freezing or melting transitions between the bulk solid and liquid phases. **(b)** Exact reproduction of a chart-recorder trace of the friction force for hexadecane between two untreated mica surfaces at increasing sliding velocity v, plotted as a function of time. In general, with increasing sliding speed, the stick–slip spikes increase in frequency and decrease in magnitude. As the critical sliding velocity v_c is approached, the spikes become erratic, eventually disappearing altogether at $v = v_c$. At higher sliding velocities the sliding continues smoothly in the kinetic state. Such friction traces are fairly typical for simple liquid lubricants and dry boundary lubricant systems (see Fig. 18.31a) and may be referred to as the "conventional" type of static–kinetic friction (in contrast to Fig. 18.25). Experimental conditions: contact area $A = 4 \times 10^{-9}\,\mathrm{m}^2$, load $L = 10\,\mathrm{mN}$, film thickness $D = 0.4$–$0.8\,\mathrm{nm}$, $v = 0.08$–$0.4\,\mu\mathrm{m\,s}^{-1}$, $v_c \approx 0.3\,\mu\mathrm{m\,s}^{-1}$, atmosphere: dry N_2 gas, $T = 18\,°\mathrm{C}$. [**(a)** and **(b)** after [18.276] with permission. Copyright 1993 American Chemical Society.] **(c)** Friction response of a thin squalane (a branched hydrocarbon) film at different loads and a constant sliding velocity $v = 0.08\,\mu\mathrm{m\,s}^{-1}$, slightly above the critical velocity for this system at low loads. Initally, with increasing load, the stick–slip amplitude and the mean friction force decrease with sliding time or sliding distance. However, at high loads or pressures, the mean friction force increases with time, and the stick–slip takes on a more symmetrical, sinusoidal shape. At all loads investigated, the stick–slip component gradually decayed as the friction proceeded towards smooth sliding. (*Gourdon* and *Israelachvili*, unpublished data)

particular temperature, T_0. The temperature dependence of these forces can, therefore, be represented on a friction phase diagram such as the one shown in Fig. 18.28. Experiments have shown that T_0, and the whole bell-shaped curve, are shifted along the temperature-axis (as well as in the vertical direction) in a systematic way when the load, sliding velocity, etc., are varied. These shifts also appear to be highly correlated with one another, for example, an increase in temperature producing effects that are similar to *decreasing* the sliding speed or load.

Such effects are also commonly observed in other energy dissipating phenomena such as polymer viscoelasticity [18.277], and it is likely that a similar physical mechanism is at the heart all of such phenomena. A possible molecular process underlying the energy dissipation of chain molecules during boundary layer sliding is illustrated in Fig. 18.29, which shows the three main dynamic phase states of boundary monolayers.

In contrast to the characteristic relaxation time associated with fluid lubricants, it has been established

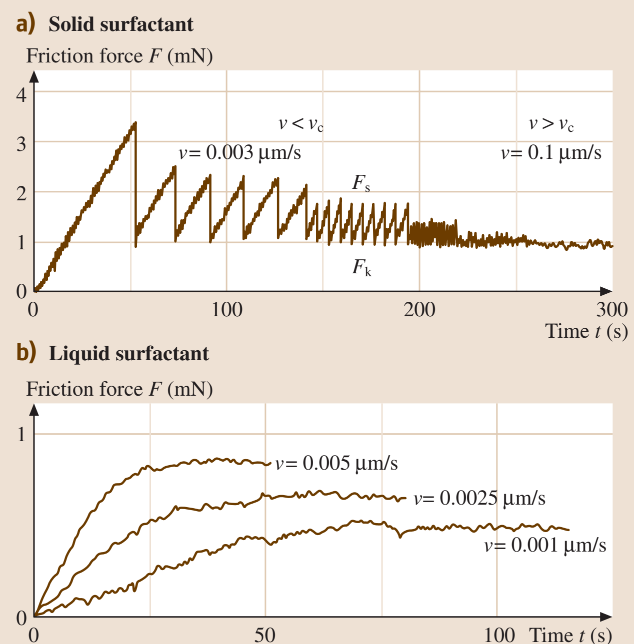

Fig. 18.31 (a) Exact reproduction of chart-recorder trace for the friction of closely packed surfactant monolayers (L-α-dimirystoyl-phosphatidyl-ethanolamine, DMPE) on mica (dry boundary friction) showing qualitatively similar behavior to that obtained with a liquid hexadecane film (Fig. 18.30b). In this case, $L = 0$, $v_c \approx 0.1\,\mu m\,s^{-1}$, atmosphere: dry N_2 gas, $T = 25\,°C$. **(b)** Sliding typical of liquid-like monolayers, here shown for calcium alkylbenzene sulfonate in dry N_2 gas at $T = 25\,°C$ and $L = 0$. (After [18.207] with permission. Copyright 1993 American Chemical Society)

that for unlubricated (dry, solid, rough) surfaces, there is a characteristic memory distance that must be exceeded before the system looses all memory of its initial state (original surface topography). The underlying mechanism for a characteristic distance was first used to successfully explain rock mechanics and earthquake faults [18.278] and, more recently, the tribological behavior of unlubricated surfaces of ceramics, paper and elastomeric polymers [18.252, 279]. Recent experiments [18.275, 280, 281] suggest that fluid lubricants composed of complex branched-chained or polymer molecules may also have characteristic distances (in addition to characteristic relaxation times) associated with their tribological behavior – the characteristic distance being the total sliding distance that must be exceeded before the system reaches its steady-state tribological conditions (see Sect. 18.8.3).

Abrupt vs. Continuous Transitions Between Smooth and Stick–Slip Sliding

An understanding of stick–slip is of great practical importance in tribology [18.282], since these spikes are the major cause of damage and wear of moving parts. Stick–slip motion is a very common phenomenon and is also the cause of sound generation (the sound of a violin string, a squeaking door, or the chatter of machinery), sensory perception (taste texture and feel), earthquakes, granular flow, nonuniform fluid flow such as the spurting flow of polymeric liquids, etc. In the previous section, the stick–slip motion arising from freezing–melting transitions in thin interfacial films was described. There are other mechanisms that can give rise to stick–slip friction, which will now be considered. However, before proceeding with this, it is important to clarify exactly what one is measuring during a friction experiment.

Most tribological systems and experiments can be described in terms of an equivalent mechanical circuit with certain characteristics. The friction force F_0, which is generated at the surfaces, is generally measured as F at some other place in the setup. The mechanical coupling between the two may be described in terms of a simple elastic stiffness or compliance, K, or as more complex nonelastic coefficients, depending on the system. The distinction between F and F_0 is important because in almost all practical cases, the applied, measured, or detected force, F, is *not* the same as the "real" or "intrinsic" friction force, F_0, generated at the surfaces. F and F_0 are coupled in a way that depends on the mechanical construction of the system, for example, the axle of a car wheel that connects it to the engine. This coupling can be modeled as an elastic spring of stiffness K and mass m. This is the simplest type of mechanical coupling and is also the same as in SFA and AFM type experiments. More complicated real systems can be reduced to a system of springs and dashpots, as described by *Peachey* et al. [18.283] and *Luengo* et al. [18.47].

We now consider four different models of stick–slip friction, where the mechanical couplings are assumed to be of the simple elastic spring type. The first three mechanisms may be considered traditional or classical mechanisms or models [18.282], the fourth is essentially the same as the freezing–melting phase-transition model described in Sect. 18.8.3.

Rough Surfaces or Surface Topology Model. Rapid slips can occur whenever an asperity on one surface goes over the top of an asperity on the other surface. The extent of the slip will depend on asperity heights and slopes, on the speed of sliding, and on the elastic

compliance of the surfaces and the moving stage. As in all cases of stick–slip motion, the driving velocity v may be constant, but the resulting motion at the surfaces v_0 will display large slips. This type of stick–slip has been described by *Rabinowicz* [18.282]. It will not be of much concern here since it is essentially a noise-type fluctuation, resulting from surface imperfections rather than from the intrinsic interaction between two surfaces. Actually, at the atomic level, the regular atomic-scale corrugations of surfaces can lead to periodic stick–slip motion of the type shown here. This is what is sometimes measured by AFM tips [18.10, 53, 231, 272].

Distance-Dependent or Creep Model. Another theory of stick–slip, observed in solid-on-solid sliding, is one that involves a characteristic *distance*, but also a characteristic time, τ_s, this being the characteristic time required for two asperities to increase their adhesion strength after coming into contact. Originally proposed by *Rabinowicz* [18.282, 284], this model suggests that two rough macroscopic surfaces adhere through their microscopic asperities of characteristic length. During shearing, each surface must first creep this distance (the size of the contacting junctions) after which the surfaces continue to slide, but with a lower (kinetic) friction force than the original (static) value. The reason for the decrease in the friction force is that even though, on average, new asperity junctions should form as rapidly as the old ones break, the time-dependent adhesion and friction of the new ones will be lower than the old ones.

The friction force, therefore, remains high during the creep stage of the slip. But once the surfaces have moved the characteristic distance, the friction rapidly drops to the kinetic value. For any system where the kinetic friction is less than the static force (or one that has a negative slope over some part of its F_0 versus v_0 curve) will exhibit regular stick–slip sliding motion for certain values of K, m, and driving velocity, v.

This type of friction has been observed in a variety of dry (unlubricated) systems such as paper-on-paper [18.285, 286] and steel-on-steel [18.284, 287, 288]. This model is also used extensively in geologic systems to analyze rock-on-rock sliding [18.289, 290]. While originally described for adhering macroscopic asperity junctions, the distance-dependent model may also apply to molecularly smooth surfaces. For example, for polymer lubricant films, the characteristic length would now be the chain–chain entanglement length, which could be much larger in a confined geometry than in the bulk.

Velocity-Dependent Friction Model. In contrast to the two friction models mentioned above, which apply mainly to unlubricated, solid-on-solid contacts, the stick–slip of surfaces with thin liquid films between them is better described by other mechanisms. The velocity-dependent friction model is the most studied mechanism of stick–slip and, until recently, was considered to be the only cause of intrinsic stick–slip. If a friction force decreases with increasing sliding velocity, as occurs with boundary films exhibiting shear thinning, the force (F_s) needed to initiate motion will be higher than the force (F_k) needed to maintain motion.

A decreasing intrinsic friction force F_0 with sliding velocity v_0 results in the sliding surface or stage moving in a periodic fashion, where during each cycle rapid acceleration is followed by rapid deceleration. So long as the drive continues to move at a fixed velocity v, the surfaces will continue to move in a periodic fashion punctuated by abrupt stops and starts whose frequency and amplitude depend not only on the function $F_0(v_0)$, but also on the stiffness K and mass m of the moving stage, and on the starting conditions at $t = 0$.

More precisely, the motion of the sliding surface or stage can be determined by solving the following differential equation:

$$\begin{aligned} m\ddot{x} &= (F_0 - F) = F_0 - (x_0 - x)K \\ \text{or} \quad m\ddot{x} &+ (x_0 - x)K - F_0 = 0\,, \end{aligned} \tag{18.47}$$

where $F_0 = F_0(x_0, v_0, t)$ is the intrinsic or "real" friction force at the shearing surfaces, F is the force on the spring (the externally applied or measured force), and $(F_0 - F)$ is the force on the stage. To fully solve (18.47), one must also know the initial (starting) conditions at $t = 0$, and the driving or steady-state conditions at finite t. Commonly, the driving condition is: $x = 0$ for $t < 0$ and $x = vt$ for $t > 0$, where $v =$ constant. In other systems, the appropriate driving condition may be $F =$ constant.

Various, mainly phenomenological, forms for $F_0 = F_0(x_0, v_0, t)$ have been proposed to explain various kinds of stick–slip phenomena. These models generally assume a particular functional form for the friction as a function of velocity only, $F_0 = F_0(v_0)$, and they may also contain a number of mechanically coupled elements comprising the stage [18.291, 292]. One version is a two-state model characterized by two friction forces, F_s and F_k, which is a simplified version of the phase transitions model described below. More complicated versions can have a rich F–v spectrum, as proposed by *Persson* [18.293]. Unless the experimental data is very detailed and extensive, these models cannot generally distinguish between different types of mechanisms.

Neither do they address the basic question of the *origin* of the friction force, since this is assumed to begin with.

Experimental data has been used to calculate the friction force as a function of velocity *within* an individual stick–slip cycle [18.294]. For a macroscopic granular material confined between solid surfaces, the data shows a velocity-weakening friction force during the first half of the slip. However, the data also shows a hysteresis loop in the friction–velocity plot, with a different behavior in the deceleration half of the slip phase. Similar results were observed for a 1–2 nm liquid lubricant film between mica surfaces [18.275]. These results indicate that a purely velocity-dependent friction law is insufficient to describe such systems, and an additional element such as the *state* of the confined material must be considered.

Phase Transitions Model. In recent molecular dynamics computer simulations it has been found that thin interfacial films undergo first-order phase transitions between solid-like and liquid-like states during sliding [18.201, 273]. It has been suggested that this is responsible for the observed stick–slip behavior of simple isotropic liquids between two solid crystalline surfaces. With this interpretation, stick–slip is seen to arise because of the abrupt change in the flow properties of a film at a transition [18.224, 225, 261], rather than the gradual or continuous change, as occurs in the previous example. Other computer simulations indicate that it is the stick–slip that induces a disorder ("shear-melting") in the film, not the other way around [18.295].

An interpretation of the well-known phenomenon of decreasing coefficient of friction with increasing sliding velocity has been proposed by *Thompson* and *Robbins* [18.201] based on their computer simulation. This postulates that it is not the friction that changes with sliding speed v, but rather the time various parts of the system spend in the sticking and sliding modes. In other words, at any instant during sliding, the friction at any local region is always F_s or F_k, corresponding to the "static" or "kinetic" values. The measured frictional force, however, is the sum of all these discrete values averaged over the whole contact area. Since as v increases each local region spends more time in the sliding regime (F_k) and less in the sticking regime (F_s), the overall friction coefficient falls. One may note that this interpretation reverses the traditional way that stick–slip has been explained. Rather than invoking a decreasing friction with velocity to explain stick–slip, it is now the more fundamental stick–slip phenomenon that is producing the apparent decrease in the friction force with increasing sliding velocity. This approach has been studied analytically by *Carlson* and *Batista* [18.296], with a comprehensive rate- and state- dependent friction force law. This model includes an analytic description of the freezing–melting transitions of a film, resulting in a friction force that is a function of sliding velocity in a natural way. This model predicts a full range of stick–slip behavior observed experimentally.

An example of the rate- and state-dependent model is observed when shearing thin films of OMCTS between mica surfaces [18.297, 298]. In this case, the static friction between the surfaces is dependent on the time that the surfaces are at rest with respect to each other, while the intrinsic kinetic friction $F_{k,0}$ is relatively constant over the range of velocities. At slow driving velocities, the system responds with stick–slip sliding with the surfaces reaching maximum static friction before each slip event, and the amplitude of the stick–slip, $F_s - F_k$, is relatively constant. As the driving velocity increases, the static friction decreases as the time at relative rest becomes shorter with respect to the characteristic time of the lubricant film. As the static friction decreases with increasing drive velocity, it eventually equals the intrinsic kinetic friction $F_{k,0}$, which defines the critical velocity v_c, above which the surfaces slide smoothly without the jerky stick–slip motion.

The above classifications of stick–slip are not exclusive, and molecular mechanisms of real systems may exhibit aspects of different models simultaneously. They do, however, provide a convenient classification of existing models and indicate which experimental parameters should be varied to test the different models.

Critical Velocity for Stick–Slip. For any given set of conditions, stick–slip disappears above some critical sliding velocity v_c, above which the motion continues smoothly in the liquid-like or kinetic state. The critical velocity is well described by two simple equations. Both are based on the phase transition model, and both include some parameter associated with the inertia of the measuring instrument. The first equation is based on both experiments and simple theoretical modeling [18.276]:

$$v_c \approx \frac{(F_s - F_k)}{5K\tau_0}\,, \qquad (18.48)$$

where τ_0 is the *characteristic nucleation time* or freezing time of the film. For example, inserting the following typically measured values for a ~1-nm-thick hexadecane film between mica: $(F_s - F_k) \approx 5\,\mathrm{mN}$, spring constant $K \approx 500\,\mathrm{N\,m^{-1}}$, and nucleation time [18.276]

$\tau_0 \approx 5$ s, we obtain $v_c \approx 0.4\,\mu\text{m s}^{-1}$, which is close to typically measured values (Fig. 18.30b).

The second equation is based on computer simulations [18.273]:

$$v_c \approx 0.1\sqrt{\frac{F_s\sigma}{m}}\,, \qquad (18.49)$$

where σ is a molecular dimension and m is the mass of the stage. Again, inserting typical experimental values into this equation, viz., $m \approx 20$ g, $\sigma \approx 0.5$ nm, and $(F_s - F_k) \approx 5$ mN as before, we obtain $v_c \approx 0.3\,\mu\text{m s}^{-1}$, which is also close to measured values.

Stick–slip also disappears above some critical temperature T_c, which is not the same as the melting temperature of the bulk fluid. Certain correlations have been found between v_c and T_c and between various other tribological parameters that appear to be consistent with the principle of time–temperature superposition (see Sect. 18.8.3), similar to that occurring in viscoelastic polymer fluids [18.277, 299, 300].

Recent work on the coupling between the mechanical resonances of the sliding system and molecular-scale relaxations [18.234, 301–303] has resulted in a better understanding of a phenomenon previously noted in various engineering applications: the vibrating of one of the sliding surfaces perpendicularly to the sliding direction can lead to a significant reduction of the friction. At certain oscillation amplitudes and a frequency higher than the molecular-scale relaxation frequency, stick–slip friction can be eliminated and replaced by an ultralow kinetic friction state.

18.9 Role of Molecular Shape and Surface Structure in Friction

The above scenario is already quite complicated, and yet this is the situation for the simplest type of experimental system. The factors that appear to determine the critical velocity v_c depend on the type of liquid between the surfaces (as well as on the surface lattice structure). Small spherical molecules such as cyclohexane and OMCTS have been found to have very high v_c, which indicates that these molecules can rearrange relatively quickly in thin films. Chain molecules and especially branched chain molecules have been found to have much lower v_c, which is to be expected, and such liquids tend to slide smoothly or with erratic stick–slip [18.275], rather than in a stick–slip fashion (see Table 18.5). With highly asymmetric molecules, such as multiply branched isoparaffins and polymer melts, no regular spikes or stick–slip behavior occurs at any speed, since these molecules can never order themselves sufficiently to solidify. Examples of such liquids are some perfluoropolyethers and polydimethylsiloxanes (PDMS).

Recent computer simulations [18.274, 304, 305] of the structure, interaction forces, and tribological behavior of chain molecules between two shearing surfaces indicate that both linear *and* singly or doubly branched chain molecules order between two flat surfaces by aligning into discrete layers parallel to the surfaces. However, in the case of the weakly branched molecules, the expected oscillatory forces do not appear because of a complex cancellation of entropic and enthalpic contributions to the interaction free energy, which results in a monotonically smooth interaction, exhibiting a weak energy minimum rather than the oscillatory force profile that is characteristic of linear molecules. During sliding, however, these molecules can be induced to further align, which can result in a transition from smooth to stick–slip sliding.

Table 18.5 shows the trends observed with some organic and polymeric liquid between smooth mica surfaces. Also listed are the bulk viscosities of the liquids. From the data of Table 18.5 it appears that there is a direct correlation between the shapes of molecules and their coefficient of friction or effectiveness as lubricants (at least at low shear rates). Small spherical or chain molecules have high friction with stick–slip, because they can pack into ordered solid-like layers. In contrast, longer chained and irregularly shaped molecules remain in an entangled, disordered, fluid-like state even in very thin films, and these give low friction and smoother sliding. It is probably for this reason that irregularly shaped branched chain molecules are usually better lubricants. It is interesting to note that the friction coefficient generally decreases as the bulk viscosity of the liquids *increases*. This unexpected trend occurs because the factors that are conducive to low friction are generally conducive to high viscosity. Thus molecules with side groups such as branched alkanes and polymer melts usually have higher bulk viscosities than their linear homologues for obvious reasons. However, in thin films the linear molecules have higher shear stresses, because of their ability to become ordered. The only exception to the

Table 18.5 Effect of molecular shape and short-range forces on tribological properties[a]

Liquid	Short-range force	Type of friction	Friction coefficient	Bulk liquid viscosity (cP)
Organic (water-free)				
Cyclohexane	Oscillatory	Quantized stick–slip	$\gg 1$	0.6
OMCTS[b]	Oscillatory	Quantized stick–slip	$\gg 1$	2.3
Octane	Oscillatory	Quantized stick–slip	1.5	0.5
Tetradecane	Oscillatory ↔ smooth	stick–slip ↔ smooth	1.0	2.3
Octadecane (branched)	Oscillatory ↔ smooth	stick–slip ↔ smooth	0.3	5.5
PDMS[b] ($M = 3{,}700\,\mathrm{g\,mol^{-1}}$, melt)	Oscillatory ↔ smooth	Smooth	0.4	50
PBD[b] ($M = 3{,}500\,\mathrm{g\,mol^{-1}}$, branched)	Smooth	Smooth	0.03	800
Water				
Water (KCl solution)	Smooth	Smooth	0.01–0.03	1.0

[a] For molecularly thin liquid films between two shearing mica surfaces at 20 °C
[b] OMCTS: Octamethylcyclotetrasiloxane, PDMS: Polydimethylsiloxane, PBD: Polybutadiene

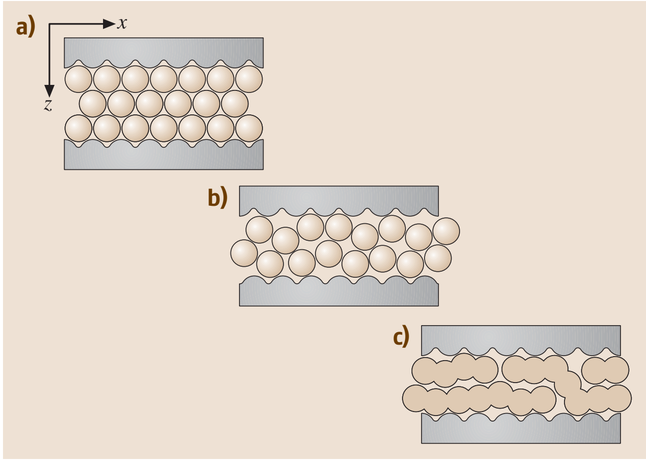

Fig. 18.32a–c Schematic view of interfacial film composed of spherical molecules under a compressive pressure between two solid crystalline surfaces. **(a)** If the two surface lattices are free to move in the x-y-z directions, so as to attain the lowest energy state, they could equilibrate at values of x, y, and z, which induce the trapped molecules to become "epitaxially" ordered into a "solid-like" film. **(b)** Similar view of trapped molecules between two solid surfaces that are not free to adjust their positions, for example, as occurs in capillary pores or in brittle cracks. **(c)** Similar to **(a)**, but with chain molecules replacing the spherical molecules in the gap. These may not be able to order as easily as do spherical molecules even if x, y, and z can adjust, resulting in a situation that is more akin to **(b)**. (After [18.276] with permission. Copyright 1993 American Chemical Society)

above correlations is water, which has been found to exhibit both low viscosity *and* low friction (see Fig. 18.20, and Sect. 18.7.3). In addition, the presence of water can drastically lower the friction and eliminate the stick–slip of hydrocarbon liquids when the sliding surfaces are hydrophilic.

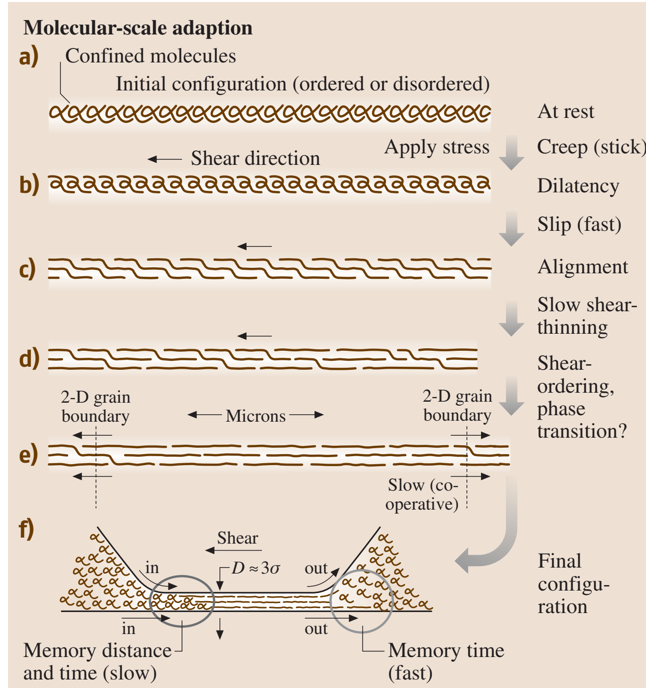

Fig. 18.33a–f Schematic representation of the film under shear. **(a)** The lubricant molecules are just confined, but not oriented in any particular direction. Because of the need to shear, the film dilates **(b)**. The molecules disentangle **(c)** and get oriented in a certain direction related to the shear direction **(d)**. **(e)** Slowly evolving domains grow inside the contact region. These macroscopic domains are responsible for the long relaxation times. **(f)** At the steady-state, a continuous gradient of confinement time and molecular order is established in the contact region, which is different for molecules adsorbed on the upper and lower surfaces. Molecules entering into the contact are not oriented or ordered. The required sliding distance to modify their state defines a characteristic distance. Molecules leaving the contact region need some (short) characteristic time to regain their bulk, unconfined configuration. (After [18.281] with permission. Copyright 2000 American Chemical Society)

If an "effective" viscosity, η_{eff}, were to be calculated for the liquids of Table 18.5, the values would be many orders of magnitude higher than those of the bulk liquids. This can be demonstrated by the following simple calculation based on the usual equation for Couette flow (see (18.44)):

$$\eta_{eff} = F_k D / A v \,, \qquad (18.50)$$

where F_k is the kinetic friction force, D is the film thickness, A the contact area, and v the sliding velocity. Using typical values for experiments with hexadecane [18.276]: $F_k = 5\,mN$, $D = 1\,nm$, $A = 3 \times 10^{-9}\,m^2$, and $v = 1\,\mu m\,s^{-1}$, one gets $\eta_{eff} \approx 2{,}000\,Ns\,m^{-2}$, or 20,000 Poise, which is $\sim 10^6$ times higher than the bulk viscosity, η_{bulk}, of the liquid. It is instructive to consider that this very high effective viscosity nevertheless still produces a low friction force or friction coefficient μ of about 0.25. It is interesting to speculate that if a 1 nm film were to exhibit bulk viscous behavior, the friction coefficient under the same sliding conditions would be as low as 0.000001. While such a low value has never been reported for any tribological system, one may consider it a theoretical lower limit that could conceivably be attained under certain experimental conditions.

Various studies [18.44, 219, 220, 222] have shown that confinement and load generally increase the effective viscosity and/or relaxation times of molecules, suggestive of an increased glassiness or solid-like behavior (Figs. 18.32 and 18.33). This is in marked contrast to studies of liquids in small confining capillaries where the opposite effects have been observed [18.306, 307]. The reason for this is probably because the two modes of confinement are different. In the former case (confinement of molecules between two structured solid surfaces), there is generally little opposition to any lateral or vertical displacement of the two surface lattices relative to each other. This means that the two lattices can shift in the x-y-z plane (Fig. 18.32a) to accommodate the trapped molecules in the most crystallographically commensurate or epitaxial way, which would favor an ordered, solid-like state. In contrast, the walls of capillaries are rigid and cannot easily move or adjust to accommodate the confined molecules (Fig. 18.32b), which will therefore be forced into a more disordered, liquid-like state (unless the capillary wall geometry and lattice are *exactly* commensurate with the liquid molecules, as occurs in certain zeolites [18.307]).

Experiments have demonstrated the effects of surface lattice mismatch on the friction between surfaces [18.203, 204, 308]. Similar to the effects of lattice mismatch on adhesion (Fig. 18.11), the static friction of a confined liquid film is maximum when the lattices of the confining surfaces are aligned. For OMCTS confined between mica surfaces [18.204] the static friction was found to vary by more than a factor of 4, while

for bare mica surfaces the variation was by a factor of 3.5 [18.308]. In contrast to the sharp variations in adhesion energy over small twist angles, the variations in friction as a function of twist angle were much more broad both in magnitude and angular spread. Similar variations in friction as a function of twist or misfit angles have also been observed in computer simulations [18.309].

Robbins et al. [18.274] computed the friction forces of two clean crystalline surfaces as a function of the angle between their surface lattices. They found that for all non-zero angles (finite "twist" angles) the friction forces fell to zero due to incommensurability effects. They further found that submonolayer amounts of organic or other impurities trapped between two incommensurate surfaces can generate a finite friction force. They, therefore, concluded that any finite friction force measured between incommensurate surfaces is probably due to such "third body" effects.

With rough surfaces, i. e., those that have *random* protrusions rather than being periodically structured, we expect a smearing out of the correlated intermolecular interactions that are involved in film freezing and melting (and in phase transitions in general). This should effectively eliminate the highly regular stick–slip and may also affect the location of the slipping planes [18.123, 252, 279]. The stick–slip friction of "real" surfaces, which are generally rough, may, therefore, be quite different from those of perfectly smooth surfaces composed of the same material. We should note, however, that even between rough surfaces, most of the contacts occur between the tips of microscopic asperities, which may be smooth over their microscopic contact area.

19. Scanning Probe Studies of Nanoscale Adhesion Between Solids in the Presence of Liquids and Monolayer Films

Adhesion between solids is a ubiquitous phenomenon whose importance is magnified at the micrometer and nanometer scales, where the surface-to-volume ratio diverges as we approach the single atom.

Numerous techniques for measuring adhesion at the atomic scale have been developed. Yet significant limitations exist. Instrumental improvements and reliable quantification are still needed.

Recent studies have highlighted the unique and important effect of liquid capillaries, particularly water, at the nanometer scale. The results demonstrate that macroscopic considerations of classic meniscus theory must be, at the very least, corrected to take into account new scaling and geometric relationships unique to the nanometer scale. More generally, a molecular-scale description of wetting and capillary condensation as it applies to nanometer-scale interfaces is clearly desirable, but remains an important challenge.

The measurement of adhesion between self-assembled monolayers has proven to be a reliable means for probing the influence of surface chemistry and local environment on adhesion. To date, however, few systems have been investigated quantitatively in detail. The molecular origins of adhesion down to the single bond level remain to be fully investigated. The most recent studies illustrate that although new information about adhesion in these systems has been revealed, further enhancements of current techniques, as well as the development of new methodologies, coupled with accurate theoretical modeling, are required to adequately tackle these complex measurements.

19.1 The Importance of Adhesion at the Nanoscale

The mutual attraction and bonding of two surfaces, which can occur with or without an intervening medium, is a commonly observed phenomenon with far-reaching manifestations and applications in society. The adherence between a raindrop and a window pane, the climbing of a gecko up a vine, the sticking of multiple adhesive note pads to a professor's wall, the force required to separate hook-and-eye (Velcro^{TM}) strips, the building

of a sand castle, and the book page turned by a wetted finger are all examples in which adhesion is important. Within the complexity of these examples and others lies a central theme: The mechanical forces between a pair of materials can be fundamentally affected not just by the macroscopic or microscopic structure of the surfaces, but also by the interatomic and intermolecular forces between them.

Adhesion and intermolecular forces have been studied for many years dating back to ancient times [19.1], and active research continues today of topics as broad as insect and reptile locomotion [19.2], interactions between cells in the body [19.3], and the design of self-healing composites [19.4], to name a few. While adhesion is clearly of interest for a wide range of macroscopic applications, its importance becomes dominant at the micrometer and nanometer scales. This is primarily due to the dramatic increase in the surface-to-volume ratio of materials at these scales, an effect that renders friction and interfacial wear critical phenomena [19.5]. For example, the dominating effect of adhesion at this scale has affected the development of microelectromechanical systems (MEMS), in which interfacial forces can prevent devices from functioning properly, since the small flexible parts often emerge from the fabrication line stuck together. Studies of adhesion in MEMS are ongoing, and commercially deployed MEMS devices rely upon sophisticated surface treatments to reduce and control adhesion [19.6–8].

Detailed control of adhesion at the molecular level will be essential for the proposed design of the smaller nanoelectromechanical systems (NEMS). Much has been written about the possibilities for nanoscale machines, sensors, and actuators, etc. It is crucial to understand that a molecule is *all* surface, and, therefore, molecular and nanoscale devices cannot be properly designed, implemented, or characterized unless an understanding of atomic-scale adhesion is thoroughly presented, particularly if these devices are to involve any moving parts that will come into and out of contact with each other. Studying adhesion at the nanoscale is important for other reasons. The protruding asperities in most MEMS materials often have nanoscale dimensions, and, therefore, a complete understanding of adhesion in MEMS requires the investigation of the adhesive properties of the individual nanoscale asperities. In addition, the experimental study of adhesion at the nanoscale is required for the development of detailed atomic-scale models of adhesion. Such progress requires close collaboration between experiment and theory.

There has been significant progress in the experimental study of adhesion at the nanometer scale using scanning probe methods, but numerous challenges exist. A discussion of solid-solid adhesion without an intervening medium is provided in part B and C of this book. This chapter focuses on how adhesion is affected by the ubiquitous presence of water, and how it can be controlled through the application of self-assembled monolayer (SAM) coatings, again in the presence of a liquid medium. In addition, we discuss specific instrumental challenges that are inherent to adhesion measurements. We do not delve into the realm of atomic-scale modeling of adhesion, nor do we discuss the role of more complex coatings such as polymer brushes and blends. Rather, we will focus on critically evaluating the relevant experimental techniques and critically reviewing recent results from studies of water and SAM films, which are perhaps the two most commonly encountered media in nanoscale adhesion applications.

19.2 Techniques for Measuring Adhesion

The experimental study of adhesion at the nanoscale has experienced two renaisances in this century. The first occurred with the development of the surface forces apparatus (SFA) [19.9, 10], and the second with the later development of the AFM [19.11] and other related scanning force techniques.

SFA experiments have contributed profoundly to our understanding of adhesion. The SFA consists of a pair of atomically smooth surfaces, usually mica sheets, mounted on crossed cylinders that can be pressed together to form a controlled circular contact. The applied load, normal displacement, surface separation, contact area, and shear force (if applied) can all be controlled and/or measured [19.9, 12–14]. The SFA can be operated in air, a controlled environment, or under liquid conditions. The surfaces are often treated to attach molecules whose behavior under confinement can be studied. Alternately, the behavior of a confined fluid layer can be observed. The surface separation can be measured and controlled in the Ångstrom (Å) regime. The lateral resolution is limited to the range of several tens of micrometers. However, the true contact

area between the interfaces can be directly measured, which is a key advantage since it allows an adhesive force to be converted to a force (or energy) per unit area (or per molecule), thus separating geometrical contributions to adhesion from chemical contributions. In this chapter, we will refer to relevant results in the context of the scanning probe experiments. As a very brief summary, some of the most important results pertaining to adhesion include: the observation of capillary effects on adhesion [19.15, 16], the presence of hysteresis in adhesion due to pressure-induced restructuring of the interface [19.17], and numerous studies of how interfacial chemistry (hydrophilicity, surface charge, specific chemical groups, etc.) affect adhesive forces [19.1, 18, 19].

AFM instrumentation is described in part B of this book. Key ways in which the AFM differs from the SFA are: (1) the lateral contact size is nm, not μm, due to the fact that the tip is usually < 100 nm in radius, and the contact area at low applied loads will be a fraction of this radius [19.20]; (2) the force resolution is as good as 10^{-10} N or better, as opposed to $\sim 10^{-6}$ N with the SFA; (3) the contact area is not directly observable, although it may be derived through other means; (4) the actual separation between the tip and sample are not directly observable, which is a key disadvantage; (5) the relative separation between the sample and the *cantilever* (not the tip) is controlled in the 0.1 nm range or better; (6) the measurement bandwidth is typically in the kHz regime, but can extend into the MHz regime depending on the data acquisition technique; (7) the operating environment includes ultrahigh vacuum (UHV) and cryogenic to elevated temperatures; (8) there is virtually no limit to the range of materials that can be probed by the AFM; and (9) half of the interface (the tip) is essentially unknown or uncontrolled, whereas with the SFA, both surfaces are well-defined, which is another key challenge for AFM that has yet to be consistently addressed.

The general setup of the AFM is as follows. A small sharp tip (with a radius typically between 10–100 nm) is attached to the end of a compliant cantilever (see Fig. 19.1). The tip is brought into close proximity with a sample surface in a fashion that is identical to STM tip–sample approach mechanisms. Forces acting between the AFM tip and the sample will result in deflections of the cantilever (Fig. 19.2). The cantilever bends vertically (i. e., toward the sample) in response to attractive and/or repulsive forces acting on the tip. The deflection of the cantilever from its equilibrium position is proportional to the normal load applied to the tip by the cantilever. Lateral forces result in a twisting of the cantilever from its equilibrium position. These measurements can be performed in a variety of environments: ambient air, controlled atmosphere, liquids [19.21], or UHV [19.22–24].

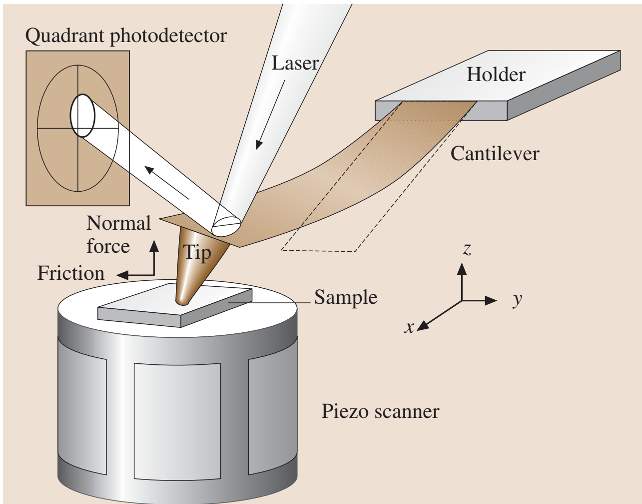

Fig. 19.1 Diagram of the AFM setup for the optical beam deflection method. The tip is in contact with a sample surface. A laser beam is focused on the back of the cantilever and reflects into a four-quadrant photodetector. Normal forces deflect the cantilever up or down, lateral forces twist the cantilever left and right. These deflections are simultaneously and independently measured by monitoring the deflection of the reflected laser beam

The simplest way (perhaps deceptively so) to measure adhesion with the AFM is through so-called force–displacement plots (also referred to in the literature as force curves and force–distance curves or plots). A force-displacement plot displays the vertical cantilever bending (i. e., the cantilever deflection, which can be calibrated to give the tip–sample interaction force) vs. lever–sample displacement. This displacement is measured between the sample and the rigidly held back end of the cantilever (as opposed to the front end with the tip, which will bend in response to interaction forces). This displacement is altered by varying the vertical position of the piezo tube, which, depending on the type of AFM, displaces the tip or the sample in the direction normal to the sample. Referring to Fig. 19.2a, the stages of acquisition of the force curve are as follows: (a) The lever and sample are initially far apart and no forces act. (b) As the lever is brought close to the sample, the tip senses attractive forces that cause the tip end of the lever to bend downward, thus signifying a negative (attractive) force. These forces may be of electrostatic, van der

Fig. 19.2 (a) A "force-displacement" curve displays the vertical cantilever deflection vs. lever–sample displacement. This displacement is measured between the sample and the rigidly held back end of the cantilever (as opposed to the front end with the tip that will bend in response to interaction forces). **(b)** The true tip–sample interaction as a function of tip–sample separation. **(c)** Tip–sample interaction energy, lever strain energy, and total energy as a function of tip–sample separation

Waals, or other origin. (c) At this point, the attractive force gradient (slope) of the tip-sample interaction force exceeds the spring constant k of the lever, and this instability causes the tip to snap into contact (d) with the sample. The lever-sample displacement can continue to be reduced and eventually crosses the force axis (e), which corresponds to zero externally applied load. As this tip is in repulsive contact with the sample, the front end of the lever is pushed further and further upward, and the force corresponds to the externally applied load. (f) The displacement direction is reversed at a point chosen by the user. As the lever-sample distance is reduced, the force becomes negative. Adhesion between the tip and sample maintains the contact, although there is now a net negative (tensile) load. Eventually the tip passes through the point of maximum adhesion (g), which is not distinguishable on this plot (see Fig. 19.2b). Finally, an unstable point is reached at which the cantilever stiffness exceeds the force gradient of the tip-sample interaction, and the tip snaps out of contact with the sample (h–i). The resulting force relaxation is usually called the pull-off force. Note that the forces and distances are not drawn to scale, and, in particular, the attractive part of the interaction is exaggerated beyond that which often occurs for inert, neutral surfaces.

The force-displacement curve can be measured at a single point, or a series of measurements can be carried out over an area of interest. The so-called adhesion

mapping techniques allow for spatially resolved adhesion measurements to be correlated with other sample properties such as friction, chemical termination, and other types of material heterogeneity.

In order to properly derive adhesion measurements from the AFM, it is critical to understand the nature of the mechanical instability of both the snap-in and pull-off processes. The fundamental point to comprehend is that *the pull-off force is* not *the adhesive bond strength*. In other words, *it is not a direct measure of the actual adhesive forces that were acting between the tip and sample in the absence of applied load*. This important point is often overlooked or misunderstood, and so we discuss it here in some detail.

A cartoon of the interaction force (F_{ts}) between the tip and sample is sketched (not to any particular scale) as a function of the true tip-sample separation in Fig. 19.2b. Superimposed on this is the force-distance relation of the cantilever: a straight line with slope k (N/m), the cantilever stiffness (diagonal dashed lines). Points of instability are shown as gray dots, labels, and arrows, as opposed to stable points, shown as black dots, labels, and arrows. Snap-in occurs when the attractive force gradient $\mathrm{d}F_{ts}/\mathrm{d}z$ just exceeds k, in other words, when the dashed line is tangent to the tip-sample force curve, as shown for point c. This instability is a direct consequence of Newton's 2nd law and is explained further below. Similarly, the pull-off occurs during retraction when k finally just exceeds $\mathrm{d}F_{ts}/\mathrm{d}z$, as shown for point h, where once again, the diagonal line is just tangent to the tip-sample force curve. By definition, since k is finite, this point *cannot* correspond to the point of maximum attractive force (or adhesive force), g. Thus, the force at which pull-off occurs is *not* precisely equal to the true adhesion force. The significance of this deviation is discussed below.

This can also be illustrated from an energetic perspective. In Fig. 19.2c, we show separately the tip-sample interaction energy, E_{ts}, as a function of tip-sample separation (top), followed by the quadratic elastic strain energy, E_{lever}, of the cantilever (middle) and the sum, E_{total}, of the two (bottom). As the lever-sample displacement is varied, the elastic energy curve is shifted to the appropriate position, which, for this example, is represented on the tip-sample separation axis. Far away from the sample, the system resides in a deep minimum, points a and b (not shown). As the tip-sample separation is reduced, this minimum becomes more and more shallow (evolving along the dashed arrow). At the snap-in point c, the minimum is eliminated, since the attractive energy of the tip-sample interaction has overwhelmed the energy minimum of the cantilever. Mathematically this is described as an inflection point, where:

$$\frac{\mathrm{d}^2 E_{tot}}{\mathrm{d}z^2} = 0 .$$

Now,

$$E_{tot} = E_{ts} + E_{lever} = E_{ts} + \tfrac{1}{2}k(z-z_0)^2 \quad (19.1)$$

∴ snap-in occurs when

$$\frac{\mathrm{d}^2 E_{ts}}{\mathrm{d}z^2} = -\frac{\mathrm{d}F_{ts}}{\mathrm{d}z} = -k .$$

This explains why the instability is described by the line of slope k being tangent to the tip-sample force curve, as shown in Fig. 19.2b. The system now rapidly finds the new minimum by following the gray arrow to point d, where a mechanical contact between the tip and sample is now formed.

Note that once the contact is formed, the tip and sample elastically deform, and so, strictly speaking, the tip-sample potential will be distinct from the potential shown before contact occurs. For simplicity, we have left out this change and instead have drawn the potential as a single-valued function. However, such changes in the energy landscape should be considered in a complete description of the problem [19.25].

Nevertheless, it will also hold true that upon retracting the tip from the surface, the stable minimum seen at e, f, and then g becomes more shallow, and eventually disappears as it is overwhelmed by the strain energy of the cantilever. Again, an inflection point is created when

$$\frac{\mathrm{d}^2 E_{attr}}{\mathrm{d}z^2} = -k , \quad (19.2)$$

in other words, when again

$$\frac{\mathrm{d}F_{ts}}{\mathrm{d}z} = k . \quad (19.3)$$

This second instability occurs at point h, the pull-off point. The system then follows the gray arrow to point i, whereby the tip is now out of contact with the sample.

If the spring is sufficiently compliant (low k), or the potential sufficiently stiff (large $\mathrm{d}F/\mathrm{d}z$ shortly past the minimum at g), then the pull-off force *does* nearly correspond to the attractive force minimum F_{min}. In other words, point h would occur very close to point g. But if the cantilever is somewhat stiff, or if the potential is rather compliant (which may be the case for organic, polymeric, biological, or liquid systems), then the pull-off force may differ substantially from F_{min}. For such

cases, this distinction between pull-off force and true adhesion is important, and the limitations imposed by the AFM's intrinsic instabilities become apparent. Of course, if a cantilever is used whose stiffness exceeds the attractive force gradient at all points, one will avoid the instabilities. But since it is the deflection of the cantilever that is used to sense the force, one would have to trade force sensitivity for stability, which is usually an unsuitable compromise.

When a compliant spring or holder is used to manipulate a probe, as is the case for AFM, the technique is generally referred to as being "load-controlled", since the load can be prescribed, but the actual displacement of the probe with respect to the sample cannot (as illustrated by the jump in displacement that occurs during snap-in or pull-off).

In contrast, "displacement-controlled" techniques avoid this instability by effectively eliminating the compliance of the spring or holder. This has been carried out for decades in the mechanical testing community, and over the past 10 years, displacement-controlled scanning probe, have been developed. This is accomplished by displacing the tip by applying force to the tip itself. *Pethica* et al. [19.26, 27] use a magnetic coating on the tip and external coils to apply forces to the tip. They refer to the instrument as a "force-controlled microscope". *Houston* et al. [19.28, 29] control the force electrostatically and refer to the instrument as an "interfacial force microscope" (IFM). *Lieber* et al. use a variation on Pethica's method, whereby a magnetic coil is used to apply a force to the cantilever [19.30], and adapted it to work in solution.

An example of an adhesion measurement with the IFM is shown in [19.31]. which shows that the instrument is able to measure the entire interaction force curve without instabilities. Thus, this provides a *direct* measurement of the minimum interaction force (as well as forces at all other tip-sample separations) and is a more reliable measure of adhesion. The disadvantage with these techniques is primarily one of inconvenience: The probes require extra manufacturing steps and control electronics. However, given the importance of adhesion in nanoscale science and technology, the extra information gained makes these techniques clearly worth the effort.

Pull-off instabilities can occur even in a displacement-controlled experiment. In this case, the instability is an "intrinsic" instability, whereby the adhesive force gradient competes with the stiffness of the *contact itself* [19.32, 33]. Adhesive materials with low stiffness, such as polymers, may show this behavior.

Finally, the pull-off force may show a time dependence that arises from intrinsic viscoelasticity of the tip or sample materials [19.34], or kinetic effects due to adsorption or reaction of materials at the interface [19.35]. These regimes remain relatively unexplored, but certainly, to compare adhesion measurements between labs, the velocity of approach and retraction, as well as the time in contact ought to be reported for any published experimental results.

A quantitative and reliable examination of adhesion, therefore, requires careful consideration of the mechanics of the contact and the cantilever. For an AFM experiment in which instabilities occur, one can conclude that the pull-off force is a good measure of adhesion only if

1. the materials are fully elastic with little or no viscoelastic character,
2. the interface is chemically stable,
3. the cantilever stiffness is sufficiently low compared with the adhesive force gradient, and
4. the contact stiffness is sufficiently high compared with the adhesive force gradient. Otherwise, a more thorough investigation is required.

19.3 Calibration of Forces, Displacements, and Tips

Whether the forces are to be measured with load-controlled or displacement-controlled techniques, measurements cannot be compared between laboratories unless the forces are properly calibrated. Unfortunately, this can be a rather involved task, and adoption of standards has yet to become widespread and robust. Here we provide a summary of the pertinent issues with references to other work for further reading; these issues are also discussed in part B and C of this book.

19.3.1 Force Calibration

Commercially available AFM cantilevers often come in two forms: V-shaped and rectangular. Silicon and silicon nitride are the typical materials, and reflective coatings are often applied to enhance the reflectivity of the laser beam. The normal force constant of a monolithic rectangular cantilever beam is well-defined [19.36], but it relies on knowledge of all lever dimensions and its mod-

ulus. For a rectangular beam of length L, width w, thickness t, Young's modulus E, the stiffness k is given by:

$$k = \frac{Ewt^3}{4L^3} . \tag{19.4}$$

The cubic dependence on thickness is particularly problematic since in microfabrication processes t is usually determined by an etching process that is not precisely controlled, and is, therefore, difficult and cumbersome to measure experimentally. Variations in E can also occur depending on the type of cantilever, particularly for silicon nitride cantilevers, although the dependence on E is clearly not as critical. If a bulk value for E is used, the thickness can be determined by measuring the resonance frequency of the cantilever [19.37]. However, this method only works for uncoated monolithic cantilevers, since the metal coatings applied to enhance reflectivity, or for other purposes, will also alter substantially the spring constant [19.38]. In addition, formulae for V-shaped levers are substantially more complicated. Uncoated, single-crystal silicon cantilevers are perhaps the only ones for which the force constant can be reliably determined by using (19.4) and the resonance frequency [19.39]. Otherwise, an experimental, preferably in situ calibration method is strongly encouraged.

Experimental methods to calibrate the force constant of AFM cantilevers have been discussed extensively [19.37, 40–50]. It has been shown repeatedly that the manufacturer's quoted spring constants can be in error by large factors and should simply not be used in any quantitative research effort. We will not delve into the details of these calibration methods, but we do make note of one particularly recent method proposed by *Sader* et al. [19.51] that appears to be reliable and simple to carry out for rectangular levers. It relies on measuring the resonance frequency and the quality factor of the cantilever in air. Use of the hydrodynamic function relates the damping of air to the quality factor, and the dependence of E and t is eliminated from the resulting formula for the force constant.

19.3.2 Probe Tip Characterization

A problem of quite a different nature is that the geometry of the contact formed between the AFM tip and sample surface is not defined if the tip shape and composition is not known. This issue is of crucial importance since one is trying to understand the properties of an interface, and the tip is half of that interface.

The adhesion force between the tip and sample is a meaningless quantity in the absence of any knowledge of the tip shape [19.20]. The only use for such measurements is in cases where the *same* tip is used to compare different samples or different conditions, and verification by cyclic repetition of the experiments is carried out to ensure that the tip itself did not change during the experiment.

There are several in situ methods to characterize the tip shape. A topographic AFM image is actually a convolution of the tip and sample geometry [19.52]. Separation of the tip and sample contributions by contact imaging of known, or at least sharp, sample features allows determination of the tip shape to a significant extent [19.53–64]. Ex-situ tip imaging by transmission electron microscopy has also been performed [19.61, 65]. Some of these measurements have revealed that a *majority* of microfabricated cantilevers possess double tips and other unsuitable tip structures [19.56, 60, 64]. This convincingly demonstrates that tip characterization is absolutely necessary for useful nanotribological measurements with AFM. Thin film coatings applied to microfabricated levers can provide robust, smooth, and even conductive coatings [19.65–67]. Further work in this direction would be useful so as to provide a wider array of dependable tip structures and materials.

In addition to the shape of the tip, its chemical composition is equally important, but is also challenging to determine or control. *Xiao* et al. have shown that the AFM tip is readily chemically modified when scanned in contact with various materials [19.68], even tips that have been coated with self-assembled monolayers in order to control their chemistry. They recommend "running in" the tip with a standard sample to give reproducible results. The stresses that take place in a nano-contact can be very large [19.5], and so modification of both the chemistry and structure of the tip is important to consider.

One class of experiments for which the tip shape and chemistry is not as critical is when a molecule or nanostructure is tethered to the end of the tip and specific interactions are probed [19.69–73]. Another alternative method is to use colloid probes [19.74,75], whereby colloidal particles are attached to the cantilever on top of (or in place of) the tip. This method requires a unique calibration procedure [19.76], but provides particles whose structure and chemistry can be measured and perhaps controlled prior to attachment to the lever.

19.3.3 Displacement Calibration

Proper signal and spatial calibration also requires knowing the sensitivity of the piezoelectric scanning elements. This can involve complications due to instrumental drift [19.77] and inherent piezoelectric effects, namely nonlinearity, hysteresis, creep, and variations of sensitivity with applied voltage [19.78–82]. Caution must be exercised when determining and relying upon these parameters. Techniques such as laser interferometry [19.83], scanning sloped samples [19.45, 78], scanning known surface step heights [19.84], or the use of pre-calibrated piezoelectrics [19.85] can facilitate piezo calibration.

19.4 The Effect of Liquid Capillaries on Adhesion

The adsorption of water and other liquids onto surfaces, and their subsequent behavior at interfaces, continue to be a vibrant area of research. The importance of liquid-solid interface behavior is massive, encompassing topics as broad as paints, textiles, lubricants, geology, and environmental chemistry, and covering all corners of biology.

19.4.1 Theoretical Background

The ability to measure forces at the nanoscale using scanning probe microscopy has generated much interest in these fields. For any force measurement carried out in ambient laboratory conditions, one must consider the possibility of a capillary neck forming between the tip and sample. The study of such necks may, in turn, provide insight into the behavior of the liquid, which is discussed in other chapters in this book. In order to provide background for these emerging areas, we consider here the fundamental mechanical and chemical aspects of adhesion in the presence of a liquid meniscus. By way of introduction, *Israelachvili* [19.17] and *de Gennes* [19.87] provide rigorous coverage of the terminology, physics, and chemistry of liquid films and their wetting properties.

Water readily adsorbs at many surfaces. At a crack or sharp corner it can condense to form a meniscus if its contact angle is small enough. The small gap between an AFM tip and a surface is, therefore, an ideal occasion for such condensation. Early on, it was realized that liquid condensation plays a significant role in tip-sample interactions [19.88, 89].

The classic theory of capillary condensation starts by considering the thermodynamics of capillary formation. The general geometry of the capillary is shown in Fig. 19.3, adapted from [19.86], with hydrophobic surfaces sketched on the left half ($r_1 > 0$) and hydrophilic surfaces on the right half ($r_1 < 0$). The tip is idealized as a sphere of radius R. The water contact angles with the sample and tip respectively are θ_1 and θ_2. D represents the separation of the tip and sample. The angle ϕ is referred to as the "filling angle". The pressure difference, or Laplace pressure, across a curved interface is given by the Young–Laplace equation [19.17, 86]:

$$\Delta p = \gamma \left(\frac{1}{r_1} + \frac{1}{r_2} \right) , \qquad (19.5)$$

where r_1 and r_2 are defined in Fig. 19.3 and γ is the surface tension of the liquid. The resulting force is attractive if $\Delta p < 0$. Note that $r_1 > 0$ and $r_2 < 0$. If the capillary formation is isothermal, then one can derive the Kelvin equation:

$$RT \ln \frac{p}{p_0} = \gamma V \left(\frac{1}{r_1} + \frac{1}{r_2} \right) , \qquad (19.6)$$

where p_0 is the saturation pressure of the liquid, V is the molar volume of the liquid, T is the temperature, and R the molar gas constant. The ratio p/p_0 simply corresponds to the relative vapor pressure of the liquid,

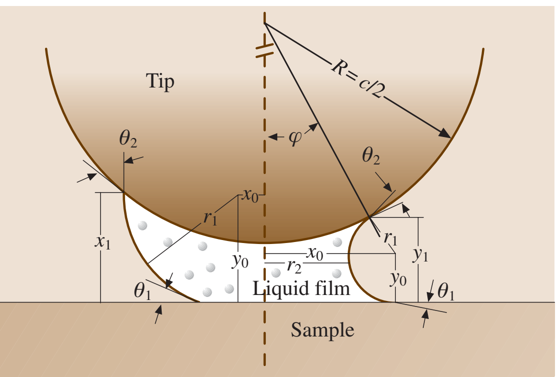

Fig. 19.3 The AFM tip considered as a sphere at a distance D from the sample. The liquid film in between may form a concave (*right*) or convex (*left*) shaped meniscus in the plane shown (adapted after [19.86])

which in the case of water is just the relative humidity (RH). This is often rewritten in terms of the Kelvin radius r_k:

$$r_k^{-1} = \left(\frac{1}{r_1} + \frac{1}{r_2}\right) = \frac{R_\mathrm{M} T}{\gamma V} \ln \frac{p}{p_0} \,. \quad (19.7)$$

The Kelvin radius varies logarithmically with the partial pressure of the liquid and is by definition less than zero (negative values correspond to convex curvature). For water at 20 °C, $\gamma V / RT = 0.54\,\mathrm{nm}$. A graph of r_k vs. p/p_0 is shown in Fig. 19.4. Of particular note is the fact that starting from $p/p_0 = 0.35$ and higher, we find $|r_\mathrm{k}| < 2\,\mathrm{nm}$. The application of this classic theory to capillaries with such small curvature radii is certainly a question to be considered carefully, and we will address it below.

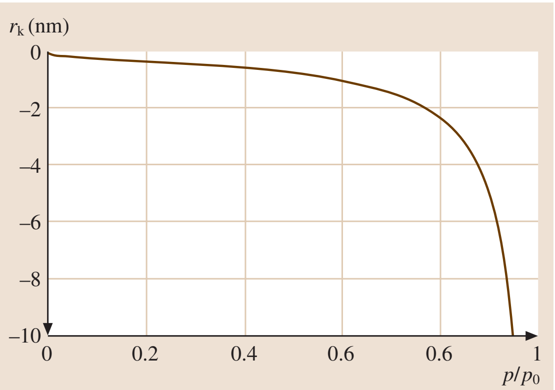

Fig. 19.4 The Kelvin radius of water at 20 °C plotted as a function of the relative humidity

A simple equation for the maximum attractive capillary force F_c between the tip and sample that is commonly used is:

$$F_\mathrm{c} = -4\pi\gamma R \cos\theta \,. \quad (19.8)$$

This equation is calculated by considering the Laplace pressure only. The adhesion force is predicted to be independent of RH. Notice that an immediate problem arises, which is that it predicts a finite force even at 0% RH, where there can be no capillary formation. Derivations of (19.8) are presented in several other publications [19.17, 86, 90, 91]. Significantly, this equation and its use with AFM experiments contain several assumptions, *many of which may not be valid for an AFM experiment*:

1. $|r_1| \ll R$, which is equivalent to saying ϕ is small,
2. $|r_1| \ll |r_2|$,
3. $\theta_1 = \theta_2$,
4. $D \ll |r_1|, |r_2|$,
5. the tip is shaped like a perfect sphere,
6. the effect of solid-solid adhesion is negligible with respect to the meniscus force,
7. the meniscus cross sections are perfect, circular arcs,
8. the force from the Laplace pressure dominates the force due to the resolved surface tension of the meniscus,
9. the surface tension γ is independent of the meniscus size,
10. the meniscus volume remains constant as the tip is retracted,
11. the maximum force of attraction is equal to the pull-off force,
12. the tip and sample are perfectly rigid.

Assumption 1 may not be true, since the tip radius may indeed be small and comparable to the meniscus curvature radii. Assumption 2 may not be true since the small tip geometry may lead the two meniscus curvature radii to be similar. Assumption 3 is by no means true if the tip and sample are made of different materials. Assumption 4 may not be true since both the separation of the tip and sample, as well as the radii r_1 and r_2 may be in the nanometer range. Assumption 5 may be slightly or grossly in error and is a particularly dubious assumption in the absence of tip characterization. In addition, for large menisci, the capillary will grow beyond the end of the tip and start climbing up its shank, which may be pyramidal or conical in shape. Assumption 6 may also be inaccurate if van der Waals or other adhesive forces are significant (this is discussed further in the next section). Assumption 7 is not correct [19.90], and the regimes where it is a reasonable approximation require close scrutiny. Assumption 8 will be inaccurate at high relative vapor pressures [19.17, 91]. The nature of assumptions 1 to 8 and corrections to the theory to account for their violation are presented in the work of *Orr* and *Scriven* [19.90]. This theory remains within the bounds of the classical picture of capillary formation.

Assumption 9 concerns an important scientific question that has not been fully resolved and represents the possible violation of the classical framework of molecular effects at the nanoscale. SFA measurements by *Israelachvili* have indicated that for cyclohexane and other inert organic liquids, γ remains nearly equal to its macroscopic value even for Kelvin radii that, remarkably, correspond to one or two molecular diameters. However, for water, the adhesion force comes to within

10% of the bulk prediction only when $p/p_0 > 0.9$, which corresponds to a Kelvin radius greater than ~ 5 nm in magnitude [19.16]. This deviation from macroscopic thermodynamic predictions alone calls the use of (19.8) into serious question for AFM measurements. Rather, the exploration of this deviation at the molecular scale presents a unique opportunity for scanning probe measurements.

Assumptions 10 and 11 are not assumptions of (19.8) itself, but rather are assumptions that are often used when applying (19.8) to AFM measurements. Equation (19.8) simply gives the maximum force of attraction between the tip and sample. As discussed above, an AFM does *not* measure this quantity. Rather, it measures the force at which an instability occurs. If a capillary has formed between the tip and sample, then the force as a function of distance can be calculated. Calculating this force requires making one of two assumptions: Either the volume of the capillary is conserved (i. e., the rate of displacement is large with respect to the adsorption or desorption kinetics of the liquid), or the Kelvin radius is conserved (i. e., the rate of displacement is slow with respect to the adsorption or desorption kinetics of the liquid, and so the capillary remains in equilibrium). The constant volume assumption 10 has been used in every paper we have reviewed. *Israelachvili*, however, pointed out the difference between these two approaches in his book [19.17] and left the solution of the problem as an exercise to the reader! As with the problem of scale-dependent surface tension mentioned above, the kinetics of capillary formation and dissolution is a relatively unexplored problem and is therefore worthy of further investigation. A recent study of the humidity dependence of friction as a function of sliding speed is an example where this issue is raised [19.92].

Once an assumption about how the meniscus changes with displacement has been made, one still needs to consider the nature of the instability in order to relate the AFM pull-off measurement to the capillary's properties. As stated above and shown in Fig. 19.2, a low lever stiffness k or a strongly varying adhesive force will lead to a pull-off force that is nearly equal to the adhesive force, and so assumption 11 would be valid. However, if k is sufficiently large, or the capillary stiffness sufficiently weak, this assumption will fail. As we shall see below, experimental efforts to investigate this point, and theoretical work to predict it, have yet to be carried out.

Finally, assumption 12, if violated, requires a substantially more complex analysis. The question has been addressed independently by *Maugis* [19.93] and *Fogden* and *White* [19.94]. Both papers provide a nondimensional parameter that allows one to determine the severity of the effect. In the limit of small tips, stiff materials, large (in magnitude) Kelvin radii, and low surface tensions, the effect of elastic deformation is negligible. However, for relatively compliant materials, large tips, and small Kelvin radii, the meniscus can appreciably deform the contact in the immediate vicinity of the meniscus. This can substantially alter the mechanics of adhesion, as well as significantly affect the stresses. The dependence on the Kelvin radius is particularly critical. This effect may be of particular concern with soft materials like polymers or biological specimens. According to *Maugis*, the problem is analogous to the adhesive contact problem for solids, discussed by *Johnson* et al. [19.95] and studied further in many papers since [19.25, 96, 97].

19.4.2 Experimental and Theoretical Studies of Capillary Formation with Scanning Probes

There have been several experimental and theoretical investigations of how pull-off forces are affected by liquid capillaries. These studies have mostly focused on the effect of relative humidity. We do not present an exhaustive review here, but rather summarize a few key results that highlight the important trends observed and the outstanding questions that remain.

Early on, it was realized that water capillary formation occurred readily if at least one of the two surfaces in contact was hydrophilic. Higher adhesion will lead to higher contact forces and therefore larger elastic contact areas, and this can degrade the lateral spatial resolution of the AFM, as observed by *Thundat* et al. [19.98]. Furthermore, several observations have confirmed the expected result that capillary formation was readily prevented for hydrophobic surfaces. For example, *Binggeli* and *Mate* [19.88, 99] showed that tungsten tips in contact with clean silicon wafers with a hydrophilic native oxide exhibited strong adhesion and long pull-off lengths, whereas surfaces treated with a hydrophobic perfluoropolyether (such as Z-dol) showed pull-off forces reduced by a factor of 2 to 3. These results were confirmed by *Bhushan* and *Sundararajan* [19.100] who investigated the pull-off force between silicon nitride tips and Si(100) with and without Z-dol coatings for a range of relative humidities. As another example, MoO_3 films, likely hydrophilic, showed a sixfold increase in pull-off force measured with silicon tips from 0 to 50% RH [19.101].

While these examples illustrate some basic trends, the need for more finely resolved measurements as

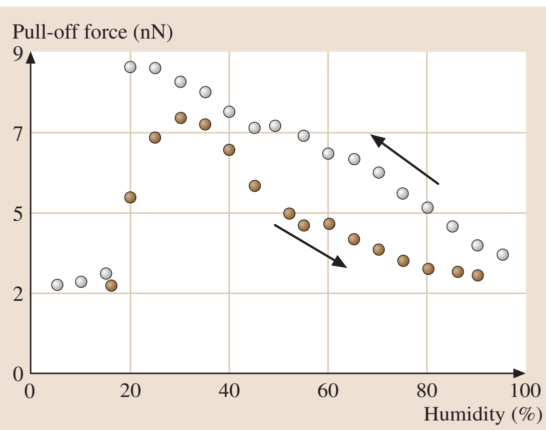

Fig. 19.5 Pull-off force between a silicon nitride tip and the muscovite mica surface as a function of RH. Two sets of data are shown: increasing (*grey circles*) and decreasing (*brown circles*) humidity (after [19.35])

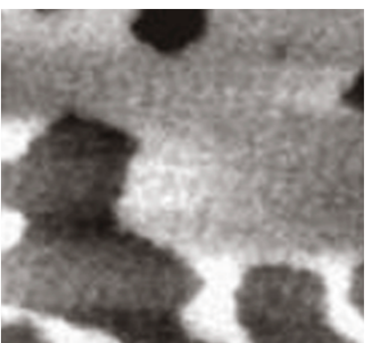

Fig. 19.6 Scanning polarization for microscopy image of water structures on the muscovite mica surface. A degree of polygonal shape to the boundaries is seen. The signal represents two distinct phases of water that are present as a molecular film below 45% RH (after [19.35])

a function of humidity has been addressed only quite recently. For example, *Xu* et al. measured adhesion between a silicon nitride tip and (hydrophilic) muscovite mica in $\sim 5\%$ RH increments. The result is shown in Fig. 19.5. There are three identifiable regions: constant adhesion at low RH ($< 20\%$), increasing adhesion, and then decreasing adhesion. Some hysteresis is seen between experiments conducted with increasing and decreasing RH, but the overall trend is preserved. *Xu* et al. correlated their measurements with detailed studies of the growth of molecular water films on the mica surface, which they could image directly using scanning polarization force microscopy (Fig. 19.6). They proposed that below 20%, capillary condensation does not occur, and, indeed, they saw no evidence of a water film at these low humidities. Above 20% RH, a strongly bound molecular water layer was formed on the bare mica surface (Fig. 19.6). In the presence of the tip, a capillary meniscus condensed. Above 40% RH, the pull-off force decreased. Recognizing one of the limitations of (19.8), *Xu* et al. attribute this to the violation of assumption 5, listed above. They argue that for a pyramidal AFM tip, r_1 and r_2 become comparable in magnitude (and remain opposite in sign) once the capillary reaches the shank of the tip, leading to a near cancellation of the Laplace pressure given in (19.5). This argument is certainly plausible, although a rigorous proof is not provided, and the other limitations of (19.8) are not discussed in relation to this issue. Nevertheless, the correlation between the onset of adhesion increase and the formation of the molecular water film, as seen directly in their dramatic images, is an extremely convincing case where the classical assumptions of (19.8) must be modified to account for the molecular structure of the water film.

Further considerations of the limitations to the (19.8) were measured, discussed, and modeled in a detailed paper by *Xiao* and *Qian* [19.91]. Adhesion measurements, collected in large numbers for good statistics, were carried out with the same silicon nitride tip on two different surfaces: hydrophilic SiO_2 and a hydrophobic layer of *n*-octadecyltrimethoxysilane (OTE) on SiO_2. Contact angle measurements to confirm the assertion of hydrophilicity were not presented, however, the OTE surface was confirmed to be hydrophobic with a water contact angle of 108°. The results are shown in Fig. 19.7. The hydrophobic surface shows no dependence on RH, whereas the hydrophilic bare SiO_2 surface

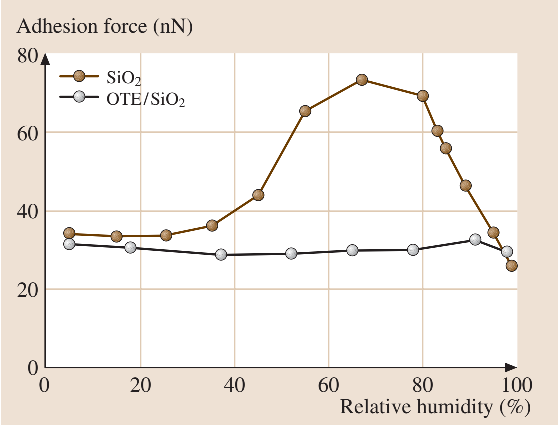

Fig. 19.7 Pull-off force as a function of RH for adhesion between a silicon nitride tip and SiO_2 (*brown circles*) and OTE/SiO_2 (*grey circles*) samples (after [19.91])

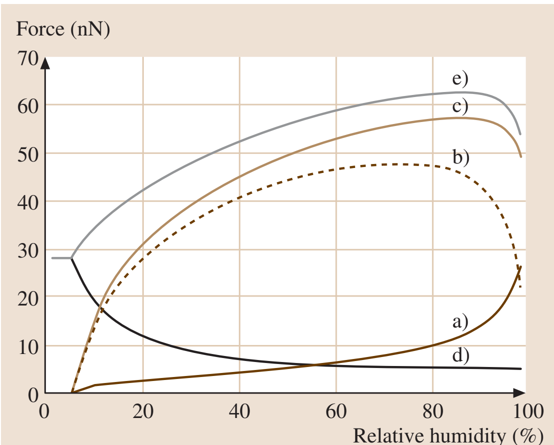

Fig. 19.8 Contributions to the adhesion force as a function of humidity: a) resolved surface tension force; b) Laplace pressure force; c) total capillary force (Laplace + surface tension); d) van der Waals force; e) total adhesion force. (After [19.91])

shows three regimes similar to the result of *Xu* et al.: constant pull-off force (>∼ 30% RH), increasing pull-off force (30%–70% RH), and then decreasing pull-off force. *Xiao* and *Qian* discuss the limitations of (19.8) in substantial detail. In particular, they consider the violation of assumptions 1 through 8 listed above. This includes a treatment of van der Waals adhesion, taking into consideration the effect of electrostatic screening of this force by the water itself. Equations for this more general case are presented. With all these aspects taken into account, they are only able to fit the model to their data qualitatively (Fig. 19.8). At low RH (< 10%), the van der Waals force dominates and the adhesion is initially constant. At intermediate values, the Laplace pressure contribution increases and then begins to saturate. The contribution from the resolved surface tension becomes significant at high RH (above ∼ 80%), and the contribution from the Laplace pressure begins to drop strongly around this same point. Qualitatively, this reproduces their results (and the aforementioned ones) by producing regimes of constant, increasing, and then decreasing adhesion. However, the humidities at which the transitions occur, and the relative changes in adhesion, do not match the data. Somewhat better agreement at high RH (> 70%) is found by considering alternate (blunt) tip shapes. Nevertheless, the most significant discrepancy occurs for low RH, where the extent of the constant adhesion force is underestimated by the classical theory. The authors attribute this to the failure of the classical continuum theory to properly describe the properties of a molecular-scale meniscus. Another interesting point of this study is that at low RH, the adhesion is very similar for both samples, a fact that the authors attribute to the dominance of the van der Waals force for both samples (which is largely determined by the substrate and not affected significantly by the OTE film).

Slightly more recently, *He* et al. have studied capillary forces for a variety of tip-sample pairs [19.102]. Hydrophilic tips (silicon and silicon nitride with no surface treatment) and hydrophobic tips (coated with *n*-octadecyltricholorsilane) were used. The hydrophobic character of the tip was asserted based on a water contact angle measurement of 105.5°, presumably taken on

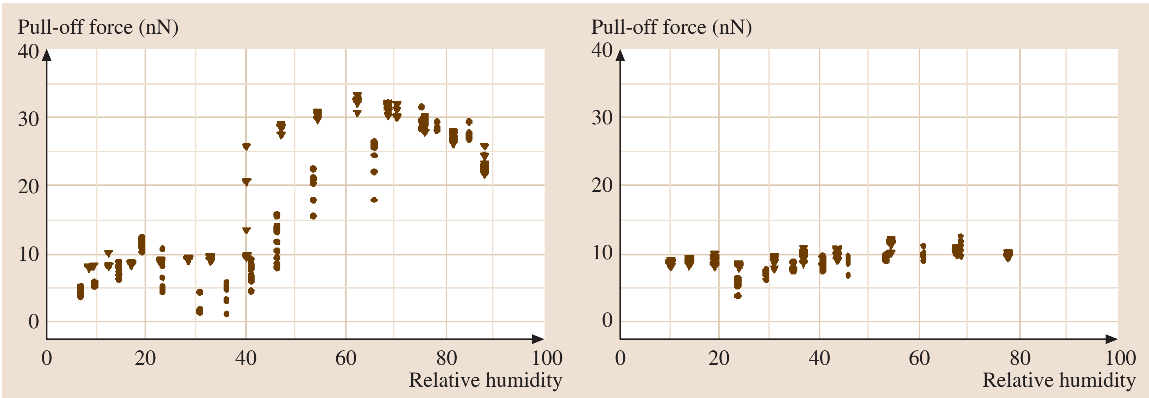

Fig. 19.9 **(a)** Pull-off force vs. RH measured between a hydrophilic tip and a flat silicon sample. *Circles*: measured when increasing RH. *Triangles*: measured when decreasing RH. **(b)** Pull-off force vs. RH measured between a sharp SFM tip coated with OTS and a flat silicon sample. The pull-off force is independent of humidity. (After [19.102])

a different region of the cantilever chip. Solvent-cleaned silicon samples and calcium fluoride films were used as hydrophilic substrates. As with the measurements of Xiao and Qian, contact angle measurements for the hydrophilic samples and tips were not presented. Results for hydrophobic and hydrophilic tips are shown in Fig. 19.9.

These results, which were carried out independently and without knowledge of Xiao and Qian's work, show impressive agreement. This is particularly interesting given that here the tip was varied from hydrophilic to hydrophobic (while the sample stayed hydrophilic), whereas in Xiao and Qian's work, the tip presumably remained hydrophilic and the sample was varied from hydrophilic to hydrophobic. For the hydrophobic tip, the pull-off force remains constant, indicating once again that capillary formation was suppressed. However, for the hydrophilic tip, three regimes of adhesion are found (Fig. 19.9). Similar results are found when a hydrophilic glass microsphere is used as a tip. The authors refer to these three regimes as the van der Waals regime, the mixed van der Waals–capillary regime, and the capillary regime. In agreement with Xiao and Qian's assessment, the authors propose that at low RH ($<\sim 35\%$ in this case), the formation of the water meniscus is suppressed and the adhesion is dominated by solid-solid (presumably van der Waals) interactions. They propose, based on the work of *de Gennes* on the theory of spreading [19.87], that a minimum precursor film thickness is required to form the meniscus. The authors also present a calculation of the adhesion force when assumptions 1 and 2 are relaxed.

Note that the results discussed above consistently indicate that only one hydrophilic surface is required to form the water film. This means that should meniscus formation be undesirable in a nanoscale application (as is the case for MEMS), then hydrophobic treatment of *both* contacting surfaces is likely required.

Practical guidance for discerning the dependence of capillary and van der Waals force is provided by *Stifter* et al. [19.86], who have produced a detailed theoretical model of the meniscus as a function of contact angles, tip size, relative humidity, separation, and surface tension (to represent liquids other than water). An example is shown in Fig. 19.11. The model relaxes assumptions

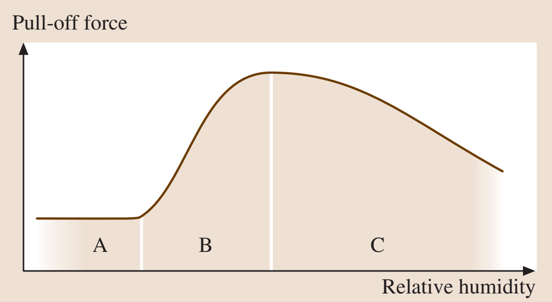

Fig. 19.10 Figure illustrating the distinct regimes of the pull-off force as a function of RH. Regimes A, B, and C are referred to as the van der Waals regime, mixed van der Waals–capillary regime, and capillary regime, respectively. (After [19.102])

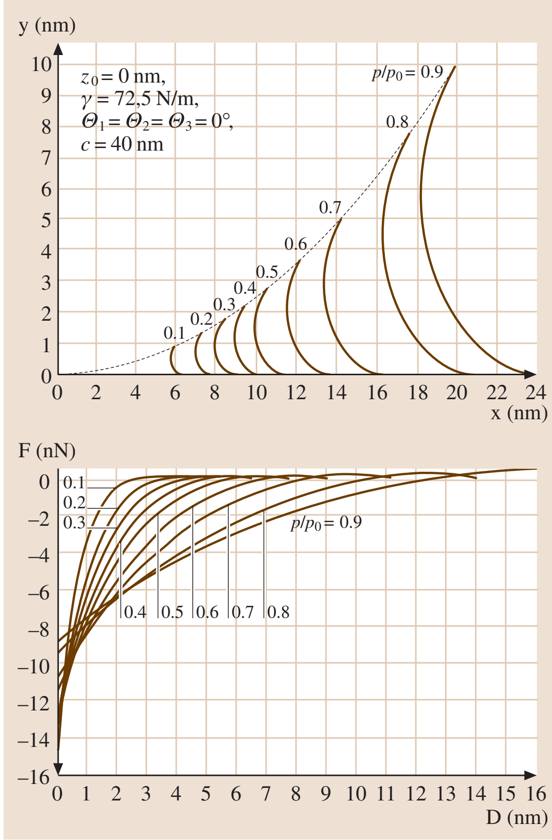

Fig. 19.11 *Top*: geometric shape of the meniscus for a range of RH values. *Bottom*: the meniscus force between the tip and the surface due to the Laplace pressure. The *dashed line* represents a cantilever with force constant 1 N/m. This relatively stiff value is still less stiff than the capillary force curve and suggests that the pull-off force would be very close to the true adhesion force. Of course, summation of the van der Waals and other contributions are necessary to make a full comparison of this sort. (After [19.86])

1 through 4 and 6. These studies show regimes where either van der Waals force or Laplace pressure forces dominate and provide guidance for actual values of the tip geometry and contact angles that minimize the capillary forces. It is not clear how much of an effect the resolved surface tension would have, as that is not included in this particular calculation. Another practical result is that for most of the plots of force vs. displacement, the "stiffness" (gradient) of the curve rarely drops below 1 N/m. This indicates that, within the assumptions of this paper, using cantilevers with force constants of 0.1 N/m will give pull-off forces that are reasonably accurate measurements of the adhesion force. This is consistent with the results of *He* et al., who found no dependence of their measurements when using cantilevers whose nominal force constants ranged from 0.032–0.5 N/m.

19.4.3 Future Directions

The results and modeling so far indicate the possibility of two trends. Hydrophobic surfaces will exhibit little dependence of adhesion on RH, whereas if one surface is hydrophilic, three regimes of behavior occur: constant solid-solid adhesion at low RH, increasing adhesion at intermediate RH, and decreasing adhesion at the highest RH. Some insight into the physical mechanisms behind these regimes has been presented, but it would be desirable to pursue further work in this area.

Perhaps most critically needed is an atomic-scale picture of the menisci and water films present under low partial pressures. This could address the question of why adhesion is initially independent of RH, and when the meniscus itself would start to form. Further theoretical developments that address the assumptions laid out above would help to clarify the picture. It is also important to extend these studies beyond simply the case of water, as the properties of other liquids are also of great interest and could be compared to previous experiments with the SFA and other tools.

Studies that clarify the kinetics of meniscus formation are also needed. There should be a noticeable transition in behavior once the rate of displacement becomes comparable to the appropriate kinetic rates, and this could provide valuable information about these kinetic processes at the nanometer scale.

Finally, as mentioned before, there continues to be a gap in reproducibility and comparability between laboratories that will only be bridged when standard techniques for tip characterization and force and displacement calibration are addressed. Efforts that take these considerations into account are worthy of support.

19.5 Self-Assembled Monolayers

When thinking about adhesion and the related phenomenon of friction, it is important to realize that the interfaces of real surfaces in contact are rarely atomically smooth. Surfaces that appear smooth on the macroscopic scale, upon closer inspection are found to consist of nanometer-scaled asperities (typically on the order of 10 nanometers) whose intentional or accidental interactions ultimately control adhesion, friction, and wear at contacts [19.6, 7, 103–105]. The size of these asperities becomes particularly important when one considers that the true contact area between interfaces for the load distribution is localized through these asperity-asperity interactions in wich extremely high pressures can be produced, sharply increasing local stress fields that can cause materials to yield and shear as they encounter each other during sliding and intermittent contact. In addition to load distribution at nanoscale asperity-asperity contacts, their size will influence surface wetting and adhesion due to capillary forces localized at the contacts [19.7, 104, 105]. The structure of applied lubricant films at such asperities will be highly dependent upon asperity curvature, and defects in lubricant film structure may form more readily here than on atomically flat surfaces.

19.5.1 Adhesion at SAM Interfaces

The minimization of adhesion at such asperity-asperity contacts is a critical issue in MEMS devices [19.6, 7, 104, 105]. In fact, the intentional introduction of surface roughness (on the order of 10 nm RMS) can be employed to lead to reduced stiction during post–processing feature release. These same asperities, however, must later resist wear during controlled or accidental contact during device operation. Thus, the specific details of adhesion and energy dissipation at such asperity-asperity contacts are required for the rational design of such systems.

To function as a protective lubricant layer in such systems, self-assembled monolayers (SAMs) of alkylsilane and fluorosilane compounds with chain lengths

ranging from C_{10} to C_{18} have been useful in the reduction of friction and adhesion in MEMS [19.7, 104–106]. Such direct applications of SAMs as lubricant films, combined with the ease of sample preparation and the ability to generate model surfaces with well-defined film chemistry and structure, have made nanotribological and adhesion studies of SAMs a rich area of research [19.5]. Many of these nanotribological studies have used AFM to examine either SAMs of alkylsilane films on atomically smooth Si wafers, glass, or mica surfaces. Alternatively, many researchers have examined alkanethiol films on atomically smooth Au(111) surfaces. Using this approach, many molecular level details, such as the influence of film chemistry and molecular organization on friction, and the adhesion and wear of SAMs, can be obtained. Developing a clear understanding of the details of adhesion at SAM-modified surfaces allows for the complex links between surface chemistry, adhesion, and friction to be understood at the molecular level. In this section, we overview AFM studies of adhesion on SAM-modified surfaces.

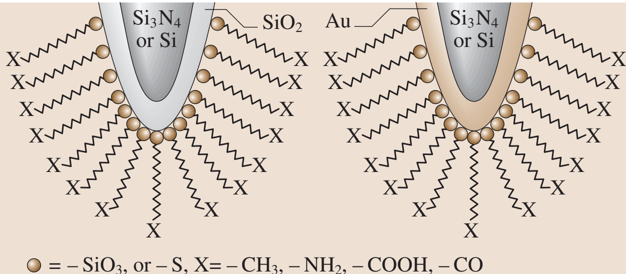

Fig. 19.12 The modification of AFM tips for chemical force microscopy is frequently carried out by chemical functionalization by alkylsilane monolayers on the oxidized surfaces of Si- or Si_3N_4-based tips, or by alkylthiol monolayers assembled on Au-coated (∼ 50 nm) AFM tips. The Au tips also typically have a Cr binding layer (∼ 5 nm) placed on before Au coating

19.5.2 Chemical Force Microscopy: General Methodology

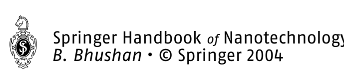
In order to probe adhesion between chemically modified surfaces using AFM, the probe tips and sample surfaces are typically modified via self-assembly of monolayers using organosilanes on such surfaces as mica, glass, or oxidized Si or Si_3N_4 (the latter two being the typical materials of which AFM tips are made), or formed from thiols on Au-coated AFM tips and surfaces (Fig. 19.12) [19.107, 108]. While this has been shown to be a facile method for the modification of AFM tips for chemical force measurements, it should be noted that the details of the packing densities of the monolayers formed on the AFM tips are generally not known. This lack of detail regarding molecular overlayers on AFM probe tips can be a problem that requires careful consideration when using such chemically modified tips for the quantitative determination of adhesion forces and molecular interactions, as the number density of species in the tip sample contact is related to the measured adhesion.

Details of the environment in which the adhesion measurements are carried out are also an important consideration. Under ambient environmental lab conditions, surfaces are contaminated with organic compounds from the air, as well as with a layer of condensed water vapor, which varies with humidity. The condensed water layer can form a contact meniscus between the tip and sample, introducing a capillary force into the measured adhesion [19.109]. The presence of this capillary force can overwhelm the details of the adhesion from the SAM-terminated surfaces to be probed. To eliminate capillary forces, many studies are performed under liquid environments or ultrahigh vacuum. Under liquids, the nature of the solvent will of course impact the measured adhesion for a given pair of interacting surfaces, as solvent exclusion plays an important role. Also, in the case of water, the pH and ionic strength of the water environment can influence the measured adhesion in the presence of any surface-bound charges.

In quantifying adhesion energies from AFM measurements, the contact mechanics model developed by Johnson, Kendall, and Roberts (JKR model) [19.20, 95] is often employed in the analysis of the adhesion data acquired by force-distance spectroscopy, whereby the number of interacting species (and consequently the average "unit" interaction force or energy) can be derived from the estimated contact area and the average molecular packing density. Using the JKR model, the force of adhesion (AFM pull-off force) is related to the work of adhesion, W_{adh}, and the reduced radius, R, of the tip-surface contact:

$$F_{adh} = -\frac{3}{2}\pi R W_{adh} \,. \quad (19.9)$$

The work of adhesion is a combination of the tip-surface (γ_{ts}), tip-solvent (γ_{tl}) and surface-solvent (γ_{sl}) interfacial energies ($W_{adh} = \gamma_{sl} + \gamma_{tl} - \gamma_{ts}$), and for tip-surface combinations that have the same chemical composition, the surface energy may be estimated directly from the adhesion measurement as W_{adh}. The effective contact radius at separation, r_s, from the JKR



model is given as:

$$r_s = \left(\frac{3\pi W_{adh} R^2}{2K}\right)^{1/3} , \quad (19.10)$$

where K is the reduced elastic moduli of the tip and surface. Using the contact area at separation and the assumed packing density of the molecules at the surfaces in contact, an estimate of the adhesion force or interaction energy on a per molecule basis can be made.

The accuracy of the interfacial energies and per molecule values obtained using this approach, however, must be carefully considered, due to the accumulation of error carried by the imprecise knowledge of the contact, including the tip radius, molecular packing densities of the modified surfaces, as well as the associated elastic properties of the contact at the monolayer level. As the details of the elastic properties of self-assembled monolayers are generally not known, the elastic properties of the contacts are typically assumed to be dominated by those of the underlying substrate, and the bulk values of the surface and/or tip materials (Au, Si, mica, Si_3N_4, SiO_2) are often employed in these calculations. Moreover, as mentioned above, if the molecular packing densities of the monolayers being evaluated are not known (as is the case with a typical AFM tip), then estimations must be used. For contact areas at pull-off approaching 1 nm^2, if the error in packing density is as much as 1 molecule per nm^2, this can lead to an error as high as 25% for a typical alkanethiol, or more in the reported per molecule adhesion force. Such details should be taken into consideration when describing quantitative measurements.

An alternative approach to the measure of adhesive interactions based on Poisson statistics has been promoted by *Beebe* et al. for the statistical evaluation of single bond forces without a priori knowledge of the tip-surface contact details involved [19.119, 121, 122]. A principal limitation of this approach, however, is that a completely homogeneous chemical system is assumed, i. e., that there is only one type of discrete interaction present that gives rise to the observed adhesion. Unfortunately, for many solution phase systems a number of different interactions are typically operative, including energetic exchange with and reorganization of solvent molecules, depending on the solution conditions. These issues have never been thoroughly addressed in any molecular-level measurement of adhesion.

19.5.3 Adhesion at SAM-Modified Surfaces in Liquids

A number of researchers have used AFM to probe interfacial adhesion for a variety of different chemical systems. Most notably, *Lieber* et al. promoted the use of chemically modified substrates and AFM tips to study selective molecular interactions [19.73, 107, 110, 114, 117, 124]. A number of other researchers have adopted a similar methodology, leading to the measurement of adhesion forces and interfacial energies for the interactions of a variety of molecular functional groups in various environments, although to date few specific types of interactions have been thoroughly investigated (Table 19.1) [19.30, 107, 110–115, 120, 122, 125–129].

As described above, measurements in air suffer from difficulties of water vapor, thus, the adhesion of many SAM-terminated surfaces have been evaluated under liquids, and it is these systems that we shall focus on here. The value of the adhesion is of course modified depending on the solvent. For example, the interaction of methyl-terminated interfaces is much stronger in water than in nonpolar solvents, in agreement with the

general concept that upon separation the generation of hydrophobic interfaces in a polar solvent is highly energetically unfavorable. The impact of solvent on adhesion can be addressed basically as a variation on the Hamaker constant.

When ionizable end groups are studied in water, the details of the adhesion measurements and results become more complicated, as the chemical nature of the surfaces are now dependent on the pH and ionic strength of the solution. In these circumstances, multiple interactions, including ionic, van der Waals and double-layer forces, come into play simultaneously. Under these conditions, the general form for the JKR adhesion force may be modified to include the following additional forces:

$$F_{\mathrm{adh}} = -\frac{3}{2}\pi R W_{\mathrm{adh}} - \frac{AR}{6D} + 6\pi R W_{\mathrm{dl}} , \qquad (19.11)$$

where the second term now includes the attractive van der Waals component and the third term is the repulsive double layer.

Several groups have utilized the ability of AFM to function as a local probe of ionicity and to carry out local force titration measurements on several functional groups, including $-COOH$ [19.30, 114–118, 122], $-NH_2$ [19.116–118, 123], $-SO_3H$ [19.123] and $-PO_3H_2$ [19.116, 130] (see Table 19.1). The force-distance curves can give a general sense of the local chemical state based on whether the approach curve is attractive or repulsive. In force titrations, the adhesion is measured as a function of pH, and the change in force is dependent upon the equilibrium mixture of charged species within the tip-samples contact at the time of measurement. Peaks in the adhesion force vs. pH allow for the determination of the local pK values for the ionized species, which are shown to be dependent on ionic strength. A force titration of a diprotic acid (11-thioundecyl-1-phosphonic acid) is shown in Fig. 19.13. Shifts in the pK values from those measured in free solution have been ascribed to a variety of factors, including buildup of excess surface charge and solvation effects of the surface-bound ionic species. The localization of charge and change migration are effects that have yet to be fully explored in these systems, however.

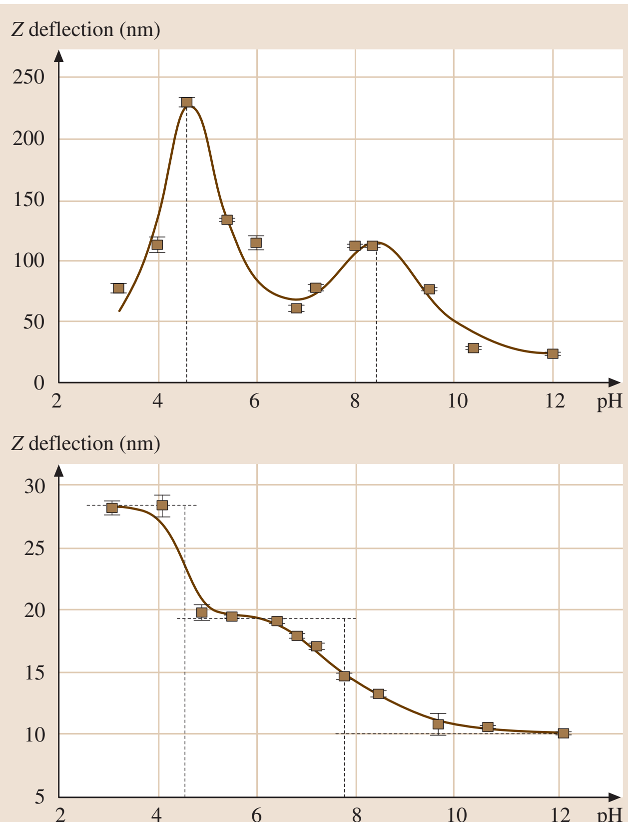

Fig. 19.13a,b Adhesion vs. pH for 11-thioundecyl-1-phosphonic acid in buffer illustrating the impact of pH and ionic strength, **(a)** 10^{-4} M and **(b)** 10^{-1} M on the measured adhesion. The peaks in adhesion provide local measures of the surface pK (adapted after [19.130])

19.5.4 Impact of Intra- and Inter-Chain Interactions on Adhesion

Several studies of the effects of chain length on friction and adhesion have found that, in general, adhesion decreases with increasing chain length, due to increased stability from lateral chain–chain van der Waals interactions within the film, which increases the overall film stiffness. The increased stiffness of the films acts to reduce the effective contact area that develops under compression, consequently reducing adhesion and friction [19.126, 127, 131]. In alkyl chain-based monolayers, the end-group orientation, however, is also dependent on chain length. This results in an "odd-even" effect on the measured adhesion/friction of the monolayer. With $-CH_3$-terminated films, the methyl group orientation differs for odd and even length molecules. This impacts the orientation of the methyl group net dipole and, hence, the local surface free energy [19.73]. In circumstances where interchain hydrogen bonding can occur, additional film stability can be introduced, also yielding an odd–even effect, as observed by *Houston* et al. [19.111, 125].

Studies by AFM of alkanethiol films on Au surfaces have shown that, depending upon the tip size, under varying loads, the tip can readily penetrate the SAM film, displacing the thiol layer from the tip-sample contact [19.132–134]. Upon reduction of the force, the tip again moves out of the SAM film and the surface structure is returned to its original condition. Of key importance in such studies is the mechanism by which the film is displaced. Recently, this has been modeled by *Harrison* using molecular dynamics simulations [19.135]. These studies have clearly demonstrated that in the initial stages of film compression and penetration by an asperity, gauche defects within the typically all-trans configurations of molecules in the SAM layers appear and propagate. The introduction of such defects is the catalyst for the weakening of the chain-chain lateral interactions that help stabilize and maintain film integrity. As this is lost, the asperity can rapidly penetrate the film, and alkanethiol displacement can occur either via chain collapse or bond scission from the surface. *Salmeron* et al. demonstrated that the prevalence of molecular displacement versus film compression depends heavily on the AFM tip size, with sharp tips readily penetrating and displacing surface-bound thiols, while large tips spread the load over more molecules and induce compression over displacement (Fig. 19.14).

The inherent stability of the film structure has also been confirmed by sum-frequency generation spectroscopic studies that have indicated that without the presence of lateral chain-chain interactions, gauche defects appear within the chain structure that reduce overall order and lateral interactions within films [19.136]. The ability to form these defects through poor film order will consequently increase adhesion, friction, and wear of the film. This same spectroscopic study further demonstrated that the appearance of gauche defects can be induced by controlling the local environment, i. e., with the presence of water, causing chains to collapse back upon themselves.

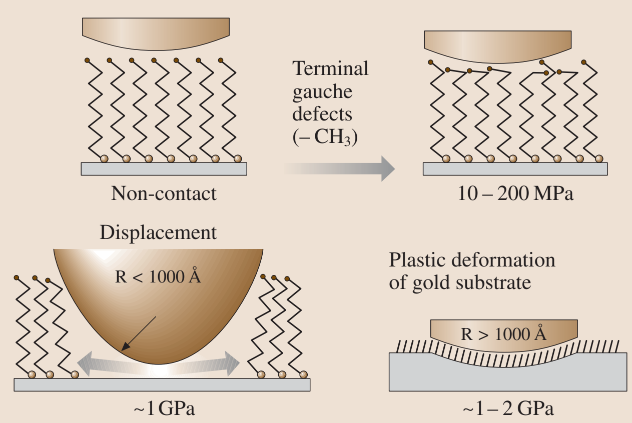

Fig. 19.14 Schematic illustrating the compression of a model lubricant layer under an AMF tip. At low pressures, the gauche defects can form at the tip–sample junction, but the molecules remain in place. Depending on tip size and load, displacement (for sharp tips) or trapping of monolayer molecules (for blunt tips) can occur (adapted after [19.5])

As molecular structure in SAMs moves away from ideally organized layers, chain-chain interactions between the contacting surfaces can also result in entanglements. A recent study of the adhesive interactions of Au(111) surfaces modified with dialkylsulfides [$CH_3(CH_2)_n-S-(CH_2)_9CH_3$; $n = 9, 11, 13, 15, 17$] with varying chain arm lengths probed the combined effect of chain length, solvent, and inter-surface chain entanglement on friction and adhesion using simultaneously modified surfaces and AFM tips [19.137]. This study found that chain-chain interpenetration produced the reverse dependence on chain length on the measured adhesion mentioned above. This work points to the need to examine the nature of inter-surface chain entanglements in nanoscaled systems. Such entanglements should be more prevalent in asperity-asperity contacts where ideal film structure will not be feasible.

19.5.5 Adhesion at the Single-Bond Level

The ability to resolve the discrete components of interactions is highly desirable. There have been few reports of the direct observation of discrete force components observed with the separation of an AFM tip from a surface. *Beebe* et al., have utilized a statistical method (as described above) for the direct determination of single-bond forces for a variety of interactions [19.119, 121, 122], including biological systems such as biotin-avidin [19.138, 139]. The first report of quantized force measurements was described by *Hoh* et al., which lead to the estimation of single hydrogen bonding forces from studies of glass surfaces in water to be on the order of 10 pN [19.140]. The use of AFM for the study of the energetics of true single chemical bond cleavage has also received little attention. One previous report described discrete covalent bond scission using AFM. In that case, it was proposed that the jumps in the observed pull-off curves were due to sequential scission of chemical bonds contained in a large,

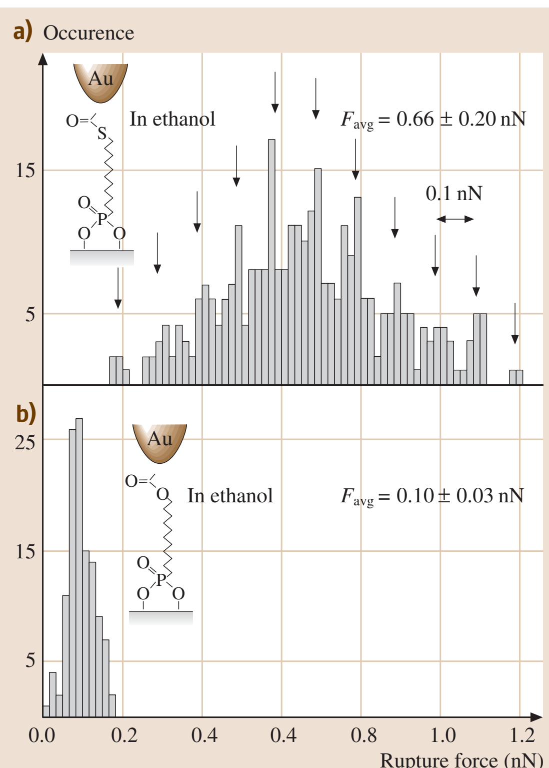

Fig. 19.15 Pull-off force distribution for Au atom abstraction in ethanol. The 100 pN peaks in the distribution represent quantized numbers of Au atoms being abstracted from the sample surface (adapted after [19.129])

multifunctional, polymeric species as it progressively detached from the substrate [19.141]. However, the identification of the relevant chemical bonds involved at each stage was largely based on the known (gas phase) bond strengths of the potentially active functional groups such that solvation effects on the bond energies were ignored – a simplification that profoundly affects the estimated energetics, as energetic exchange with the solvent must be included. More recently, the measurement of discrete bond scission was reported by *Frisbie* et al. for Au-thiol complexes (Fig. 19.15). Here the details of Au atom abstraction were reported with a quantized value of 100 pN (estimated at ∼ 10 kJ/mol, based on an assumed bond rupture length of 1 Å) [19.129]. These studies have demonstrated the feasibility of probing local single bond energetics and have suggested some general requirements for the measurement of adhesion quantization in SAM layers, including the need for a significant negative tip-surface interfacial energy coupled with minimal solvent surface tension [19.129, 142].

19.5.6 Future Directions

Extending AFM adhesion measurements to reactive systems in which chemical bonds can form between the tip and surface affords an expansion of chemical reaction dynamics to solution-based chemistries, whereby the energetic details of single reaction events, previously only accessible for gas phase scattering experiments, may be obtained. Studies of such complex heterogeneous systems will open the door to the evaluation of the energetic pathways of solution-based chemistries for any system in which the appropriate functionalization of surfaces can be exploited. Adhesion has already been demonstrated as a reasonable local probe of surface reaction kinetics, whereby the local changes in the chemical forces may be followed as a function of time during surface chemical reactions [19.143, 144]. In addition to advances in measurements of reactive systems by AFM, complete insight into the operative molecular mechanisms can only be gained when combined with detailed theory that takes into account not only the specific types of interactions present between the surfaces, but also the requisite energetic exchange with local solvent molecules. Advances in computer technologies and in computational theory have made this realistic [19.128].

To advance the area of adhesion measurements at the molecular level, energetic barriers for specific interactions also need to be evaluated, with attention given to the nature of the molecular interactions being probed, *including* the details of energetic exchange with the solvent surrounding the interacting molecules. Studies by AFM of molecular interactions within sharply confined geometries (i. e., ∼ 1 nm^2 contact area) provide an opportunity to evaluate such contributions with molecular detail. Here again, *Lieber* et al. have been advancing the approach of chemically functionalizing carbon nanotubes to reduce both the type and number of specific interacting species [19.73]. This approach may hold some promise for probing well-defined, specific chemical interactions and/or reactions, as long as the nanotubes can be sufficiently stabilized against buckling [19.135, 145, 146].

In addition to the modification of probe geometries to improve localization of interactions for adhesion measurements, one of the principle difficulties in performing AFM measurements of adhesion at SAM surfaces is the unavoidable snap to contact. This makes the details of

the long-range interaction potential almost completely inaccessible. To address this issue, *Lieber* et al. have developed a modified AFM system in which the cantilever is magnetized, providing an additional feedback mechanism to aid in avoiding snap-in [19.30]. When used, this approach provides a smooth approach and retract curve. Similarly, the capacitive coupling feedback mechanism of the interfacial force microscope (IFM) also affords measurements of this transition without snap-in [19.125].

19.6 Concluding Remarks

Scanning probes are powerful tools for determining the fundamental molecular basis of adhesion. Continuum models of adhesion and capillary condensations are useful, but careful attention must be paid to their limits and assumptions. Further progress in these areas requires detailed analysis of the structure and chemistry of both the tip and sample, as well as their environment (solvent, humidity, etc.).

The ability to determine the effects of molecular-scale water menisci or single bond energetics are truly spectacular accomplishments that continue to inspire researchers worldwide to pursue these measurements. With attention paid to previous literature and consideration of issues raised in this chapter, many more discoveries are sure to be made.

20. Friction and Wear on the Atomic Scale

Friction and W

Friction is an old subject of research: the empirical da Vinci–Amontons laws are common knowledge. Macroscopic experiments systematically performed by the school of *Bowden* and *Tabor* have revealed that macroscopic friction can be related to the collective action of small asperities. During the last 15 years, experiments performed with the atomic force microscope gave new insight into the physics of single asperities sliding over surfaces. This development, together with complementary experiments by means of surface force apparatus and quartz microbalance, established the new field of nanotribology. At the same time, increasing computing power allowed for the simulation of the processes in sliding contacts consisting of several hundred atoms. It became clear that atomic processes cannot be neglected in the interpretation of nanotribology experiments. Experiments on even well-defined surfaces directly revealed atomic structures in friction forces. This chapter will describe friction force microscopy experiments that reveal, more or less directly, atomic processes in the sliding contact.

We will begin by introducing friction force microscopy, including the calibration of cantilever force sensors and special aspects of the ultra-high vacuum environment. The empirical Tomlinson model largely describes atomic stick-slip results and is therefore presented in detail. We review experimental results regarding atomic friction. These include thermal activation, velocity dependence, as well as temperature dependence. The geometry of the contact plays a crucial role in the interpretation of experimental results, as we will demonstrate, for example, for the calculation of the lateral contact stiffness. The onset of wear on atomic scale has recently come into the scope of experimental studies and is described here. In order to compare the respective results, we present molecular dynamics simulations that are directly related to atomic friction experiments. We close the chapter with a discussion of dissipation measurements performed in noncontact force microscopy, which may become an important complementary tool for the study of mechanical dissipation in nanoscopic devices.

20.1 Friction Force Microscopy in Ultra-High Vacuum

The *friction force microscope* (FFM, also called lateral force microscope, LFM) exploits the interaction of a sharp tip sliding on a surface to quantify dissipative processes down to the atomic scale (Fig. 20.1).

20.1.1 Friction Force Microscopy

The relative motion of tip and surface is realized by a *scanner* formed by piezoelectric elements, which moves the surface perpendicularly to the tip with a certain periodicity. The scanner can be also extended or retracted in order to vary the normal force, F_N, which is applied on the surface. This force is responsible for the deflection of the *cantilever* that supports the tip. If the normal force F_N increases while scanning due to the local slope of the surface, the scanner is retracted by a feedback loop. On the other hand, if F_N decreases, the surface is brought closer to the tip by extending the scanner. In such way, the surface topography can be determined line by line from the vertical displacement of the scanner. An accurate control of such vertical movement is made possible by a light beam, which is reflected from the rear of the lever into a photodetector. When the bending of the cantilever changes, the light spot on the detector moves up or down and causes a variation of the photocurrent that corresponds to the normal force F_N to be controlled.

Usually the relative sliding of tip and surface is also accompanied by *friction*. A lateral force, F_L, with the opposite direction of the scan velocity, v, hinders the motion of the tip. This force provokes the torsion of the cantilever, and it can be observed with the topography if the photodetector can reveal not only the normal deflection but also the lateral movement of the lever while scanning. In practice this is realized by four-quadrants photodetectors, as shown in Fig. 20.1. We should notice that friction forces also cause the lateral bending of the cantilever, but this effect is negligible if the thickness of the lever is much less than the width.

The FFM was first used by *Mate* et al. in 1987 to reveal friction with atomic features [20.1], i.e. just one year after *Binnig*, *Quate*, and *Gerber* introduced the atomic force microscope [20.2]. In their experiment, Mate used a tungsten wire and a slightly different technique to detect lateral forces (non-fiber interferometry). The optical beam deflection was introduced later by *Marti* et al., and *Meyer* et al. [20.3, 4]. Other methods to measure the forces between tip and surface are given by capacitance detection [20.5], dual fiber interferometry [20.6], and piezolevers [20.7]. In the first method, two plates close to the cantilever reveal capacitance while scanning. The second technique uses two optical fibers to detect the cantilever deflection along two orthogonal directions angled 45° with respect to the surface normal. Finally, in the third method, cantilevers with two Wheatstone bridges at their base reveal normal and lateral forces, which are respectively proportional to the sum and the difference of both bridge signals.

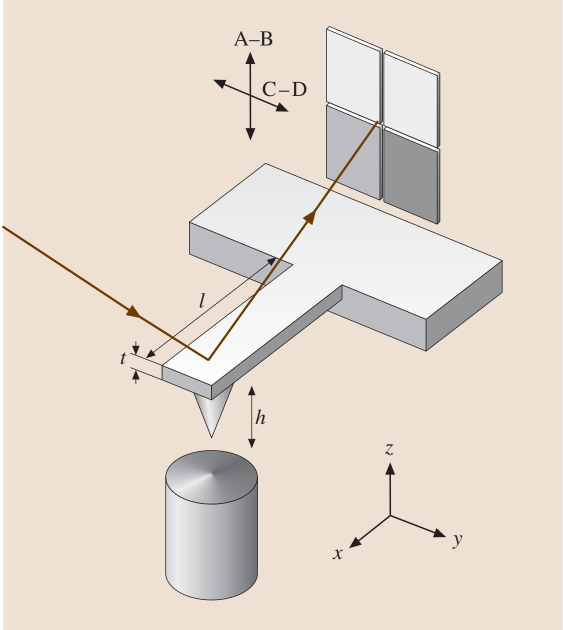

Fig. 20.1 Schematic diagram of a beam-deflection friction force microscope

20.1.2 Force Calibration

The force calibration is relatively simple if rectangular cantilevers are used. Due to possible discrepancies with the geometric values provided by manufacturers, one should use optical and electron microscopes to determine the width, thickness, and length of cantilever, w, t, l, the tip height, h, and the position of the tip with respect to the cantilever. The thickness of the cantilever can also be determined from the resonance frequency of the lever, f_0, using the

relation [20.8]:

$$t = \frac{2\sqrt{12}\pi}{1.875^2}\sqrt{\frac{\rho}{E}}f_0 l^2\,, \tag{20.1}$$

In (20.1) ρ is the density of the cantilever and E is its Young's modulus. The normal spring constant, c_N, and the lateral spring constant, c_L, of the lever are given by

$$c_\mathrm{N} = \frac{Ewt^3}{4l^3}\,, \quad c_\mathrm{L} = \frac{Gwt^3}{3h^2 l}\,, \tag{20.2}$$

where G is the shear modulus. Figure 20.2 shows some SEM images of rectangular silicon cantilevers used for FFM. In the case of silicon, $\rho = 2.33\times10^3\,\mathrm{kg/m^3}$, $E = 1.69\times10^{11}\,\mathrm{N/m^2}$ and $G = 0.5\times10^{11}\mathrm{N/m^2}$. Thus, for the cantilever in Fig. 20.2, $c_\mathrm{N} = 1.9\,\mathrm{N/m}$ and $c_\mathrm{L} = 675\,\mathrm{N/m}$.

The next step in force calibration consists of measuring the sensitivity of the photodetector, S_z (nm/V). For beam-deflection FFMs, the sensitivity S_z can be determined by force vs. distance curves measured on hard surfaces (e.g., $\mathrm{Al_2O_3}$), where elastic deformations are negligible and the vertical movement of the scanner equals the deflection of the cantilever. A typical relation between the difference of the vertical signals on the four-quadrant detector, V_N, and the distance from the surface, z, is sketched in Fig. 20.3. When the tip is approached, no signal is revealed until the tip jumps into contact at $z = z_1$. Further extension or retraction of the scanner results in an elastic behavior until the tip jumps again out of contact at a distance $z_2 > z_1$. The slope of the elastic part of the curve gives the required sensitivity, S_z.

The normal and lateral forces are related to the voltage V_N, and the difference between the horizontal signals, V_L, as follows:

$$F_\mathrm{N} = c_\mathrm{N} S_z V_\mathrm{N}\,, \quad F_\mathrm{L} = \frac{3}{2}c_\mathrm{L}\frac{h}{l}S_z V_\mathrm{L}\,, \tag{20.3}$$

in which it is assumed that the light beam is positioned above the probing tip.

The normal spring constant c_N can also be calibrated with alternative methods. *Cleveland* et al. [20.10] attached tungsten spheres to the tip, which changes the resonance frequency f_0 according to the formula

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{c_\mathrm{N}}{M+m^*}}\,. \tag{20.4}$$

M is the mass of the added object, and m^* is an effective mass of the cantilever, which depends on its geometry [20.10]. The spring constant can be extrapolated from the frequency shifts corresponding to the different masses attached.

As an alternative, *Hutter* et al. observed that the spring constant c_N can be related to the area of the power spectrum of the thermal fluctuations of the cantilever, P [20.11]. The correct relation is $c_\mathrm{N} = 4k_\mathrm{B}T/3P$, where $k_\mathrm{B} = 1.38\times10^{-3}$ J/K is the Boltzmann's constant and T is the temperature [20.12].

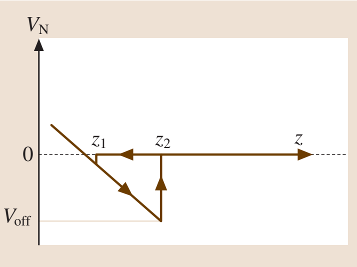

Fig. 20.3 Sketch of a typical force vs. distance curve

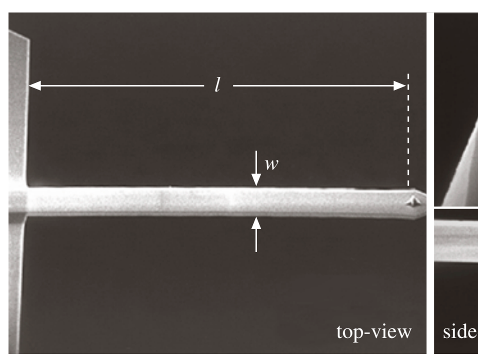

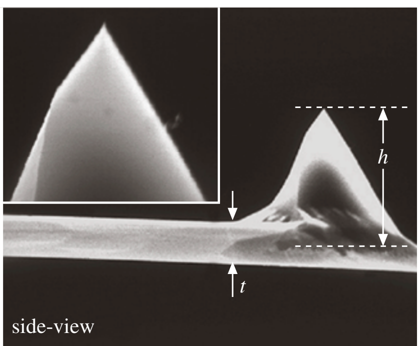

Fig. 20.2 SEM images of a rectangular cantilever. The relevant dimensions are $l = 445\,\mu\mathrm{m}$, $w = 43\,\mu\mathrm{m}$, $t = 4.5\,\mu\mathrm{m}$, $h = 14.75\,\mu\mathrm{m}$. Note that h is given by the sum of the tip height and half of the cantilever thickness. (After [20.9])

Cantilevers with different shape require finite element analysis, although in few cases analytical formulas can be derived. For V-shaped cantilevers, *Neumeister* et al. found the following approximation for the lateral spring constant c_L [20.13]:

$$c_L = \frac{Et^3}{3(1+\nu)h^2} \times \left(\frac{1}{\tan\alpha} \ln \frac{w}{d \sin\alpha} + \frac{L\cos\alpha}{w} - \frac{3\sin 2\alpha}{8} \right)^{-1}, \tag{20.5}$$

where the geometrical quantities L, w, α, d, t, and h are defined in Fig. 20.4. The expression for the normal constant is more complex and can be found in the cited reference.

Surfaces with well-defined profiles provide an alternative in situ calibration of lateral forces [20.14]. We present a slightly modified version of the method [20.15]. Figure 20.5 shows a commercial grating formed by alternated faces with opposite inclinations with respect to the scan direction. When the tip slides on the inclined planes, the normal force, F_N, and the lateral force, F_L, with respect to the surface, are different from the two components $F_\perp$ and $F_\parallel$, which are separated by the photodiode (see Fig. 20.6a).

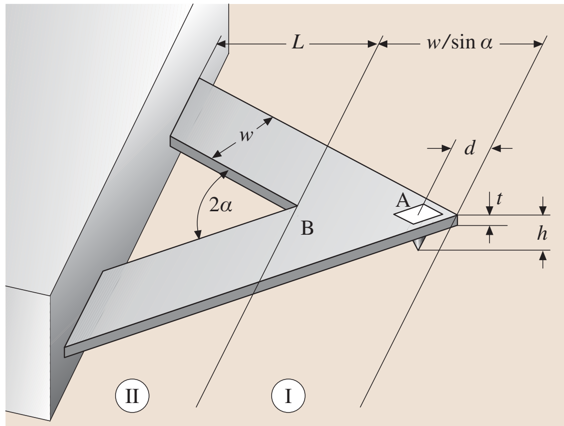

Fig. 20.4 Geometry of a V-shaped cantilever. (After [20.13])

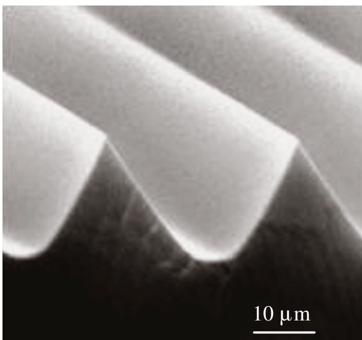

Fig. 20.5 Silicon grating formed by alternated faces angled ±55° (courtesy Silicon-MDT Ltd., POB 50, 103305, Moscow, Russia)

If the linear relation $F_L = \mu F_N$ holds (see Sect. 20.5), the component $F_\parallel$ can be expressed in terms of $F_\perp$:

$$F_\parallel = \frac{\mu + \tan\theta}{1 - \mu\tan\theta} F_\perp \,. \tag{20.6}$$

The component $F_\perp$ is kept constant by the feedback loop. The sum and the difference of $F_\parallel$ on the two planes (1) and (2) are given by

$$F_+ \equiv F_\parallel^{(1)} + F_\parallel^{(2)} = \frac{2\mu\left(1+\tan^2\theta\right)}{1-\mu^2\tan^2\theta} F_\perp$$
$$F_- \equiv F_\parallel^{(1)} - F_\parallel^{(2)} = \frac{2\left(1+\mu^2\right)\tan\theta}{1-\mu^2\tan^2\theta} F_\perp \,. \tag{20.7}$$

The values of F_+ and F_- (in volts) can be measured by scanning the profile back and forth (Fig. 20.6b). If F_+ and F_- are recorded with different values of $F_\perp$, one can determine the conversion ratio between volts and nanonewtons as well as the coefficient of friction, μ.

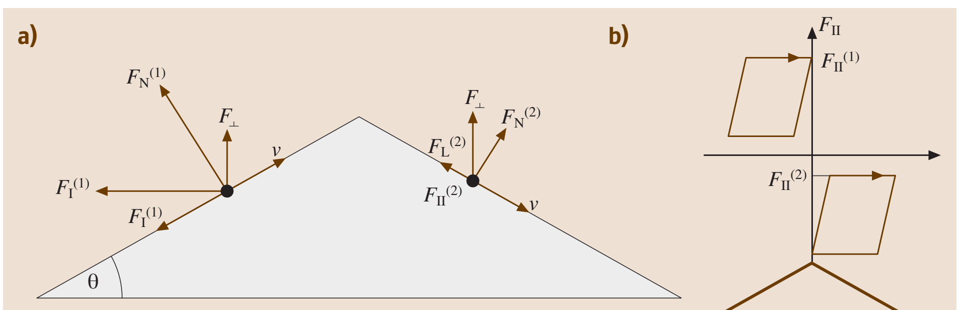

Fig. 20.6 **(a)** Forces acting on a FFM tip sliding on the grating in Fig. 20.5; **(b)** Friction loops acquired on the two faces

An accurate analysis of the errors in lateral force calibration was given by *Schwarz* et al., who revealed the important role of the cantilever's oscillations induced by the feedback loop and of the so-called pull-off force (Sect. 20.5) in friction measurements, aside from the geometrical setting of cantilevers and laser beams [20.16].

For some applications, an adequate estimation of the radius of curvature of the tip, R, is important (Sect. 20.5.2). This quantity can be evaluated with a scanning electron microscope. Otherwise, well-defined structures as step sites [20.17, 18] or whiskers [20.19] can be imaged. The image of these high-aspect ratio structures is a convolution with the tip structure. A deconvolution algorithm that allows for the extraction of the probing tip's radius of curvature was suggested by *Villarrubia* [20.21].

20.1.3 The Ultra-high Vacuum Environment

Atomic friction studies require well-defined surfaces and – whenever possible – tips. For the surfaces, the established methods of surface science can be employed working in ultra-high vacuum (UHV). Ionic crystals such as NaCl have become standard materials for friction force microscopy on atomic scale. Atomically clean and flat surfaces can be prepared by cleavage in UHV. The crystal has to be heated to about 150 °C for 1 h in order to remove charging after the cleavage process. Metal surfaces can be cleaned and flattened by cycles of sputtering with argon ions and annealing. Even surfaces prepared in air or liquids like self-assembled molecular monolayers can be transferred into the vacuum and studied after careful heating procedures, which remove water layers.

Tip preparation in UHV is a more difficult subject. Most force sensors for friction studies have silicon nitride or pure silicon tips. Tips can be cleaned and oxide layers removed by sputtering with argon ions. But the sharpness of the tip is normally reduced by sputtering. As an alternative, tips can be etched in fluoric acid directly before transfer to the UHV. The significance of tip preparation is limited by the fact that the chemical and geometrical structure of the tip can undergo significant changes when sliding over the surface.

The implementation of the friction force microscope into UHV requires some additional efforts. First of all, only materials with a low vapor pressure can be used, thereby excluding most plastics and lubricants. Beam-deflection type force microscopes employ either a light source in the vacuum chamber or an optical fiber guiding the light into the chamber. The positioning of the light beam onto the cantilever and of the reflected beam onto the position-sensitive detector is performed by motorized mirrors [20.20] or by moving light source or detector [20.22]. Furthermore, a motorized sample approach has to be realized.

The quality force sensor's electrical signal can seriously deteriorate on the way out of the vacuum chamber. Low noise and high bandwidth can be preserved by implementing a pre-amplifier into the vacuum. Again the choice of materials for print and devices is limited by the condition of low vapor pressure. Stronger heating of the electrical circuitry in vacuum, therefore, must be considered.

20.1.4 A Typical Microscope in UHV

A typical AFM for UHV application is shown in Fig. 20.7. The housing (1) contains the light source and a set of lenses that focus the light onto the cantilever. Alternatively, the light can be guided via an optical fiber into the vacuum. By using light emitting diodes with low coherency you avoid disturbing interference effects often found in instruments equipped with lasers as light source. A plane mirror fixed on the spherical rotor of a first stepping motor (2) can be rotated

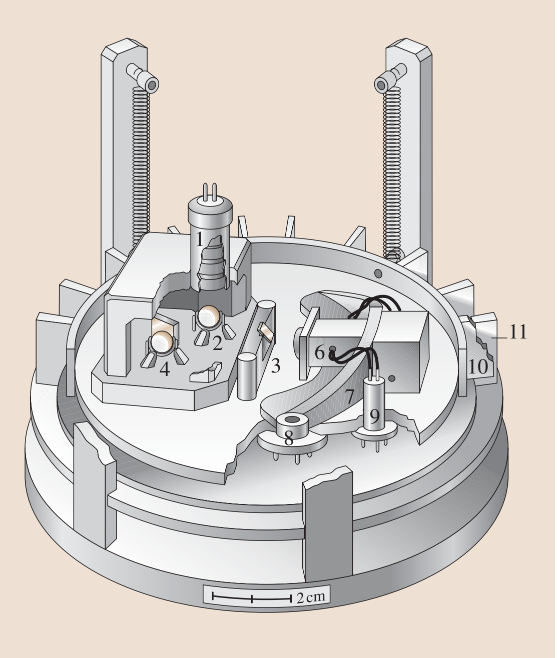

Fig. 20.7 Schematic view of the UHV-AVM realized at the University of Basel. (After [20.20])

Part C | 20.1

around a vertical and horizontal axis to guide the light beam onto the rear of the cantilever, mounted on a removable carrier plate (3). The light is reflected off the cantilever toward a second motorized mirror (4) that guides the beam to the center of the quadrant photodiode (5), where the light is then converted into four photo-currents. Four pre-amplifiers in close vicinity to the photodiode allow low-noise measurements with 3 MHz bandwidth.

The two motors with spherical rotors, used to realign the light path after exchange of the cantilever, work as *inertial stepping motors*: the sphere is resting on three piezoelectric legs that can be moved by a small amount tangentially to the sphere. Each step of the motor consists of a slow forward motion of two legs followed by an abrupt jump backwards. During the slow forward motion the sphere follows the legs due to friction, whereas it cannot follow the sudden jump due to its inertia. A series of such tiny steps rotates the sphere macroscopically.

The sample, also on an exchangeable carrier plate, is mounted on the end of a tube scanner (6), which can move the sample in three dimensions over several micrometers. The whole scanning head (7) is the slider of a third inertial stepping motor for coarse positioning of the sample. It rests with its flat and polished bottom on three supports. Two of them are symmetrically placed piezoelectric legs (8), whereas the third central support is passive. The slider (7) can be translated in two dimensions and rotated about a vertical axis by several millimeters (rotation is achieved by antiparallel operation of the two legs). The slider is held down by two magnets, close to the active supports, and its travel is limited by two fixed posts (9) that also serve as cable attachments. The whole platform is suspended by four springs. A ring of radial copper lamellae (10), floating between a ring of permanent magnets (11) on the base flange, acts as efficient eddy current damping.

20.2 The Tomlinson Model

In Sect. 20.3, we will show that the FFM can reveal friction forces down to the atomic scale, which are characterized by a typical sawtooth pattern. This phenomenon can be seen as a consequence of a *stick-slip* mechanism, first discussed by *Tomlinson* in 1929 [20.23].

20.2.1 One-dimensional Tomlinson Model

In the Tomlinson model the motion of the tip is influenced by both the interaction with the atomic lattice of the surface and the elastic deformations of the cantilever. The shape of the tip-surface potential, $V(\boldsymbol{r})$, depends on several factors, such as the chemical composition of the materials in contact and the atomic arrangement at the tip end. For the sake of simplicity, we will start the analysis in the one-dimensional case considering a sinusoidal profile with the periodicity of the atomic lattice, a, and a peak-to-peak amplitude E_0. In Sect. 20.5, we will show how the elasticity of the cantilever and of the contact area are described in a unique framework by introducing an effective lateral spring constant, k_{eff}. If the cantilever moves with a constant velocity v along the x direction, the total energy of the system is

$$E_{\text{tot}}(x,t) = -\frac{E_0}{2}\cos\frac{2\pi x}{a} + \frac{1}{2}k_{\text{eff}}(vt-x)^2\,. \quad (20.8)$$

Figure 20.8 shows the energy profile $E_{\text{tot}}(x,t)$ at two different instants. When $t=0$ the tip is localized in the absolute minimum of E_{tot}. This minimum increases with time due to the cantilever motion, until the tip position becomes unstable when $t=t^*$.

At a given time t the position of the tip can be determined by equating to zero the first derivative of $E_{\text{tot}}(x,t)$ with respect to x:

$$\frac{\partial E_{\text{tot}}}{\partial x} = \frac{\pi E_0}{a}\sin\frac{2\pi x}{a} - k_{\text{eff}}(vt-x) = 0\,. \quad (20.9)$$

The critical position x^* corresponding to $t=t^*$ is determined by equating to zero the second derivative

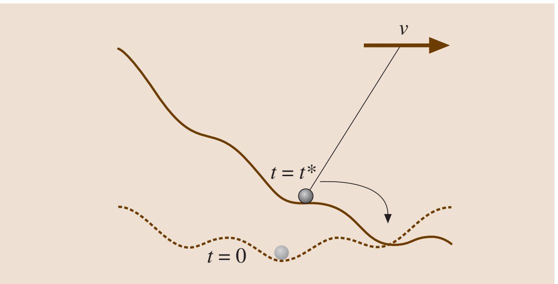

Fig. 20.8 Energy profile experienced by the FFM tip (*black circle*) at $t=0$ (*dotted line*) and $t=t^*$ (*continuous line*)

$\partial^2 E_{\text{tot}}(x,t)/\partial x^2$, which gives

$$x^* = \frac{a}{4}\arccos\left(-\frac{1}{\gamma}\right), \quad \gamma = \frac{2\pi^2 E_0}{k_{\text{eff}} a^2}. \tag{20.10}$$

The coefficient γ compares the strength of interaction between tip and surface with the stiffness of the system. When $t = t^*$ the tip suddenly *jumps* into the next minimum of the potential profile. The lateral force $F^* = k_{\text{eff}}(vt - x^*)$, which induces the jump, can be evaluated from (20.9) and (20.10):

$$F^* = \frac{k_{\text{eff}}\, a}{2\pi}\sqrt{\gamma^2 - 1}. \tag{20.11}$$

Thus the stick-slip is observed only if $\gamma > 1$, i. e. when the system is not too stiff or the tip–surface interaction is strong enough. Figure 20.9 shows the lateral force F_L as a function of the cantilever position, X. When the cantilever is moved rightward, the lower part of the curve in Fig. 20.9 is obtained. If, at a certain point, the cantilever's direction of motion is suddenly inverted, the force has the profile in the upper part of the curve. The area of the *friction loop* obtained by scanning back and forth gives the total energy dissipated.

20.2.2 Two-dimensional Tomlinson Model

In two dimensions, the energy of our system is given by

$$E_{\text{tot}}(\boldsymbol{r}, t) = U(\boldsymbol{r}) + \frac{k_{\text{eff}}}{2}(\boldsymbol{v}t - \boldsymbol{r})^2, \tag{20.12}$$

where $\boldsymbol{r} \equiv (x, y)$ and $\boldsymbol{v}$ is arbitrarily oriented on the surface (note that $\boldsymbol{v} \neq \mathrm{d}\boldsymbol{r}/\mathrm{d}t$!). Figure 20.10 shows the total energy corresponding to a periodic potential of the form

$$U(x, y, t) = -\frac{E_0}{2}\left(\cos\frac{2\pi x}{a} + \cos\frac{2\pi y}{a}\right) + E_1 \cos\frac{2\pi x}{a}\cos\frac{2\pi y}{a}. \tag{20.13}$$

The equilibrium condition becomes

$$\nabla E_{\text{tot}}(\boldsymbol{r}, t) = \nabla U(\boldsymbol{r}) + k_{\text{eff}}(\boldsymbol{r} - \boldsymbol{v}t) = 0. \tag{20.14}$$

The stability of the equilibrium can be discussed introducing the Hessian matrix

$$H = \begin{pmatrix} \frac{\partial^2 U}{\partial x^2} + k_{\text{eff}} & \frac{\partial^2 U}{\partial x \partial y} \\ \frac{\partial^2 U}{\partial y \partial x} & \frac{\partial^2 U}{\partial y^2} + k_{\text{eff}} \end{pmatrix}. \tag{20.15}$$

When both eigenvalues $\lambda_{1,2}$ of the Hessian are positive, the position of the tip is stable. Figure 20.11 shows such regions for a potential of the form (20.13). The tip follows the cantilever adiabatically as long as it remains in the $(++)$-region. When the tip is dragged to the border of the region, it suddenly jumps into the next $(++)$-region. A comparison between a theoretical friction map deduced from the 2-D Tomlinson model and an experimental map acquired by UHV-FFM is given in the next section.

20.2.3 Friction Between Atomically Flat Surfaces

So far we have implicitly assumed that the tip is terminated by only one atom. It is also instructive to consider the case of a periodic surface sliding on another periodic surface. In the Frenkel–Kontorova–Tomlinson (FKT) model, the atoms of one surface are harmonically coupled with their nearest neighbors. We will restrict ourselves to the case of quadratic symmetries, with lattice constants a_1 and a_2 for the upper and lower surface, respectively (Fig. 20.12). In such context the role of *commensurability* is essential. It is well known that any real number z can be represented as a continued

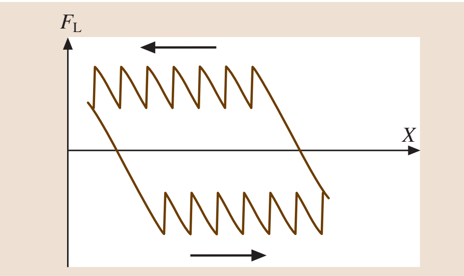

Fig. 20.9 Friction loop obtained by scanning back and forth in the 1-D Tomlinson model. The effective spring constant k_{eff} is the slope of the sticking part of the loop (if $\gamma \gg 1$)

fraction:

$$z = N_0 + \frac{1}{N_1 + \frac{1}{N_2 + \ldots}} . \tag{20.16}$$

The sequence that converges most slowly is obtained when all $N_i = 1$, which corresponds to the *golden mean* $\bar{z} = (\sqrt{5} - 1)/2$. In 1-D *Weiss* and *Elmer* predicted that friction should decrease with decreasing commensurability, the minimum of friction being reached when $a_1/a_2 = \bar{z}$ [20.26].

In 2-D *Gyalog* and *Thomas* studied the case $a_1 = a_2$, with a misalignment between the two lattices given by an angle θ [20.25]. When the sliding direction changes, friction also varies from a minimum value corresponding to the sliding angle $\varphi = \theta/2$ to a maximum value, which is reached when $\varphi = \theta/2 + \pi/4$ (Fig. 20.13). The misfit angle θ is related with commensurability. Since the misfit angles giving rise to commensurate structure form a dense subset, the dependence of friction on θ should be discontinuous. The numerical simulations performed by Gyalog are in agreement with this conclusion.

20.3 Friction Experiments on Atomic Scale

Figure 20.14 shows the first friction map observed by Mate on atomic scale. The periodicity of the lateral force is the same as of the atomic lattice of graphite. The series of friction loops in Fig. 20.15 reveals the stick-slip effect discussed in the previous section. The applied loads are in the range of tens of μN. According to the continuum models discussed in Sect. 20.5 these values correspond to contact diameters of 100 nm. A possible explanation for the atomic features observed at such high loads is that graphite flakes might have been detached from the surface and adhered on the tip [20.27]. Another explanation is that the contact between tip and surface consisted of few nm-scale asperities and the corrugation was not entirely averaged out while sliding. The load dependence of friction found by Mate is rather linear, with a small friction coefficient $\mu = 0.01$ (Fig. 20.16).

The UHV environment reduces the influence of contaminants on the surface and leads to more precise and reproducible results. *Meyer* et al. [20.28] obtained

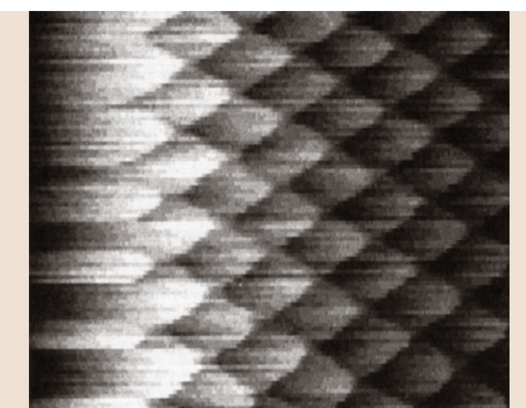

Fig. 20.14 First atomic friction map acquired on graphite with a normal force $F_N = 56\,\mu N$. Frame size: 2 nm. (After [20.1])

a series of interesting results on ionic crystals using the UHV-FFM apparatus described in Sect. 20.1.4. In Fig. 20.17 a friction map recorded on KBr(100) is compared with a theoretical map, which was obtained with the 2-D-Tomlinson model. The periodicity $a = 0.47$ nm corresponds to the spacing between equally charged

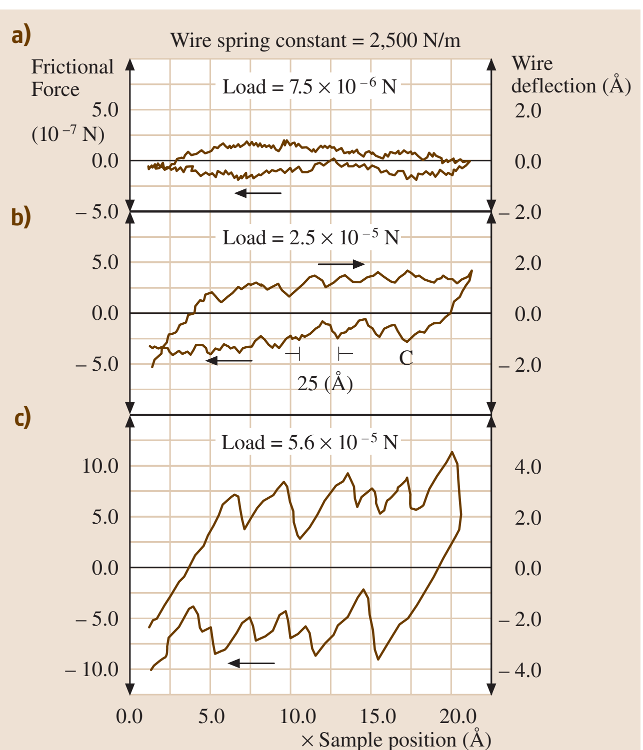

Fig. 20.15a–c Friction loops on graphite acquired with **(a)** $F_N = 7.5\,\mu N$, **(b)** $24\,\mu N$ and **(c)** $75\,\mu N$. (After [20.1])

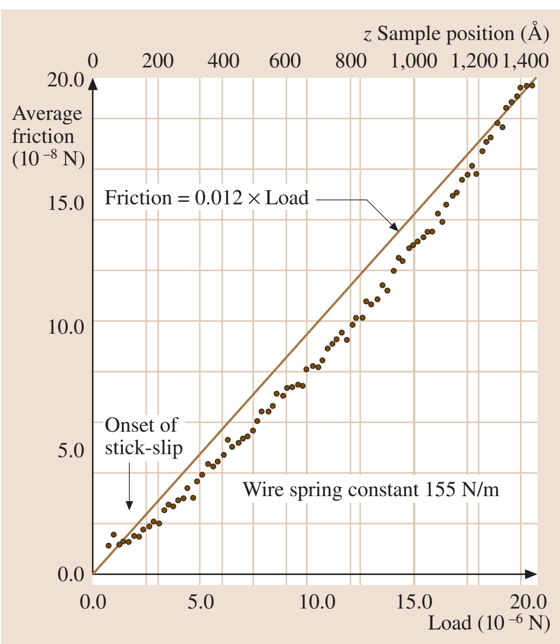

Fig. 20.16 Load dependence of friction on graphite. (After [20.1])

ions. No individual defects were observed. One possible reason is that the contact realized by the FFM tip is always formed by many atoms, which superimpose and average their effects. Molecular dynamics (MD) calculations (Sect. 20.7) show that even a single-atom contact may cause rather large stresses in the sample, which lead to the motion of defects far away from the contact area. In a picturesque frame, we can say that "defects behave like dolphins that swim away in front of an ocean cruiser" [20.28].

Lüthi et al. [20.29] detected atomic-scale friction even on the reconstructed Si(111)7×7 surface. But uncoated Si-tips and tips coated with Pt, Au, Ag, Cr, Pt/C damaged the sample irreversibly, and the observation of atomic features was achieved only after coating the tips with polytetrafluoroethylene (PTFE), which has lubricant properties and does not react with the dangling bonds of Si(111)7×7 (Fig. 20.18).

Recently friction could be resolved on atomic scale even on metallic surfaces in UHV [20.30]. In Fig. 20.19a a reproducible stick-slip process on Cu(111) is shown.

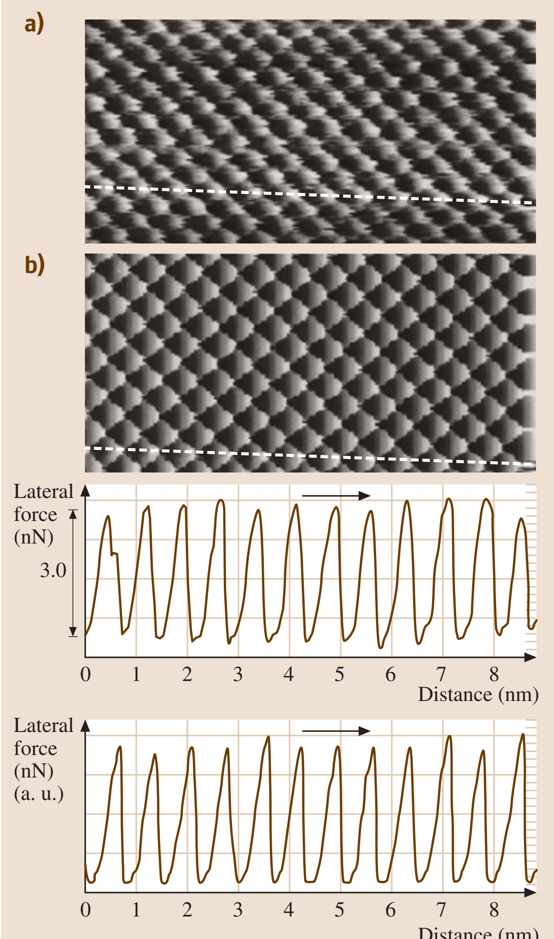

Fig. 20.17 **(a)** Measured and **(b)** theoretical friction map on KBr(100). (After [20.31])

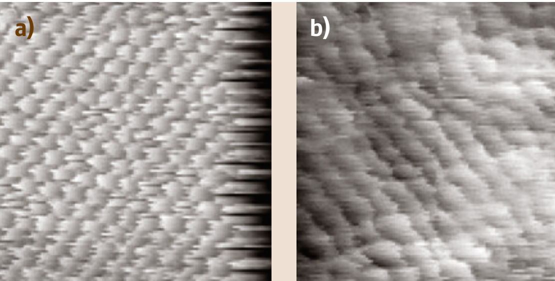

Fig. 20.19a,b Friction images of **(a)** Cu(111) and **(b)** Cu(100). Frame size: 3 nm. (After [20.34])

Sliding on the (100) surface of copper produced irregular patterns, although atomic features were recognized even in this case (Fig. 20.19b). Molecular dynamics suggests that wear should occur more easily on the Cu(100) surface than on the closed packed Cu(111) (Sect. 20.7). This conclusion was achieved by adopting copper tips in computer simulations. The assumption that the FFM tip used in the experiments was covered by copper is supported by current measurements performed at the same time.

Atomic stick-slip on diamond was observed by *Germann* et al. with an apposite diamond tip prepared by chemical vapor deposition [20.32] and, a few years later, by *van der Oetelaar* et al. [20.33] with standard silicon tips. The values of friction have huge discrepancies corresponding to the presence or absence of hydrogen on the surface.

Fujisawa et al. [20.35] measured friction on mica and on MoS_2 with a 2-D-FFM apparatus, which could also reveal forces perpendicular to the scan direction. The features in Fig. 20.20 correspond to a zig-zag walk of the tip, which is predicted by the 2-D-Tomlinson model [20.36]. The 2-D stick-slip on NaF was detected with normal forces below 14 nN, whereas loads up to 10 μN could be applied on layered materials. The contact between tip and NaF was thus formed by one or a few atoms. The zig-zag walk on mica was also observed by *Kawakatsu* et al. using an original 2-D-FFM with two laser beams and two quadrant photodetectors [20.37].

20.3.1 Anisotropy of Friction

The importance of the misfit angle in the reciprocal sliding of two flat surfaces was first observed experimentally by *Hirano* et al. in the contact of two mica sheets [20.41]. Friction increased when the two surfaces formed commensurate structures, in agreement with the discussion in Sect. 20.2.3. In more recent measurements with a monocrystalline tungsten tip on Si(001), *Hirano* et al. observed *superlubricity* in the incommensurate case [20.42].

Overney et al. [20.43] studied the effects of friction anisotropy on a bilayer lipid film. In such case different molecular alignments resulted in significant variation of friction. Other measurements of friction anisotropy on stearic acid single crystals were reported by *Takano* and *Fujihira* [20.44].

Liley et al. [20.38] observed flower-shaped islands of a lipid monolayer on mica, which consisted of domains with different molecular orientation (Fig. 20.21). The angular dependence of friction reflects the tilt direction of the alkyl chains of the monolayer, which was revealed by other techniques.

Lüthi et al. [20.39] used the FFM tip to move C_{60} islands, which slided on sodium chloride in UHV without disruption (Fig. 20.22). In this experiment friction was found to be independent of the sliding direction. This was not the case in other experiments performed by *Sheehan* and *Lieber*, who observed that the misfit angle is relevant when MoO_3 islands are dragged on the MoS_2 surface [20.45]. In these experiments, sliding was possible only along low index directions. The weak orientation dependence found by *Lüthi* et al. [20.39] is probably due to the large mismatch of C_{60} on NaCl.

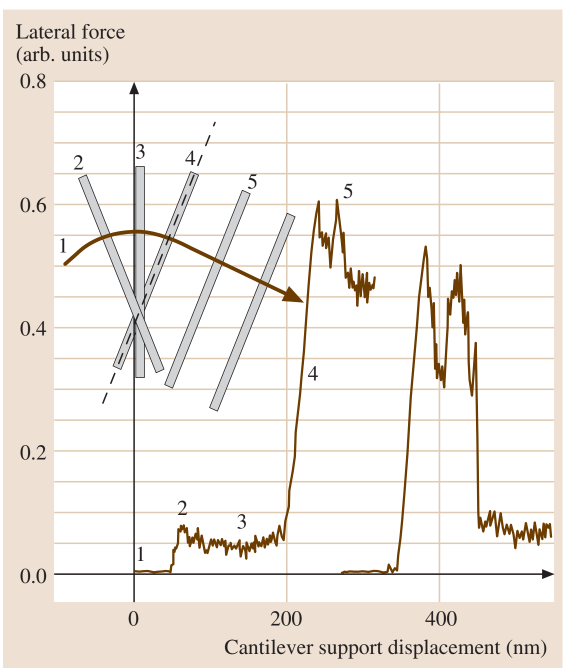

Fig. 20.23 Friction force experienced as a carbon nanotube is rotated into (*left trace*) and out of (*right trace*) commensurate contact. (After [20.40])

A recent example of friction anisotropy is related to carbon nanotubes. *Falvo* et al. [20.40] manipulated nanotubes on graphite using a FFM tip (Fig. 20.23). A dramatic increase of the lateral force was found in the directions corresponding to commensurate contact. At the same time, the nanotube motion changed from sliding/rotating to stick-roll.

20.4 Thermal Effects on Atomic Friction

Although the Tomlinson model gives a good interpretation of the basic mechanism of the atomic stick-slip discussed in Sect. 20.2, it cannot explain some minor features observed in the atomic friction. For example, Fig. 20.24 shows a friction loop acquired on NaCl(100). The peaks in the sawtooth profile have different heights, which is in contrast to the result in Fig. 20.9. Another effect is observed if the scan velocity v is varied: the mean friction force increases with the logarithm of v (Fig. 20.25). This effect cannot be interpreted within the mechanical approach in Sect. 20.2 without further assumptions.

20.4.1 The Tomlinson Model at Finite Temperature

Let us focus again on the energy profile discussed in Sect. 20.2.1. For sake of simplicity, we will assume that $\gamma \gg 1$. At a given time $t < t^*$, the tip jump is prevented by the energy barrier $\Delta E = E(x_{\max}, t) - E(x_{\min}, t)$, where $x_{\max}$ corresponds to the first maximum observed in the energy profile and $x_{\min}$ is the actual position of the tip (Fig. 20.26). The quantity ΔE decreases with time or, equivalently, with the frictional force F_L until it vanishes when $F_L = F^*$ (Fig. 20.27). Close to the critical

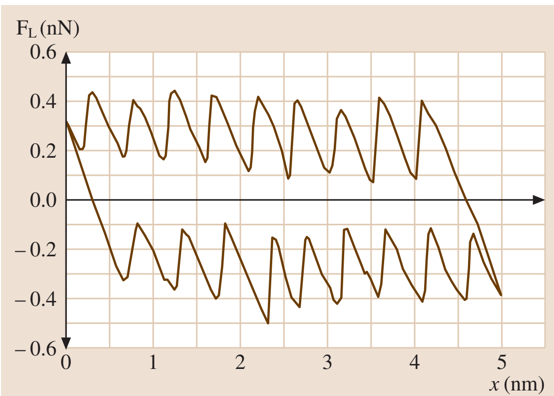

Fig. 20.24 Friction loop on NaCl(100). (After [20.46])

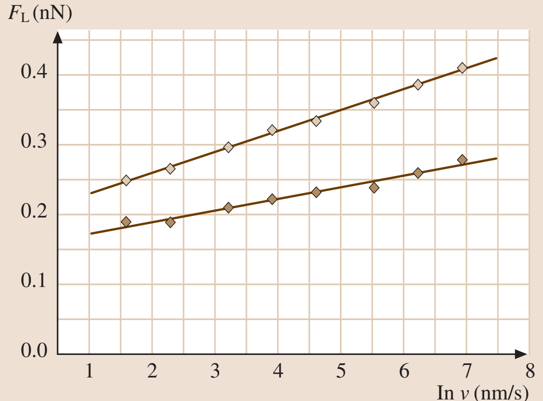

Fig. 20.25 Mean friction force vs. scanning velocity on NaCl(100) at $F_N = 0.44$nN (+) and $F_N = 0.65$nN (×). (After [20.46])

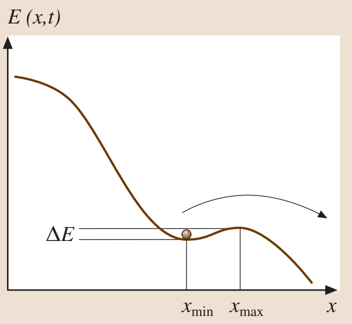

Fig. 20.26 Energy barrier that hinders the tip jump in the Tomlinson model

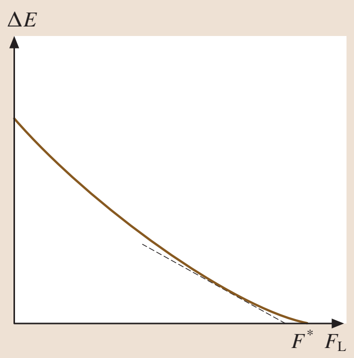

Fig. 20.27 Energy barrier ΔE as a function of the lateral force F_L. The *dashed line* close to the critical value corresponds to the linear approximation (20.17)

point the energy barrier can be written approximately as

$$\Delta E = \lambda(\tilde{F} - F_L) , \qquad (20.17)$$

where $\tilde{F}$ is close to the critical value $F^* = \pi E_0/a$.

At finite temperature T, the lateral force required to induce a jump is lower than F^*. To estimate the most probable value of F_L at this point, we first consider the probability p that the tip does *not* jump. The probability p changes with time t according to the master equation

$$\frac{dp(t)}{dt} = -f_0 \exp\left(-\frac{\Delta E(t)}{k_B T}\right) p(t) , \qquad (20.18)$$

where f_0 is a characteristic frequency of the system. The physical meaning of this frequency is discussed in Sect. 20.4.2. We should note that the probability of a reverse jump is neglected, since in this case the energy barrier to overcome is much higher than ΔE. If time is replaced by the corresponding lateral force, the master equation becomes

$$\frac{dp(F_L)}{dF_L} = -f_0 \exp\left(-\frac{\Delta E(F_L)}{k_B T}\right)\left(\frac{dF_L}{dt}\right)^{-1} p(F_L) . \qquad (20.19)$$

At this point, we substitute

$$\frac{dF_L}{dt} = \frac{dF_L}{dX}\frac{dX}{dt} = k_{eff} v \qquad (20.20)$$

and use the approximation (20.17). The maximum probability transition condition $d^2 p(F)/dF^2 = 0$ then yields

$$F_L(v) = F^* - \frac{k_B T}{\lambda} \ln \frac{v_c}{v} \qquad (20.21)$$

with

$$v_c = \frac{f_0 k_B T}{k_{eff}\lambda} . \qquad (20.22)$$

Thus the lateral force depends logarithmically on the sliding velocity, as observed experimentally. But the approximation (20.17) does not hold when the tip jump occurs very close to the critical point $x = x^*$, which is the case at high velocities. In this instance, the factor $(\mathrm{d}F_\mathrm{L}/\mathrm{d}t)^{-1}$ in (20.19) is small and, consequently, the probability $p(t)$ does not change significantly until it suddenly approaches 1 when $t \to t^*$. Thus friction is constant at high velocities, in agreement with the classical Coulomb's law of friction [20.28].

Sang et al. [20.48] observed that the energy barrier close to the critical point is better approximated by a relation like

$$\Delta E = \mu (F^* - F_\mathrm{L})^{3/2} . \tag{20.23}$$

The same analysis performed using the approximation (20.23) instead of (20.17) leads to the expression [20.49]

$$\frac{\mu (F^* - F_\mathrm{L})^{3/2}}{k_\mathrm{B} T} = \ln \frac{v_\mathrm{c}}{v} - \ln \sqrt{1 - \frac{F^*}{F_\mathrm{L}}} , \tag{20.24}$$

where the critical velocity v_c is now

$$v_\mathrm{c} = \frac{\pi \sqrt{2}}{2} \frac{f_0 k_\mathrm{B} T}{k_\mathrm{eff} a} . \tag{20.25}$$

The velocity v_c discriminates between two different regimes. If $v \ll v_\mathrm{c}$ the second logarithm in (20.24) can be neglected, which leads to the logarithmic dependence

$$F_\mathrm{L}(v) = F^* - \left(\frac{k_\mathrm{B} T}{\mu} \right)^{2/3} \left(\ln \frac{v_\mathrm{c}}{v} \right)^{2/3} . \tag{20.26}$$

In the opposite case, $v \gg v_\mathrm{c}$, the term on the left in (20.23) is negligible and

$$F_\mathrm{L}(v) = F^* \left(1 - \frac{v_\mathrm{c}}{v} \right)^2 . \tag{20.27}$$

In such a case, the lateral force F_L tends to F^*, as expected.

20.4.2 Velocity Dependence of Friction

The velocity dependence of friction was studied by FFM only recently. *Zwörner* et al. observed that friction between silicon tips and diamond, graphite or amorphous carbon is constant with scan velocities of few µm/s [20.50]. Friction decreased when v is reduced below 1 µm/s. In their experiment on lipid films on mica (Sect. 20.3.1), *Gourdon* et al. [20.47] explored a range of velocities from 0.01 to 50 µm/s and found a critical velocity $v_\mathrm{c} = 3.5$ µm/s, which discriminates between an increasing friction and a constant friction regime (Fig. 20.28). Although these results were not explained with thermal activation, we argue that the previous theoretical discussion gives the correct interpretative key. A clear observation of a logarithmic dependence of friction on the micrometer scale was reported by *Bouhacina* et al., who studied friction on triethoxysilane molecules and polymers grafted on silica with sliding velocity up to $v = 300$ µm/s [20.51]. The result was explained with a thermally activated Eyring model, which does not differ significantly from the model discussed in the previous subsection [20.52, 53].

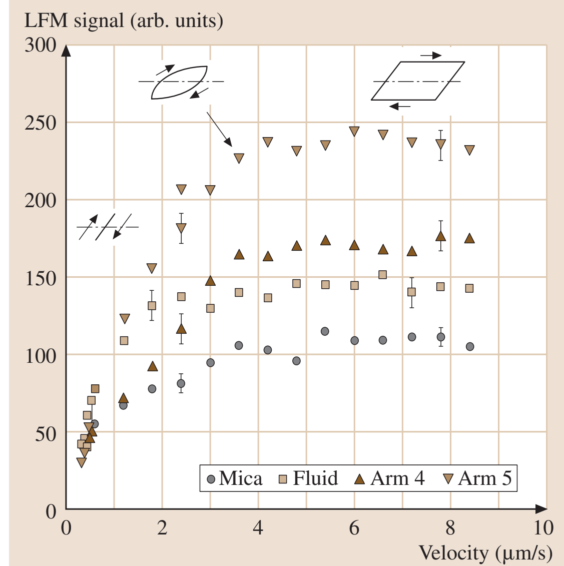

Fig. 20.28 Velocity dependence of friction on mica and on lipid films with different orientation (arms 4 and 5) and in a fluid phase. (After [20.47])

The first measurements on the atomic scale were performed by *Bennewitz* et al. on copper and sodium chloride [20.30, 46]; in both cases a logarithmic dependence of friction was revealed up to $v < 1$ µm/s (Fig. 20.25), in agreement with (20.21). Higher values of velocities were not explored, due to the limited range of the scan frequencies applicable by FFM on atomic scale. The same limitation does not allow a clear distinction between (20.21) and (20.26) in the interpretation of the experimental results.

At this point we would like to discuss the physical meaning of the characteristic frequency f_0. With lattice constants a of a few angstroms and effective spring

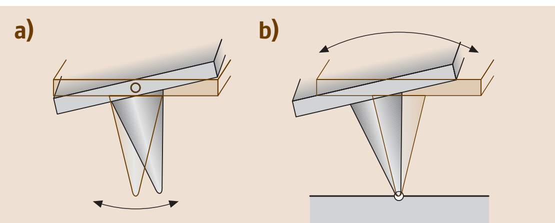

Fig. 20.29a,b Torsional modes of cantilever oscillations **(a)** when the tip is free and **(b)** when the tip is in contact with a surface. (After [20.54])

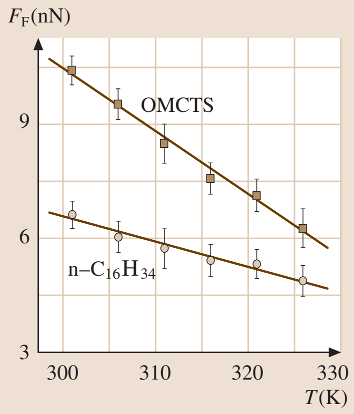

Fig. 20.31 Temperature dependence of friction on n-hexadecane and octamethylcyclotetrasiloxane. (After [20.56])

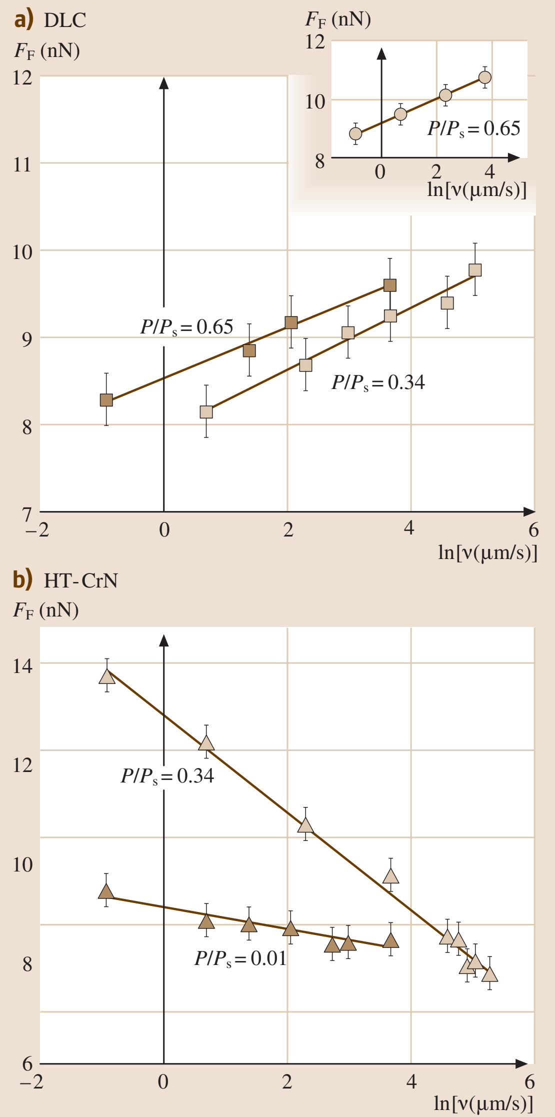

Fig. 20.30a,b Friction vs. sliding velocity **(a)** on hydrophobic surfaces and **(b)** on hydrophilic surfaces (After [20.55])

constants k_{eff} of about 1 N/m, which is typical in FFM experiments, (20.25) gives values of few hundreds of kHz for f_0. This is the characteristic range in which the torsional eigenfrequencies of the cantilevers are located in both contact and noncontact modes (Fig. 20.29). Future work might clarify whether or not f_0 has to be identified with these frequencies.

To conclude this paragraph, we should emphasize that the increase of friction with increasing velocity is ultimately related to the materials and the environment in which the measurements are realized. In humid environment, *Riedo* et al. observed that the surface wettability has an important role [20.55]. Friction *decreases* with increasing velocity on hydrophilic surfaces, and the rate of such decrease depends drastically on humidity. On partially hydrophobic surfaces, a logarithmic increase is found again (Fig. 20.30). These results were interpreted considering the thermally activated nucleation of water bridges between tip and sample asperities, as discussed in the cited reference.

20.4.3 Temperature Dependence of Friction

Thus far we have used thermal activation to explain the velocity dependence of friction. The same mechanism also predicts that friction should change with temperature. Master equation (20.18) shows that the probability of a tip jump is reduced at low temperatures T until it vanishes when $T = 0$. Within this limit case, thermal ac-

tivation is excluded, and the lateral force F_L is equal to F^*, independently of the scanning velocity v.

To our knowledge stick-slip processes at low temperatures have not been reported. A significant increase of the mean friction with decreasing temperature was recently measured by *He* et al. [20.56] by FFM (Fig. 20.31). Neglecting the logarithmic contributions (20.21) and (20.26) predict $(F^* - F_L) \sim T$ and $(F^* - F_L) \sim T^{2/3}$ respectively for the temperature dependence of friction. Although He et al. applied a linear fit to their data, the range of 30 K they considered is again not large enough to prove that a $T^{2/3}$ fit would be preferable.

20.5 Geometry Effects in Nanocontacts

Friction is ultimately related to the real shape of the contact between the sliding surfaces. On macroscopic scale the contact between two bodies is studied within continuum mechanics, which are all based on the elasticity theory developed by Hertz in 19th century. Various FFM experiments showed that continuum mechanics is still valid down to contact areas a few nanometers in size. Only when contact is reduced to few atoms does the continuum frame become unsuitable, and other approaches like molecular dynamics are necessary. This section will deal with continuum mechanics theory; molecular dynamics will be discussed in Sect. 20.7.

20.5.1 Continuum Mechanics of Single Asperities

The lateral force F_L between two surfaces in reciprocal motion depends on the size of the real area of contact, A, which can be a few orders of magnitude smaller than the apparent area of contact. The simplest assumption is that friction is proportional to A; the proportionality factor is called *shear strength* σ [20.57]:

$$F_L = \sigma A \,. \tag{20.28}$$

In case of plastic deformation, the asperities are compressed until the pressure, p, equals a certain yield value, p^*. The resulting contact area is thus $A = F_N/p^*$, and the well-known Amontons' law is obtained: $F_L = \mu F_N$, where $\mu = \sigma/p^*$ is the *coefficient of friction*. The same idea can be extended to contacts formed by many asperities, and it leads again to the Amontons' law. The simplicity of this analysis explains why most of the friction processes were related to plastic deformation for a long time. Such mechanism, however, should provoke a quick disruption of the surfaces, which is not observed in practice.

Elastic deformation can be easily studied in the case of a sphere of radius R pressed against a flat surface. In such case the contact area is

$$A(F_N) = \pi \left(\frac{R}{K}\right)^{2/3} F_N^{2/3} \,, \tag{20.29}$$

where $K = 3E^*/4$ and E^* is an effective Young's modulus, related to the Young's moduli, E_1 and E_2, and the Poisson's numbers, ν_1 and ν_2, of sphere and plane, by the following relation [20.58]:

$$\frac{1}{E^*} = \frac{1-\nu_1^2}{E_1} + \frac{1-\nu_2^2}{E_2} \,. \tag{20.30}$$

The result $A \propto F_N^{2/3}$ is in contrast with the Amontons' law. But a linear relation between F_L and F_N can be obtained for contacts formed by several asperities in particular cases. For example, the area of contact between a flat surface and a set of asperities with an exponential height distribution and the same radius of curvature R depends linearly on the normal force F_N [20.59]. The same conclusion holds approximately even for a Gaussian height distribution. But the hypothesis that the radii of curvature are the same for all asperities is not realistic. A general model was recently proposed by *Persson*, who derived analytically the proportionality between contact area and load for a large variety of elastoplastic contacts formed by surfaces with arbitrary roughness [20.60]. The discussion is not straightforward and goes beyond the purposes of this section.

Further effects are observed if adhesive forces between the asperities are taken into account. If the range of action of these forces is smaller than the elastic deformation, (20.29) is extended to the Johnson–Kendall–Roberts (JKR) relation

$$A(F_N) = \pi \left(\frac{R}{K}\right)^{2/3} \times \left(F_N + 3\pi\gamma R + \sqrt{6\pi\gamma R F_N + (3\pi\gamma R)^2}\right)^{2/3} , \tag{20.31}$$

where γ is the surface tension of sphere and plane [20.61]. The real contact area at zero load is

finite and the sphere can be detached only by pulling it away with a certain force. This is also true in the opposite case, in which the range of action of adhesive forces is larger than the elastic deformation. In such a case, the relation between contact area and load has the simple form

$$A(F_N) = \pi \left(\frac{R}{K}\right)^{2/3} (F_N - F_{off})^{2/3} , \qquad (20.32)$$

where F_{off} is the negative load required to break the contact. The Hertz-plus-offset relation (20.32) can be derived from the Derjaguin–Muller–Toporov (DMT) model [20.63]. To discriminate between the JKR or DMT models *Tabor* introduced a nondimensional parameter

$$\Phi = \left(\frac{9R\gamma^2}{4K^2 z_0^3}\right)^{1/3} , \qquad (20.33)$$

where z_0 is the equilibrium distance in contact. The JKR model can be applied if $\Phi > 5$; the DMT model holds when $\Phi < 0.1$ [20.64]. For intermediate values of Φ, the Maugis–Dugdale model [20.65] could reasonably explain experimental results (Sect. 20.5.3).

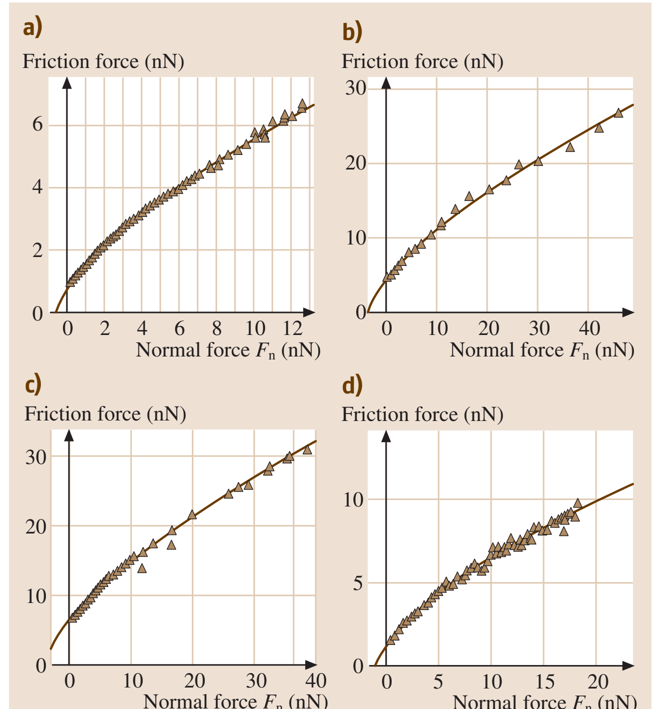

Fig. 20.32a–d Friction vs. load curve on amorphous carbon in argon atmosphere. Curves **(a)**–**(d)** refer to tips with different radii of curvature. (After [20.62])

20.5.2 Load Dependence of Friction

The FFM tip represents a single asperity sliding on a surface. The previous discussion suggests a nonlinear dependence of friction on the applied load, provided that continuum mechanics is applicable. Schwarz et al. observed the Hertz-plus-offset relation (20.32) on graphite, diamond, amorphous carbon and C_{60} in argon atmosphere (Fig. 20.32). In their measurements they used well-defined spherical tips with radii of curvature of tens of nanometers, obtained by contaminating silicon tips with amorphous carbon in a transmission electron microscope. In order to compare the tribological behavior of different materials, *Schwarz* et al. suggested the introduction of an effective coefficient of friction, $\tilde{C}$, which is independent of the tip curvature [20.62].

Meyer et al., *Carpick* et al., and *Polaczyc* et al. performed friction measurements in UHV in agreement with JKR theory [20.17, 66, 67]. In these experiments different materials were considered, i. e. ionic crystals, mica and metals. In order to correlate lateral and normal forces with improved statistics, Meyer et al. applied an original 2-D-histogram technique (Fig. 20.33). Carpick et al. extended the JKR relation (20.32) to include nonspherical tips. In the case of axisymmetric tip profile $z \propto r^{2n}$ ($n > 1$), it can be proven analytically that the increase of friction becomes less pronounced with increasing n (Fig. 20.34).

20.5.3 Estimation of the Contact Area

In contrast to other tribological instruments, such as the surface force apparatus [20.68], the contact area cannot be directly measured by FFM. Indirect methods are provided by contact stiffness measurements. The contact between the FFM tip and the sample can be modeled by a series of two springs (Fig. 20.35). The effective constant k^z_{eff} of the series is given by

$$\frac{1}{k^z_{eff}} = \frac{1}{k^z_{contact}} + \frac{1}{c_N} , \qquad (20.34)$$

where c_N is the normal spring constant of the cantilever and $k^z_{contact}$ is the normal stiffness of the contact. This quantity is related to the radius of the contact area a, by the simple relation

$$k^z_{contact} = 2aE^* , \qquad (20.35)$$

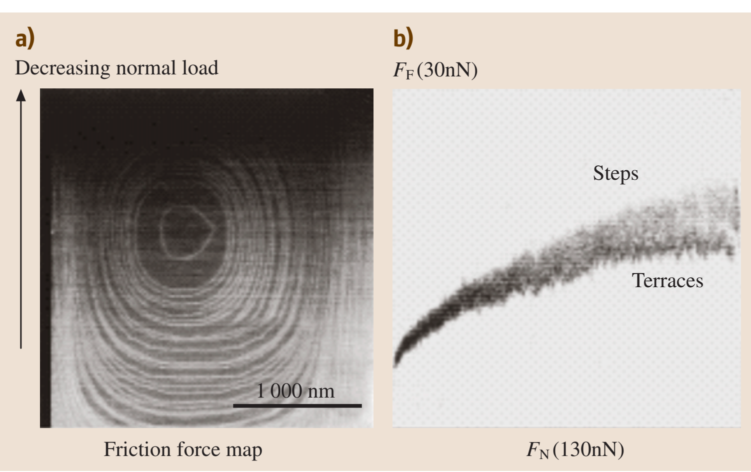

Fig. 20.33 **(a)** Friction force map on NaCl(100). The load is decreased from 140 to 0 nN (jump-off point) during imaging. **(b)** 2-D-hystogram of **(a)**. (After [20.17])

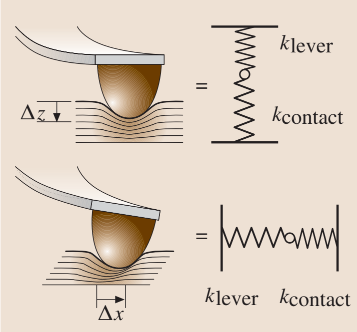

Fig. 20.35 Sketch of normal and lateral stiffness of the contact between tip and surface. (After [20.70])

where E^* is the effective Young's modulus previously introduced [20.69]. Typical values of k^z_{contact} are order of magnitude larger than c_N, however, and a practical application of (20.34) is not possible.

Carpick et al. suggested an alternative method independently [20.70, 71]. According to various models, the *lateral* contact stiffness of the contact between a sphere and a flat surface is [20.72]

$$k^x_{\text{contact}} = 8aG^* , \tag{20.36}$$

where the effective shear stress G^* is defined by

$$\frac{1}{G^*} = \frac{2-\nu_1^2}{G_1} + \frac{2-\nu_2^2}{G_2} \tag{20.37}$$

(G_1, G_2 are the shear moduli of sphere and plane). The contact between the FFM tip and the sample can be modeled again by a series of springs (Fig. 20.35). The effective constant k^x_{eff} of the series is given by

$$\frac{1}{k^x_{\text{eff}}} = \frac{1}{k^x_{\text{contact}}} + \frac{1}{k^x_{\text{tip}}} + \frac{1}{c_L} , \tag{20.38}$$

where c_L is the lateral spring constant of the cantilever and $k^x_{contact}$ is the lateral stiffness of the contact. As suggested by Lantz, (20.38) includes also the lateral stiffness of the tip, k^x_{tip}, which can be comparable to the lateral spring constant. The effective spring constant k^x_{eff} is simply given by the slope dF_L/dx of the friction loops (Sect. 20.2.1). Once $k^x_{contact}$ is determined, the contact radius a is easily estimated by (20.36).

The lateral stiffness method was applied to contacts between silicon nitride and muscovite mica in air and between $NbSe_2$ and graphite in UHV. Both the spring constant k^x_{eff} and the lateral force F_L dependence on the load F_N were explained within the same models (JKR and Maugis–Dugdale, respectively), which confirms that friction is proportional to the contact area in the applied range of loads (up to $F_N = 40$ nN in both experiments).

Enachescu et al. estimated the contact area by measuring the contact conductance on diamond as a function of the applied load [20.73, 74]. Their experimental data were fitted with the DMT model, which was also used to explain the dependence of friction vs. load. Since the contact conductance is proportional to the contact area, the validity of the hypothesis (20.28) was confirmed again.

20.6 Wear on the Atomic Scale

If the normal force F_N applied with the FFM exceeds a critical value, which depends on the tip shape and on the material under investigation, the surface topography is permanently modified. In some cases wear is exploited to create patterns with well-defined shape. Here we will focus on the mechanisms acting on the nanometer scale, where recent experiments have proven the unique capability of the FFM in both scratching and imaging surfaces down to the atomic scale.

20.6.1 Abrasive Wear on the Atomic Scale

In the case of ionic crystals, *Lüthi* et al. observed the appearance of wear at very low loads, i. e. $F_N = 3$ nN [20.31]. Atomically resolved images of the damage produced by scratching the FFM tip areas on potassium bromide were obtained very recently by *Gnecco* et al. [20.75]. In Fig. 20.36 a small mound grown up at the end of a groove on KBr(100) is shown under different magnifications. The groove was created a few minutes before imaging by repeated scanning with the normal force $F_N = 21$ nN. The image shows a lateral force map acquired with a load of about 1 nN; no atomic features were observed in the corresponding topography signal. Figure 20.36a,b shows that the debris extracted from the groove recrystallized with the same atomic arrangement of the undamaged surface, which suggests that the wear process occurred like an epitaxial growth assisted by the microscope tip.

Although it is not straightforward to understand how wear is initiated and how the tip transports the debris, important indications are given by the profile of the lateral force F_L recorded while scratching. Figure 20.37 shows some friction loops acquired when the tip was scanned laterally on 5×5 nm^2 areas. The mean lateral force multiplied by the scanned length gives the total energy dissipated in the process. The result of the tip movement are the pits in Fig. 20.38a. Thanks to the pseudo-atomic

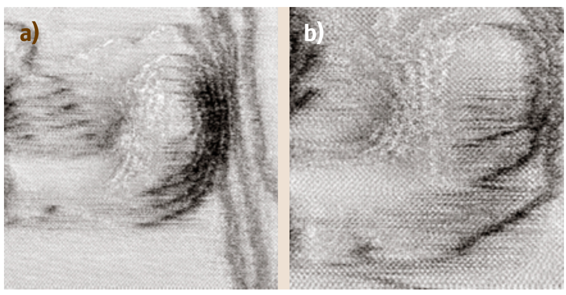

Fig. 20.36a,b Lateral force images acquired at the end of a groove scratched 256 times with a normal force $F_N =$ 21nN. Frame sizes: **(a)** 39 nm, **(b)** 25 nm

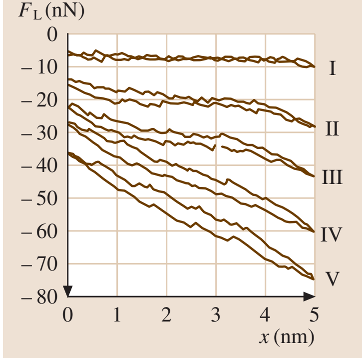

Fig. 20.37 Friction loops acquired while scratching the KBr surface on 5 nm long lines with different loads $F_N = 5.7$ to 22.8 nN. (After [20.75])

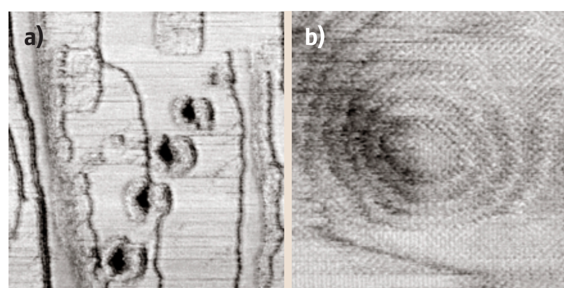

Fig. 20.38 **(a)** Lateral force images of the pits produced with $F_N = 5.7$ to 22.8 nN. Frame size: 150 nm; **(b)** Detailed image of the fourth pit from the top with psuedo-atomic resolution. Frame size: 20 nm

resolution obtained by FFM (Fig. 20.38b), the number of removed atoms could be determined from the lateral force images, which allowed estimating that 70% of the dissipated energy went into wear-less friction [20.75]. Figures 20.37 and 20.38 clearly show that the damage increases with increasing load. On the other hand, changing the scan velocity v between 25 and 100 nm/s did not produce any significant variation in the wear process.

A different kind of wear was observed on layered materials. *Kopta* et al. [20.76] could remove layers from a muscovite mica surface by scratching with the normal force $F_N = 230$ nN (Fig. 20.39a). Fourier filtered images acquired on very small areas revealed the different periodicities of the underlying layers, which reflect the complex structure of the muscovite mica (Fig. 20.39b,c).

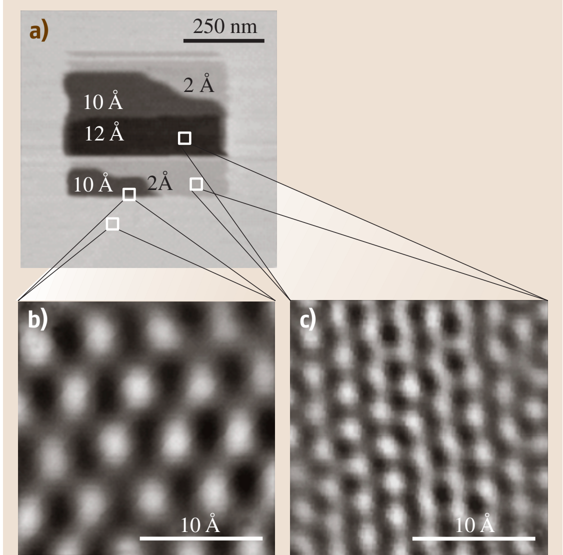

Fig. 20.39 **(a)** Topography image of an area scratched on muscovite mica with $F_N = 230$ nN; **(b)**,**(c)** Fourier filtered images of different regions. (After [20.76])

To interpret their experiment on mica, Kopta et al. assumed that wear is initiated by atomic defects. When the defects accumulate beyond a critical concentration, they grow to form the scars shown in Fig. 20.39. Such process was once again related to thermal activation. The number of defects created in the contact area $A(F_N)$ is

$$N_{def}(F_N) = t_{res} n_0 A(F_N) f_0 \exp\left(-\frac{\Delta E}{k_B T}\right) , \quad (20.41)$$

20.6.2 Wear Contribution to Friction

In Fig. 20.40 the mean lateral force detected while scratching the KBr(100) surface with a fixed load $F_N = 11$ nN is shown. A rather continuous increase of "friction" with the number of scratches N is observed, which can be approximated with the following exponential law:

$$F_L = F_0 \, e^{-N/N_0} + F_\infty \left(1 - e^{-N/N_0}\right) . \quad (20.39)$$

Equation (20.39) is easily interpreted assuming that friction is proportional to the contact area $A(N)$, and that time evolution of $A(N)$ can be described by

$$\frac{dA}{dN} = \frac{A_\infty - A(N)}{N_0} , \quad (20.40)$$

A_∞ being the limit area in which the applied load can be balanced without scratching.

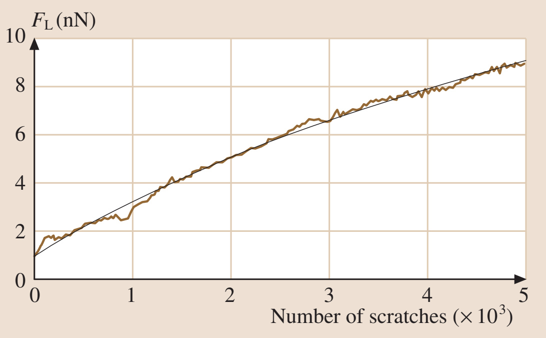

Fig. 20.40 Mean value of the lateral force during repeated scratching with $F_N = 11$ nN on a 500 nm line. (After [20.75])

where t_{res} is the residence time of the tip, n_0 is the surface density of atoms, and f_0 is the attempt frequency to overcome the energy barrier ΔE to break a Si–O bond, which depends on the applied load. When the defect density reaches a critical value, a hole is nucleated. The friction force during the creation of a hole could also be estimated with thermal activation by Kopta et al., who derived the formula

$$F_L = c(F_N - F_{off})^{2/3} + \gamma F_N^{2/3} \exp\left(B_0 F_N^{2/3}\right) . \qquad (20.42)$$

The first term on the right gives the wearless dependence of friction in the Hertz-plus-offset model (Sect. 20.5.1); the second term is the contribution of the defect production. The agreement between (20.42) and the experiment can be observed in Fig. 20.41.

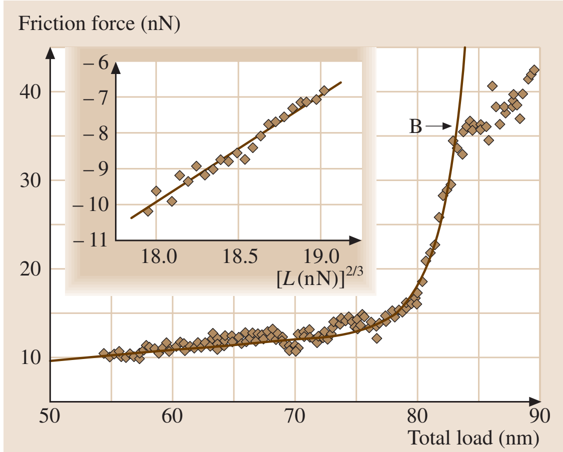

Fig. 20.41 Friction vs. load curve during the creation of a hole in the muscovite mica. (After [20.76])

20.7 Molecular Dynamics Simulations of Atomic Friction and Wear

Section 20.5 has introduced how small sliding contacts can be modeled by continuum mechanics. This modeling has several limitations. The first, most obvious, is that continuum mechanics cannot account for atomic-scale processes like atomic stick-slip. While this limit can be overcome by semiclassical descriptions like the Tomlinson model, a definite limit is the determination of contact stiffness for contacts with a radius of a few nanometers. Interpretation of experimental results with the methods introduced in Sect. 20.5.3 regularly yields contact radii of atomic or even smaller size, in clear contradiction to the minimal contact size given by adhesion forces. Such macroscopic quantities as shear modulus or pressure fail to describe the mechanical behavior of these contacts. A microscopic modeling including the atomic structure of the contact is therefore required. This is usually done by a *molecular dynamics* (MD) simulation of the contact. In such simulations, the sliding contact is set up by boundaries of fixed atoms in relative motion and the atoms of the contact, which are allowed to relax their positions according to interactions between each pair of atoms. The methods of computer simulations in tribology are discussed elsewhere in this book. In Sect. 20.7.1 we will discuss such simulations, which can be directly compared to experimental results showing atomic friction processes. The major outcome of the simulations beyond the inclusion of the atomic structure is the importance of displacement of atoms for a correct prediction of forces. In the following Sect. 20.7.2, we will present simulation studies including wear of tip or surface.

20.7.1 Molecular Dynamics Simulation of Friction Processes

The first experiments that exhibited atomic friction features were performed on layered materials, often graphite. A theoretical study of forces between an atomically sharp diamond tip and the graphite surface has been reported by *Tang* et al. [20.77]. The authors found a significant distance dependence of forces, in which the strongest contrast appeared at different distances for normal and lateral forces due to the strong displacement of surface atoms. The order of magnitude found in this study was one nanonewton, much less than in most experimental reports, which indicated that in such experiments a contact area of far larger dimension was realized. Tang et al. already determined that the distance dependence of forces could even change the symmetry appearance of the observed lateral forces. The experimental situation has also been studied in numerical simulations using simplified one-atom potential for the tip–surface interaction but including the spring potential of the probing force sensor [20.36]. The motivation for

these studies was the observation of a hexagonal pattern in the friction force, while the surface atoms of graphite are ordered in a honeycomb structure. The simulations revealed how the jump path of the tip under lateral force is dependent on the force constant of the probing force sensor.

Surfaces of ionic crystals have become model systems for studies in atomic friction. Atomic stick-slip behavior has been observed by several groups with a lateral force modulation of the order of 1 nN. Pioneering work in atomistic simulation of sliding contacts has been done by *Landman* et al.. The first ionic system studied was a CaF_2 tip sliding over a $CaF_2(111)$ surface [20.78]. In MD calculation with controlled temperature, the tip was first approached toward the surface up to the point at which an attractive normal force of −3 nN acted on the tip. Then the tip was laterally moved, and the lateral force determined. An oscillation with the atomic periodicity of the surface and with an amplitude decreasing from 8 nN was found. Inspection of the atomic positions revealed a wear process by shear cleavage of the tip. Such transfer of atoms between tip and surface plays a crucial role in atomic friction studies as was shown by *Shluger* et al. [20.79]. These authors simulated a MgO tip scanning laterally over a LiF(100) surface. Initially an irregular oscillation of the system's energy is found together with transfer of atoms between surface and tip. After a while, the tip apex structure is changed by adsorption of Li and F ions in such a way that nondestructive sliding with perfectly regular oscillation of the energy with the periodicity of the surface could be observed. The authors called this effect self-lubrication and speculate that generally a dynamic self-organization of the surface material on the tip might promote the observation of periodic forces. In a less costly approach of a molecular mechanics study, in which the forces are calculated for each fixed tip–sample configuration, *Tang* et al. produced lateral and normal force maps for a diamond tip over a NaCl(100) surface including such defects as vacancies and a step [20.80]. In accordance with the studies mentioned before, they found that significant atomic force contrast can be expected for tip–sample distances below 0.35 nm, while distances below 0.15 nm result in destructive forces. For the idealized conditions of scanning at constant height in this regime, the authors predict that even atomic-sized defects could be imaged. Experimentally, these conditions cannot be stabilized in static modes, which so far have been used in lateral force measurements. But dynamic modes of force microscopy have proven atomic resolution of defects when entering the distance regime between 0.2 and 0.4 nm [20.81]. Recent experimental progress in atomic friction studies of surfaces of ionic crystals include the velocity dependence of lateral forces and atomic-scale wear processes. Such phenomena are not yet accessible by MD studies: the experimentally realized scanning time scale is too far from the atomic relaxation time scales that govern MD simulations. Furthermore, the number of freely transferable atoms that can be included in a simulation is simply limited by meaningful calculation time.

Landman et al. also simulated a system of high reactivity, namely a silicon tip sliding over a silicon surface [20.82]. A clear stick-slip variation of the lateral force was observed for this situation. Strong atom displacements created an interstitial atom under the influence of the tip, which was annealed as the tip moved on. Permanent damage was predicted, however, in the case that the tip enters the repulsive force regime. Although the simulated Si(111) surface is experimentally not accessible, it should be mentioned that on the Si(111)7×7 reconstructed surface the tip had to be passivated by a Teflon layer before nondestructive contact-mode measurements became possible (Sect. 20.3). It is worth noting that the simulations for the Cu(111) surface revealed a linear relation between contact area and mean lateral force, similar to classical macroscopic laws.

For metallic sliding over metallic surfaces, wear processes are predicted by several MD studies, which will be discussed in the following section. For a (111)-terminated copper tip over the Cu(111) surface, however, *Sørensen* et al. found that nondestructive sliding is possible while the lateral force exhibits the sawtooth-like shape characteristic of atomic stick-slip (Fig. 20.42). In contrast, a Cu(100) surface would be disordered by a sliding contact (Fig. 20.43). This difference between the (100) and (111) plane as well as the absolute lateral forces has been confirmed experimentally (Sect. 20.3).

20.7.2 Molecular Dynamics Simulations of Abrasive Wear

The long time scales characteristic of the wear processes and the large amount of material involved make any attempt to simulate these mechanisms on a computer a tremendous challenge. Despite these premises, MD can provide useful insight on the mechanism of removal and deposition of single atoms operated by the FFM tip, which is a kind of information not directly observable in the experiments. Complex processes like

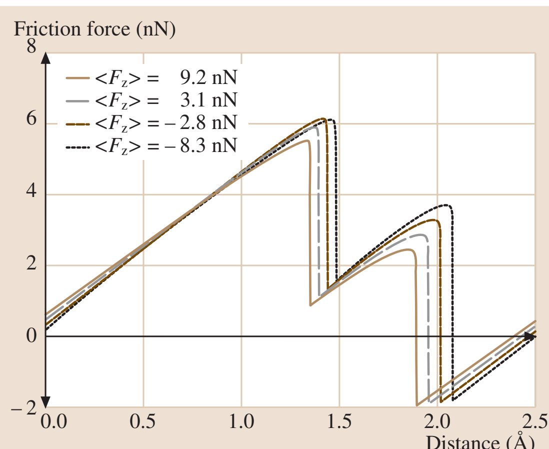

Fig. 20.42 Lateral force acting on a Cu(111) tip in matching contact with a Cu(111) substrate as a function of the sliding distance at different loads. (After [20.83])

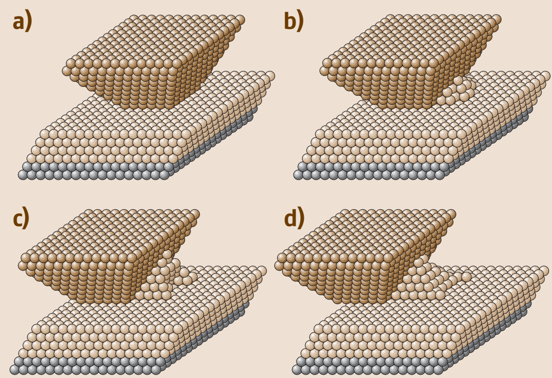

Fig. 20.43a–d Snapshot of a Cu(100) tip on a Cu(100) substrate during sliding. **(a)** Starting configuration; **(b)**–**(d)** snapshots after 2, 4, and 6 slips. (After [20.83])

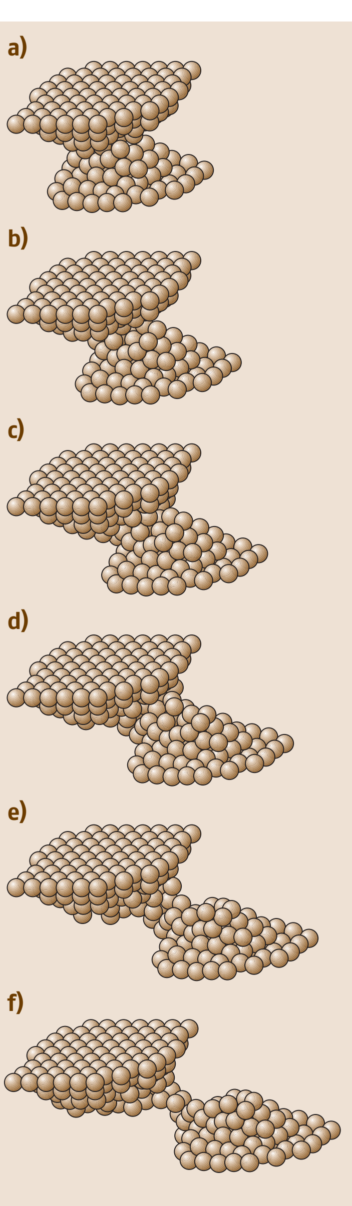

Fig. 20.44a–f Snapshot of a Cu(100) neck during shearing starting from the configuration **(a)**. The upper substrate has been displaced 4.2 Å between subsequent pictures. (After [20.83])

abrasive wear and nanolithography can be investigated only within approximate classical mechanics.

The observation made by *Livshits* and *Shluger* that the FFM tip undergoes a process of self-lubrication when scanning ionic surfaces (Sect. 20.7.1) proves that friction and wear are strictly related phenomena. In their MD simulations on copper, *Sørensen* et al. considered not only ordered (111) and (100) terminated tips but even amorphous structures obtained by "heating" the tip at high temperatures [20.83]. The lateral motion of the neck thus formed revealed a stick-slip behavior due to combined sliding and stretching, and also ruptures, accompanied by deposition of debris on the surface (Fig. 20.44).

To our knowledge, only a few examples of abrasive wear simulations on the atomic scale have been reported. *Buldum* and *Ciraci*, for instance, studied nanoindentation and sliding of a sharp Ni(111) tip on Cu(110) and of a blunt Ni(001) tip on Cu(100) [20.84]. In the case of the sharp tip quasiperiodic variations of the lateral

force were observed, due to stick-slip involving phase-transition. One layer of the asperity was deformed to match the substrate during the first slip and then two asperity layers merged into one through structural transition during the second slip. In the case of the blunt tip, the stick-slip was less regular.

Different results have been reported in which the tip is harder than the underlying sample. *Komanduri* et al. considered an infinitely hard Ni indenter scratching single crystal aluminum at extremely low depths (Fig. 20.45) [20.85]. In this case a linear relation between friction and load was found, with a high coefficient of friction $\mu = 0.6$, independent of the scratch depth. Nanolithography simulations were recently performed by *Fang* et al. [20.86], who investigated the role of the displacement of the FFM tip along the direction of slow motion between a scan line and the next one. They found a certain correlation with FFM experiments on silicon films coated with aluminum.

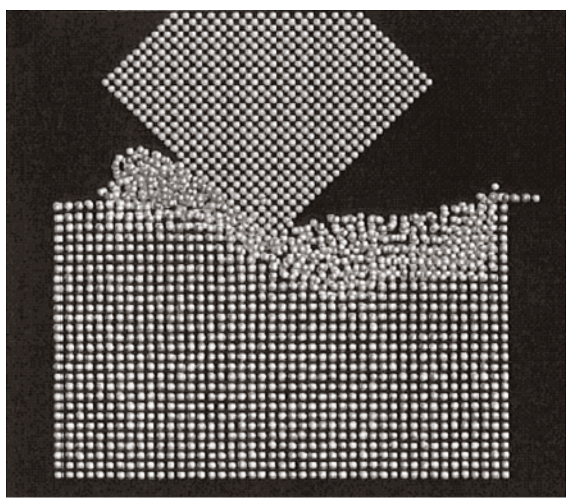

Fig. 20.45 MD simulation of a scratch realized with an infinitely hard tool. (After [20.85])

20.8 Energy Dissipation in Noncontact Atomic Force Microscopy

Historically, the measurement of energy dissipation induced by tip–sample interaction has been the domain of friction-force microscopy, where the sharp AFM-tip is sliding in gentle contact over a sample. The origins of dissipation in friction are related to phonon excitation, electronic excitation, and irreversible changes of the surface. In a typical stick-slip experiment, the energy dissipated in a single atomic slip event is of the order of 1 eV.

But the lateral resolution of force microscopy in the contact mode is limited by a minimum contact area containing several atoms due to adhesion between tip and sample.

This problem has been overcome in noncontact dynamic force microscopy. In the dynamic mode, the tip is oscillating with a constant amplitude A of typically 1–20 nm at the eigenfrequency f of the cantilever, which shifts by Δf due to interaction forces between tip and sample. This technique has been described in detail in Part B of this book.

Dissipation also occurs in noncontact mode of force microscopy, where the atomic structure of tip and sample are reliably preserved. In this dynamic mode, the damping of the cantilever oscillation can be deduced from the excitation amplitude A_{exc} required to maintain the constant tip oscillation amplitude on resonance.

Compared to friction force microscopy, the interpretation of noncontact-AFM (nc-AFM) experiments is complicated due to the perpendicular oscillation of the tip, typically with an amplitude that is large compared to the minimum tip–sample separation. Another problem is to relate the measured damping of the cantilever to the different origins of dissipation.

In all dynamic force microscopy measurements a power dissipation P_0 caused by internal friction of the freely oscillating cantilever is observed, which is proportional to the eigenfrequency ω_0 and to the square of the amplitude A and inverse proportional to the known Q-value of the cantilever. When the tip–sample distance is reduced, the tip interacts with the sample and therefore an additional damping of the oscillation is encountered. This extra dissipation P_{ts} caused by tip–sample interaction can be calculated from the excitation signal A_{exc} [20.87].

The observed energy losses per oscillation cycle (100 meV) [20.88] are roughly similar to the 1 eV energy loss in the contact slip-process. When estimating the contact area in the contact-mode to a few atoms, the energy dissipation per atom that can be associated with a bond being broken and reformed is also around 100 meV.

The idea to relate additional damping of the tip oscillation to dissipative tip–sample interaction has

recently attracted much attention [20.89]. The origin of this additional dissipation are manifold: one may distinguish between apparent energy dissipation (for example from an inharmonic cantilever-motion, artifacts from the phase-controller, or slow fluctuations round the steady-state solution [20.89, 90]), velocity dependent dissipation (for example electric- and magnetic-field mediated Joule dissipation [20.91, 92]) and hysteresis-related dissipation (due to atomic instabilities [20.93, 94] or hysteresis due to adhesion [20.95]).

By recording Δf and A_{exc} simultaneously during a typical AFM-experiment, forces and dissipation can be measured. Many experiments show true atomic contrast in topography (controlled by Δf) and in the dissipation-signal A_{exc} [20.96]; however, the origin of the atomic energy dissipation process is still not completely resolved.

To prove that the observed atomic-scale variation of the damping is indeed due to atomic-scale energy dissipation and not an artefact of the distance feedback, *Loppacher* et al. [20.88] carried out an nc-AFM experiment on Si(111)-7×7 at constant height, i. e. with stopped distance feedback. Frequency-shift and dissipation exhibit an atomic-scale contrast, demonstrating a true atomic-scale variation of force and dissipation.

A strong atomic-scale dissipation contrast at step edges has been demonstrated in a few experiments (NaCl on Cu [20.81]; or measurements on KBr [20.97]). In Fig. 20.46 ultrathin NaCl islands grown on Cu(111) are shown. As it is shown in Fig. 20.46a, the island edges have a higher contrast compared to the NaCl-terrace and show an atomically resolved corrugation. The strongly enhanced contrast of the step edges and kink sites could be attributed to a slower decay of the electric field and to easier relaxation of theses positions of the ions at these locations. The dissipation image shown in Fig. 20.46b was recorded simultaneously. To establish a direct spatial correspondence between the excitation and the topography-signal, the match between topography and A_{exc} on many images has been studied. Sometimes topography and A_{exc} are in phase, sometimes they are shifted a little bit, and sometimes A_{exc} is at a minimum when topography is at a maximum. The local contrast formation thus depends strongly on the atomic tip structure. In fact, the strong dependence of the dissipation contrast on the atomic state of the tip apex is impressively confirmed by the tip change observed in the experimental images shown in Fig. 20.46b. The dissipation contrast is seriously enhanced, while the topography contrast remains nearly unchanged. Clearly, the dissipation depends strongly on the state of the tip and exhibits more short-range character than the frequency shift.

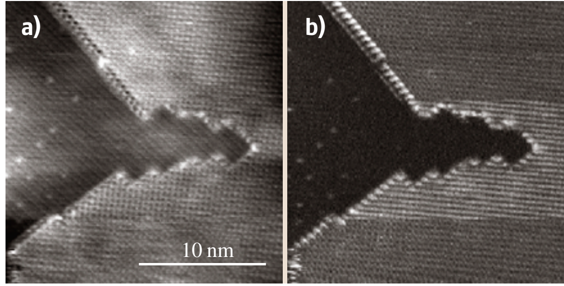

Fig. 20.46 (a) Topography and **(b)** A_{exc} images of a NaCl island on Cu(111). The tip changes after 1/4 of the scan, thereby changing the contrast in the topography and enhancing the contrast in A_{exc}. After 2/3 of the scan, the contrast from the *lower part* of the image is reproduced, indicating that the tip change was reversible. (After [20.81])

More directly related to friction measurements, where the tip is sliding in contact over the sample, are nc-AFM experiments, where the tip is oscillating parallel to the surface. *Stowe* et al. [20.98] oriented cantilever beams with in-plane tips perpendicular to the surface, so that the tip motion was approximately parallel to the surface. The noncontact damping of the lever was used to measure localized electrical Joule dissipation. They were able to image the dopant density for n- and p-type silicon samples with 150 nm spatial resolution. An U_{ts}^2 dependence on the tip–sample voltage for the dissipation was found, as proposed by *Denk* and *Pohl* [20.91] for electric-field Joule-dissipation.

Stipe et al. [20.99] measured the noncontact friction between a Au(111)-surface and a gold-coated tip with the same setup. They observed the same U_{ts}^2 dependence of the Bias-voltage and a distance dependence that follows a power law $1/d^n$, where n is between 1.3 and 3 [20.99, 100]. Even when the external Bias-voltage is zero, a substantial electric-field is present. The presence of inhomogeneous tip–sample electric fields is difficult to avoid, even under the best experimental conditions. Although this dissipation is electrical in origin, the detailed mechanism is not totally clear. The most straightforward mechanism is to assume that inhomogeneous fields emanating from the tip and the sample induce surface charges in the nearby metallic sample. When the tip moves, currents are induced, caus-

ing Ohmic dissipation [20.91, 98]. But in metals with good electrical conductivity, Ohmic dissipation is insufficient to account for the observed effect [20.101]. Thus the tip–sample electric field must have an additional effect, such as driving the motion of adsorbates and surface defects.

When exciting the torsional oscillation of commercial, rectangular AFM cantilevers, the tip is oscillating approximately parallel to the surface. In this mode, lateral forces acting on the tip at step edges and near impurities could be measured quantitatively [20.54]. An enhanced energy-dissipation was observed at the impurities as well. When the tip is further approached toward the sample, contact formation transforms the nearly free torsional oscillation of the cantilever into a different mode with the tip–sample contact acting as a hinge. When this contact is formed, a rapid increase of the power required to maintain a constant tip oscillation amplitude and a positive frequency shift are found. The onset of the simultaneously recorded damping and positive frequency shift are sharp and essentially coincide. It is assumed that these changes indicate the formation of a tip–sample contact. Two recent studies [20.102, 103] report on the use of the torsional eigenmode for measuring the elastic properties of the tip–sample contact, where the tip is in contact with the sample and the shear stiffness depends on the normal load.

Kawagishi et al. [20.104] scanned with lateral amplitudes in the order of 10 pm to 3 nm; their imaging technique gave contrast between graphite terraces, silicon and silicon dioxide, graphite and mica. Torsional self-excitation showed nanometric features of self-assembled monolayer islands due to different lateral dissipation.

Recently *Giessibl* et al. [20.105] established true atomic resolution of both conservative and dissipative forces by lateral force microscopy. The interaction between a single-tip atom oscillated parallel to an Si(111)-7×7 surface is measured. A dissipation energy of up to 4 eV per oscillation cycle is found, which is explained by a plucking action of one atom on to the other as described by *Tomlinson* in 1929 [20.23].

A detailed review of dissipation phenomena in noncontact force microscopy has been given by *Hug* [20.106].

20.9 Conclusion

Over the last 15 years, two instrumental developments have stimulated scientific activities in the field of nanotribology. On the one hand, the invention and development of friction force microscopy allows us to quantitatively study friction of a single asperity. As we have discussed in this chapter, atomic processes are observed by forces on the order of 1 nN, i. e. forces related to single chemical bonds. On the other hand, the enormous increase of achievable computing power provides the basis for molecular dynamics simulations of systems containing several hundred atoms. Therewithin, the development of the atomic structure in a sliding contact can be analyzed and forces predicted.

The most prominent observation of atomic friction is a stick-slip behavior with the periodicity of the surface atomic lattice. Semiclassical models can explain the experimental findings including the velocity dependence, which is a consequence of thermal activation of slip events. Classical continuum mechanics can also describe the load dependence of friction in contacts with an extension of several ten nanometers. But when trying to apply continuum mechanics to contacts formed at just ten atoms, obviously wrong numbers result, such as, for example, for the contact radius. Only a comparison with atomistic simulations can provide a full meaningful picture of the physical parameters of such sliding contacts. These simulations predict a close connection between wear and friction, in particular a transfer of atoms between surface and tip, which in some case can even lower friction in a process of self-lubrication.

First experiments have succeeded in studying the onset of wear with atomic resolution. The research in microscopic wear processes will certainly grow in importance as nanostructures are produced and their mechanical properties exploited. Simulation of such processes involving transfer of thousands of atoms will become feasible with further increase of computing power. Another perspective of nanotribology is the expansion of atomic friction experiments toward surfaces with a well-defined roughness. In general, the problem of bridging the gap between single asperity experiments on well-defined surfaces and macroscopic friction should be approached, both experimentally and in modeling.

21. Nanoscale Mechanical Properties – Measuring Techniques and Applications

The first part of this chapter describes local (at the scale of nanometers) measurements of mechanical properties. It includes detailed state-of-the-art presentation and in-depth analysis of experimental techniques, results, and interpretations.

After a short introduction, the second part describes local mechanical spectroscopy using coupled Atomic Force Microscopy and ultrasound. This technique allows us to map quickly not only spatial distribution of the elasticity but anelastic properties as well. At one point in the sample, semi-quantitative measurements can be made as a function of the temperature. On the nanometer scale, results have close similitudes to bulk measurements and interpretable differences. Local elasticity and damping were measured during phase transition of polymer samples and shape-memory alloys.

The third part describes the "nano-Swiss cheese" method of measuring the elastic properties of such tubular nanometer size objects as carbon nanotubes and microtubules. It is probably the only experiment in which properties of single-wall nanotube ropes were measured as a function of the rope diameter. We extended this idea to biological objects, microtubules, and successfully solved major experimental difficulties. We not only measured the temperature dependency of microtubule modulus in pseudo-physiological conditions but also estimated shear modulus using the same microtubule with several lengths of suspended segments.

The fourth section demonstrates the scanning nanoindentation technique as applied to human bone tissue. This instrument allows performing topography scans and indentation tests using the identical tip. The available surface scan allows a high positioning precision of the indenter tip on the structure of interest. For very inhomogeneous samples, such as bone tissue, this tool provides a probe to detect local variations of the mechanical properties. The indentation test supplies quantitative parameters like elastic modulus and hardness on the submicron level. Local mechanical properties of compact and trabecular bone lamellae were tested under both dry and pseudo-physiological conditions.

Finally, last part is given to a discussion of future prospects and conclusions.

Experiments measuring the mechanical properties at nanoscale are key to understanding mesoscopic materials and inhomogeneous materials.

The most prominent technique for such local measurements implements an Atomic Force Microscopy in static mode to obtain force–distance curves (f-d). Ideally this provides the force applied to the tip and the tip–sample distance allowing the local reduced Young's modulus to be determined. In practice, however, these values are not measured directly. Instead, the applied force is offset by adhesive and capillary forces. Furthermore, the tip–sample distance must be obtained by subtraction of the sample (Z-piezo) displacement and the deflection of the cantilever, neither of which are calibrated on most commercial instruments. Usually only the voltage applied to nonlinear and hysteretic Z-piezo and the uncalibrated cantilever deflection is available. These available data must be tediously calibrated and converted to real displacements and forces. The calibration procedure given by *Radmacher* [21.1] works well but only when applied to very compliant materials such as biological or polymer samples. An additional difficulty is that since one end of the cantilever is fixed, neither the orientation of the tip nor its position on the sample surface remains constant during f-d curve acquisition. Movement of the tip on the sample surface, therefore occurs not only vertically but also along the cantilever axis. As a result, applied contact mechanics may not be valid. Finally, uncertainty about the exact tip shape and radius complicate the procedure even further. Instrumental challenges are so significant that applying static AFM to obtain absolute values of the elastic modulus using commercial instruments is difficult at best, especially on stiff surfaces. And this, of course, is the motivation for developing of other techniques.

Although absolute values of mechanical properties are difficult to measure, relative measurements or maps (images of physical properties) are still very interesting. Using acoustic vibrations of the AFM sample surface one can access local elastic and anelastic properties. The first part of this chapter describes these techniques and applications.

Studies of mesoscopic specimens are even more challenging: it is difficult and time consuming to locate a sample, specially properly positioned. In the second part of the chapter, we used 'nano Swiss cheese' technique to get insight into the axial and shear modulus of several species of carbon nanotubes. The method was further extended to biological microtubules, where The experiment was performed in liquid and as a function of the temperature.

Reliable mechanical measurements can be obtained by combining the best of two worlds, AFM and nanoindenter. Classical nanoindenters use optical tip positioning, which are inadequate in the nanoworld. Scanning nanoindenter uses the same diamond tip for imaging (with microNewton forces) and measuring. Its application to human bones in liquid and 37 °C is described in the third part of this chapter.

One should underline the importance of AFM linearity and stability for such experiments: only good designs may limit frustration and experiment time of courageous PhD students, and lot of improvements are still lacking.

21.1 Local Mechanical Spectroscopy by Contact AFM

Mechanical properties of solids (elasticity, anelasticity, plasticity) are generally measured on macroscopic samples. But many phenomena in materials science require measurements of mechanical properties at the surface of a material or at the interfaces between thin layers deposited on a surface. High spatial resolution is also important, for example in the cases of multiphased materials or composite materials, phase transitions, lattice softening in shape-memory alloys, precipitation in light alloys, and glass transition of amorphous materials.

In the case of multiphased materials, such as nanomaterials, composites, alloys, or polymer blends, the location of the dissipative mechanism in one phase must be determined either through modeling or by separately studying each phase, when possible, without changing its behavior. The latter is only possible in a limited number of cases due to the interactions between the different phases within a material. To give an example, the global behavior of a composite is mostly driven by the stress transfer properties between the reinforcement and the matrix, which are controlled by the local mechanical properties in the interface region and in particular the dynamics of the structural defects in this area. It is obviously impossible to prepare a sample only composed of interface regions. Therefore a method for locally studying the dynamics of the structural defects will thus

provide important steps in the understanding and the improvement of such materials.

Different techniques based on Scanning Probe Microscopies (SPM) have been developed to probe the elastic and anelastic properties of surfaces, interfaces, or phases of inhomogeneous materials at the micrometer and the nanometer scales. Scanning Acoustic Microscopy (SAM), first developped in the mid-1970s, allows one to study the materials properties at the micrometer scale.

Among the different ways explored to study local mechanical properties of materials, several groups have recently used techniques based on Scanning Force Microscopy (SFM) [21.2]. For most of these, the focus has been placed on "elasticity," using the so-called Force Modulation Mode (FMM) at low frequencies [21.3]. Force modulation mode generally uses a large amplitude (greater than 10 nm), low frequency (some kHz) vibration of the sample underneath the SFM tip. The component of the tip motion at the excitation frequency and the tip mean position are simultaneously recorded, giving several images of the sample surface. In particular, the in-phase and out-of-phase components of force modulation mode at room temperatures have been interpreted in terms of stiffness ("elasticity") and damping ("viscoelasticity") [21.4, 5]. But, it has been recently shown by *Mazeran* et al. [21.6] that the contrast of force modulation mode is dominated by friction properties, giving only little information on the elasticity. Consequently, some care has to be taken in the interpretation of these low-frequency studies. A way to suppress the influence of friction on the contrast is to use smaller amplitudes (some Å) at higher frequencies [21.7]. Scanning Local-Acceleration Microscopy (SLAM) implements this idea [21.8]: SLAM is a modification of contact-mode scanning force microscopy. Its principle is to vibrate the sample at a frequency just above the resonance of the tip–sample system. In this case, the inertia of the tip prevents it from completely following the imposed high frequency displacement, inducing nonnegligible forces and giving rise to elastic deformation of the sample. Contact stiffness is obtained from the measure of the residual displacement of the tip. Mapping the contact stiffness at different temperatures with SLAM [21.9] has allowed local mechanical spectroscopy. Some other techniques also use high frequencies but with different approaches to image elasticity at room temperature [21.7, 10, 11]. Each of these high-frequency techniques is capable of mapping properties such as stiffness or adhesion at constant temperature with a very high lateral resolution.

21.1.1 The Variable-Temperature SLAM (T-SLAM)

The technique described here combines the lateral resolution of scanning force microscopy with the physical information available from temperature ramps. It is the variable-temperature SLAM (T-SLAM) [21.12, 13]. Ramping the temperature of the sample during a SLAM measurement and acquiring both the amplitude and the phase of the tip's motion allows one to obtain local mechanical spectroscopy data. A simple model enables the interpretation of the measurement in terms of material properties.

T-SLAM is based on SLAM [21.8, 14], using a variable temperature sample holder [21.9, 15]. An ultrasonic transducer is placed beneath the sample in a commercial scanning force microscope (Fig. 21.1) and excited by means of a function generator. The ultrasound is

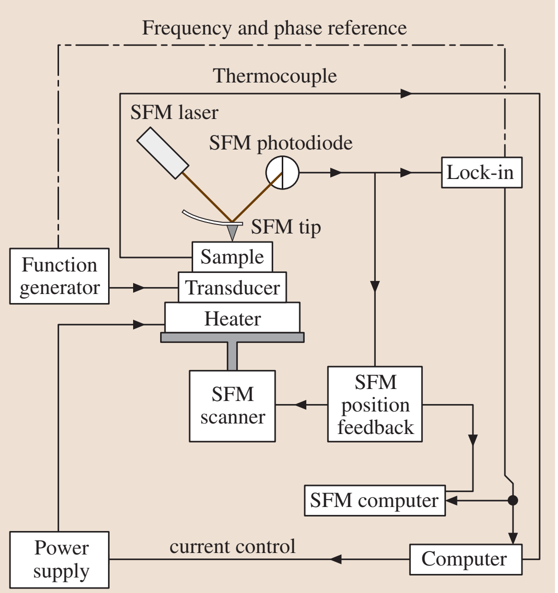

Fig. 21.1 *Schematic diagram of T-SLAM*. Ultrasound is generated with a transducer connected to a function generator and placed beneath the sample. The motion of the scanning force microscope tip is detected optically. The detection signal is fed to a lock-in amplifier, which extracts amplitude and phase relative to the transducer's motion. The temperature is controlled with a small resistive heater and measured with a thermocouple. The rest of the microscope head, to which the tip, the laser and the photodiode are attached, is not represented in this diagram

transmitted through the sample, forcing periodic local deformation of the sample's surface underneath the tip. The motion of the scanning force microscopy tip is detected optically by laser beam deflection from the backside of the cantilever. The detection signal is then fed to a lock-in amplifier, which extracts the tip's amplitude (related to elasticity) and phase (related to viscoelasticity) relative to the transducer's motion. The transducer's typical frequency is 825 kHz. This installation can operate in two ways, either by mapping the amplitude and phase of the signal as a function of position at fixed temperature or by recording the amplitude and phase as a function of temperature at a "fixed" location. The first method is known as "SLAM imaging," where the output signal of the lock-in is fed into an auxiliary data acquisition channel of the microscope. An extra computer is used to store local mechanical spectroscopy data as a function of the temperature at a fixed location and to control temperature. The heat is produced with a small resistive heater below the transducer, and the temperature is measured with a thermocouple. The sample must be prepared with a sufficiently low surface roughness in order to avoid artifacts in the measurements due to the sample's topography. Due to the geometry of the contact, SLAM measures only a small volume near the surface. Viewing SLAM as a very fast indentation measurement, the probed volume is approximately a half-sphere with a radius of $10a$, where a is the contact radius between tip and sample [21.16]. The typical value of a is some nm. So even if the sample is a thick film, T-SLAM gives access to the near-surface mechanical properties that may differ from bulk.

The mechanical properties of the deformed region are obtained from the measure of the residual displacement of the tip. The tip vibration amplitude d_1 is related to the contact stiffness, proportional to the dynamic elastic modulus, while the phase lag φ between the tip motion and the surface motions is related to the internal friction (energy dissipation inside the deformed volume). Mapping d_1 and φ at different temperatures with T-SLAM allows the study of the homogeneity of mechanical relaxations or of phase transitions. By recording d_1 and φ as a function of temperature at a fixed location, local mechanical spectroscopy can be performed.

When used just above the first resonance of the tip–sample system, the SLAM system can be described and analyzed using a point mass rheological model [21.9, 12], which allows one to obtain the equation relating the damping (loss factor η') to the measured parameters

$$\eta' = \left(\frac{1}{2}\frac{k_e}{k_c - m\omega^2}\right)\frac{\sin\varphi}{d_1/z_1}\,, \tag{21.1}$$

where ω is the measurement frequency, k_c is a parameter related to the elastic modulus of the AFM cantilever and k_e to the elastic modulus of the sample, z_1 is the transducer vibration amplitude, and $m = k_c/\omega_c^2$ is the equivalent point mass of the tip, where ω_c is the free resonant frequency of the cantilever.

The principal limitation of (21.1) comes from the model assumption that the cantilever is a point mass restricted to vertical displacements. Due to the possible lateral displacements of the tip [21.6] or the existence of other vibrational modes of the cantilever, which are not described by the point mass model, (21.1) is only reliable for the measurement of the damping just above the first resonance of the tip–sample system. In order to obtain a quantitative measurement of this quantity in a larger frequency spectrum, it is necessary to develop a more realistic model of the cantilever interacting with the sample surface such as, for example, the model presented by *Dupas* et al. [21.17], in which the cantilever is modeled as a beam.

21.1.2 Example One: Local Mechanical Spectroscopy of Polymers

Figure 21.2 shows local mechanical spectra [21.13, 18] obtained in bulk technical PVC (including plasticizer and pigments and taken off-the-shelf) as a function of temperature (Fig. 21.2a) and a Differential Scanning Calorimetry (DSC) measurement of the same sample (Fig. 21.2b). The mechanical measurement (Fig. 21.2a) displays the amplitude of vibration of the SLAM tip (thin line) and its phase lag (thick line) as a function of temperature. Four temperature domains can be identified. At lower temperatures (1), the first domain shows a phase lag peak associated with a decrease of amplitude. The second temperature (2) domain corresponds to a zone where the vibration amplitude increases, without any variation in the phase lag. The third temperature domain (3) is characterized by a large phase lag peak and a significant decrease of vibration amplitude. The last temperature domain (4) shows a slow increase in the phase lag without variation of the vibration amplitude.

The calorimetry curves (b) display the heat flow as a function of temperature for the same material but at a larger size scale. For clarity, the same temperature do-

Part C | 21.1

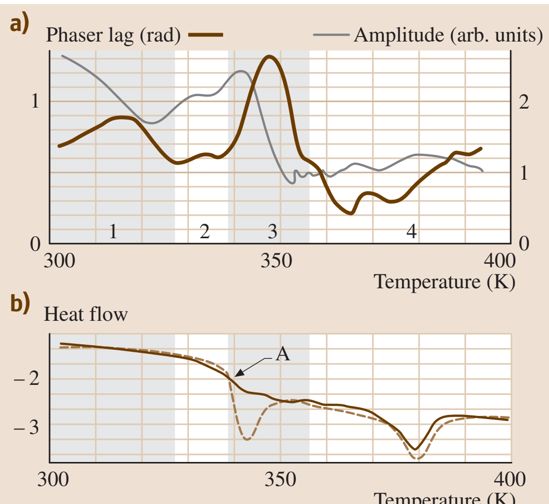

Fig. 21.2 **(a)** *Local mechanical spectroscopy spectra as a function of temperature of a technical PVC*: The vibration amplitude is displayed as a *thin line* and the phase lag as a *thick line*. Four temperature domains can be distinguished: From left to right, a small "vibration amplitude" decrease is associated with a first "phase lag" peak (1), in the next domain, "vibration amplitude" increases (2), then a large decrease of "vibration amplitude" is associated with a large "phase lag" peak (3) and finally "phase lag" increases slowly (4). **(b)** *DSC measurements of the same sample*. For clarity, the temperature domains observed on Fig. 21.5a have been reported. The graph displays the first (*dashed line*) and the second (*solid line*) heating. The glass transition can easily be recognized around 340 K (labeled *A*), slightly below the temperature range of domain 3. An irreversible endothermic relaxation takes place in the same temperature range (only visible on the first run). A reversible endothermic event occurs around 380 K

mains have been reported on the graph. The dashed line displays the first heating, where both reversible and irreversible events are present; the solid line shows the second heating, where only reversible events are still present. On the solid line, an endothermic event (labeled A) can be observed near the border between temperature domains 2 and 3. An irreversible endothermic relaxation is superimposed with (A) on the first heating. A reversible endothermic peak is observed around 380 K, in domain 4. The endothermic event (A) has the characteristics of a glass transition: the specific heat goes from one value to another without a peak [21.19]. The glass transition temperature of this PVC is, therefore, approximately 340 K. The irreversible relaxation occurring in the same temperature range is certainly associated with physical aging or structural relaxation. The reversible peak at higher temperature is associated with the melting of the small crystalline volume fraction.

These local mechanical spectroscopy results are in good qualitative agreement with macroscopic global measurements [21.13, 18]. They yield the same information as the macroscopic global measurements, but from a much smaller volume, and allow as a consequence the location of the different mechanisms. Both measurements (local and global) show a peak in phase for the primary and secondary relaxations, connected with a large decrease of the stiffness for the primary relaxation and a much smaller one for the secondary relaxation. Plasticity induces an increase of the phase lag in both cases. The temperatures observed for the relaxation related to the glass transition compare well with the calorimetric data. Based on all these examples, there is no doubt that the amplitude and phase lag of T-SLAM are functions of the stiffness and damping. In this regard, T-SLAM provides an extension of the global method, allowing location of dissipative phenomena and study of the spatial homogeneity of phase transitions or of relaxations. This will bring new insight into the field of inhomogeneous or composite materials. In addition, T-SLAM measures only a small volume near the surface. So even if the sample is a thick film, T-SLAM gives access to the near-surface mechanical properties, which may differ from bulk properties. This will bring interesting perspectives to the still debated field of surface dynamics.

21.1.3 Example Two: Local Mechanical Spectroscopy of NiTi

Near-stoichiometric NiTi alloys exhibit a martensitic phase transformation between a low-temperature monoclinic phase, called martensite, and a high temperature cubic phase with B2 structure, called austenite (1). This transformation is responsible for the shape memory and pseudo-elastic effects in deformed NiTi alloys. Upon transformation to the martensitic phase, an intermediate rhombohedral (R) phase can be formed [21.20, 21]. Although *Bataillard* [21.21] tends to demonstrate that the R phase is finely dispersed inside the material, a controversy remains over the spatial scale at which the decomposition of the transformation occurs. Another puzzling question concerns the transformation itself. Optical microscopy observation suggests that the transformation occurs very suddenly inside an austen-

ite grain. This has led to the concept of "military transformation." The width of the globally measured transformation would then be a sum of different narrow contributions coming from different places inside the sample. This image is, however, not universally accepted.

A measurement inside one single grain of a polycrystal would be a way to address these questions. Both the spatial scale of the R phase distribution and the "military" character of the transformation will have an effect on the result of such a measurement. This is the reason for which local mechanical spectroscopy measurements of the martensitic phase transition of NiTi by T-SLAM have been performed [21.12, 22]. They are presented in Fig. 21.3. The global transformation behavior of NiTi is defined by calorimetry spectra (Fig. 21.3b, temperature scanning rate 10 K/min).

The vibration amplitude ("elasticity") and the phase lag ("internal friction") are shown in the top and bottom curves, respectively. The presented data is incomplete due to experimental limitations. A phase lag peak can be observed upon heating at approximately 370 K, associated with a change in the vibration amplitude level. This event can be correlated with the phase transformation from martensite to austenite observed by calorimetry (Fig. 21.3b). Upon cooling, no event is observed around 370 K: the vibration amplitude is stable and the phase lag curve does not exhibit any peak. But, an intense phase lag peak can be observed upon cooling near 330 K, associated with a restoration of the vibration amplitude level characteristic of the martensite. This event correlates with the phase transformation from austenite to martensite observed by calorimetry. A change in the vibration amplitude spectrum is correlated with each event on the phase lag spectrum. Two main features should be noted. First, the transformation peaks observed with the SLAM method are narrower than those observed with the (global) calorimetry measurement. Second, the measured temperatures for the local peak are located on the high temperature side of the peaks measured by calorimetry. Details of the two transformation peaks are displayed in Figs. 21.3c and 21.3d. The reverse transformation (Fig. 21.3c) is characterized by a change in the vibration amplitude level and a phase lag peak. This peak (A1) may have a shoulder on the low temperature

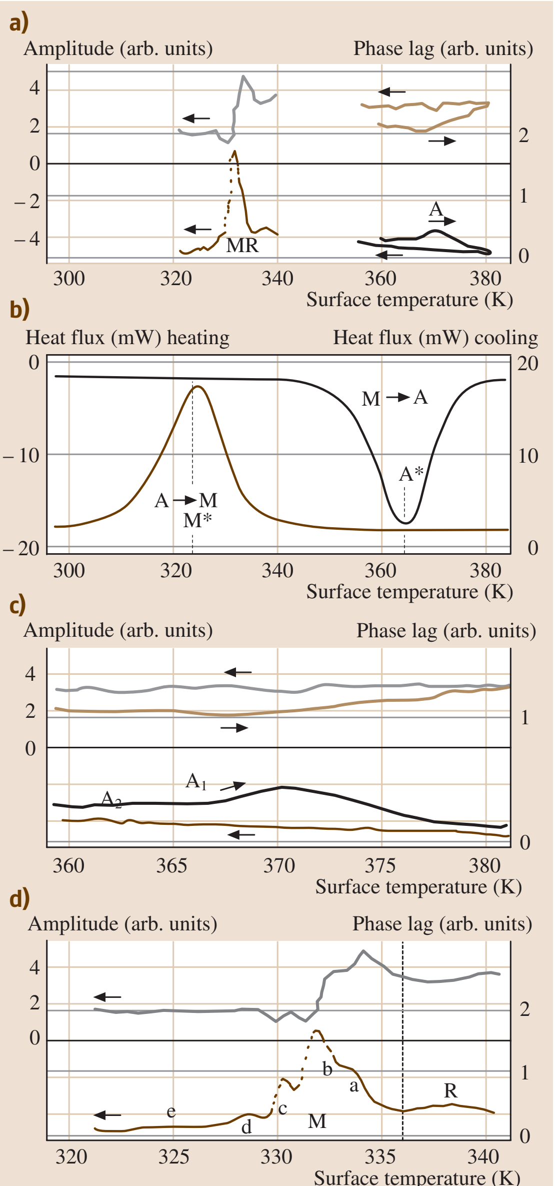

Fig. 21.3 (a)–(b) *Comparison of the local mechanical spectroscopy measurements of* NiTi *with calorimetric experiment*. **(a)** Both the reverse and direct transformation are associated with a phase lag peak and a modulus variation. **(b)** Calorimetric measurement of the same sample. **(c)–(d)** *Zoom on the reverse* **(c)** *and direct* **(d)** *transformation's temperature ranges*. The peak (A1) may exhibit a shoulder on the low temperature side (A2). The direct transformation is characterized by a recovery of the original vibration amplitude and a complex phase lag spectrum, formed of two main maxima, noted R and M. Peaks a,b,c,d,e are a substructure of the M peak

Part C | 21.1

side (A2). A small decrease of the vibration amplitude may precede this increase. But, the magnitude of this softening and the very low intensity of peak A2 are too small to exclude experimental artifacts. The direct transformation (Fig. 21.3d) displays a recovery of the original vibration amplitude and a complicated phase lag maximum.

The correlation of the transition temperatures measured by calorimetry and the local mechanical spectroscopy lead to the conclusion that the peaks observed in phase lag and the change in vibration amplitude originate from the martensitic phase transition. At the scale of the observation, the martensite transforms into austenite around 370 K (A1 peak) and the austenite transforms into martensite close to 332 K (M peak), with the formation of the rhombohedral R phase at 337 K (R peak). The peaks A2 and e could be linked to the presence of two different types of martensite as already observed elsewhere [21.20, 21]. It is striking to note that all the events observed in macroscopic experiments seem to be reproducible at the scale of observation, namely less than 10^{-3} μm^3. In particular, this would confirm that the R phase precipitates are very finely distributed in the austenite matrix as observed by Bataillard [21.21]. Otherwise the R peak could not be observed reproducibly using such a technique. The local measurement differs from global ones in at least two aspects: first, the width of the transformation temperature range is smaller; second, the M peak exhibits a substructure.

Global internal friction measurements on these materials have given spectra with peaks having a similar breadth as the calorimetry peaks [21.23], whereas the peaks measured locally are narrower. This is easy to understand if the martensitic transformation occurs inhomogeneously inside the sample. Grains tend to transform at different temperatures depending on their stress state. As the local measurement has sufficient spatial resolution to probe a single grain inside the material, it is logical that the transformation occurs over a narrower temperature range than in a global experiment probing a large number of grains.

The substructure in the M peak could have three origins: (i) the technique is sensitive to the mechanical relaxation inside newly formed plates, such as stress relaxation by twin motion; (ii) the probed volume contains several martensite plates that grow one by one, each with its own, distinct "elementary" peak (a, b, etc.); (iii) the analyzed region of the sample surface changes due to thermal drifts, therefore probing the transformation of several growing martensite plates, leading to multiple "elementary" peaks.

21.2 Static Methods – Mesoscopic Samples

21.2.1 Carbon Nanotubes – Introduction to Basic Morphologies and Production Methods

Carbon nanotubes (CNTs) are the newest form of carbon, found in 1991 by *Iijima* [21.24]. Because of their remarkable properties, this discovery has opened whole new fields of study in physics, chemistry, and material science. They possess a unique combination of small size (diameters ranging from ~ 1 to 50 nm with lengths up to ~ 10 μm), low density (similar to that of graphite), high stiffness, high strength, and a broad range of electronic properties from metallic to p- and n-doped semiconducting. Their potential field of application is immense and includes reinforcing elements in high strength composites, electron sources in field emission displays and small X-ray sources, ultra-sharp and resistant AFM tips with high aspect ratios, gas sensors, and components of future, nanoscale electronics. In addition, they represent a widely used system for studying fundamental physical phenomena on the mesoscopic scale. Following advances in manufacturing and processing they are likely to be integral to many devices we use in our everyday life.

From the structural point of view, carbon nanotubes can be thought of as rolled up single sheets of graphite, *graphene*. They can be divided in two distinct groups. The first, multiwalled carbon nanotubes (MWNT), exhibit a Russian doll-like structure of nested, concentric tubes, Fig. 21.4a and b. They were also the first CNT to be discovered experimentally. The interlayer spacing can range from 0.342 to 0.375 nm, depending on the diameter and number of shells comprising the tube [21.25]. For comparison, the interlayer spacing in graphite is 0.335 nm, suggesting relatively weak interaction between individual shells. This fact has been corroborated by studies of mechanical and electronic properties of CNTs.

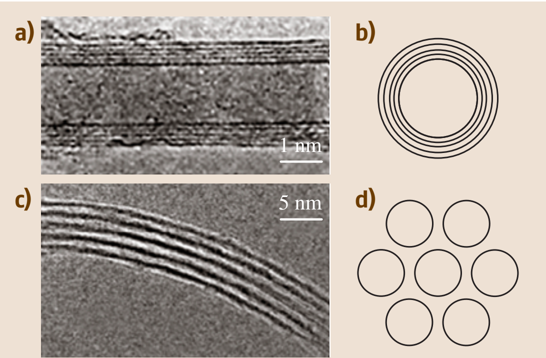

Fig. 21.4a–d TEM images and schematic drawings of cross sections for different morphologies of carbon nanotubes. **(a)** and **(b)** Multiwalled carbon nanotubes, consisting of concentric, nested tubes (MWNT). **(c)** and **(d)** ropes of single-walled carbon nanotubes, consisting of single carbon nanotubes bundled up in ropes and held together by van der Waals interaction

The second type of carbon nanotubes is in the basic form of a rolled-up graphitic sheet: a single-walled CNT (SWNT). During the production, their diameter distribution is relatively narrow so they often bundle in the form of crystalline "ropes" [21.26], Fig. 21.4c and d, in which the single tubes are held together by van der Waals interaction.

There are several distinct classes of production methods. The earliest is based on the cooling of carbon plasma. When voltage is applied between two graphitic electrodes in an inert atmosphere, they gradually evaporate and form plasma. On cooling, soot containing multiwalled nanotubes is formed [21.24]. If the anode is filled with catalysts such as, for example, cobalt of iron particles, SWNT ropes form. Another way of producing CNTs from carbon plasma is by laser ablation of a graphitic target [21.26]. It is considered that, in general, these methods produce CNTs of higher quality albeit in very small quantities and without the possibility of scale-up to industrial production. Other methods are based on chemical vapor deposition (CVD), a catalytic decomposition of various hydrocarbons, e.g. methane or acetylene mixed with nitrogen or hydrogen in the presence of catalysts [21.27]. This method offers the possibility of controlling the growth of nanotubes by patterning the catalyst [21.28] and is therefore more suitable for producing nanoscale structures with integrated CNTs. This method is also capable of producing CNTs in industrial quantities. Their main disadvantage is the higher concentration of defects, which as a consequence diminish their mechanical properties.

21.2.2 Measurements of the Mechanical Properties of Carbon Nanotubes by SPM

Mechanical measurements on CNTs performed with the AFM have confirmed theoretical expectations [21.29] of their superior mechanical properties. They involve measurements of deformations under controlled forces by bending immobilized carbon nanotubes either in the lateral [21.30] or normal direction [21.31] and also tensile stretching of CNTs fixed on their two ends to AFM tips observed in an electron microscope [21.32].

It is not obvious that continuum mechanics and its concepts like Young's, shear moduli, and tensile strength should work on the nanoscale. In order to apply them, one should also define the "thickness" of the nanotube's walls, a graphene sheet, in the frame of the continuous beam approximation. Most scientists working in this field are using the value 0.34 nm, close to the interlayer separation in graphite as the thickness of a nanotube. When comparing different results, however, one has to bear in mind that to convert relatively precise force–displacement measurements into macroscopic quantities like Young's or shear modulus, one has to introduce various geometrical factors, including diameter and length. Even a small imprecision in their determination is very unforgiving because the diameter d enters into equations for beam deformation as d^4 and length l as l^3, leading to large uncertainty in final results.

The first quantitative measurement of the Young's modulus of carbon nanotubes was reported by *Wong* et al. [21.30] in which they laterally bent MWNTs and SiC nanorods (similar in dimensions to MWNTs) deposited on flat surfaces. MWNTs were first randomly dispersed on a flat surface of MoS_2 single crystals that were used because of their low friction coefficient and exceedingly flat surface. Friction between the tubes and substrate was further reduced by performing the measurements in water. Tubes were then pinned on one side to this substrate by a deposition of an array of square pads through a shadow mask, Fig. 21.5a–c. AFM was used to locate and characterize the dimensions of protruding tubes. The beam was deformed laterally by the AFM tip, until at a certain deformation the tip would pass over the tube, allowing the tube to snap back to its relaxed position. During measurements, the force–distance curves were acquired at different positions along the chosen beam, Fig. 21.5d–e. Maximum

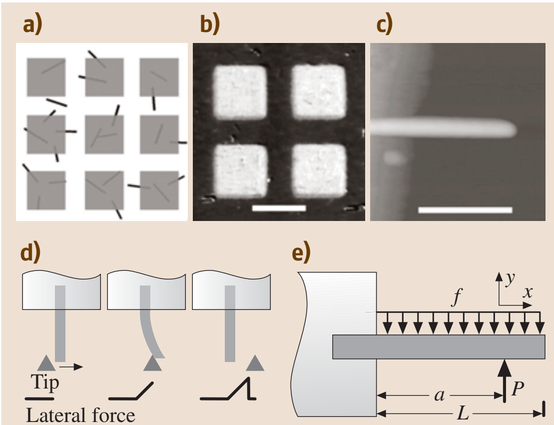

Fig. 21.5a–e Schematic of the experiment performed by *Wong* et al. [21.30] **(a)** nanotubes were dispersed on a substrate and pinned down by a deposition of SiO pads. **(b)** Optical micrograph showing the pads (*light*) and MoS_2 substrate (*dark*). The scale bar is 8 µm long. **(c)** AFM image of a SiC nanorod protruding from the pad. The scale bar is 500 nm long. The same experimental setup was used for elastically deforming MWNTs. **(d)** The tip shown as a triangle moves in the direction of the arrow. The lateral force is indicated by the trace at the bottom. Before the tip contacts the beam, the lateral force remains constant and equal to the friction force. During the bending a linear increase in the lateral force with deflection is measured. After the tip has passed over the beam the lateral force drops to its initial value and the beam snaps back to its equilibrium position. **(e)** Schematic of a pinned beam with a free end. The beam of length L is subjected to a point load P at $x = a$ and friction force f (abstracted with permission from [21.30] © American Association for the Advancement of Science)

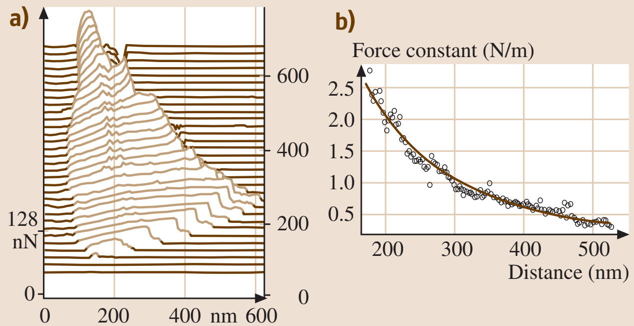

Fig. 21.6 **(a)** A series of lateral force distance curves acquired by *Wong* et al. [21.30] for different positions along a MWNT. **(b)** The lateral spring constant as a function of position on the beam. The curve is a fit to (21.3) (abstracted with permission from [21.30] © American Association for the Advancement of Science)

deflection of the nanobeam can be controlled to a certain degree by the applied normal load, and in this way tube breaking can be avoided or achieved in a controlled manner. The applied lateral load P in terms of lateral displacement y at the position x along the beam is given by the equation:

$$P(x, y) = 3EI\frac{y}{x^3} + \frac{f}{8}\left(x - 4L - 6\frac{L^2}{x}\right) , \qquad (21.2)$$

where E is the Young's modulus of the beam, I the second moment of the cross section, equal to $\pi d^4/64$ for a solid cylinder of diameter d and f the unknown friction force, presumably small due to the experimental design. The lateral force, Fig. 21.6a, is known only up to a factor of proportionality because the AFM lever's lateral force constant wasn't calibrated for these measurements. This uncertainty and the effect of friction were eliminated by calculating the nanobeam lateral force constant:

$$\frac{\mathrm{d}P}{\mathrm{d}y} \equiv k = \frac{3\pi d^4}{64x^3}E \qquad (21.3)$$

shown in Fig. 21.6b.

The mean value for the Young's modulus of MWNTs was $E = 1.3 \pm 0.6$ TPa, similar to that of diamond ($E = 1.2$ TPa). For larger deformations, discontinuities in bending curves were also observed, attributed to elastic buckling of nanotubes [21.33].

In another series of experiments, *Salvetat* et al. measured the Young's modulus of isolated SWNTs and SWNT ropes [21.31], MWNTs produced using different methods [21.34], and the shear modulus of SWNT ropes [21.35]. The experimental setup that enabled them to perform measurements on such a wide range of CNT morphologies involved measuring the vertical deflection of nanotubes bridging holes in a porous membrane.

In their measurement method, they suspended CNTs in ethanol and deposited them on the surface of a well-polished alumina Al_2O_3 ultrafiltration membrane. Tubes adhered to the surface due to the van der Waals interaction occasionally spanning holes, Fig. 21.7a. After a suitable nanotube had been found, a series of AFM images was taken under different loads, in which every image would thus correspond to the surface (and the tube) under a given normal load. Extracted linescans across the tube revealed the vertical deformation, Fig. 21.7b. For the range of applied normal loads, the deflection of a thin, long nanotube at the midpoint δ as

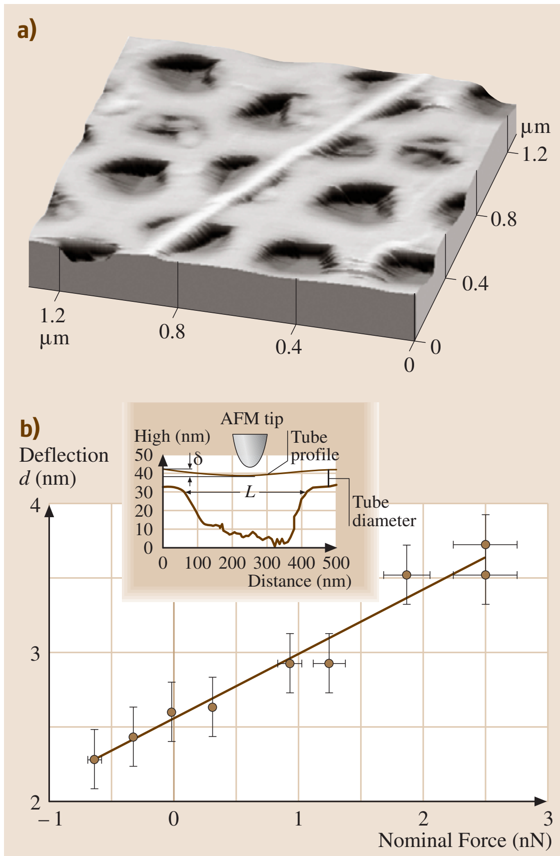

Fig. 21.7 **(a)** An AFM image of a CNT lying on a porous alumina [21.35] filter. **(b)** Measured dependence of vertical deflection on the applied nominal force. The inset shows a comparison between linescans taken on the tube and over a hole [21.34] (abstracted with permission **(a)** from [21.35] © 1999 American Physical Society, **(b)** from [21.34] © 1999 Wiley)

a function of the normal force F can be fitted using the clamped beam formula [21.36]:

$$\delta = \frac{FL^3}{192EI} , \qquad (21.4)$$

where L is the suspended length.

The fitted line does not pass through the origin because the force acting on the nanotube is not equal to the nominal force alone; it contains a constant term arising from the attractive force between the AFM tip and the tube. The tube's deflection should also contain a term corresponding to the interaction between the tube and the substrate, but this is generally regarded as negligible.

This variable load imaging technique is advantageous for obtaining quantitative information as one is assured that the AFM tip is in the desired location when deforming the tube. Equation (21.4) is valid only if the tubes adhere well to the substrate, confirmed by the fact that the images reveal no displacement of the parts of the tube in contact with the membrane.

Using this technique, Young's modulus of 1 TPa was found for SWNTs. Values for the MWNTs show a strong dependence on the amount of disorder in the graphitic layers: an average value of $E = 870$ GPa was found for the arc-discharge grown tubes, while the catalytically grown MWNTs, known to include a high concentration of deffects, can have a Young's modulus as low as 12 GPa.

For the deflection of SWNT ropes, an additional term in the bending formula has to be taken into account because of the influence of shearing between the tubes comprising the rope. Single CNTs are held together in the tube only by weak, van der Waals interactions. Ropes, therefore, behave as an assembly of individual tubes rather than as a thick beam. The deflection can be modeled as a sum of deflections due to bending and shearing [21.36]:

$$\delta = \delta_{\text{bending}} + \delta_{\text{shearing}} = \frac{FL^3}{192EI} + f_s \frac{FL}{4GA} = \frac{FL^3}{192E_{\text{bending}}I} , \qquad (21.5)$$

where f_s is a shape factor, equal to 10/9 for a cylinder, G the shear modulus and A the area of the beam's cross section. E_{bending} is the effective, bending modulus, equal to Young's modulus in the case in which the influence of shearing can be neglected (for thin, long ropes).

The Young's and the shear modulus can thus be extrapolated by measuring the E_{bending} of an ensemble of ropes with different diameter to length ratios: for thin ropes one obtains the value of the Young's modulus, while for the thick ones, the E_{bending} approaches the value of G on the order of 10 GPa (see Fig. 21.8).

Walters et al. pinned ropes of single-wall nanotubes beneath metal pads on an oxidized silicon surface, then released them by wet etching, Fig. 21.9a. The SWNT rope was deflected in the lateral direction using an AFM tip, Fig. 21.9b. As the suspended length is on the order of μm, the SWNT rope can be modeled as an elastic string stretched between the pads. Upon deformation all of the strain goes into stretching. In the simple case of a tube lying perpendicular to the trench and the AFM tip deforming the tube in the middle, the force F exerted on

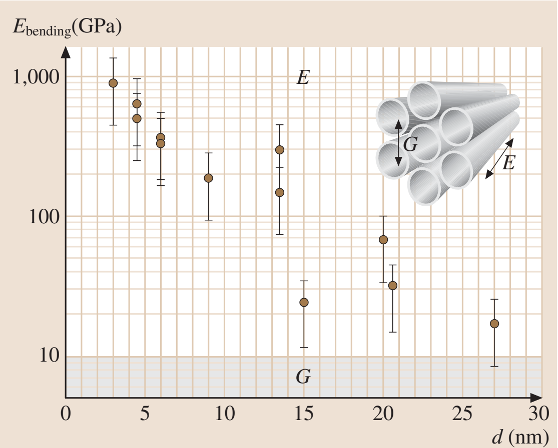

Fig. 21.8 Values of the shear modulus for 12 SWNT ropes of different diameters. The measured $E_{bending}$ of thin ropes corresponds to E, while for thick ropes one obtains the value of shear modulus G (abstracted with permission from [21.35] © 1999 American Physical Society)

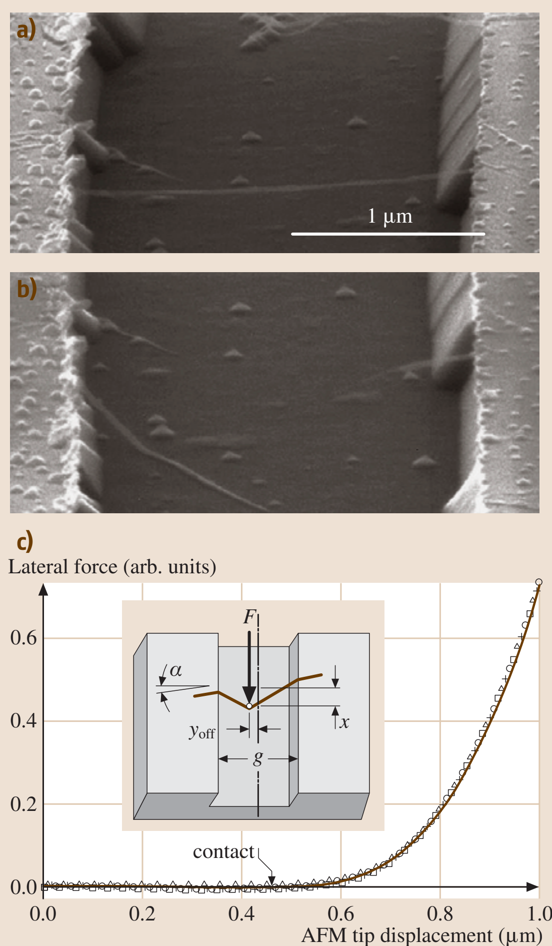

Fig. 21.9 **(a)** SEM image of a SWNT rope suspended over trench in silicon before and **(b)** after being deformed past its elastic limit. **(c)** Lateral force on a single-wall nanotube rope as a function of AFM tip displacement (abstracted with permission from [21.37] © American Institute of Physics)

the tube by the AFM tip is given by the expression:

$$F = 2T\sin\theta = 2T\frac{2x}{L} \approx \frac{8kx^3}{L_0}\,, \tag{21.6}$$

where T is the tension in the string, L_0 its equilibrium length, k the spring constant and x the lateral deflection in the middle. Using this setup, they deformed SNWT ropes to the maximal strain of $5.8\pm0.9\,\%$ and determined a lower bound of 45 ± 7 GPa on the tensile strength, assuming a value of 1.2 TPa for the Young's modulus.

Kim et al. used a setup in which the SWNT rope was embedded in metallic electrodes deposited on a silicon substrate coated with poly(methylmethacrylate) (PMMA). In their experiment the tube can also be modeled as an elastic string. Using an AFM tip, they vertically deformed the rope and obtained an estimate of $E = 0.4$ TPa for the Young's modulus of an SWNT rope.

Finally, the first direct measurements of the elastic properties of CNTs that haven't relied on the beam or stretching string setup involved deforming MWNTs [21.38] and SWNT ropes [21.32] under axial strain. This was achieved by identifying and attaching opposite ends of MWNTs or SWNT ropes to two AFM tips, all inside a SEM. The AFM tips were integrated with different cantilevers, one rigid with a spring constant above 20 N/m and the other compliant with a spring constant of 0.1 N/m, Fig. 21.10. The rigid lever was then driven using a linear piezomotor. On the other end, the compliant lever bent under the applied tensile load. The deflection of the compliant cantilever – corresponding to the force applied on the nanotube – and the strain of the nanotube were simultaneously measured. The force F is calculated as $F = kd$ where k is the spring constant of the flexible AFM lever and d its displacement in the vertical direction. The strain of the nanotube is $\delta L/L$, Fig. 21.11. From the stress–strain curves obtained in this fashion, Fig. 21.11b, Young's moduli ranging from 270–950 GPa were found. Exami-

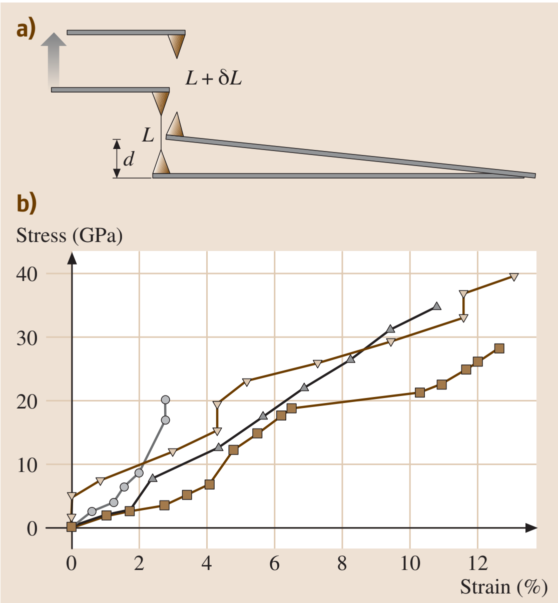

Fig. 21.11 **(a)** The principle of the experiment performed by *Yu* et al. As the rigid cantilever is driven upward, the lower, compliant cantilever bends by the amount d and the nanotube is stretched by δL. As a result, the nanotube is strained by $\delta L/L$ under the action of force $F = kd$, where k is the elastic constant of the lower AFM lever. **(b)** Plot of stress vs. strain curves for different individual MWNTs (abstracted with permission from [21.38] © 1999 American Association for the Advancement of Science)

nations of the same broken tubes inside a TEM revealed that nanotubes break with the "sword in sheath" mechanism, where only the outer layer appears to have carried the load. After it breaks, pullout of inner shells follows. An average bending strength of 14 GPa and axial strengths up to 63 GPa were found.

Firm attachment of nanotubes to AFM tips was ensured by a deposition of carbonaceous material induced by the electron beam concentrated in the contact area [21.40].

All these measurements of the elastic properties of carbon nanotubes are summarized in Table 21.1.

Before comparing them, it should be noted that the absolute values of these mechanical constants have relatively large uncertainties because of the huge influence of the precision of determining tube diameters and lengths on the final result. Also, the cited values represent mean values of results obtained on several tubes, with the exceptions of the lowest value given for catalytically grown MWNTs by Salvetat et al. [21.31], a single value for an individual SWNT rope from *Kim* et al. [21.39], and the lowest and highest values from *Yu* et al. [21.38]. One also has to bear in mind that concepts

Table 21.1 Summary of the mechanical properties of carbon nanotubes measured using SPM methods

Young's modulus E (GPa)	Shear modulus G (GPa)	Tensile strength σ (GPa)	Nanotube type	Deformation method	Reference
1,300±600	–	–	MWNTs arc grown	Lateral bending	[21.30]
1,000±600	–	–	SWNTs	Normal bending	[21.31]
1,000±600	∼ 1 GPa		SWNT ropes	Normal bending	[21.35]
870±400	–	–	MWNT arc-grown	Normal bending	[21.31]
12±6	–	–	MWNT catalytic	Normal bending	[21.31]
–	–	45±7	SWNT rope	Lateral bending	[21.37]
400	–	–	SWNT rope	Normal bending	[21.39]
1,020	–	30	SWNT ropes	Tensile loading	[21.32]
270–950	–	11–63	MWNTs arc-grown	Tensile loading	[21.38]

like Young's and shear moduli and tensile strength were introduced for describing macroscopic and continuous structures. Their application for describing mesoscopic objects like nanotubes, therefore, has its limitations.

The methods presented above are all in their nature "single-molecule" methods, in the sense that they measure properties of individual objects. A result of a single experiment, therefore, represents properties of a particular object and differs from case to case because of, for example, defects coming from production and purification, or for more prosaic reasons such as experimental errors. In order to perform comparisons, therefore, it is more practical to deal with values averaged for multiple tubes. The average values for the Young's modulus of high quality tubes are, within the experimental error, all on the order of 1 TPa, close to that of diamond (1.2 TPa), while the tensile strength can be 30 times higher than that of steel (1.9 GPa). Catalytically grown MWNTs with the Young's modulus that can be as low as 12±6 GPa are definitely disappointing and show that the production method plays an important role in the quality of carbon nanotubes from the point of view of their mechanical properties.

Future improvements in large scale production and processing are therefore necessary before applying them as the ultimate reinforcement fiber. Even so, the progress in measuring the mechanical properties of CNTs will continue to be closely related to, and often motivate, the progress in nanoscale manipulation in general.

21.2.3 Microtubules and Their Elastic Properties

Microtubules are a vital biological nanostructure, similar in dimension and shape to carbon nanotubes. In fact, the first name given to carbon nanotubes by their discoverer Iijima was "microtubules of graphitic carbon." From the structural point of view, they are much more complicated, as is common for biological structures. They self-assemble in buffers maintained at the physiological temperature of 37 °C out of protein subunits, α and β-tubulin, each having a molecular weight of 40 kDa. These protein subunits are bound laterally into protofilaments, which in turn are arranged in a shape of a hollow cylinder with an external diameter of 25 nm and an internal diameter of 15 nm. Microtubules are a remarkable material: inside living cells, their length incessantly fluctuates; they can even completely disassemble and consume energy in the form of GTP.

Together with actin and intermediate filaments, microtubules constitute the cellular cytoskeleton. In addition, they perform various unique vital functions: they act as tracks along which molecular motors move, they help pull apart chromosomes during cell division and form bundles that propel sperm and some bacteria. All these roles are determined by their structure and mechanical properties. Yet, after more than a decade, there is still a large discrepancy in the values of their Young's modulus reported in the literature. Several methods have been applied, such as bending or buckling microtubules using optical tweezers [21.42], hydrodynamic flow [21.43], thermally induced vibrations or shape fluctuations [21.44], buckling in vesicles [21.45], or squashing with an AFM tip [21.46]. These methods yielded results ranging from 1 MPa [21.46] to several GPa [21.42].

Since microtubules are geometrically similar to nanotubes, *Kis* et al. [21.41] used the suspended tube configuration. Microtubules were deposited on porous membranes, and AFM images were acquired under different nominal normal loads. All the measurements were performed in liquid and at controlled temperatures, in order to prevent the degradation of proteins, so the substrate had to be functionalized in order to ensure good adhesion between the tubes and the support. They used

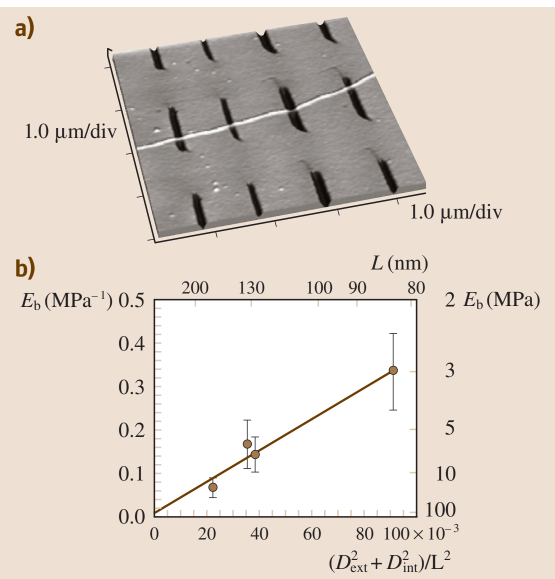

Fig. 21.12 (a) A pseudo 3-D rendering of a single microtubule suspended over four different-sized holes in PMMA. **(b)** From the variation of the $E_{bending}$ with varying length, the shear and the Young's modulus have been determined for the microtubule displayed in **(a)** (abtracted with permission from [21.41] © 2002 American Physical Society)

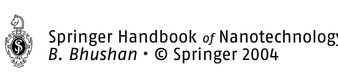

silicon with a layer of PMMA as a support. Slits were prepared in PMMA using electron-beam lithography, providing the possibility to measure the elastic response of individual microtubules lying over four different-sized holes ranging from 80–200 nm across and 400 nm deep, Fig. 21.12.

Clearly the results are dependent on the hole diameter, which could only result from a shear component within the microtubules. Simplifying (21.5), the deformation of microtubules can be modeled as:

$$\frac{1}{E_{\text{bending}}} = \frac{1}{E} + \frac{10}{3}\frac{D_{\text{ext}}^2 + D_{\text{int}}^2}{L^2}\frac{1}{G}\,, \tag{21.7}$$

where and D_{int} represent the external and internal MT's diameter. From the plot of $1/E_{\text{bending}}$ vs. the $\left(D_{\text{ext}}^2 + D_{\text{int}}^2\right)/L^2$ the shear modulus can be calculated from the slope of the fit, and the inverse Young's modulus will be equal to the intercept on the y-axis. In this way the shear modulus of $G = 1.4 \pm 0.3\,\text{GPa}$ and a lower limit of $E = 150\,\text{MPa}$ were simultaneously obtained from a measurement on an individual microtubule.

This anisotropy comes from the fact that microtubules are built of monomers that are strongly bound in the longitudinal direction, along single protofilaments. The link between neighboring protofilaments is much weaker. Microtubules, therefore, have to be considered as anisotropic beams, having an E_{bending} that depends on the scale on which they are deformed [21.41]. This is in all respects analogous to the situation in SWNT ropes that are built of stiff individual SWNTs, held together in bundles by a weak van der Waals interaction. This conclusion may explain the large discrepancy in the value of Young's moduli reported in the literature over the past ten years using inadequate modeling.

As in the case of carbon nanotubes, measuring the mechanical properties of microtubules can provide valuable insight into their structure and provide deeper understanding about the functioning of these remarkable structures.

21.3 Scanning Nanoindentation: An Application to Bone Tissue

In the following section we discuss nanoindentation as a tool to determine nanomechanical properties. This method was developed in the early 1980s evolving from traditional Vicker hardness testing devices. The latter is based on the concept that a pyramidal tip is loaded into a material applying a known force. After the test, the size of the remaining imprint is measured under an optical microscope. The ratio of the employed force and the imprint area after load removal was defined as hardness that represents a mean pressure the material can resist. Unfortunately this mechanical parameter is a complex combination of elastic and postyield properties and can't be easily explained on the level of continuum mechanics. This point raised important concerns for determining elastic constants such as the Young modulus from an indentation test. Further improvements on the transducer sensitivity were necessary to provide continuous acquisition of the employed load and the resulting indentation depth. Nanoindentation represents the state of the art of this development allowing mechanical tests on the nanometer scale.

21.3.1 Scanning Nanoindentation

Based on this continuous force–displacement data, an elastic modulus of volumes in the submicron regime can be quantified. To investigate features down to the micrometer regime, classical nanoindentation tools are combined with an optical microscope for positioning the indenter tip on the region of interest. But to defeat the limits of optical resolution, indentation and scanning probe microscopy were combined using the same tip to allow nanoscale control of the indenting tip position [21.47]. This instrument allows for scanning the material topography in an AFM mode and performing nanoindentation tests employing the same tip. The mechanical tests are restricted to the scanned area ($100\,\mu\text{m} \times 100\,\mu\text{m}$ maximum) where the indenter can be positioned with a precision of better than 100 nm. The surface roughness can be measured, which is helpful for choosing the area to be indented. Furthermore the available in situ scan of the indented region can provide information about the piling-up or sink-in behavior of the material. *Kulkarni* and *Bhushan* [21.48, 49] introduced this device and demonstrated that measurements on aluminum and silicon were similar to results of non-scanning indentation systems.

21.3.2 Application of Scanning Nanoindentation

The development of the scanning nanoindentation (SN) technique has led to a variety of studies, primarily characterizing thin layers. Applications range

from the mechanical characterization of corrosion-free film apposition on single-crystalline iron [21.50] to indentation and microscratch tests on Fe-N/Ti-N multilayers [21.51]. One author included nanoindentation to discuss two different electrochemical deposition techniques of thin Ni-P layers on pure Ni [21.52]. *Rar* et al. [21.53] reported studies on the growth of thin gold layer on native oxides of silicium while other investigations focussed on wear-resistant $TiB_2(N)$ coatings [21.54].

Studies of heterogeneous materials clearly demonstrate the advantage of the available surface scanning. *Malkow* and *Bull* [21.55] investigated the elastic/plastic behaviour of carbon-nitride films deposited on silicon. Therefore they determined the load-on and load-off hardness, the latter being accessible by scanning the remaining indent impression. *Shima* et al. [21.56] studied silicon oxynitride films on pure silicon and demonstrated hardness as a function of the employed deposition temperature. *Göken* et al. [21.57] used the high positioning precision to characterize individual lamellae of a TiAl alloy that consists of a two-phase structure and also to study the mechanical properties of nanometer-size precipitates of nickel-based super-alloys [21.58]. Performing in situ electrochemical treatments of iron single crystals, *Seo* et al. [21.59] used SN to study the variation of the remaining imprint shape with time.

In the field of biomechanics, work was done on bone tissue in wild-type and gene-mutated zebrafish. The characterization of the residual indentations in AFM mode supported the statement that gene mutation can change bone brittleness [21.60]. Other investigations focussed on the demineralising effects of soft drinks on tooth enamel by studying changes of elastic properties and surface topography [21.61]. *Habelitz* et al. [21.62] and *Marshall* et al. [21.63] characterized the junction between human tooth enamel and the mechanically different dentin.

Hengsberger et al. [21.64] took advantage of the nanometer positioning capability of the SN to investigate the elastic and plastic properties of individual human bone lamellae. Related work is presented in greater detail below to demonstrate the use and benefits of the SN technique at this example.

21.3.3 Example: Study of Mechanical Properties of Bone Lamellae Using SN

Before we discuss nanomechanical properties of bone lamellae, it is useful to know the structure on the macroscopic level. Figure 21.13 presents the hierarchy of human bone tissue at the example of the femoral neck. The outer shell is constituted of cortical bone while the porous trabecular bone structure gives inner support. On the next lower level, both bone types show structural units (BSU, after [21.65]) constituted of some tens of lamellae. For compact bone the lamellae have a concentric organization while for trabecular bone these lamellae are parallel. The nomenclature "BSU" was motivated by its underlying cellular process. The formation of such an individual structural unit occurs within a single cellular process. The optical contrast shows two alternating types of lamellae, thin lamellae that appear dark, and thick lamellae that appear bright. These bone lamellae show widths ranging from 1 to 3 μm for thin and 2 to 4 μm for thick lamellae [21.64]. On the next lower level the bone matrix is constituted of a complex collagen and mineral structure. It is still not entirely understood what type of variations in the collagen/mineral meshwork are responsible for the lamellar structure.

The mechanical properties on these different levels of bone hierarchy are increasingly well understood. But,

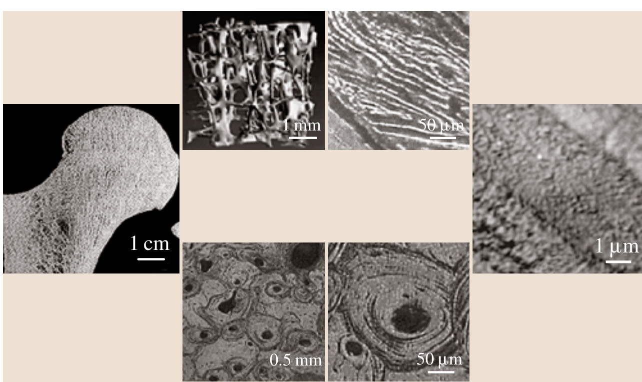

Fig. 21.13 Hierarchy of the human femoral neck (from left to the right) the far left figure shows a cut through a frontal plane of the femoral neck. The outer shell is constituted of compact bone while the inside is made of the spongier trabecular bone. The left pair of images shows the trabecular structure (*top*) and a transverse cut of the compact shell that shows vascular canals (*bottom*).
The right pair of images shows packets of trabecular bone lamellae (*top*) and a single osteon (*bottom*), a vascular canal surrounded by concentric lamellae. Packets of trabecular bone lamellae and osteons represent a structural unit (BSU). Note the alternation of bright (*thick*) and dark (*thin*) lamellae.
The figure far right shows three bone lamellae, structures that are similar for trabecular and compact bone. The bone matrix within the lamellae are mainly constituted of collagen fibers and hydroxyapatite crystals

little is known about how the macroscopic mechanical properties of the whole bone relate to its nanomechanical properties. The possibility that factors such as fracture risk might be better understood with an analysis of small bone volumes motivates the application of nanoindentation in this field.

A set of nanoindentation studies is available (mainly employing the device combined with an optical microscope) that presents the intrinsic mechanical properties of bone tissue. Among recent work, differences were reported between donors, anatomical sites, BSU, and thin and thick lamellae [21.64, 66–69]. Due to technical constraints of this sensitive nanomechanical device, the majority of these studies present dehydrated or dried tissue properties measured at ambient temperature [21.70–73]. But, removal of the water content may lead to anisotropic shrinking of the matrix that creates microcracks and alters the mechanical properties of the bone constituents. For an accurate characterization of the in vivo properties, the nanomechanical tests should therefore be done under physiological conditions.

There have been a few attempts to characterize the in vivo bone properties [21.66, 68, 74]. This was achieved by studying fresh bone samples that are kept moist with a thin layer of liquid (less than a hundred microns) on the surface or with subsurface water irrigation. But, local evaporation of the thin liquid layer may have led to indents on areas that were partially dried during the test. One possible solution to such local drying might be to conduct measurements in which the indentation tip and tissue sample are both fully immersed in a liquid cell and simultaneously heated to body temperature.

Practical limitations on temperature stability and inaccuracy in contact force detection due to liquid on the surface make such measurements extraordinarily difficult, however. For statistically powerful studies it seems unavoidable to dry the samples.

The objective of this study was to use SN to determine the effect of drying on the stiffness of single bone lamellae. The goal was to determine a conversion factor that allows dry tissue properties to be recalculated into their in vivo properties.

For this purpose, we measured the identical set of lamellae selected from human trabecular and compact bone at first under physiological and then under dry conditions.

Experimental Setup and Technical Features:

Figure 21.14 demonstrates an optical picture and a sketch of the combined AFM and nanoindenter device (Hysitron Inc. Minneapolis, MN). The transducer consists of a three-plate capacitor on whose central plate a Berkovich (three-sided pyramid) diamond tip is mounted. The transducer provides a contact force feedback between the tip and the sample surface. The sample is mounted on a piezoelectric scanner that allows moving in the x, y and z-directions. During x, y-surface scanning, the piezoelectric scanner keeps this feedback signal constant by correcting the z-height. The movement of the piezoelectric scanner, therefore, describes the negative surface of constant contact force, commonly called an AFM-scan. For the liquid cell tests, the sample was glued in a plexiglass cup for the addition of a several millimeter high liquid layer. A commercially available liquid cell tip (Hysitron Inc. Minneapolis, MN) was used, which contains an additional shaft of approximately 300 µm diameter and 5 mm length to protect the transducer from the fluid. A small layer of latex was placed between the sample holder and the magnetic stick of the piezoelectric scanner to protect the latter from liquid. The additional shaft of the indenter tip and the latex layer

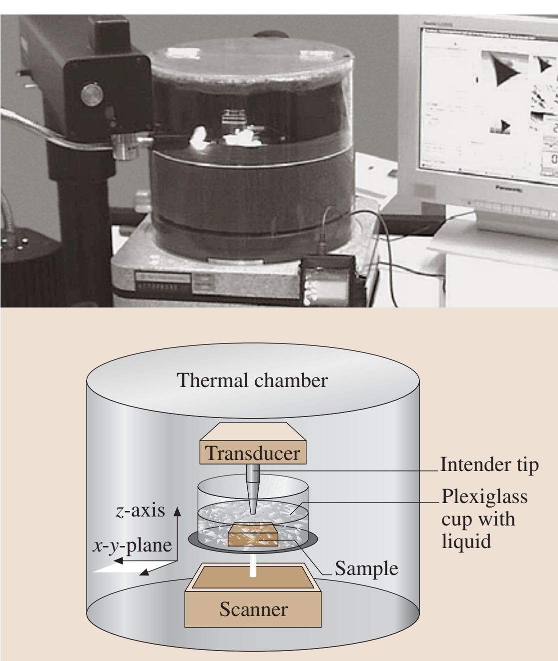

Fig. 21.14 Optical picture (*top*) and sketch (*bottom*) of the scanning nanoindentation device for measurements under physiological conditions. For this purpose the sample was installed in a plexiglass cup for addition of liquid. The entire instrument was heated in a custom-made thermal chamber

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

represent elastic components that increased the machine compliance ($C_m = 7\,nm/mN$ instead of $3\,nm/mN$). This variable corrects the deformation of all the machine components while indentation data are recorded and can be determined from the tip shape calibration curve (Hysitron, Minneapolis). The nanoindentation device was installed in a custom-made thermal chamber to allow sample heating to 37 °C. Note that the increased temperature and humidity also changed the value of the electrostatic force constant (EFC). The latter corrects the force due to the springs that support the central plate on which the indenter tip is mounted. The EFC can be calibrated doing out-of-contact indents and varying this value until a zero-line in the force–displacement curve is measured.

Based on an image acquired in AFM mode, the indentation area can be selected with a high spatial resolution ($< 0.1\,\mu m$). Figure 21.15 shows the force–displacement data of a typical nanoindentation curve. In the first step, the tip is pressed into the material, resulting in indistinguishable elastic and plastic deformation. Then the tip is held at maximum force resulting in creep of the material under the tip. In a third step, unloading is done that leads to elastic recovery of the material. Typically each indent requires between 15 seconds to several minutes, representing a compromise between a desired quasistatic strain rate and the thermal drift of the instrument (possibly below 0.1 nm/second). This device is load-controlled, and linearly increasing and decreasing loading protocols were therefore applied. The loading rate corresponds to

$$\frac{\mathrm{d}P}{\mathrm{d}t} = \frac{P_{\max}}{T} \tag{21.8}$$

with $P_{\max}$ as the maximum load and T as the (un)loading time.

The elastic constants of the sample were determined using the unloading part (step 3) of the nanoindentation curve. Based on the analytical work by *Sneddon* [21.75], *Oliver* and *Pharr* [21.76] derived the following equation for an indenter of revolution pressed into an isotropic elastic material:

$$S\,(h_{\max}) = \frac{\mathrm{d}P}{\mathrm{d}h}\,(h_{\max}) = \frac{2}{\sqrt{\pi}} E_{\mathrm{r}} \sqrt{A_{\mathrm{c}}\,(h_{\max})}\,. \tag{21.9}$$

Pharr et al. [21.77] showed that this equation is a good approximation for a Berkovich indenter tip. P represents the applied load, $S\,(h_{\max})$ is the derivative of the unloading curve at the point of initial unloading $h_{\max}$. This variable is determined by fitting typically 40% to 95% of the unloading curve to avoid the influence of viscoelastic effects at initial unloading when a singularity in the strain rate occurs. $A_c(h)$ is the contact area over which the material and the indenter are in instantaneous contact. The latter function has to be calibrated by performing indents with increasing depth in a standard material, typically fused silica. The latter has a known reduced modulus of $E_r = 69.9$ GPa that allows calibration of the contact area $A_c\,(h)$ using the measured contact stiffness $S\,(h)$ and (21.9). The reduced modulus E_r combines the deformation of the material and the diamond tip as follows [21.78]:

$$\frac{1}{E_{\mathrm{r}}} = \frac{1-\nu_{\mathrm{specimen}}^2}{E_{\mathrm{specimen}}} + \frac{1-\nu_{\mathrm{tip}}^2}{E_{\mathrm{tip}}}\,. \tag{21.10}$$

We use the indentation modulus

$$E_{\mathrm{ind}} = \left(\frac{1}{E_{\mathrm{r}}} - \frac{1-\nu_{\mathrm{tip}}^2}{E_{\mathrm{tip}}}\right)^{-1} \tag{21.11}$$

that can be calculated with the reduced modulus and the elastic properties of the diamond indenter tip $\nu_{\mathrm{tip}} = 0.07$ and $E_{\mathrm{tip}} = 1{,}140$ GPa. This variable combines with

$$E_{\mathrm{ind}} = \frac{E_{\mathrm{specimen}}}{1-\nu_{\mathrm{specimen}}^2} \tag{21.12}$$

the local Young's modulus E_{specimen} and Poisson ratio ν_{specimen} of the specimen.

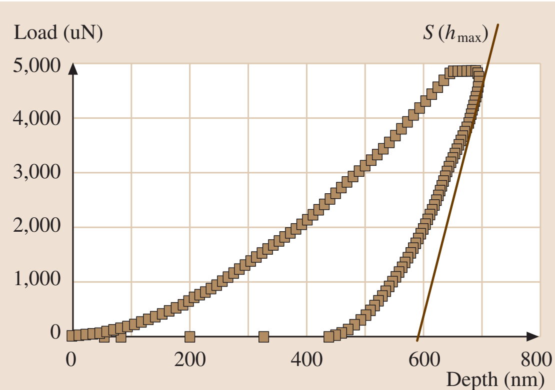

Fig. 21.15 Force–displacement curve obtained during a nanoindentation test that consists of three parts (see text). Hardness is determined at maximum load. The elastic indentation modulus is calculated with the slope at the point of initial unloading $S(h_{\max})$

It is important to note that this theory assumes an isotropic material. For an anisotropic material the indentation modulus represents some average of the elastic properties in all directions. The latter strongly depends on the geometry of the indenter. For indents with a blunt indenter (such as Berkovich with an opening angle of 143°) nonnegligible deformations will occur in the plane perpendicular to the loading direction. In this context it is useful to present an approximation of the volume ganged by the indentation test.

The stress field generated by the indentation process is heterogeneous and leads to plastic deformation and damage in the vicinity of the tip. Using Hertz's theory [21.78], the spatial dependence of the stress components during indentation can be estimated by considering the elastic contact of a spherical indenter with a semi-infinite half space. In the direction of loading (z-axis), the stress component below the indenter decreases according to

$$\frac{\sigma_{zz}}{p_0} = -\left(1 + \frac{z^2}{a^2}\right) , \tag{21.13}$$

where p_0 indicates the maximum pressure below the indenter and a the contact radius.

In a horizontal plane at the surface ($z = 0$), the radial and circumferential components of the stress field next to the contact area obey

$$\frac{\sigma_{rr}}{p_0} = -\frac{\sigma_{\theta\theta}}{p_0} = \frac{(1-2\nu)\,a^2}{3r^2} , \tag{21.14}$$

where θ and r are the cylindrical coordinates of the periphery of the indenter and ν is the Poisson ratio. For $\nu = 0.3$ the stress field components reach their 10%-boundary defined by $\sigma_{zz} = -0.1 p_0$ and $\sigma_{rr} = -\sigma_{\theta\theta} = 0.1 p_0$ at a depth of $z \cong 3a$ or in lateral direction at $r \cong 2/\sqrt{3}a$. For a Berkovich tip, the ratio between maximum indentation depth and contact radius is approximately $a \cong 3h_{\max}$. The mechanical properties measured by nanoindentation, therefore, correspond to a semi-ellipsoidal volume extending to about nine times the employed indentation depth ($z \cong 3a \cong 9h_{\max}$) in the vertical direction (z) and about seven times this same depth ($2r \cong 4/\sqrt{3}a \cong 7h_{\max}$) in the radial direction (r).

The load-on hardness is determined with

$$H = \frac{P\,(h_{\max})}{A_{\mathrm{c}}\,(h_{\max})} \tag{21.15}$$

as the ratio of the maximum load and the ("on load") contact area at maximum load. This is different from Vicker hardness in which the contact area is characterized by the remaining imprint after load removal. Differences between nanoindentation and Vicker, therefore, occur for materials with nonnegligible elastic recovery. After unloading, such materials may expose an imprint smaller than the area of contact at maximum load. Since the SN tool can be used to image the remaining imprint after unloading, hardness values using both definitions may thus be compared.

For fused silica the literature provides a hardness range between 8.3 to 9.5 GPa while an intercomparison of SN-users showed an average of 8.96 GPa (Surface, Hückelhoven). Conveniently, the hardness value also represents a possibility to check the area function of the tip based on the reduced modulus of the calibration material.

Tests of Bone Tissue Under Pseudo-physiological Conditions

Samples containing trabecular and compact bone lamellae were dissected from the medial part of the femoral neck of an 86-year-old female. After embedding in PMMA, the samples were polished with successive grades of carbide paper and finished with 0.05 μm alumina solution. Polishing represents an important preparation step since the here-employed theory assumes an infinitely flat surface. The mean surface roughness of the indented area should, therefore, be far below the employed indentation depth. Unfortunately no objective criteria that determines the maximum allowable surface roughness as a function of the indentation depth has been formulated so far.

Thin and thick lamellae of trabecular and compact bone were first characterized under physiological conditions, i. e. fully wet and at 37 °C. Then the specimens were dried for 24 h at 50 °C and identical tests were carried out again but under dry conditions.

In both cases 16 indentation tests were performed to maximum depths of 100 nm and 500 nm. Each test consisted of 10 s loading, 10 s holding, and 10 s unloading. The maximum allowable thermal drift was set 0.1 nm/s. To avoid proximity effects of neighbouring indents, an adjacent testing area in the identical lamellae was chosen after changing the testing conditions.

The tests under fully wet conditions at body temperature were found to be very sensitive with respect to thermal stability. The nanoindentation device was heated for several days to reach stable thermal conditions of the instrument components before the sample could be installed. The electrostatic force constant (EFC) was checked daily before beginning data acquisition. The approach of the indenter tip in the liquid environment was performed employing a contact force of 7 μN. This

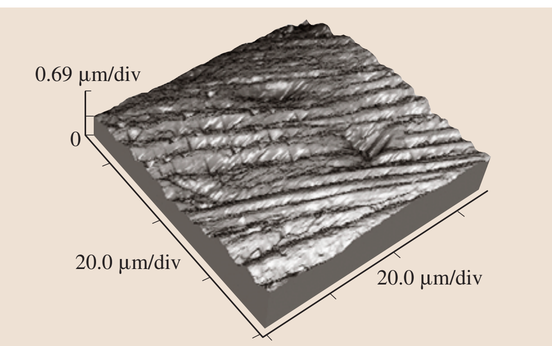

Fig. 21.16 Surface topography of a trabecular bone structural unit that shows the lamellar structure. Thick (*bright*) lamellae correspond to the tops in the topography. Note, the two holes are not remaining indents but are ellipsoidal lacunae that embed bone cells

value is offset by approximately 1 μN per mm of water penetration, however, due to Archimedes force acting on the fluid cell tip. Such additional effects as water surface tension may also have a repulsive force on the tip.

AFM-scans as in Fig. 21.16, which shows the topography of trabecular bone lamellae under dry conditions, allowed the two lamella types to be identified. Thick lamellae correspond to the tops (bright contrast) and thin lamellae to the valleys (dark contrast) where the surface relief results from preferential polishing.

Indentation Modulus

Trabecular bone showed under wet conditions a mean indentation modulus of 12.5 ± 4.0 GPa when the data of both lamella types and indentation depths were combined. Under dry conditions the results showed a mean of 19.6 ± 2.6 GPa, an increase of 57%. Lamellae of compact bone increased their mean stiffness by 76.5% from 14.9 ± 4.5 GPa to 26.4 ± 3.8 GPa.

These determined conversion factors between dried and fully wet tissue properties should be compared with other studies. *Rho* [21.74] has reported an increase of indentation modulus of bovine compact bone by 15.8%. Our study demonstrates a change of +76.5% for human compact bone. This high discrepancy may be attributed to different preparation and testing protocols. Rho tested the bone samples at ambient temperature while kept moist by a thin film of deionized water. In our study the tissue properties were determined under fully wet conditions and at body temperature. Furthermore, Rho dried for 14 days at ambient temperature while in our study the drying process occurred during 24 h at 50 °C. These points may explain the different relative change of mechanical properties we detected.

Figure 21.17 presents the indentation moduli (combining both depths) normalized with respect to their initial wet values under physiological conditions. It is interesting that the increase of this elastic parameter after drying was significantly ($p < 0.00001$) higher for thin than for thick lamellae. The relative change of stiffness due to drying was +44% for thick lamellae and +109% for thin lamellae of compact bone. For trabecular bone the corresponding values were +37% and +78% for thick and thin lamellae, respectively.

Table 21.2 shows the results for both indentation depths. The differences are likely related to the volume sampled during the indentation, a semi-ellipsoid following the approximations of (21.13) and (21.14) with 0.7 μm diameter and 0.9 μm height for 100 nm indents (and 3.5 μm × 4.5 μm for 500 nm indents). Given the typical lamellae dimensions of 1–4 μm, the shallow indentation measurements, therefore, represent properties of single lamellae whereas the deeper indents include neighboring lamellae. It is also worth noting that thin lamellae showed a greater effect of drying when only the shallow indents were considered.

This important result should be discussed in the frame of published models that address the phenomenon of bone lamellation. *Marotti* [21.79] proposed that bone lamellae are the result of alternating changes of the collagen fiber density. According to his SEM-results the density of collagen is higher in thin lamellae than in thick lamellae. Collagen fibers are long chains of proteins and contain adsorption sites for polar water

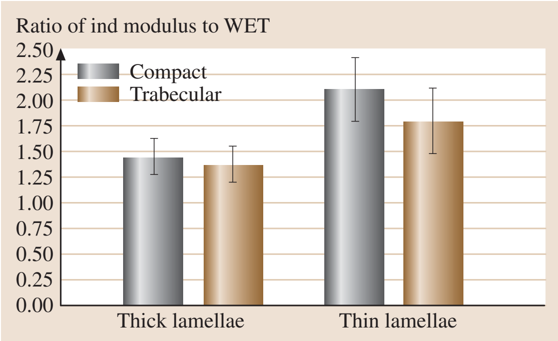

Fig. 21.17 Relative increase of indentation modulus for compact and trabecular bone lamellae after drying. The results are normalized with respect to their initial value under wet conditions. Note that thin lamellae are more affected by drying for both types of bone

Table 21.2 Absolute and relative changes of the indentation modulus with respect to the initial values under wet conditions. Note the greater increase for the thin lamellae after drying. Indents to 100 nm depth represent properties of single lamellae while 500 nm indents are also influenced by neighboring lamellae

Indentation modulus	Lamella	Ind. depth (nm)	Wet (GPa)	Dry (GPa)	Rel. change (%)
Trabecular bone	Thin	100	11.6 ± 4.1	20.5 ± 4.3	+76
		500	9.8 ± 1.9	18.1 ± 3.2	+84
	Thick	100	12.4±5	19.1 ± 1.11	+54
		500	15.6 ± 1.3	19.0 ± 1.1	+22
Compact bone	Thin	100	10.4 ± 0.2	23.4 ± 3.6	+124
		500	13.9 ± 2.0	27.1 ± 3.1	+95
	Thick	100	19.9 ± 4.8	27.9 ± 4.6	+40
		500	15.5 ± 2.6	23.0 ± 0.8	+49

molecules. A higher density of the collagen fibers in the thinner lamellae results in a higher water binding capacity that may explain the higher relative influence of drying.

Giraud-Guille [21.80], on the other hand, proposed a nested-arc structure for bone lamellae with smooth orientation changes between adjacent collagen fibers. According to this model indents on thick lamellae load into the longitudinal direction of the fibers, whereas the load is perpendicular to the long axis for thin lamellae. Removal of the liquid phase leads to packaging of the collagen fibers, an effect that is intuitively anisotropic and that may explain why the effect of drying was different for both lamella types. In addition, drying leads to microfracture initiation within thick lamellae [21.64], possibly explaining the diminished effect of drying on these structure.

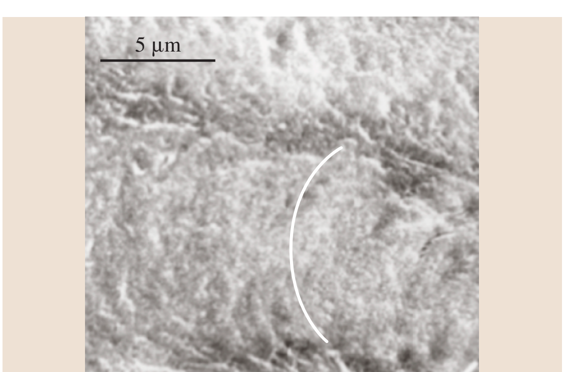

Fig. 21.18 SEM-scan of bone lamellae adjacent to the spot characterized by nanoindentation. This SEM-scan gives support for the bone lamellation model that is based on a smooth orientation change of collagen fibers [21.80]

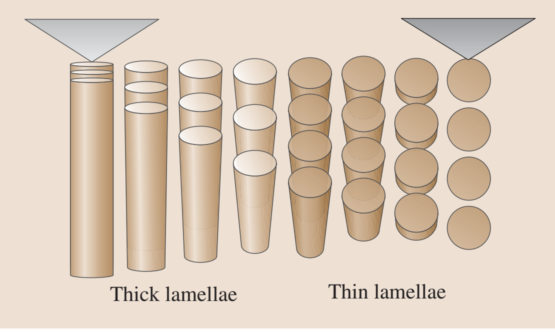

Fig. 21.19 Bone lamellation model proposed by this study. This model represents a combination of a smooth orientation change and density variations of the collagen fibers. Note also the spots where the indentations were done. For thin lamellae a greater change of mechanical properties was detected after drying

Figure 21.18 presents a SEM-image from a bone sample used in this study. This scan confirms the nested-arc structure Giraud-Guille observed with TEM.

Our results are, therefore, in agreement with both the Marotti and the Giraud-Guille models. This implies a model that combines smooth orientation changes of the collagen fibers with density changes. Such an architecture is sketched in Fig. 21.19. Note also the spots where the indentations were done.

Hardness

Compact bone revealed a mean hardness of 0.46 GPa under wet conditions that increased by 74% to 0.80 GPa after drying. Due to drying trabecular bone lamellae showed a mean hardness change of 76% from 0.41 up to 0.72 GPa.

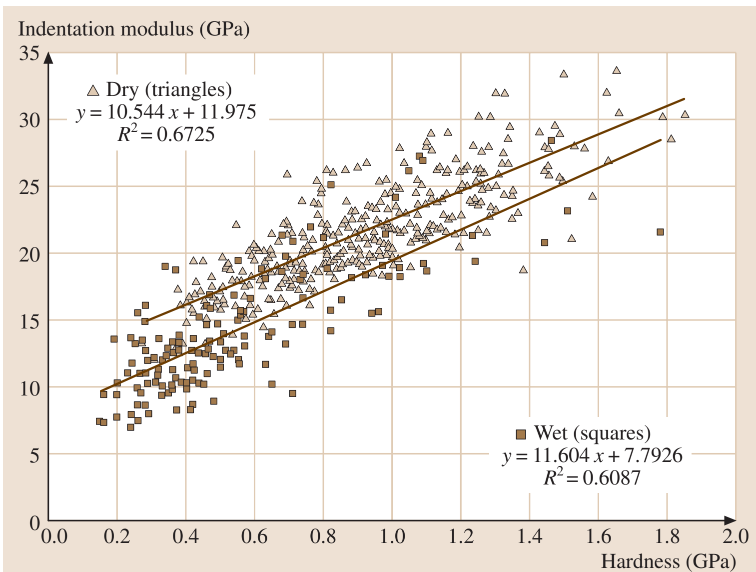

Fig. 21.20 Indentation modulus and hardness under dry and wet conditions using raw data from *Hengsberger* et al. [21.64]. Drying does not change the correlation coefficient and changes slightly but significantly the slope of the regression curve

For compact bone the effect of drying was again significantly ($p = 0.0006$) greater for thin lamellae (+108%) than for thick lamellae (+44%). Similar results were found for trabecular bone lamellae with a +99% increase for thin and a +56% increase for thick lamellae.

The results for hardness, therefore, appear to similar trends as the indentation modulus. This motivates us to discuss a further point, the correlation between indentation modulus and hardness. These mechanical parameters show an empirically proven relationship [21.81] that may change as a result of drying. For this purpose we related the data of the indentation modulus of Hengsberger et al. [21.64] with the corresponding unpublished hardness results. The correlation between hardness and indentation modulus is similar under wet ($R^2 = 0.61$) and under dry ($R^2 = 0.67$) conditions (Fig. 21.20). The slopes of the linear regression, however, show close but significantly different values ($p < 0.0001$) for the wet and dry samples. Hardness and indentation modulus show a similar but significantly different relative shift as a result of drying.

21.3.4 Conclusion

Modern scanning nanoindentation has clearly solved two problems: indentations in the nanometer scale can be performed with high force and displacement resolution, and nanometer lateral control of the indentation position allows the characterization of small structures of heterogeneous materials. Interfaces in composites, local density or composition variations of chemical products, or biological structures can then be investigated using the SN tool.

Based on recent theoretical progress [21.82], the nanoindentation technique can also be used to characterize anisotropic materials by indenting in different directions. Other parameters can also be determined. For instance, creep behavior is accessible when the indentation load is held constant at a maximum load. Hysteresis of the force–displacement curve represents the energy dissipated during an indentation providing information about post-elastic behavior of a sample. Such dynamical variables as viscoelastic properties are also accessible by including sinusoidal oscillations of different frequencies to the loading history.

Future interests of the nanotechnology community may direct the work towards tests on lower levels of structural organization like the molecular or atomic level. This would require strong improvements of the transducer sensitivity and of the indenter tip machining. New concepts to reduce the thermal drifting properties would also be necessary for the next generation of this device.

21.4 Conclusions and Perspectives

We have demonstrated that AFM is an ideal tool for investigating variations in local properties of bulk materials, like bone, and also for performing physical measurements on individual nanometer scale objects such as, for example, carbon nanotubes and protein polymers. In the latter case, the technique provides previously inaccessible quantities in living matter such as, for instance, the shear modulus. It should be emphasized that shear is omnipresent since biostructures are "composite" materials, with strong anisotropic interactions between their constituents. In the case of proteins, we have explored the mechanical properties as a function of temperature, as well. Interactions can vary remarkably even over a range of a few tens of degrees, providing deeper insight in the functioning of these structures. One task, which seems very difficult for the time being, is the frequency dependent response of nano and biostructures. In the latter case it is limited to a few kilohertz, mainly because of the surrounding liquid, but for a meaningful analysis one requires several decades in frequency.

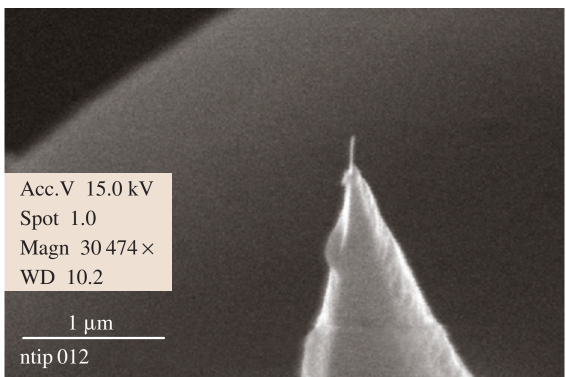

Fig. 21.21 SEM picture of an AFM tip with attached multi-wall Carbon nanotube

Regarding the scanning probe tips themselves, improvements are necessary to provide better resolution, longer lifetimes, and easy functionalization for sensing different chemical environments. This might be achieved by carbon nanotube tips (Fig. 21.21), which have a Young's modulus of 1 TPa, a very well-defined and sharp tip structure, and pentagon "defects" at the apex providing a site for functionalization. It is generally agreed upon by the scanning probe community that carbon nanotubes will open new avenues for the study of living matter.

Finally the development of the photonic force microscope in Heidelberg has allowed imaging of bio-structures with unprecedented three-dimensional resolution, even including features that are otherwise inaccessible to AFM tips. In the future, this instrument will certainly provide radical new insight in biological functioning.

22. Nanomechanical Properties of Solid Surfaces and Thin Films

Instrumentation for the testing of mechanical properties on the submicron scale has developed enormously in recent years. This has enabled the mechanical behavior of surfaces, thin films, and coatings to be studied with unprecedented accuracy. In this chapter, the various techniques available for studying nanomechanical properties are reviewed with particular emphasis on nanoindentation. The standard methods for analyzing the raw data obtained using these techniques are described, along with the main sources of error. These include residual stresses, environmental effects, elastic anisotropy, and substrate effects. The methods that have been developed for extracting thin-film mechanical properties from the often convoluted mix of film and substrate properties measured by nanoindentation are discussed. Interpreting the data is frequently difficult, as residual stresses can modify the contact geometry and, hence, invalidate the standard analysis routines. Work hardening in the deformed region can also result in variations in mechanical behavior with indentation depth. A further unavoidable complication stems from the ratio of film to substrate mechanical properties and the depth of indentation in comparison to film thickness. Even very shallow indentations may be influenced by substrate properties if the film is hard and very elastic but the substrate is compliant. Under these circumstances nonstandard methods of analysis must be used. For multilayered systems many different mechanisms affect the nanomechanical behavior, including Orowan strengthening, Hall–Petch behavior, image force effects, coherency and thermal stresses, and composition modulation.

The application of nanoindentation to the study of phase transformations in semiconductors, fracture in brittle materials, and mechanical properties in biological materials are described. Recent developments such as the testing of viscoelasticity using nanoindentation methods are likely to be particularly important in future studies of polymers and biological materials. The importance of using a range of complementary methods such as electron microscopy, in situ AFM imaging, acoustic monitoring, and electrical contact measurements is emphasized. These are especially important on the nanoscale because so many different physical and chemical processes can affect the measured mechanical properties.

When two bodies come into contact their surfaces experience the first and usually largest mechanical loads. Hence, characterizing and understanding the mechanical properties of surfaces is of paramount importance in a wide range of engineering applications. Obvious examples of where surface mechanical properties are important are in wear-resistant coatings on reciprocating surfaces and hard coatings for machine tool bits. This chapter details the current methods for measuring the mechanical properties of surfaces and highlights some of the key experimental results that have been obtained.

The experimental technique that is highlighted in this chapter is nanoindentation. This is for the simple reason that it is now recognized as the preferred method for testing thin film and surface mechanical properties. Despite this recognition, there are still many pitfalls for the unwary researcher when performing nanoindentation tests. The commercial instruments that are currently available all have attractive, user-friendly software, which makes the performance and analysis of nanoindentation tests easy. Hidden within the software, however, are a myriad of assumptions regarding the tests that are being performed and the material that is being examined. Unless the researcher is aware of these, there is a real danger that the results obtained will say more about the analysis routines than they do about the material being tested.

22.1 Instrumentation

The instruments used to examine nanomechanical properties of surfaces and thin films can be split into those based on point probes and those complimentary methods that can be used separately or in conjunction with point probes. The complimentary methods include a wide variety of techniques ranging from optical tests such as micro-Raman spectroscopy to high-energy diffraction studies using X-rays, neutrons, or electrons to mechanical tests such as bulge or blister testing.

Point-probe methods have developed from two historically different methodologies, namely, scanning probe microscopy [22.1] and microindentation [22.2]. The two converge at a length scale between 10–1,000 nm. Point-probe mechanical tests in this range are often referred to as nanoindentation.

22.1.1 AFM and Scanning Probe Microscopy

Atomic force microscopy (AFM) and other scanning probe microscopies are covered in detail elsewhere in this volume, but it is worth briefly highlighting the main features in order to demonstrate the similarities to nanoindentation. There are now a myriad of different variants on the basic scanning probe microscope. All use piezoelectric stacks to move either a probe tip or the sample with subnanometer precision in the lateral and vertical planes. The probe itself can be as simple as a tungsten wire electrochemically polished to give a single atom at the tip, or as complex as an AFM tip that is bio-active with, for instance, antigens attached. A range of scanning probes have been developed with the intention of measuring specific physical properties such as magnetism and heat capacity.

To measure mechanical properties with an AFM, the standard configuration is a hard probe tip (such as silicon nitride or diamond) mounted on a cantilever (see Fig. 22.1). The elastic deflection of the cantilever is monitored either directly or via a feedback mechanism

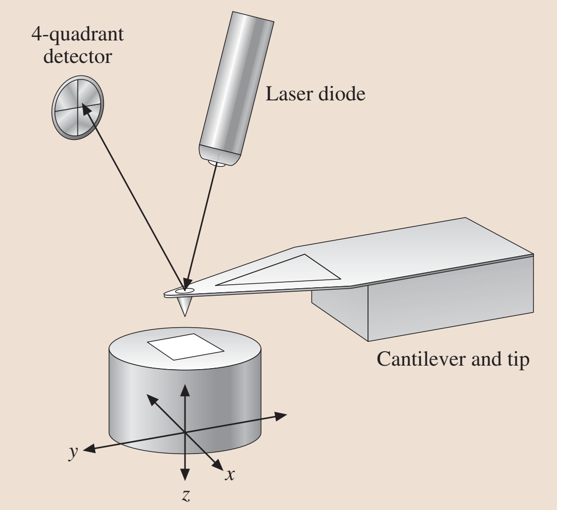

Fig. 22.1 Diagram of a commercial AFM. The AFM tip is mounted on a compliant cantilever, and a laser light is reflected off the back of the cantilever onto a position-sensitive detector (4-quadrant detector). Any movements of the cantilever beam cause a deflection of the laser light that the detector senses. The sample is moved using piezoelectric stack, and forces are calculated from the cantilever's stiffness and the measured deflection

to measure the forces acting on the probe. In general, the forces experienced by the probe tip split into attractive or repulsive forces. As the tip approaches the surface, it experiences intermolecular forces that are attractive, although they can be repulsive under certain circumstances [22.3]. Once in contact with the surface the tip usually experiences a combination of attractive intermolecular forces and repulsive elastic forces. Two schools of thought exist regarding the attractive forces when the tip is in contact with the surface. The first is often referred to as the DMT or Bradley model. It holds that attractive forces only act outside the region of contact [22.4–7]. The second theory, usually called the JKR model, assumes that all the forces experienced by the tip, whether attractive or repulsive, act in the region of contact [22.8]. Most real nanoscale contacts lie somewhere between these two theoretical extremes.

22.1.2 Nanoindentation

The fundamental difference between AFM and nanoindentation is that during a nanoindentation experiment an external load is applied to the indenter tip. This load enables the tip to be pushed into the sample, creating a nanoscale impression on the surface, otherwise referred to as a nanoindentation or nanoindent.

Conventional indentation or microindentation tests involve pushing a hard tip of known geometry into the sample surface using a fixed peak load. The area of indentation that is created is then measured, and the mechanical properties of the sample, in particular its hardness, is calculated from the peak load and the indentation area. Various types of indentation testing are used in measuring hardness, including Rockwell, Vickers, and Knoop tests. The geometries and definitions of hardness used in these tests are shown by Fig. 22.2.

When indentations are performed on the nanoscale there is a basic problem in measuring the size of the indents. Standard optical techniques cannot easily be used to image anything smaller than a micron, while electron microscopy is simply impractical due to the time involved in finding and imaging small indents. To overcome these difficulties, nanoindentation methods have been developed that continuously record the load, displacement, time, and contact stiffness throughout the indentation process. This type of continuously recording indentation testing was originally developed in the former Soviet Union [22.9–13] as an extension of microindentation tests. It was applied to nanoscale indentation testing in the early

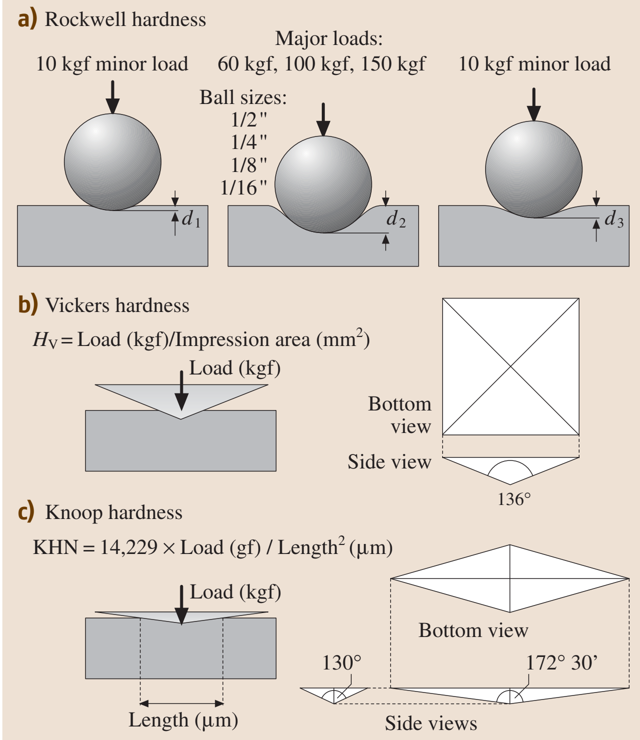

Fig. 22.2 **(a)** The standard Rockwell hardness test involves pushing a ball into the sample with a minor load, recording the depth, d_1, then applying a major load and recording the depth, d_2, then returning to the lower load and recording the depth, d_3. Using the depths, the hardness is calculated. **(b)** Vickers hardness testing uses a four-sided pyramid pushed into the sample with a known load. The area of the resulting indentation is measured optically and the hardness calculated as the load is divided by area. **(c)** Knoop indentation uses the same definition of hardness as the Vickers test, load divided by area, but the indenter geometry has one long diagonal and one short diagonal

1980s [22.14, 15], hence, giving rise to the field of nanoindentation testing.

In general, nanoindentation instruments include a loading system that may be electrostatic, electromagnetic, or mechanical, along with a displacement measuring system that may be capacitive or optical. Schematics of several commercial nanoindentation instruments are shown in Fig. 22.3a–c.

Among the many advantages of nanoindentation over conventional microindentation testing is the ability to measure the elastic, as well as the plastic properties of the test sample. The elastic modulus is obtained from the contact stiffness (S) using the following equation that

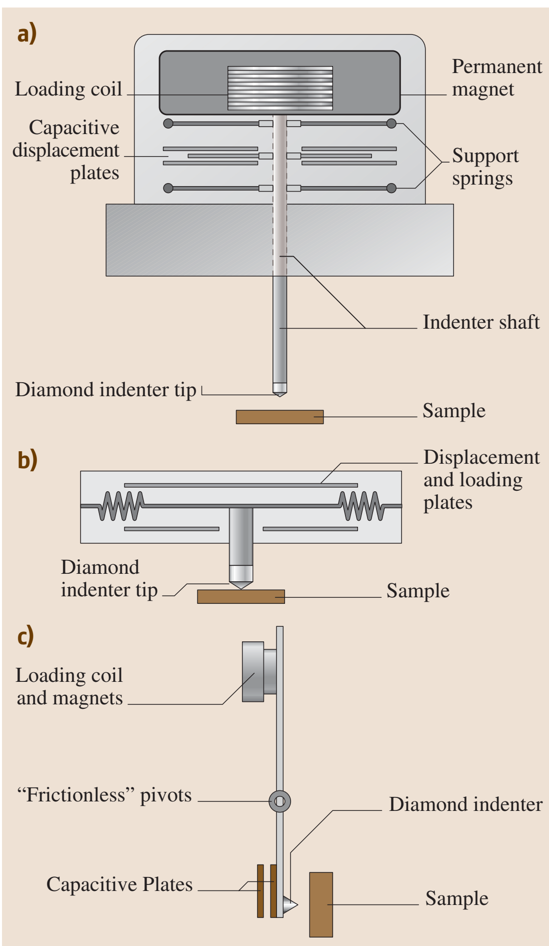

Fig. 22.3a–c Schematics of three commercial nanoindentation devices made by **(a)** MTS Nanoinstruments, Oak Ridge, Tennessee, **(b)** Hysitron Inc., Minneapolis, Minnesota, **(c)** Micro Materials Limited, Wrexham, UK. Instruments **(a)** and **(c)** use electromagnetic loading, while **(b)** uses electrostatic loads

appears to be valid for all elastic contacts [22.16, 17]:

$$S = \frac{2}{\sqrt{\pi}} E_r \sqrt{A} . \quad (22.1)$$

A is the contact area and E_r is the reduced modulus of the tip and sample as given by:

$$\frac{1}{E_r} = \frac{(1-\nu_t^2)}{E_t} + \frac{(1-\nu_s^2)}{E_s} , \quad (22.2)$$

where E_t, ν_t and E_s, ν_s are the elastic modulus and Poissons ratio of the tip and sample, respectively.

22.1.3 Adaptations of Nanoindentation

Several adaptations to the basic nanoindentation setup have been used to obtain additional information about the processes that occur during nanoindentation testing, for example, in situ measurements of acoustic emissions and contact resistance. Environmental control has also been used to examine the effects of temperature and surface chemistry on the mechanical behavior of nanocontacts. In general, it is fair to say that the more information that can be obtained and the greater the control over the experimental parameters the easier it will be to understand the nanoindentation results. Load-displacement curves provide a lot of information, but they are only part of the story.

During nanoindentation testing discontinuities are frequently seen in the load–displacement curve. These are often called "pop-ins" or "pop-outs", depending on their direction. These sudden changes in the indenter displacement, at a constant load (see Fig. 22.4), can be caused by a wide range of events, including fracture, delamination, dislocation multiplication, or nucleation and phase transformations. To help distinguish between the various sources of discontinuities, acoustic transducers have been placed either in contact with the sample or immediately behind the indenter tip. For example, the results of nanoindentation tests that monitor acoustic emissions have shown that the phase transformations seen in silicon during nanoindentation are not the sudden events that they would appear to be from the load–displacement curve. There is no acoustic emission associated with the pop-out seen in the unloading curve of silicon [22.18]. An acoustic emission would be expected if there were a very rapid phase transformation causing a sudden change in volume. Fracture and delamination of films, however, give very strong acoustic signals [22.19],

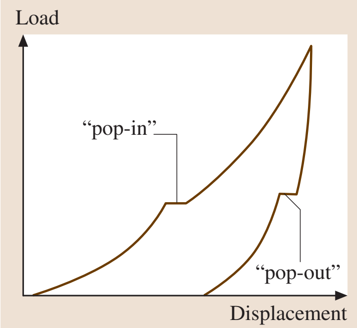

Fig. 22.4 Sketch of a load/displacement curve showing a pop-in and a pop-out

but the exact form of the signal appears to be more closely related to the sample geometry than to the event [22.20].

Additional information about the nature of the deformed region under the nanoindentation can be obtained by performing in situ measurements of contact resistance. The basic setup for this type of testing is shown in Fig. 22.5. An electrically conductive tip is needed to study contact resistance. Consequently, a conventional diamond tip is of limited use. Elastic, hard, and metallically conductive materials such as vanadium carbide can be used as substitutes for diamond [22.21, 22], or a thin conductive film (e.g., Ag) can be deposited on the diamond's surface (such a film is easily transferred to the indented surface so great care must be taken if multiple indents are performed). Measurements of contact resistance have been most useful for examining phase transformations in semiconductors [22.21, 22] and the dielectric breakdown of oxide films under mechanical loading [22.23].

One factor that is all too frequently neglected during nanoindentation testing is the effect of the experimental environment. Two obvious ways in which the environment can affect the results of nanoindentation tests are increases in temperature, which give elevated creep rates, and condensation of water vapor, which modifies the tip-sample interactions. Both of these environmental effects have been shown to significantly affect the measured mechanical properties and the modes of deformation that occur during nanoindentation [22.24–27]. Other environmental effects, for instance, those due to photoplasticity or hydrogen ion absorption, are also possible, but they are generally less troublesome than temperature fluctuations and variations in atmospheric humidity.

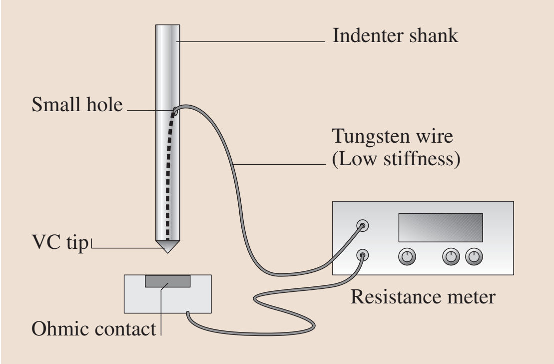

Fig. 22.5 Schematic of the basic setup for making contact resistance measurements during nanoindentation testing

22.1.4 Complimentary Techniques

Nanoindentation testing is probably the most important technique for characterizing the mechanical properties of thin films and surfaces, but there are many alternative or additional techniques that can be used. One of the most important alternative methods for measuring the mechanical properties of thin films uses bulge or blister testing [22.28]. Bulge tests are performed on thin films mounted on supporting substrates. A small area of the substrate is removed to give a window of unsupported film. A pressure is then applied to one side of the window causing it to bulge. By measuring the height of the bulge, the stress-strain curve and the residual stress are obtained. The basic configuration for bulge testing is shown in Fig. 22.6.

22.1.5 Bulge Tests

The original bulge tests used circular windows because they are easier to analyze mathematically, but now square and rectangular windows have become common [22.29]. These geometries tend to be easier to fabricate. Unfortunately, there are several sources of errors in bulge testing that can potentially lead to large errors in the measured mechanical properties. These errors at one time led to the belief that multilayer films can show a "super modulus" effect, where the elastic modulus of the multilayer is several times that of its constituent

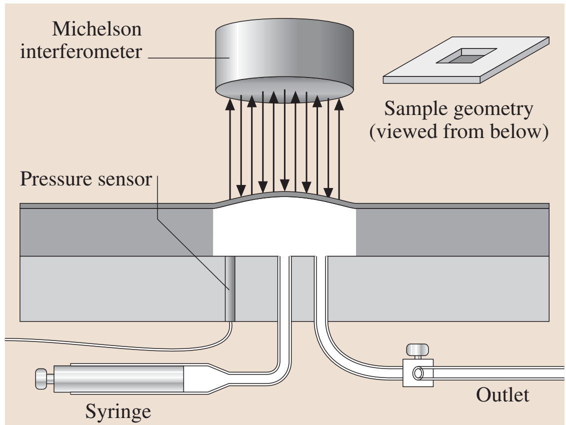

Fig. 22.6 Schematic of the basic setup for bulge testing. The sample is prepared so that it is a thin membrane, and then a pressure is applied to the back of the membrane to make it bulge upwards. The height of the bulge is measured using an interferometer

layers [22.30]. It is now accepted that any enhancement to the elastic modulus in multilayer films is small, on the order of 15% [22.31]. The main sources of error stem from compressive stresses in the film (tensile stress is not a problem), small variations in the dimensions of the window, and uncertainty in the exact height of the bulge. Despite these difficulties, one advantage of bulge testing over nanoindentation testing is that the stress state is biaxial, so that only properties in the plane of the film are measured. In contrast, nanoindentation testing measures a combination of in-plane and out-of-plane properties.

22.1.6 Acoustic Methods

Acoustic and ultrasonic techniques have been used for many years to study the elastic properties of materials. Essentially, these techniques take advantage of the fact that the velocity of sound in a material is dependent on the inter-atomic or inter-molecular forces in the material. These, of course, are directly related to the material's elastic constants. In fact, any nonlinearity of inter-atomic forces enables slight variations in acoustic signals to be used as a measure of residual stress.

An acoustic method ideally suited to studying surfaces is scanning acoustic microscopy (SAM) [22.32]. There are also several other techniques that have been used to study surface films and multilayers, but we will first consider SAM in detail. In a SAM, a lens made of sapphire is used to bring acoustic waves to focus via a coupling fluid on the surface. A small piezoelectric transducer at the top of the lens generates the acoustic signal. The same transducer can be used to detect the signal when the SAM is used in reflection mode. The use of a transducer as both generator and detector, a common imaging mode, necessitates the use of a pulsed rather than a continuous acoustic signal. Continuous waves can be used if phase changes are used to build up the image. The transducer lens generates two types of acoustic waves in the material: longitudinal and shear. The ability of a solid to sustain both types of wave (liquids can only sustain longitudinal waves) gives rise to a third type of acoustic wave called a Rayleigh, or surface, wave. These waves are generated as a result of superposition of the shear and longitudinal waves with a common phase velocity. The stresses and displacements associated with a Rayleigh wave are only of significance to a depth of ≈ 0.6 Rayleigh wavelengths below the solid surface. Hence, using SAM to examine Rayleigh waves in a material is a true surface characterization technique.

Using a SAM in reflection mode gives an image where the contrast is directly related to the Rayleigh wave velocity, which is in turn a function of the material's elastic constants. The resolution of the image depends on the frequency of the transducer used, i. e., for a 2 GHz signal a resolution better than 1 μm is achievable. The contrast in the image results from the interference of two different waves in the coupling fluid. Rayleigh waves that are excited in the surface "leak" into the coupling fluid and interfere with the acoustic signal that is directly reflected back from the surface. It is usually assumed that the properties of the coupling fluid are well characterized. The interference of the two waves gives a characteristic $V(z)$ curve, as illustrated by Fig. 22.7, where z is the separation between the lens and the surface. Analyzing the periodicity of the $V(z)$ curves provides information on the Rayleigh wave velocity. As with other acoustic waves, the Rayleigh velocity is related to the elastic constants of the material. When using the SAM for a material's characterization, the lens is usually held in a fixed position on the surface. By using a lens designed specifically to give a line-focus beam, rather than the standard spherical lens, it is possible to use SAM to look at anisotropy in the wave velocity [22.33] and hence in elastic properties by producing waves with a specific direction.

One advantage of using SAM in conjunction with nanoindentation to characterize a surface is that the measurements obtained with the two methods have a slightly different dependence on the test material's elastic properties, E_s and ν_s (the elastic modulus and Poisson's ratio). As a result, it is possible to use SAM

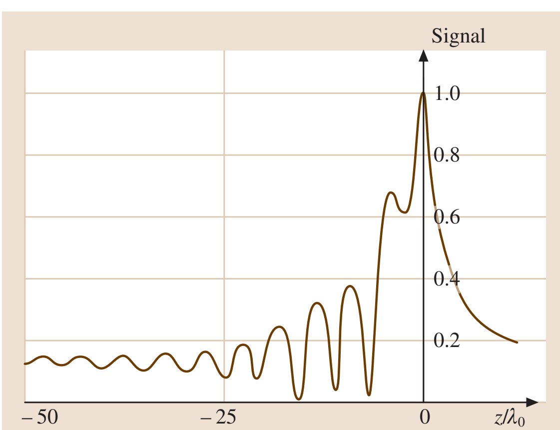

Fig. 22.7 A typical $V(z)$ curve obtained with a SAM when testing fused silica

and nanoindentation combined to find both E_s and ν_s, as illustrated by Fig. 22.8 [22.34]. This is not possible when using only one of the techniques alone.

In addition to measuring surface properties, SAM has been used to study thin films on a surface. However, the Rayleigh wave velocity can be dependent on a complex mix of the film and substrate properties. Other acoustic methods have been utilized to study freestanding films. A freestanding film can be regarded as a plate, and, therefore, it is possible to excite Lamb waves in the film. Using a pulsed laser to generate the waves and a heterodyne interferometer to detect the arrival of the Lamb wave, it is possible to measure the flexural modulus of the film [22.35]. This has been successfully demonstrated for multilayer films with a total thickness $< 10\,\mu m$. In the plate configuration, due to the nonlinearity of elastic properties, it is also possible to measure stress. This has been demonstrated for horizontally polarized shear waves in plates [22.36], but thin plates require very high frequency transducers or laser sources.

Fig. 22.8 Because SAM and nanoindentation have different dependencies on Young's modulus, E, and Poissons ratio, ν, it is possible to use the two techniques in combination to find E and ν [22.34]. On the graph, the intersection of the curves gives E and ν

22.1.7 Imaging Methods

When measuring the mechanical properties of a surface or thin film using nanoindentation, it is not always easy to visualize what is happening. In many instances there is a risk that the mechanical data can be completely misinterpreted if the geometry of the test is not as expected. To expedite the correct interpretation of the mechanical data, it is generally worthwhile to use optical, electron, or atomic force microscopy to image the nanoindentations. Obviously, optical techniques are only of use for larger indentations, but they will often reveal the presence of median or lateral cracks [22.37]. Electron microscopy and AFM, however, can be used to examine even the smallest nanoindentations. The principle problem with these microscopy techniques is the difficulty in finding the nanoindentations. It is usually necessary to make large, "marker" indentations in the vicinity of the nanoindentations to be examined in order to find them [22.38].

It is possible to see features such as extrusions with a scanning electron microscope (SEM) [22.39], as well as pile-up and sink-in around the nanoindents, though AFM is generally better for this. Transmission electron microscopy (TEM) is useful for examining what has happened subsurface, for instance, the indentation induced dislocations in a metal [22.40] or the phases present under a nanoindent in silicon [22.21]. However, with TEM there is the added difficulty of sample preparation and the associated risk of observing artifacts. Recently, there has been considerable interest in the use of focused ion beams to cut cross sections through nanoindents [22.41]. When used in conjunction with SEM or TEM this provides an excellent means to see what has happened in the subsurface region.

One other technique that has proved to be useful in studying nanoindents is micro-Raman spectroscopy. This involves using a microscope to focus a laser on the sample surface. The same microscope is also used to collect the scattered laser light, which is then fed into a spectroscope. The Raman peaks in the spectrum provide information on the bonding present in a material, while small shifts in the wave number of the peaks can be used as a measure of strain. Micro-Raman has proven to be particularly useful for examining the phases present around nanoindentations in silicon [22.42].

22.2 Data Analysis

The analysis of nanoindentation data is far from simple. This is mostly due to the lack of effective models that are able to combine elastic and plastic deformation under a contact. However, provided certain precautions are taken, the models for perfectly elastic deformation and ideal plastic materials can be used in the analysis of nanoindentation data. For this reason, it is worth briefly reviewing the models for perfect contacts.

22.2.1 Elastic Contacts

The theoretical modeling of elastic contacts can be traced back many years, at least to the late nineteenth century and the work of *Hertz* (1882) [22.43] and *Boussinesq* (1885) [22.44]. These models, which are still widely used today, consider two axisymmetric curved surfaces in contact over an elliptical region (see Fig. 22.9). The contact region is taken to be small in comparison to the radius of curvature of the contacting surfaces, which are treated as elastic half-spaces. For an elastic sphere, radius R, in contact with a flat, elastic half-space, the contact region will be circular and the Hertz model gives the following relationships:

$$a = \sqrt[3]{\frac{3PR}{4E_r}} , \tag{22.3}$$

$$\delta = \sqrt[3]{\frac{9P^2}{16RE_r^2}} , \tag{22.4}$$

$$P_0 = \sqrt[3]{\frac{6PE_r^2}{\pi^3 R^2}} , \tag{22.5}$$

where a is the radius of the contact region, E_r is given by (22.2), δ is the displacement of the sphere into the surface, P is the applied load and P_0 is the maximum pressure under the contact (in this case at the center of the contact).

The work of *Hertz* and *Boussinesq* was extended by *Love* [22.45, 46] and later by *Sneddon* [22.47], who simplified the analysis using Hankel transforms. *Love* showed how *Boussinesq*'s model could be used for a flat-ended cylinder and a conical indenter, while *Sneddon* produced a generalized relationship for any rigid axisymmetric punch pushed into an elastic half-space. *Sneddon* applied his new analysis to punches of various shapes and derived the following relationships between the applied load, P, and displacement, δ, into the elastic half-space for, respectively, a flat-ended cylinder, a cone

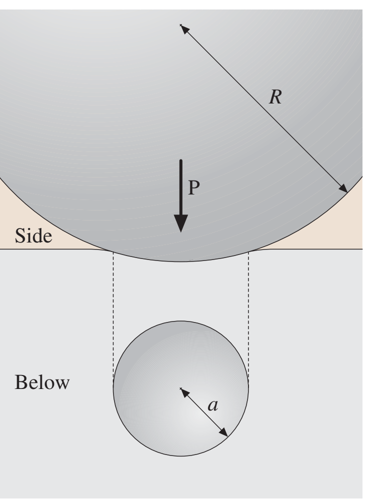

Fig. 22.9 Hertzian contact of a sphere, radius R, on a semi-infinite, flat surface. The contact in this case is a circular region of radius a

of semi-vertical angle ϕ, and a parabola of revolution where $a^2 = 2k\delta$:

$$P = \frac{4\mu a\delta}{1-\nu} , \tag{22.6}$$

$$P = \frac{4\mu \cot\phi}{\pi(1-\nu)}\delta^2 , \tag{22.7}$$

$$P = \frac{8\mu}{3(1-\nu)}\left(2k\delta^3\right)^{1/2} , \tag{22.8}$$

where μ and ν are the shear modulus and Poisson's ratio of the elastic half-space, respectively.

The key point to note about (22.6), (22.7), and (22.8) is that they all have the same basic form, namely:

$$P = \alpha\delta^m , \tag{22.9}$$

where α and m are constants for each geometry.

Equation (22.9) and the relationships developed by Hertz and his successors, (22.3–22.8), form the foundation for much of the current nanoindentation data analysis routines.

22.2.2 Indentation of Ideal Plastic Materials

Plastic deformation during indentation testing is not easy to model. However, the indentation response of ideal plastic metals was considered by *Tabor* in his classic text, "The Hardness of Metals" [22.48]. An ideal plastic material (or more accurately an ideal elastic-plastic material) has a linear stress-strain curve until

it reaches its elastic limit and then yields plastically at a yield stress, Y_0, that remains constant even after deformation has commenced. In a 2-D problem, the yielding occurs because the Huber-Mises [22.49] criterion has been reached. In other words, the maximum shear stress acting on the material is around $1.15Y_0/2$.

First, we consider a 2-D flat punch pushed into an ideal plastic material. By using the method of slip lines it is found that the mean pressure, P_m, across the end of the punch is related to the yield stress by:

$$P_m = 3Y_0 . \quad (22.10)$$

If the *Tresca* criterion [22.50] is used, then P_m is closer to $2.6Y_0$. In general, for both 2-D and three-dimensional punches pushed into ideal plastic materials, full plasticity across the entire contact region can be expected when $P_m = 2.6$ to $3.0Y_0$. However, significant deviations from this range can be seen if, for instance, the material undergoes work-hardening during indentation, or the material is a ceramic, or there is friction between the indenter and the surface.

The apparently straightforward relationship between P_m and Y_0 makes the mean pressure a very useful quantity to measure. In fact, P_m is very similar to the Vickers hardness, H_V, of a material:

$$H_V = 0.927P_m . \quad (22.11)$$

During nanoindentation testing it is the convention to take the mean pressure as the nanohardness. Thus, the "nanohardness", H, is defined as the peak load, P, applied during a nanoindentation divided by the projected area, A, of the nanoindentation in the plane of the surface, hence:

$$H = \frac{P}{A} . \quad (22.12)$$

22.2.3 Adhesive Contacts

During microindentation testing and even most nanoindentation testing the effects of intermolecular and surface forces can be neglected. Very small nanoindentations, however, can be influenced by the effects of intermolecular forces between the sample and the tip. These adhesive effects are most readily seen when testing soft polymers, but there is some evidence that forces between the tip and sample may be important in even relatively strong materials [22.51, 52].

Contact adhesion is usually described by either the JKR or DMT model, as discussed earlier in this chapter. Both the models consider totally elastic spherical contacts under the influence of attractive surface forces. The JKR model considers the surface forces in terms of the associated surface energy, whereas the DMT model considers the effects of adding van der Waals forces to the Hertzian contact model. The differences between the two models are illustrated by Fig. 22.10.

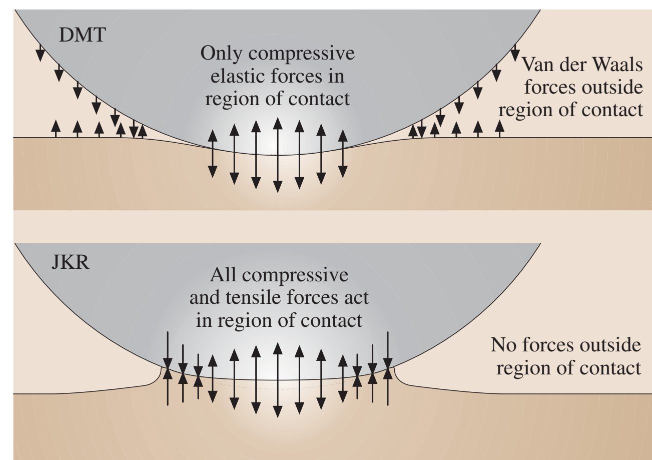

Fig. 22.10 The contact geometry for the DMT and JKR models for adhesive contact. Both models are based on the Hertzian model. In the DMT, model van der Waals forces outside the region of contact introduce an additional load in the Hertz model. But for the JKR model, it is assumed that tensile, as well as compressive stresses can be sustained within the region of contact

For nanoindentation tests conducted in air the condensation of water vapor at the tip-sample interface usually determines the size of the adhesive force acting during unloading. The effects of water vapor on a single nanoasperity contact have been studied using force-controlled AFM techniques [22.53] and, more recently, nanoindentation methods [22.26]. Unsurprisingly, it has also been found that water vapor can affect the deformation of surfaces during nanoindentation testing [22.27].

In addition to water vapor, other surface adsorbates can cause dramatic changes in the nanoscale mechanical behavior. For instance, oxygen on a clean metal surface can cause an increase in the apparent strength of the metal [22.54]. These effects are likely to be related to, firstly, changes in the surface and intermolecular forces acting between the tip and the sample and, secondly, changes in the mechanical stability of surface nanoasperities and ledges. Adsorbates can help stabilize atomic-scale variations in surface morphology, thereby making defect generation at the surface more difficult.

22.2.4 Indenter Geometry

All of the indenter geometries considered up to this point have been axisymmetric, largely because they are easier to deal with theoretically. Unfortunately, fabricating axisymmetric nanoindentation tips is extremely difficult, because shaping a hard tip on the scale of a few nanometers is virtually impossible. Despite these problems, there has been considerable effort put into the use of spherical nanoindentation tips [22.55]. This clearly demonstrates that the spherical geometry can be useful at larger indentation depths.

Because of the problems associated with creating axisymmetric nanoindentation tips, pyramidal indenter geometries have now become standard during nanoindentation testing. The most common geometries are the three-sided Berkovich pyramid and cube-corner (see Fig. 22.11). The Berkovich pyramid is based on the four-sided Vickers pyramid, the opposite sides of which make an 136° angle. For both the Vickers and Berkovich pyramids the cross-sectional area of the pyramid's base, A, is related to the pyramid's height, D, by:

$$A = 24.5D^2 . \quad (22.13)$$

The cube-corner geometry is now widely used for making very small nanoindentations, because it is much sharper than the Berkovich pyramid. This makes it easier to initiate plastic deformation at very light loads, but great care should be taken when using the cube-corner geometry. Sharp cube-corners can wear down quickly and become blunt, hence the cross-sectional area as a function of depth can change over the course of several indentations. There is also a potential problem with the standard analysis routines [22.56], which were developed for much blunter geometries and are based on the elastic contact models outlined earlier. The elastic contact models all assume the displacement into the surface is small compared to the tip radius. For the cube-corner geometry this is probably only the case for nanoindentations that are no more than a few nanometers deep.

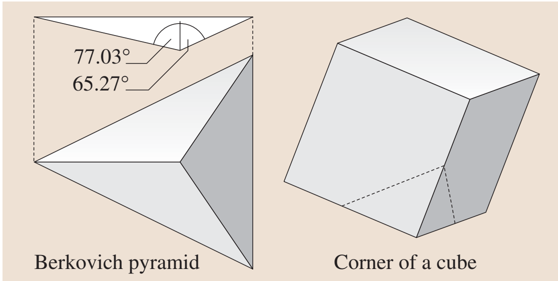

Fig. 22.11 The ideal geometry for the three-sided Berkovich pyramid and cube corner tips

22.2.5 Analyzing Load/Displacement Curves

The load/displacement curves obtained during nanoindentation testing are deceptively simple. Most newcomers to the area will see the curves as being somewhat akin to the stress/strain curves obtained during tensile testing. There is also a real temptation just to use the values of hardness, H, and elastic modulus, E, obtained from standard analysis software packages as the "true" values. This may be the case in many instances, but for very shallow nanoindents and tests on thin films the geometry of the contact can differ significantly from the geometry assumed in the analysis routines. Consequently, experimentalists should think very carefully about the test itself before concluding that the values of H and E are correct.

The basic shape of a load/displacement curve can reveal a great deal about the type of material being tested. Figure 22.12 shows some examples of ideal curves for materials with different elastic moduli and yield stresses. Discontinuities in the load/displacement curve can also provide information on such processes as fracture, dislocation nucleation, and phase transformations. Initially,

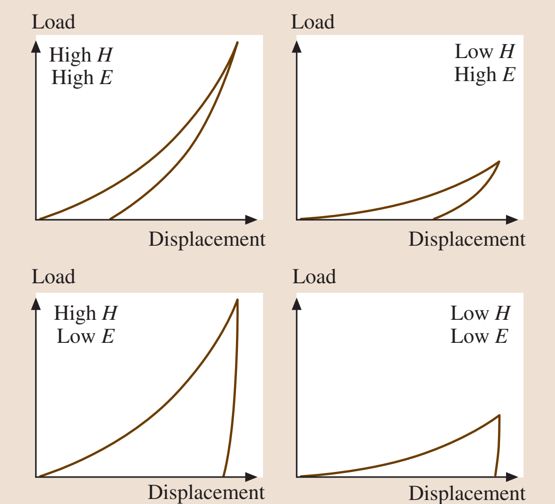

Fig. 22.12 Examples of load/displacement curves for idealized materials with a range of hardness and elastic properties

though, we will consider ideal situations such as those illustrated by Fig. 22.12.

The loading section of the load/displacement curve approximates a parabola [22.60] whose width depends on a combination of the material's elastic and plastic properties. The unloading curve, however, has been shown to follow a more general relationship [22.56] of the form:

$$P = \alpha (\delta - \delta_i)^m \ , \quad (22.14)$$

where δ is the total displacement and δ_i is the intercept of the unloading curve with the displacement axis shown in Fig. 22.13.

Equation (22.14) is essentially the same as (22.9) but with the origin displaced. Since (22.9) is obtained by considering purely elastic deformation, it follows that the unloading curve is exhibiting purely elastic behavior. Since the shape of the unloading curve is determined by the elastic recovery of the indented region, it is not entirely surprising that its shape resembles that found for purely elastic deformation. What is fortuitous is that the elastic analysis used for an elastic half-space seems to be valid for a surface where there is a plastically formed indentation crater present under the contact. However, the validity of this analysis may only hold when the crater is relatively shallow and the geometry of the surface does not differ significantly from that of a flat, elastic half-space. For nanoindentations with a Berkovich pyramid, this is generally the case.

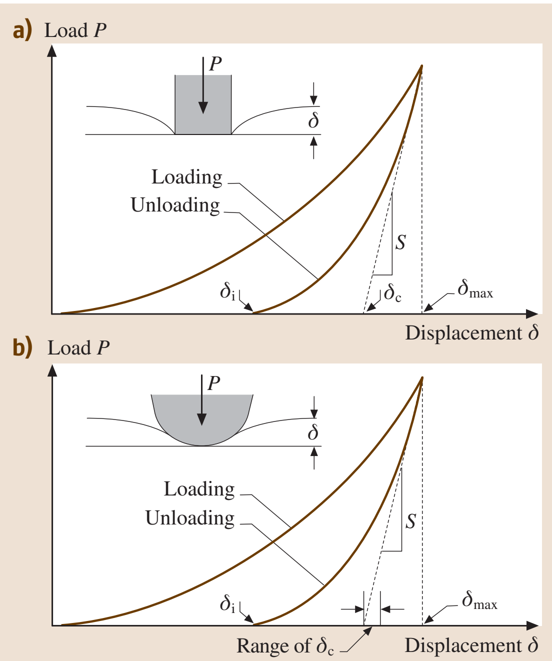

Fig. 22.13a,b Analysis of the load/displacement curve gives the contact stiffness, S, and the contact depth, δ_c. These can then be used to find the hardness, H, and elastic, or Young's modulus, E. **(a)** The first method of analysis [22.57–59] assumed the unloading curve could be approximated by a flat punch on an elastic half-space. **(b)** A more refined analysis [22.56] uses a paraboloid on an elastic half-space

Before *Oliver* and *Pharr* [22.56] proposed their now standard method for analyzing nanoindentation data, the analysis had been based on the observation that the initial part of the unloading curve is almost linear. A linear unloading curve, equivalent to $m = 1$ in (22.14), is expected when a flat punch is used on an elastic half-space. The flat punch approximation for the unloading curve was used in [22.57–59] to analyze nanoindentation data. When Oliver and Pharr looked at a range of materials they found m was typically larger than 1, and that $m = 1.5$, or a paraboloid, was a better approximation than a flat punch. Oliver and Pharr used (22.1) and (22.12) to obtain the values for a material's elastic modulus and hardness. Equation (22.1) relates the contact stiffness during the initial part of the unloading curve (see Fig. 22.13) to the reduced elastic modulus and the contact area at the peak load. Equation (22.12) gives the hardness as the peak load divided by the contact area. It is immediately obvious that the key to measuring the mechanical properties of a material is knowing the contact area at the peak load. This is the single most important factor in analyzing nanoindentation data. Most mistakes in the analysis come from incorrect assumptions about the contact area.

To find the contact area, a function relating the contact area, A_c, to the contact depth, δ_c, is needed. For a perfect Berkovich pyramid this would be the same as (22.13). But since making a perfect nanoindenter tip is impossible, an expanded equation is used:

$$A_c(\delta_c) = 24.5\delta_c^2 + \sum_{j=1}^{7} C_j \sqrt[2^j]{\delta_c} \ , \quad (22.15)$$

where C_j are calibration constants of the tip.

There is a crucial step in the analysis before A_c can be calculated, namely, finding δ_c. The contact depth is not the same as the indentation depth, because the surface around the indentation will be elastically deflected during loading, as illustrated by Fig. 22.14. Sneddon's analysis [22.47] provides a way to calculate the deflection of the surface at the edge of an axisymmetric

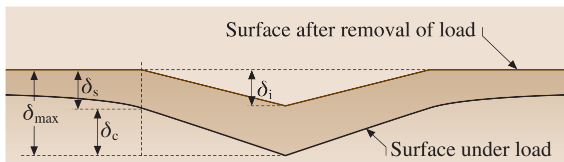

Fig. 22.14 Profile of surface under load and unloaded showing how δ_c compares to δ_i and δ_{max}

contact. Subtracting the deflection from the total indentation depth at peak load gives the contact depth. For a paraboloid, as used by *Oliver* and *Pharr* [22.56] in their analysis, the elastic deflection at the edge of the contact is given by:

$$\delta_s = \varepsilon \frac{P}{S} = 0.75 \frac{P}{S} , \tag{22.16}$$

where S is the contact stiffness and P the peak load. The constant ε is 0.75 for a paraboloid, but ranges between 0.72 (conic indenter) and 1 (flat punch). Figure 22.15 shows how the contact depth depends on the value of ε. The contact depth at the peak load is, therefore:

$$\delta_c = \delta - \delta_s . \tag{22.17}$$

Using the load/displacement data from the unloading curve and (22.1), (22.2), (22.12), (22.14–22.17), the hardness and reduced elastic modulus for the test sample can be calculated. To find the elastic modulus of the sample, E_s, it is also necessary to know Poisson's ratio, ν_s, for the sample, as well as the elastic modulus, E_t, and Poisson's ratio, ν_t, of the indenter tip. For diamond these are 1,141 GPa and 0.07, respectively.

There also remains the issue of calibrating the tip shape, or finding the values for C_j in (22.15). Knowing the exact expansion of $A_c(\delta_c)$ is vital if the values for E_s and H are to be accurate. Several methods for calibrating the tip shape have been used, including imaging the tip with an electron microscope, measuring the size of nanoindentations using SEM or TEM of negative replicas, and using scanning probes to examine either the tip itself or the nanoindentations made with the tip. There are strengths and weaknesses to each of these methods. In general, however, the accuracy and usefulness of the methods depends largely on how patient and rigorous the experimentalist is in performing the calibration.

Because of the experimental difficulties and time involved in calibrating the tip shape by these methods, *Oliver* and *Pharr* [22.56] developed a method for calibration based on standard specimens. With a standard specimen that is mechanically isotropic and has a known E and H that does not vary with indentation depth, it should be possible to perform nanoindentations to a range of depths, and then use the analysis routines in reverse to deduce the tip area function, $A_c(\delta_c)$. In other words, if you perform a nanoindentation test, you can find the contact stiffness, S, at the peak load, P, and the contact depth, δ_c, from the unloading curve. Then if you know E a priori, (22.1) can be used to calculate the contact area, A, and, hence, you have a value for A_c at a depth δ_c. Repeating this procedure for a range of depths will give a numerical version of the function $A_c(\delta_c)$. Then, it is simply a case of fitting (22.15) to the numerical data. If the hardness, H, is known and not a function of depth, and the calibration specimen was fully plastic during testing, then essentially the same approach could be used but based on (22.12). Situations where a constant H is used to calibrate the tip are extremely rare.

In addition to the tip shape function, the machine compliance must be calibrated. Basic Newtonian mechanics tells us that for the tip to be pushed into a surface the tip must be pushing off of another body. During nanoindentation testing the other body is the machine frame. As a result, during a nanoindentation test it is not just the sample, but the machine frame that is being loaded. Consequently, a very small elastic deformation of the machine frame contributes to the total stiffness obtained from the unloading curve. The machine frame is usually very stiff, $> 10^6$ N/m, so the effect is only important at relatively large loads.

To calibrate the machine frame stiffness or compliance, large nanoindentations are made in a soft material such as aluminum with a known, isotropic elastic modulus. For very deep nanoindentations made with a Berkovich pyramid, the contact area, $A_c(\delta_c)$, can be reasonably approximated to $24.5\delta_c^2$, thus (22.1) can be used to find the expected contact stiffness for the material. Any difference between the expected value of S

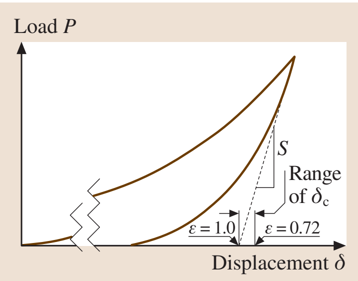

Fig. 22.15 Load-displacement curve showing how δ_c varies with ε

and the value measured from the unloading curve will be due to the compliance of the machine frame. Performing a number of deep nanoindentations enables an accurate value for the machine frame compliance to be obtained.

Currently, because of its ready availability and predictable mechanical properties, the most popular calibration material is fused silica ($E = 72$ GPa, $\nu = 0.17$), though aluminum is still used occasionally.

22.2.6 Modifications to the Analysis

Since the development of the analysis routines in the early 1990s, it has become apparent that the standard analysis of nanoindentation data is not applicable in all situations, usually because errors occur in the calculated contact depth or contact area. *Pharr* et al. [22.61–64] have used finite element modeling (FEM) to help understand and overcome the limitations of the standard analysis. Two important sources of errors have been identified in this way. The first is residual stress at the sample surface. The second is the change in the shape of nanoindents after elastic recovery.

The effect of residual stresses at a surface on the indentation properties has been the subject of debate for many years [22.65–67]. The perceived effect was that compressive stresses increased hardness, while tensile stresses decreased hardness. Using FEM it is possible to model a pointed nanoindenter being pushed into a model material that is in residual tension or compression. An FEM model of nanoindentation into aluminum alloy 8009 [22.61] has confirmed earlier experimental observations [22.68] indicating that the contact area calculated from the unloading curve is incorrect if there are residual stresses. In the FEM model of an aluminum alloy the mechanical behavior of the material is modeled using a stress-strain curve, which resembles that of an elastic-perfectly-plastic metal with a flow stress of 425.6 MPa. Yielding starts at 353.1 MPa and includes a small amount of work hardening. The FEM model was used to find the contact area directly and using the simulated unloading curve in conjunction with Oliver and Pharr's method. The results as a function of residual stress are illustrated in Fig. 22.16. Note that the differences between the two measured contact areas lead to miscalculations of E and H.

Errors in the calculated contact area stem from incorrect assumptions about the pile-up and sink-in at the edge of the contact, as illustrated by Fig. 22.17. The Oliver and Pharr analysis assumes the geometry of the sample surface is the same as that given by *Sneddon* [22.47] in his analytical model for the indentation of elastic surfaces. Clearly, for materials where there is significant plastic deformation, it is possible that there will be large deviations from the surface geometry found using Sneddon's elastic model. In reality, the error in the contact area depends on how much the geometry of the test sample surface differs from that of the calibration material (typically fused silica). It is possible that a test sample, even without a residual stress, will have a different surface geometry and, hence, contact area at a given depth, when compared to the calibration material. This is often seen for thin films on a substrate (e.g., *Tsui* et al. [22.69, 70]). Residual stresses increase the likelihood that the contact area calculated using Oliver and Pharr's method will be incorrect.

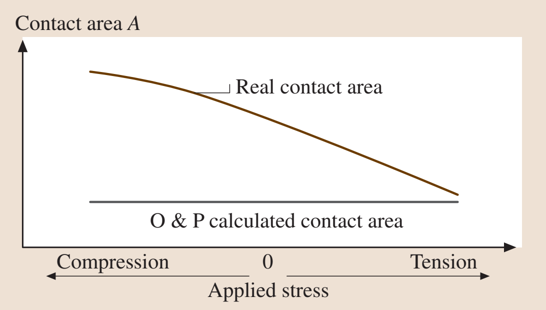

Fig. 22.16 When a surface is in a state of stress there is a significant difference between the contact area calculated using the Oliver and Pharr method and the actual contact area [22.61]. For an aluminum alloy this can lead to significant errors in the calculated hardness and elastic modulus

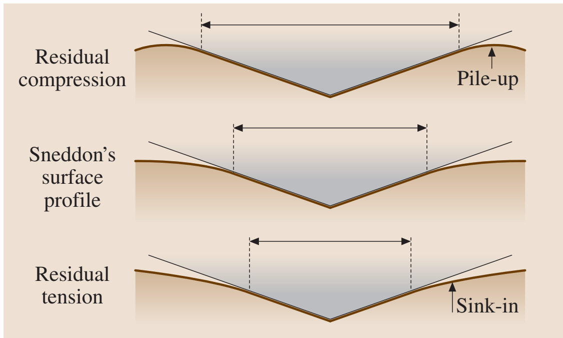

Fig. 22.17 Pile-up and sink-in are affected by residual stresses, and, hence, errors are introduced into standard Oliver and Pharr analysis

The issue of sink-in and pile-up is always a factor in nanoindentation testing. However, there is still no effective way to deal with these phenomena other than reverting to imaging of the indentations to identify the true contact area. Even this is difficult, as the edge of an indentation is not easy to identify using AFM or electron microscopy. One approach that has been used [22.71] with some success is measuring the ratio E_r^2/H, rather than E_r and H separately. Because E_r is proportional to $1/\sqrt{A}$ and H is proportional to $1/A$, E_r^2/H should be independent of A and, hence, unaffected by pile-up or sink-in. While this does not provide quantitative values for mechanical properties, it does provide a way to identify any variations in mechanical properties with indentation depth or between similar samples with different residual stresses.

Another source of error in the Oliver and Pharr analysis is due to incorrect assumptions about the nanoindentation geometry after unloading [22.63]. Once again, this is due to differences between the test sample and the calibration material. The exact shape of an unloaded nanoindentation on a material exhibiting elastic recovery is not simply an impression of the tip shape; rather, there is some elastic recovery of the nanoindentation sides giving them a slightly convex shape (see Fig. 22.18). The shape actually depends on Poisson's ratio, so the standard Oliver and Pharr analysis will only be valid for a material where $\nu = 0.17$, the value for fused silica, assuming it is used for the calibration.

To deal with the variations in the recovered nanoindentation shape, it has been suggested [22.63] that a modified nanoindenter geometry with a slightly concave side be used in the analysis (see Fig. 22.18). This

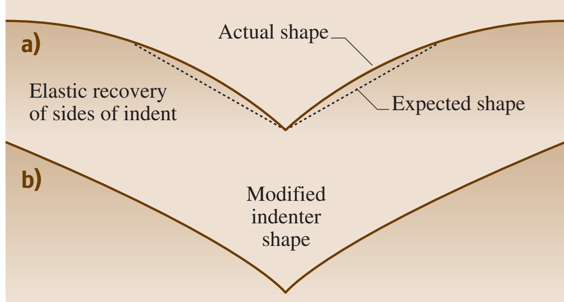

Fig. 22.18 **(a)** *Hay* et al. [22.63] found from experiments and FEM simulations that the actual shape of an indentation after unloading is not as expected. **(b)** They introduced a γ term to correct for this effect. This assumes the indenter has slightly concave sides

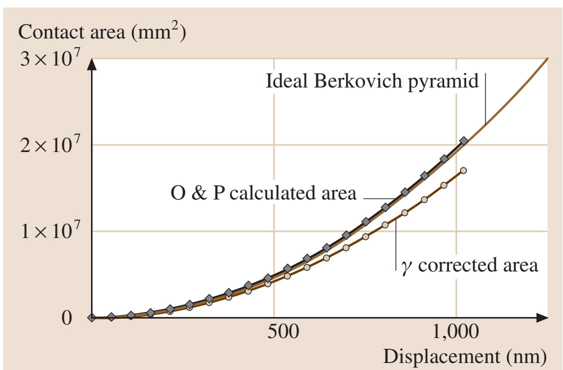

Fig. 22.19 For a real Berkovich tip the γ corrected area [22.63] is less at a given depth than the area calculated using the Oliver and Pharr method

requires a modification to (22.1):

$$S = \gamma 2 E_r \sqrt{\frac{A}{\pi}}\,, \tag{22.18}$$

where γ is a correction term dependent on the tip geometry. For a Berkovich pyramid the best value is:

$$\gamma = \frac{\frac{\pi}{4} + 0.15483073 \cot \Phi \left(\frac{(1-2\nu_s)}{4(1-\nu_s)}\right)}{\left[\frac{\pi}{2} - 0.83119312 \cot \Phi \left(\frac{(1-2\nu_s)}{4(1-\nu_s)}\right)\right]^2}\,, \tag{22.19}$$

where $\Phi = 70.32°$. For a cube corner the correction can be even larger and γ is given by:

$$\gamma = 1 + \left(\frac{(1-2\nu_s)}{4(1-\nu_s)\tan \Phi}\right)\,, \tag{22.20}$$

where $\Phi = 42.28°$. Figure 22.19 shows how the modified contact area varies with depth for a real diamond Berkovich pyramid.

The validity of the γ-modified geometry is questionable from the perspective of contact mechanics since it relies on assuming an incorrect geometry for the nanoindenter tip to correct for an error in the geometry of the nanoindentation impression. The values for E and H obtained using the γ-modification are, however, good and can be significantly different to the values obtained with the standard Oliver and Pharr analysis.

22.2.7 Alternative Methods of Analysis

All of the preceding discussion on the analysis of nanoindentation curves has focused on the unloading curve, virtually ignoring the loading curve data. This is for the

simple reason that the unloading curve can in many cases be regarded as purely elastic, whereas the shape of the loading curve is determined by a complex mix of elastic and plastic properties.

It is clear that there is substantially more data in the loading curve if it can be extracted. *Page* et al. [22.60, 72] have explored the possibility of curve fitting to the loading data using a combination of elastic and plastic properties. By a combination of analysis and empirical fitting to experimental data, it was suggested that the loading curve is of the following form:

$$P = E\left(\psi\sqrt{\frac{H}{E}}+\phi\sqrt{\frac{E}{H}}\right)^{-2}\delta^2\,, \qquad (22.21)$$

where ψ and ϕ are determined experimentally to be 0.930 and 0.194, respectively. For homogenous samples this equation gives a linear relationship between P and δ^2. Coatings, thin film systems, and samples that strain-harden can give significant deviations from linearity. Analysis of the loading curve has yet to gain popularity as a standard method for examining nanoindentation data, but it should certainly be regarded as a prime area for further investigation.

Another alternative method of analysis is based on the work involved in making an indentation. In essence, the nanoindentation curve is a plot of force against distance indicating integration under the loading curve will give the total work of indentation, or the sum of the elastic strain energy and the plastic work of indentation. Integrating under the unloading curve should give only the elastic strain energy. Thus, the work involved in both elastic and plastic deformation during nanoindentation can be found. *Cheng* and *Cheng* [22.73] combined measurements of the work of indentation with a dimensional analysis that deals with the effects of scaling in a material that work-hardens to estimate H/E_r. They subsequently evaluated H and E using the Oliver and Pharr approach to find the contact area.

22.2.8 Measuring Contact Stiffness

As discussed earlier, it is possible to add a small AC load on top of the DC load used during nanoindentation testing, providing a way to measure the contact stiffness throughout the entire loading and unloading cycle [22.74, 75]. The AC load is typically at a frequency of ≈ 60 Hz and creates a dynamic system, with the sample acting as a spring with stiffness S (the contact stiffness), and the nanoindentation system acting as a series of springs and dampers. Figure 22.20 illustrates

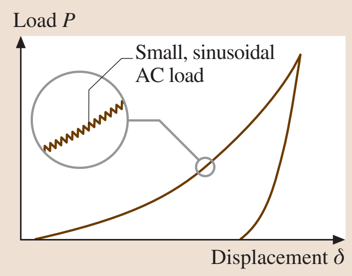

Fig. 22.20 A small AC load can be added to the DC load. This enables the contact stiffness, S, to be calculated throughout the indentation cycle

how the small AC load is added to the DC load. Figure 22.21 shows how the resulting dynamic system can be modeled. An analysis of the dynamic system gives the following relationships for S based on the amplitude of the AC displacement oscillation and the phase difference between the AC load and displacement signals:

$$\left|\frac{P_{os}}{\delta(\omega)}\right| = \sqrt{\left[\left(S^{-1}+C_f\right)^{-1}+K_s-m\omega^2\right]^2+\omega^2 D^2}\,, \qquad (22.22)$$

$$\tan(\chi) = \frac{\omega D}{\left(S^{-1}+C_f\right)^{-1}+K_s-m\omega^2}\,, \qquad (22.23)$$

where C_f is the load frame compliance (the reciprocal of the load frame stiffness), K_s is the stiffness of the support springs (typically in the region of 50–100 N/m), D is the damping coefficient, P_{os} is the magnitude of the load oscillation, $\delta(\omega)$ is the magnitude of the displacement oscillation, ω is the oscillation frequency, m is the mass of the indenter, and χ is the phase angle between the force and the displacement.

In order to find S using either (22.22) or (22.23), it is necessary to calibrate the dynamic response of the system when the tip is not in contact with a sample ($S^{-1}=0$). This calibration combined with the standard

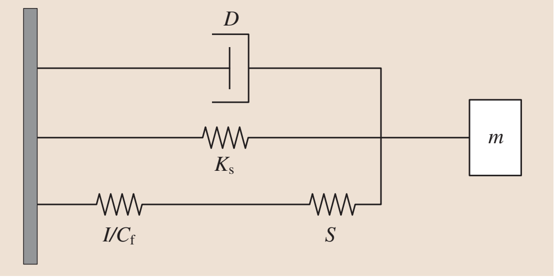

Fig. 22.21 The dynamic model used in the analysis of the AC response of a nanoindentation device

Part C | 22.2

DC calibrations will provide the values for all of the constants in the two equations. All that needs to be measured in order to obtain S is either $\delta(\omega)$ or χ, both of which are measured by the lock-in amplifier used to generate the AC signal. Since the S obtained is the same as the S in (22.1), it follows that the Oliver and Pharr analysis can be applied to obtain E_r and H throughout the entire nanoindentation cycle.

The dynamic analysis detailed here was developed for the MTS Nanoindenter™ (Oakridge, Tennessee), but a similar analysis has been applied to other commercial instruments such as the Hysitron Triboscope™ (Minneapolis, Minnesota) [22.76]. For all instruments, an AC oscillation is used in addition to the DC voltage, and a dynamic model is used to analyze the response.

22.2.9 Measuring Viscoelasticity

Using an AC oscillation in addition to the DC load introduces the possibility of measuring viscoelastic properties during nanoindentation testing. This has recently been the subject of considerable interest with researchers looking at the loss modulus, storage modulus, and loss tangent of various polymeric materials [22.25, 77]. Recording the displacement response to the AC force oscillation enables the complex modulus (including the loss and storage modulus) to be found. If the modulus is complex, it is clear from (22.1) that the stiffness also becomes complex. In fact, the stiffness will have two components: S', the component in phase with the AC force and S'', the component out of phase with the AC force.

The dynamic model illustrated in Fig. 22.21 is no longer appropriate for this situation, as the contact on the test sample also includes a damping term, shown in Fig. 22.22. Equations (22.22) and (22.23) must also be revised. Neglecting the load frame compliance, C_f, which in most real situations is negligible, (22.22) and (22.23) when the sample damping, D_s, is included become:

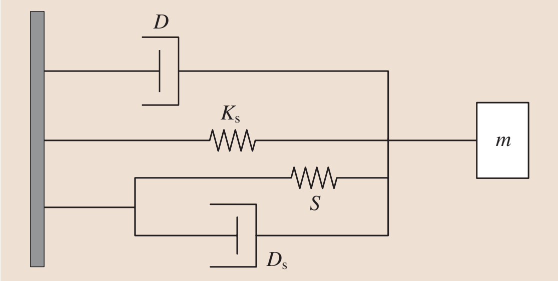

Fig. 22.22 The simplified dynamic model used when the sample is viscoelastic. It is assumed that the load frame compliance is negligible

$$\left|\frac{P_{os}}{\delta(\omega)}\right| = \sqrt{\left\{S+K_s-m\omega^2\right\}^2+\omega^2\,(D+D_s)^2}\,, \tag{22.24}$$

$$\tan(\chi) = \frac{\omega\,(D+D_s)}{S+K_s-m\omega^2}\,. \tag{22.25}$$

In order to find the loss modulus and storage modulus, (22.1) is used to relate S' (storage component) and S'' (loss component) to the complex modulus.

This method for measuring viscoelastic properties using nanoindentation has now been proven in principal, but has still only been applied to a very small range of polymers and remains an area of future growth.

22.3 Modes of Deformation

As described earlier, the analysis of nanoindentation data is based firmly on the results of elastic continuum mechanics. In reality, this idealized, purely elastic situation rarely occurs. For very shallow contacts on metals with thin surface films such as oxides, carbon layers, or organic layers [22.78, 79], the contact can initially be very similar to that modeled by Hertz and, later, Sneddon. It is very important to realize that this in itself does not constitute proof that the contact is purely elastic, because in many cases a small number of defects are present. These may be preexisting defects that move in the strain-field generated beneath the contact. Alternatively, defects can be generated either when the contact is first made or during the initial loading [22.52, 80]. When defects such as short lengths of dislocation are present the curves may still appear to be elastic even though inelastic processes like dislocation glide and cross-slip are taking place.

22.3.1 Defect Nucleation

Nucleation of defects during nanoindentation testing has been the subject of many experimental [22.81, 82] and theoretical studies [22.83, 84]. This is probably because

nanoindentation is seen as a way to deform a small, defect-free volume of material to its elastic limit and beyond in a highly controlled geometry. There are, unfortunately, problems in comparing experimental results with theoretical predictions, largely because the kinetic processes involved in defect nucleation are difficult to model. Simulations conducted at 0 K do not permit kinetic processes, and molecular dynamics simulations are too fast (nanoseconds or picoseconds). Real nanoindentation experiments take place at ≈ 293 K and last for seconds or even minutes.

Kinetic effects appear in many forms, for instance, during the initial contact between the indenter tip and the surface when defects can be generated by the combined action of the impact velocity and surface forces [22.51]. A second example of a kinetic effect occurs during hold cycles at large loads when what appears to be an elastic contact can suddenly exhibit a large discontinuity in the displacement data [22.80]. Figure 22.23 shows how these kinetic effects can affect the nanoindentation data and the apparent yield point load.

During the initial formation of a contact, the deformation of surface asperities [22.51] and ledges [22.85] can create either point defects or short lengths of dislocation line. During the subsequent loading, the defects can help in the nucleation and multiplication of dislocations. The large strains present in the region surrounding the contact, coupled with the existence of defects generated on contact, can result in the extremely rapid multiplication of dislocations and, hence, pronounced discontinuities in the load-displacement curve. It is important to realize that the discontinuities are due to the rapid multiplication of dislocations, which may or may not occur at the same time that the first dislocation is nucleated. Dislocations may have been present for some time with the discontinuity only occurring when the existing defects are configured appropriately, as a Frank-Read source, for instance. Even under large strains, the time taken for a dislocation source to form from preexisting defects may be long. It is, therefore, not surprising that large discontinuities can be seen during hold cycles or unloading.

The generation of defects at the surface and the initiation of yielding is a complex process that is extremely dependent on surface asperities and surface forces. These, in turn, are closely related to the surface chemistry. It is not only the magnitude of surface forces, but also their range in comparison to the height of surface asperities that determines whether defects are generated on contact. Small changes in the surface chemistry or

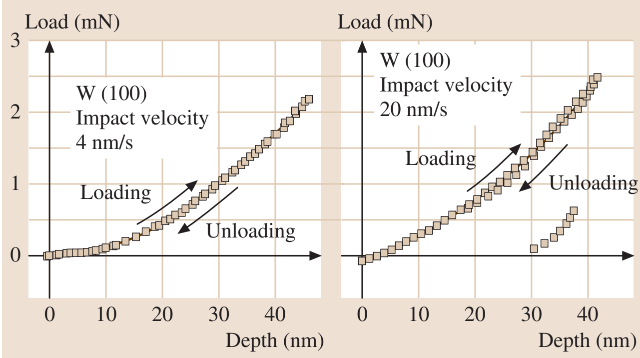

Fig. 22.23a,b Load-displacement curves for W(100) showing how changes in the impact velocity can cause a transition from perfectly elastic behavior to yielding during unloading

the velocity of the indenter tip when it first contacts the surface, can cause a transition from a situation in which defects are generated on contact to one where the contact is purely elastic [22.52].

When the generation of defects during the initial contact is avoided and the deformed region under the contact is truly defect free, then the yielding of the sample should occur at the yield stress of a perfect crystal lattice. The load at which plastic deformation commences under these circumstances becomes very reproducible [22.86]. Unfortunately, nanoindenter tips on the near-atomic scale are not perfectly smooth or axisymmetric. As a result, accurately measuring the yield stress is very difficult. In fact, a slight rotation in the plane of the surface of either the sample or the tip can give a substantial change in the observed yield point load. Coating the surface in a cushioning self-assembled monolayer [22.87] can alleviate some of these variations, but it also introduces a large uncertainty in the contact area. Surface oxide layers, which may be several nanometers thick, have also been found to enhance the elastic behavior seen for very shallow nanoindentations on metallic surfaces [22.78]. Removal of the oxide has been shown to alleviate the initial elastic response.

While nanoindentation testing is ideal for examining the mechanical properties of defect-free volumes and looking at the generation of defects in perfect crystal lattices, it should be clear from the preceding discussion that great care must be taken in examining how the surface properties and the loading rate affect the results, particularly when comparisons are being made to theoretical models for defect generation.

22.3.2 Variations with Depth

Ideal elastic-plastic behavior, as described by *Tabor* [22.48], can be seen during indentation testing, provided the sample has been work-hardened so that the flow stress is a constant. However, it is often the case that the mechanical properties appear to change as the load (or depth) is increased. This apparent change can be a result of several processes, including work-hardening during the test. This is a particularly important effect for soft metals like copper. These metals usually have a high hardness at shallow depths, but it decreases asymptotically with increasing indentation depth to a hardness value that may be less than half that observed at shallow depths. This type of behavior is due to the increasing density of geometrically necessary dislocations at shallow depths [22.88]. Hence the effects of work-hardening are most pronounced at shallow depths. For hard materials the effect is less obvious.

Work-hardening is one of the factors that contribute to the so-called indentation size effect (ISE), whereby at shallow indentation depths the material appears to be harder. The ISE has been widely observed during microindentation testing, with at least part of the effect appearing to result from the increased difficulty in optically measuring the area of an indentation when it is small. During nanoindentation testing the ISE can also be observed, but it is often due to the tip area function, $A_c(\delta_c)$, being incorrectly calibrated. However, there are physical reasons other than work-hardening for expecting an increase in mechanical strength in small volumes. As described in the previous section, small volumes of crystalline materials can have either no defects or only a small number of defects present, making plastic yielding more difficult. Also, because of dislocation line tension, the shear stress required to make a dislocation bow out increases as the radius of the bow decreases. Thus, the shear stress needed to make a dislocation bow out in a small volume is greater than it is in a large volume. These physical reasons for small volumes appearing stronger than large volumes are particularly important in thin film systems, as will be discussed later. Note, however, that these physical reasons for increased hardness do not apply for an amorphous material such as fused silica, which partially explains its value as a calibration material.

22.3.3 Anisotropic Materials

The analysis methods detailed earlier were concerned primarily with the interpretation of data from nanoindentations in isotropic materials where the elastic modulus is assumed to be either independent of direction or a polycrystalline average of a material's elastic constants. Many crystalline materials exhibit considerable anisotropy in their elastic constants, hence, these analysis techniques may not always be appropriate. The theoretical problem of a rigid indenter pressed into an elastic, anisotropic half-space has been considered by *Vlassak* and *Nix* [22.89]. Their aim was to identify the feasibility of interpreting data from a depth-sensing indentation apparatus for samples with elastic constants that are anisotropic. Nanoindentation experiments [22.90] have shown the validity of the elastic analysis for crystalline zinc, copper, and beta-brass. The observed indentation modulus for zinc, as predicted, varied by as much as a factor of 2 between different orientations. The variations in the observed hardness values for the same materials were smaller, with a maximum variation with orientation of 20% detected in zinc. While these variations are clearly detectable with nanoindentation techniques, the variations are small in comparison to the actual anisotropy of the test material's elastic properties. This is because the indentation modulus is a weighted average of the stiffness in all directions.

At this time the effects of anisotropy on the hardness measured using nanoindentation have not been fully explored. For materials with many active slip planes it is likely that the small anisotropy observed by *Vlassak* and *Nix* is correct once plastic flow has been initiated. It is possible, however, that for defect-free crystalline specimens with a limited number of active slip planes that very shallow nanoindentations may show a much larger anisotropy in the observed hardness and initial yield point load.

22.3.4 Fracture and Delamination

Indentation testing has been widely used to study fracture in brittle materials [22.91], but the lower loads and smaller deformation regions of nanoindentation tests make it harder to initiate cracks and, hence, less useful as a way to evaluate fracture toughness. To overcome these problems the cube corner geometry, which generates larger shear stresses than the Berkovich pyramid, has been used with nanoindentation testing to study fracture [22.92]. These studies have had mixed success, because the cube corner geometry blunts very quickly when used on hard materials. In many cases, brittle materials are very hard.

Depth sensing indentation is better suited to studying delamination of thin films. Recent work extends the

Part C | 22.3

research conducted by *Marshall* et al. [22.93, 94], who examined the deformation of residually stressed films by indentation. A schematic of their analysis is given by Fig. 22.24. Their indentations were several microns deep, but the basic analysis is valid for nanoindentations. The analysis has been extended to multilayers [22.95], which is important since it enables a quantitative assessment of adhesion energy when an additional stressed film has been deposited on top of the film and substrate of interest. The additional film limits the plastic deformation of the film of interest and also applies extra stress that aids in the delamination. After indentation, the area of the delaminated film is measured optically or with an AFM to assess the extent of the delamination. This measurement, coupled with the load-displacement data, enables quantitative assessment of the adhesion energy to be made for metals [22.96] and polymers [22.97].

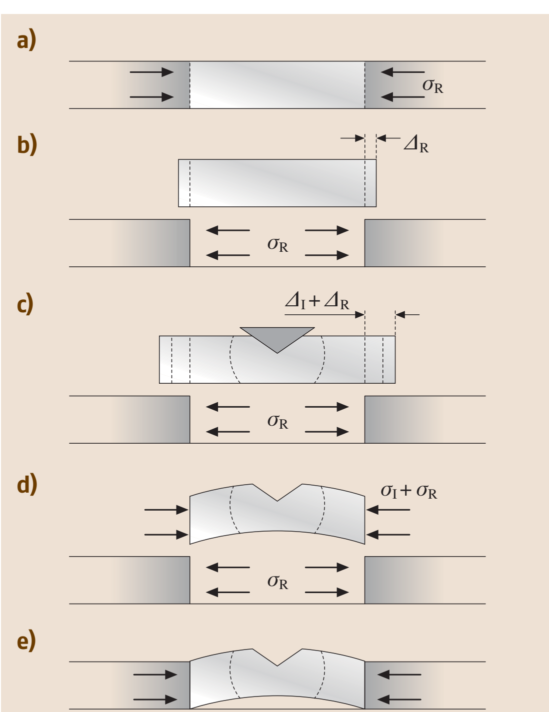

Fig. 22.24a–e To model delamination *Kriese* et al. [22.95] adapted the model developed by *Marshall* and *Evans* [22.93]. The model considers a segment of removed stressed film that is allowed to expand and then indented, thereby expanding it further. Replacing the segment in its original position requires an additional stress, and the segment bulges upwards

22.3.5 Phase Transformations

The pressure applied to the surface of a material during indentation testing can be very high. Equation (22.10) indicates that the pressure during plastic yielding is about three times the yield stress. For many materials, high hydrostatic pressures can cause phase transformations, and provided the transformation pressure is less than the pressure required to cause plastic yielding, it is possible during indentation testing to induce a phase transformation. This was first reported for silicon [22.98], but it has also been speculated [22.99] that many other materials may show the same effects. Most studies still focus on silicon because of its enormous technological importance, although there is some evidence that germanium also undergoes a phase transformation during the nanoindentation testing [22.100].

Recent results [22.21, 22, 41, 101, 102] indicate that there are actually multiple phase transformations during the nanoindentation of silicon. TEM of nanoindenta-

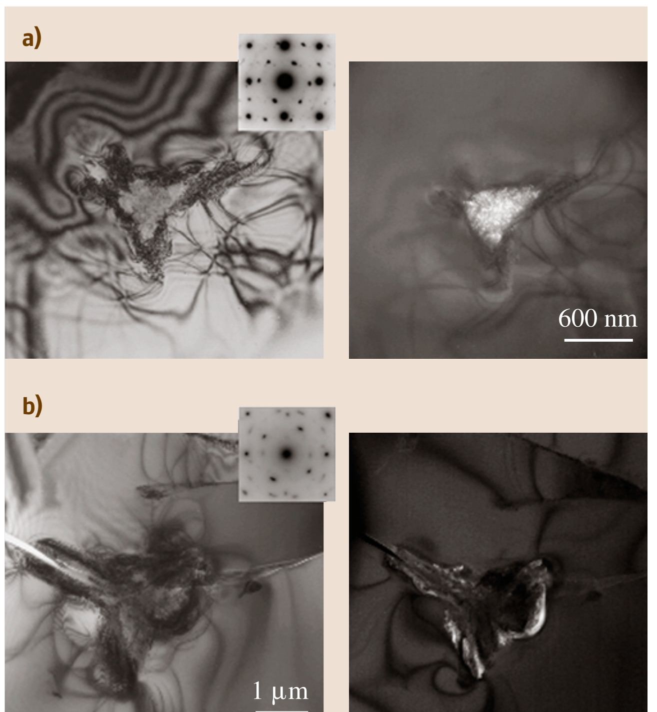

Fig. 22.25a,b Bright-field and dark-field TEM of **(a)** small and **(b)** large nanoindentations in Si. In small nanoindents the metastable phase BC-8 is seen in the center, but for large nanoindents BC-8 is confined to the edge of the indent, while the center is amorphous

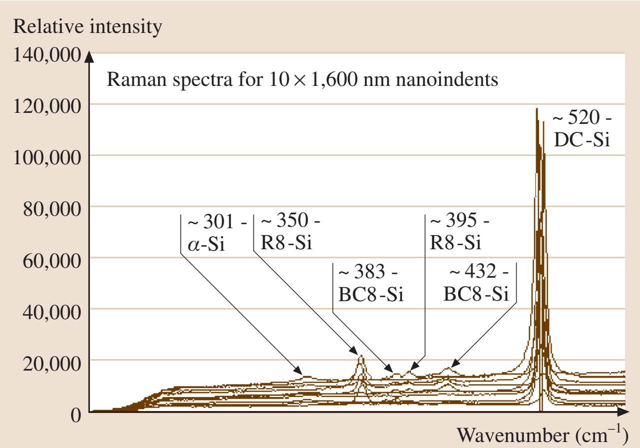

Fig. 22.26 Micro-Raman generally shows the BC-8 and R-8 Si phases that are at the edge of the nanoindents, but the amorphous phase in the center is not easy to detect, as it is often subsurface and the Raman peak is broad

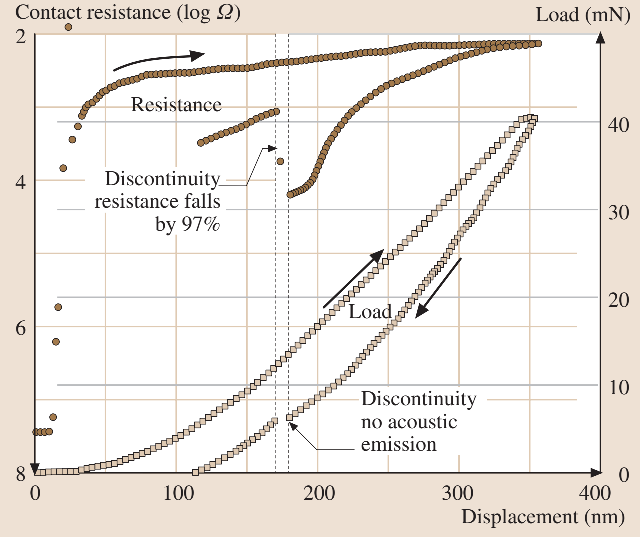

Fig. 22.27 Nanoindentation curves for deep indents on Si show a discontinuity during unloading and simultaneously a large drop in contact resistance

tions in diamond cubic silicon have shown the presence of amorphous-Si and the body-centered cubic BC-8 phase (see Fig. 22.25). Micro-Raman spectroscopy has indicated the presence of a further phase, the rhombhedral R-8 (see Fig. 22.26). For many nanoindentations on silicon there is a characteristic discontinuity in the unloading curve (see Fig. 22.27), which seems to correlate with a phase transformation. The exact sequence in which the phases form is still highly controversial with some [22.42], suggesting that the sequence during loading and unloading is:

Increasing load →
Diamond cubic Si → β-Sn Si

← Decreasing load
BC-8 Si and R-8 Si ← β-Sn Si

Other groups [22.21,22] suggest that the above sequence is only valid for shallow nanoindentations that do not exhibit an unloading discontinuity. For large nanoindentations that show an unloading discontinuity, they suggest the sequence will be:

Increasing load →
Diamond cubic Si → β-Sn Si

← Decreasing load
α-Si ← BC-8 Si and R-8 Si ← β-Sn Si

The disagreement is over the origin of the unloading discontinuity. *Mann* et al. [22.21] suggest it is due to the formation of amorphous silicon, while *Gogotsi* et al. [22.42] believe it is the β-Sn Si to BC-8 or R-8 transformation. Mann et al. argue that the high contact resistance before the discontinuity and the low contact resistance afterwards rule out the discontinuity being the metallic β-Sn Si transforming to the more resistive BC-8 or R-8. The counterargument is that amorphous Si is only seen with micro-Raman spectroscopy when the unloading is very rapid or there is a large nanoindentation with no unloading discontinuity. The importance of unloading rate and cracking in determining the phases present are further complications. The controversy will remain until in situ characterization of the phases present is undertaken.

22.4 Thin Films and Multilayers

In almost all real applications, surfaces are coated with thin films. These may be intentionally added such as hard carbide coatings on a tool bit, or they may simply be native films such as an oxide layer. It is also likely that there will be adsorbed films of water and organic contaminants that can range from a single molecule in thickness up to several nanometers. All of these films, whether native or intentionally placed on the surface, will affect the surface's mechanical behavior on the nanoscale. Adsorbates can have a significant impact on the surface forces [22.3] and, hence, the geometry and stability of asperity contacts. Oxide films can have dramatically different mechanical properties to the bulk and will also modify the surface forces. Some of the effects of native films have been detailed in the earlier sections on dislocation nucleation and adhesive contacts.

The importance of thin films in enhancing the mechanical behavior of surfaces is illustrated by the abundance of publications on thin film mechanical properties (see for instance *Nix* [22.88] or *Cammarata* [22.31] or *Was* and *Foecke* [22.103]). In the following sections, the mechanical properties of films intentionally deposited on the surface will be discussed.

22.4.1 Thin Films

Measuring the mechanical properties of a single thin surface film has always been difficult. Any measurement performed on the whole sample will inevitably be dominated by the bulk substrate. Nanoindentation, since it looks at the mechanical properties of a very small region close to the surface, offers a possible solution to the problem of measuring thin film mechanical properties. However, there are certain inherent problems in using nanoindentation testing to examine the properties of thin films. The problems stem in part from the presence of an interface between the film and substrate. The quality of the interface can be affected by many variables, resulting in a range of effects on the apparent elastic and plastic properties of the film. In particular, when the deformation region around the indent approaches the interface, the indentation curve may exhibit features due to the thin film, the bulk, the interface, or a combination of all three. As a direct consequence of these complications, models for thin-film behavior must attempt to take into account not only the properties of the film and substrate, but also the interface between them.

If, initially, the effect of the interface is neglected, it is possible to divide thin-coated systems into a number of categories that depend on the values of E (elastic modulus) and Y (the yield stress) of the film and substrate. These categories are typically [22.104, 105]:

1. coatings with high E and high Y, substrates with high E and high Y;
2. coatings with high E and high Y, substrates with high or low E and low Y;
3. coatings with high or low E and low Y, substrates with high E and high Y;
4. coatings with high or low E and low Y, substrates with high or low E and low Y.

The reasons for splitting thin film systems into these different categories have been amply demonstrated experimentally by *Whitehead* and *Page* [22.104, 105] and theoretically by *Fabes* et al. [22.106]. Essentially, hard, elastic materials (high E and Y) will possess smaller plastic zones than soft, inelastic (low E and Y) materials. Thus, when different combinations of materials are used as film and substrate, the overall plastic zone will differ significantly. In some cases, the plasticity is confined to the film, and in other cases, it is in both the film and substrate, as shown by Fig. 22.28. If the standard nanoindentation analysis routines are to be used, it is essential that the plastic zone and the elastic strain field are

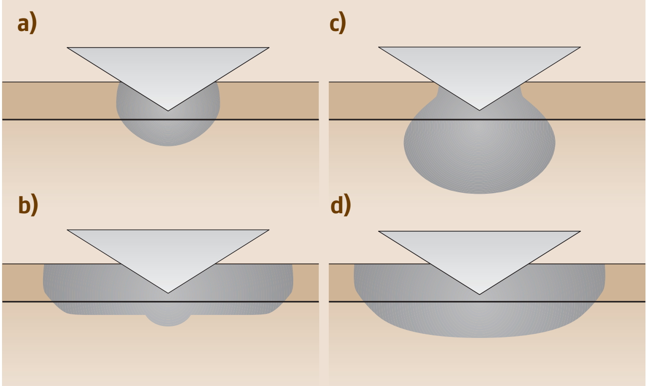

Fig. 22.28a–d Variations in the plastic zone for indents on films and substrates of different properties. **(a)** Film and substrate have high E and Y, **(b)** film has a high E and Y, substrate has a high or low E and low Y, **(c)** film has a high or low E and a low Y, and substrate has a high E and Y, **(d)** film has a high or low E and a low Y, and substrate has a high or low E and a low Y

both confined to the film and do not reach the substrate. Clearly, this is difficult to achieve unless extremely shallow nanoindentations are used. There is an often quoted 10% rule, that says nanoindents in a film must have a depth of less than 10% of the film's thickness if only the film properties are to be measured. This has no real validity [22.107]. There are film/substrate combinations for which 10% is very conservative, while for other combinations even 5% may be too deep. The effect of the substrate for different combinations of film and substrate properties has been studied using FEM [22.108], which has shown that the maximum nanoindentation depth to measure film only properties decreases in moving from soft on hard to hard on soft combinations. For a very soft film on a hard substrate, nanoindentations of 50% of the film thickness are alright, but this drops to $< 10\%$ for a hard film on a soft substrate. For a very strong film on a soft substrate, the surface film behaves like an elastic membrane or a bending plate.

Theoretical analysis of thin-film mechanical behavior is difficult. One theoretical approach that has been adopted uses the volumes of plastically deformed material in the film and substrate to predict the overall hardness of the system. However, it should be noted that this method is only really appropriate for soft coatings and indentation depths below the thickness of the coating (see cases c and d of Fig. 22.28), otherwise the behavior will be closer to that detailed later and shown by Fig. 22.29.

The technique of combining the mechanical properties of the film and substrate to evaluate the overall hardness of the system is generally referred to as the rule of mixtures. It stems from work by *Burnett* et al. [22.109–111] and *Sargent* [22.112], who derived a weighted average to relate the "composite" hardness (H) to the volumes of plastically deformed material in the film (V_f) and substrate (V_s) and their respective values of hardness, H_f and H_s. Thus,

$$H = \frac{H_f V_f + H_s V_s}{V_{total}} , \tag{22.26}$$

where V_{total} is $V_f + V_s$.

Equation (22.26) was further developed by *Burnett* and *Page* [22.109] to take into account the indentation size effect. They replaced H_s with $K\delta_c^{n-2}$, where K and n are experimentally determined constants dependent on the indenter and sample, and δ_c is the contact depth. This expression is derived directly from Meyer's law for spherical indentations, which gives the relationship $P = Kd^n$ between load, P, and the indentation dimension, d. Burnett and Page also employed a further refinement to enable the theory to fit experimental results from a specific sample, ion-implanted silicon. This particular modification essentially took into account the different sizes of the plastic zones in the two materials by multiplying H_s by a dimensionless factor (V_s/V_{total}). While this seems to be a sensible approach, it is mostly empirical, and the physical justification for using this particular factor is not entirely clear. Later, *Burnett* and *Rickerby* [22.110, 111] took this idea further and tried to generalize the equations to take into account all of the possible scenarios. Thus, the following equations were suggested:

$$H = \frac{H_f \left(\Omega^3\right) V_f + H_s V_s}{V_{total}} , \tag{22.27}$$

$$H = \frac{H_f V_f + H_s \left(\Omega^3\right) V_s}{V_{total}} . \tag{22.28}$$

The first of these, (22.27), deals with the case of a soft film on a hard substrate, and the second, (22.28), with a hard film on a soft substrate. The Ω term expresses the variation of the total plastic zone from the ideal hemispherical shape. This was taken still further by *Bull* and *Rickerby* [22.113], who derived an approximation for Ω based on the film and substrate zone radii being related to their respective hardness and elastic modulii [22.114, 115]. Hence:

$$\Omega = (E_f H_s / E_s H_f)^l , \tag{22.29}$$

where l is determined empirically. E_f and H_f and E_s and H_s are the elastic modulus and hardness of the film and substrate, respectively.

Experimental data [22.116] indicate that the effect of the substrate on the elastic modulus of the film can be quite different than the effect on hardness, due to

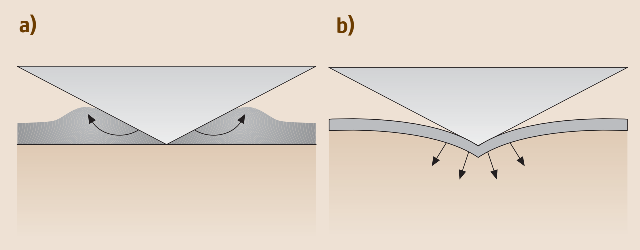

Fig. 22.29a,b Two different modes of deformation during nanoindentation of films. In **(a)** materials move upwards and outwards, while in **(b)** the film acts like a membrane and the substrate deforms

the zones of the elastic and plastic strain fields being different sizes.

Chechechin et al. [22.117] have recently studied the behavior of Al_2O_3 films of various thicknesses on different substrates. Their results indicate that many of the models correctly predict the transition between the properties of the film and those of the substrate, but do not always fit the observed hardness against depth curves. This group have also studied the pop-in behavior of Al_2O_3 films [22.118] and have attempted to model the range of loads and depths at which they occur via a Weibull-type distribution, as utilized in fracture analysis.

A point raised by Burnett and Rickerby should be emphasized. They state that there are two very distinct modes of deformation during nanoindentation testing. The first, referred to as *Tabor*'s [22.48] model for low Y/E materials, involves the buildup of material at the side of the indenter through movement of material at slip lines. The second, for materials with large Y/E does not result in surface pile-up. The displaced material is then accommodated by radial displacements [22.115]. The point is that a thin, strong, and well-bonded surface film can cause a substrate that would normally deform by Tabor's method to behave more like a material with high Y/E (see Fig. 22.29). It should be noted that this only applies as long as the film does not fail.

In recent theoretical and experimental studies the importance of material pile-up and sink-in has been investigated extensively. As discussed in an earlier section, pile-up can be increased by residual compressive stresses, but even in the absence of residual stresses pile-up can introduce a significant error in the calculated contact area. This is most pronounced in materials that do not work-harden [22.62]. For these materials using the Oliver and Pharr method fails to account for the pile-up and results in a large error in the values for E and H. For thin films *Tsui* et al. have used a focused ion beam to section through Knoop indentations in both soft films on hard substrates [22.69] and hard films on soft substrates [22.70]. The soft films, as expected, exhibit pile-up, while the hard film acts more like a membrane and the indentation exhibits sink-in with most of the plasticity in the substrate. Thus, there are three clearly identifiable factors affecting the pile-up and sink-in around nanoindents during testing of thin films:

1. Residual stresses
2. Degree of work-hardening
3. Ratio of film and substrate mechanical properties.

The bonding or adhesion between the film and substrate could also be added to this list. And it should not be forgotten that the depth of the nanoindentation relative to the film thickness also affects pile-up. For a very deep nanoindentation into a thin, soft film on a hard substrate pile-up is reduced, due to the combined constraints on the film of the tip and substrate [22.119]. Due to all of these complications, using nanoindentation to study thin film mechanical properties is fraught with danger. Many unprepared researchers have misguidedly taken the values of E and H obtained during nanoindentation testing to be absolute values only to find out later that the values contain significant errors.

Many of the problems associated with nanoindentation testing are related to incorrectly calculating the contact area, A. The *Joslin* and *Oliver* method [22.71] is one way that A can be removed from the calculations. This approach has been used with some success to look at strained epitaxial II/VI semiconductor films [22.120], but there is evidence that the lattice mismatch in these films can cause dramatic changes in the mechanical properties of the films [22.121]. This may be due to image forces and the film/substrate interface acting as a barrier to dislocation motion. Recently, it has been shown that using films and substrates with known matching elastic moduli, it is possible to use the assumption of constant elastic modulus with depth to evaluate H [22.122]. In effect, this is using (22.1) to evaluate A from the contact stiffness data, and then substituting the value for A into (22.12). The value of E is measured independently, for instance, using acoustic techniques.

22.4.2 Multilayers

Multilayered materials with individual layers that are a micron or less in thickness, sometimes referred to as superlattices, can exhibit substantial enhancements in hardness or strength. This should be distinguished from the super modulus effect discussed earlier, which has been shown to be largely an artifact. The enhancements in hardness can be as much as 100% when compared to the value expected from the rule of mixtures, which is essentially a weighted average of the hardness for the constituents of the two layers [22.123]. Table 22.1 shows how the properties of isostructural multilayers can show a substantial increase in hardness over that for fully interdiffused layers. The table also shows how there can be a substantial enhancement in hardness for non-isostructural multilayers compared to the values for the same materials when they are homogeneous.

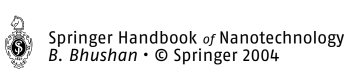

Table 22.1 Results for some experimental studies of multilayer hardness

Study	Multilayer	Maximum hardness and multilayer repeat length	Reference hardness value	Range of hardness values for multilayers
Isostructural Knoop hardness [22.124]	Cu/Ni	524 at 11.6 nm	284 (interdiffused)	295–524
Non-isostructural Nanoindentation [22.125]	Mo/NbN	33 GPa at 2 nm	NbN – 17 GPa Mo – 2.7 GPa Wo – 7 GPa	12–33 GPa
	W/NbN	29 GPa at 3 nm	(individual layer materials)	23–29 GPa

There are many factors that contribute to enhanced hardness in multilayers. These can be summarized as [22.103]:

1. Hall-Petch behavior
2. Orowan strengthening
3. Image effects
4. Coherency and thermal stresses
5. Composition modulation

Hall-Petch behavior is related to dislocations piling-up at grain boundaries. (Note that pile-up is used to describe two distinct effects: One is material building up at the side of an indentation, the other is an accumulation of dislocations on a slip-plane.) The dislocation pile-up at grain boundaries impedes the motion of dislocations. For materials with a fine grain structure there are many grain boundaries, and, hence, dislocations find it hard to move. In polycrystalline multilayers, it is often the case that the size of the grains within a layer scales with the layer thickness so that reducing the layer thickness reduces the grain size. Thus, the Hall-Petch relationship (below) should be applicable to polycrystalline multilayer films with the grain size, d_g, replaced by the layer thickness.

$$Y = Y_0 + k_{HP}\, d_g^{-0.5} , \quad (22.30)$$

where Y is the enhanced yield stress, Y_0 is the yield stress for a single crystal, and k_{HP} is a constant.

There is an ongoing argument about whether Hall-Petch behavior really takes place in nanostructured multilayers. The basic model assumes many dislocations are present in the pile-up, but such large dislocation pile-ups are not seen in small grains [22.126] and are unlikely to be present in multilayers. As a direct consequence, studies have found a range of values, between 0 and −1, for the exponent in (22.30), rather than the −0.5 predicted for Hall-Petch behavior.

Orowan strengthening is due to dislocations in layered materials being effectively pinned at the interfaces. As a result, the dislocations are forced to bow out along the layers. In narrow films, dislocations are pinned at both the top and bottom interfaces of a layer and bow out parallel to the plane of the interface [22.127, 128]. Forcing a dislocation to bow out in a layered material requires an increase in the applied shear stress beyond that required to bow out a dislocation in a homogeneous sample. This additional shear stress would be expected to increase as the film thickness is reduced.

Image effects were suggested by *Koehler* [22.129] as a possible source of enhanced yield stress in multilayered materials. If two metals, A and B, are used to make a laminate and one of them, A, has a high dislocation line energy, but the other, B, has a low dislocation line energy, then there will be an increased resistance to dislocation motion due to image forces. However, if the individual layers are thick enough that there may be a dislocation source present within the layer, then dislocations could pile-up at the interface. This will create a local stress concentration point and the enhancement to the strength will be very limited. If the layers are thin enough that there will be no dislocation source present, the enhanced mechanical strength may be substantial. In Koehler's model only nearest neighbor layers were taken to contribute to the image forces. However, this was extended to include more layers [22.130] without substantial changes in the results. The consequence on image effects of reducing the thickness of the individual layers in a multilayer is that it prevents dislocation sources from being active within the layer.

For many multilayer systems there is an increase in strength as the bilayer repeat length is reduced, but there is often a critical repeat length (e.g., 3 nm for the W/NbN multilayer of Table 22.1) below which the strength falls. One explanation for the fall in strength involves the effects of coherency and thermal stresses on dislocation energy. Unlike image effects where the energy of dislocations are a maximum or minimum in the center of layers, the energy maxima and minima are at the interfaces for coherency stresses. Combining the effects of varying moduli and coherency stresses shows that the dependence of strength on layer thickness has a peak near the repeat period where coherency strains begin decreasing [22.131].

Another source of deviations in behavior at very small repeat periods is the imperfect nature of interfaces. With the exception of atomically perfect epitaxial films, interfaces are generally not atomically flat and there is some interdiffusion. For the Cu/Ni film of Table 22.1, the effects of interdiffusion on hardness were examined [22.124] by annealing the multilayers. The results were in agreement with a model by *Krzanowski* [22.132] that predicted the variations in hardness would be proportional to the amplitude of the composition modulation.

It is interesting to note that the explanations for enhanced mechanical properties in multilayered materials are all based on dislocation mechanisms. So it would seem natural to assume that multilayered materials that do not contain dislocations will show no enhanced hardness over their rule of mixtures values. This has been verified by studies on amorphous metal multilayers [22.133], which shows that the hardness of the multilayers, firstly, lies between that of the two individual materials and, secondly, has almost no variation with repeat period.

22.5 Developing Areas

Over the past 20 to 30 years, the driving force for studying nanomechanical behavior of surfaces and thin films has been largely, though not exclusively, the microelectronics industry. The importance of electronics to the modern world is only likely to grow in the foreseeable future, but other technological areas may overtake microelectronics as the driving force for research, including the broad fields of biomaterials and nanotechnology. In several places in this chapter, a number of developing areas have been mentioned. These include nanoscale measurements of viscoelasticity and the study of environmental effects (temperature and surface chemistry) on nanomechanical properties. Both of these topics will be vital in the study of biological systems and, as a result, will be increasingly important from a research point of view.

We still have a relatively rudimentary understanding of the nanomechanics of complex biological systems such as bone cells (osteoblasts and osteoclasts) and skin cells (fibroblasts), or even, for that matter, simpler biological structures such as dental enamel. For example, Fig. 22.30 shows how the mechanical properties of dental enamel can vary within a single tooth [22.134]. But this is still a relatively large-scale measure of mechanical behavior. The prismatic structure of enamel means that there are variations in mechanical properties on a range of scales from millimeters down to nanometers.

In terms of data analysis, there remains much to be done. If an analysis method can be developed that deals with the problems of pile-up and sink-in, the utility of nanoindentation testing will be greatly enhanced.

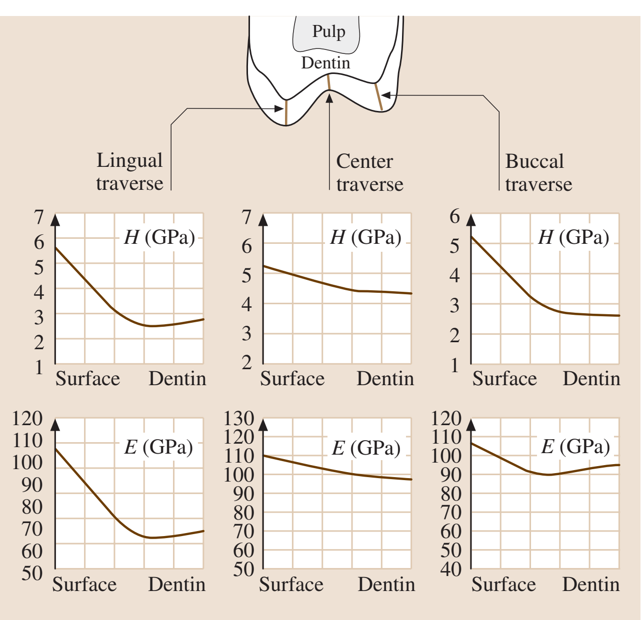

Fig. 22.30 Variations in E and H across human dental enamel. The sample is an upper 2nd molar cut in cross section from the lingual to the buccal side. Nanoindentations are performed across the surface to examine how the mechanical properties vary

23. Atomistic Computer Simulations of Nanotribology

Molecular dynamics (MD) and related simulation techniques are powerful tools for improving our understanding of nanotribology. In simulations, materials properties and boundary conditions can be varied at will, and the resulting changes in both macroscopic variables and the dynamics of individual atoms can be observed. This allows one to study systematically the effects of many different factors on friction and wear at the nano-scale. Some examples that are considered in this chapter are (i) the symmetry of contacting surfaces (disordered vs. crystalline and with or without common periods), (ii) surface elasticity, (iii) surface curvature or topology, (iv) interfacial adhesion, and (v) lubricant and/or contaminant molecules present at the interface. Results from simulations and experiments on isolated nano-scale contacts often contradict our experience from macroscopic systems. Kinetic friction coefficients can be orders of magnitude smaller than those observed in macroscopic experiments. Detailed calculations even suggest that there should be no static friction between most pairs of clean, chemically passivated surfaces unless the load is large enough to produce wear. Simulations that test a series of possible mechanisms for static friction are described. Geometrical interlocking can produce static friction in contacts containing only a few atoms, such as an atomic force microscope tip. Larger contacts only exhibit static friction when there is wear, or when the surfaces are separated by a glassy contaminant layer that locks them together. Most surfaces are coated by such films and they are shown to yield friction forces that agree with both nanoscale and macroscopic experiments.

References 735

One of the main barriers to the design of nanodevices with moving parts is our limited understanding of nanotribology; friction, lubrication and wear at the nanometer scale. New experimental methods such as the atomic force microscope (AFM) [23.1,2], quartz-crystal microbalance (QCM) [23.3], and surface forces apparatus (SFA) [23.4, 5] have revolutionalized our ability to measure friction in systems with atomic scale dimensions. However, the results are often qualitatively different than in macroscopic systems. For example, solids may slide more easily than fluids [23.3, 6] and fluids may behave like solids [23.4, 7]. These results have also revealed that there are gaps in our understanding of the molecular underpinnings of macroscopic tribology. There is a growing recognition that the behavior of nanometer-thick interfacial layers is crucial to tribology in systems of all scales, which has led to a fruitful convergence of researchers from many disciplines.

Understanding friction is an interesting and challenging scientific task, owing to the many factors that come into play: elastic and plastic properties of the two solids in relative sliding motion, surface roughness in multi-asperity contacts and tip geometry in single asperity contacts, geometric correlation between the solids in a microcontact, the amount of lubricant between the two solids, the physical nature of the lubricants, chemical

properties and reactions, adhesion, thermal fluctuations and aging, heat conductivity, etc.

Computer simulations have played an increasingly important role in improving our understanding of tribological phenomena. Unlike experiments, they allow us to perfectly control the geometry, the chemical composition, the sliding conditions, etc. and thus make it possible to explore the effect of each variable on friction, lubrication, and wear. Moreover, theorists have no other general approach to analyze processes like friction and wear. There is no known principle like minimization of free energy that determines the steady state of nonequilibrium systems. Even if there were, simulations would be needed to address the complex systems of interest, just as in many equilibrium problems.

Two different types of friction are commonly defined. Static friction, F_s, is the lateral force that must be applied to initiate sliding of one object over another, while kinetic friction, F_k, is the lateral force that must be applied to maintain sliding. At the macroscopic scale both forces usually obey Amontons's laws, which state that friction is proportional to the load pushing the surfaces together and is independent of area. However, there are obvious exceptions, such as tape, where friction occurs at zero load.

Despite significant experimental, theoretical, and computational efforts, no consensus has yet been reached on the relevant atomistic origins of friction between two solid bodies. Strictly speaking, static friction is not a force but a threshold. Its presence implies that the objects have locked together into a local energy minimum that must be overcome by the external force. This threshold force is observed between all the objects around us, yet its molecular origins have remained baffling. How does almost every pair of surfaces manage to lock together, and why does the friction usually obey Amontons's laws? Why does F_k not vanish linearly at small sliding velocities as it would if sliding occurred adiabatically? Different mechanisms have been suggested, such as geometric interlocking, elastic instabilities, interlocking mediated by so-called third bodies, plastic deformation, and crack propagation, to name a few. All these mechanisms may well be applicable, although each one under different circumstances.

In the following, we present a selected overview of the major results from the growing simulation literature. The emphasis is on providing a coherent picture of the key issues in the field, rather than a historical or a complete review. A much more detailed review of tribological computer simulations, including the sliding of adsorbed layers on surfaces, stick-slip motion, tribochemistry, cutting, high-velocity friction between metals, etc. has been given recently by *Robbins* et al. [23.8], and a review of the theoretical foundations of nanotribological issues is given in *Müser* et al. [23.9]. Reviews emphasizing the importance of surface chemistry and the role of self-assembled monolayers have been provided by *Harrison* et al. [23.10, 11].

23.1 Molecular Dynamics

The simulations described in this chapter all use an approach called classical molecular dynamics (MD), which is described extensively in a number of review articles and books [23.12, 13]. The basic outline of the method is straightforward. One begins by defining the interaction potentials. These produce forces on the individual particles whose dynamics will be followed, typically atoms or molecules. Next, the geometry and boundary conditions are specified, and initial coordinates and velocities are given to each particle. Then, the equations of motion for the particles are integrated numerically, stepping forward in time by discrete steps of size Δt. Quantities such as forces, velocities, work, heat flow, and correlation functions are calculated as a function of time to determine their steady-state values and dynamic fluctuations. The relation between changes in these quantities and the motion of individual molecules is also explored.

When designing a simulation, care must be taken to choose interaction potentials and ensembles that capture the essential physics that is to be addressed. The potentials may be as simple as ideal spring constants for studies of general phenomena, or as complex as electronic density-functional calculations in quantitative simulations. The ensemble can also be tailored to the problem of interest. Solving Newton's equations yields a constant energy and volume, or microcanonical, ensemble. By adding terms in the equation of motion that simulate heat baths or pistons, simulations can be done at constant temperature, pressure, lateral force, or velocity. Constant chemical potential can also be maintained by adding or removing particles using Monte Carlo methods or explicit particle baths.

The amount of computational effort typically grows linearly with both the number of particles, N, and the number of time-steps, M. The prefactor increases rapidly

with the complexity of the interactions, and substantial ingenuity is required to achieve linear scaling with N for long-range interactions or density-functional approaches. Complex interactions also lead to a wide range of characteristic frequencies such as fast bond-stretching and slow bond-bending modes. Unfortunately, the time step Δt must be small compared to the period of the slowest mode ($\lessapprox 5\%$). This means that many time steps are needed before one obtains information about the slow modes.

The maximum feasible simulation size has increased continuously with advances in computer technology, but remains relatively limited. The product of N times M in the largest simulations described below is about 10^{12}. A cubic region of 10^6 atoms would have a side of about 50 nm. Such linear dimensions allow reasonable models of an atomic force microscope tip, the boundary lubricant in a surface force apparatus, or an individual asperity contact on a rough surface. However, 10^6 time steps is only about 10 ns, which is much shorter than experimental measurement times. This requires intelligent choices in the problems that are attacked and how results are extrapolated to experiments. It also limits sliding velocities to relatively high values, typically meters per second or above.

A number of efforts are underway to increase the accessible time scale, but the problem remains unsolved. Current algorithms attempt to follow the deterministic equations of motion, usually with the Verlet or predictor-corrector algorithms [23.12]. One alternative approach is to make stochastic steps. This would be a nonequilibrium generalization of the Monte Carlo approach that is commonly used in equilibrium systems. The difficulty is that there is no general principle for determining the appropriate probability distribution of steps in a nonequilibrium system.

In the following subsection, we describe some of the potentials that are commonly used and the situations where they are appropriate. The next two subsections describe methods for maintaining constant temperature and constant load. The section concludes with discussions of the challenges associated with the wide range of relevant time and length scales, and common pitfalls in simulations.

23.1.1 Model Potentials

A wide range of potentials has been employed in studies of tribology. Many of the studies described in the next section use simple ideal springs and sine-wave potentials. The Lennard-Jones potential gives a more realistic representation of typical interatomic interactions and is also commonly used in studies of general behavior. In order to model specific materials, more detail must be built into the potential. Simulations of metals frequently use the embedded atom method, while studies of hydrocarbons use potentials that include bond-stretching, bending, torsional forces, and even chemical reactivity. In this section, we give a brief definition of the most commonly used models. The reader may consult the original literature for more detail.

The Lennard-Jones (LJ) potential is a two-body potential that is commonly used for interactions between atoms or molecules with closed electron shells. It is applied not only to the interaction between noble gases, but also to the interaction between different segments on polymers. In the latter case, one LJ particle may reflect a single atom on the chain (explicit atom model), a CH_2 segment (united atom model), or even a Kuhn's segment consisting of several CH_2 units (coarse-grained model). United atom models [23.14] have been shown by *Paul* et al. [23.15] to successfully reproduce explicit atom results for polymer melts. Significant progress has been made recently to map back from the coarse-grained models to more detailed models [23.16, 17].

The 12-6 LJ potential has the form

$$U(r_{ij}) = 4\epsilon\left[\left(\frac{\sigma}{r_{ij}}\right)^{12} - \left(\frac{\sigma}{r_{ij}}\right)^{6}\right] , \qquad (23.1)$$

where r_{ij} is the distance between particles i and j, ϵ is the LJ interaction energy, and σ is the LJ diameter. The exponents 12 and 6 used above are very common, but other values may be chosen depending on the system of interest. Many of the simulation results discussed in subsequent sections are expressed in units derived from ϵ, σ, and a characteristic mass of the particles. For example, the standard LJ time unit is defined as $t_{LJ} = \sqrt{m\sigma^2/\epsilon}$ and would typically correspond to a few picoseconds. A convenient time step is $\Delta t = 0.005 t_{LJ}$ for a LJ liquid or solid at external pressures and temperatures that are not too large.

Most realistic atomic potentials cannot be expressed as two-body potentials. For example, bond angle potentials in a polymer are effectively three-body interactions and torsional potentials correspond to four-body interactions. Classical models of these interactions [23.18, 19] assume that a polymer is chemically inert and interactions between different molecules are modeled by two-body potentials. In the most sophisticated models, bond-stretching, bending, and torsional energies depend on the position of neighboring molecules and bonds

are allowed to rearrange [23.20, 21]. Such generalized model potentials are needed to model friction-induced chemical interactions.

For the interaction between metals, a different approach has proven fruitful. The embedded atom method (EAM) developed by *Daw* et al. [23.22] includes a contribution in the potential energy associated with the cost of "embedding" an atom in the local electron density ρ_i produced by surrounding atoms. The total potential energy U is approximated by

$$U = \sum_i \tilde{F}_i(\rho_i) + \sum_i \sum_{j<i} \phi_{ij}(r_{ij}) \,, \qquad (23.2)$$

where $\tilde{F}_i$ is the embedding energy, whose functional form depends on the particular metal. The pair potential $\phi_{ij}(r_{ij})$ is a doubly screened short-range potential reflecting core-core repulsion. The computational cost of the EAM is not substantially greater than pair potential calculations, because the density ρ_i is approximated by a sum of independent atomic densities. When compared to simple two-body potentials such as Lennard–Jones or Morse potentials, the EAM has been particularly successful in reproducing experimental vacancy formation energies and surface energies, even though the potential parameters were only adjusted to reproduce bulk properties. This feature makes the EAM an important tool in tribological applications, where surfaces and defects play a major role.

23.1.2 Maintaining Constant Temperature

An important issue for tribological simulations is temperature regulation. The work done when two walls slide past each other is ultimately converted into random thermal motion. The temperature of the system would increase indefinitely if there was no way for this heat to flow out of the system. In an experiment, heat flows away from the sliding interface into the surrounding solid. In simulations, the effect of the surrounding solid must be mimicked by coupling the particles to a heat bath.

Techniques for maintaining constant temperature T in equilibrium systems are well developed. Equipartition guarantees that the average kinetic energy of each particle along each Cartesian coordinate is $k_B T/2$, where k_B is Boltzmann's constant. To thermostat the system, the equations of motion are modified, so that the average kinetic energy stays at this equilibrium value. This approach assumes that T is not too small compared to the Debye temperature, so that quantum statistics are not important. The applicability of classical MD decreases at lower T.

One class of approaches removes or adds kinetic energy to the system by multiplying the velocities of all particles by the same global factor. In the simplest version, velocity rescaling, the factor is chosen to keep the kinetic energy exactly constant at each time step. However, in a true constant temperature ensemble there are fluctuations in the kinetic energy. Improvements such as the Berendsen and Nosé–Hoover methods [23.23] add equations of motion that gradually scale the velocities to maintain the correct average kinetic energy over a longer time scale.

Another approach is to couple each atom to its own local thermostat [23.24, 25]. The exchange of energy with the outside world is modeled by a Langevin equation that includes a damping coefficient γ and a random force $f_i(t)$ on each atom i. The equations of motion for the α component of the position $x_{i\alpha}$ become:

$$m_i \frac{d^2 x_{i\alpha}}{dt^2} = -\frac{\partial}{\partial x_{i\alpha}} U - m_i \gamma \frac{dx_{i\alpha}}{dt} + f_{i\alpha}(t) \,, \qquad (23.3)$$

where U is the total potential energy and m_i is the mass of the atom. To produce the appropriate temperature, the forces must be completely random, have zero mean, and have a second moment given by

$$\langle \delta f_{i\alpha}(t)^2 \rangle = 2 k_B T m_i \gamma / \Delta t \,. \qquad (23.4)$$

The damping coefficient γ must be large enough that energy can be removed from the atoms without substantial temperature increases. However, it should be small enough that the trajectories of individual particles are not perturbed too strongly.

The first issue in nonequilibrium simulations is what temperature means. Near equilibrium hydrodynamic theories define a local temperature in terms of the equilibrium equipartition formula and the kinetic energy relative to the local rest frame [23.26]. In d dimensions, the definition is

$$k_B T = \frac{1}{dN} \sum_i m_i \left[\frac{d\boldsymbol{x}_i}{dt} - \langle \boldsymbol{v}(\boldsymbol{x}) \rangle \right]^2 \,, \qquad (23.5)$$

where the sum is over all N particles and $\langle \boldsymbol{v}(\boldsymbol{x}) \rangle$ is the mean velocity in a region around $\boldsymbol{x}$. As long as the change in mean velocity with position is sufficiently slow, $\langle \boldsymbol{v}(\boldsymbol{x}) \rangle$ is well-defined and this definition of temperature is on solid theoretical ground.

When the mean velocity difference between neighboring molecules becomes comparable to the random thermal velocities, temperature is not well-defined. An important consequence is that different strategies for defining and controlling temperature give very different structural order and shear forces [23.27–29]. In

addition, the distribution of velocities may become non-Gaussian, and different directions, α, may have different effective temperatures. Care should be taken in drawing conclusions from simulations in this extreme regime. Fortunately, the above condition typically implies that the velocities of neighboring atoms differ by something approaching 10% of the speed of sound. This is generally higher than any experimental velocity and would certainly lead to heat buildup and melting at the interface.

In order to mimic experiments, the thermostat is often applied only to those atoms that are at the outer boundary of the simulation cell. This models the flow of heat into surrounding material that is not included explicitly in the simulation. The resulting temperature profile is peaked at the shearing interface (e.g., *Bowden* et al. [23.30], *Khare* et al. [23.31]). In some cases the temperature rise may lead to undesirable changes in the structure and dynamics, even at the lowest velocity, that can be treated in the available simulation time. In this case, a weak thermostat applied throughout the system may maintain the correct temperature and yield the dynamics that would be observed in longer simulations at lower velocities. The safest course is to couple the thermostat only to those velocity components that are perpendicular to the mean flow.

There may be a marginal advantage to local Langevin methods in nonequilibrium simulations, because they remove heat only from atoms that are too hot. Global methods like Nosé–Hoover remove heat everywhere. This can leave high temperatures in the region where heat is generated, while other regions are at an artificially low temperature.

23.1.3 Imposing Load and Shear

The magnitude of the friction that is measured in an experiment or simulation may be strongly influenced by the way in which the normal load and tangential motion are imposed [23.32]. Experiments almost always impose a constant normal load. The mechanical system applying shear can usually be described as a spring attached to a stage moving at controlled velocity. The effective spring constant includes the compliance of all elements of the loading device, including the material on either side of the interface. Very compliant springs apply a nearly constant force, while very stiff springs apply a nearly constant velocity.

In simulations, it is easiest to treat the boundary of the system as rigid and to translate atoms in this region at a constant height and tangential velocity. However, this does not allow atoms to move around or up and over atoms on the opposing surface. Even the atomic-scale roughness of a crystalline surface can lead to order of magnitude variations in normal and tangential force with lateral position when sliding is imposed in this way [23.33]. The difference between constant separation and pressure simulations of thin films can be arbitrarily large, since they produce different power law relations between viscosity and sliding velocity [23.34].

One way of minimizing the difference between constant separation and pressure ensembles is to include a large portion of the elastic solids that bound the interface. This extra compliance allows the surfaces to slide at a more uniform normal and lateral force. However, the extra atoms greatly increase the computational effort.

To simulate the usual experimental ensemble more directly, one can add equations of motion that describe the position of the boundary [23.34–36], much as equations are added to maintain constant temperature. The boundary is given an effective mass that moves in response to the net force from interactions with mobile atoms and from the external pressure and lateral spring. The mass of the wall should be large enough that its dynamics are slower than those of individual atoms, but not too much slower or the response time will be long compared to the simulation time. The spring constant should also be chosen to produce an appropriate response time and ensemble.

23.1.4 The Time-Scale and Length-Scale Gaps

One important motivation of tribological computer simulations is to find the relevant atomistic processes that occur in a single, well-defined sliding contact such as in the SFA or in the AFM. While it has become computationally feasible to study atomistically the core of a nanometer-scale AFM contact, the sliding speeds, v_{sl}, employed in the simulations are still about ten decades larger than in experiments. The use of clever new algorithms such as kinetic Monte Carlo might prove fruitful to overcome this time-scale gap in a brute-force way. However, such an approach is not necessarily required in order to make a meaningful comparison between experiment and simulation. Instead, one can try to find out what the relevant time scales are and what parameters define them, e.g., by studying a phenomenological description of an embedded system under shear. In such an analysis, *Porto* et al. [23.37] found that the motion of the top plate/tip is not sensitive to the characteristic atomic frequencies ω_{mic} – as long as there is a rea-

sonable time-scale separation between ω_{mic} and the characteristic frequency of the tip Ω_{tip}. The experimentally relevant time scale Ω_{tip} is given by $\sqrt{K/M}$, where K is a restoring spring constant (defined by the tip's elasticity and/or the tip-substrate interactions) and M is the tip's inertia, eventually including the cantilever's mass. The experimental value of M will be about 20 decades larger than in the simulation, so values of the relevant parameter $v_{\text{sl}}\Omega_{\text{tip}}$ end up being similar in simulation and experiment. However, there is controvery over whether the tip can be treated as a mass point, or whether long-range elastic deformations in the tip are important [23.35], [23.38, Chap. 9.9].

Another way to overcome the gap in time scales is to alter interaction strengths, temperature, or other variables in order to accelerate the processes of interest. One such example is the cold welding study of *Müser* [23.40], where two dissimilar solids were placed on top of each other in vacuum. It would have been by no means desirable to base the calculations on interfacial interactions that correspond to typical experimental values, because the resulting time scales would be too long. By increasing the magnitude of the mixing energy, one drives the mixing process toward the same ground state on simulation time scales. This simple trick makes it possible to indirectly bridge several orders of magnitude in time scale between experiment and simulation.

Some open issues appear to require the explicit treatment of many different length scales. For example, the distribution of contacts and total contact area depend on both atomic-scale interactions at the surface and long-range elastic deformation of the bounding solid. Of particular interest is whether different contacting asperities can move independently, or whether those within an elastic coherence length l_{e} move in lock-step. Estimates of l_{e} range from the size of a single asperity [23.41] to many times the linear dimension of most objects of interest [23.42]. The correct value is of great importance to the question of whether clean, corrugated (macroscopic) surfaces have the potential to show elastic pinning and, hence, wearless friction. In order to address such issues, it will be necessary to do simulations that incorporate both atomistic and finite element methods (e.g., *Abraham* et al. [23.43]).

23.1.5 A Summary of Possible Traps

There are many possible traps that may render a well-done simulation useless or applicable only to highly idealized situations. In some aspects more care has to be taken than in equilibrium simulations, in other aspects one gets away with less care. We hope that this section helps to create some sensitivity as to what "ingredients" are relevant. For example, if we calculate the static friction force between two solids separated by a boundary lubricant in a MD simulation, the results will be fairly insensitive to the thermostat and to whether or not the thermostat is applied to the boundary lubricant. One should also avoid moves in which a "stuck" atom magically disappears from the contact through a grand canonical-type Monte Carlo move. The results depend more strongly on the thermostat if the lubricant is thick and the heating effects are of interest. In such a case, only the outermost atoms in the confining solids should be thermostated.

The typical situation in experiment is constant load, *not* constant separation. In some cases, there is something like a correspondence between these two "ensembles", but often there are *qualitative* differences between them, in particular, when strongly irreversible processes take place such as the production of wear particles [23.40]. Contacting experimental surfaces are also likely to have different geometry and chemistry – or at least different crystallographic orientations. However, most simulations consider the artificial case of contact

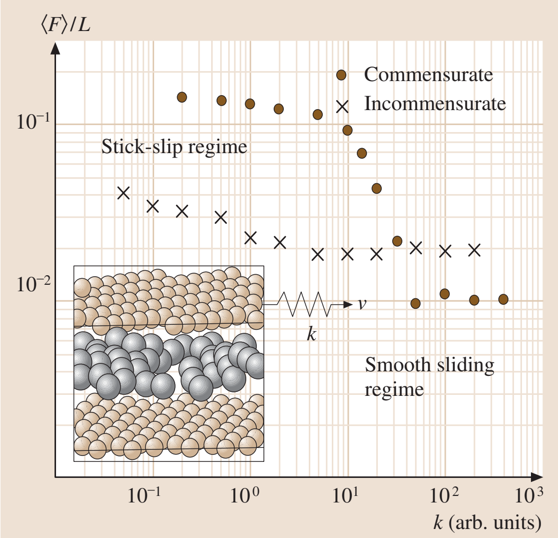

Fig. 23.1 Kinetic friction force F_{k} divided by load L as a function of spring constant k for commensurate and incommensurate walls lubricated by a quarter monolayer of LJ atoms. A schematic of the simulation is shown as well. The data shown was produced at a normal pressure of 0.4 GPa and a velocity of about 1 m/s. (After [23.39])

between identical, aligned crystals. This is the simplest example of a commensurate system, where the two surfaces share a common spatial period. As discussed below, the tribological behavior of commensurate systems is dramatically different than the more realistic case of incommensurate surfaces – even in the presence of a few layers of lubricant. One example of this is shown in Fig. 23.1 [23.39].

Another issue is the curvature of the surfaces. Real contacts typically take place between two curved surfaces or a curved and a flat surface. The pressure profiles differ from those in "flat" contacts, and that discrepancy can be relevant in certain circumstances. If we want to incorporate curvature effects, care should be taken that the resulting pressure profiles resemble a realistic profile, as was done by *Wenning* et al. [23.44].

23.2 Friction Mechanisms at the Atomic Scale

As noted in the introduction, static friction implies that the contacting surfaces have locked into a local free energy minimum. There have been many suggestions for how this can happen between nearly every pair of surfaces, whether macroscopic or nanoscale. The purpose of this section is to review some of these mechanisms and discuss their relevance to nanotribological experiments.

One obvious way that surfaces can interlock is through plastic deformation that brings the surfaces into conformity. A classic example is called plowing friction [23.30]. In this case a sharp feature on one surface penetrates into the opposing surface, causing permanent plastic deformation. The static friction represents the force needed to plow a groove through the surface. This type of motion has been observed in simulations [23.8, 9, 45]. and experiments (Sect. 20.6.1) using AFM probes with hard tips Because it leads to rapid wear, it is only desirable when one wants to remove material by abrasion or cutting.

Many nanotribological studies show friction without measurable wear, and this is the desirable mode of operation in most applications. For this reason, the following subsections focus on mechanisms that lock surfaces together without plastic deformation. We begin by discussing contact between rigid surfaces (Sect. 23.2.1), and then explore the ability of elastic deformations at the atomic scale (Sect. 23.2.2) or between contacts (Sect. 23.2.3) to lock surfaces together. We then describe one of the simulations that shows how unlikely these mechanisms are to yield static friction without wear unless the contact contains only a few tens of atoms (Sect. 23.2.4). The final two subsections consider the role of contaminants or "third bodies" that are present in the contacts between nearly all surfaces. First, changes in the behavior of lubricants with film thickness are discussed. Then molecularly thin films are shown to produce static and kinetic friction that is consistent with both nanoscale experiments and macroscopic observations.

23.2.1 Geometric Interlocking

Early theories of friction were based on the purely geometric argument that friction is caused by the interlocking of impenetrable and rigid surface asperities [23.30, 46]. The idea (Fig. 23.2) is that the top solid must be lifted up a typical slope, $\tan\alpha$, determined by roughness on the bottom surface. If there is no microscopic friction between the surfaces, then the minimum force to initiate sliding is

$$F_s = \mu_s L \tag{23.6}$$

with $\mu_s = \tan\alpha$. This result satisfies Amontons's laws with a constant coefficient of friction $\mu_s \equiv F_s/L = \tan\alpha$. In 1737, Bélidor obtained a typical experimental value of $\mu_s \approx 0.35$ by modeling rough surfaces as spherical asperities arranged to form commensurate crystalline walls [23.46]. However, asperities on real surfaces do not match as well as envisioned in these models or as sketched in Fig. 23.2. In most cases the average force vanishes because for every asperity or atom going up a ramp, there is another going down.

The sum of forces between crystalline surfaces is considered explicitly in the next subsection, and shown

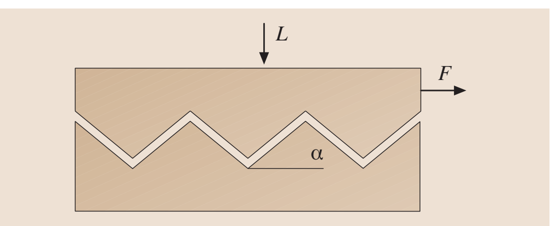

Fig. 23.2 Sketch of two surfaces with interlocking asperities. The top surface experiences a normal load L and a lateral force F, which attempts to pull the top surface up the slope $\tan\alpha$. The bottom wall is fixed

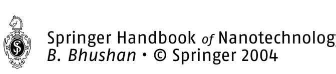

to vanish except in the unusual case where the surfaces have the same periodicity. In the case were one or both surfaces are random, simple analytic arguments show that μ_s will fall as $\mathcal{L}^{-d_{int}/2}$ when the linear size $\mathcal{L}$ of the contact goes to infinity [23.47], provided that the surface roughnesses are small and the solids are completely rigid. Here, d_{int} is the dimension of the contact and the pressure normal to the interface is assumed to be kept constant. This result is in contradiction with one of Amontons's laws, namely, the independence of F_s on the area of contact A. Nevertheless, the linear relation between F_s and L at fixed A is maintained if one assumes that the surfaces are not completely impenetrable but repel via an energy penalty that increases exponentially fast with increasing overlap of the two solids [23.47]. The resulting theoretical prediction that $F_s \propto L/\sqrt{A}$ between rigid, flat, disordered walls also holds reasonably well for more general interactions between the solids, as tested explicitly by atomistic computer simulations.

Most real surfaces are rough and disordered. The minimal model that includes the effect of roughness consists of a single asperity contact, for instance the curved tip of an AFM [23.2] on a flat substrate. The tip is usually assumed to be disordered. Moreover, the contact mechanics of a nanoscale tip and a substrate in vacuum can best be described by the so-called Derjaguin–Müller–Toporov (DMT) limit [23.48]. DMT is similar to Hertzian contact mechanics, but it includes an additional adhesive off-set load L_{adh} that is incorporated into the effective load $L_{eff} = L + L_{adh}$. The area of contact is then given by $A \propto L_{eff}^{2/3}$, Substituting this proportionality into the relation $F_s \propto L_{eff}/\sqrt{A}$ discussed above, *Wenning* et al. [23.44] found

$$F_s \propto L^{2/3} . \tag{23.7}$$

This relationship is indeed observed experimentally in ultrahigh vacuum (UHV) [23.49,50], as well as in atomistic computer simulations [23.44]. Of course, when the contacts are commensurate, we can expect the effective friction coefficient $\mu_{eff} = F_s/L_{eff}$ to be independent of L_{eff}, while for amorphous systems and in particular incommensurate systems, μ_{eff} decreases with increasing L_{eff}. The scaling with load in Fig. 23.3 confirms this expectation.

As noted above, the discussion thus far only deals with atomic/geometric interlocking. From Fig. 23.2 and the discussion above, one can understand how this interlocking leads to static friction, which is the threshold force to initiate sliding. However, kinetic friction $F_k(v)$ may nevertheless vanish in the limit of zero sliding velocity v, since in principle the energy that is gained when the system slides "downhill" can be stored and used later to make the slider go "uphill" again. Such a process would require that we can drive the system adiabatically. In the following, we will discuss atomistic processes (instabilities) that make it impossible to drive the system adiabatically. The presence of instabilities automatically leads to finite kinetic and static friction even in the absence of geometric interlocking.

23.2.2 Elastic Instabilities

In principle, elastic deflections of atoms can be large enough to prevent the interfacial forces from averaging to zero. Two simple ball and spring models are useful in illustrating how such motion can affect static and kinetic friction in principle as well as in understanding the results of detailed simulations or laboratory experiments. Both models consider two clean, flat, crystalline surfaces in direct contact (Fig. 23.4a). The bottom solid is assumed to be rigid, so that it can be treated as a fixed periodic substrate potential acting on the

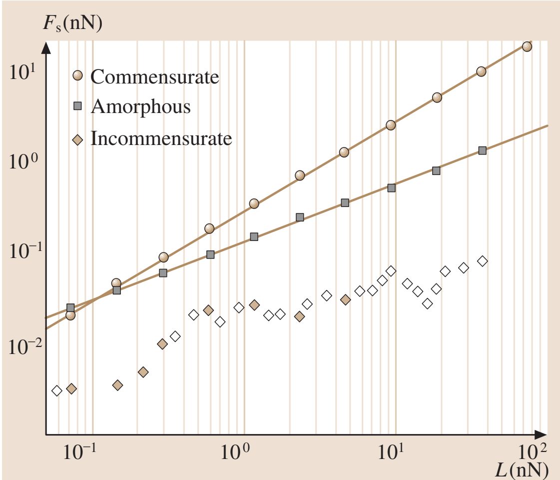

Fig. 23.3 Static friction force F_s vs. normal load L for a commensurate tip, an incommensurate tip, and an amorphous tip. In all three cases, the radius of curvature was $R_c = 70$ Å and contacts were nonadhesive. Straight lines are fits according to $F_s \propto L^\beta$ with the results $\beta = 0.97 \pm 0.005$ (commensurate) and $\beta = 0.63 \pm 0.01$ (amorphous). [After [23.44] plus new data from *L. Wenning* (*open diamonds*)]

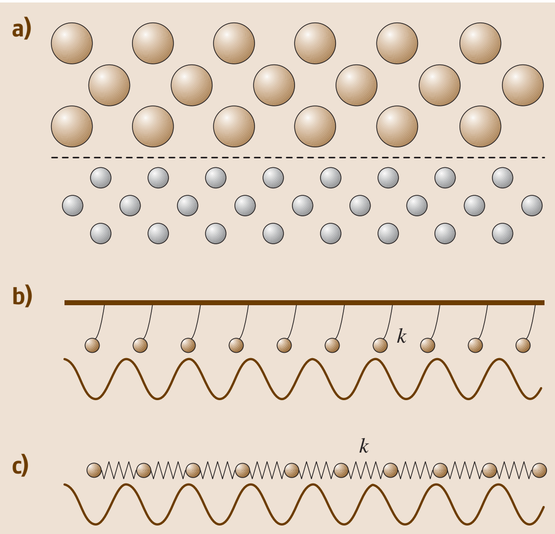

Fig. 23.4 (a) Two ideal, flat crystals making contact at the plane indicated by the *dashed line*. The nearest-neighbor spacings in the bottom and top walls are a and b, respectively. The Prandtl–Tomlinson model **(b)** and Frenkel–Kontorova model **(c)** replace the bottom surface by a periodic potential. The former model keeps elastic forces between atoms on the top surface and the center of mass of the top wall, and the latter includes springs of stiffness k between neighbors in the top wall. (After [23.56])

top solid. In order to make the problem analytically tractable, only the bottom layer of atoms from the top solid is retained, and the interactions within the top wall are simplified. In the Prandtl–Tomlinson model (Fig. 23.4b), the atoms are coupled to the center of mass of the top wall by springs of stiffness k, and coupling between neighboring atoms is ignored [23.51–53]. In the Frenkel–Kontorova model (Fig. 23.4c), the atoms are coupled to nearest-neighbors by springs, and the coupling to the atoms above is ignored [23.54, 55]. Due to their simplicity, these models arise in a number of different problems and a great deal is known about their properties.

Many features of the Prandtl–Tomlinson and Frenkel–Kontorova models can be understood from their 1-D versions. One important parameter is the ratio η between the lattice constants of the two surfaces $\eta \equiv b/a$. The other is the strength of the periodic potential from the substrate relative to the spring stiffness k that represents interactions within the top solid. If the substrate potential has a single Fourier component, then the periodic force can be written as

$$f(x) = -f_1 \sin\left(\frac{2\pi}{a}x\right) . \quad (23.8)$$

The relative strength of the potential and springs can be characterized by the dimensionless constant $\lambda \equiv 2\pi f_1/ka$.

In the limit of infinitely strong springs ($\lambda \to 0$), both models represent rigid solids. The atoms of the top wall are confined to lattice sites $x_l^0 = x_{\mathrm{CM}} + lb$, where the integer l labels successive atoms and x_{CM} represents a rigid translation of the entire wall. The total lateral or friction force is given by summing (23.8):

$$F = -f_1 \sum_{l=1}^{N} \sin\left[\frac{2\pi}{a}(lb + x_{\mathrm{CM}})\right] , \quad (23.9)$$

where N is the number of atoms in the top wall. In the special case of equal lattice constants ($\eta = b/a = 1$), the forces on all atoms add in phase and $F = -N f_1 \sin(2\pi x_{\mathrm{CM}}/a)$. The maximum of this restraining force gives the static friction $F_\mathrm{s} = N f_1$.

As noted above, the case of equal lattice constants is artificial and for real surfaces η is most likely to be an irrational number. Such surfaces are called incommensurate, while surfaces with a rational value of η are commensurate. When η is irrational, atoms on the top surface sample all phases of the periodic force with equal probability and the net force (23.9) vanishes exactly. When η is a rational number, it can be expressed as p/q, where p and q are integers with no common factors. In this case, atoms only sample q different phases. The net force from (23.9) still vanishes, because the force is a pure sine wave and the phases are equally spaced. However, the static friction is finite if the potential has higher harmonics. A Fourier component with wave vector $q2\pi/a$ and magnitude f_q contributes $N f_q$ to F_s. Studies of surface potentials [23.57] show that f_q drops exponentially with increasing q and thus imply that F_s will only be significant for small q.

As the springs become weaker, the top wall deforms more easily into a configuration that lowers the potential energy. The Prandtl–Tomlinson model is the simplest case to consider, because each atom can be treated as an independent oscillator within the upper surface. The equations of motion for the position x_l of the lth atom can be written as

$$m\ddot{x}_l = -\gamma \dot{x}_l - f_1 \sin\left(\frac{2\pi}{a}x_l\right) - k(x_l - x_l^0) , \quad (23.10)$$

where m is the atomic mass and x_l^0 is the position of the lattice site. Here γ is a phenomenological damping coefficient, like that in a Langevin thermostat, that allows

Part C | 23.2

work done on the atom to be dissipated as heat. It represents the coupling to external degrees of freedom such as lattice vibrations in the solids.

In any steady state of the system, the total friction can be determined either from the sum of the forces exerted by the springs on the top wall, or from the sum of the periodic potentials acting on the atoms (23.9). If the time average of these forces differed, there would be a net force on the atoms and a steady acceleration. The static friction is related to the force in metastable states of the system where $\ddot{x}_l = \dot{x}_l = 0$. This requires that spring and substrate forces cancel for each l,

$$k(x_l - x_l^0) = -f_1 \sin\left(\frac{2\pi}{a}x_l\right) . \tag{23.11}$$

As shown graphically in Fig. 23.5a, there is only one solution for weak interfacial potentials and stiff solids ($\lambda < 1$). In this limit, the behavior is essentially the same as for infinitely rigid solids. There is static friction for $\eta = 1$, but not for incommensurate cases. Even though incommensurate potentials displace atoms from lattice sites, there are exactly as many displaced to the right as to the left, and the force sums to zero.

A new type of behavior sets in when λ exceeds unity. The interfacial potential is now strong enough compared to the springs that multiple metastable states are possible. These states must satisfy both (23.11) and the condition that the second derivative of the potential energy is positive: $1 + \lambda \cos(2\pi x_l/a) > 0$. The number of metastable solutions increases as λ increases. As illustrated in Fig. 23.5b, once an atom is in a given metastable minimum it is trapped there until the center of mass moves far enough away that the second derivative of the potential vanishes and the minimum becomes unstable. The atom then pops forward very rapidly to the nearest remaining metastable state. Such motion, where a system is stuck for a long time and then suddenly jumps forward by an atomic spacing, is called atomic-scale stick-slip motion. During the pops, atoms reach large velocities and hence dissipate a large amount of energy into the lattice vibrations. This makes it possible to have a finite kinetic friction that does not vanish linearly with sliding velocity even when the surfaces are incommensurate [23.8, 9].

A similar analysis can be done for the 1-D Frenkel–Kontorova model [23.55, 58, 59]. The main difference is that the static friction and ground state depend strongly on η. For any given irrational value of η, there is a threshold potential strength λ_c. For weaker potentials, the static friction vanishes. For stronger potentials, elastic metastability produces a finite static friction. The transition to the onset of static friction was termed a breaking of analyticity by *Aubry* [23.59] and is often called the Aubry transition. The metastable states for $\lambda > \lambda_c$ take the form of locally commensurate regions that are separated by domain walls where the two crystals are out of phase. Within the locally commensurate regions the ratio of the periods is a rational number p/q that is close to η. The range of η where locking occurs grows with increasing potential strength (λ) until it spans all values. At this point there is an infinite number of different metastable ground states that form a fascinating "Devil's staircase" as η varies [23.55, 59].

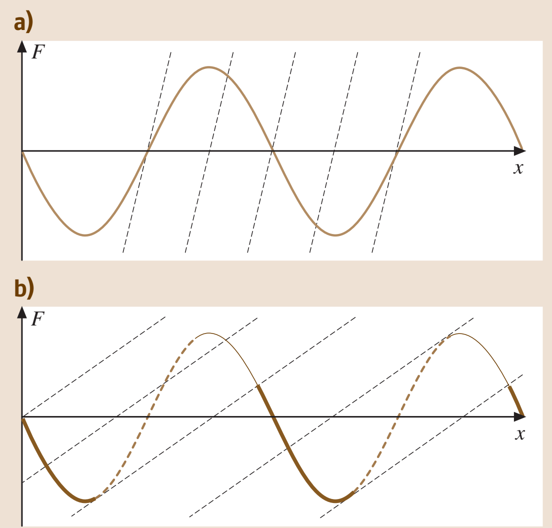

Fig. 23.5a,b Graphical solution for metastability of an atom in the Prandtl–Tomlinson model for **(a)** $\lambda = 0.5$ and **(b)** $\lambda = 3$. The *straight dashed lines* show the force from the spring, $k(x_l - x_l^0)$, at different x_l^0, and the *curved lines* show the periodic substrate potential. For $\lambda < 1$, there is a single intersection of the *dashed lines* with the substrate potential for each value of x_l^0, and thus a single metastable state. For $\lambda > 1$, there are multiple intersections with the substrate potential. *Dotted portions* of the potential curve indicate unstable maxima, and *solid regions* indicate metastable solutions. Fast pops with concurrent energy dissipation cannot be avoided for $\lambda > 1$ even when the slider moves slowly. (After [23.56])

Although elastic instabilities can, in principle, induce finite static friction at the atomic scale, this appears to be rare. There have been a significant number of computer simulations showing that the *wearless* static friction between crystalline surfaces is extremely

small, except in the artificial case of identical and perfectly aligned walls [23.8, 10]. Studies of iron on iron [23.60], a blunt pyramidal diamond tip on a metal surface [23.61], a blunt pyramidal copper tip on incommensurate copper substrates [23.62], interlayer sliding in multiwalled carbon nanotubes [23.63], and Lennard-Jonesium on Lennard-Jonesium [23.40] all confirm the simple prediction that lateral forces cancel out. These simulations have in common that the solids were treated truly three-dimensionally and that the atoms (interacting via microscopic interaction potentials) were allowed to relax, thus making long-range elastic deformations possible. Significant lateral forces were only observed in combination with strongly irreversible processes such as production of wear debris, plastic deformation, material mixing, or cold welding and not due to geometric interlocking or elastic instabilities alone.

23.2.3 Role of Dimensionality and Disorder

The previous section considered whether local atomic displacements could lead to static friction. Long-range deformations between individual contacts could also allow surfaces to lock together [23.41, 42] Although we are concerned with the friction between two 3-D solid bodies, it is instructive to analyze the role of dimensionality in determining the effect of disorder. To do this, let us consider a d_{obj}-dimensional elastic solid, for example, a generalization of the elastic Frenkel–Kontorova chain to higher dimensions. We may safely assume the free elastic solid to be mechanically stable, meaning that the tensor of the elastic constants is positive definite. The dimension of the interface between the slider and disordered substrate is denoted by d_{int}.

In such a situation, there will be a competition between the random substrate-slider interactions and the elastic coupling within the solids. An important question to ask is how the interactions change when we change the scale of the system, for example, how strong are the random and the elastic interactions on a length scale $2\mathcal{L}$ if we know their respective strengths on a scale $\mathcal{L}$. Here $\mathcal{L}$ gives the linear dimension of the solids in all directions, that is to say, parallel and normal to the interface. As discussed above, the random forces between substrate and slider add incoherently and thus their sum scales as the square root of the interface area $\sim \mathcal{L}^{d_{\text{int}}/2}$. The elastic forces, on the other hand, scale as $\mathcal{L}^{d_{\text{obj}}-2}$. A linear chain can be more easily compressed if we replace one spring with two springs coupled in series. In two dimensions, springs are not only coupled in series but also in parallel, so that the elastic coupling remains invariant to a "block transformation". Each additional dimension strengthens the effect of "parallel" coupling.

In the thermodynamic limit $\mathcal{L} \to \infty$, the effect of disorder will always dominate the elastic interactions or vice versa, except in the special case where

$$\mathcal{L}^{d_{\text{int}}/2} \propto \mathcal{L}^{d_{\text{obj}}-2} \,. \qquad (23.12)$$

For $\lim_{\mathcal{L}\to\infty} \mathcal{L}^{d_{\text{int}}/2}/\mathcal{L}^{d_{\text{obj}}-2} \gg 1$, the random interactions will dominate, and hence pinning via elastic instabilities cannot be avoided. This disorder-induced elastic pinning is similar to the pinning of compliant, ordered systems, as discussed above within the context of the Prandtl–Tomlinson and the Frenkel–Kontorova models. For $\lim_{\mathcal{L}\to\infty} \mathcal{L}^{d_{\text{int}}/2}/\mathcal{L}^{d_{\text{obj}}-2} \ll 1$, the long-range elastic forces dominate the long-range random forces. The slider's motion can only be opposed by elastic instabilities if the elastic coupling is sufficiently weak at finite $\mathcal{L}$ in order to make local pinning possible, again akin to the case of $\lambda > 1$ in the Prandtl–Tomlinson model.

The so-called *marginal* dimension, in which both contributions scale with the same exponent, $d_{\text{int}}/2 = d_{\text{obj}} - 2$, occurs in the important case of 3-D solid bodies with 2-D surfaces. In the marginal dimension, the friction force can stay finite, however, detailed analysis [23.42, 64] shows the friction force per unit area, and hence the friction coefficient, to be exponentially small. Even for objects with a dimensionality d_{mar} less than their marginal dimension $d_{\text{mar}} = 2 + d_{\text{int}}/2$ (see (23.12)), friction forces may turn out to be small. One example is an experimental quartz crystal microbalance study [23.65] of solid and liquid krypton films on disordered gold surfaces for which the pinning forces were undetectably small. For adsorbed layers, which satisfy $d_{\text{obj}} = d_{\text{int}}$, the marginal dimension would be $d_{\text{mar}} = 4$.

23.2.4 Elastic Instabilities vs. Wear in Atomistic Models

As mentioned in Sect. 23.2.2, there is no published computer simulation study known to us in which the solids were treated truly atomistically in three dimensions and where the interfacial interactions lead to elastic pinning according to Prandtl–Tomlinson or Frenkel–Kontorova. In this context, we want to discuss exemplarily computer simulations of a copper tip on copper by *Sørensen* et al. [23.62]. We consider their study to be rather generic and also well-done from a technical point of view for a variety of reasons: The effects of commensurability and finite contact area were examined in detail, the simulations were done at constant normal load instead of

constant separation, the interaction potentials were realistic, and initial and boundary conditions were chosen such that the tip had the possibility to deform. Snapshots of one of their sliding simulations are shown in Fig. 23.6. Note that one must keep in mind that the simulation only addresses the tribological properties in UHV.

Flat, clean tips with (111) or (100) surfaces were brought into contact with corresponding crystalline substrates [23.62]. The two exterior layers of tip and surface were treated as rigid units, and the dynamics of the remaining mobile layers was followed. Interatomic forces and energies were calculated using semi-empirical potentials derived from effective medium theory [23.66]. At finite temperatures, the outer mobile layers of both tip and surface were coupled to a Langevin thermostat. Zero temperature simulations gave similar results.

In the commensurate Cu(111) case, *Sørensen* et al. [23.62] observed atomic-scale stick-slip motion of the tip like that described above for the Tomlinson model. The trajectory was of zigzag form, which could be related to jumps of the tip's surface between fcc and hcp positions. Detailed analysis of the slips showed that they occurred via a dislocation mechanism. Dislocations were nucleated at the corner of the interface, and then moved rapidly through the contact region.

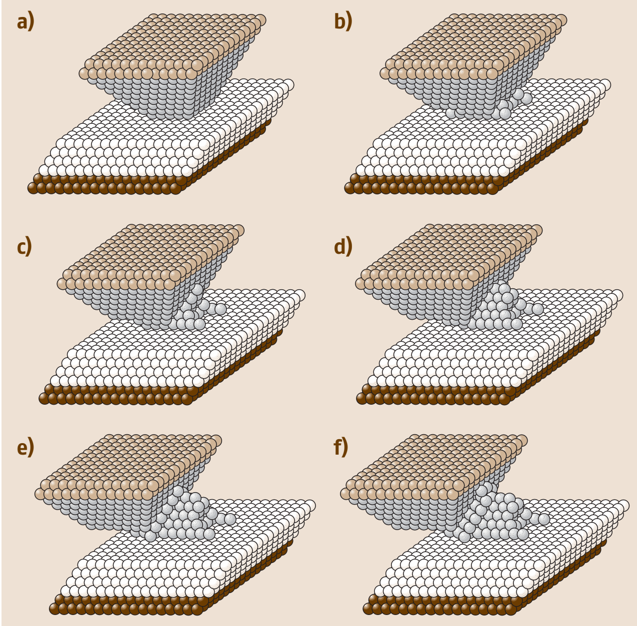

Fig. 23.6 Snapshots showing the evolution of a Cu(100) tip on a Cu(100) substrate during sliding to the left. (After [23.62])

Adhesion led to a large static friction at zero load: The static friction per unit area, or critical yield stress, dropped from 3.0 GPa to 2.3 GPa as T increased from 0 to 300 K. The kinetic friction increased linearly with load with a surprisingly small differential friction coefficient $\tilde{\mu}_\mathrm{k} \equiv \partial F_\mathrm{k}/\partial L \approx 0.03$. In the load regime investigated, $\tilde{\mu}_\mathrm{k}$ was independent of temperature and load. No velocity dependence was detectable up to sliding velocities of $v = 5$ m/s. At higher velocities, the friction decreased. Even though the interactions between the surfaces are identical to those within the surfaces, no wear was observed. This was attributed to the fact that (111) surfaces are the preferred slip planes in fcc metals.

Adhesive wear was observed between a commensurate (100) tip and substrate (Fig. 23.6). Sliding in the (011) direction at either constant height or constant load led to inter-plane sliding between (111) planes inside the tip. As shown in Fig. 23.6, this plastic deformation led to wear of the tip, which left a trail of atoms in its wake. The total energy was an increasing function of sliding distance due to the extra surface area. The constant evolution of the tip kept the motion from being periodic, but the sawtoothed variation of force with displacement that is characteristic of atomic-scale stick-slip was still observed.

Sørensen et al. [23.62] also examined the effect of incommensurability. An incommensurate Cu(111) system was obtained by rotating the tip by 16.1° about the axis perpendicular to the substrate. For a small tip (5×5 atoms), they observed an Aubry transition from smooth sliding with no static friction at low loads to atomic-scale stick-slip motion at larger loads. Further increases in load led to sliding within the tip and plastic deformation. Finite systems are never truly incommensurate, and pinning was found to occur at the corners of the contact, suggesting it was a finite-size effect. Larger tips (19×19) slid without static friction at all loads. Similar behavior was observed for incommensurate Cu(100) systems.

These results confirm the conclusions of *Hirano* et al. [23.60] that even bare metal surfaces of the same material will not exhibit static friction if the surfaces are incommensurate. They also indicate that contact areas as small as a few hundred atoms are large enough to exhibit this effect. Similar results were obtained for Lennard Jonesium [23.6, 40, 67]: The interbulk interactions between unlike atoms (each solid is initially composed of one Lennard-Jones species) have to be distinctly larger than the intrabulk interactions between identical atoms in order to induce elastic instability. However, as soon as the interactions between unlike atoms are larger than

those between like atoms, there is a mixing instability leading to a cold welded junction.

Lancon [23.69] reported that there is the possibility for elastic instabilities under carefully designed conditions between two incommensurate gold surfaces. The importance of the interfacial interactions with respect to the intrabulk interactions was increased through the application of a pressure normal to the interface. At 4 GPa, an elastic Aubry transition was observed concurrently with finite static friction. The normal pressures employed in those simulations were well above the yield strength of gold. However, plastic flow at the contact's circumference could be avoided by the use of flat surfaces that filled out the whole simulation cell parallel to the interface. Additional examples of elastic instabilities may be found for very compliant solids, but the majority of simple solids will not pin elastically on an atomic scale. Note, however, that cold welding may still occur on long time scales due to diffusion. On such time scales, the interface geometry may rearrange to produce locally commensurate regions that lower the interfacial free energy and allow geometrical pinning.

23.2.5 Hydrodynamic Lubrication and Its Confinement-Induced Breakdown

So far, we have been concerned with dry friction. However, most surfaces are covered by dirt and/or lubricants. Hydrodynamics and elasto-hydrodynamics have been very successful in describing lubrication by micron-thick films [23.70]. These continuum theories begin to break down as atomic structure becomes important. Experiments and simulations reveal a sequence of dramatic changes in the static and dynamic properties of fluid films as their thickness decreases from microns down to molecular scales. These changes have important implications for the function of boundary lubricants and the origins of static friction.

Let us consider two flat, lubricated walls separated by a distance d and sliding with a relative parallel velocity v. Let us further assume that the lubricant's viscosity μ in the center of the contact equals that of the bulk fluid phase. The shear stress must be uniform in steady state, because any imbalance would lead to accelerations. Since the velocity gradient times the viscosity μ gives the stress in the fluid, the kinetic friction per unit area is

$$F_{\mathrm{k}} = \frac{v\mu}{d + \mathcal{S}}\,, \qquad (23.13)$$

where we introduce the so-called slip length $\mathcal{S}$. It represents the distance into the wall at which the velocity gradient would extrapolate to zero; see Fig. 23.7f for a graphical illustration of $\mathcal{S}$. The calculation of slip length from velocity profiles has some ambiguity, and we refer to work by *Bocquet* et al. [23.71] for the least ambiguous resolution to the definition of the slip length known to us.

Macroscopic experiments are generally well-described by a "no-slip" boundary condition (BC), where $\mathcal{S} = 0$ and the tangential component of the fluid velocity equals that of the solid at the surface. The one prominent exception is contact-line motion, where an interface between two fluids moves along a solid surface. This motion would require an infinite force in hydrodynamic theory, unless slip occurred near the contact line.

As d decreases, any deviation from $\mathcal{S} = 0$ becomes more evident in (23.13). Studies of confined films show

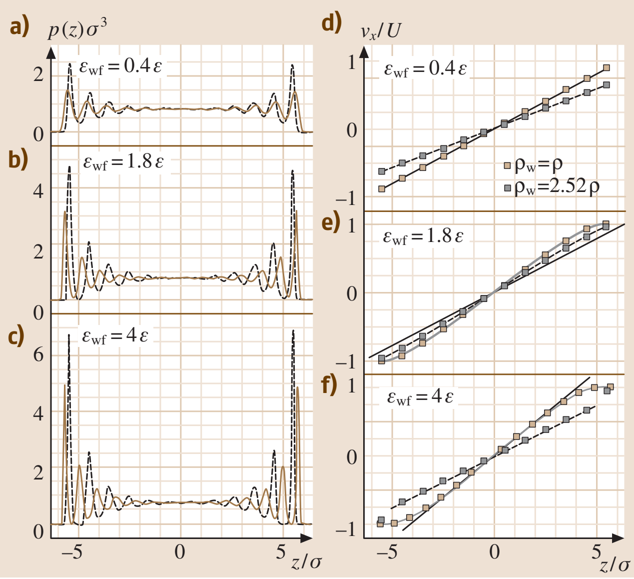

Fig. 23.7a–f Panels **(a)–(c)** show density as a function of position z relative to two walls whose atoms are centered at $z/\sigma = \pm 6.4$. Values of ϵ_{wf} are indicated. *Solid lines* are for equal wall and fluid densities ($\rho = 0.81\sigma^{-3}$), and *dotted lines* are for $\rho_w = 2.52\rho$. *Squares* in panels **(d)–(f)** show the average velocity in each layer as a function of z, and *solid* and *dotted lines* are fits through these values for low and high density walls, respectively. For this data, the walls were moved in opposite directions at speed $U = 1\sigma/t_{\mathrm{LJ}}$. The *dashed line* in **(e)** represents the flow expected from hydrodynamics with a no-slip BC ($\mathcal{S} = 0$). As shown in **(f)**, the slope (*dashed line*) far from the walls is used to define $\mathcal{S}$. (From [23.8] after [23.68])

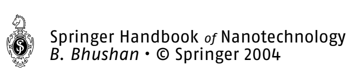


that slip may occur ($\mathcal{S} > 0$) or layers may stick onto the solid ($\mathcal{S} < 0$) [23.68, 71–73]. These deviations from the no-slip BC have been correlated with structural changes in the fluid near the walls. The first observation was that layering occurs in planes parallel to the walls. It is induced by the sharp cutoff in fluid density at the wall and the pair correlation function $g(r)$ between fluid atoms. An initial fluid layer forms at the preferred wall-fluid spacing. Additional fluid molecules tend to lie in a second layer, at the preferred fluid-fluid spacing. This layer induces a third, and so on. Layering can alter the BC and the viscosity of the confined fluid. As suggested by the contrasting behavior of commensurate and incommensurate solids, the BC depends sensitively on the degree to which the walls imprint their in-plane density modulations into the lubricant.

Some of the trends that are observed in the degree and extent of layering are illustrated in Fig. 23.7 [23.68, 72]. The fluid density is plotted as a function of the distance between walls for a model that is also considered in almost all of the other studies of flow BCs described below. The fluid consists of spherical molecules interacting through a Lennard-Jones potential (23.1) with characteristic energy and length scales ϵ and σ. They are confined by crystalline walls containing discrete atoms. In this case, the walls were planar (001) surfaces of an fcc crystal. Wall and fluid atoms also interact with a Lennard-Jones potential, but with a different binding energy ϵ_{wf}.

The net adsorption potential from the walls can be increased by raising ϵ_{wf}, or by increasing the density of the walls ρ_w, so that more wall atoms attract the fluid. Figure 23.7 shows that both increases lead to increases in the height of the first density peak. The height also increases with the pressure in the fluid [23.73], since that forces atoms into steeper regions of the adsorption potential. The height of subsequent density peaks decreases smoothly with distance from the wall, and only four or five well-defined layers are seen near each wall in Fig. 23.7. The rate at which the density oscillations decay is determined by the decay length of structure in the bulk pair-correlation function of the fluid. Since all panels of Fig. 23.7 have the same conditions in the bulk, the decay rate is the same. The adsorption potential only determines the initial height of the peaks.

As mentioned above, solid surfaces also induce density modulations within the plane of the layers [23.7]. These modulations can be quantified by the 2-D static structure factor at the shortest reciprocal lattice vector Q of the substrate [23.35, 68]. When normalized by the number of atoms in the layer, N_l, this becomes an intensive variable that would correspond to the Debye–Waller factor in a crystal. The maximum possible value, $S(Q)/N_l = 1$, corresponds to fixing all atoms exactly at crystalline lattice sites. In a strongly ordered case such as $\rho_w = \rho$ in Fig. 23.7c, the small oscillations about lattice sites in the first layer only decrease $S(Q)/N_l$ to 0.71. This is well above the value of 0.6 that is typical of bulk 3-D solids at their melting point [23.74] and indicates that the first layer has crystallized onto the wall. The values of $S(Q)/N_l$ in the second and third layers are 0.31 and 0.07, respectively, and atoms in these layers exhibit typical fluid diffusion.

There is some correlation between the factors that produce strong layering and those that produce strong in-plane modulations. For example, chain molecules have several conflicting length scales that tend to frustrate both layering and in-plane order [23.36, 75, 76]. However, the dependence of in-plane order on the density of substrate atoms is more complicated than for layering. When $\rho_w = \rho$, the fluid atoms can naturally sit on the sites of a commensurate lattice, and $S(Q)$ is large. When the substrate density ρ_w is increased by a factor of 2.52, the fluid atoms no longer fit easily into the corrugation potential. The degree of induced in-plane order drops sharply, although the layering becomes stronger (Fig. 23.7). Sufficiently strong adsorption potentials may eventually lead to crystalline order in the first layers and stronger layering. However, this may actually increase slip.

Thompson et al. [23.68] found that all of their results for $\mathcal{S}$ collapsed onto a universal curve when plotted against the structure factor $S(Q)/N_l$. When one or more layers crystallized onto the wall, the same collapse could be applied as long as the effective wall position was shifted by a layer and the Q for the outer wall layer was used. The success of this collapse at small $S(Q)/N_l$ can be understood from a perturbation theory [23.6, 77] developed to quantitatively explain the kinetic friction on adsorbed monolayers [23.3].

One of the surprising features of Fig. 23.7 is that the viscosity remains the same even in regions near the wall where there is pronounced layering. Any change in viscosity would produce a change in the velocity gradient, since the stress is constant. However, the flow profiles in panel (d) remain linear throughout the cell. The profile for the dense walls in panel (f) is linear up to the last layer, which has crystallized onto the wall. From Fig. 23.7 it is apparent that local density variations by at least a factor of seven can be accommodated without a viscosity change.

Bitsanis et al. [23.78] examined the change in viscosity with film thickness. They found that results for film thicknesses $h > 4\sigma$ could be fit using the bulk viscosity for the average density. However, as h decreased below 4σ, the viscosity diverged much more rapidly than any model based on bulk viscosity could explain. These observations were consistent with surface force apparatus (SFA) experiments on nanometer thick films of a wide variety of small molecules [23.4, 5]. Layering in molecularly thin films gave rise to oscillations in the energy, normal force, and effective viscosity as the film thickness decreased. Most films of one to three molecular layers exhibited a yield stress characteristic of solid-like behavior, even though the molecules form a simple Newtonian fluid in the bulk. Deviations from the no-slip condition might cause μ_{eff} to differ from the bulk viscosity by an order of magnitude. However, they could not explain the observed changes of μ_{eff} by more than five orders of magnitude, or the even more dramatic changes by 10 to 12 orders of magnitude in the characteristic viscoelastic relaxation time determined from the shear rate dependence of μ_{eff} [23.5].

More recent experimental and theoretical studies confirm that most fluids exhibit a glass transition when confined to channels less than 3 to 10 molecular diameters [23.33,79]. *Thompson* et al. [23.34, 36] considered changes in flow with film thickness in a wide range of model systems. As in experiment, they found dramatic divergences in the viscosity and relaxation time that suggested confinement induced a glass transition. Later work by *Baljon* et al. [23.33, 80] indicates that the same glass transition is produced by changes in thickness, pressure, or temperature. In particular, the shear-rate-dependent viscoelastic response of systems of all sizes, pressures, and temperatures can be collapsed onto the same universal curve above the glass transition [23.33].

23.2.6 Submonolayer Films

Physisorbed molecules such as short hydrocarbon chains can be expected to sit on any surface exposed to atmospheric conditions. Even in ultrahigh vacuum, special surface treatments are needed to remove strongly physisorbed species from surfaces. Given the generic observation of glassy behavior in thin films, *Robbins* et al. [23.81] suggested that these submonolayer contaminants could provide a general explanation for the universal observation of static friction. Subsequent simulations have confirmed that physisorbed molecules qualitatively alter tribological behavior. For example, they lead to static friction between two incommensurate walls [23.67, 82] or two disordered walls [23.47] that would slide without friction if they were clean. The theoretical explanation of this effect can be understood from a simple analytical model considered by *Müser* et al. [23.47]. In order to make two surfaces pin, a nonvanishing fraction of the density modulations must share the same period and lock into phase. This happens automatically for commensurate surfaces, but not for incommensurate surfaces unless they are unrealistically compliant. However, a submonolayer of atoms or molecules that does not form strong covalent bonds with the confining solids can simultaneously lock to the density modulations of two incommensurate walls and hence give rise to a finite friction coefficient.

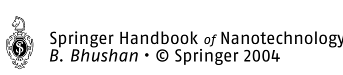
Simulation results for the friction due to physisorbed layers are consistent with a large number of experimental observations. While Amontons's laws state that the friction is independent of the macroscopic area, it is well established that the friction is proportional to the real area of molecular contact A_{real} [23.30, 83, 84]. Experiments where both the friction and molecular area can be measured [23.4, 85–89] show that the local shear stress τ_{s} needed to initiate sliding rises linearly with the normal pressure P:

$$\tau_{\text{s}} = \tau_0 + \alpha P \,. \tag{23.14}$$

This gives a macroscopic friction force $F_{\text{s}} = \tau_0 A_{\text{real}} + \mu L$, where the total load is just $L = PA_{\text{real}}$. This friction law is actually more general than Amontons's laws, reducing to it at large loads and small areas, but explaining why the friction between adhesive surfaces (like tape) does not vanish at zero load.

For a wide range of parameters [23.82, 90], the friction calculated for physisorbed monolayers follows (23.14) up to the gigapascal pressures that are present in real contacts. Moreover, the results are remarkably insensitive to parameters that are not controlled in experiments such as the crystallographic orientation of the solids, the thickness of the adsorbed layer, and the direction of sliding. The only exceptions occur for the unlikely case of commensurate walls [23.90, 91], as discussed further below. Subsequent studies of kinetic friction [23.39, 92] explain both the close relation between experimental values of static friction and the slow variation with velocity. In particular, the logarithmic rate dependence seen in τ for many systems [23.83] can be explained through thermally activated hopping of physisorbed molecules [23.92].

Müser et al. [23.47] have constructed a simple analytical theory that captures many of the results and conclusions from the above simulations. At the pres-



sures of interest, the atoms act like hard spheres. In order to slide, the bounding surfaces must lift up over these spheres against the normal pressure. The situation is analogous to the simple cartoon in Fig. 23.2, but with atomic-scale ramps, and the required stress increases linearly with pressure for the same reason. The offset, τ_0, is related to adhesive interactions between the two surfaces that increase the effective load [23.90]. Unlike the original model of geometrical interlocking, the atomic-scale ramps rearrange during sliding. The dissipation during these rearrangements is responsible for kinetic friction [23.47, 92], which, as we now discuss, is very different for commensurate and incommensurate walls.

The characteristic motion of individual boundary lubricant atoms depends on the relative displacement for commensurate walls, because the distribution of metastable states depends on the relative alignment of the two walls [23.90, 92]. For example, no "pops" of the lubricant atoms are observed when the two commensurate solids are aligned directly above each other. This behavior is in contrast with that for incommensurate surfaces for which the distribution of metastable states does not change as the slider is translated with respect to the substrate. Stressing the analogy to the Prandtl–Tomlinson model, static and kinetic friction are related for incommensurate, boundary-lubricated solids, while they are not necessarily related for commensurate, boundary-lubricated solids. Indeed, commensurate, boundary-lubricated surfaces exhibit a dramatic decrease in friction at the transition from stick-slip motion to smooth sliding, while this dramatic decrease is absent for incommensurate, boundary-lubricated walls [23.39].

It has been noted recently, that dimensionality not only plays an important role for elastic objects, but also for boundary lubricants [23.39]. It was predicted that kinetic friction would be Stokes-like (i. e., vanish linearly with velocity) between incommensurate surfaces, if it were possible to confine lubricant particles into trenches of (sub)nanometer depth and width, so that the motion of the lubricant embedded between the surfaces becomes 1-D. At the same time, however, static friction would remain finite.

The above results suggest that adsorbed molecules and other "third-bodies" may prove key to understanding macroscopic friction measurements. It will be interesting to extend these studies to more realistic molecular potentials and to rough surfaces. To date, realistic potentials have only been used for "between-sorbed" particles between commensurate surfaces. This work is reviewed elsewhere [23.8, 10, 11].

23.3 Stick-Slip Dynamics

The dynamics of sliding systems can be very complex and depend on many factors, including the types of metastable states in the system, the times needed to transform between states, and the mechanical properties of the device that imposes the stress. At high rates or stresses, systems usually slide smoothly. At low rates, the motion often becomes intermittent, with the system alternately sticking and slipping forward [23.30,32]. Everyday examples of such stick-slip motion include the squeak of hinges and the music of violins.

The alternation between stuck and sliding states of the system reflects changes in the way energy is stored. While the system is stuck, elastic energy is pumped into the system by the driving device. When the system slips, this elastic energy is released into kinetic energy and eventually dissipated as heat. The system then sticks once more, begins to store elastic energy, and the process continues. Both elastic and kinetic energy can be stored in all the mechanical elements that drive the system. The whole coupled assembly must be included in any analysis of the dynamics.

The simplest type of intermittent motion is the atomic-scale stick-slip that occurs in the multistable regime ($\lambda > 1$) of the Prandtl–Tomlinson model. Energy is stored in the springs while atoms are trapped in a metastable state, and converted to kinetic energy as they pop to the next metastable state. This phenomenon is quite general and has been observed in many simulations of wearless friction [23.8, 10], as well as in the motion of atomic force microscope tips [23.1, 2]. In these cases, motion involves a simple ratcheting over the surface potential through a regular series of hops between neighboring metastable states. The slip distance is determined entirely by the periodicity of the surface potential.

Many examples of stick-slip involve a rather different type of motion that can lead to intermittency and chaos [23.93–97]. Instead of jumping between neighboring metastable states, the system slips for very long distances before sticking. For example, *Gee* et al. [23.4] and *Yoshizawa* et al. [23.98] observed slip distances of many microns in their studies of confined films with the

SFA. This distance is much larger than any characteristic periodicity in the potential and varied with velocity, load, and the mass and stiffness of the SFA. The fact that the SFA does not stick after moving by a lattice constant indicates that sliding has changed the state of the system in some manner, so that it can continue sliding even at forces less than the yield stress.

One simple property that depends on past history is the amount of stored kinetic energy. This can carry a system over potential energy barriers even when the stress is below the yield stress. The simplest example is the underdamped Prandtl–Tomlinson model, which has been thoroughly studied in the mathematically equivalent case of an underdamped Josephson junction [23.99]. One finds a hysteretic response function, where static and moving steady-states coexist over a range of forces between $F_{\min}$ and the static friction F_s. There is a minimum stable steady-state velocity $v_{\min}$ corresponding to $F_{\min}$. At lower velocities, the only steady state is linearly unstable because $\partial v/\partial F < 0$ – pulling harder slows the system [23.30, 32]. If the top wall of the Tomlinson model is pulled at an average velocity less than $v_{\min}$ by a sufficiently compliant system, it will exhibit large-scale stick-slip motion.

Experimental systems typically have many other internal degrees of freedom that may depend on past history. Macroscopic models normally assume that a single unspecified state variable is relevant and add dynamical rules for this variable to create a phenomenological rate-state model [23.94, 100]. This approach has captured experimental behavior from a wide range of systems, including surface force apparatus experiments [23.38, 101], paper sliding on paper [23.93], and earthquakes [23.102]. However, in most cases, there is no microscopic model for the state variable and its time dependence.

One set of systems where microscopic pictures for the state variable have been considered are confined films in SFA experiments. Confined films have structural degrees of freedom that can change during sliding, and this provides an alternative mechanism for stick-slip motion [23.35]. Some of these structural changes are illustrated in Fig. 23.8, which shows stick-slip motion of a two-layer film of simple spherical molecules. The bounding walls were held together by a constant normal load. A lateral force was applied to the top wall through a spring k attached to a stage that moved with fixed velocity v in the x direction. The equilibrium configuration of the film at $v = 0$ is a commensurate crystal that resists shear. Thus at small times, the center of mass of the top wall remains pinned at $X = 0$. The force grows linearly

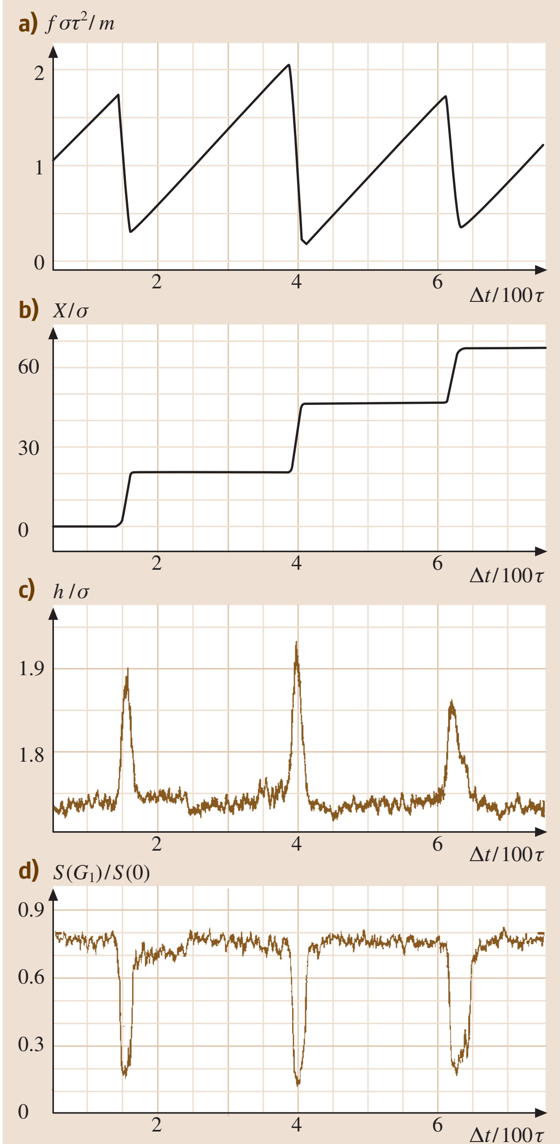


Fig. 23.8a–d Time dependence of **(a)** force per unit area f, **(b)** lateral position of the top wall X, **(c)** wall spacing h, and **(d)** degree of crystallinity $S(G_1)/S(0)$ as a function of time during stick-slip motion of walls confining two layers of spherical molecules. (After [23.35])

with time, $F = kv$, as the stage advances ahead of the wall. When F exceeds F_s, the wall slips forward. The force drops rapidly because the slip velocity $\dot{X}$ is much greater than v. When the force drops sufficiently, the

Part C | 23.3

film recrystallizes, the wall stops, and the force begins to rise once more.

One structural change that occurs during each slip event is dilation by about 10% (Fig. 23.8c). *Dhinojwala* et al. [23.103] have recently confirmed that dilation occurs during slip in SFA experiments. The increased volume makes it easier for atoms to slide past each other and is part of the reason the sliding friction is lower than F_s. The system may be able to keep sliding in this dilated state as long as it takes more time for the volume to contract than for the wall to advance by a lattice constant. Dilation of this type plays a crucial role in the yield, flow, and stick-slip dynamics of granular media [23.104–106]. In some simulations, the dilation is localized at a single plane – either a wall/film interface or a plane within the film [23.33, 107]. In some cases, there is also in-plane ordering of the film to enable it to slide more easily over the wall. This ordering remains after sliding stops and provides a mechanism for the long-term memory seen in some experiments [23.4, 98, 108].

The degree of crystallinity throughout the film may also change during sliding. Deviations from an ideal crystalline structure can be quantified by the Debye–Waller factor $S(G_1)/S(0)$ (Fig. 23.8d), where G_1 is one of the shortest reciprocal lattice vectors and $S(0) = N$ is the total number of atoms in the film. When the system is stuck, $S(G_1)/S(0)$ has a large value that is characteristic of a 3-D crystal. During each slip event, $S(G_1)/S(0)$ drops dramatically. The minimum values are characteristic of simple fluids that would show a no-slip boundary condition (Sect. 23.2.5). The atoms also exhibit rapid diffusion that is characteristic of a fluid. The periodic melting and freezing transitions that occur during stick-slip are induced by shear, not by the negligible changes in temperature. Shear-melting transitions at constant temperature have been observed in both theoretical and experimental studies of bulk colloidal systems [23.29, 109]. While the above simulations of confined films used a fixed number of particles, *Lupowski* et al. [23.110] found equivalent results at fixed chemical potential.

Very similar behavior has been observed in simulations of sand [23.104], chain molecules [23.33], incommensurate or amorphous walls [23.35], and minimal models with single molecules between surfaces [23.95–97]. These systems transform between glassy and fluid states during stick-slip motion. As in equilibrium, the structural differences between glass and fluid states are small. However, there are strong changes in the self-diffusion and other dynamic properties when the film goes from the static glassy to sliding fluid state. *Buldum* and *Ciraci* [23.111] found stick-slip motion due to periodic structural transformations in the bottom layers of a pyramidal Ni(111) tip sliding on an incommensurate Cu(110) surface.

23.4 Conclusions

The discussion of computer simulations in this chapter aimed to build a general atomistic understanding of tribological processes rather than to elucidate a specific sliding system. The advantage of studying simplified models, as opposed to chemically realistic systems, is that system properties can be varied at will. This allows the role of adhesion, surface curvature, contaminant layers and other factors to be isolated and explored. For example, to explore the effects of adhesion one can compare results from a simulation that includes the long-range attractive interactions between atoms with those from a simulation where all attractive interactions between surfaces are eliminated, leaving all other parameters unchanged. Care should be taken to avoid simplifications that are known to yield atypical results. In particular, the use of commensurate, perfectly aligned, crystalline surfaces has been shown to produce qualitatively different results, even in the presence of a lubricating film! Surface curvature must also be included in a way that properly models stress distributions from the bounding solids.

One central question is how contacting surfaces lock together to produce a static friction force. This is particularly perplexing in the context of many nanotribological systems where friction occurs without significant plastic deformation or wear. Many theories for wearless solid friction assume that surfaces deform elastically to conform to each other, and that atoms advance in a series of elastic instabilities during sliding. However, the simulations discussed above show that simple solids should hardly ever show elastic instabilities on an atomic scale without concurrent plastic flow or material transfer. Despite extensive efforts to design an atomistic system whose static friction mechanism is entirely elastic, no such model could be found as long as the ingredients were: three-dimensional incommensurate solids,

flat or smoothly curved contacts, and two-body interactions between all atoms. Under these conditions the relative lateral motion is only opposed by a viscous-like force that goes to zero for small sliding velocities. When interfacial interactions are increased in an attempt to produce elastic instabilities, plastic flow is also observed.

Wearless friction between clean solid surfaces is only found in simulations of very small contacts. The geometric interlocking in such contacts is particularly relevant to AFM experiments. When only a few atoms on the tip make contact, the potential from the substrate does not average to zero. Static friction can then occur without elastic instabilities within the tip. The Prandtl–Tomlinson model can be applied to these systems with the cantilever stiffness replacing the internal stiffness of the material in the tip. As the diameter of the contact increases, due to blunting of the tip or increased load, the friction coefficient produced by geometric interlocking decreases. In the specific case of non-adhesive contacts, the friction between an amorphous tip and a clean crystalline substrate scales as $F \propto L^{2/3}$ and μ vanishes as $L^{-1/3}$. Thus geometric interlocking is not expected to yield significant friction when the contact area contains more than $\sim 10^3$ atoms.

Most contacting solids are separated by contaminant layers, or third bodies, that introduce many additional structural degrees of freedom. The intervening atoms can rearrange into a local free energy minimum for any geometry of the bounding solids without paying the large elastic energy cost that limits rearrangements within these solids. Simulations that include these layers reproduce many details of SFA experiments. They also provide an explanation for Amontons's laws, and exceptions to them, in larger contacts.

Many important problems remain to be addressed by simulations. Of particular interest are the roles of realistic, random surface roughness and subsurface plastic deformation. Studies of these phenomena will require new multiscale approaches that treat long-range elastic and plastic deformations in the solids. Other important problems will require extensions in the time available to simulations. Examples include cold-welding through inter-surface diffusion, wear, and fatigue. Addressing these problems will be a continuing challenge to the computer modeling community.

24. Mechanics of Biological Nanotechnology

Mechanics of

One of the most compelling areas to be touched by nanotechnology is biological science. Indeed, we will argue that there is a fascinating interplay between these two subjects, with biology as a key beneficiary of advances in nanotechnology as a result of a new generation of single molecule experiments that complement traditional assays involving statistical assemblages of molecules. This interplay runs in both directions, with nanotechnology continually receiving inspiration from biology itself. The goal of this chapter is to highlight some representative examples of the exchange between biology and nanotechnology and to illustrate the role of nanomechanics in this field and how mechanical models have arisen in response to the emergence of this new field. Primary attention will be given to the particular example of the processes that attend the life cycle of bacterial viruses. Viruses feature many of the key lessons of biological nanotechnology, including self assembly, as evidenced in the spontaneous formation of the protein shell (capsid) within which the viral genome is packaged, and a motor-mediated biological process, namely, the packaging of DNA in this capsid by a molecular motor that pushes the DNA into the capsid. We argue that these processes in viruses are a compelling real-world example of nature's nanotechnology and reveal the nanomechanical challenges that will continue to be confronted at the nanotechnology-biology interface.

Nanotechnology is the seat of a broad variety of interdisciplinary activity with applications as diverse as optoelectronics, microfluidics, and medicine. However, one of the richest interdisciplinary areas only now beginning to be harvested is the interface between the biological sciences and nanotechnology. The aim of the present chapter is threefold. First, we wish to illustrate the synergy that exists between biological nanotechnology (e.g., molecular motors, transmembrane pumps, etc.) and biologically inspired nanotechnology (e.g., synthetic proteins, artificial viruses aimed at delivering drugs, biofunctionalized cantilevers, etc.). Secondly, through a series of order-of-magnitude estimates and an associated examination of the units for describing spatial dimensions, temporal processes, forces at the nanoscale, and the energy budget in nanoscale systems, we aim to build an intuitive sense of the workings of nanotechnology in the biological set-

ting. Finally, through several specific case studies, we hope to illustrate some of the challenges faced in modeling the mechanical processes of biological nanotechnology and show how such challenges have been met thus far and how they might be met in the future.

24.1 Science at the Biology–Nanotechnology Interface

24.1.1 Biological Nanotechnology

Though the innovations leading to the adoption of the expression "nanotechnology" are indeed impressive, the perspective of this chapter is that one need only look inward to the way that our muscles move, to how we digest and synthesize molecules of dazzling complexity, to the way in which we think the thoughts that permit us to fill the shelves of libraries with scientific journals to realize that the greatest nanotechnology of all is that which is revealed in the living world. That is, one of the central thrusts is the idea that the microscopic workings of life offer an inspiring vision of nanotechnology. Clearly, the diversity of the examples of "nanotechnology" seen in the living world can (and do) fill the pages of learned texts. A guided tour of the machinery of the cell can be found in *Alberts* et al. [24.1], while a vision of the cell as an assemblage of "protein machines" has been argued for by *Alberts* [24.2]. The ambition of the present section is to provide several cursory examples of the nanotechnological marvels that power the living realm.

24.1.2 Self-Assembly as Biological Nanotechnology

One of the most intriguing nanotechnological tricks of the living world is the central role played by self-assembly in such systems. Whether we consider the spontaneous assembly of viruses, either in test tubes or in the interior of an infected cell, or the fusion of one membrane-bound region to another through vesicle fusion, spontaneous formation of functional "materials" is a key part of the biological repertoire. To be more concrete, we note that self-assembly in biological systems takes place in a number of different guises. First, the self-assembly of linear assemblies is a key part of the cytoskeletal assembly process with G-actin associating to form actin filaments and, similarly, tubulin monomers joining to form microtubules. This is also the process that is used by certain bacteria such as *Listeria* for locomotion. Both of these examples are described more fully in [24.3]. This same type of process is taken to the next level of sophistication in simple viruses such as tobacco mosaic virus that involve not only the assembly of protein monomers, but also the genetic message in the form of long RNA molecules. A second broad class of self-assembly processes is associated with the formation of containers such as liposomes or viral capsids. In the case of liposomes, lipid molecules such as phosphatidylcholine spontaneously organize in a way that sequesters the hydrophobic tails from the surrounding water. Similarly, protein subunits spontaneously assemble to form viral capsids [24.4]. These structures play a variety of roles in the biological realm, from serving as containers for different macromolecules to providing for concentration gradients of small ions that are maintained and utilized by molecular motors such as ATPsynthase [24.1].

Beyond the simplistic description of self-assembly advanced above, a second key feature of biological self-assembly must also be considered. In particular, a variety of self-assembly processes in the biological realm are templated (or coded). As is well-known, proteins are a hugely versatile class of molecules all based upon the same fundamental building blocks. Interestingly, the enormous diversity of protein action is founded upon 20 distinct amino acid building blocks, and the template for assembling a given protein is carried in the form of messenger RNA, which is then read and used as the basis for protein synthesis by the ribosome. One of the most exciting developments in modern nanotechnology is the attempt to exploit templated self-assembly processes for the purposes of creating new materials. An example in the context of protein-based materials can be found in the article of *van Hest* and *Tirrell* [24.5], where the machinery of the cell has been tricked into incorporating artificial amino acids into synthetic proteins.

24.1.3 Molecular Motors as Biological Nanotechnology

One of the hallmarks of life is change and motion. At the cellular level, such motion is effected through a dizzying variety of mechanisms, most of which when viewed at the molecular level are seen to be the result of the action of molecular motors [24.3]. For example, muscle con-

traction reflects the coherent action of huge numbers of myosin motor molecules as they march along actin filaments. Similarly, the motion of certain bacteria can be traced to the rotation of a rotary motor embedded in the cell wall, which is attached to filaments known as flagella [24.6]. In a similar vein, just as our modern society is replete with examples of systems aimed at allowing for communication and transport between widely separated geographic locations, so, too, has the living world had to answer these same challenges. As will be shown in the section of this chapter aimed at making estimates of various scales and processes in nanotechnology, one of the key mechanisms for communication and transport is diffusion. That is, a chemical concentration at one place can make its presence known at a distance x with a characteristic time, $t_{\text{diffusive}} \approx x^2/2D$, where D is the diffusion constant. However, as will be shown later in the chapter, there are many cellular processes that cannot wait as long as $t_{\text{diffusion}}$. As a result, a host of molecular motors and an associated transport system (the elements of the cytoskeleton) permit active transport. For example, kinesin is a motor molecule that transports material along long, relatively rigid polymeric assemblies known as microtubules [24.1].

Even more incredible are rotary machines like those associated with ATPsynthase and bacterial flagella. ATPsynthase is a membrane-embedded machine that rotates and, in so doing, synthesizes new ATP molecules (adenosine triphosphate, energy currency of the cell) [24.1, 7–9]. Similarly, the bacterial flagellar motor rotates with the result that the attached bacterial flagellum rotates and thereby induces motion of the cell [24.3, 6]. The exquisite details of the construction of these devices are themselves breathtaking. The rotary motors in bacteria are constructed from several components that are much like a rotor and stator and perform periodic motions by deriving energy from the flow of protons across a membrane [24.6]. These rotary motors are very powerful, as evidenced by F_1-ATPsynthase, which can generate a torque large enough to rotate a molecule of actin 100 times its own length [24.10]. In addition, bacterial motors have another layer of sophistication in that stimuli from the external environment, which are sensed by the bacteria through the pores on its membrane, can change the direction of rotation of the motor in a process known as chemotaxis [24.3]. Feedback and signal transmission are implemented in engineering devices by means of complex circuitry, whereas in the living world these functions are often accomplished by means of chemistry and conformational changes in large molecules.

All of these molecular machines involve a rich interplay between chemistry, thermodynamics, and mechanics. From a structural perspective, most molecular motors are proteins with different subunits performing different functions [24.11]. Often there is some region within the motor where chemical energy is derived from the hydrolysis of adenosine triphosphate (ATP). This chemical energy is then converted to mechanical energy through a conformational change in the protein. These examples serve to call the reader's attention to the importance and variety of motor molecules found throughout the living world and which almost any sensible definition of nanotechnology would have to include as particulary sophisticated examples.

24.1.4 Molecular Channels and Pumps as Biological Nanotechnology

From a structural perspective, one of the most intriguing features of cellular systems is their division into a number of separate membrane-bound compartments. We have already touched upon this compartmentalization in the context of self-assembly, and note that the role of membranes and the proteins bound within them is described clearly in *Alberts* et al. [24.1]. The presence of such compartments, often marked by large concentration gradients with respect to the surrounding medium, hints at another nanotechnological wonder of the living world, namely, the presence of a wide range of transmembrane channels that mediate the exchange of material between these different compartments. Certain passive versions of these channels are gated by various mechanisms such as the arrival of signaling molecules or tension in the membrane within which they are found [24.12–14]. Once the channel is in the open state, ions pass through passively, by diffusion. Active versions of ion channels that transfer ions such as Na^+ and Ca^{2+} are similarly critical for the functioning of a cell, both in the case of unicellular and multicellular organisms. For example, in the case of Na^+ ions, typical concentrations within the cell can be as much as a factor of 10–20 less than those in the extracellular milieu. Such concentration gradients imply the need for sophisticated active "devices" which can do work against such gradients. One of the most remarkable of machines of this type is the Na^+–K^+ pump [24.1]. This machine is powered by hydrolysis of ATP (i. e., the consumption of ATP fuel), and it can pump ions up a potential gradient. In particular, this pump hydrolyzes ATP and pumps Na^+ ions *out* of the cell against a very steep concentration gradient while pumping K^+ ions *in* again against a steep gradient.

The point of this brief discussion has been to illustrate the first of several perspectives that we will bring to bear on the question of the biology-nanotechnology interface. Thus far, we have noted that nature is replete with examples of macromolecules and macromolecular assemblies that perform nanotechnological tasks and in this capacity serve as examples of biological nanotechnology. Next, we wish to examine the ways in which biological phenomena can inspire nanotechnology itself.

24.1.5 Biologically Inspired Nanotechnology

As noted in the beginning of this chapter, biological systems are nanotechnologically relevant for several reasons. First, as shown above, the living world is full of examples of nanotechnological devices. However, a second key point is that nanotechnology has been driven and inspired by the example of biological systems and the need (for example, in medicine) to influence biological systems at the scale of a single cell. In addition, preliminary steps have been taken to harness the nanotechnology of biological systems and use it to perform useful functions.

One compelling example of a proof-of-principle, biologically inspired device emerged from work aimed at exploring the function of ATPsynthase, the rotary device already described above. Fluorescently labelled filamentous proteins from the cytoskeleton, known as actin, were attached to the putative rotary component of the F_1 subunit. The point of this exercise is that such filaments are observable using light microscopy. It was then observed that the long actin filament rotated like a propeller when the ATPsynthase performed ATP hydrolysis [24.15].

A second example, also involving ATPsynthase, is suggested by a set of beautiful experiments done by *Racker* and others [24.16, 17]. The idea is illustrated schematically in Fig. 24.1. Two different protein machines are "reconstituted" in an artificial membrane-bound region known as a liposome. One of these devices is known as bacteriorhodopsin and has the capacity to pump hydrogen ions when it is exposed to light. Since both the bacteriorhodopsin and ATPsynthase are embedded in the same membrane, the ATPsynthase can then exploit the light-induced proton gradient to perform ATP synthesis. Again, these experiments were undertaken not for their role as possible devices, but rather to probe the nature of various molecular machines. Nevertheless, we view them as a provocative demonstration of both the manipulation and use of such machines in artificial environments. As such, they provide an inspiring vision of the possibilities for biologically inspired nanotechnology.

Another fascinating example of biologically inspired nanotechnology is that of biofunctionalized cantilevers (see Fig. 24.2). A typical example is provided by the experiments of *Wu* et al. [24.18], who have demonstrated the use of a biofunctionalized cantilever as a scheme for detecting small concentrations of biologically interesting molecules such as prostrate-specific antigen and single-stranded DNA. One surface of the cantilever is coated with an antibody, and then it is placed in environments containing different concentrations of the antigen. The key ideas from a mechanical perspective are: i) the difference in surface energy between the top and bottom surfaces of the cantilever induces spontaneous bending and ii) the binding of molecules of interest to target molecules initially present on the surface leads to surface energy differences and bending that can be detected by optical means. In this way the concentration of the molecules of interest can be measured. The specificity and sensitivity of the method makes it viable for use in the laboratory, as well as for commercial purposes. We return to this example in our discussion of the modeling challenges posed by problems at the interface between biology and nanotechnology.

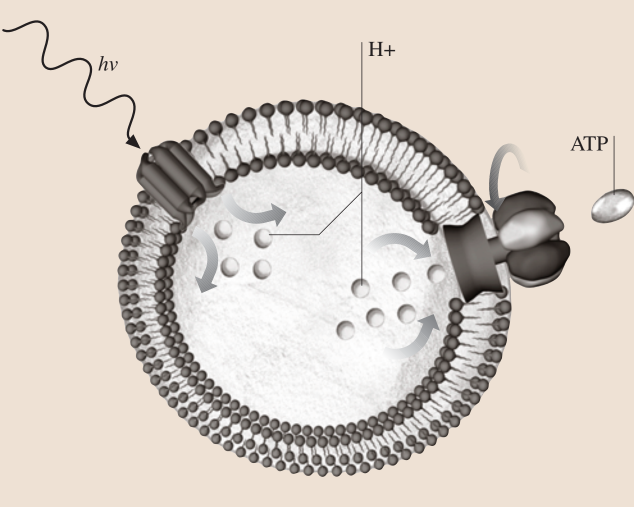

Fig. 24.1 Schematic of the experiment in which bacteriorhodopsin (*top of figure*) and ATPsynthase (*right of figure*) are artificially reconstituted in a liposome, and they act in unison to produce ATP molecules

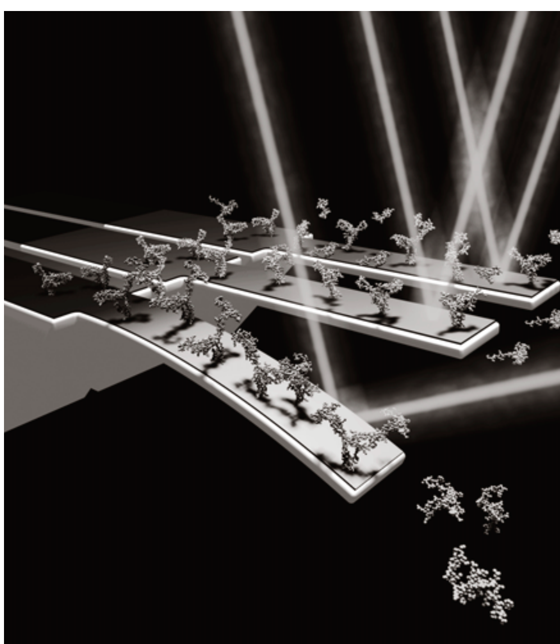

Fig. 24.2 Schematic of the use of biofunctionalized cantilevers as a tool for detecting molecules of biological interest (figure courtesy of Arun Majumdar, Berkeley)

24.1.6 Nanotechnology and Single Molecule Assays in Biology

One of the key refrains of the nanotechnological era is Feynman's quip that "there is plenty of room at the bottom" [24.19]. The benefits of miniaturization are evident at every turn in applications ranging from our cars to our computers. Associated with the development of the inspiring new techniques made possible by nanotechnology has been the emergence of a host of scientific opportunities. One of the arenas to benefit from these new techniques is biology. As scientists and engineers have taken the plunge to the nanotechnological "bottom" foreseen by Feynman, opportunities have constantly arisen to manipulate biological systems in ways that were heretofore unimagined, culminating in a new era of single molecule biology. Single molecule experiments have, in fact, presented us with a view of Feynman's "room at the bottom" as being filled with very complicated machines whose functioning makes life possible.

Single molecule assays complement statistical/collective studies involving a large number of molecular actors by revealing the prominent role of fluctuations at the sub-cellular scale. For example, a photospectrometer measures the optical response of a huge collection of molecules, whereas optical tweezers pull on a single molecule of DNA and enable us to follow the changes in conformation or the breakage of bonds. In fact, experimental methods are so advanced that it is now possible to manipulate a single molecule even as we watch it on a screen as it jiggles around in different conformations. In what follows, we give several examples of how nanotechnology has reached out to help create single molecule biology and in the process has led to the advent of new quantitative opportunities to investigate biological systems.

Atomic-Force Microscopy

One of the tools that has revolutionized nanotechnology, in general, and single molecule biology, in particular, is the atomic-force microscope. The AFM has helped create the field of single molecule force spectroscopy [24.20]. We note that mechanics has a long tradition of using force-extension data (much like the electrical engineer uses current-voltage data) to probe the inner workings of various materials. It is now possible to apply forces of known magnitude on a macromolecule and study how it deforms under the force. This furnishes structural information and provides insights into the energy landscape the molecule needs to navigate as it undergoes force-induced conformational changes. The energy of deformation associated with such molecules is primarily determined by weak forces such as hydrogen bonds, van der Waals contacts, and hydration effects. On a more philosophical note, these experiments force us to think in terms of forces and not energy, complementing the traditional views held in molecular biology, and they can lead to many new insights about the relation between structure and function in proteins, polynucleotides, and other macromolecular entities.

The AFM has been used in a wide variety of single molecule experiments on many of the key classes of molecules found in the living world, including nucleic acids, proteins, and carbohydrates. One fascinating example is the use of atomic force microscopy to examine the mechanical properties of the muscle protein titin [24.21]. The experiment is illustrated schematically in Fig. 24.3, which shows that there is a series of force-extension signatures (increasing force and extension followed by a precipitous load drop) that correspond to the unbinding of the individual domains that make up this protein.

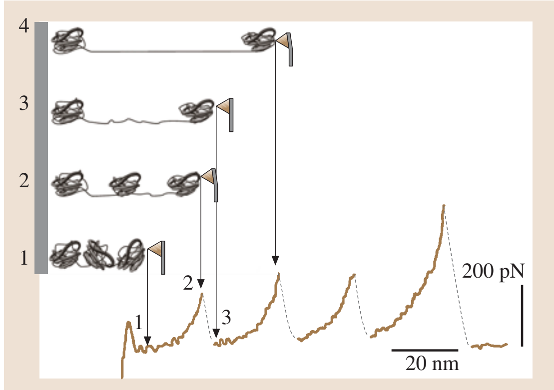

Fig. 24.3 Schematic illustrating the way that the AFM has been harnessed as a nanotechnological analogue of the Instron machine for the measurement of the force-extension properties of single molecules. Four snapshots in the life history of a globular protein subject to loading are shown, as well as the measured force-extension curve. Each sawtooth corresponds to the unfolding of a single protein domain. (Figure adapted from [24.22])

Optical Tweezers

Another instrument that has been used with great success in the realm of biophysics for the purposes of performing nanomechanical measurements on macromolecules and their assemblies is the optical tweezer [24.23, 24]. While the AFM is relatively stiff and applies large forces (on the order of 100–1,000 pN), optical tweezers are compliant and can measure smaller forces (on the order of 0.1–10 pN). Some of the most interesting experiments performed with optical tweezers concern the functioning of molecular motors, which by themselves are marvels of nanotechnology. For example, *Svoboda* et al. [24.25] attached kinesin to an optically trapped bead and observed its movement along a microtubule. An example of the type of data to emerge from such experiments is shown in Fig. 24.4. One of the conclusions to emerge from such experiments is that kinesin can exert forces on the order of 5–7 pN before it stalls. Such experiments also permit an examination of the effect of changing the concentration of ATP on the functioning of kinesin [24.26]. Similar experiments have been performed on RNA polymerase as it advances along DNA to deduce not only the stall force, but also its velocity as a function of the constraining force [24.27]. Such measurements provide a mechano-chemical basis of biological function and go a long way in revealing connections between chemical kinetics and mechanical processes at the molecular level.

As noted in the abstract, one of the most fascinating examples of the biology-nanotechnology interface is that of bacterial viruses, known as bacteriophages. The life cycle of a large class of bacteriophages is characterized by self-assembly processes that lead to the formation of the protein shell of the virus followed by active packaging of the viral DNA within this shell by a motor. The structure of this so-called "viral portal motor" has recently been solved using X-ray crystallography [24.28]. In a recent experiment, *Smith* et al. used optical tweezers to study the characteristics of the DNA packaging process of the ϕ-29 bacteriophage [24.29]. One of the conclusions of this experiment is that the motor has to act against an increasing resistive force as more and more of the DNA is packed inside the capsid. From a quantitative perspective, this experiment yields the force and the rate of packing as a function of the fraction of the genome packed. It is also important to note that bacteriophages are not only an obscure subject of quiet enquiry, but are also the basis of a huge range of cloning products (see, for example, the lambda ZAP vectors of Stratagene) used for doing experiments with recombinant DNA, and more generally, viruses are being explored as the basis of gene therapy.

Our discussion thus far has been aimed at providing a rough overview of the vast landscape that sits at the interface between biology and nanotechnology. It is hoped that the few representative case studies set forth above suffice to illustrate our basic thesis, namely, that biological nanotechnology represents nanotechnology at its best.

24.1.7 The Challenge of Modeling the Bio–Nano Interface

As highlighted in the previous two subsections, there have been huge advances at the interface between nanotechnology and biology. We have argued that there are two distinct representations of the interface between biology and nanotechnology, and each has its own associated set of modeling challenges. The argument of the present discussion is that another key part of the infrastructure that must attend these developments is that associated with the modeling of these systems. One of the intriguing ways in which modeling at the biology-nanotechnology interface is assuming greater importance is that with increasing regularity, experimental data on biological systems is of a quantitative character. As a result, the models that are put forth to greet these experiments must similarly be of a quantitative character [24.30].

Part C | 24.1

As an example of the type of modeling challenges that must be faced in contemplating the types of problems described above, we return to the example of biofunctionalized cantilevers as a problem in nanomechanics [24.18, 31]. The basic physics behind the use of biofunctionalized cantilevers as sensors is a competition between elastic bending energy and the surface free energy difference between the upper and lower faces of the cantilever. The face with the lower free energy per unit area tends to increase its area by bending the cantilever. The amount of bending, on the other hand, is limited by the elastic energy cost. The utility of this device derives from the fact that the difference in the surface free energy is affected by specific binding of target molecules to probe molecules that are initially deposited on one side of the cantilever.

To provide a quantitative model of the biofunctionalized cantilever, we construct an energy functional that takes into account the elastic energy of beam bending and the surface energy. Both contributions to the total energy can be written as functionals of $u(x)$, the deflection of the cantilever. Note that in the case in which the two surfaces have the same free energy per unit area, $\gamma_{up} = \gamma_{down}$, the equilibrium configuration corresponds to $u(x) = 0$. The case of interest here is that in which the two surfaces have different energies.

We recall that the energy associated with beam bending is of the form [24.32]

$$E_{bend}[u(x)] = \frac{EI}{2}\int_0^L \left[u''(x)\right]^2 \mathrm{d}x\,, \tag{24.1}$$

where E is Young's modulus, L is the length of the beam, and $I = wt^3/12$ is the areal moment of inertia; t and w are the beam thickness and width. The main approximation we have made in writing (24.1) is that the cross section of the beam remains unchanged by the bending process. The surface contribution to the total energy is associated with the changes of the areas of the upper and lower surfaces by virtue of the beam deforming. In particular, we have

$$E_{surf}[u(x)] = \gamma_{up} w\left[L - \frac{t}{2}\int_0^L u''(x)\,\mathrm{d}x\right] + \gamma_{down} w\left[L + \frac{t}{2}\int_0^L u''(x)\,\mathrm{d}x\right]\,, \tag{24.2}$$

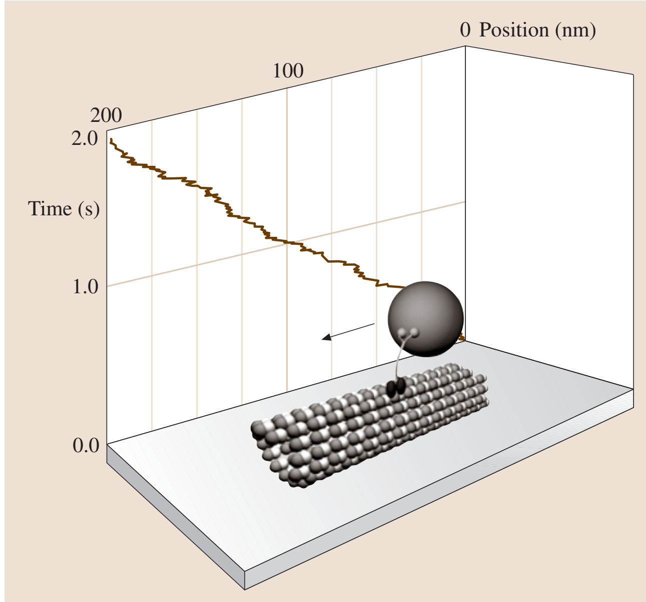

Fig. 24.4 Schematic illustrating the use of optical tweezers to measure the speed of the molecular motor kinesin in its journey along a microtubule

where the terms in parentheses are the arc lengths along the top and bottom surface of the beam, respectively. The physical content of this functional is the idea that if $u'' > 0$ (concave upward) then the upper surface area will shrink while the lower surface area will increase. Neglecting uninteresting constant terms, the total energy functional is

$$E_{tot}[u(x)] = \frac{EI}{2}\int_0^L \left[u''(x)\right]^2 \mathrm{d}x + \frac{tw}{2}(\gamma_{down} - \gamma_{up})\int_0^L u''(x)\,\mathrm{d}x\,. \tag{24.3}$$

Our goal is to find the displacement profile $u(x)$ that yields the minimum value for the total energy. The general mathematical framework for effecting this minimization is the calculus of variations. For the functional in (24.3), a more direct route to the result can be obtained by completing the square. Namely, we note that the E_{tot} involves a term quadratic in $u''(x)$ and a second term that is linear in the same function. As a result, the

total energy can be rewritten in the form

$$E_{\mathrm{tot}}[u(x)] = \frac{EI}{2}\int_0^L \mathrm{d}x \left[u''(x) + \frac{tw\Delta\gamma}{2EI}\right]^2 , \qquad (24.4)$$

where we have introduced $\Delta\gamma = \gamma_{\mathrm{down}} - \gamma_{\mathrm{up}}$, and we neglect an uninteresting constant term. Clearly the $u(x)$ that minimizes the energy is one for which the integrand vanishes everywhere, or

$$u''(x) + \frac{tw\Delta\gamma}{2EI} = 0 . \qquad (24.5)$$

At this point, we are left with a standard differential equation whose solution, given the boundary conditions $u(0) = 0$ and $u'(0) = 0$, is

$$u(x) = -\frac{tw}{4EI}\Delta\gamma x^2 . \qquad (24.6)$$

The physical meaning of this solution is hinted at by observing that if $\gamma_{\mathrm{down}} > \gamma_{\mathrm{up}}$ then the beam curves downward with the result that the area of the lower surface is reduced.

Measurements of *Wu* et al. [24.31] indicate an upward cantilever deflection when single stranded DNA (ssDNA), up to 20 nucleotides in length, hybridizes with complementary strands of ssDNA, which were deposited initially so as to functionalize the beam. This effect might be attributed to the difference in elastic properties of ssDNA and its double stranded counterpart. Namely, under physiological conditions, ssDNA has a persistence length equal to two nucleotides, while dsDNA is much stiffer (due to hydrogen bonding and base stacking interactions between the two strands) and has a persistence length of 150 nucleotides. Therefore, deposition of the flexible ssDNA molecules initially leads to bending of the cantilever downward due to entropic repulsion between the ssDNA chains. After hybridization, rigid dsDNA strands are formed, there is no longer any entropy to be gained by increasing the area of the top surface, and the beam bends back upwards. Remarkably, *Wu* et al. demonstrate that their biofunctionalized cantilever is sensitive to ssDNA differing in length by a single nucleotide!

To gain further insight into the physics of the biofunctionalized cantilever, it is instructive to examine some quantitative aspects of the experiment using (24.6). Namely, *Wu* et al. find a deflection of $u(L) = 12\,\mathrm{nm}$ when a 20-nucleotide strand of ssDNA hybridizes with a 20-nucleotide-long complementary target. Using the quoted numbers for the cantilever, $E = 180\,\mathrm{GPa}$, $L = 200\,\mu\mathrm{m}$, $t = 0.5\,\mu\mathrm{m}$, $w = 20\,\mu\mathrm{m}$, leads to $\Delta\gamma = 4.5\,\mathrm{fJ}/\mu\mathrm{m}^2$. From this result we can estimate the change in surface free energy due to beam bending,

$$\Delta E_{\mathrm{surf}} \approx wL\Delta\gamma . \qquad (24.7)$$

We find $\Delta E_{\mathrm{surf}} = -18\,\mathrm{pJ}$, which, given the quoted areal chain density of $6\times10^{12}\,\mathrm{cm}^{-2}$, leads to a decrease in free energy of 75 pN nm, or $18\,k_{\mathrm{B}}T$, per chain. This is comparable to the entropy of a 20 nt ssDNA, which is on the order of $10\,k_{\mathrm{B}}$, lending support to the idea that entropic repulsion between ssDNA strands is implicated in cantilever bending.

While this example gives a feel for the way in which quantitative models have been put forth to respond to biologically inspired nanotechnologies, the remainder of the chapter will emphasize attempts to construct nanomechanical models of biological nanotechnology itself. We turn first to a discussion of the various scales that arise in thinking about the biology-nanotechnology interface and then conclude with several modeling examples.

24.2 Scales at the Bio–Nano Interface

Every scientific discipline has a preferred set of units that lends itself to building intuition concerning the system at hand. For example, an astronomer thinks of distances between stars in light years, not kilometers. Though most of us have an intuitive sense of the meaning of a kilometer, by the time we add more than six zeros, all intuition is lost. At terrestrial scales, we talk of distances between cities in terms of the flying time or the driving time between them and usually not in terms of hundreds of miles. Similar choices must be faced in the biological setting. For example, a biologist might characterize the complexity of an organism by the size (in kilo basepairs) of the genome and not by the organism's physical size. The aim of the present section is to highlight some of the key scales and units that reveal themselves at the interface between biology and nanotechnology. Indeed, we go further and assert that as yet we are still in the process of searching for the most suitable units to

characterize the biology-nanotechnology interface. Although our attempt to determine such units and scales might involve seemingly complicated interconversions, such as measuring distances in terms of time (via diffusion), or measuring concentrations in terms of distances, we hold that the approximate *numerical* characterization of the scales of interest is of crucial importance to the endeavor of considering nanomechanics at the biology-nanotechnology interface. In particular, the right choice of units can assist us in building intuition about these systems. Our goal in this section is to emphasize the scales in length, time, force, energy, and power that are relevant in contemplating the nanomechanics of biological systems.

24.2.1 Spatial Scales and Structures

We begin with a discussion of the length scales that arise in contemplating nanomechanics at the biology-nanotechnology interface. In this case, the prefix *nano* leads justifiably to a consideration of the nanometer as one possible choice as the fundamental unit of length. However, to prepare ourselves for the question of how best to describe the dimensions of the spatial structures of interest here, it is important to consider the *hierarchy* of length scales that arise in the nano-bio arena. After examining this hierarchy of structures, we reformulate these length scales in terms of the volumes of these structures measured in units of the volume of a typical bacterial cell, and conclude the present section with a discussion of the way that chemical concentrations can also be interpreted as determining a length scale.

As noted above, a first step in developing intuition concerning the spatial scales found at the biology-nanotechnology interface is through reference to the hierarchy of scales and structures that arise in this arena. The shortest distance in this hierarchy of scales that will interest us is that associated with the size of individual atoms. We recall that the size of a hydrogen atom is roughly 0.1 nm. The scale characterizing the linkage between atoms is that of typical bond lengths that range from roughly 0.1–0.3 nm. A step further in this hierarchy brings us to the basic building blocks of the biological world such as amino acids, nucleotides, individual sugars, lipid molecules, etc. A typical length scale that characterizes these building blocks is the nanometer itself. For example, we have already made reference to the importance of lipid-bilayer membranes in bounding different regions of the cell. Phosphatidylcholine is one of the molecular building blocks of many such membranes. It has a polar head group and a hydrocarbon tail with an overall dimension of 2–3 nm. Similarly, the dimensions of single amino acids and nucleotides are on the order of 1 nm as well.

As is well-known, individual nucleotides are assembled to form nucleic acids such as DNA, amino acids are assembled to form proteins, sugars combine to form polysaccharides, and lipids self-assemble to form membranes. One way of estimating the size of the resulting molecules is by taking the scale of the individual units and scaling up with the number of such units. The various molecular actors of relevance to the present discussion can also be characterized by a length, scale known as the persistence length, which gives a rough description of the length over which the molecule behaves as a stiff rod. For example, the persistence length of DNA is ≈ 50 nm, while that of the cytoskeletal filaments is in the range of 15 μm for actin and 6 mm for microtubules [24.11]. We note that in our later discussions of viruses as a profound example of biological nanotechnology, the ratio of the persistence length of DNA to the size of the viral capsid (the container within which the DNA is packaged) will serve as a measure of the energetic cost of packing the DNA within the capsid and will signal the need for molecular motors to take active part in the packaging process.

The next scale above that of the various macromolecular building blocks are assemblies of such molecules in the form of various molecular machines which are some of the most compelling examples of nature's nanotechnology. The ability to begin formulating mechanistic models of such machines is founded upon key advances in both X-ray crystallography and cryo-electron microscopy [24.33, 34]. Examples of such machines and their associated dimensions include: the machine responsible for making the message carried by DNA readable by the protein synthesis machinery, namely, RNA polymerase (≈ 15 nm) [24.35], the machine that produces ATP, the energy currency of the cell, namely, ATPsynthase (≈ 10 nm) [24.9], and the machine that carries out protein synthesis, namely, the ribosome (≈ 25 nm) [24.36]. A second class of assemblies of particular relevance to the present article are viruses, representative examples of which include lambda phage (≈ 27 nm), tobacco mosaic virus (≈ 250 nm in length), and the HIV virus (≈ 110–125 nm) [24.37].

From the standpoint of cellular function, the next level of structural organization is associated with the various organelles within the cell, structures such as the cell nucleus (3–10 μm), the mitochondria that serve

as the power plant of the cell (≈ 1,000 nm), the Golgi apparatus wherein modifications are made to newly synthesized macromolecular components (≈ 1,000 nm), and so on [24.1]. These organelles should be thought of as factories in which many molecular motors of the type described earlier do their job simultaneously. At larger scales yet, and constituting a higher level of overall organization, life as nanotechnology is revealed as cells themselves, the fundamental unit of life that is self-replicating and self-sustaining. We will make special reference to one particular bacterial cell, namely, *E. coli* with typical dimensions of 1 µm. This should be contrasted with a typical eucaryotic cell such as yeast, which has linear dimensions roughly a factor of 10 larger than the *E. coli* cell.

We note that the various biological structures described above should be seen with reference to the sorts of man-made structures to which they are interfaced. For example, earlier in the chapter we mentioned the importance of optical tweezers as a means of communicating forces to macromolecules and their assemblies. Typical dimensions for the optical beads used in optical tweezers are on the scale of 500–1,000 nm. We note that though such dimensions are characteristic of organelles, they are much larger than the individual molecules they are used to study. A second way in which individual macromolecules are communicated with is through small tips such as those found on an AFM. In this case, the size of the tip can be understood through reference to its radius of curvature, which is typically of the order of 50 nm.

Our discussion thus far has centered on the use of a single characteristic length to describe the spatial extent of biological structures. In our quest to develop intuition about the typical spatial scales found at the biology-nanotechnology interface we note that a second way to evaluate such scales is through reference to the typical *volumes* of the various structures of interest. As noted in the introduction to this section, we claim that a key way to develop intuition is by making sure to use appropriate and revealing units. For the present purposes, we argue that one useful unit of volume is that of an *E. coli* bacterium, which if idealized as a cylinder with diameter 1 µm and height 2 µm, has a volume of $\approx 1.5 \times 10^9$ nm^3. In particular, we will measure the sizes of the various entities described above in terms of how many of them can fit into a single *E. coli* bacterium. Our estimates of the comparative sizes of various structures of interest are given in Table 24.1. Note that we do not claim that this is literally how many of each of these entities are found in an *E. coli* bacterium, but rather we seek to give an impression of the relative volumes of some of the different structures that arise when contemplating biological nanotechnology.

Table 24.1 Sizes of entities in comparison to the size of *E. coli*

Entity	Size (nm)	# fitting in an *E. coli*
Amino acid	1	5.0×10^9
Nucleotide	1	5.0×10^9
Monosaccharide	1	5.0×10^9
Phosphatidyl choline	2–3	2.0×10^8
Proteins	5–6	3.0×10^7
Ribosome	20	1.0×10^6
Mitochondria	500–1,000	3–4
T4 phage	100	5,000

The idea of counting the number of molecules that fit into a given volume is actually quite standard. This is exactly what chemists do when they invoke the notion of concentration: measuring the strength of an acid or base using pH amounts to expressing the concentration of H^+ ions in solution. Similarly, when we refer to the molarity of a given solution, it is a statement of how many copies of a given molecule will be found per liter of solution. These ideas are pertinent for our examination of the scales that arise in contemplating biological nanotechnology. As an example, we consider the action of molecular pumps such as that which maintains the concentration gradient in Ca^{2+} ions between the cellular interior and the extracellular medium. Note that this is described in detail in chapter 12 of *Alberts* et al. [24.1]. The Ca^{2+} pump is responsible for insuring that the intercellular concentration of Ca^{2+} ions is 10^{-7} smaller than that in the cellular exterior. One explanation for this low a concentration of Ca^{2+} in the cell is the role played by these ions in signaling other activities. The low concentration might serve as a scheme for increasing the signal-to-noise ratio. The reported intracellular concentration of such ions is roughly 10^{-7} mM. It is interesting to ask how many Ca^{2+} ions this corresponds to in a eucaryotic cell. The volume of a eucaryotic cell measuring 20 µm in diameter is about 4×10^{-12} liters, which translates into ≈ 250 Ca^{2+} ions in the cytoplasm. For the case of *E. coli*, which has a volume approximately 1,000 smaller, this concentration would correspond to one ion for every four cells. This number gives us far greater insight than the standard molar (M = mol/liter) method of expressing concentrations. In a similar vein, we argue that distances between in-

dividual ions/molecules in solution are perhaps a better way of thinking about pH and molarity when using them in the context of biological nanosystems. To this end, Fig. 24.5 shows a plot of pH and molarity versus average distance *d* in nm between individual ions/molecules. Note that, in addition, we have also translated these concentrations into number of copies per *E. coli* cell and the time for an ion to diffuse over the average separation distance. For the time estimate we make use of the typical diffusion constant for small ions in water at 25 °C, $D = 2{,}000\,\mu\text{m}^2/\text{s}$.

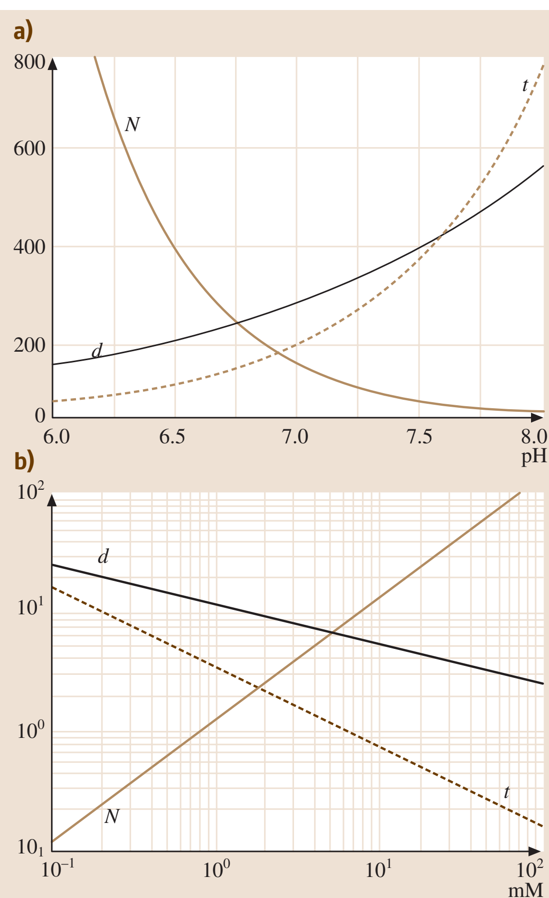

Fig. 24.5 **(a)** Representations of pH in terms of average distance between ions (*d* in nm), the number of ions per one *E. coli* cell volume (*N*), and the typical time for an ion to diffuse over a distance equal to their average separation (*t* in 100 ns). **(b)** Concentration unit millimolar (mM) represented in terms of *d* (nm), *N* (millions of molecules), and *t* (10 ns)

We have seen that the world of biological nanotechnology utilizes length scales that span a rather wide range, from fractions of a nanometer to tens of microns. This provides a challenge to modeling, whereby methods with atomic-scale resolution need to be combined in a consistent and seamless way with coarse-grained continuum descriptions to provide a complete picture. An example of such modeling will be provided in later sections when we take up the mechanical aspect of the viral life cycle.

24.2.2 Temporal Scales and Processes

We have seen that a study of spatial scales is a first step in our quest to understand the units that are suited to characterizing the biology-nanotechnology interface. We note that our understanding of spatial structures both in the living world, as well as those used in intriguing man-made technologies such as microelectronics have been built around important advances such as electron microscopy, X-ray crystallography, nuclear magnetic resonance, etc. that have revolutionized structural biology and materials science alike. On the other hand, one of the key challenges that remain in really appreciating the structure-properties paradigm, which is as central to biology as it is to materials science, is the need to acknowledge the dynamical evolution of these structures.

We note that just as there is a hierarchy of spatial scales that are important to consider in describing biological nanotechnology, so too is there a hierarchy of *temporal processes* that also demand a careful consideration of relevant units. An impressive representation of the temporal hierarchy that must be faced in contemplating biological systems is given by *Chan* and *Dill* [24.38] in their Fig. 5. They organize their temporal hierarchy according to factors of 1,000, starting at the femtosecond time scale and ending with time scales representative of the cell cycle itself. One of the elementary dynamical processes undergone by all of the molecular actors of the living world is thermal vibration. Vibrations of atoms occur at the time scales of 10^{-15} to 10^{-12} s. As will be noted later, from a modeling perspective, this depressing fact manifests itself in the necessity of using time steps of the same order when integrating the equations of motion describing molecular dynamics. The reason that this is unfortunate is that almost everything of dynamical interest occurs at time scales much longer than the femtosecond time scale characteristic of molecular jiggling, thus making molecular dynamics investigations computationally very expensive.

We follow *Chan* and *Dill* [24.38] in examining how successive thousandfold increases in our temporal resolution smears out features such as vibrational motion and brings into focus more interesting processes characteristic of macromolecular function. Indeed, the side chains of amino acids rotate with a characteristic period on the order of 10^{-9} s. Another thousandfold increase in time scale begins to bring key biological processes such as polymerization into view. Just as a length scale on the order of 10–100 nm is perhaps most characteristic of the length scales of biological nanotechnology, the time scale that is most relevant for considering the processes associated with biological nanotechnology is something between a microsecond and a millisecond. To drive home this point, we reconsider the machines described in the previous section from the length scale perspective, but now with an eye toward how fast they perform their function. Several of the molecular machines considered in the previous section mediate polymerization reactions. For example, RNA polymerase produces messenger RNA molecules by the repeated addition of nucleotides to a chain of ever increasing length. Such messenger RNA molecules serve in turn as the template for synthesis of new proteins by the ribosome, which reads the message contained in the RNA and adds individual amino acids onto the protein. From the temporal perspective of the present section, it is of interest to examine the rate at which new monomers are added to these polymers – roughly 10 per s in the case of RNA polymerase [24.39], and 2 per s in the case of the ribosome in eucaryotic cells [24.1] (bacterial ribosomes are 10 times faster). Once proteins are synthesized, in order to assume their full cellular responsibilities, they must fold into their native state, a process that occurs on time scales on the order of a millisecond.

In addition to translational machines like RNA polymerase and the ribosome, there are a host of intriguing rotary machines such as ATP synthase and the flagellar rotary motor. The flagellar motor, which is the means of locomotion for several bacteria, rotates at about 100 rpm [24.6]. ATP synthase makes use of a proton gradient across a lipid bilayer to provide rotation at a rate of roughly 6,000 rpm [24.41], approaching that of turbojet engines.

Thus far, our discussion has emphasized the rate of a variety of active processes of importance to biological nanotechnology. It is of interest to contrast these scales with those pertaining to diffusion. We note that in many instances in the biological setting the time scale of interest is that determined by the time it takes for diffusive communication of two spatially separated regions. In particular, as noted earlier in the chapter, the operative time scale is given by $t_{\text{diffusive}} = x^2/2D$, where D is the diffusion constant and x is the distance over which the diffusion has taken place.

To get a sense for all of the time scales described in this section, Table 24.2 presents a variety of results considered above in tabular form, but now with all times measured in units of the time it takes for ATPsynthase to make one rotation ($\approx$ 10 ms). Our reason for adopting ATPsynthase rotation as defining a unit of time is that it exhibits motions associated with one of the most important of life's processes, namely, the synthesis of new ATP molecules. In addition, our later discussion of units associated with both energy and power will once again appeal to the central role played by ATP in biological nanotechnology.

24.2.3 Force and Energy Scales: The Interplay of Deterministic and Thermal Forces

Another set of scales of great relevance and importance to the nano-bio interface concerns the nature of the forces that act in this setting. Thus far, we have examined the spatial extent and the cycle time of a variety of examples of biological nanotechnology. As a next step in our examination of scales, we consider the forces

Table 24.2 Time scales of various events in biological nanotechnology measured in units of the average time taken for ATPsynthase to make a single rotation

Process	Time scale (units of ATPase rotation)	Ref.
1/(frequency of amino acid addition) – eukaryotic ribosome	50	[24.1]
1/(frequency of monomer addition) – RNA polymerase	10	[24.39]
Time between motion reset of *E. coli*	10	[24.6]
Kinesin step	1	[24.26]
Diffusion time for protein (ion) to cross an *E. coli*	0.5 (0.02)	[24.11]
Vibrational period of nanocantilever	10^{-3}–10^{-5}	[24.40]

and energies associated with these structures. Two outstanding sources for developing a feel for the relevant numbers are the books of *Wrigglesworth* [24.42] and *Smil* [24.43]. Perhaps the most compelling feature when thinking about forces at these scales is the interplay between deterministic and thermal forces. To substantiate this claim, we note that at room temperature the fundamental energetic quantity is $k_B T \approx 4.1$ pN nm. The reason this number is of interest to the current endeavor is the realization that many of the molecular motors that have thus far been investigated act with forces on the piconewton scale over distances of nanometers.

The fact that the piconewton is the relevant unit of force can be gleaned from a simple estimate. Namely, consider a typical skeletal muscle in the human arm. The cross-sectional size of the muscle is of order 3 cm. The muscle consists of cylindrical rods of protein called myofibrils, which are roughly 2 μm in diameter, while the myofibrils themselves are made of strands of actin and myosin filaments, which total some 60 nm in diameter [24.1]. This gives 10^{12} myosin filaments per cross-sectional area of the muscle. As each myosin filament over the length of a single sarcomere (the contractile unit of myofibrils, some 2.5 μm long) contains some 300 myosin heads, lifting a 30 kg load corresponds to a force of 1 pN per myosin head. This is certainly an underestimate, since not all myosin heads are attached to the actin filament at the same time. Since our estimate leaves out many details, we might wonder how it compares to the measured forces exerted by molecular motors. Sophisticated experiments with optical tweezers have revealed that actin-myosin motors stall at a force of around 5 pN [24.44]; RNA polymerase stalls at a force of about 20 pN [24.39]; the portal motor of the ϕ-29 bacteriophage exerts forces up to 50 pN [24.29].

As noted earlier, RNA polymerase is a molecular motor that moves along DNA while transcribing genes into messenger RNA. The DNA itself is an elastic object that is deformed by forces exerted on it by various proteins. At forces less than 0.1 pN its response is that of an entropic spring with a stretch modulus of 0.1 pN, while at forces exceeding 10 pN its stretch modulus is determined by hydrogen bonding of the base pairs and is roughly 1,000 pN [24.45]. All the above mentioned data reinforces the argument that piconewton is the relevant unit of force in the nanomechanical world of the cell.

The concept of "stress" is closely related to that of force. Stress is a continuum mechanical concept of force per unit area, and it has been used with great success in solid and fluid mechanics. We extend the idea of stress to the nanomechanical level to see what numbers we arrive at. From the data above we can deduce that a single myosin fiber sustains a stress of about 10^{-2} pN/nm^2, which is the same as 10^{-2} MPa. Migratory animal cells such as fibroblasts, which are responsible for scavenging and destroying undesirable products in tissues, can generate a maximum stress on their substrate on the order of 3.0×10^{-2} MPa [24.46]. DNA can sustain stresses in the excess of 20 pN/nm^2, or 20 MPa, at which point an interesting structural transition accompanied by an overall increase of its contour length is observed [24.45]. Engineering materials such as steel and aluminium, on the other hand, can sustain stresses of about 100 MPa. This goes to show that nanotechnology in the context of biological systems is built from rather soft materials.

It is of interest to translate our intuition concerning piconewton forces into corresponding energetic terms. The kinesin motor advances 8 nm in each step against forces as high as 5 pN [24.25]. This translates to a work done on the order of 40 pN nm. A myosin motor suffers displacements of about 15 nm with forces in the piconewton range. ATP hydrolysis (to ADP) releases energy (at pH 7 and room temperature) of about 50 pN nm [24.1]. When a titin molecule is pulled, it unfolds under forces of 30–300 pN, causing discrete expansions of 10–30 nm [24.22], implying energies in the range of 300–9,000 pN nm. Experimental data provides a compelling argument in favor of thinking of the pN nm as a unit of energy for nanomechanics. However, the observation that $k_B T = 4.1$ pN nm at room temperature gives important insight, since it reveals that thermal forces and entropic effects play a competing role in biological nanomechanics. This provides nature with unique design challenges, whereby molecular motors that can perform useful work must do so in the presence of strong thermal fluctuations for the normal functioning of the cell. Operation of motors in such a noisy environment is governed by laws that are probabilistic in nature. This is manifest in single molecule experiments that observe motors stalling and sometimes reversing direction.

Energy conversion is crucial to any developmental or evolutionary process. The steam engine powered the industrial revolution. However, long before thinking beings with man-made machines founded the industrial revolution, power generation had already become a central part of life's nanotechnology. Indeed, the development of ATP-synthase is one of the cornerstones for the evolution of higher life-forms. An inevitable concomitant of evolution is the necessity for faster and more efficient operations. The industrial revolution led to the emergence of bigger and faster modes of transport; biological evolution led to the emergence of complex and

intelligent organisms. Invariably, a machine or an organism is limited in its abilities by the speed at which it can convert one form of energy (usually chemical) to other forms of energy (usually mechanical). This is why a study of their "power plants" becomes important.

Power plants (or engines) are usually characterized by their force-velocity curves and compared using their power-to-weight (P/W) ratio. For example, the myosin motor has a P/W ratio of 2×10^4 W/kg, the bacterial flagellar motor stands at 100 W/kg, an internal combustion engine is at about 300 W/kg, and a turbojet engine stands at 3,000 W/kg [24.47]. These figures tell us that linear motors like myosin and kinesin are extremely powerful machines.

24.3 Modeling at the Nano–Bio Interface

We have already provided a number of different views of the biology-nanotechnology interface, all of which reveal the insights that can emerge from model building. Indeed, one of the key thrusts of this entire chapter is the view that as the type of data that emerges concerning biological systems becomes increasingly quantitative, it must be responded to with models that are also quantitative [24.30]. The plan of this section is to show how atomistic and continuum analyses each offer insights into problems of nanotechnological significance, but under some circumstances, both are found wanting and it is only through a synthesis of both types of models that certain problems will surrender. The plan of this section is to examine the advantages and difficulties associated with adopting both atomistic and continuum perspectives and then to hint at the benefits of seeking mixed representations.

24.3.1 Tension Between Universality and Specificity

One of the key insights concerning model building in nanomechanics, whether we are talking about the nanoscale tribological questions pertinent to magnetic recording or the operations of molecular motors, is that such questions live in the no-man's-land between traditional continuum analysis at one extreme and all-atom approaches such as molecular dynamics on the other. Indeed, there is much discussion about the breakdown of continuum mechanics in modeling the mechanics of systems at the nanoscale. This dichotomy between continuum theories, which treat matter as continuously distributed, and atomic-level models, which explicitly acknowledge the graininess of matter, can be restated in a different (and perhaps more enlightening) way. In particular, it is possible to see atomistic and continuum theories as offering complementary views of the same underlying physics. Continuum models are suitable for characterizing those features of a system that can be thought of as averages over the underlying microscopic fluctuations. By way of contrast, atomistic models reveal the details that a continuum model will never capture, and in particular, they shed light on the specificity of the problem at hand.

The perspective adopted here is that continuum models and atomistic models each reveal important features of a given problem. For example, in contemplating the competition between fracture and plasticity at crack tips, a continuum analysis provides critical insights into the nature of the elastic fields surrounding a defect such as a crack. These fields adopt a fundamental and universal form at large scales with all detailed material features buried in simple material parameters. By way of contrast, the precise details of the dissipative processes occurring at a crack tip (in particular, the competition between bond breaking with the creation of new free surface and dislocation nucleation) require detailed atomic-level descriptions of the energetics of bond stretching and breaking. In the biological setting, similar remarks can be made. In certain instances, the description of biological polymers as random coils suffices and yields insights into features such as the mean size of the polymer chain as a function of its length. On the other hand, if our objective is mechanistic understanding of processes such as how phosphorylation of a particular protein induces conformational change, this is an intrinsically atomic-level question. The language we invoke to describe this dichotomy is the use of the terms *universality* and *specificity*, where, as described above, insights of a universal character refer to those features of systems that are generic, while specificity refers to the features of systems that depend upon precise details such as whether or not a particular molecule is bound at a particular site. This fundamental tension between atomistic and continuum perspectives is elaborated in *Phillips* et al. [24.48].

24.3.2 Atomic-Level Analysis of Biological Systems

As already described in the introduction, one of the intriguing roles of nanotechnology in the biological setting is that it has brought the Instron technology of traditional solid mechanics to the nanoscale and has permitted the investigation of the force-extension characteristics of nanoscale systems (macromolecules and their assemblies, in particular). As noted earlier, mechanical force spectroscopy [24.20] is emerging as a profound tool for exploring the connection between structure, force, and chemistry, in much the same way that conventional stress-strain tests provided insights into the connection between structure and properties of conventional materials. Figure 24.3 gives one such example in the case of the muscle protein titin. Similar insights have been obtained through systematic examination of the force-extension properties of DNA [24.49].

The objective of this section is to call the reader's attention to the types of modeling that can be done from an all-atom perspective. What exactly is meant by a model in this setting? We begin by noting that for the purposes of the general discussion given here, the same basic ideas are present whether one is modeling tribological processes such as the sliding of adjacent surfaces, or attempting to examine the operation of a protein machine such as ATPsynthase. The set of degrees of freedom considered by the atomic-scale modeler is the full set of atomic positions $(\boldsymbol{R}_1, \boldsymbol{R}_2, \cdots \boldsymbol{R}_N)$, which we also refer to as $\{\boldsymbol{R}_i\}$. For most purposes, one proceeds through reference to a *classical* potential energy function, $E_{\text{tot}}(\{\boldsymbol{R}_i\})$, which is a rule that assigns an energy for every configuration $\{\boldsymbol{R}_i\}$. While it would be most appealing to be able to perform a full quantum mechanical analysis, such calculations are computationally prohibitive. Given the potential energy, the forces on each and every atom can be computed where, for example, the force in the αth Cartesian direction on the ith atom is given by

$$F_{i,\alpha} = -\frac{\partial E_{\text{tot}}}{\partial R_{i,\alpha}} . \qquad (24.8)$$

For those interested in finding the energy minimizers, such forces can be used in conjunction with methods such as the conjugate gradient method or the Newton–Raphson method. Alternatively, many questions are of a dynamic character, and in these cases, Newton's equations of motion are integrated, thus permitting an investigation of the temporal evolution of the system of interest. We note that we have neglected to discuss subtleties of how one maintains the system at constant temperature, and we leave such subtleties to the curious reader, who can learn more about them in *Frenkel* and *Smit* [24.50].

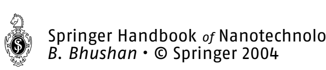
To give a flavor of where such calculations can lead we note that the same force-extension characteristics already shown in Fig. 24.3 have been computed in a molecular dynamics simulation [24.51]. One of the insights to emerge from these calculations was the particular dynamical pathway, namely, the breaking of a particular collection of hydrogen bonds during the rupture process of each of the immunoglobulin domains. We further note that in the case of titin there has been an especially pleasing synergy between the atomic-scale calculations and the corresponding force-extension measurements. In particular, in response to the suggestion that it was a particular set of hydrogen bonds that were impugned in the rupture process, mutated versions of the titin protein were created in which the number of such hydrogen bonds was changed with the result that the rupture force was changed according to expectation [24.52]. This can be seen as a primitive example of the ultimate goal of tailoring new materials (both biological and otherwise) through appropriate computer modeling.

24.3.3 Continuum Analysis of Biological Systems

We have already noted that there are many appealing features to strictly continuum analyses of material systems. In particular, models based upon continuum mechanics result in a mathematical formulation that permits us to uncork the traditional tools associated with partial differential equations and functional analysis. In keeping with our argument that it is the role of models to serve our intuition, the ability to write down continuum models raises the possibility of obtaining analytic solutions to problems of interest, an eventuality that is nearly impossible once the all-atom framework has been adopted.

Macromolecules as Elastic Rods

Whether we contemplate the information carrying nucleic acids, the workhorse proteins, or energy storing sugars, ultimately, the molecular business of the living world is dominated by long chain molecules. For the model builder, such molecules suggest two complementary perspectives, each of which contains a part of the whole truth. On the one hand, polymer physicists have gained huge insights [24.53] by thinking of long chain molecules as random walks. Stated simply, the key virtue



of the random-walk description of long chain molecules is that it reflects the overwhelming importance of entropy in governing the geometric conformations that can be adopted by macromolecules. The other side of the same coin considers long chain molecules as elastic rods with a stiffness that governs their propensity for bending. We will take up this perspective in great detail in the final section of this chapter when we consider the energetics of DNA packaging in viruses.

For our present purposes, we examine one case study in treating macromolecules as elastic rods. The example of interest here is chosen in part because it reflects another fascinating aspect of biological nanotechnology, namely, regulation and control. It is well-known that genes are switched on and off as they are needed. These topics are described beautifully in the work of *Ptashne* [24.54]. The basic idea can be elucidated through the example of a particular set of genes in *E. coli*: the *lac* operon. There are a set of enzymes exploited by this bacterial cell when it needs to digest the sugar lactose. The gene that codes for these enzymes is only turned on when lactose is present and certain other sugars are absent. The nanotechnological solution to the problem of regulating this gene has been solved by nature through the presence of a molecule known as the *lac* repressor, which binds onto the DNA in the region of this *lac* gene and prevents the gene from being expressed. More specifically, the *lac* repressor binds onto two different regions of the DNA molecule simultaneously, forming a loop in the intervening region, and thus rendering that region inoperative for transcription.

We have belabored the difficulties that attend the all-atom simulation of most problems of nanotechnological interest – system sizes are too small and simulated times are too short. On the other hand, clearly it is of great interest to probe the atomic-level dynamics of the way that molecules such as *lac* repressor interact with DNA and thereby serve as gene regulators. A compromise position adopted by *Balaeff* et al. [24.55] was to use elasticity theory to model the structure and energetics of DNA, which then served effectively as a boundary condition for their all-atom calculation of the properties of the *lac* repressor/DNA complex. The simulation cell is shown in Fig. 24.6, which also shows the looped region of DNA that serves as a boundary condition for the atomic-level model of the complex.

Membranes as Elastic Media

One way to classify biological structures is along the lines of their dimensionality. In the previous discussion, we examined the sense in which many of the key macromolecules of the living world can be thought of as one-dimensional rods. The next level in this dimensional hierarchy is to consider the various membranes that compartmentalize the cell and which can be examined from the perspective of two-dimensional elasticity. Just as there are a huge number of modeling questions to be posed concerning the structure and function of long chain molecules such as nucleic acids and proteins, there is a similar list of questions that attend the presence of a host of different membranes throughout the cell. To name a few, we first remind the reader that such membranes are full of various proteins that serve in a variety of different capacities, some of which depend upon the mechanical state of the membrane itself. In a different vein, there has been great interest in examining the factors that give rise to the equilibrium shapes of cells [24.56, 57]. In both instances, the logic associated

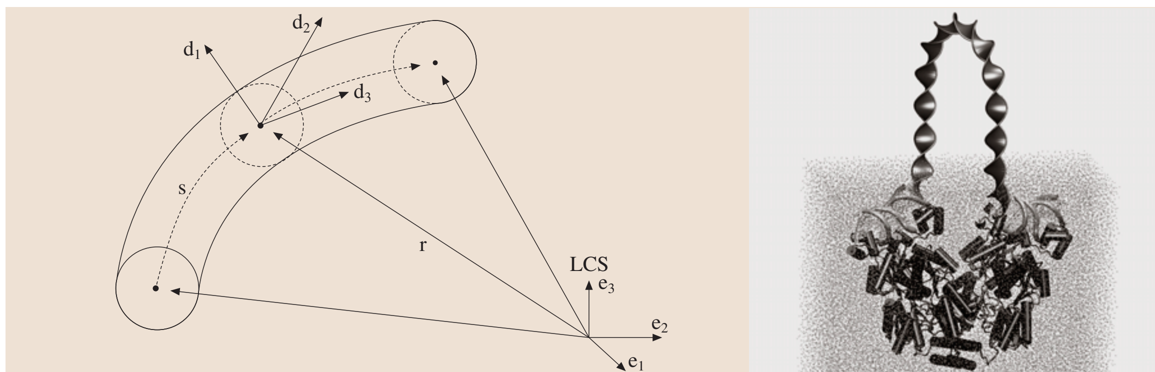


Fig. 24.6 Illustration of the way that the properties of a particular DNA-protein binding interaction were modeled by virtue of an elastic treatment of the looped region of the DNA [24.48]

with building models of these phenomena centers on the construction of an elastic Hamiltonian that captures the energetics of deformations expressed in terms of surface area, curvature, and variations in thickness. Also, just as there has been great progress in measuring the properties of single proteins and nucleic acids, there has been considerable progress in examining the force response of membranes as well [24.58].

The prospect of bringing the tools of traditional continuum theory to bear on problems of biological significance is indeed a daunting one. As noted earlier, to our way of thinking one of the biggest challenges posed by biological problems is the dependence of these systems on detailed molecular structures and dynamics – what we have earlier characterized as "specificity", one of the hallmarks of biological action.

24.4 Nature's Nanotechnology Revealed: Viruses as a Case Study

Over the course of this chapter, we have presented different facets of the relationship between biology and nanotechnology and the modeling challenges they encompass. For example, we have noted that two key aspects of nature's nanotechnologies are the exploitation of self-assembly processes for the construction of molecular machines and the role of active processes mediated by molecular motors. We have also argued for the synergistic role of nanotechnology in producing new methods for the experimental analysis of biological systems with examples ranging from new molecular dyes to the use of optical tweezers. Finally, we have described some of the modeling challenges posed by contemplating the biology-nanotechnology interface and the sorts of coarse-grained models that have arisen to meet these challenges. In this final section, we present a discussion of viruses as a case study at the confluence of these different themes.

Though the importance of viruses from a health perspective are well-known even to the casual observer, they are similarly important both from the technological perspective (as will be explained below) and as a compelling and profound example of nature's nanotechnology par excellence. To appreciate the sense in which viruses serve as a compelling example of biological nanotechnology, we begin by reviewing the nature of the viral life cycle with special reference to the case of bacterial viruses (i. e., viruses that infect bacteria), known as bacteriophages. For concreteness, we consider the life cycle of a bacteriophage such as the famed lambda phage that infects *E. coli*. The life cycle of such viruses is shown schematically in Fig. 24.7. Upon an encounter with the *E. coli* host, the virus attaches to a receptor (protein) embedded in the bacterial membrane and ejects its DNA into the host cell, leaving an empty capsid as refuse from the process. As an aside, it is worth noting that experiments such as the famed Hershey–Chase experiment used tagged DNA and tagged proteins on viruses to settle the question of whether proteins or nucleic acids are the carriers of genetic information. The outcome of these experiments was the conclusion that DNA is the genetic material. For the purposes of the present discussion, the other interesting outcome of the Hershey–Chase experiment is that it provides insights into the mechanistic process associated with delivery of the viral genome.

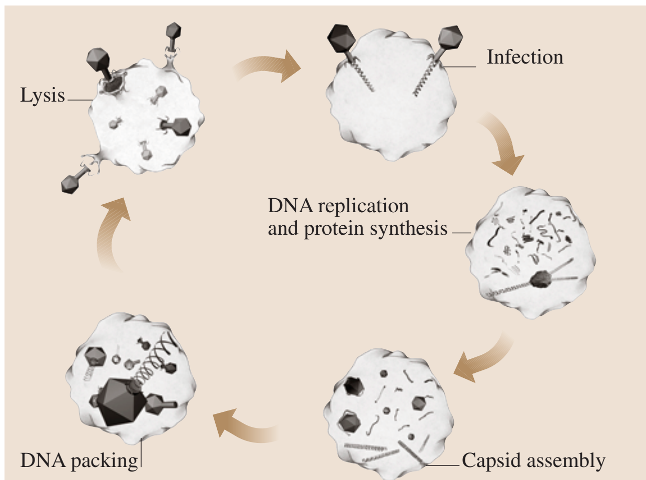

Fig. 24.7 Schematic representation of the viral life cycle illustrating the various nanotechnological actions in this cycle. During the infection stage, the viral genome is delivered to the victimized bacterial cell. During the process labeled DNA replication and protein synthesis, the machinery of the host cell is enlisted to produce renegade DNA and proteins to be used in the assembly of new viral particles. The capsid assembly process involves the attachment of the various protein building blocks that make up the capsid. DNA packing refers to the active packaging of DNA into the newly formed capsids by a molecular motor. Finally, once the assembly process is complete, the infectious phage particles are released from the victimized cell to repeat their infectious act elsewhere

Once the viral genome has been delivered to the host cell (we now oversimplify), the replication machinery of *E. coli* is hijacked to do the virus' bidding. In particular, the genes coded for in the viral DNA are expressed, and the proteins needed to make copies of the phage particle (i. e., the ingredients for an eventual self-assembly process) are created. Interestingly, part of the gene products associated with this process are the components of the molecular motor, which is responsible for packaging the replicated viral DNA into the new protein capsids that will eventually become the next generation of viruses. Indeed, once assembled, this motor takes the replicated viral DNA and packs it into the viral capsid. Recall our insistence that another of the important themes presented by biological examples of nanotechnology is the huge role played by active processes that reflect mechanochemical coupling. Once the packaging process is completed, and the remaining parts of the self-assembly process have been effected (such as the attachment of the viral sheath and legs whereby the phage attaches to host cells), enzymes are released that breakdown the cell wall of the infected cell with the ultimate result that what started as a single bacteriophage has in less than an hour become on the order of 100 new phage particles ready to infect new cells.

As noted above, a second sense in which viruses are deserving of case study status in the current chapter is the role viruses such as lambda phage play in biotechnology itself. For example, from the standpoint of both cloning and the construction of genomic libraries, the use of viruses is commonplace. From a more speculative perspective, viruses are also drawing increasing attention from the standpoint of gene therapy (as a way of delivering DNA to specific locations) and, more generally, as small-scale containers. To substantiate these assertions, we briefly consider the construction of genomic libraries and the role played by viruses in these manipulations. We pose the following question: Given that the length of the human genome is on the order of 10^9 base pairs, how can one organize and store all of this genetic information for the purposes of experiments such as the sequencing of the human genome? One answer to this challenge is the use of bacteriophage to deliver phage DNA to *E. coli* cells, but with the subtlety that the delivered DNA fragments have ligated within them fragments of the human genome whose lengths are on the order of 10 kb (kb = kilo base-pairs). The particulars of this procedure involve first cutting the DNA into fragments of roughly 10 kb in length using a class of enzymes known as restriction enzymes. The result of this operation is that the original genome is now separated into a random collection of fragments. These fragments are then mixed with the original lambda phage DNA that has also been cut at a single site such that the genomic fragments and the lambda fragments are complementary. Using a second enzyme known as ligase, the genomic DNA is joined to the original lambda phage fragments so that the resulting DNA resembles the original lambda DNA, but now with a 10 kb fragment inserted in the middle. These cloned lambda DNA molecules are then packaged into the lambda phage using a packaging reaction (see the website www.stratagene.com for an example of these products). The resulting lambda phage, now fully packed with cloned DNA, are used to infect *E. coli* cells, and the cloned DNA, once in the bacterial cell, circularizes into a DNA fragment known as a plasmid. The plasmid is then passed from one generation of *E. coli* to the next. This is the so-called prophage pathway in which, unlike the lytic pathway shown in Fig. 24.7, the bacteriophage is latent and does not destroy the cell [24.1]. Note that different *E. coli* cells are infected with viruses containing different cloned fragments. As a result, the collection of all such *E. coli* cells constitute a library of the original genomic DNA.

We round out our introductory discussion on viruses with a discussion of the compelling recent experiments that have been performed to investigate the problem of viral packing and, similarly, how ideas like those described in this chapter can be used to model these processes. *Smith* et al. [24.29] used optical tweezers to measure the force applied by the packaging motor of the ϕ-29 bacteriophage during the DNA packaging process. In particular, they measured the force and rate of packaging as a function of the amount of DNA packed into the viral head with the result that as more DNA is packed, the resistive force due to the packed DNA increases, and the packing rate is reduced.

As noted above, the viral problem is interesting not only because it exemplifies many of the features of biological nanotechnology introduced throughout this chapter, but also illustrates the way in which model building has arisen in response to experimental insights. The various competing energies that are implicated in the DNA packing process have been described by *Riemer* and *Bloomfield* [24.59]. The energetics of viral packing is characterized by a number of different factors, including: i) the entropic-spring effect that causes the DNA in solution to adopt a more spread out configuration than that in the viral capsid, ii) the energetics of elastic bending, which results from inducing curvature in the DNA on a scale that is considerably smaller than the persistence length of $\xi_p \approx 50$ nm, and iii) those

factors related to the presence of charge both on the DNA itself and in the surrounding solution. As shown by *Riemer* and *Bloomfield* [24.59], the entropic contribution is smaller by a factor of 10 or more relative to the bending energies and those mediated by the charges on the DNA and the surrounding solution, and hence we make no further reference to it. As a result, just like in earlier work [24.60, 61], we examine the interplay of elastic and interaction forces, though we neglect surface terms originating from DNA-capsid and DNA-solvent interactions.

We note that the viral packing process involves DNA segments with lengths on the order of 10 μm and takes place on the time scale of minutes. As a result, from a modeling perspective, it is clear that such problems are clearly out of reach of conventional molecular dynamics. As a result, we exploit a continuum description of the DNA packing process with the proviso that such models will ultimately need to be refined to account for the sequence dependence of the elasticity of DNA.

A mathematical description of the energetics of viral packing must account for two competing factors, namely, the energy cost to bend the DNA and place it in the capsid and the repulsive interaction between adjacent DNA segments that are too close together. The structural picture of the packaged DNA is inspired by experiments that indicate that the DNA is packed in concentric rings from large radii inwards [24.62–64]. The bending energy cost of accumulating hoops within the capsid is given by

$$E_{\text{el}} = \pi \xi_{\text{p}} k_{\text{B}} T \sum_i \frac{N(R_i)}{R_i} , \quad (24.9)$$

where $N(R_i)$ is the number of hoops that are packed at the radius R_i [24.59]. The basic idea of this expression is that we are adding up the elastic energy on a hoop by hoop basis, with each hoop penalized by the usual energy cost to bend an elastic beam into a circular arc. The presence of $N(R_i)$ reflects the fact that because of the shape of the capsid, as the radius gets smaller the DNA can pack higher up into the capsid, thus increasing the number of allowed hoops. To make analytic progress with the expression for the stored elastic energy given above, we convert it into an integral of the form

$$E_{\text{el}} = \frac{\pi \xi_{\text{p}} k_{\text{B}} T}{\sqrt{3} d_{\text{s}}/2} \int_R^{R_{\text{out}}} \frac{N(R')}{R'} \, \mathrm{d}R' . \quad (24.10)$$

The summation $\sum_i$ has been replaced by an integral $\int_R^{R_{\text{out}}} \mathrm{d}R'/(\sqrt{3} d_{\text{s}}/2)$, where the integration bounds are the inner and outer radii of the inner spool and $\sqrt{3} d_{\text{s}}/2$ is the horizontal spacing between adjacent strands of the DNA. The geometrical factor $\sqrt{3}/2$ owes its presence to the hexagonal packing of the DNA strands. R is the radius of the innermost stack of hoops, R_{out} is the radius of the capsid, $N(R')$ is the number of hoops at radius R', d_{s} is the spacing between adjacent hoops, and ξ_{p} is the persistence length of DNA. We note that this expression is a manifestation of the first term in the energy functional in (24.3), used earlier in the context of the biofunctionalized cantilever and now specialized to the geometry of a partially filled capsid. Just as the energy functional in the cantilever context reflected a competition between different contributions to the total energy (in that case, elastic bending energy and surface terms), the DNA packing problem reflects a similar competition, this time between the elastic bending and the interactions between nearby DNA segments by virtue of the charge along the DNA. In particular, the interaction energy between the DNA hoops packed in the viral capsid scales with the length and is given by

$$E_{\text{int}} = F_0 L (c^2 + c d_{\text{s}}) \exp(-d_{\text{s}}/c) , \quad (24.11)$$

where c and F_0 are constants for a given solvent and L is the length of the packed DNA. This form of the interaction energy was shown to be very robust for a variety of solvents containing monovalent and divalent cations in a series of experiments by *Rau* et al. [24.65, 66] and *Parsegian* et al. [24.67]. The forces arising from this kind of an energy are purely repulsive in character. Interestingly, in this setting, rather than using temperature as a control parameter, it is much more common to change the circumstances in such experiments by tuning concentrations of various chemical constituents. In particular, when trivalent or tetravalent cations are present in solution there is an effective attractive interaction between DNA segments. In that case, the forces are repulsive only when d_{s} is smaller than a certain critical separation d_0 (and attractive otherwise) and the form of the interaction energy changes to

$$E_{\text{int}} = F_0 L (c^2 + c d_{\text{s}}) \exp\left(\frac{d_0 - d_{\text{s}}}{c}\right) . \quad (24.12)$$

Once both the elastic and interaction contributions to the energy have been reckoned, we are in a position to compute the total energy. If we recognize that the length L of the packed DNA is given by

$$L = \frac{2}{\sqrt{3} d_{\text{s}}} \int_R^{R_{\text{out}}} 2\pi R' N(R') \, \mathrm{d}R' , \quad (24.13)$$

then the total energy for the packed DNA, in terms of L and d_s, is given by

$$E(L, d_s) = \frac{\pi \xi_p k_B T}{\sqrt{3} d_s / 2} \int_R^{R_{out}} \frac{N(R')}{R'} \mathrm{d}R' \quad (24.14)$$

$$+ F_0 (c^2 + c d_s) \exp(-d_s / c) \frac{2}{\sqrt{3} d_s} \int_R^{R_{out}} 2\pi R' N(R') \mathrm{d}R' \,.$$

The spacing at a given length L is determined by requiring that the packed DNA be in a minimum energy configuration, which is equivalent to asking that $\partial E / \partial d_s = 0$. Hence, for a given geometry and length packed, one obtains d_s and thereby calculates the energy. Thus the energy is known as a function of the length packed, and to compute the force as a function of length of DNA packed one need only differentiate this energy with respect to the length packed. The result of this procedure is an expression for the force of the form

$$F(L) = F_0 (c^2 + c d_s) \exp\left(-\frac{d_s}{c}\right) + \frac{\xi_P k_B T}{2 R^2} \,. \quad (24.15)$$

This is a generic expression valid for a capsid of any shape. The effect of the geometry is captured in the variation of d_s as a function of the length packed, as well as through the inner packing radius R. The resulting force-packing curves are shown in Fig. 24.8. In particular, this figure shows the packing force as a function of a fraction of the genome packed for a number of different solutions, with the different curves revealing the large role played by positive counterions in dictating the overall energetics of these processes.

On the basis of calculations like those given above, *Kindt* et al. [24.61] estimate that the pressure inside the capsid of the phage is on the order of 35 atmospheres. A crude estimate by *Smith* et al. [24.29] gives a figure close to 60 atmospheres. These numbers are intriguing in their own right, but more importantly they demonstrate the promise that proteins and other biological materials hold as candidates for engineering materials. To further explore the structural integrity of viruses in their role as pressurized protein shells, we now turn to an examination of the rupture stress of viral capsids.

Throughout this chapter, one of our main arguments has been the idea that whether it is our ambition to model conventional materials or their biological counterparts, modeling at the nanoscale implies challenges that can not be met either by purely continuum ideas or by traditional all-atom thinking. Indeed, one set of powerful methods is built around the attempt to borrow those features of continuum and atomistic thinking that are most robust, while rejecting those that are inapplicable at the atomic scale. As an example of this type of thinking, we examine another question drawn from the viruses-as-nanotechnology setting. In particular, since viruses have been considered a means of transporting material other than the genetic material of the virus itself, it is of interest to consider the maximum internal pressure viral capsids can sustain without rupture, as this will determine how much material can be safely packaged. To that end, we use continuum mechanics to estimate the stresses within the capsid walls. These stresses are then mapped onto atomic-level forces by appealing to the details of the protein structure of the monomers making up the capsid and a knowledge of the forces that link them. By relating the continuum and atomistic calculations, we then determine the maximum sustainable internal pressure.

We imagine the capsid to be a hollow sphere loaded by a pressure p_i from inside and a pressure p_o from outside. The inner and outer radii are R_i and R_o, respectively. As a representative example, bacteriophage

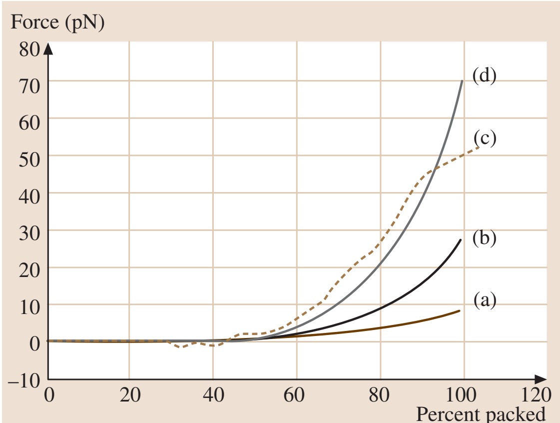

Fig. 24.8 Force as a function of the percent packed for a cylindrical capsid under purely repulsive solvent conditions. The dimensions of the capsid and the length of genome packed were chosen to represent the ϕ29 phage: $R_{out} = 210$ Å, $z = 540$ Å, and $L = 6.6$ µm. Curve (c) shows the experimental results of *Smith* et al. [24.29], while theoretical curves (a), (b), and (d) are given by (24.15), with $F_0 = 10 \times 55{,}000$, $40 \times 55{,}000$, and $100 \times 55{,}000$ pN/nm^2, respectively

GA is characterized geometrically by $R_\text{i} = 123\,\text{Å}$ and $R_\text{o} = 145\,\text{Å}$. Evaluation of a number of different capsid types suggests that treating capsids as though they have a mean thickness of roughly 15 Å suffices for the level of modeling being considered here. For the purposes of computing the internal stresses within the capsid, we begin with a statement of equilibrium from continuum mechanics that requires that at every point in the capsid

$$\nabla \cdot \sigma = \mathbf{0}\,, \tag{24.16}$$

where σ is the stress tensor comprising three normal stresses and three shear stresses. For a problem with spherical symmetry, like that considered here, the stresses reduce to a radial stress σ_R and a circumferential stress σ_T. Solution of the equilibrium equations results in stresses of the form [24.32]

$$\sigma_R = \frac{C}{r^3} + D, \quad \sigma_T = -\frac{C}{2r^3} + D\,. \tag{24.17}$$

By using the boundary conditions $\sigma_R|_{r=R_\text{i}} = -p_\text{i}$ and $\sigma_R|_{r=R_\text{o}} = -p_\text{o}$, the constants C and D can be determined with the result

$$\sigma_R = \frac{p_\text{o} R_\text{o}^3 \left(r^3 - R_\text{i}^3\right)}{r^3\left(R_\text{i}^3 - R_\text{o}^3\right)} + \frac{p_\text{i} R_\text{i}^3 \left(R_\text{o}^3 - r^3\right)}{r^3\left(R_\text{i}^3 - R_\text{o}^3\right)}\,, \tag{24.18}$$

$$\sigma_T = \frac{p_\text{o} R_\text{o}^3 \left(2r^3 + R_\text{i}^3\right)}{2r^3\left(R_\text{i}^3 - R_\text{o}^3\right)} - \frac{p_\text{i} R_\text{i}^3 \left(2r^3 + R_\text{o}^3\right)}{2r^3\left(R_\text{i}^3 - R_\text{o}^3\right)}\,. \tag{24.19}$$

The stress σ_T is our primary concern, since it acts so as to tear the sphere apart. By looking at the expressions above, we can see that this stress is maximum at $r = R_\text{i}$ and the maximum value is given by

$$\sigma_T^\text{max} = \frac{3p_\text{o}R_\text{o}^3 - p_\text{i}\left(2R_\text{i}^3 + R_\text{o}^3\right)}{2\left(R_\text{i}^3 - R_\text{o}^3\right)}\,. \tag{24.20}$$

We note that elasticity theory in and of itself is unable to comment on σ_T^max, since this is effectively a material parameter that characterizes the contacts between the various protein monomers that make up the capsid. As a result, we first examine how the rupture strength depends upon capsid dimensions in abstract terms and then turn to a concrete estimate of σ_T^max itself from several complementary perspectives. If (24.20) is rewritten using $p_\text{i} = p_\text{o} + \Delta p$ and $R_\text{o} = R_\text{i} + \Delta R$, and, further, it is realized that for typical capsid dimensions $\Delta R/R_\text{i} \ll 1$, it can be shown by rearranging (24.20) and by considering the case in which σ_T^max is much larger than p_o, the maximum sustainable internal pressure is given by

$$p_\text{i}^\text{max} = \frac{2\sigma_T^\text{max}\Delta R}{R_\text{i}}\,, \tag{24.21}$$

where p_i^max is really the quantity of interest, namely, the maximum sustainable internal pressure.

To make concrete progress to the point where we can actually estimate the rupture stress in atm, we need to consider capsids for which the structure is known and for which, at least approximately, the bonds between the monomers making up the capsid are understood. We note that in the language of fracture mechanics, what we seek is a cohesive surface model that provides a measure of the energy of interaction between two surfaces as a function of their separation [24.68]. There are a number of different ways to go about estimating the effective interaction between the monomers making up the capsid, one of which is by appealing to atomic-level calculations like those made by *Reddy* et al. [24.69]. The Viper website has systematized such information for a number of capsids, and one of the avenues we take to estimate σ_T^max is to appeal directly to their calculations. To that end, we assume that the energy of interaction per unit area as a function of separation x between adjacent monomers making up the capsid can be written in the form

$$E(x) = V_0\left[\frac{1}{4}\left(\frac{x^*}{x}\right)^{12} - \frac{1}{2}\left(\frac{x^*}{x}\right)^{6}\right]\,. \tag{24.22}$$

The motivation for this functional form is the idea that the energy of interaction between adjacent monomeric units making up the capsid is the result of van der Waals contacts, and hence our cohesive surface law has inherited the properties of the underlying atomic force fields. To proceed to an estimate of σ_T^max itself, we must determine the parameters in the cohesive model described above. To that end, we note that *Reddy* et al. [24.69] have computed the association energies of various inequivalent contacts throughout a number of different icosahedral capsids. Their calculations result in a roughly constant value of $\approx -45\,\text{cal/mole}\,\text{Å}^2$ as the association energy, which in the language of our cohesive potential results in $V_0 \approx 12.5\,\text{pN/Å}$. This may be seen by noting that the association energy is given by $E(x^*) = -V_0/4$.

Once we have fixed x^*, which amounts to choosing a particular value for the equilibrium separation between two monomers, the material parameter σ_T^max is obtained by evaluating $\partial E(x)/\partial x$ at a value of x corresponding to the point of inflection ($\partial^2 E(x)/\partial x^2 = 0$) in the cohesive surface function. For the cohesive surface function used

above, this results in a maximum stress of the form

$$\sigma_T^{\max} = \frac{7^{7/6} \times 18}{13^{13/6}} \frac{V_0}{x^*} . \quad (24.23)$$

With $\sigma_T^{\max}$ in hand, the maximum sustainable pressure is obtained from (24.21), and the results are shown in Fig. 24.9. These estimates suggest that the pressures within capsids as a result of packed DNA while large, are still smaller than our estimated rupture stresses. To more completely examine this question we have undertaken finite element elasticity calculations to examine the stresses in capsids exhibiting irregularities in both shape and thickness. In addition, further atomistic analysis of $\sigma_T^{\max}$ is needed with special reference to its dependence on distance between protein units. It would also be of interest to examine mutant versions of the monomeric units making up the capsid to see the implications of such mutations for $\sigma_T^{\max}$.

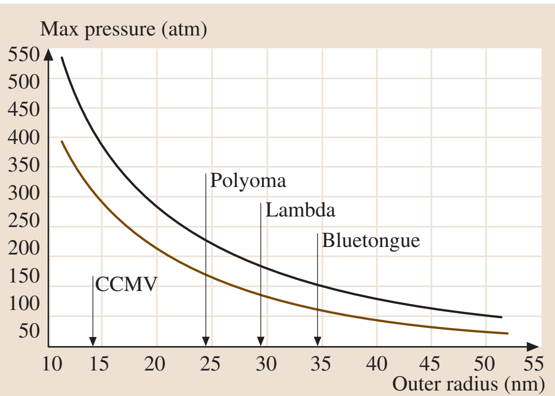

Fig. 24.9 Rupture pressure as a function of capsid radius for $x^* = 3$ Å (*upper curve*) and $x^* = 4$ Å (*lower curve*). The width of the capsid walls was set to $\Delta R = 1.5$ nm, while $V_0 = 180$ cal/molÅ^2

24.5 Concluding Remarks

One of the most compelling areas to be touched by nanotechnology is biological science. Indeed, we have argued that there is a fascinating interplay between these two subjects, with biology as a key beneficiary of advances in nanotechnology as a result of a new generation of single molecule experiments that complement traditional assays involving statistical assemblages of molecules. This interplay runs in both directions with nanotechnology continually receiving inspiration from biology itself. The goal of this chapter has been to highlight some representative examples of the interplay between biology and nanotechnology and to illustrate the role of nanomechanics in this field and how mechanical models have arisen in response to the emergence of this new field. Primary attention has been given to the particular example of the processes that attend the life cycle of bacterial viruses. Viruses feature many of the key lessons of biological nanotechnology, including self-assembly, as evidenced in the spontaneous formation of the protein shell (capsid) within which the viral genome is packaged and a motor-mediated biological process, namely, the packaging of DNA in this capsid by a molecular motor that pushes the DNA into the capsid. We argue that these processes in viruses are a compelling real-world example of nature's nanotechnology and reveal the nanomechanical challenges that will continue to be confronted at the nanotechnology-biology interface.

Though this chapter represents something of a departure from the rest of the chapters in this volume, it advances the view that biological nanotechnology serves as an inspiring vision of what nanotechnology can offer and reflects the authors' views that biologically inspired nanotechnology will play an ever increasing role as Feynman's view that "there is plenty of room at the bottom" continues to play out. Moreover, developing simple models of nature's nanotechnology can provide important insights into viable strategies for making machines at the nanoscale.

We have argued that the advance of single molecule technology presents both scientific and technological possibilities. Both classes of questions imply significant modeling demands, just as earlier advances in other settings, such as in materials for microelectronics applications, did. We claim that these modeling challenges are perhaps more acute as a result of the vicious chemical and structural nonhomogeneity of biological systems. As a result, we see an ever increasing role for modeling methods that aim to keep atomic-level specificity where needed, while rejecting such resolution elsewhere.

25. Mechanical Properties of Nanostructures

Knowledge of the mechanical properties of nanostructures is necessary for designing realistic MEMS/NEMS devices. Microelectromechanical systems (MEMS) refer to microscopic devices that have a characteristic length of less than 1 mm but more than 1 μm and combine electrical and mechanical components. Nanoelectromechanical systems (NEMS) refer to nanoscopic devices that have a characteristic length of less than 1 μm and combine electrical and mechanical components.

Elastic and inelastic properties are needed to predict deformation from an applied load in the elastic and inelastic regimes, respectively. The strength property is needed to predict the allowable operating limit. Some of the properties of interest are hardness, elastic modulus, bending strength, fracture toughness, and fatigue strength.

Structural integrity is of paramount importance in all devices. Load applied during the use of devices can result in component failure. Cracks can develop and propagate under tensile stresses, leading to failure. Atomic force microscopy and nanoindenters can be used satisfactorily to evaluate the mechanical properties of micro/nanoscale structures for use in MEMS/NEMS.

The most commonly used materials are single-crystal silicon and silicon-based materials, e.g., SiO_2 and polysilicon films deposited by low-pressure chemical vapor deposition. An early study showed silicon to be a mechanically resilient material in addition to its favorable electronic properties. Single-crystal SiC deposited on large-area silicon substrates is used for high-temperature micro/nanosensors and actuators. Amorphous alloys can be formed on both metal and silicon substrates by sputtering and plating techniques, providing more flexibility in surface-integration. Electroless deposited Ni-P amorphous thin films have been used to construct microdevices, especially using the so-called LIGA techniques. Micro/nanodevices need conductors to provide power, as well as electrical/magnetic signals to make them functional. Electroplated gold films have found wide applications in electronic devices because of their ability to make thin films and process simply. Use of SiC, Ni-P, and Au films, together with silicon and silicon-based materials, opens up new design opportunities for MEMS/NEMS devices.

This chapter presents a review of mechanical property measurements on the nanoscale of various materials of interest and stress and deformation analyses of nanostructures.

References 786

Microelectromechanical systems (MEMS) refer to microscopic devices that have a characteristic length of less than 1 mm but more than 1 μm and combine electrical and mechanical components. Nanoelectromechanical systems (NEMS) refer to nanoscopic devices that have a characteristic length of less than 1 μm and combine electrical and mechanical components. To put the dimensions in perspective, individual atoms are typically fraction of a nanometer in diameter, DNA molecules are about 2.5 nm wide, biological cells are in the range of thousands of nm in diameter, and human hair is about 75 μm in diameter. The mass of a micromachined silicon structure can be as low as 1 nN, and NEMS can be built with a mass as low as 10^{-20} N with cross sections of about 10 nm. In comparison, the mass of a drop of water is about 10 μN and the mass of an eyelash is about 100 nN. The acronym MEMS originated in the United States. The term commonly used in Europe and Japan is micro/nanodevices, which is used in a much broader sense. MEMS/NEMS terms are also now used in a broad sense. A micro/nanosystem, a term commonly used in Europe, is referred to as an intelligent miniaturized system comprising sensing, processing, and/or actuating functions.

A wide variety of MEMS, including Si-based devices, chemical and biological sensors and actuators, and miniature non-silicon structures (e.g., devices made from plastics or ceramics) have been fabricated with dimensions in the range of a couple to a few thousand microns (see e.g., [25.1–9]). A variety of NEMS have also been produced [25.10–15]. Two of the largest "killer" industrial applications of MEMS are accelerometers (about 85 million units in 2002) and digital micromirror devices (about $ 400 million in revenues in 2002). BIOMEMS and BIONEMS are increasingly used in commercial applications. The largest applications of BIOMEMS include silicon-based disposable blood pressure sensor chips for blood pressure monitoring (about 20 million units in 2002) and a variety of biosensors.

Structural integrity is of paramount importance in all devices. Load applied during the use of devices can result in component failure. Cracks can develop and propagate under tensile stresses, leading to failure [25.16, 17]. Friction/stiction and wear limit the lifetimes and compromise the performance and reliability of the devices involving relative motion [25.4, 18]. Most MEMS/NEMS applications demand extreme reliability. Stress and deformation analyses are carried out for an optimal design. MEMS/NEMS designers require mechanical properties on the nanoscale. Mechanical properties include elastic, inelastic (plastic, fracture, or viscoelastic), and strength. Elastic and inelastic properties are needed to predict deformation from an applied load in the elastic and inelastic regimes, respectively. The strength property is needed to predict the allowable operating limit. Some of the properties of interest are hardness, elastic modulus, bending strength (fracture stress), fracture toughness, and fatigue strength. Micro/nanostructures have some surface topography and local scratches dependent upon the manufacturing process. Surface roughness and local scratches may compromise the reliability of the devices and their effect needs to be studied.

Most mechanical properties are size-dependent [25.11, 16, 17]. Several researchers have measured mechanical properties of silicon and silicon-based milli- to microscale structures using tensile tests and bending tests [25.19–28], resonant structure tests for measurement of elastic properties [25.29], fracture toughness tests [25.20, 22, 30–34], and fatigue tests [25.32, 35, 36]. Most recently, a few researchers have measured mechanical properties of nanoscale structures using atomic force microscopy (AFM) [25.37, 38] and nanoindentation [25.39, 40]. For stress and deformation analyses of simple geometries and boundary condition, analytical models can be used. For analysis of complex geometries, numerical models are needed. The conventional finite element method (FEM) can be used down to a few tens of nanometers, although its applicability is questionable at the nanoscale. FEM has been used for simulation and prediction of residual stresses and strains induced in MEMS devices during fabrication [25.41], to perform fault analysis in order to study MEMS faulty behavior [25.42], to compute mechanical strain resulting from the doping of silicon [25.43], and to analyze micromechanical experimental data [25.22, 44, 45] and nanomechanical experimental data [25.38]. FEM analysis of nanostructures has been carried out to analyze the effect of types of surface roughness and scratches on stresses in nanostructures [25.46, 47].

The most commonly used materials for MEMS/NEMS are single-crystal silicon and silicon-based materials (e.g., SiO_2 and polysilicon films deposited by low pressure chemical vapor deposition (LPCVD) process) [25.11]. An early study showed silicon to be a mechanically resilient material in addition to its favorable electronic properties [25.48]. Single-crystal 3C-SiC (cubic or β-SiC) films deposited by atmospheric pressure chemical vapor deposition (APCVD) process on large-area silicon substrates are produced for high-temperature micro/nanosensor and actuator appli-

cations [25.49–51]. Amorphous alloys can be formed on both metal and silicon substrates by sputtering and plating techniques, providing more flexibility in surface-integration. Electroless deposited Ni-P amorphous thin films have been used to construct microdevices, especially using the so-called LIGA techniques [25.11, 40]. Micro/nanodevices need conductors to provide power, as well as electrical/magnetic signals to make them functional. Electroplated gold films have found wide applications in electronic devices, because of their ability to make thin films and process simplicity [25.40]. Use of SiC, Ni-P, and Au films together with silicon and silicon-based materials open up new design opportunities for MEMS/NEMS devices.

This chapter presents a review of mechanical property measurements on the nanoscale of various materials of interest, and stress and deformation analyses of nanostructures.

25.1 Experimental Techniques for Measurement of Mechanical Properties of Nanostructures

25.1.1 Indentation and Scratch Tests Using Micro/Nanoindenters

A nanoindenter is commonly used to measure hardness, elastic modulus, and fracture toughness and to perform micro/nanoscratch studies to get a measure of scratch/wear resistance of materials [25.11, 52].

Hardness and Elastic Modulus

The nanoindenter monitors and records the dynamic load and displacement of the three-sided pyramidal diamond (Berkovich) indenter during indentation with a force resolution of about 75 nN and displacement resolution of about 0.1 nm. Hardness and elastic modulus are calculated from the load-displacement data [25.11]. The peak indentation load depends on the mechanical properties of the specimen; a harder material requires higher load for a reasonable indentation depth.

Fracture Toughness

The indentation technique for fracture toughness measurement on the microscale is based on the measurement of the lengths of median-radial cracks produced by indentation. A Vickers indenter (a four-sided diamond pyramid) is used in a microhardness test. A load on the order of 0.5 N is typically used in making the Vickers indentations. The indentation impressions are examined using an optical microscope with Nomarski interference contrast to measure the length of median-radial cracks, c. The fracture toughness (K_{IC}) is calculated by the following relation [25.53]:

$$K_{\mathrm{IC}} = \alpha \left(\frac{E}{H}\right)^{1/2} \left(\frac{P}{c^{3/2}}\right) , \qquad (25.1)$$

where α is an empirical constant depending on the geometry of the indenter, H and E are hardness and elastic moduli, and P is the peak indentation load. For Vickers indenters, α has been empirically found based on experimental data and is equal to 0.016 [25.11]. Both E and H values are obtained from the nanoindentation data. The crack length is measured from the center of the indent to the end of the crack using an optical microscope. For one indent, all crack lengths are measured. The crack length c is obtained from the average values of several indents.

Scratch Resistance

In micro/nanoscratch studies, a conical diamond indenter with a tip radius of about 1 μm and an included angle of 60° is drawn over the sample surface, and the load is ramped up until substantial damage occurs [25.11]. The coefficient of friction is monitored during scratching. In order to obtain scratch depths during scratching, the surface profile of the sample surface is first obtained by translating the sample at a low load of about 0.2 mN, which is insufficient to damage a hard sample surface. The 500-μm-long scratches are made by translating the sample while ramping the loads on the conical tip over different loads depending on the material hardness. The actual depth during scratching is obtained by subtracting the initial profile from the scratch depth measured during scratching. In order to measure the scratch depth after the scratch, the scratched surface is profiled at a low load of 0.2 mN and is subtracted from the actual surface profile before scratching.

25.1.2 Bending Tests of Nanostructures Using an AFM

Quasi-static bending tests of fixed nanobeam arrays are carried out using an AFM [25.37, 38, 54]. A three-sided pyramidal diamond tip (with a radius of about 200 nm)

B. Bhushan • © Springer 2004

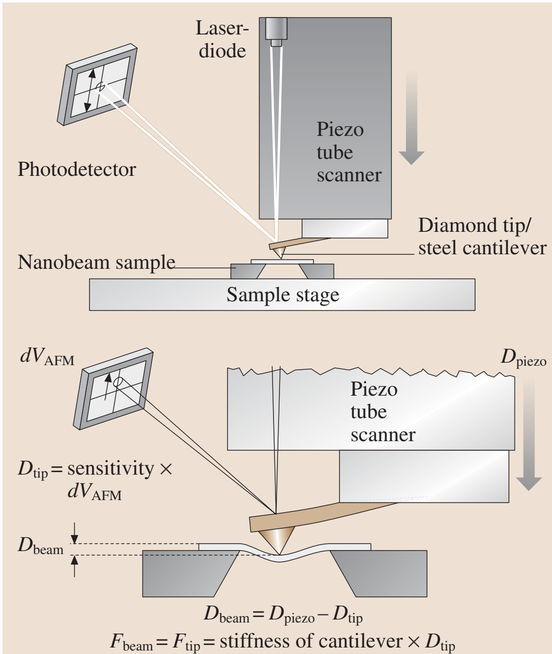

Fig. 25.1 Schematic showing the details of a nanoscale bending test. The AFM tip is brought to the center of the nanobeam and the piezo is extended over a known distance. By measuring the tip displacement, a load-displacement curve of the nanobeam can be obtained [25.38]

mounted on a rectangular stainless steel cantilever is used for the bending tests. The beam stiffness is selected based on the desired load range. The stiffness of the cantilever beams for application of normal load up to 100 μN is about 150–200 N/m.

The wafer with nanobeam array is fixed onto a flat sample chuck using double-stick tape [25.38]. For the bending test, the tip is brought over the nanobeam array with the help of the sample stage of the AFM and a built-in high magnification optical microscope (Fig. 25.1). For the fine positioning of the tip over a chosen beam, the array is scanned in contact mode at a contact load of about 2–4 μN, which results in negligible damage to the sample. After scanning, the tip is located at one end of a chosen beam. To position the tip at the center of the beam span, the tip is moved to the other end of the beam by giving the X-piezo an offset voltage. The value of this offset is determined after several such attempts have been made in order to minimize effects of piezo drift. Half of this offset is then applied to the X-piezo after the tip is positioned at one end of the beam, which usually results in the tip being moved to the center of the span. Once the tip is positioned over the center of the beam span, the tip is held stationary without scanning, and the Z-piezo is extended by a known distance, typically about 2.5 μm, at a rate of 10 nm/s, as shown in Fig. 25.1. During this time, the vertical deflection signal (dV_{AFM}), which is proportional to the deflection of the cantilever (D_{tip}), is monitored. The displacement of the piezo is equal to the sum of the displacements of the cantilever and nanobeam. Hence, the displacement of the nanobeam (D_{beam}) under the point of load can be determined as

$$D_{beam} = D_{piezo} - D_{tip} . \tag{25.2}$$

The load (F_{beam}) on the nanobeam is the same as the load on the tip/cantilever (F_{tip}) and is given by

$$F_{beam} = F_{tip} = D_{tip} \times k , \tag{25.3}$$

where k is the stiffness of the tip/cantilever. In this manner, a load displacement curve for each nanobeam can be obtained.

The photodetector sensitivity of the cantilever needs to be calibrated to obtain D_{tip} in nm. For this calibration, the tip is pushed against a smooth diamond sample by moving the Z-piezo over a known distance. For the hard diamond material, the actual deflection of the tip can be assumed to be the same as the Z-piezo travel (D_{piezo}), and the photodetector sensitivity (S) for the cantilever setup is determined as

$$S = D_{piezo}/dV_{AFM} \text{ nm/V} . \tag{25.4}$$

In the measurements, D_{tip} is given as $dV_{AFM} \times S$.

Since a sharp tip would result in an undesirable large local indentation, *Sundararajan* and *Bhushan* [25.38] used a worn (blunt) diamond tip. Indentation experiments using this tip on a silicon substrate yielded a residual depth of less than 8 nm at a maximum load of 120 μN, which is negligible compared to displacements of the beams (several hundred nm). Hence, we can assume that negligible local indentation or damage is created during the bending process of the beams, and that the displacement calculated from (25.2) is entirely that of the beam structure.

Elastic Modulus and Bending Strength

Elastic modulus and bending strength (fracture stress) of the beams can be estimated by equations based on the assumption that the beams follow linear elastic theory of an isotropic material. This is probably valid since the beams have high length-to-width (ℓ/w) and length-to-thickness (ℓ/t) ratios and also since the length direction

is along the principal stress direction during the test. For a fixed elastic beam loaded at the center of the span, the elastic modulus is expressed as

$$E = \frac{\ell^3}{192I} m , \tag{25.5}$$

where ℓ is the beam length, I is the area moment of inertia for the beam cross section, and m is the slope of the load-displacement curve during bending [25.55]. The area moment of inertia for a beam with a trapezoidal cross section is calculated from the following equation:

$$I = \frac{w_1^2 + 4w_1 w_2 + w_2^2}{36(w_1 + w_2)} t^3 , \tag{25.6}$$

where w_1 and w_2 are the upper and lower widths, respectively, and t is the thickness of the beam. According to linear elastic theory, for a centrally loaded beam, the moment diagram is shown in Fig. 25.2. The maximum moments are generated at the ends (negative moment) and under the loading point (positive moment), as shown in Fig. 25.2. The bending stresses generated in the beam are proportional to the moments and are compressive or tensile about the neutral axis (line of zero stress). The maximum tensile stress (σ_b, which is the bending strength or fracture stress) is produced on the top surface at both the ends and is given by [25.55]

$$\sigma_b = \frac{F_{max} \ell e_1}{8I} , \tag{25.7}$$

where F_{max} is the applied load at failure and e_1 is the distance of the top surface from the neutral plane of the beam cross section and is given by [25.55]

$$e_1 = \frac{t(w_1 + 2w_2)}{3(w_1 + w_2)} . \tag{25.8}$$

Although the moment value at the center of the beam is the same as at the ends, the tensile stresses at the center (generated on the bottom surface) are less than those generated at the ends, as per (25.7), because the distance from the neutral axis to the bottom surface is less than e_1. This is because of the trapezoidal cross section of the beam, which results in the neutral axis being closer to the bottom surface than the top (Fig. 25.2).

In the preceding analysis, the beams were assumed to have fixed ends. However, in the nanobeams used by *Sundararajan* and *Bhushan* [25.38], the underside of the beams was pinned over some distance on either side of the span. Hence, a finite element model of the beams was created to see if the difference in the boundary conditions affected the stresses and displacements of the beams. It was found that the difference in the stresses was less than

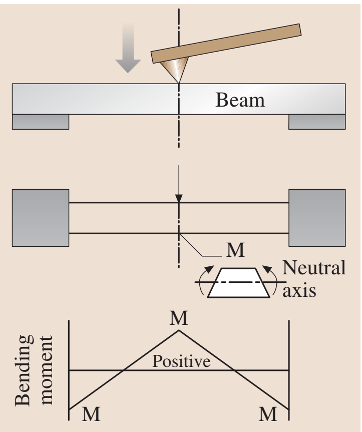

Fig. 25.2 A schematic of the bending moments generated in the beam during a quasi-static bending experiment with the load at the center of the span. The maximum moments occur under the load and at the fixed ends. Due to the trapezoidal cross section, the maximum tensile bending stresses occur at the top surfaces at the fixed ends

1%. This indicates that the boundary conditions near the ends of the actual beams are not that different from that of the fixed ends. Therefore, the bending strength values can be calculated from (25.7).

Fracture Toughness

Fracture toughness is another important parameter for brittle materials such as silicon. In the case of the nanobeam arrays, these are not best suited for fracture toughness measurements, because they do not possess regions of uniform stress during bending. *Sundararajan* and *Bhushan* [25.38] developed a methodology, and its steps are outlined schematically in Fig. 25.3a. First, a crack of known geometry is introduced in the region of maximum tensile bending stress, i. e., on the top surface near the ends of the beam. This is achieved by generating a scratch at high normal load across the width (w_1) of the beam using a sharp diamond tip (radius < 100 nm). A typical scratch thus generated is shown in Fig. 25.3b. By bending the beam as shown, a stress concentration will be formed under the scratch. This will lead to failure of the beam under the scratch once a critical load (fracture load) is attained. The fracture load and relevant dimensions of the scratch are input into the FEM model, which is used to generate the fracture stress plots. Figure 25.3c shows an FEM simulation of one such experiment, which reveals that the maximum stress does occur under the scratch.

If we assume that the scratch tip acts as a crack tip, a bending stress will tend to open the crack in Mode I. In this case, the stress field around the crack tip can be described by the stress intensity parameter K_I (for Mode I) for linear elastic materials [25.56]. In particular, the stresses corresponding to the bending stresses are

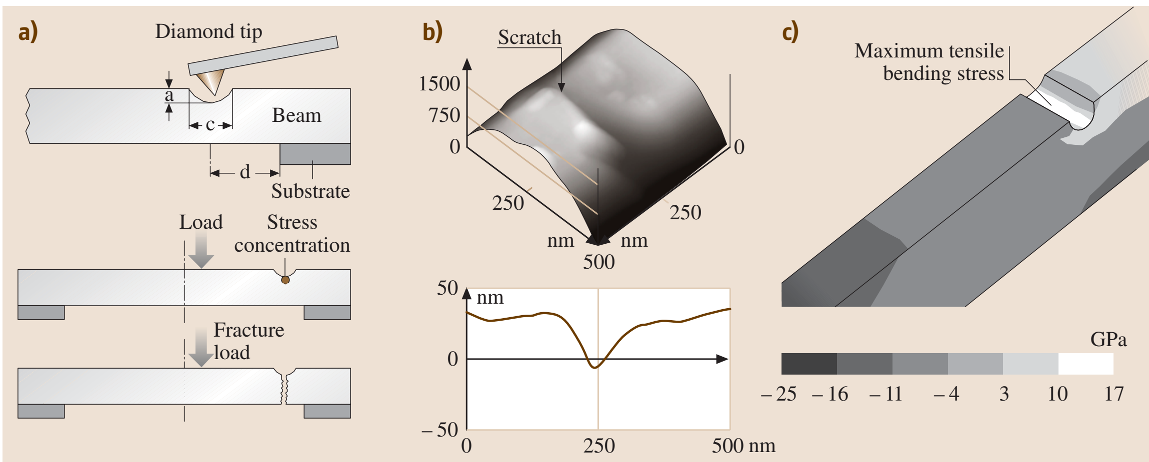

Fig. 25.3 **(a)** Schematic of technique to generate a defect (crack) of known dimensions in order to estimate fracture toughness. A diamond tip is used to generate a scratch across the width of the beam. When the beam is loaded as shown, a stress concentration is formed at the bottom of the scratch. The fracture load is then used to evaluate the stresses using FEM. **(b)** AFM 3-D image and 2-D profile of a typical scratch. **(c)** Finite element model results verifying that the maximum bending stress occurs at the bottom of the scratch [25.38]

described by

$$\sigma = \frac{K_I}{\sqrt{2\pi r}} \cos\left(\frac{\theta}{2}\right)\left[1+\sin\left(\frac{\theta}{2}\right)\sin\left(\frac{3\theta}{2}\right)\right] \tag{25.9}$$

for every point $p(r,\theta)$ around the crack tip, as shown in Fig. 25.4. If we substitute the fracture stress (σ_f) to the left hand side of (25.9), then the K_I value can be substituted with its critical value, which is the fracture toughness K_{IC}. Now, the fracture stress can be determined for the point ($r=0$, $\theta=0$), i. e., right under the crack tip as explained above. However, we cannot substitute $r=0$ in (25.9). The alternative is to substitute a value for r, which is as close to zero as possible. For silicon, a reasonable number is the distance between neighboring atoms in the (111) plane, the plane along which silicon exhibits the lowest fracture energy. This value was calculated from silicon unit cell dimensions of 0.5431 nm [25.57] to be 0.4 nm (half of the face diagonal). This assumes that Si displays no plastic zone around the crack tip, which is reasonable since in tension, silicon is not known to display much plastic deformation at room temperature. *Sundararajan* and *Bhushan* [25.38] used values $r = 0.4–1.6$ nm (i. e., distances up to four times the distance between the nearest neighboring atoms) to estimate the fracture toughness for both Si and SiO_2 according to the following equation:

$$K_{IC} = \sigma_f\sqrt{2\pi r} \qquad r = 0.4–1.6\,\text{nm}\,. \tag{25.10}$$

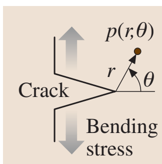

Fig. 25.4 Schematic of crack tip and coordinate systems used in (25.9) to describe a stress field around the crack tip in terms of the stress intensity parameter, K_I [25.38]

Fatigue Strength

In addition to the properties mentioned so far that can be evaluated from quasi-static bending tests, the fatigue properties of nanostructures are also of interest. This is especially true for MEMS/NEMS involving vibrating structures such as oscillators and comb drives [25.58] and hinges in digital micromirror devices [25.59]. To study the fatigue properties of the nanobeams, *Sundararajan* and *Bhushan* [25.38] applied monotonic cyclic stresses using an AFM, Fig. 25.5a. Similar to the bending test, the diamond tip is first positioned at the center of the beam span. In order to ensure that the tip is always in contact with the beam (as opposed to impacting it), the piezo is first extended by a distance D_1, which ensures a minimum stress on the beam. After this extension, a cyclic displacement of amplitude, D_2, is applied continuously until failure of the beam occurs.

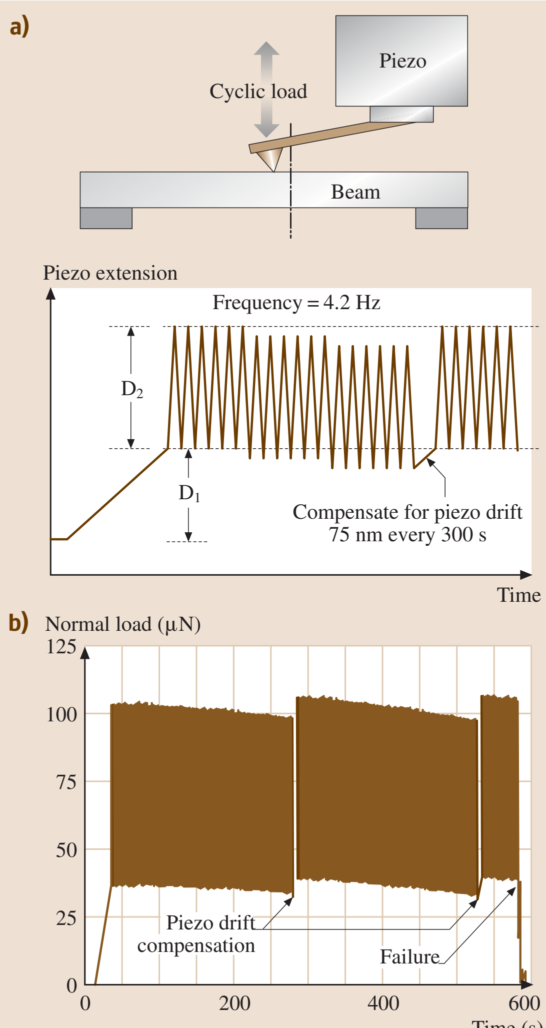

Fig. 25.5 **(a)** Schematic showing the details of the technique to study fatigue behavior of the nanobeams. The diamond tip is located at the middle of the span, and a cyclic load at 4.2 Hz is applied to the beam by forcing the piezo to move in the pattern shown. An extension is made every 300 s to compensate for the piezo drift to ensure that the load on the beam is kept fairly constant. **(b)** Data from a fatigue experiment on a nanobeam until failure. The normal load is computed from the raw vertical deflection signal. The compensations for piezo drift keep the load fairly constant [25.38]

This results in the application of a cyclic load to the beam. The maximum frequency of the cyclic load that could be attained using the AFM by *Sundararajan* and *Bhushan* [25.38] was 4.2 Hz. The vertical deflection signal of the tip is monitored throughout the experiment. The signal follows the pattern of the piezo input up to failure, which is indicated by a sudden drop in the signal. During initial runs, piezo drift was observed that caused the piezo to gradually move away from the beam (i. e., to retract), resulting in a continuous decrease in the applied normal load. In order to compensate for this, the piezo is given a finite extension of 75 nm every 300 s, as shown in Fig. 25.5a. This results in keeping the applied loads fairly constant. The normal load variation (calculated from the vertical deflection signal) from a fatigue test is shown in Fig. 25.5b. The cyclic stress amplitudes (corresponding to D_2) and fatigue lives are recorded for every sample tested. Values for D_1 are set such that minimum stress levels are about 20% of the bending strengths.

25.1.3 Bending Tests Using a Nanoindenter

Quasi-static bending tests of micro/nanostructures are also carried out using a nanoindenter [25.39, 40]. The advantage of the nanoindenter is that loads up to about 500 mN, higher than that in AFM (up to about 100 μN), can be used for structures requiring high loads for experiments. To avoid the indenter tip pushing into the specimen, a blunt tip is used in the bending and fatigue tests. *Li* et al. [25.40] used a diamond conical indenter with a radius of 1 μm and an included angle of 60°. The load position used was at the center of the span for the bridge beams and 10 μm off from the free end of the cantilever beams. An optical microscope with a magnification of 1,500× or an in situ AFM is used to locate the loading position. Then the specimen is moved under the indenter location with a resolution of about 200 nm in the longitudinal direction and less than 100 nm in the lateral direction.

Using the analysis presented earlier, elastic modulus and bending strength of the beams can be obtained from the load-displacement curves [25.40]. For fatigue tests, an oscillating load is applied and contact stiffness is measured during the tests. A significant drop in the contact stiffness during the test is a measure of the number of cycles to failure [25.39].

25.2 Experimental Results and Discussion

25.2.1 Indentation and Scratch Tests of Various Materials Using Micro/Nanoindenters

Studies have been conducted on five different materials: undoped single-crystal Si(100), undoped polysilicon film, SiO_2 film, SiC film, electroless deposited Ni-11.5 wt% P amorphous film, and electroplated Au film [25.40, 50, 51]. A 3-µm thick polysilicon film was deposited by a low pressure chemical vapor deposition (LPCVD) process on a Si(100) substrate. The 1-µm thick SiO_2 film was deposited by a plasma enhanced chemical vapor deposition (PECVD) process on a Si(111) substrate. A 3-µm thick 3C-SiC film was epitaxially grown using an atmospheric pressure chemical vapor deposition (APCVD) process on a Si(100) substrate. A 12-µm thick Ni-P film was electroless plated on a 0.8-mm-thick Al-4.5 wt% Mg alloy substrate. A 3-µm-thick Au film was electroplated on a Si(100) substrate.

Hardness and Elastic Modulus

Hardness and elastic modulus measurements are made using a nanoindenter [25.40]. The hardness and elastic modulus values of various materials at a peak indentation depth of 50 nm are summarized in Fig. 25.6 and Table 25.1. The SiC film exhibits the highest hardness of about 25 GPa and an elastic modulus of about 395 GPa among the samples examined, followed by the undoped Si(100), undoped polysilicon film, SiO_2 film, Ni-P film, and Au film. The hardness and elastic modulus data of the undoped Si(100) and undoped polysilicon film are comparable. For the metal alloy films, the Ni-P film exhibits higher hardness and elastic modulus than the Au film.

Table 25.1 Hardness, elastic modulus, fracture toughness, and critical load results of the bulk single-crystal Si(100) and thin films of undoped polysilicon, SiO_2, SiC, Ni-P, and Au

Samples	Hardness (GPa)	Elastic modulus (GPa)	Fracture toughness ($MPa\,m^{1/2}$)	Critical load (mN)
Undoped Si(100)	12	165	0.75	11
Undoped polysilicon film	12	167	1.11	11
SiO_2 film	9.5	144	0.58 (Bulk)	9.5
SiC film	24.5	395	0.78	14
Ni-P film	6.5	130		0.4 (Plowing)
Au film	4	72		0.4 (Plowing)

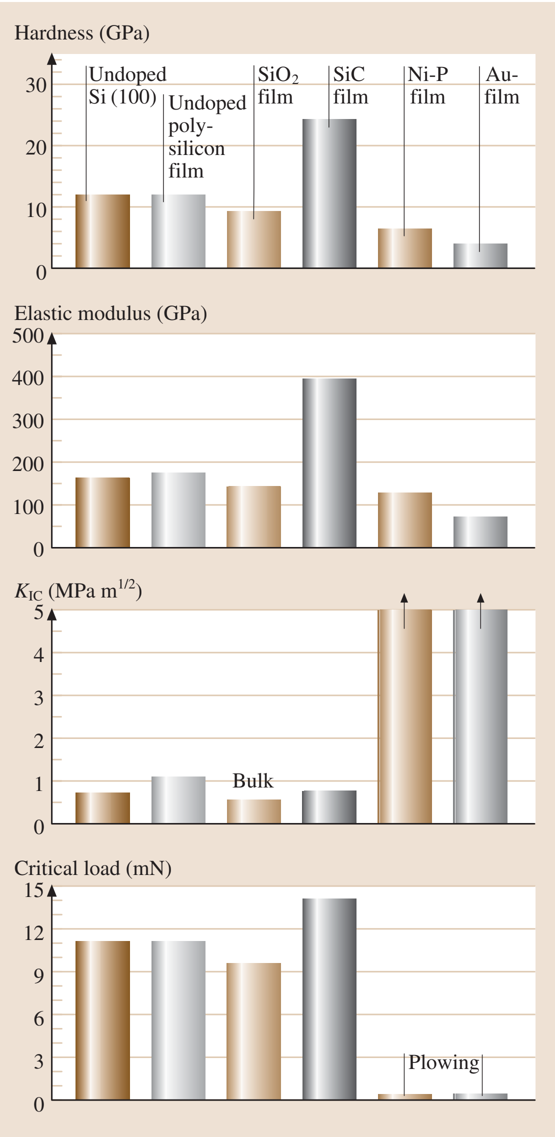

Fig. 25.6 Bar chart summarizing the hardness, elastic modulus, fracture toughness, and critical load (from scratch tests) results of the bulk undoped single-crystal Si(100) and thin films of undoped polysilicon, SiO_2, SiC, Ni-P, and Au [25.40]

Fracture Toughness

The optical images of Vickers indentations made using a microindenter at a normal load of 0.5 N held for 15 s on the undoped Si(100), undoped polysilicon film, and SiC film are shown in Fig. 25.7 [25.51]. The SiC film exhibits the smallest indentation mark, followed by the undoped polysilicon film and undoped Si(100). These Vickers indentation depths are smaller than one-third of the film thickness. Thus, the influence of the substrate on the fracture toughness of the films can be ignored. In addition to the indentation marks, radial cracks are observed emanating from the indentation corners. The SiC film shows the longest radial crack length, followed by the undoped Si(100) and undoped polysilicon film. The radial cracks for the undoped Si(100) are straight, whereas those for the SiC and undoped polysilicon film are not straight but go in a zigzag manner. The fracture toughness (K_{IC}) is calculated using (25.1).

The fracture toughness values of all samples are summarized in Fig. 25.6 and Table 25.1. The SiO_2 film used in this study is about 1 μm thick, which is not thick enough for a fracture toughness measurement. The fracture toughness values of bulk silica are listed instead for a reference. The Ni-P and Au films exhibit very high fracture toughness values that cannot be measured by indentation methods. For other samples, the undoped polysilicon film has the highest value, followed by the undoped Si(100), SiC film, and SiO_2 film. For the undoped polysilicon film, the grain boundaries can stop the radial cracks and change the propagation directions of the radial cracks, making the propagation of these cracks more difficult. Values of fracture toughness for the undoped Si(100) and SiC film are comparable. Since the undoped Si(100) and SiC film are single crystal, no grain boundaries are present to stop the radial cracks and change the propagation directions of the radial cracks. This is why the SiC film shows a lower fracture toughness value than the bulk polycrystal SiC materials of 3.6 MPa $m^{1/2}$ [25.60].

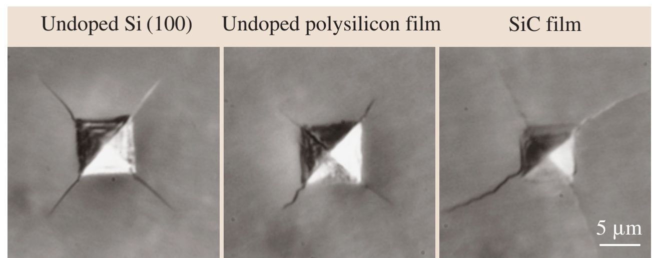

Fig. 25.7 Optical images of Vickers indentations made at a normal load of 0.5 N held for 15 s on the undoped Si(100), undoped polysilicon film, and SiC film [25.51]

Scratch Resistance

The scratch resistance of various materials has been studied using a nanoindenter by *Li* et al. [25.40]. Figure 25.8 compares the coefficient of friction and scratch depth profiles as a function of increasing normal load and optical images of three regions over scratches: at the beginning of the scratch (indicated by A on the friction profile), at the point of initiation of damage at which the coefficient of friction increases to a high value or increases abruptly (indicated by B on the friction profile), and towards the end of the scratch (indicated by C on the friction profile) for all samples. Note that the ramp loads for the Ni-P and Au range are from 0.2 to 5 mN, whereas the ramp loads for other samples are from 0.2 to 20 mN. All samples exhibit a continuous increase in the coefficient of friction with increasing normal load from the beginning of the scratch. The continuous increase in the coefficient of friction during scratching is attributed to the increasing plowing of the sample by the tip with increasing normal load, as shown in the SEM images in Fig. 25.8. The abrupt increase in the coefficient of friction is associated with catastrophic failure, as well as significant plowing of the tip into the sample. Before the critical load, the coefficient of friction of the undoped polysilicon, SiC, and SiO_2 films increased at a slower rate and was smoother than that of the other samples. The undoped Si(100) exhibits some bursts in the friction profiles before the critical load. At the critical load, the SiC and undoped polysilicon films exhibit a small increase in the coefficient of friction, whereas the undoped Si(100) and undoped polysilicon film exhibit a sudden increase in the coefficient of friction. The Ni-P and Au films show a continuous increase in the coefficient of friction, indicating the behavior of a ductile metal. The bursts in the friction profile might result from the plastic deformation and material pile-up in front of the scratch tip. The Au film exhibits a higher coefficient of friction than the Ni-P film, because it has lower hardness and elastic modulus values than the Ni-P film.

The SEM images show that below the critical loads the undoped Si(100) and undoped polysilicon film were damaged by plowing, associated with the plastic flow of the material and formation of debris on the sides of the scratch. For the SiC and SiO_2 films, in region A, a plowing scratch track was found without any debris on the side of the scratch, which is probably responsible for the smoother curve and slower increase in the

Fig. 25.8 Coefficient of friction and scratch depth profiles as a function of increasing normal load and optical images of three regions over scratches: at the beginning of the scratch (indicated by A on the friction profile), at the point of initiation of damage at which the coefficient of friction increases to a high value or increases abruptly (indicated by B on the friction profile), and towards the end of the scratch (indicated by C on the friction profile) for all samples [25.40]

coefficient of friction before the critical load. After the critical load, for the SiO_2 film, delamination of the film from the substrate occurred, followed by cracking along the scratch track. For the SiC film, only several small debris particles were found without any cracks on the side of the scratch, which is responsible for the small increase in the coefficient of friction at the critical load. For the undoped Si(100), cracks were found on the side of the scratch right from the critical load and up, which is probably responsible for the big bursts in the friction profile. For the undoped polysilicon film, no cracks were found on the side of the scratch at the critical load. This might result from grain boundaries, which can stop the propagation of cracks. At the end of the scratch, some of the surface material was torn away and cracks were found on the side of the scratch in the undoped Si(100). A couple of small cracks were found in the undoped polysilicon and SiO_2 films. No crack was found in the SiC film. Even at the end of the scratch, less debris was found in the SiC film. A curly chip was found at the end of the scratch in both Ni-P and Au films. This is a typical characteristic of ductile metal alloys. The Ni-P and Au films were damaged by plowing right from the beginning of the scratch with material pile-up at the side of the scratch.

The scratch depth profiles obtained during and after the scratch on all samples with respect to initial profile, after the cylindrical curvature is removed, are plotted in Fig. 25.8. Reduction in scratch depth is observed after scratching as opposed to during scratching. This reduction in scratch depth is attributed to an elastic recovery after removal of the normal load. The scratch depth after scratching indicates the final depth, which reflects the extent of permanent damage and plowing of the tip into the sample surface and is probably more relevant for visualizing the damage that can occur in real applications. For the undoped Si(100), undoped polysilicon film, and SiO_2 film, there is a large scatter in the scratch depth data after the critical loads, which is associated with the generation of cracks, material removal, and debris. The scratch depth profile is smooth for the SiC film. It is noted that the SiC film exhibits the lowest scratch depth among the samples examined. The scratch depths of the undoped Si(100), undoped polysilicon film, and SiO_2 film are comparable. The Ni-P and Au films exhibit much larger scratch depths than other samples. The scratch depth of the Ni-P film is smaller than that of the Au film.

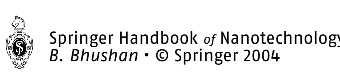
The critical loads estimated from friction profiles for all samples are compared in Fig. 25.6 and Table 25.1. The SiC film exhibits the highest critical load of about 14 mN, as compared to other samples. The undoped Si(100) and undoped polysilicon film show comparable critical load of about 11 mN, whereas the SiO_2 film shows a low critical load of about 9.5 mN. The Ni-P and Au films were damaged by plowing right from the beginning of the scratch.

25.2.2 Bending Tests of Nanobeams Using an AFM

Bending tests have been performed on Si and SiO_2 nanobeam arrays [25.38, 54]. The single-crystal silicon bridge nanobeams were fabricated by bulk micromachining incorporating enhanced-field anodization using an AFM [25.37]. The Si nanobeams are oriented along the [110] direction in the (001) plane. Subsequent thermal oxidation of the beams results in the formation of SiO_2 beams. The cross section of the nanobeams is trapezoidal owing to the anisotropic wet etching process. SEM micrographs of Si and SiO_2 nanobeam arrays and a schematic of the shape of a typical nanobeam are shown in Fig. 25.9. The actual widths and thicknesses of nanobeams were measured using an AFM in tapping mode prior to tests using a standard Si tapping mode tip (tip radius < 10 nm). Surface roughness measurements of the nanobeam surfaces in tapping mode yielded a σ of 0.7 ± 0.2 nm and peak-to-valley (P–V) distance of 4 ± 1.2 nm for Si and a σ of 0.8 ± 0.3 nm and a P–V distance of 3.1 ± 0.8 nm for SiO_2. Prior to testing, the Si nanobeams were cleaned by immersing them in a "piranha etch" solution (3 : 1 solution by volume of 98% sulphuric acid and 30% hydrogen peroxide) for 600 s to remove any organic contaminants.

Bending Strength

Figure 25.10 shows typical load-displacement curves for Si and SiO_2 beams that were bent to failure [25.38, 54]. The upper width (w_1) of the beams is indicated in the figure. Also indicated are the elastic modulus values obtained from the slope of the load-displacement curve



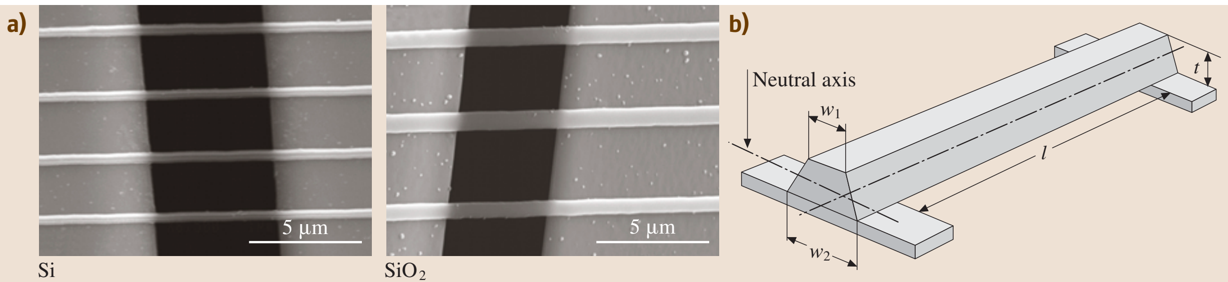


Fig. 25.9 (a) SEM micrographs of nanobeam arrays, and **(b)** a schematic of the shape of a typical nanobeam. The trapezoidal cross section is due to the anisotropic wet etching during the fabrication [25.54]

(25.5). All the beams tested showed linear elastic behavior followed by abrupt failure, which is suggestive of brittle fracture. Figure 25.11 shows the scatter in the values of elastic modulus obtained for both Si and SiO_2

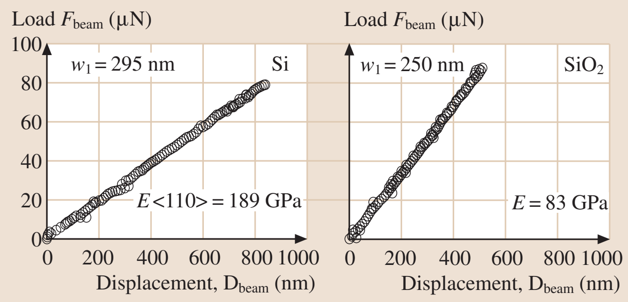

Fig. 25.10 Typical load-displacement curves of silicon and SiO_2 nanobeams. The curves are linear until sudden failure, indicative of brittle fracture of the beams. The elastic modulus (E) values calculated from the curves are shown. The dimensions of the Si beam were $w_1 = 295$ nm, $w_2 = 484$ nm, and $t = 255$ nm, while those of the SiO_2 beam were $w_1 = 250$ nm, $w_2 = 560$ nm, and $t = 425$ nm [25.54]

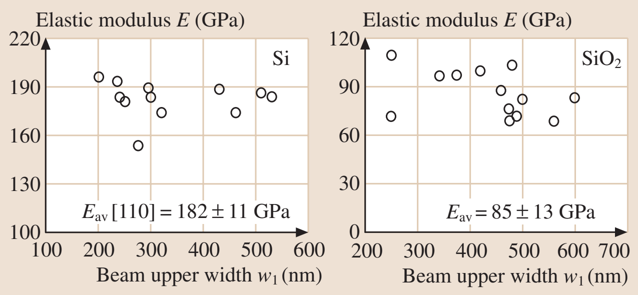

Fig. 25.11 Elastic modulus values measured for Si and SiO_2. The average values are shown. These are comparable to bulk values, which demonstrates that elastic modulus shows no specimen size dependence [25.38]

along with the average values (± standard deviation). The scatter in the values may be due to differences in the orientation of the beams with respect to the trench and the loading point being a little off center with respect to the beam span. The average values are a little higher than the bulk values (169 GPa for Si[110] and 73 GPa for SiO_2 in Table 25.2). However, the values of E obtained from (25.5) have an error of about 20% due to the uncertainties in beam dimensions and spring constant of the tip/cantilever (which affects the measured load). Hence the elastic modulus values on the nanoscale can be considered comparable to bulk values.

Most of the beams when loaded quasi-statically at the center of the span broke at the ends, as shown in Fig. 25.12a, which is consistent with the fact that maximum tensile stresses occur on the top surfaces near the ends. (See FEM stress distribution results in Fig. 25.12b.) Figure 25.13 shows the values of bending strength obtained for different beams. There appears to be no trend in bending strength with the upper width (w_1) of the beams. The large scatter is expected for the strength of brittle materials, since they are dependent on preexisting flaw population in the material and, hence, are statistical in nature. The Weibull distribution, a statistical analysis, can be used to describe the scatter in the bending strength values. The means of the Weibull distributions were found to be 17.9 GPa and 7.6 GPa for Si and SiO_2, respectively. Previously reported numbers of strengths range from 1 to 6 GPa for silicon [25.19, 20, 22–25, 27, 45, 61, 62] and about 1 GPa for SiO_2 [25.34] microscale specimens. This clearly indicates that bending strength shows a specimen size dependence. Strength of brittle materials is dependent on preexisting flaws in the material. Since for nanoscale specimens the volume is smaller than for micro- and macroscale specimens, the flaw population will be smaller as well, resulting in higher values of strength.

Table 25.2 Summary of measured parameters from quasi-static bending tests

Sample	Elastic modulus E (GPa)		Bending strength σ_b (GPa)		Fracture toughness K_{IC} (MPa $\sqrt{m}$)		
	Measured	Bulk value	Measured	Reported (microscale)	Estimated	Reported (microscale)	Bulk value
Si	182±11	169[1]	18±3	< 10[3]	1.67 ± 0.4	$0.6-1.65$[5]	0.9[6]
SiO_2	85±13	73[2]	7.6±2	< 2[4]	0.60 ± 0.2	$0.5-0.9$[4]	–

[1] Si(110), [25.63] [2] [25.64] [3] [25.19, 20, 22–25, 45, 61, 62] [4] [25.34] [5] [25.30–33] [6] [25.57]

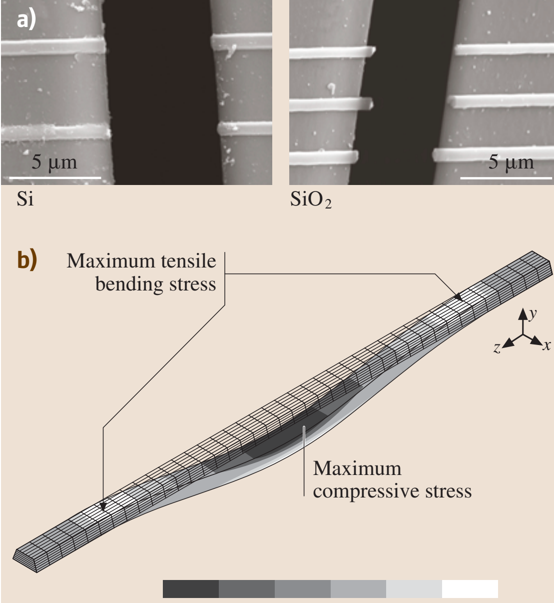

Fig. 25.12 **(a)** SEM micrographs of nanobeams that failed during quasi-static bending experiments. The beams failed at or near the ends, which is the location of maximum tensile bending stress [25.54], and **(b)** bending stress distribution for silicon nanobeam, indicating that the maximum tensile stresses occur on the top surfaces near the fixed ends

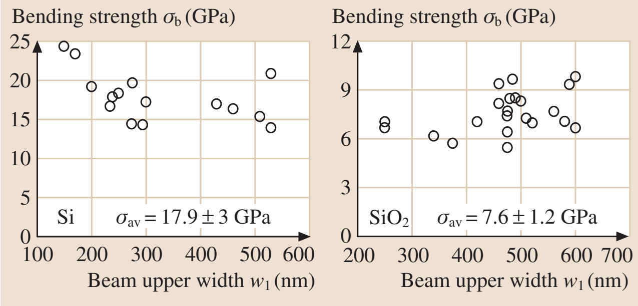

Fig. 25.13 Bending strength values obtained from bending experiments. Average values are indicated. These values are much higher than values reported for microscale specimens, indicating that bending strength shows a specimen size effect [25.38]

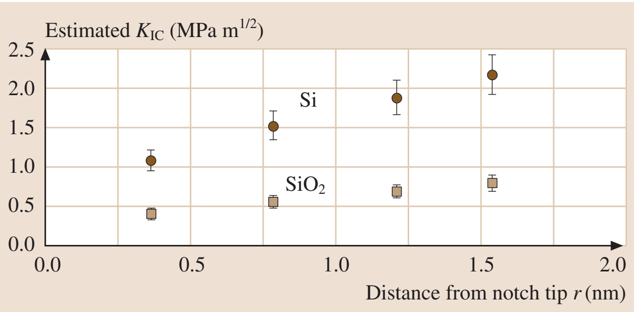

Fig. 25.14 Fracture toughness (K_{IC}) values for increasing values of r corresponding to distance between neighboring atoms in {111} planes of silicon (0.4 nm). Hence r values between 0.4 and 1.6 nm are chosen. The K_{IC} values thus estimated are comparable to values reported by others for both Si and SiO_2 [25.38]

Fracture Toughness

Estimates of fracture toughness calculated using (25.10) for Si and SiO_2 are shown in Fig. 25.14 [25.38]. The results show that the K_{IC} estimate for Si is about 1–2 MPa $\sqrt{m}$, whereas for SiO_2 the estimate is about 0.5–0.9 MPa $\sqrt{m}$. These values are comparable to values reported by others on larger specimens for Si [25.30–33] and SiO_2 [25.34]. The high values obtained for Si could be due to the fact that the scratches, despite being quite sharp, still have a finite radius of about 100 nm. The bulk value for silicon is about 0.9 MPa $\sqrt{m}$ (Table 25.2). Fracture toughness is considered a material property and is believed to be in-

dependent of specimen size. The values obtained in this study, given its limitations, appear to show that fracture toughness is comparable, if not a little higher on the nanoscale.

Fatigue Strength

Fatigue strength measurements of Si nanobeams have been carried out by *Sundararajan* and *Bhushan* [25.38] using an AFM and *Li* and *Bhushan* [25.39] using a nanoindenter. Various stress levels were applied to nanobeams by *Sundararajan* and *Bhushan* [25.38]. The minimum stress was 3.5 GPa for Si beams and 2.2 GPa for SiO_2 beams. The frequency of applied load was 4.2 Hz. In general, the fatigue life decreased with increasing mean stress as well as increasing stress amplitude. When the stress amplitude was less than 15% of the bending strength, the fatigue life was greater than 30,000 cycles for both Si and SiO_2. However, the mean stress had to be less than 30% of the bending strength for a life of greater than 30,000 for Si, whereas even at a mean stress of 43% of the bending strength, SiO_2 beams showed a life greater than 30,000. During fatigue, the beams broke under the loading point or at the ends when loaded at the center of the span. This was different from the quasi-static bending tests, where the beams broke at the ends almost every time. This could be due to the fact that the stress levels under the load and at the ends are not that different and fatigue crack propagation could occur at either location. Figure 25.15 shows a nanoscale *S*-*N* curve with bending stress (*S*) as a function of fatigue in cycles (*N*) with an apparent endurance life at lower stress. This study clearly demonstrates that fatigue properties of nanoscale specimens can be studied.

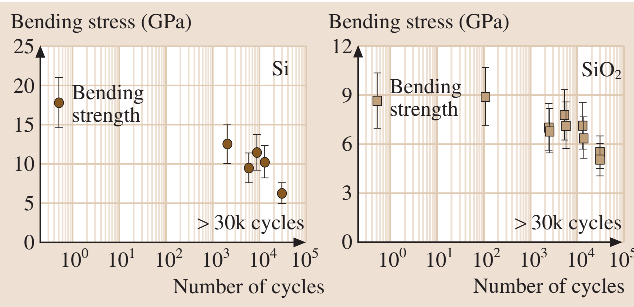

Fig. 25.15 Fatigue test data showing applied bending stress as a function of number of cycles. A single load-unload sequence is considered 1 cycle. The bending strength data points are, therefore, associated with $\frac{1}{2}$ cycle, since failure occurs upon loading [25.38]

SEM Observations of Fracture Surfaces

Figure 25.16 shows SEM images of the fracture surfaces of nanobeams broken during quasi-static bending, as well as fatigue [25.38]. In the quasi-static cases, the maximum tensile stresses occur on the top surface, so it is reasonable to assume that fracture initiated at or

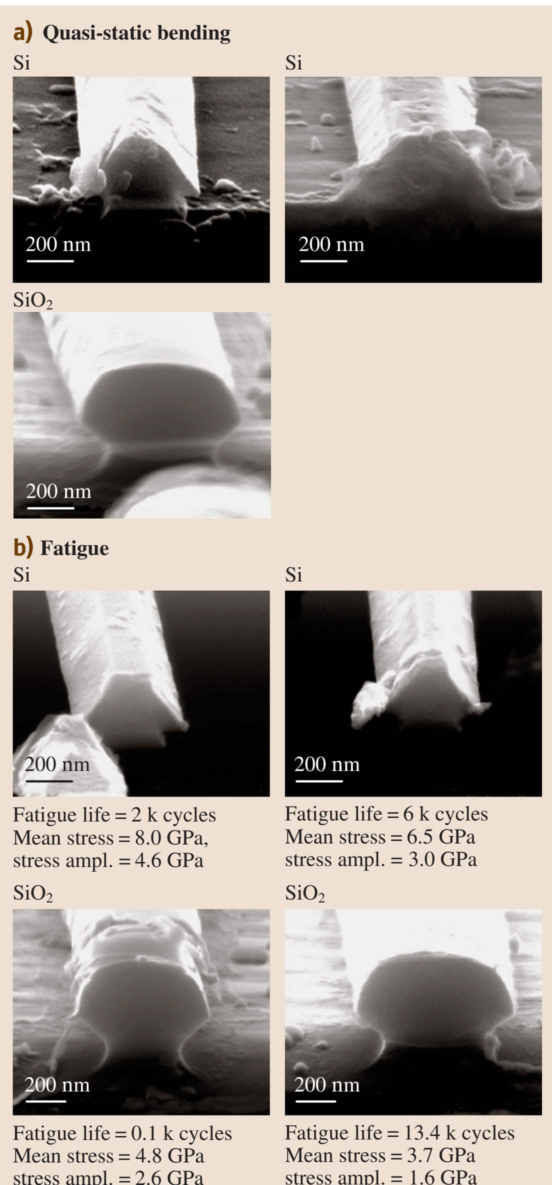

Fig. 25.16a,b SEM micrographs of fracture surfaces of silicon and SiO_2 beams subjected to **(a)** quasi-static bending and **(b)** fatigue [25.38]

near the top surface and propagated downward. The fracture surfaces of the beams suggest a cleavage type of fracture. Silicon beam surfaces show various ledges or facets, which is typical for crystalline brittle materials. Silicon usually fractures along the (111) plane, due to this plane having the lowest surface energy to overcome by a propagating crack. However, failure has also been known to occur along the (110) planes in microscale specimens, despite the higher energy required compared to the (111) planes [25.45]. The plane normal to the beam direction in these samples is the (110) plane, while (111) planes will be oriented at 35° from the (110) plane. The presence of facets and irregularities on the silicon surface in Fig. 25.16a suggest that it is a combination of these two types of fractures that has occurred. Since the stress levels are very high for these specimens, it is reasonable to assume that crack propagating forces will be high enough to result in (110) type failures.

In contrast, the silicon fracture surfaces under fatigue, shown in Fig. 25.16b, appear very smooth without facets or irregularities. This is suggestive of low energy fracture, i. e., of (111) type fracture. We do not see evidence of fatigue crack propagation in the form of steps or striations on the fracture surface. We believe that for the stress levels applied in these fatigue experiments, failure in silicon occurred via cleavage associated with "static fatigue" type of failures.

SiO_2 shows very smooth fracture surfaces for both quasi-static bending and fatigue. This is in contrast to the hackled surface one might expect for the brittle failure of an amorphous material on the macroscale. However, in larger scale fracture surfaces for such materials, the region near the crack initiation usually appears smooth or mirror-like. Since the fracture surface here is so small and very near the crack initiation site, it is not unreasonable to see such a smooth surface for SiO_2 on this scale. There appears to be no difference between the fracture surfaces obtained by quasi-static bending and fatigue for SiO_2.

Summary of Mechanical Properties Measured Using Quasi-Static Bending Tests

Table 25.2 summarizes the various properties measured via quasi-static bending in this study [25.38]. Also shown are bulk values of the parameters, along with values reported on larger scale specimens by other researchers. Elastic modulus and fracture toughness values appear to be comparable to bulk values and show no dependence on specimen size. However, bending strength shows a clear specimen size dependence with nanoscale numbers being twice as large as numbers reported for larger-scale specimens.

25.2.3 Bending Tests of Microbeams Using a Nanoindenter

Bending tests have been performed on Ni-P and Au microbeams [25.40]. The Ni-P cantilever microbeams were fabricated by focused ion beam machining technique. The dimensions were $10 \times 12 \times 50\,\mu m^3$. Notches with a depth of 3 μm and a tip radius of 0.25 μm were introduced in the microbeams to facilitate failure at a lower

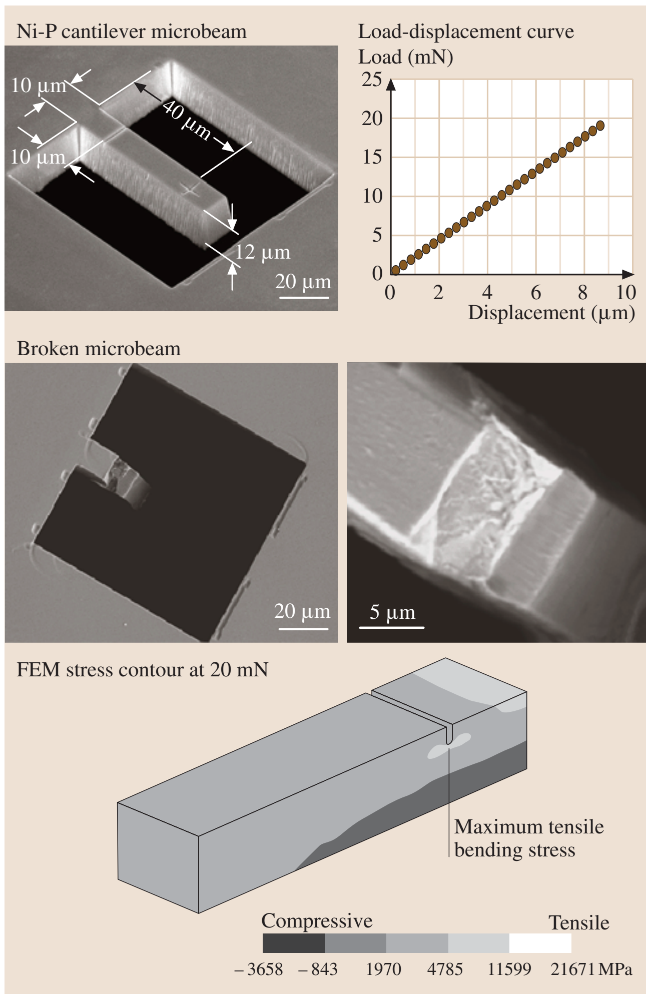

Fig. 25.17 SEM micrographs of the new and broken beams, load-displacement curve, and FEM stress contour for the notched Ni-P cantilever microbeam [25.40]

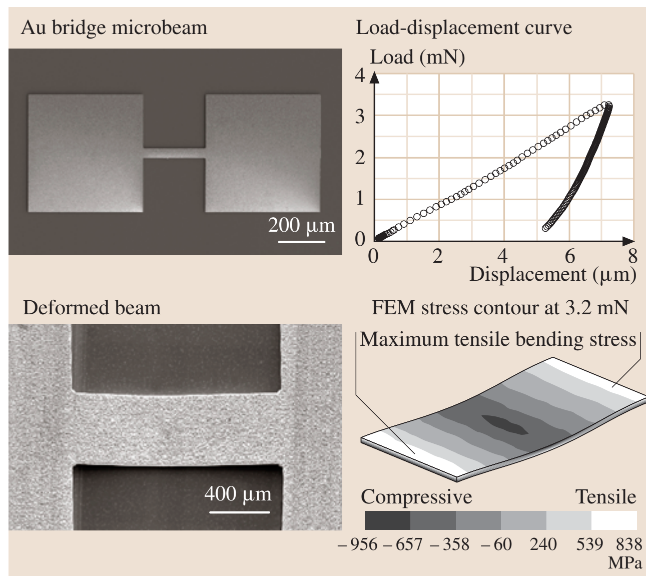

Fig. 25.18 SEM micrographs of the new and deformed beams, load-displacement curve, and FEM stress contour for the Au bridge microbeam [25.40]

load in the bending tests. The Au bridge microbeams were fabricated by electroplating technique.

Figure 25.17 shows the SEM images, load displacement curve, and FEM stress contour for the notched Ni-P cantilever microbeam that was bent to failure [25.40]. The distance between the loading position and the fixed end is 40 µm. The 3-µm-deep notch is 10 µm from the fixed end. The notched beam showed linear behavior followed by abrupt failure. The FEM stress contour shows that there is higher stress concentration at the notch tip. The maximum tensile stress σ_m at the notch tip can be analyzed using Griffith fracture theory as follows [25.53]:

$$\sigma_m \approx 2\sigma_o \left(\frac{c}{\rho}\right)^{1/2} , \quad (25.11)$$

where σ_o is the average applied tensile stress on the beam, c is the crack length, and ρ is the crack tip radius. Therefore, elastic-plastic deformation will first occur locally at the end of the notch tip, followed by abrupt fracture failure after the σ_m reaches the ultimate tensile strength of Ni-P, even though the rest of the beam is still in the elastic regime. The SEM image of the fracture surface shows that the fracture started right from the notch tip with plastic deformation characteristic. This indicates that although local plastic deformation occurred at the notch tip area, the whole beam failed catastrophically. The present study shows that FEM simulation can predict well the stress concentration and helps in understanding the failure mechanism of the notched beams.

Figure 25.18 shows the SEM images, load-displacement curve and FEM stress contour for the Au bridge microbeam that was deformed by the indenter [25.40]. The recession gap between the beam and substrate is about 7 µm, which is not large enough to break the beam at the load applied. From the load-displacement curve, we note that the beam experienced elastic-plastic deformation. The FEM stress contour shows that the maximum tensile stress is located at the fixed ends, whereas the minimum compressive stress is located around the center of the beam. The SEM image shows that the beam has been permanently deformed. No crack was found on the beam surface. The present study shows a possibility for mechanically forming the Au film into the shape as needed. This may help in designing/fabricating functionally complex smart micro/nanodevices that need conductors for power supply and input/output signals.

25.3 Finite Element Analysis of Nanostructures with Roughness and Scratches

Micro/nanostructures have some surface topography and local scratches dependent upon the manufacturing process. Surface roughness and local scratches may compromise the reliability of the devices and their effect needs to be studied. Finite element modeling is used to perform parametric analysis to study the effect of surface roughness and scratches in different well-defined forms on tensile stresses that are responsible for crack propagation [25.46, 47]. The analysis has been carried out on trapezoidal beams supported at the bottom whose data (on Si and SiO_2 nanobeams) have been presented earlier.

The finite element analysis has been carried out using the static analysis of ANSYS 5.7, which calculates the deflections and stresses produced by the applied loading. The type of element selected for the present study was

the SOLID95, which allows the use of different shapes without much loss of accuracy. This element is 3-D with 20 nodes, each node having three degrees of freedom that imply translation in the x, y, and z directions. Each nanobeam cross section is divided into six elements along the width and the thickness and 40 elements along the length. SOLID95 has plasticity, creep, stress stiffening, large deflection, and large strain capabilities. The large displacement analysis is used for large loads. The mesh is kept finer near the asperities and the scratches in order to take into account variation in the bending stresses. The beam materials studied are made of single-crystal silicon (110) and SiO_2 films whose data have been presented earlier. Based on bending experiments presented earlier, the beam materials can be assumed to be linearly elastic isotropic materials. Young's modulus of elasticity (E) and Poisson's ratio (ν) for Si and SiO_2 are 169 GPa [25.63] and 0.28 [25.57], and 73 GPa [25.64] and 0.17 [25.64], respectively. A sample nanobeam of silicon was chosen for performing most of the analysis, as silicon is the most widely used MEMS/NEMS material. The cross section of the fabricated beams used in the experiment is trapezoidal and supported at the bottom, Fig. 25.9. The following dimensions are used: $w_1 = 200$ nm, $w_2 = 370$ nm, $t = 255$ nm, and $\ell = 6$ µm. In the boundary conditions, the displacements are constrained in all directions on the bottom surface for 1 µm from each end. A point load applied at the center of the beam is simulated with the load being applied at three closely located central nodes on the beam used. It has been observed from the experimental results that the Si nanobeam breaks at around 80 µN. Therefore, in this analysis, a nominal load of 70 µN is selected. At this load, deformations are large and a large displacement option is used.

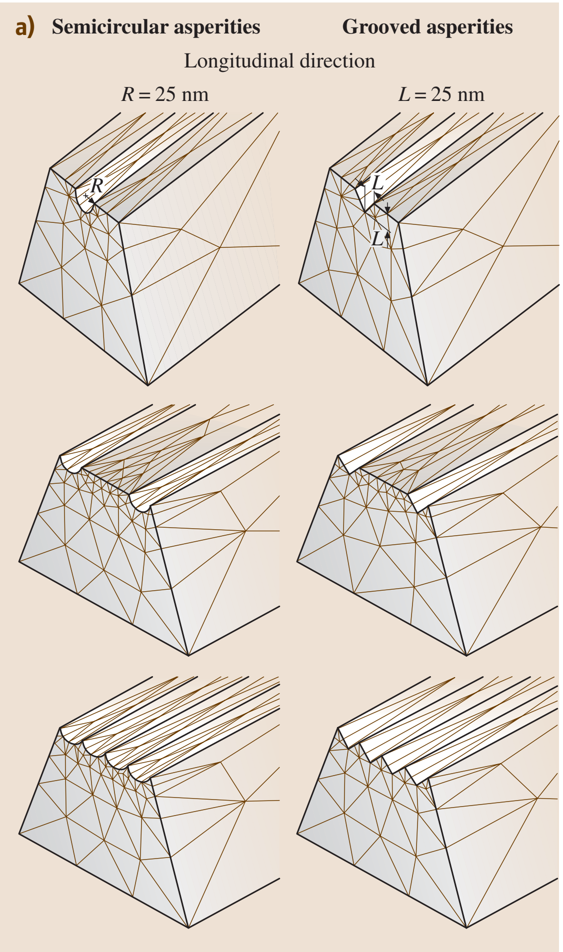

Fig. 25.19 (a) Plots showing the geometries of modeled roughness – semicircular and grooved asperities along the nanobeam length with defined geometrical parameters. **(b)** (*See on next page.*) Schematic showing semicircular asperities and scratches in the transverse direction, followed by the illustration of the mesh created on the beam with fine mesh near the asperities and scratches. Also shown are the semicircular asperities and scratches at different pitch values

To study the effect of surface roughness and scratches on the maximum bending stresses the following cases were studied. First, the semicircular and grooved asperities in the longitudinal direction with defined geometrical parameters are analyzed, Fig. 25.19a. Next, semicircular asperities and scratches placed along the transverse direction at a distance c from the end and separated by pitch p from each other are analyzed, Fig. 25.19b. Lastly, the beam material is assumed to be either purely elastic, elastic-plastic, or elastic-perfectly plastic. In the following section, we begin with the stress distribution in smooth nanobeams followed by the effect of surface roughness in the longitudinal and transverse directions and scratches in the transverse direction.

25.3.1 Stress Distribution in a Smooth Nanobeam

Figure 25.20 shows the stress and vertical displacement contours for a nanobeam supported at the bottom and loaded at the center [25.46, 47]. As expected, the maximum tensile stress occurs at the ends, while the maximum compressive stress occurs under the load at

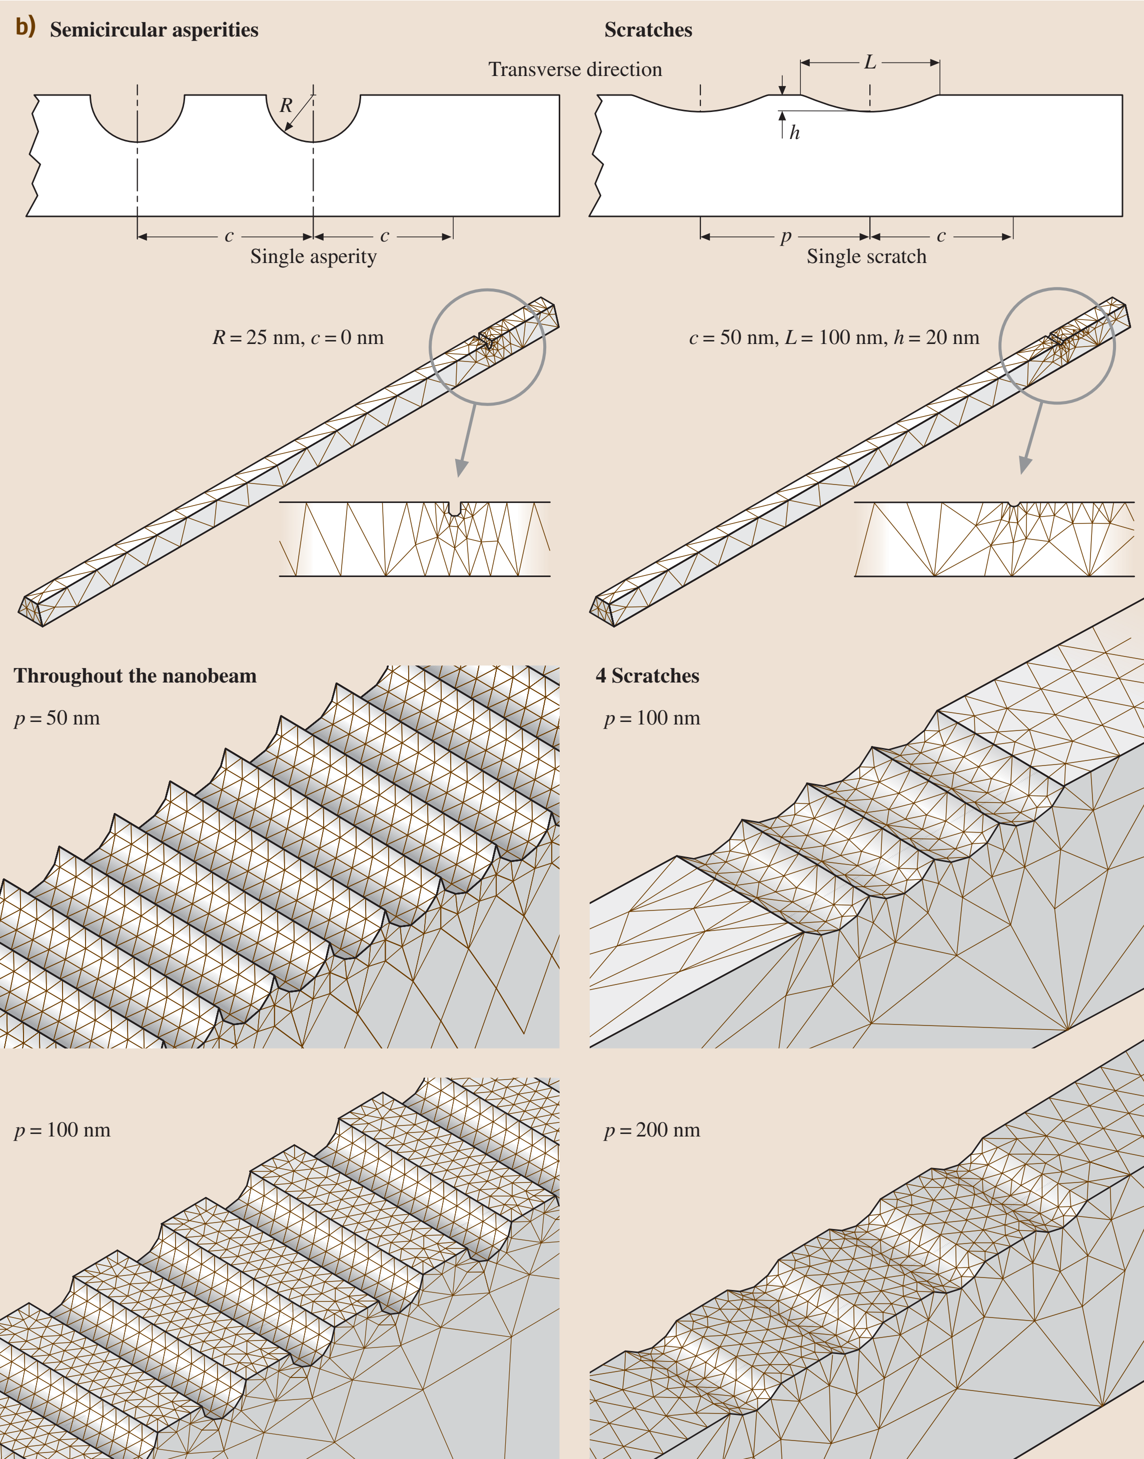

Fig. 25.19b

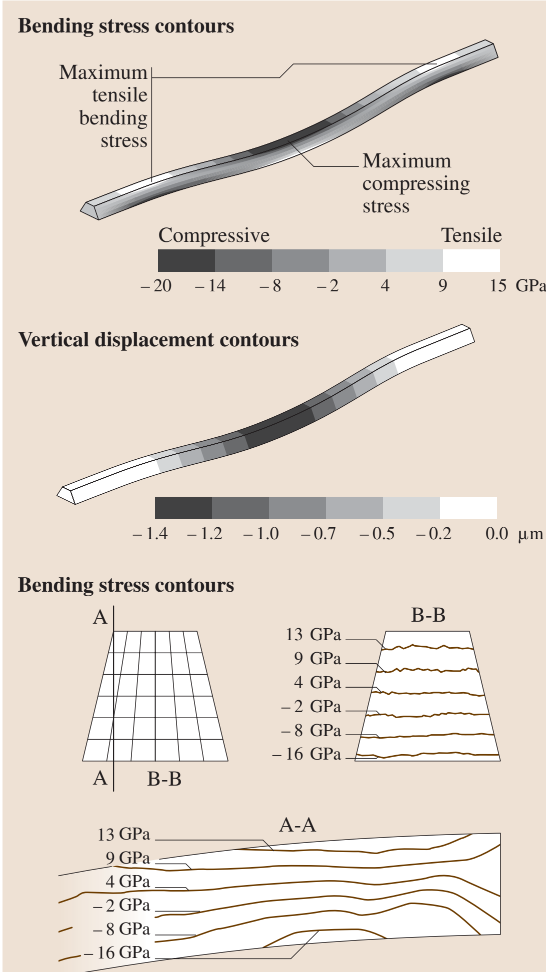

Fig. 25.20 Bending stress contours, vertical displacement contours, and bending stress contours after loading trapezoidal Si nanobeam ($w_1 = 200\,\text{nm}$, $w_2 = 370\,\text{nm}$, $t = 255\,\text{nm}$, $\ell = 6\,\mu\text{m}$, $E = 169\,\text{GPa}$, $\nu = 0.28$) at $70\,\mu\text{N}$ load [25.47]

the center. Stress contours obtained at a section of the beam from the front and side are also shown. In the beam cross section, the stresses remain constant at a given vertical distance from one side to another and change with a change in vertical location. This can be explained by the fact that the bending moment is constant at a particular cross section, so the stress is only dependent on the distance from the neutral axis. However, in cross section A-A the high tensile and compressive stresses are localized near the end of the beam at top and bottom, respectively, whereas the lower values are spread out away from the ends. High value of tensile stresses occurs near the ends because of high bending moment.

25.3.2 Effect of Roughness in the Longitudinal Direction

The roughness in the form of semicircular and grooved asperities in the longitudinal direction on the maximum bending stresses are analyzed [25.47]. The radius R and depth L are kept fixed at 25 nm, while the number of asperities is varied and their effect is observed on the maximum bending stresses. Figure 25.21 shows the variation of maximum bending stresses as a function of asperity shape and the number of asperities. The maximum bending stresses increase as the asperity number increases for both semicircular and grooved asperities. This can be attributed to the fact that as the asperity number increases, the moment of inertia decreases for that cross section. Also, the distance from the neutral axis increases because the neutral axis shifts downwards. Both these factors lead to the increase in the maximum bending stresses, and this effect is more pronounced in the case of semicircular asperity as it exhibits a higher value of maximum bending stress than that in grooved asperity. Figure 25.21 shows the stress contours obtained at a section of the beam from the front side for both cases when we have a single semicircular asperity and when four adjacent semicircular asperities are present. Trends are similar to those observed earlier for a smooth nanobeam (Fig. 25.20).

25.3.3 Effect of Roughness in the Transverse Direction and Scratches

We analyze semicircular asperities when placed along the transverse direction followed by the effect of scratches on the maximum bending stresses in varying numbers and pitch [25.47]. In the analysis of semicircular transverse asperities, three cases were considered, which included a single asperity and asperities throughout the nanobeam surface separated by pitch equal to 50 nm and 100 nm. In all of these cases, c value was kept equal to 0 nm. Figure 25.22 shows that the value of maximum tensile stress is 42 GPa, which is much larger than the maximum tensile stress value with no asperity of 16 GPa, or when the semicircular asperity is present in the longitudinal direction. It is also observed that the maximum tensile stress does not vary with the number of asperities or the pitch, while the maximum compres-

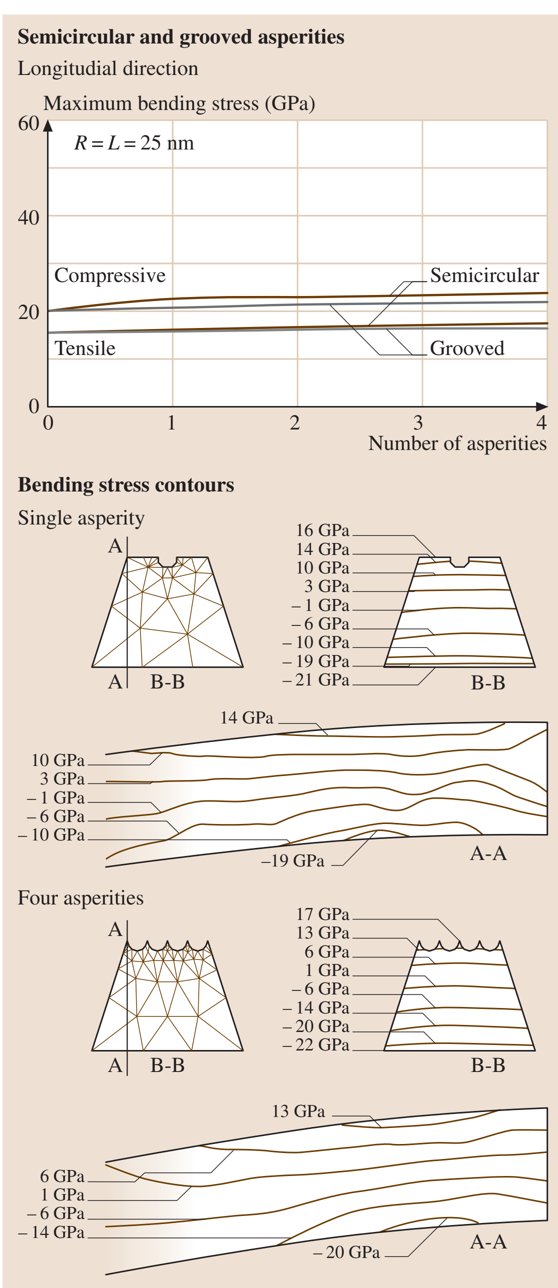

Fig. 25.21 Effect of longitudinal semicircular and grooved asperities in different numbers on maximum bending stresses after loading trapezoidal Si nanobeams ($w_1 = 200$ nm, $w_2 = 370$ nm, $t = 255$ nm, $\ell = 6$ µm, $E = 169$ GPa, $\nu = 0.28$, load = 70 µN). Bending stress contours obtained in the beam with semicircular single asperity and four adjacent asperities of $R = 25$ nm [25.47]

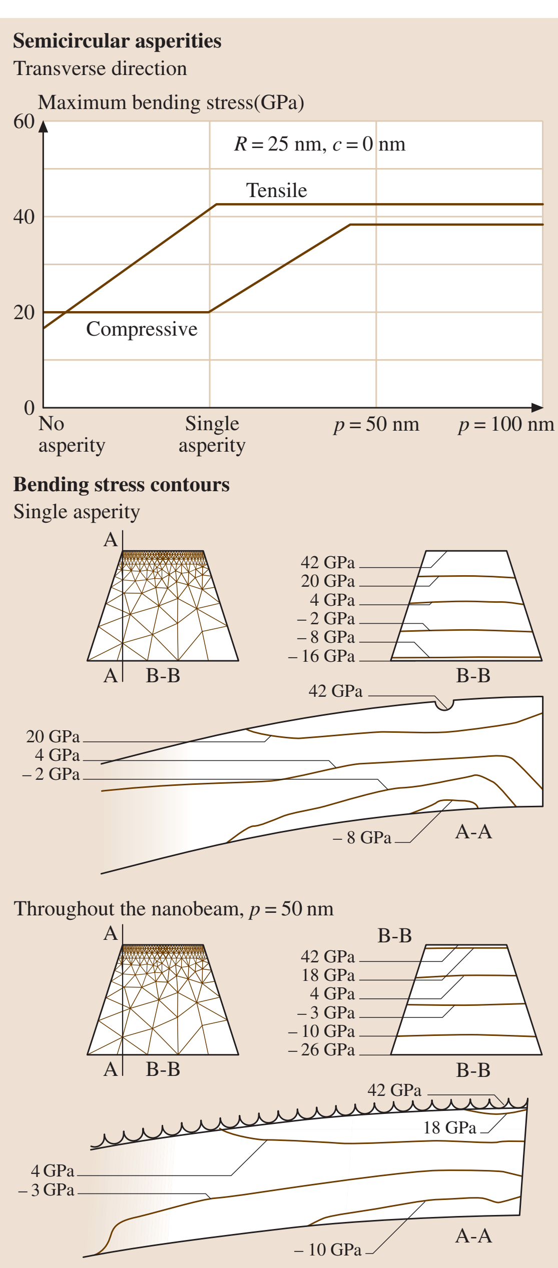

Fig. 25.22 Effect of transverse semicircular asperities located at different pitch values on the maximum bending stresses after loading trapezoidal Si nanobeams ($w_1 = 200$ nm, $w_2 = 370$ nm, $t = 255$ nm, $\ell = 6$ µm, $E = 169$ GPa, $\nu = 0.28$, load = 70 µN). Bending stress contours obtained in the beam with semicircular single asperity and semicircular asperities throughout the nanobeam surface at $p = 50$ nm [25.47]

sive stress does increase dramatically for the asperities present throughout the beam surface from its value when a single asperity is present. Maximum tensile stress occurs at the ends, and an increase in p does not add any asperities at the ends, whereas asperities are added in the central region where compressive stresses are maximum. The semicircular asperities present at the center cause the local perturbation in the stress distribution at the center of the asperity where load is being applied, leading to a high value of maximum compressive stress [25.65]. Figure 25.22 also shows the stress contours obtained at a section of the beam from the front and side for both cases when there is a single semicircular asperity and when asperities are present throughout the beam surface at a pitch equal to 50 nm. Trends are similar to those observed earlier for a smooth nanobeam (Fig. 25.20).

In the study pertaining to scratches, the number of scratches are varied along with the variation in the pitch. Furthermore, the load is applied at the center of the beam and at the center of the scratch near the end, as for all the cases. In all of these, c value was kept equal to 50 nm and L value was equal to 100 nm with h value being 20 nm. Figure 25.23 shows that the value of maximum tensile stress remains almost the same with the number of scratches for both types of loading – that is, when load is applied at the center of the beam and at the center of the scratch near the end. This is because the maximum tensile stress occurs at the beam ends no matter where the load gets applied. But the presence of scratch does increase the maximum tensile stress compared to its value for a smooth nanobeam, although the number of scratches no longer matter as the maximum tensile stress occurring at the nanobeam end is unaffected by the presence of more scratches beyond the first scratch in the direction toward the center. The value of the tensile stress is much lower when the load is applied at the center of scratch, and it can be explained as follows. The negative bending moment at the end near the applied load decreases with load offset after two-thirds of the length of the beam [25.66]. Since this negative bending moment is responsible for tensile stresses, their behavior with the load offset is the same as the negative bending moment. Also, the value of maximum compressive stress when load is applied at the center of the nanobeam remains almost the same as the center geometry is unchanged due to the number of scratches and, hence, the maximum compressive stress occurring below the load at the center is same. On the other hand, when the load is applied at the center of the scratch we observe that the maximum compressive stress in-

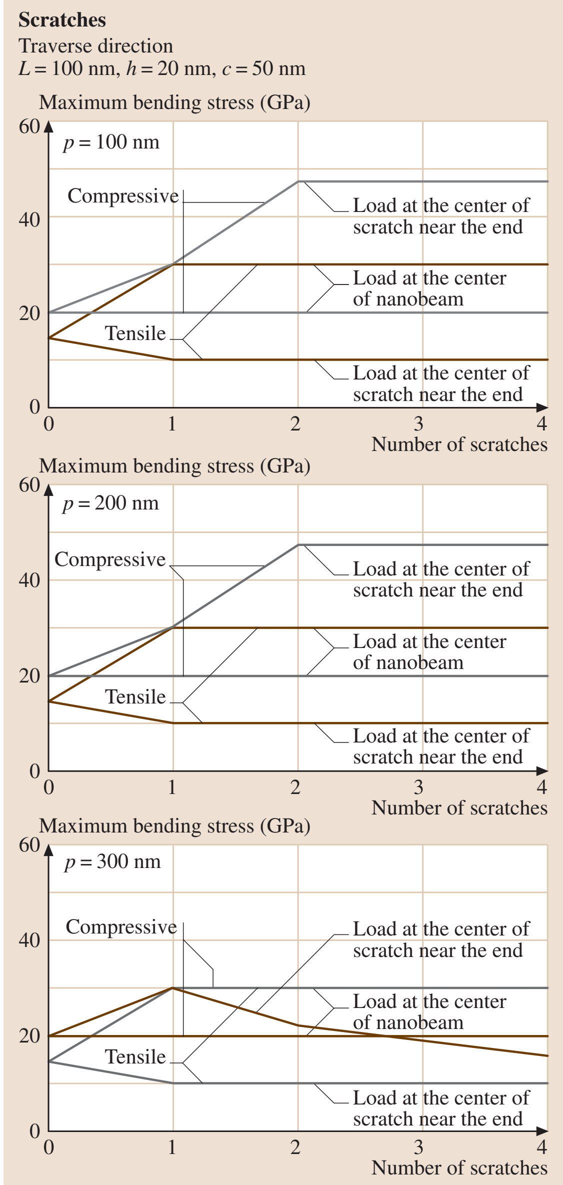

Fig. 25.23 Effect of number of scratches along with the variation in the pitch on the maximum bending stresses after loading trapezoidal Si nanobeams ($w_1 = 200$ nm, $w_2 = 370$ nm, $t = 255$ nm, $\ell = 6\,\mu$m, $E = 169$ GPa, $\nu = 0.28$, load = 70 μN). Also shown is the effect of load when applied at the center of the beam and at the center of the scratch near the end [25.47]

creases dramatically because the local perturbation in the stress distribution at the center of the scratch where load is being applied leads to a high value of maximum compressive stress [25.65]. It increases further with the number of scratches and then levels off. This can be attributed to the fact that when there is another scratch present close to the scratch near the end, the stress concentration is more, as the effect of local perturbation in the stress distribution is more significant. However, this effect is insignificant when more than two scratches are present.

Now we address the effect of pitch on the maximum compressive stress when the load is applied at the center of the scratch near the end. When the pitch is up to a value of 200 nm the maximum compressive stress increases with the number of scratches, as discussed earlier. On the other hand, when the pitch value goes beyond 225 nm this effect is reversed. This is because the presence of another scratch no longer affects the local perturbation in the stress distribution at the scratch near the end. Instead, more scratches at a fair distance distribute the maximum compressive stress at the scratch near the end and the stress starts going down. Such observations of maximum bending stresses can help in identifying the number of asperities and scratches allowed separated by an optimum distance from each other.

25.3.4 Effect on Stresses and Displacements for Materials That Are Elastic, Elastic–Plastic, or Elastic–Perfectly Plastic

This section deals with the beam modeled as elastic, elastic-plastic, and elastic-perfectly plastic to observe the variation in the stresses and displacements from an elastic model used so far [25.47]. Figure 25.24 shows the typical stress-strain curves for the three types of deformation regimes and their corresponding load-displacement curves obtained from the model of an Si nanobeam that are found to exhibit the same trends.

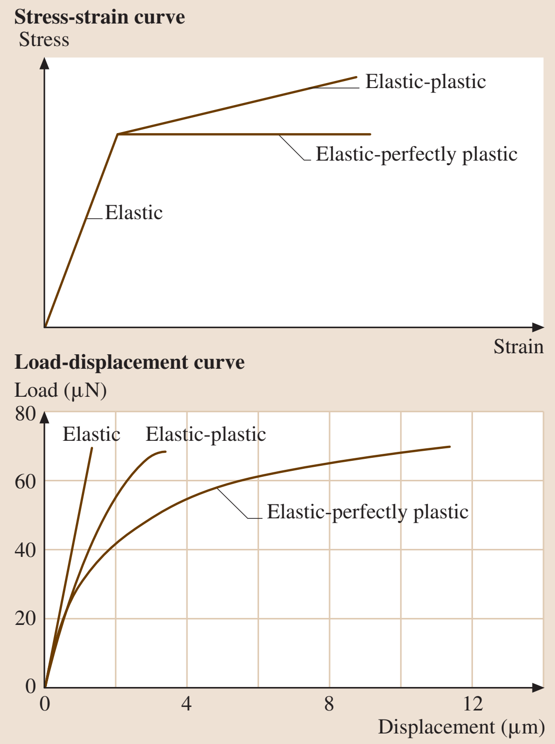

Fig. 25.24 Schematic representation of stress-strain curves and load-displacement curves for material when it is elastic, elastic-plastic, or elastic-perfectly plastic for a Si nanobeam ($w_1 = 200$ nm, $w_2 = 370$ nm, $t = 255$ nm, $\ell = 6$ μm, $E =$ 169 GPa, tangent modulus in plastic range = 0.5 E, $\nu =$ 0.28) [25.47]

Table 25.3 shows the comparison of maximum von Mises stress and maximum displacements for

Table 25.3 Stresses and displacements for materials that are elastic, elastic-plastic, or elastic-perfectly plastic (load = 70 μN, $w_1 = 200$ nm, $w_2 = 370$ nm, $t = 255$ nm, $\ell = 6$ μm, $R = 25$ nm, $E = 169$ GPa, tangent modulus in plastic range = $0.5E$, $\nu = 0.28$)

	Elastic		Elastic-plastic		Elastic-perfectly plastic	
	Smooth nanobeam	Single semicircular longitudinal asperity	Smooth nanobeam	Single semicircular longitudinal asperity	Smooth nanobeam	Single semicircular longitudinal asperity
Max. von Mises stress (GPa)	18.2	19.3	13.5	15.2	7.8	9.1
Max. displacement (μm)	1.34	1.40	3.35	3.65	11.5	12.3

both smooth nanobeam and nanobeam with a defined roughness, which is single semicircular longitudinal asperity of R value equal to 25 nm for the three different models. It is observed that the maximum value of stress is obtained at a given load for elastic material, whereas the displacement is maximum for elastic-perfectly plastic material. Also, the pattern that the maximum bending stress value increases for a rough nanobeam still holds true in the other models as well.

25.4 Closure

Mechanical properties of nanostructures are necessary in designing realistic MEMS/NEMS devices. Most mechanical properties are scale-dependent. Micro/nanomechanical properties, hardness, elastic modulus, and scratch resistance of bulk materials of undoped single-crystal silicon (Si) and thin films of undoped polysilicon, SiO_2, SiC, Ni-P, and Au are presented. It is found that the SiC film exhibits higher hardness, elastic modulus, and scratch resistance as compared to other materials.

Bending tests have been performed on the Si and SiO_2 nanobeams and Ni-P and Au microbeams using an AFM and a depth-sensing nanoindenter, respectively. The bending tests were used to evaluate elastic modulus, bending strength (fracture stress), fracture toughness (K_{IC}), and fatigue strength of the beam materials. The Si and SiO_2 nanobeams exhibited elastic linear response with sudden brittle fracture. The notched Ni-P beam showed linear deformation behavior followed by abrupt failure. The Au beam showed elastic-plastic deformation behavior. Elastic modulus values of 182 ± 11 GPa for Si(110) and 85 ± 3 GPa for SiO_2 were obtained, which are comparable to bulk values. Bending strength values of 18 ± 3 GPa for Si and 7.6 ± 2 GPa for SiO_2 were obtained, which are twice as large as values reported on larger scale specimens. This indicates that bending strength shows a specimen size dependence. Fracture toughness value estimates obtained were $1.67 \pm 0.4\,\text{MPa}\sqrt{\text{m}}$ for Si and $0.60 \pm 0.2\,\text{MPa}\sqrt{\text{m}}$ for SiO_2, which are also comparable to values obtained on larger specimens. At stress amplitudes less than 15% of their bending strength and at mean stresses of less than 30% of the bending strength, Si and SiO_2 displayed an apparent endurance life of greater than 30,000 cycles. SEM observations of the fracture surfaces revealed a cleavage type of fracture for both materials when subjected to bending, as well as fatigue. The AFM and nanoindenters used in this study can be satisfactorily used to evaluate the mechanical properties of micro/nanoscale structures for use in MEMS/NEMS.

FEM simulations are used to predict the stress and deformation in nanostructures. The FEM has been used to analyze the effect of the type of surface roughness and scratches on stresses and deformation of nanostructures. We find that roughness affects the maximum bending stresses. The maximum bending stresses increase as the asperity number increases for both semicircular and grooved asperities in the longitudinal direction. When the semicircular asperity is present in the transverse direction the maximum tensile stress is much larger than the maximum tensile stress value with no asperity or when the semicircular asperity is present in the longitudinal direction. This observation suggests that the asperity in the transverse direction is more detrimental. The presence of scratches increases the maximum tensile stress. The maximum tensile stress remains almost the same with the number of scratches for two types of loading, that is, when load is applied at the center of the beam or at the center of the scratch near the end, although the value of the tensile stress is much lower when the load is applied at the center of the scratch. This means that the load applied at the ends is less damaging. This analysis shows that FEM simulations can be useful to designers to develop the most suitable geometry for nanostructures.

26. Nanotribology of Ultrathin and Hard Amorphous Carbon Films

Diamond material and its smooth coatings are used for very low wear and relatively low friction. Major limitations of the true diamond coatings are that they need to be deposited at high temperatures, can only be deposited on selected substrates, and require surface finishing. Hard amorphous carbon, commonly known as diamond-like carbon or DLC coatings, exhibit mechanical, thermal, and optical properties close to that of diamond. These can be deposited with a large range of thicknesses by using a variety of deposition processes on a variety of substrates at or near room temperature. The coatings reproduce substrate topography, avoiding the need of post-finishing. Friction and wear properties of some DLC coatings can be very attractive for tribological applications. The largest industrial application of these coatings is in magnetic storage devices.

The prevailing atomic arrangement in the DLC coatings is amorphous or quasi-amorphous with small diamond, graphite, and other unidentifiable micro- or nanocrystallites. Most DLC coatings, except those produced by filtered cathodic arc, contain from a few to about 50 at% hydrogen. Sometimes hydrogen is deliberately incorporated in the sputtered and ion plated coatings to tailor their properties.

EELS and Raman spectroscopies can be successfully used for chemical characterization of amorphous carbon coatings. The prevailing atomic arrangement in the DLC coatings is amorphous or quasi-amorphous with small diamond (sp^3), graphite (sp^2) and other unidentifiable micro- or nanocrystallites. Most DLC coatings except those produced by filtered cathodic arc contain from a few to about 50 at% hydrogen. Sometimes hydrogen is deliberately incorporated in the sputtered and ion plated coatings to tailor their properties.

Amorphous carbon coatings deposited by various techniques exhibit different mechanical and tribological properties. The nanoindenter can be successfully used for measurement of hardness, elastic modulus, fracture toughness, and fatigue life. Microscratch and microwear experiments can be performed using either a nanoindenter or an AFM. Thin coatings deposited by filtered cathodic arc, ion beam, and ECR-CVD hold a promise for tribological applications. Coatings as thin as 5 nm or even thinner provide wear protection. Microscratch, microwear, and accelerated wear testing, if simulated properly, can be successfully used to screen coating candidates for industrial applications. In the examples shown in this chapter, trends observed in the microscratch, microwear, and accelerated macrofriction wear tests are similar to that found in functional tests.

In this chapter, the state-of-the-art of recent developments in the chemical, mechanical, and tribological characterization of ultrathin amorphous carbon coatings is presented.

Carbon exists in both crystalline and amorphous forms and exhibits both metallic and nonmetallic characteristics [26.1–3]. Crystalline carbon includes graphite, diamond, and a family of fullerenes, Fig. 26.1. The graphite and diamond are infinite periodic network solids with a planar structure, whereas the fullerenes are a molecular form of pure carbon with a finite network with a nonplanar structure. Graphite has a hexagonal, layered structure with weak interlayer bonding forces and exhibits excellent lubrication properties. The graphite crystal may be visualized as infinite parallel layers of hexagons stacked 0.34 nm apart with a 0.1415-nm interatomic distance between the carbon atoms in the basal plane. The atoms lying in the basal planes are trigonally coordinated and closely packed with strong σ (covalent) bonds to its three carbon neighbors using the hybrid sp^2 orbitals. The fourth electron lies in a p_z orbital lying normal to the σ bonding plane and forms a weak π bond by overlapping side to side with a p_z orbital of an adjacent atom to which carbon is attached by a σ bond. The layers (basal planes) themselves are relatively far apart and the forces that bond them are weak van der Waals forces. These layers can align themselves parallel to the direction of the relative motion and slide over one another with relative ease, thus providing low friction. Strong interatomic bonding and packing in each layer is thought to help reduce wear. The operating environment has a significant influence on lubrication, i. e., low friction and low wear, properties of graphite. It lubricates better in a humid environment than a dry one, resulting from adsorption of water vapor and other gases from the environment, which further weakens the interlayer bonding forces and results in easy shear and transfer of the crystallite platelets to the mating surface. Thus, transfer plays an important role in controlling friction and wear. Graphite oxidizes at high operating temperatures and can be used up to about 430 °C.

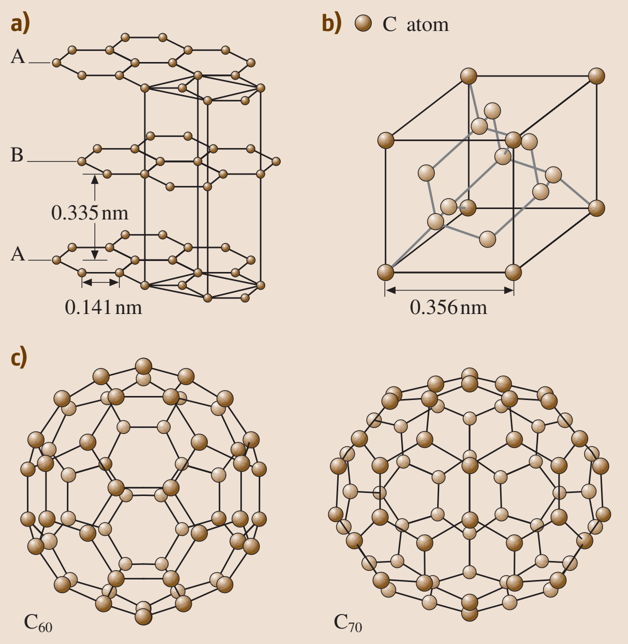

Fig. 26.1a–c The structure of three known forms of crystalline carbon **(a)** hexagonal structure of graphite, **(b)** modified face-centered cubic (fcc) structure, two interpenetrating fcc lattices displaced by one-quarter of the cube diagonal, of diamond (each atom is bonded to four others that form the corners of the pyramidal structure called tetrahedron), and **(c)** the structure of the two most common forms of fullerenes-soccer ball C_{60} and rugby ball C_{70} molecules

One of the fullerene molecules is C_{60}, commonly known as Buckyball. Since the C_{60} molecules are very stable and do not require additional atoms to satisfy chemical bonding requirements, they are expected to have low adhesion to the mating surface and low surface energy. Since C_{60} molecules with a perfect spherical symmetry are weakly bonded to other molecules, C_{60} clusters get detached readily, similar to other layered lattice structures, and either get transferred to the mating surface by mechanical compaction, or are present as loose wear particles that may roll like tiny ball bearings in a sliding contact, resulting in low friction and wear. The wear particles are expected to be harder than as-deposited C_{60} molecules, because of their phase transformation at high asperity contact pressures present in a sliding interface. The low surface energy, spherical shape of C_{60} molecules, weak intermolecular bonding, and high load bearing capacity offer potential for various mechanical and tribological applications. The sublimed C_{60} coatings and fullerene particles as an additive to mineral oils and greases have been reported to be good solid lubricants comparable to graphite and MoS_2 [26.4–6].

Diamond crystallizes in the modified face centered cubic (*fcc*) structure with an interactomic distance of 0.154 nm. The diamond cubic lattice consists of two interpenetrating fcc lattices displaced by one-quarter of the cube diagonal. Each carbon atom is tetrahedrally coordinated, making strong σ (covalent) bonds to its four carbon neighbors using the hybrid sp^3 atomic orbitals, which accounts for its highest hardness (80–104 GPa) and thermal conductivity (900–2,100 W/mK, on the or-

der of five times that of copper) of any known solid, and a high electrical resistivity, optical transmission, and a large optical band gap. It is relatively chemically inert, and it exhibits poor adhesion with other solids with consequent low friction and wear. Its high thermal conductivity allows dissipation of frictional heat during sliding and protects the interface, and the dangling carbon bonds on the surface react with the environment to form hydrocarbons that act as good lubrication films. These are some of the reasons for low friction and wear of the diamond. Diamond and its coatings find many industrial applications: tribological applications (low friction and wear), optical applications (exceptional optical transmission, high abrasion resistance), and thermal management or heat sink applications (high thermal conductivity). The diamond can be used to high temperatures, and it starts to graphitize at about 1,000 °C in ambient air and at about 1,400 °C in vacuum. Diamond is an attractive material for cutting tools, as an abrasive for grinding wheels and lapping compounds, and other extreme wear applications.

The natural diamond, particularly in large sizes, is very expensive and its coatings, a low cost alternative, are attractive. The true diamond coatings are deposited by chemical vapor deposition (CVD) processes at high substrate temperatures (on the order of 800 °C). They adhere best on a silicon substrate and require an interlayer for other substrates. A major roadblock to the widespread use of true diamond films in tribological, optical, and thermal management applications is the surface roughness. Growth of the diamond phase on a non-diamond substrate is initiated by nucleation either at randomly seeded sites or at thermally favored sites, due to statistical thermal fluctuation at the substrate surface. Based on growth temperature and pressure conditions, favored crystal orientations dominate the competitive growth process. As a result, the grown films are polycrystalline in nature with relatively large grain size (> 1 µm) and terminate in very rough surfaces with RMS roughnesses ranging from a few tenths of a micron to tens of microns. Techniques for polishing these films have been developed. It has been reported that the laser polished films exhibit friction and wear properties almost comparable to that of bulk polished diamond [26.7, 8].

Amorphous carbon has no long-range order, and the short-range order of carbon atoms can have one or more of three bonding configurations: – sp^3 (diamond), sp^2 (graphite), or sp^1 (with two electrons forming strong

σ bonds, and the remaining two electrons left in orthogonal p_y and p_z orbitals to form weak π bonds). Short-range order controls the properties of amorphous materials and coatings. Hard amorphous carbon (a-C) coatings, commonly known as diamond-like carbon or DLC (implying high hardness) coatings, are a class of coatings that are mostly metastable amorphous materials, but include a micro- or nanocrystalline phase. The coatings are random networks of covalently bonded carbon in hybridized tetragonal (sp^3) and trigonal (sp^2) local coordination with some of the bonds terminated by hydrogen. These coatings have been successfully deposited by a variety of vacuum deposition techniques on a variety of substrates at or near room temperature. These coatings generally reproduce substrate topography and do not require any post-finishing. However, these coatings mostly adhere best on silicon substrates. The best adhesion is obtained on substrates that form carbides, e.g., Si, Fe, and Ti. Based on depth profile analyses using Auger and XPS of DLC coatings deposited on silicon

substrates, it has been reported that a substantial amount of silicon carbide (on the order of 5–10 nm in thickness) is present at the carbon-silicon interface for the coatings with good adhesion and high hardness (e.g., [26.9]). For good adhesion of DLC coatings to other substrates, in most cases, an interlayer of silicon is required except for cathodic arc deposited coatings.

There is significant interest in DLC coatings because of their unique combination of desirable properties. These properties include high hardness and wear resistance, chemical inertness to both acids and alkalis, lack of magnetic response, and an optical band gap ranging from zero to a few eV, depending upon the deposition conditions. These are used in a wide range of applications, including tribological, optical, electronic, and biomedical applications [26.1, 10, 11]. The high hardness, good friction and wear properties, versatility in deposition and substrates, and no requirements of post-finishing make them very attractive for tribological applications. Two primary examples include overcoats for magnetic media (thin-film disks and ME tapes) and MR type magnetic heads for magnetic storage devices, Fig. 26.2 [26.12–20] and the emerging field of microelectromechanical systems, Fig. 26.3 [26.21–24]. The largest industrial application of the family of amorphous carbon coatings, typically deposited by DC/RF magnetron sputtering, plasma-enhanced chemical vapor deposition, or ion beam deposition techniques, is in magnetic storage devices. These are employed to protect against wear and corrosion, magnetic coatings on thin-film rigid disks and metal evaporated tapes, and the thin-film head structure of a read/write disk head (Fig. 26.2). To maintain low physical spacing between the magnetic element of a read/write head and the magnetic layer of a media, thicknesses ranging from 3 to 10 nm are employed. Mechanical properties affect friction wear and therefore need to be optimized. In 1998, Gillette introduced Mach 3 razor blades with ultrathin DLC coatings, which has the potential of becoming a very large industrial application. DLC coatings are also used in other commercial applications such as glass windows of supermarket laser barcode scanners and sunglasses. These coatings are actively pursued in microelectromechanical systems (MEMS) components [26.23].

In this chapter, a state-of-the-art review of recent developments in the chemical, mechanical, and tribological characterization of ultrathin amorphous carbon coatings is presented. An overview of the most commonly used deposition techniques is presented, and followed by typical chemical and mechanical characterization data and typical tribological data both from coupon level testing and functional testing.

26.1 Description of Commonly Used Deposition Techniques

The first hard amorphous carbon coatings were deposited by a beam of carbon ions produced in an argon plasma on room-temperature substrates, as reported by *Aisenberg* and *Chabot* [26.25]. Subsequent confirmation by *Spencer* et al. [26.26] led to the explosive growth of this field. Following the first work, several alternative techniques have been developed. The amorphous carbon coatings have been prepared by a variety of deposition techniques and precursors, including evaporation, DC, RF or ion beam sputtering, RF or DC plasma-enhanced chemical vapor deposition (PECVD), electron cyclotron resonance chemical vapor deposition (ECR-CVD), direct ion beam deposition, pulsed laser vaporization and vacuum arc, from a variety of carbon-bearing solids or gaseous source materials [26.1, 27]. Coatings with both graphitic and diamond-like properties have been produced. Evaporation and ion plating techniques have been used to produce coatings with graphitic properties (low hardness, high electrical conductivity, very low friction, etc.), and all techniques have been used to produce coatings with diamond-like properties.

The structure and properties of a coating are dependent upon the deposition technique and parameters. High-energy surface bombardment has been used to produce harder and denser coatings. It is reported that sp^3/sp^2 fractions are in the decreasing order for cathodic arc deposition, pulsed laser vaporization, direct ion beam deposition, plasma-enhanced chemical vapor deposition, ion beam sputtering, and DC/RF sputtering [26.12,28,29]. A common feature to these techniques is that the deposition is energetic, i. e., carbon species arrive with an energy significantly greater than that represented by the substrate temperature. The resultant coatings are amorphous in structure, with hydrogen content up to 50%, and display a high degree of sp^3 character. From the results of previous investigations, it has been proposed that deposition of sp^3-bonded carbon requires that the depositing species have kinetic energies on the order of 100 eV or higher, well above

Table 26.1 Summary of the most commonly used deposition techniques and the kinetic energy of depositing species and deposition rates

Deposition technique	Process	Kinetic energy (eV)	Deposition rate (nm/s)
Filtered cathodic arc (FCA)	Energetic carbon ions produced by a vacuum arc discharge between a graphite cathode and grounded anode	100–2,500	0.1–1
Direct ion beam (IB)	Carbon ions produced from methane gas in an ion source and accelerated toward a substrate	50–500	0.1–1
Plasma-enhanced chemical vapor deposition (PECVD)	Hydrocarbon species, produced by plasma decomposition of hydrocarbon gases (e.g., acetylene), are accelerated toward a DC-biased substrate	1–30	1–10
Electron cyclotron resonance plasma chemical vapor deposition (ECR-CVD)	Hydrocarbon ions, produced by plasma decomposition of ethylene gas in the presence of a plasma in electron cyclotron resonance condition, are accelerated toward a RF-biased substrate	1–50	1–10
DC/RF sputtering	Sputtering of graphite target by argon ion plasma	1–10	1–10

those obtained in thermal processes like evaporation (0–0.1 eV). The species must then be quenched into the metastable configuration via rapid energy removal. Excess energy, such as that provided by substrate heating, is detrimental to the achievement of a high sp^3 fraction. In general, a high fraction of the sp^3-bonded carbon atoms in an amorphous network results in a higher hardness [26.29–36]. The mechanical and tribological properties of a carbon coating depend on the sp^3/sp^2-bonded carbon ratio, the amount of hydrogen in the coating, and adhesion of the coating to the substrate, which are influenced by the precursor material, kinetic energy of the carbon species prior to deposition, deposition rate, substrate temperature, substrate biasing, and the substrate itself [26.29, 33, 35, 37–46]. The kinetic energies and deposition rates involved in selected deposition processes used in the deposition of DLC coatings are compared in Table 26.1 [26.1, 28].

In the studies by *Gupta* and *Bhushan* [26.12, 47], *Li* and *Bhushan* [26.48, 49], and *Sundararajan* and *Bhushan* [26.50], DLC coatings ranging typically in thickness from 3.5 nm to 20 nm were deposited on single-crystal silicon, magnetic Ni-Zn ferrite, and Al_2O_3-TiC substrates (surface roughness ≈ 1–3 nm RMS) by filtered cathodic arc (FCA) deposition, (direct) ion beam deposition (IBD), electron cyclotron resonance chemical vapor deposition (ECR-CVD), plasma-enhanced chemical vapor deposition (PECVD), and DC/RF planar, magnetron sputtering (SP) deposition techniques [26.51]. In this chapter, we will limit the presentation of data of coatings deposited by FCA, IBD, ECR-CVD, and SP deposition techniques.

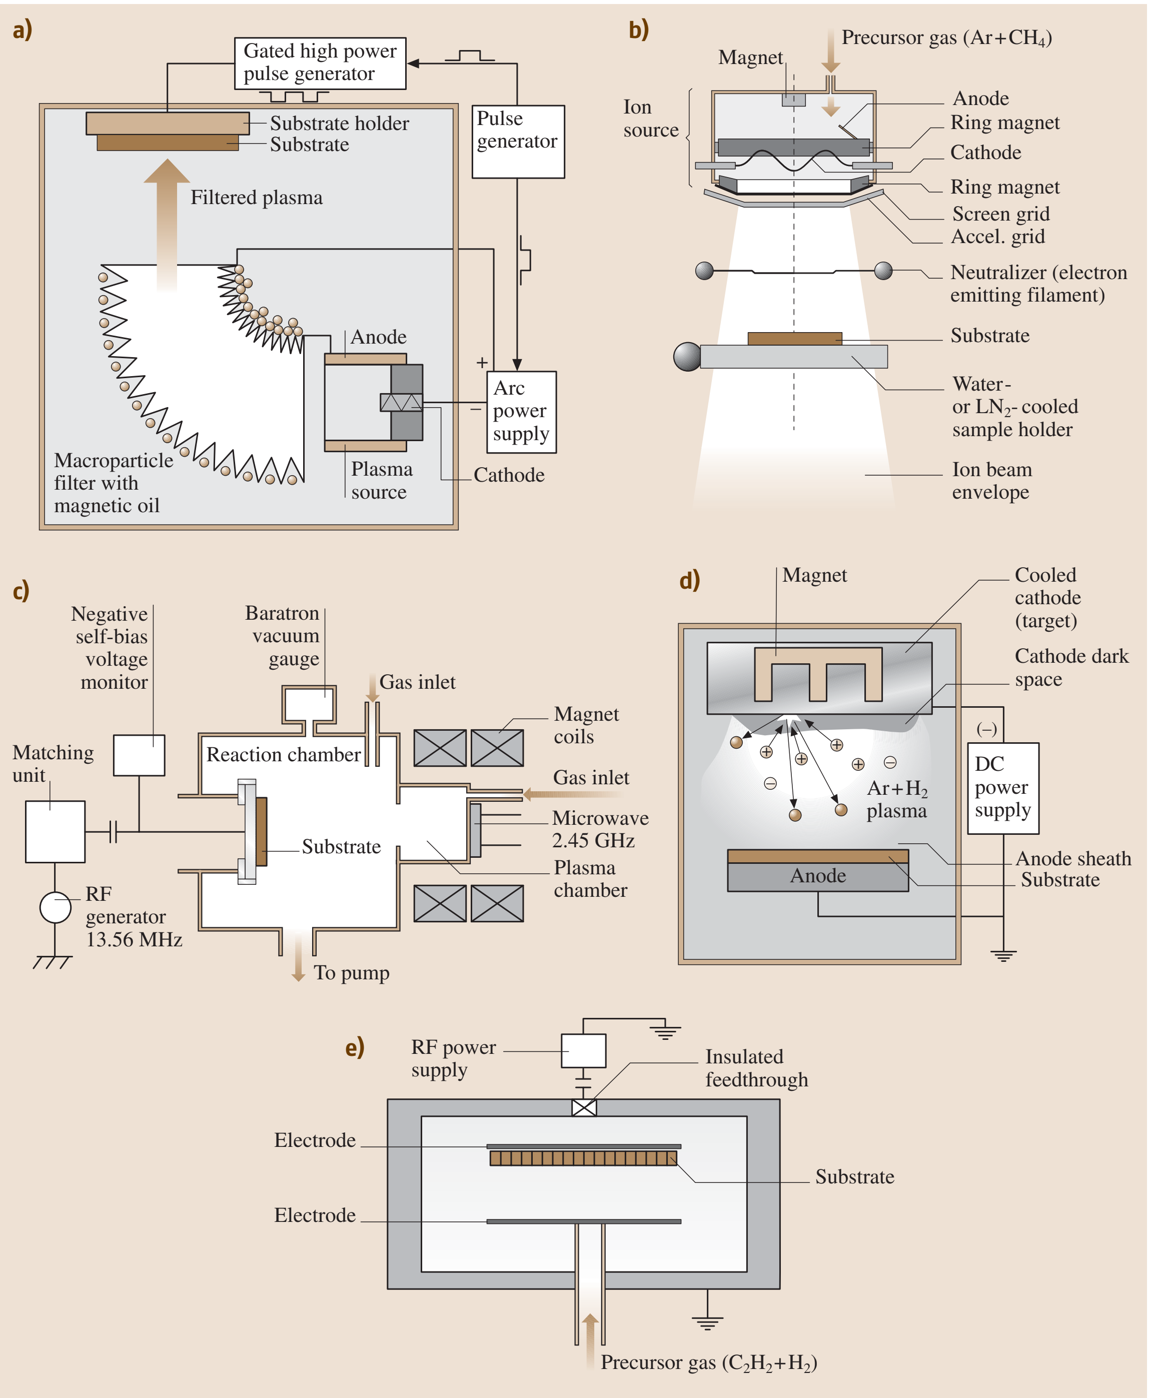

Fig. 26.4a–e Schematic diagrams of deposition by **(a)** filtered cathodic arc deposition, **(b)** ion beam deposition, **(c)** electron cyclotron resonance chemical vapor deposition (ECR-CVD), **(d)** DC planar magnetron sputtering, and **(e)** plasma-enhanced chemical vapor deposition (PECVD)

26.1.1 Filtered Cathodic Arc Deposition Technique

In the filtered cathodic arc deposition of carbon coating [26.29, 52–59], a vacuum arc plasma source is used to form carbon film. In the FCA technique used by *Bhushan* et al. (e.g., [26.12]), energetic carbon ions are produced by a vacuum arc discharge between a planar graphite cathode and grounded anode, Fig. 26.4a. The cathode is a 6-mm-diameter high-density graphite disk mounted on a water-cooled copper block. The arc is driven at an arc current of 200 A, arc duration of 5 ms, and arc repetition rate of 1 Hz. The plasma beam is guided by a magnetic field that transports current between the electrodes to form tiny, rapidly moving spots on the cathode surface. The source is coupled to a 90° bent magnetic filter to remove the macroparticles produced concurrently with the plasma in the cathode spots. The ion current density at the substrate is in the range of 10–50 mA/cm^2. The base pressure is less than 10^{-4} Pa. Compared with electron beam evaporation with auxiliary discharge, much higher plasma density is achieved with the aid of powerful arc discharge. In this process, the cathodic material suffers a complicated transition from the solid phase to an expanding, nonequilibrium plasma via liquid and dense, equilibrium non-ideal plasma phases [26.58]. The carbon ions in the vacuum arc plasma have a direct kinetic energy of 20–30 eV. The high voltage pulses are applied to the substrate mounted on a water-cooled sample holder, and ions are accelerated through the sheath and arrive at the substrate with an additional energy given by the potential difference between the plasma and the substrate. The substrate holder is pulse biased to a negative voltage up to −2 kV with a pulse duration of 1 μs. The negative biasing of −2 kV corresponds to 2 keV kinetic energy of the carbon ions. The use of a pulse bias instead of a DC bias has advantages of applying a much higher voltage and building a surface potential on a nonconducting film. The energy of the ions is varied during the deposition. For the first 10% of the deposition the substrates are pulsed biased to −2 keV with a pulse duty cycle of 25%, i. e., for 25% of the time the energy is 2 keV, for the remaining 75% it is 20 eV, which is the "natural" energy of carbon ions in a vacuum discharge. For the last 90% of the deposition the pulsed bias voltage is reduced to −200 eV with a pulse bias duty cycle of 25%, i. e., the energy is 200 eV for 25% and 20 eV for 75% of the deposition. The high energy at the beginning leads to a good intermixing and adhesion of the films, whereas the lower energy at the later stage leads to hard films. Under the conditions described, the deposition rate at the substrate is about 0.1 nm/s, which is slow. Compared with most gaseous plasma, the cathodic arc plasma is nearly fully ionized, and the ionized carbon atoms have high kinetic energy of carbon ions which help achieving a high fraction of sp^3-bonded carbon ions, which in turn result in a high hardness and higher interfacial adhesion. *Cuomo* et al. [26.42] have reported that based on electron energy loss spectroscopy (EELS) analysis, the sp^3-bonded carbon fraction of cathodic arc coating is 83% compared to 38% for the ion beam sputtered carbon. These coatings are reported to be *nonhydrogenated*.

This technique does not require an adhesion underlayer for non-silicon substrates. However, adhesion of the DLC coatings on the electrically insulating substrate is poor, as negative pulse biasing forms an electrical sheath that accelerates depositing ions to the substrate and enhances the adhesion of the coating to the substrate with associated ion implantation. It is difficult to build potential on an insulating substrate, and lack of biasing results in poor adhesion.

26.1.2 Ion Beam Deposition Technique

In the direct ion beam deposition of carbon coating [26.60–64], as used by *Bhushan* et al. (e.g., [26.12]), the carbon coating is deposited from an accelerated carbon ion beam. The sample is pre-cleaned by ion etching. For the case of non-silicon substrates, a 2–3-nm-thick amorphous silicon adhesion layer is deposited by ion beam sputtering using an ion beam of a mixture of methane and argon at 200 V. For the carbon deposition, the chamber is pumped to about 10^{-4} Pa, and methane gas is fed through the cylindrical ion source and is ionized by energetic electrons produced by a hot-wire filament, Fig. 26.4b. Ionized species then pass through a grid with a bias voltage of about 50 eV, where they gain a high acceleration energy and reach a hot-wire filament, emitting thermionic electrons that neutralize the incoming ions. The discharging of ions is important when insulating ceramics are used as substrates. The species are then deposited on a water-cooled substrate. Operating conditions are adjusted to give an ion beam with an acceleration energy of about 200 eV and a current density of about 1 mA/cm^2. At this operating condition, the deposition rate is about 0.1 nm/s, which is slow. Incidentally, tough and soft coatings are deposited at a high acceleration energy of about 400 eV and at a deposition rate of about 1 nm/s. The ion beam deposited carbon coatings are reported to be hydrogenated (30–40 at% hydrogen).

26.1.3 Electron Cyclotron Resonance Chemical Vapor Deposition Technique

ECR plasma's lack of electrodes and ability to create high densities of charged and excited species at low pressures ($\leq 10^{-4}$ Torr) make it an attractive processing discharge in the coating depositions [26.65]. In the ECR-CVD deposition process of carbon coating described by *Suzuki* and *Okada* [26.66] and used by *Li* and *Bhushan* [26.48, 49] and *Sundararajan* and *Bhushan* [26.50], microwave power is generated by a magnetron operating in continuous mode at a frequency of 2.45 GHz, Fig. 26.4c. The plasma chamber functions as a microwave cavity resonator. The magnetic coils arranged around the plasma chamber generate a magnetic field of 875 G, necessary for electron cyclotron resonance condition. The substrate is placed on a stage that is connected capacitively to a 13.56 MHz RF generator. The process gas is introduced into the plasma chamber and the hydrocarbon ions generated are accelerated by a negative self-bias voltage, which is generated by applying RF power to the substrate. Both the substrate stage and plasma chamber are water-cooled. The process gas used is 100% ethylene and its flow rate is held constant at 100 sccm. The microwave power is 100–900 W. The RF power is 30–120 W. The pressure during deposition is kept close to the optimum value of 5.5×10^{-3} Torr. Before the deposition, the substrates are cleaned using Ar ions generated in the ECR plasma chamber.

26.1.4 Sputtering Deposition Technique

In DC planar magnetron sputtered carbon coating [26.13, 33, 37, 40, 67–71], the carbon coating is deposited by the sputtering of graphite target with Ar ion plasma. In the glow discharge, positive ions from the plasma strike the target with sufficient energy to dislodge the atoms by momentum transfer, which are intercepted by the substrate. First, an about 5-nm-thick amorphous silicon adhesion layer is deposited by sputtering if the deposition is to be carried out on a non-silicon surface. In the process used by *Bhushan* et al. (e.g., [26.12]), the coating is deposited by the sputtering of a graphite target with Ar ion plasma at 300 W power for a 200-mm-diameter target and pressure of about 0.5 Pa (6 mTorr), Fig. 26.4d. Plasma is generated by applying a DC potential between the substrate and a target. *Bhushan* et al. [26.35] reported that sputtered carbon coating contains about 35 at% hydrogen. Hydrogen comes from the hydrocarbon contaminants present in the deposition chamber. To produce hydrogenated carbon coating with a larger concentration of hydrogen, deposition is carried out in Ar and hydrogen plasma.

26.1.5 Plasma-Enhanced Chemical Vapor Deposition Technique

In the RF-PECVD deposition of carbon coating, as used by *Bhushan* et al. (e.g., [26.12]), carbon coating is deposited by adsorption of most free radicals of hydrocarbon to the substrate and chemical bonding to other atoms on the surface. The hydrocarbon species are produced by the RF plasma decomposition of hydrocarbon precusors such as acetylene (C_2H_2), Fig. 26.4e [26.27, 69, 72–75]. Instead of requiring thermal energy in thermal CVD, the energetic electrons in the plasma (at pressures ranging from 1 to 5×10^2 Pa, typically less than 10 Pa) can activate almost any reaction among the gases in the glow discharge at relatively low substrate temperatures ranging from 100 to 600 °C (typically less than 300 °C). To deposit the coating on non-silicon substrates, an about 4-nm-thick amorphous silicon adhesion layer, used to improve adhesion, is first deposited under similar conditions from a gas mixture of 1% silane in argon [26.76]. In the process used by Bhushan and coworkers [26.12], the plasma is sustained in a parallel-plate geometry by a capacitive discharge at 13.56 MHz, at a surface power density on the order of 100 mW/cm^2. The deposition is performed at a flow rate on the order of 6 sccm and a pressure on the order of 4 Pa (30 mTorr) on a cathode-mounted substrate maintained at a substrate temperature of 180 °C. The cathode bias is held fixed at about −120 V with an external DC power supply attached to the substrate (powered electrode). The carbon coatings deposited by PECVD usually contain hydrogen up to 50% [26.35, 77].

26.2 Chemical Characterization and Effect of Deposition Conditions on Chemical Characteristics and Physical Properties

The chemical structure and properties of amorphous carbon coatings are a function of deposition conditions. It is important to understand the relationship of the chemical structure of amorphous carbon coatings to the properties in order to define useful deposition parameters. Amorphous carbon films are metastable phases formed when carbon particles are condensed on a substrate. The prevailing atomic arrangement in the DLC coatings is amorphous or quasi-amorphous with small diamond (sp^3), graphite (sp^2), and other unidentifiable micro- or nanocrystallites. The coating is dependent upon the deposition process and its conditions contain varying amounts of sp^3/sp^2 ratio and hydrogen. The sp^3/sp^2 ratio of DLC coatings ranges typically from 50% to close to 100% with an increase in hardness with the sp^3/sp^2 ratio. Most DLC coatings, except those produced by filtered cathodic arc, contain from a few to about 50 at% hydrogen. Sometimes hydrogen and nitrogen are deliberately added to produce hydrogenated (a-C:H) and nitrogenated amorphous carbon (a-C:N) coatings, respectively. Hydrogen helps to stabilize sp^3 sites (most of the carbon atoms attached to hydrogen have a tetrahedral structure); therefore, the sp^3/sp^2 ratio for hydrogenated carbon is higher [26.30]. Optimum sp^3/sp^2 in a random covalent network composed of sp^3 and sp^2 carbon sites (N_{sp^2} and N_{sp^3}) and hydrogen is [26.30]:

$$\frac{N_{sp^3}}{N_{sp^2}} = \frac{6X_H - 1}{8 - 13X_H}\,, \tag{26.1}$$

where X_H is the atom fraction of hydrogen. The hydrogenated carbon has a larger optical band gap, higher electrical resistivity (semiconductor), and a lower optical absorption or high optical transmission. The hydrogenated coatings have a lower density, probably because of the reduction of cross-linking due to hydrogen incorporation. However, hardness decreases with an increase of the hydrogen, even though the proportion of sp^3 sites increases (that is, as the local bonding environment becomes more diamond-like) [26.78, 79]. It is speculated that the high hydrogen content introduces frequent terminations in the otherwise strong 3-D network, and hydrogen increases the soft polymeric component of the structure more than it enhances the cross-linking sp^3 fraction.

A number of investigations have been performed to identify the microstructure of amorphous carbon films using a variety of techniques such as Raman spectroscopy, EELS, nuclear magnetic resonance, optical measurements, transmission electron microscopy, and X-ray photoelectron spectroscopy [26.33]. The structure of diamond-like amorphous carbon is amorphous or quasi-amorphous with small graphitic (sp^2) and tetrahedrally coordinated (sp^3) and other unidentifiable nanocrystallites (typically on the order of a couple nm, randomly oriented) [26.33, 80, 81]. These studies indicate that the chemical structure and physical properties of the coatings are quite variable, depending on the deposition techniques and film growth conditions. It is clear that both sp^2 and sp^3-bonded atomic sites are incorporated in diamond-like amorphous carbon coatings and that the physical and chemical properties of the coatings depend strongly on their chemical bonding and microstructure. Systematic studies have been conducted to carry out chemical characterization and investigate how the physical and chemical properties of amorphous carbon coatings vary as a function of deposition parameters (e.g., [26.33, 35, 40]). EELS and Raman spectroscopy are commonly used to characterize the chemical bonding and microstructure. Hydrogen concentration of the coatings is obtained by means of forward recoil spectrometry (FRS). A variety of physical properties of the coatings relevant to tribological performance are measured.

To present the typical data obtained for characterization of typical amorphous carbon coatings and their relationships to physical properties, we present data on several sputtered coatings, RF-PECVD amorphous carbon and microwave-PECVD (MPECVD) diamond coatings [26.33,35,40]. The sputtered coatings were DC magnetron sputtered at a chamber pressure of 10 mTorr under sputtering power densities of 0.1 and 2.1 W/cm^2 in a pure Ar plasma, labeled as W1 and W2, respectively. They were prepared at a power density of 2.1 W/cm^2 with various hydrogen fractions of 0.5, 1, 3, 5, 7 and 10% of Ar/H, the gas mixtures labeled as H1, H2, H3, H4, H5, and H6, respectively.

26.2.1 EELS and Raman Spectroscopy

EELS and Raman spectra of four sputtered (W1, W2, H1, and H3) and one PECVD carbon samples were obtained. Figure 26.5 shows the EELS spectra of these carbon coatings. EELS spectra for bulk diamond and polycrystalline graphite in an energy range up to 50 eV are also shown in Fig. 26.5. One prominent peak is seen

at 35 eV in diamond, while two peaks are seen at 27 eV and 6.5 eV in graphite, which are called $(\pi+\sigma)$ and (π) peaks, respectively. These peaks are produced by the energy loss of transmitted electrons to the plasmon oscillation of the valence electrons. The $\pi+\sigma$ peak in each coating is positioned at a lower energy region than that of graphite. The π peaks in the W series and PECVD samples are also seen at a lower energy region than that of the graphite. However, the π peaks in the H-series are comparable to or higher than that of graphite (see Table 26.2). The plasmon oscillation frequency is proportional to the square root of the corresponding electron density to a first approximation. Therefore, the samples in the H-series most likely have a higher density of π electrons than the other samples.

Amorphous carbon coatings contain (mainly) a mixture of sp^2- and sp^3-bonds, even though there is some evidence for the presence of sp-bonds as well [26.82]. The PECVD coatings and the H-series coatings in this study have nearly the same mass density, as seen in Table 26.4, to be presented later, but the former have a lower concentration of hydrogen (18.1%) than the H-series (35–39%), as seen in Table 26.3, to be presented later. The relatively low energy position of π peaks of PECVD coatings, compared to those of the H-series, indicates that the PECVD coatings contain a higher fraction of sp^3-bonds than the sputtered hydrogenated carbon coatings (H-series).

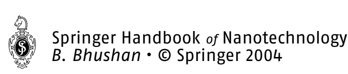
285.5 eV and 292.5 eV in graphite, while no peak is seen at 285.5 eV in diamond. The general features of the K-shell EELS spectra for the sputtered and PECVD carbon samples resemble those of graphite, but with the higher energy features smeared. The observation of the peak at 285.5 eV in the sputtered and PECVD coatings also indicates the presence of sp^2-bonded atomic sites in the coatings. All these spectra peak at 292.5 eV, similar to the spectra of graphite, but the peak in graphite is sharper.

Raman spectra from samples W1, W2, H1, and PECVD are shown in Fig. 26.6. Raman spectra could not be observed in specimens H2 and H3 due to high flourescence signals. The Raman spectra of single crystal diamond and polycrstalline graphite are also shown for comparison in Fig. 26.6. The results of the spectral fits are summarized in Table 26.2. We will focus on the G-band position, which has been shown to be related to the fraction of sp^3-bonded sites. Increasing the power density in the amorphous carbon coatings (W1 and W2) results in a higher G-band frequency, implying a smaller fraction of sp^3-bonding in W2 than in W1. This is consistent with higher density of W1. H1 and PEVCD have still lower G-band positions than W1, implying an even higher fraction of sp^3-bonding, which is presumably caused by the incorporation of H atoms into the lattice. The high hardness of H3 might be attributed to efficient sp^3 cross-linking of small, sp^2-ordered domains.

The Raman spectrum of a MPECVD diamond coating is shown in Fig. 26.6. The diamond Raman peak is at 1,333 cm^{-1} with a line width of 7.9 cm^{-1}. There is a small broad peak around 1,525 cm^{-1}, which is attributed to a small amount of a-C:H. This impurity peak is not intense enough to fit to separate G- and D-bands. The diamond peak frequency is very close to that of natural diamond (1,332.5 cm^{-1}, e.g. Fig. 26.6), indicating that the coating is not under stress [26.83]. The large line width compared to that of natural diamond (2 cm^{-1})

Fig. 26.6 Raman spectra of DLC coatings produced by DC magnetron sputtering and RF-PECVD techniques and a diamond film produced by MPECVD technique. Data for bulk diamond and microcrystalline graphite are included for comparison [26.35]



indicates that the microcrystallites likely have a high concentration of defects [26.84].

26.2.2 Hydrogen Concentrations

FRS analysis of six sputtered (W2, H2, H3, H4, H5, and H6) coatings, one PECVD coating, and one diamond coating was performed. Figure 26.7 shows an overlay of the spectra from the six sputtered samples. Similar spectra were obtained from the PECVD and the diamond films. Table 26.3 shows the H and C fractions, as well as the amount of impurities (Ar and O) in the films in atomic %. Most apparent is the large fraction of H in the sputtered films. Regardless of how much H_2 is in the Ar sputtering gas, the H content of the coatings is about the same, ~ 35 at%. Interestingly, there is still $\sim 10\%$ H present in the coating sputtered in pure Ar (W2). It is interesting to note that Ar is present only in coatings grown under low ($< 1\%$) H content in the Ar carrier gas. The presence of O in the coatings, combined with the fact that the coatings were prepared approximately nine months before the FRS analysis, caused suspicion that they had absorbed water vapor, and that this may be the cause for the H peak in specimen W2.

All samples were annealed for 24 h at 250 °C in a flowing He furnace and then reanalyzed. Surprisingly, the H content of all coatings measured increased slightly, even though the O content decreased, and W2 still had a substantial amount of H_2. This slight increase in H concentration is not understood. However, since H concentration did not decrease with the oxygen as a result of annealing, it suggests that high H concentration is not due to adsorbed water vapor. The PECVD film has more H ($\sim 18\%$) than the sputtered films initially, but after annealing it has the same fraction as specimen W2, the film sputtered in pure Ar. The diamond film has the smallest amounts of hydrogen, as seen in Table 26.3.

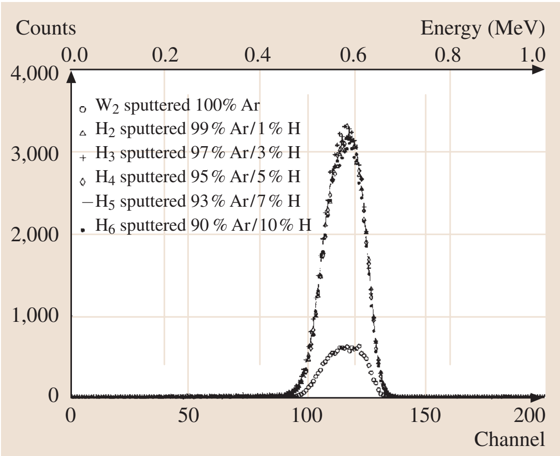


Fig. 26.7 FRS spectra of six DLC coatings produced by DC magnetron sputtering [26.35]

26.2.3 Physical Properties

Physical properties of the four sputtered (W1, W2, H1, and H3) coatings, one PECVD coating, one diamond coating, and bulk diamond and graphite are presented in Table 26.4. The hydrogenated carbon and the diamond coatings have very high resistivity compared to unhydrogenated carbon coatings. It appears that unhydrogenated carbon coatings have a higher density than the hydrogenated carbon coatings, although both groups are less dense than graphite. The density depends on the deposition technique and the deposition parameters. It appears that unhydrogenated sputtered coatings deposited at low power exhibit the highest density. Nanohardness of hydrogenated carbon is somewhat lower than that of the unhydrogenated carbon coatings. PECVD coatings are significantly harder than sputtered coatings. The nanohardness and modulus of elasticity of the diamond coatings are very high compared to that of DLC coatings, even though the hydrogen content is similar. The compressive residual stresses of the PECVD coatings are substantially higher than those of sputtered coatings, which is consistent with the hardness results.

Figure 26.8a shows the effect of hydrogen in the plasma on the residual stresses and the nanohardness for sputtered coatings W2 and H1 to H6. The coatings made with H_2 flow between 0.5 and 1.0% delaminate very quickly, even when only a few tens of nm thick. In pure Ar and at H_2 flows greater than 1%, the coatings appear to be more adhesive. The tendency of some coatings to delaminate can be caused by intrinsic stress in the coating, which is measured by substrate bending. All of the coatings in the figure are in compressive stress. The maximum stress occurs between 0 and 1% H_2 flow, but the stress cannot be quantified in this range because the coatings instantly delaminate upon exposure to air. At higher hydrogen concentrations the stress gradually diminishes. A generally decreasing trend is observed in the hardness of the coatings as hydrogen content increased. The hardness decreases slightly, going from 0% H_2 to 0.5% H_2, and then decreases sharply. These results are probably lower than the true values because of local delamination around the indentation point. This is especially likely for the 0.5% and 1.0% coatings where

delamination is visually apparent, but may also be true to a lesser extent for the other coatings. Such an adjustment would bring the hardness profile into closer correlation with the stress profile. *Weissmantel* et al. [26.68] and *Scharff* et al. [26.85] observed a downturn in hardness for high bias and low pressure of hydrocarbon gas in ion plated carbon coating, and, therefore, presumably low hydrogen content in support of the above contention.

Figure 26.8b shows the effect of sputtering power (with no hydrogen added in the plasma) on the residual stresses and nanohardness for various sputtered coatings. As the power decreases, compressive stress does not seem to change while nanohardness slowly increases. The rate of change becomes more rapid at very low power levels.

The addition of H_2 during sputtering of carbon coatings increases H concentration in the coating. Hydrogen causes the character of the C-C bonds to shift from sp^2 to sp^3, and the rising number of C-H bonds, which ultimately relieves stress and produces a softer "polymer-like" material. Low power deposition, like the presence of hydrogen, appears to stabilize the formation of sp^3 C-C bonds, increasing hardness. These coatings have relieved stress and led to better adhesion. An increase in temperature during deposition at high power density results in graphitization of the coating material, responsible for a decrease in hardness with an increase in power density. Unfortunately, low power also means impractically low deposition rates.

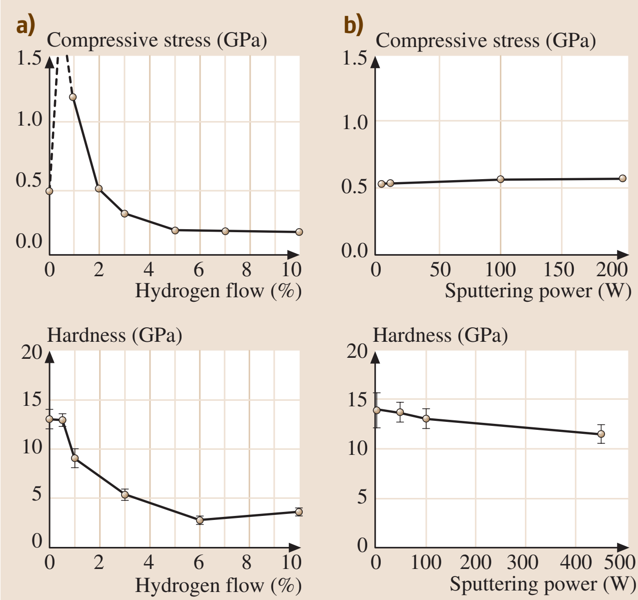

Fig. 26.8a,b Residual compressive stresses and nanohardness **(a)** as a function of hydrogen flow rate; sputtering power is 100 W and target diameter is 75 mm (power density = 2.1 W/cm^2), and **(b)** as a function of sputtering power over a 75-mm-diameter target with no hydrogen added in the plasma [26.40]

26.2.4 Summary

Based on the EELS and Raman data, all DLC coatings have both sp^2 and sp^3 bondings. The sp^2/sp^3 bonding ratio depends on the deposition techniques and parameters. The DLC coatings deposited by sputtering and PECVD contain significant concentrations of hydrogen, while the diamond coating contains only small amounts of hydrogen impurity. Sputtered coatings with no deliberate addition of hydrogen in the plasma contain a significant amount of hydrogen. Regardless of how much hydrogen is in the Ar sputtering gas, the hydrogen content of the coatings increases initially with no further increase.

Hydrogen flow and sputtering power density affect the mechanical properties of these coatings. Maximum compressive residual stress and hardness occur between 0 and 1% hydrogen flow, resulting in rapid delamination. Low sputtering power moderately increases hardness while relieving residual stress.

26.3 Micromechanical and Tribological Characterizations of Coatings Deposited by Various Techniques

26.3.1 Micromechanical Characterization

Common mechanical characterizations include measurement of hardness and elastic modulus, fracture toughness, fatigue life, and scratch and wear testing. Nanoindentation and atomic force microscopy (AFM) are used for mechanical characterization of ultrathin films.

Hardness and elastic modulus are calculated from the load displacement data obtained by nanoindentation at loads ranging typically from 0.2 to 10 mN using a commercially available nanoindenter [26.23,86].

This instrument monitors and records the dynamic load and displacement of the three-sided pyramidal diamond (Berkovich) indenter during indentation. For the fracture toughness measurement of ultrathin films ranging from 100 nm to a few μm, a nanoindentation-based technique is used in which through-thickness cracking in the coating is detected from a discontinuity observed in the load-displacement curve and energy released during the cracking is obtained from the curve [26.87–89]. Based on the energy released, fracture mechanics analysis is then used to calculate fracture toughness. An indenter with a cube-corner tip geometry is preferred because the through-thickness cracking of hard films can be accomplished at lower loads. In fatigue measurement, a conical diamond indenter having a tip radius of about one micron is used and load cycles of a sinusoidal shape are applied [26.90, 91]. The fatigue behavior of coatings is studied by monitoring the change in contact stiffness, which is sensitive to damage formation.

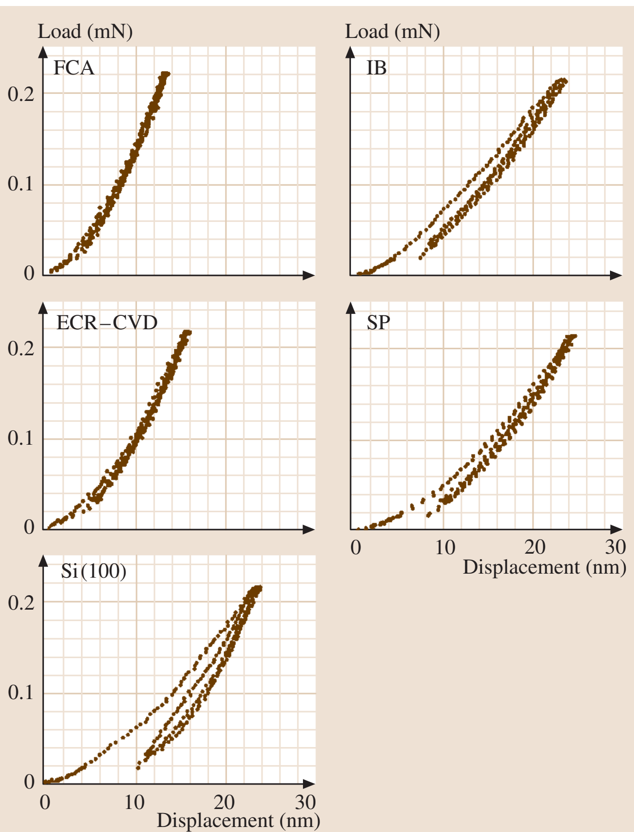

Fig. 26.9 Load versus displacement plots for various 100-nm-thick amorphous carbon coatings on single-crystal silicon substrate and bare substrate

Hardness and Elastic Modulus

For materials that undergo plastic deformation, high hardness and elastic modulus are generally needed for low friction and wear, whereas for brittle materials, high fracture toughness is needed [26.2, 3, 21]. DLC coatings used for many applications are hard and brittle, and values of hardness and fracture toughness need to be optimized.

Representative load-displacement plots of indentations made at 0.2 mN peak indentation load on 100-nm-thick DLC coatings deposited by the four deposition techniques on single-crystal silicon substrate are compared in Fig. 26.9. The indentation depths at the peak load range from about 18 to 26 nm, smaller than that of the coating thickness. Many of the coatings exhibit a discontinuity or pop-in marks in the loading curve, which indicate a sudden penetration of the tip into the sample. A nonuniform penetration of the tip into a thin coating possibly results from formation of cracks in the coating, formation of cracks at the coating-substrate interface, or debonding or delamination of the coating from the substrate.

The hardness and elastic modulus values at a peak load of 0.2 mN on the various coatings and single-crystal silicon substrate are summarized in Table 26.5 and Fig. 26.10 [26.47, 49, 89, 90]. Typical values for the peak and residual indentation depths ranged from 18 to 26 nm and 6 to 12 nm, respectively. The FCA coatings exhibit the highest hardness of 24 GPa and elastic modulus of 280 GPa of various coatings, followed by the ECR-CVD, IB, and SP coatings. Hardness and elastic modulus have been known to vary over a wide range with sp^3-to-sp^2 bonding ratio, which depends on the kinetic energy of the carbon species and amount of hydrogen [26.6, 30, 47, 92, 93]. The high hardness and elastic modulus of the FCA coatings are attributed to the high kinetic energy of carbon species involved in the FCA deposition [26.12, 47]. *Anders* et al. [26.57] also reported a high hardness, measured by nanoindentation, of about 45 GPa for cathodic arc carbon coatings. They observed a change in hardness from 25 to 45 GPa with pulsed bias voltage and bias duty cycle. The high hardness of cathodic arc carbon was attributed to the high percentage (more than 50%) of sp^3 bonding. *Savvides* and *Bell* [26.94] reported an increase in hardness from 12 to 30 GPa and an elastic modulus from 62 to 213 GPa with an increase of sp^3-to-sp^2 bonding ratio, from 3 to 6,

for a C:H coating deposited by low-energy ion-assisted unbalanced magnetron sputtering of a graphite target in an Ar-H_2 mixture.

Bhushan et al. [26.35] reported hardnesses of about 15 and 35 GPa and elastic moduli of about 140 and 200 GPa, measured by nanoindentation, for a-C:H coatings deposited by DC magnetron sputtering and RF-plasma-enhanced chemical vapor deposition techniques, respectively. The high hardness of RF-PECVD a-C:H coatings is attributed to a higher concentration of sp^3 bonding than in a sputtered hydrogenated a-C:H coating. Hydrogen is believed to play a crucial role in the bonding configuration of carbon atoms by helping to stabilize tetrahedra-coordination (sp^3 bonding) of carbon species. *Jansen* et al. [26.78] suggested that the incorporation of hydrogen efficiently passivates the dangling bonds and saturates the graphitic bonding to some extent. However, a large concentration of hydrogen in the plasma in sputter deposition is undesirable. *Cho* et al. [26.33] and *Rubin* et al. [26.40] observed that hardness decreased from 15 to 3 GPa with increased hydrogen content. *Bhushan* and *Doerner* [26.95] reported a hardness of about 10–20 GPa and an elastic modulus of about 170 GPa, measured by nanoindentation, for 100-nm-thick DC-magnetron sputtered a-C:H on the silicon substrate.

Residual stresses measured using a well-known curvature measurement technique are also presented in Table 26.5. The DLC coatings are under significant compressive internal stresses. Very high compressive stresses in FCA coatings are believed to be partly responsible for their high hardness. However, high stresses result in coating delamination and buckling. For this reason, the coatings that are thicker than about 1 μm have a tendency to delaminate from the substrates.

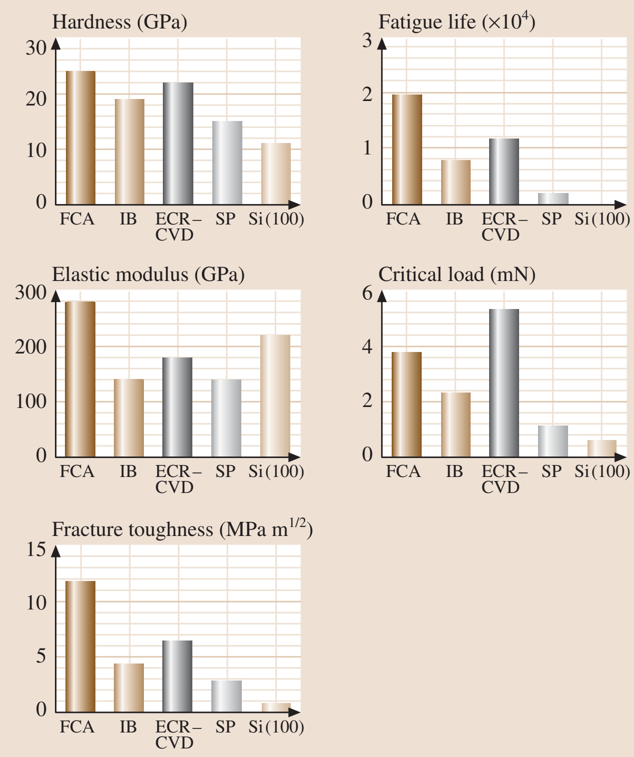

Fig. 26.10 Bar charts summarizing the data of various coatings and single-crystal silicon substrate. Hardness, elastic modulus, and fracture toughness were measured on 100-nm-thick coatings, and fatigue life and critical load during scratch were measured on 20-nm-thick coatings

Fracture Toughness

Representative load-displacement curves of indentations on the 400-nm-thick cathodic arc carbon coating on silicon at various peak loads are shown in Fig. 26.11. Steps are found in all curves, as shown by arrows in Fig. 26.11a. In the 30 mN SEM micrograph, in addition to several radial cracks, ring-like through-thickness cracking is observed with small lips of material overhanging the edge of indentation. The step at about 23 mN in the loading curves of indentations made at 30 and 100 mN peak indentation loads results from the ring-like through-thickness cracking. The step at 175 mN in the loading curve of the indentation made at 200 mN peak indentation load is caused by spalling and second ring-like through-thickness cracking.

Based on *Li* et al. [26.87], the fracture process progresses in three stages: (1) ring-like through-thickness cracks form around the indenter by high stresses in the contact area, (2) delamination and buckling occur around contact area at the coating/substrate interface by high lateral pressure, (3) second ring-like through-thickness cracks and spalling are generated by high bending stesses at the edges of the buckled coating, see Fig. 26.12a. In the first stage, if the coating under the indenter is separated from the bulk coating via the first ring-like through-thickness cracking, a corresponding step will be present in the loading curve. If discontinuous cracks form and the coating under the indenter is not separated from the remaining coating, no step appears in the loading curve, because the coating still supports the indenter and the indenter cannot suddenly advance into the material. In the second stage,

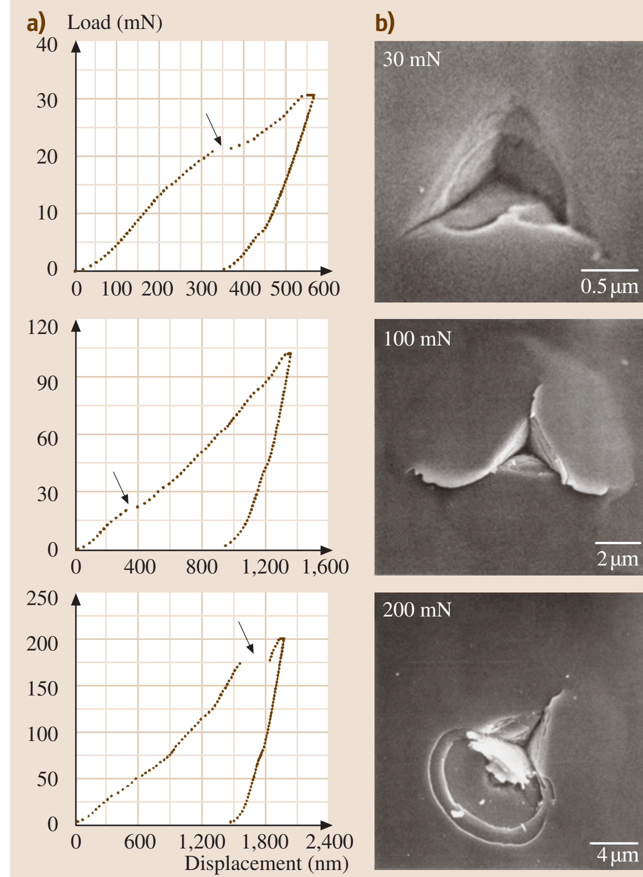

Fig. 26.11 **(a)** Load-displacement curves of indentations made at 30, 100, and 200 mN peak indentation loads using the cube corner indenter, and **(b)** the SEM micrographs of indentations on the 400-nm-thick cathodic arc carbon coating on silicon. *Arrows* indicate steps during loading portion of the load-displacement curve [26.87]

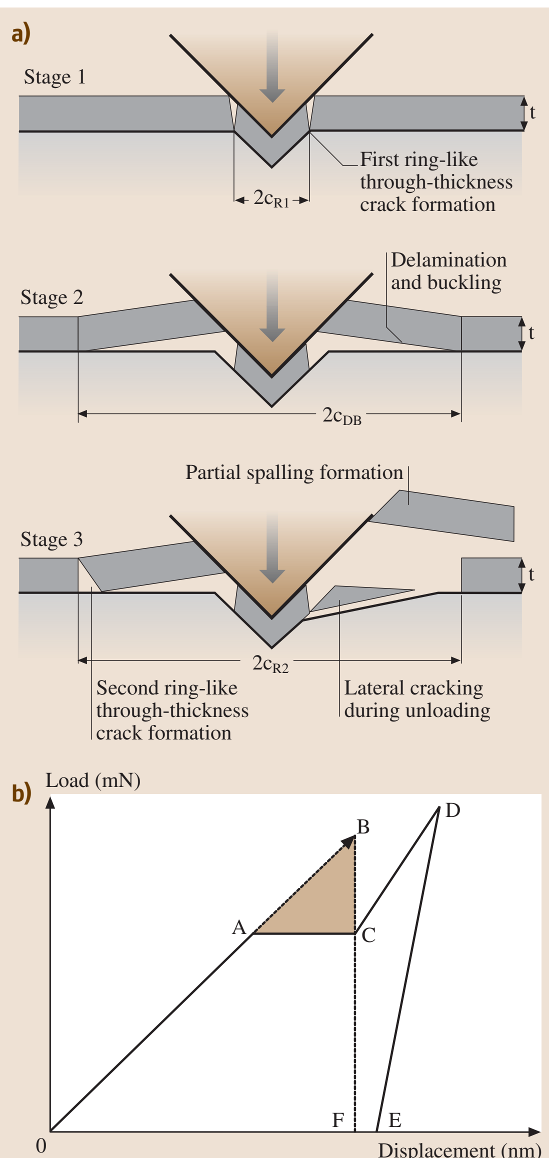

Fig. 26.12 **(a)** Schematic of various stages in nanoindentation fracture for the coatings/substrate system, and **(b)** schematic of a load-displacement curve showing a step during the loading cycle and associated energy release

for the coating used in the present study, the advances of the indenter during the radial cracking, delamination, and buckling are not big enough to form steps in the loading curve, because the coating around the indenter still supports the indenter, but generate discontinuities that change the slope of the loading curve with increasing indentation loads. In the third stage, the stress concentration at the end of the interfacial crack cannot be relaxed by the propagation of the interfacial crack. With an increase in indentation depth, the height of the bulged coating increases. When the height reaches a critical value, the bending stresses caused by the bulged coating around the indenter will result in the second ring-like through-thickness crack formation and spalling at the edge of the buckled coating, as shown in Fig. 26.12a, which leads to a step in the loading curve. This is a single event and results in the separation of the part of the coating around the indenter from the bulk

Table 26.5 Hardness, elastic modulus, fracture toughness, fatigue life, critical load during scratch, coefficient of friction during accelerated wear testing and residual stresses of various DLC coatings on single-crystal silicon substrate

Coating	Hardness[a] [26.48] (GPa)	Elastic modulus[a] [26.48] (GPa)	Fracture toughness[a] [26.89] (MPa m$^{1/2}$)	Fatigue life[b], N_f^d [26.90] $\times 10^4$	Critical load during scratch[b] [26.48] (mN)	Coefficient of friction during accelerated wear testing[b] [26.48]	Compressive residual stress[c] [26.47] (GPa)

coating via cracking through coatings. The step in the loading curve results totally from the coating cracking and not from the interfacial cracking or the substrate cracking.

The area under the load-displacement curve is the work performed by the indenter during elastic-plastic deformation of the coating/substrate system. The strain energy release in the first/second ring-like cracking and spalling can be calculated from the corresponding steps in the loading curve. Fig. 26.12b shows a modeled load-displacement curve. OACD is the loading curve and DE is the unloading curve. The first ring-like through-thickness crack should be considered. It should be emphasized that the edge of the buckled coating is far from the indenter and, therefore, it does not matter if the indentation depth exceeds the coating thickness, or if deformation of the substrate occurs around the indenter when we measure fracture toughness of the coating from the released energy during the second ring-like through-thickness cracking (spalling). Suppose that the second ring-like through-thickness cracking occurs at AC. Now, let us consider the loading curve OAC. If the second ring-like through-thickness crack does not occur, it can be understood that OA will be extended to OB to reach the same displacement as OC. This means that the crack formation changes the loading curve OAB into OAC. For point B, the elastic-plastic energy stored in the coating/substrate system should be OBF. For point C, the elastic-plastic energy stored in the coating/substrate system should be OACF. Therefore, the energy difference before and after the crack generation is the area of ABC, i. e., this energy stored in ABC will be released as strain energy to create the ring-like through-thickness crack. According to the theoretical analysis by *Li* et al. [26.87],

the fracture toughness of thin films can be written as

$$K_{\mathrm{Ic}} = \left[\left(\frac{E}{(1-\nu^2)\, 2\pi C_\mathrm{R}} \right) \left(\frac{U}{t} \right) \right]^{1/2} , \qquad (26.2)$$

where E is the elastic modulus, ν is the Poisson's ratio, $2\pi C_\mathrm{R}$ is the crack length in the coating plane, t is the coating thickness, and U is the strain energy difference before and after cracking.

Using (26.2), the fracture toughness of the coatings is calculated. The loading curve is extrapolated along the tangential direction of the loading curve from the starting point of the step up to reach the same displacement as the step. The area between the extrapolated line and the step is the estimated strain energy difference before and after cracking. C_R is measured from SEM micrographs or AFM images of indentations. The second ring-like crack is where the spalling occurs. For example, for the 400-nm-thick cathodic arc carbon coating data presented in Fig. 26.11, U of 7.1 nNm is assessed from the steps in Fig. 26.11a at the peak indentation loads of 200 mN. For C_R of 7.0 μm from Fig. 26.11b, $E = 300$ GPa measured using a nanoindenter and an assumed value of 0.25 for ν, fracture toughness values are calculated as 10.9 MPa$\sqrt{m}$ [26.87, 88]. The fracture toughness and related data for various 100-nm-thick DLC coatings are presented in Fig. 26.10 and Table 26.5.

Nanofatigue

Delayed fracture resulting from extended service is called fatigue [26.96]. Fatigue fracturing progresses through a material via changes within the material at the tip of a crack, where there is a high stress intensity. There are several situations: cyclic fatigue, stress corrosion, and static fatigue. Cyclic fatigue results from cyclic loading of machine components. In a low-flying slider in a magnetic head-disk interface, isolated asperity contacts occur during use and the fatigue failure occurs in the multilayered thin-film structure of the magnetic disk [26.13]. In many MEMS components, impact occurs and the failure mode is cyclic fatigue. Asperity contacts can be simulated using a sharp diamond tip in an oscillating contact with the component.

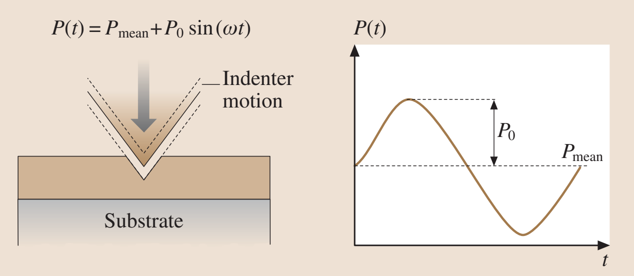

Fig. 26.13 Schematic of a fatigue test on a coating/substrate system using the continuous stiffness measurement technique

Figure 26.13 shows the schematic of a fatigue test on a coating/substrate system using a continuous stiffness measurement (CSM) technique. Load cycles are applied to the coating, resulting in a cyclic stress. P is the cyclic load, P_mean is the mean load, P_o is the oscillation load amplitude, and ω is the oscillation frequency. The following results can be obtained: (1) endurance limit, i. e., the maximum load below which there is no coating failure for a preset number of cycles; (2) number of cycles at which the coating failure occurs; and (3) changes in contact stiffness measured by using the unloading slope of each cycle, which can be used to monitor the propagation of the interfacial cracks during cyclic fatigue process.

Figure 26.14a shows the contact stiffness as a function of the number of cycles for 20-nm-thick FCA coatings cyclically deformed by various oscillation load amplitudes with a mean load of 10 μN at a frequency of 45 Hz. At 4 μN load amplitude, no change in contact stiffness was found for all coatings. This indicates that 4 μN load amplitude is not high enough to damage the coatings. At 6 μN load amplitude, an abrupt decrease in contact stiffness was found at a certain number of cycles for each coating, indicating that fatigue damage had occurred. With increasing load amplitude, the number of cycles to failure, $\mathrm{N_f}$, decreases for all coatings. Load amplitude versus $\mathrm{N_f}$, a so-called S-N curve, is plotted in Fig. 26.14b. The critical load amplitude, below which no fatigue damage occurs (an endurance limit), was identified for each coating. This critical load amplitude, together with mean load, are of critical importance to the design of head-disk interfaces or MEMS/NEMS device interfaces.

To compare the fatigue lives of different coatings studied, the contact stiffness as a function of the number of cycles for 20-nm-thick FCA, IB, ECR-CVD and SP coatings cyclically deformed by an oscillation load amplitude of 8 μN with a mean load of 10 μN at a frequency of 45 Hz is shown in Fig. 26.14c. FCA coating has the longest $\mathrm{N_f}$, followed by ECR-CVD, IB, and SP coatings. In addition, after the $\mathrm{N_f}$, the contact stiffness of the FCA coating shows a slower decrease than the other coatings. This indicates that after the $\mathrm{N_f}$, the FCA coating had less damage than the others. The fatigue behavior of FCA and ECR-CVD coatings of differ-

Fig. 26.14 **(a)** Contact stiffness as a function of the number of cycles for 20-nm-thick FCA coatings cyclically deformed by various oscillation load amplitudes with a mean load of 10 μN at a frequency of 45 Hz; **(b)** plot of load amplitude versus N_f; **(c)** contact stiffness as a function of the number of cycles for four different 20-nm-thick coatings with a mean load of 10 μN and load amplitude of 8 μN at a frequency of 45 Hz; and **(d)** contact stiffness as a function of the number of cycles for two coatings of different thicknesses at a mean load of 10 μN and load amplitude of 8 μN at a frequency of 45 Hz

ent thicknesses is compared in Fig. 26.14d. For both coatings, N_f decreases with decreasing coating thickness. At 10 nm, FCA and ECR-CVD have almost the same fatigue life. At 5 nm, ECR-CVD coating shows a slightly longer fatigue life than FCA coating. This indicates that even for nanometer-thick DLC coatings their microstructure and residual stresses are not uniform across the thickness direction. Thinner coatings are more influenced by interfacial stresses than thicker coating.

Figure 26.15a shows the high magnification SEM images of 20-nm-thick FCA coatings before, at, and after N_f. In the SEM images, the net-like structure is the gold film coated on the DLC coating, which should be ignored in analyzing the indentation fatigue damage. Before the N_f, no delamination or buckling was found except the residual indentation mark at magnifications up to 1,200,000× using SEM. This suggests that only plastic deformation occurred before the N_f. At the N_f, the coating around the indenter bulged upwards, indicating delamination and buckling. Therefore, it is believed that the decrease in contact stiffness at the N_f results from the delamination and buckling of the coating from the substrate. After the N_f, the buckled coating was broken down around the edge of the buckled area, forming a ring-like crack. The remaining coating overhung at the edge of the buckled area. It is noted that the indentation size increases with the increasing number of cycles. This indicates that deformation, delamination and buckling, and ring-like crack formation occurred over a period.

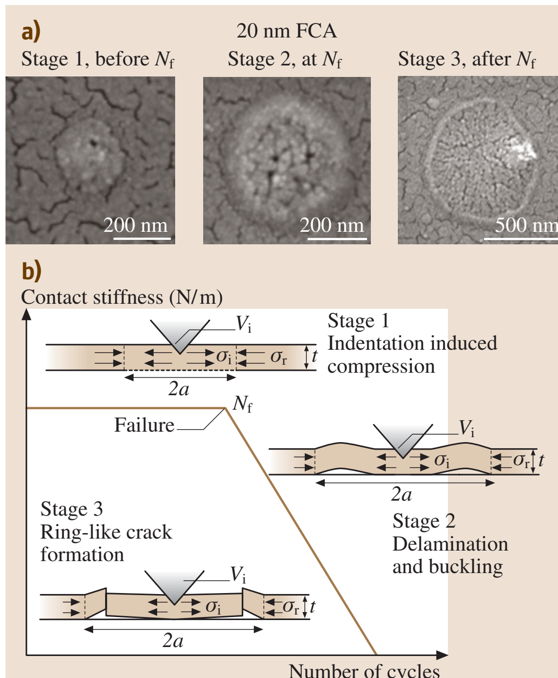

Fig. 26.15 **(a)** High magnification SEM images of a coating before, at, and after N_f, and **(b)** schematic of various stages in the indentation fatigue damage for a coating/substrate system [26.90]

The schematic in Fig. 26.15b shows various stages in the indentation fatigue damage for a coating/substrate system. Based on this study, three stages in the indentation fatigue damage appear to exist: (1) indentation-induced compression; (2) delamination and buckling; (3) ring-like crack formation at the edge of the buckled coating. The deposition process often induces residual stresses in coatings. The model shown in Fig. 26.15b considers a coating with the uniform biaxial residual compression σ_r. In the first stage, indentation induces elastic/plastic deformation, exerting an outward acting pressure on the coating around the indenter. Interfacial defects like voids and impurities act as original cracks. These cracks propagate and link up as the indentation compressive stress increases. At this stage, the coating, which is under the indenter and above the interfacial crack (with a crack length of $2a$), still maintains a solid contact with the substrate; the substrate still fully supports the coating. Therefore, this interfacial crack does not lead to an abrupt decrease in contact stiffness, but gives rise to a slight decrease in contact stiffness, as shown in Fig. 26.14. The coating above the interfacial crack is treated as a rigidly clamped disk. We assume that the crack radius, a, is large compared with the coating thickness t. Since the coating thickness ranges from 5 to 20 nm, this assumption is easily satisfied in this study (radius of the delaminated and buckled area, shown in Fig. 26.15a, is on the order of 100 nm). The compressive stress caused by indentation is given as [26.97]:

$$\sigma_i = \frac{E}{(1-\nu)}\varepsilon_i = \frac{EV_i}{2\pi t a^2(1-\nu)} , \qquad (26.3)$$

where ν and E are the Poisson's ratio and elastic modulus of the coating, V_i is the indentation volume, t is the coating thickness, and a is the crack radius. With an increasing number of cycles, the indentation volume V_i increases. Therefore, the indentation compressive stress σ_i increases accordingly. In the second stage, buckling occurs during the unloading segment of the fatigue testing cycle when the sum of indentation compressive stress σ_i and the residual stress σ_r

exceed the critical buckling stress σ_b for the delaminated circular section as given by [26.98]

$$\sigma_b = \frac{\mu^2 E}{12\left(1-\nu^2\right)}\left(\frac{t}{a}\right)^2 , \quad (26.4)$$

where the constant μ equals 42.67 for a circular clamped plate with a constrained center point and 14.68 when the center is unconstrained. The buckled coating acts as a cantilever. In this case, the indenter indents a cantilever rather than a coating/substrate system. This ultrathin coating cantilever has much less contact stiffness than the coating/substrate system. Therefore, the contact stiffness shows an abrupt decrease at the N_f. In the third stage, with an increasing number of cycles, the delaminated and buckled size increases, resulting in a further decrease in contact stiffness since the cantilever beam length increases. On the other hand, a high bending stress acts at the edge of the buckled coating. The larger the buckled size, the higher the bending stress. The cyclically bending stress causes fatigue damage at the end of the buckled coating, forming a ring-like crack. The coating under the indenter is separated from the bulk coating (caused by the ring-like crack at the edge of the buckled coating) and the substrate (caused by the delamination and buckling in the second stage). Therefore, the coating under the indenter is not constrained, but is free to move with the indenter during fatigue testing. At this point, the sharp nature of the indenter is lost, because the coating under the indenter gets stuck on the indenter. The indentation fatigue experiment results in the contact of a relative huge blunt tip with the substrate. This results in a low contact stiffness value.

Compressive residual stresses result in delamination and buckling. A coating with a higher adhesion strength and a less compressive residual stress is required for a higher fatigue life. Interfacial defects should be avoided in the coating deposition process. We know that the ring-like crack formation occurs in the coating. Formation of fatigue cracks in the coating depends upon the hardness and fracture toughness. Cracks are more difficult to form and propagate in the coating with higher strength and fracture toughness.

It is now accepted that long fatigue life in a coating/substrate almost always involves "living with crack", that the threshold or limit condition is associated with the non-propagation of exiting cracks or defects, even though these cracks may be undetectable [26.96]. For all coatings studied, at 4 μN, contact stiffness does not change much. This indicates that delamination and buckling did not occur within the number of cycles tested in this study. This is probably because the indentation-induced compressive stress was not high enough to allow the cracks to propagate and link up under the indenter, or the sum of indentation compressive stress σ_i and the residual stress σ_r did not exceed the critical buckling stress σ_b.

Figure 26.10 and Table 26.5 summarize the hardness, elastic modulus, fracture toughness, and fatigue life of all coatings studied. A good correlation exists between fatigue life and other mechanical properties. Higher mechanical properties result in a longer fatigue life. The mechanical properties of DLC coatings are controlled by the sp^3-to-sp^2 ratio. The sp^3-bonded carbon exhibits the outstanding properties of diamond [26.51]. A higher deposition kinetic energy will result in a larger fraction of sp^3-bonded carbon in an amorphous network. Thus, the higher kinetic energy for the FCA could be responsible for its better carbon structure and higher mechanical properties [26.48–50, 99]. Higher adhesion strength between the FCA coating and substrate makes the FCA coating more difficult to delaminate from the substrate.

26.3.2 Microscratch and Microwear Studies

For microscratch studies, a conical diamond indenter (e.g., having a tip radius of about one micron and included angle of 60°) is drawn over the sample surface, and the load is ramped up (typically from 2 mN to 25 mN) until substantial damage occurs. The coefficient of friction is monitored during scratching. Scratch-induced damage of coating, specifically fracture or delamination, can be monitored by in situ friction force measurements and by optical and SEM imaging of the scratches after tests. A gradual increase in friction is associated with plowing, and an abrupt increase in friction is associated with fracture or catastrophic failure [26.100]. The load, corresponding to the abrupt increase in friction or an increase in friction above a certain value (typically 2× the initial value), provides a measure of scratch resistance or adhesive strength of a coating and is called "critical load". The depth of scratches with increasing scratch length or normal load is measured using an AFM, typically with an area of 10 × 10 μm [26.48, 49, 101].

The microscratch and microwear studies are also conducted using an AFM [26.23, 50, 99, 102, 103]. A square pyramidal diamond tip (tip radius ∼ 100 nm) or a three-sided pyramidal diamond (Berkovich) tip with an apex angle of 60° and a tip radius of about 100 nm mounted on a platinum-coated, rectangular stainless steel cantilever of stiffness of about 40 N/m is scanned

Fig. 26.16a,b

orthogonal to the long axis of the cantilever to generate scratch and wear marks. During the scratch test, the normal load is either kept constant or increased (typically from 0 to 100 μN) until damage occurs. Topography images of the scratch are obtained in situ with the AFM at a low load. By scanning the sample during scratching, wear experiments can be conducted. Wear at a constant load is monitored as a function of the number of cycles. Normal loads ranging from 10–80 μN are typically used.

Microscratch

Scratch tests conducted with a sharp diamond tip simulate a sharp asperity contact. In a scratch test, the cracking or delamination of a hard coating is signaled by a sudden increase in the coefficient of friction [26.23]. The load associated with this event is called the "critical load".

Wu [26.104], *Bhushan* et al. [26.70], *Gupta* and *Bhushan* [26.12,47], and *Li* and *Bhushan* [26.48,49,101] have used a nanoindenter to perform microscratch studies (mechanical durability) of various carbon coatings. The coefficient of friction profiles as a function of increasing normal load and AFM surface height maps of regions over scratches at the respective critical loads (indicated by the arrows in the friction profiles and AFM images) made on the various coatings of different thicknesses and single-crystal silicon substrate using a conical tip are compared in Figs. 26.16 and 26.17. *Bhushan* and *Koinkar* [26.102], *Koinkar* and

Bhushan [26.103], *Bhushan* [26.23], and *Sundararajan* and *Bhushan* [26.50, 99] have used an AFM to perform microscratch studies. Data for various coatings of different thicknesses and silicon substrate using a Berkovich tip are compared in Figs. 26.18 and 26.19. Critical loads for various coatings tested using a nanoindenter and AFM are summarized in Fig. 26.20. The selected data for 20-nm-thick coatings obtained using nanoindenter are also presented in Fig. 26.10 and Table 26.5.

It can be seen that a well-defined critical load exists for each coating. The AFM images clearly show that below the critical loads the coatings were plowed by the scratch tip, associated with the plastic flow of materials.

At and after the critical loads, debris (chips) or buckling was observed on the sides of scratches. Delamination or buckling can be observed around or after the critical loads, which suggests that the damage starts from delamination and buckling. For the 3.5- and 5-nm-thick FCA coatings, before the critical loads small debris is observed on the sides of scratches. This suggests that the thinner FCA coatings are not so durable. It is obvious that for a given deposition method, the critical loads increase with increasing coating thickness. This indicates that the critical load is determined not only by the adhesion strength to the substrate, but also by the coating thickness. We note that the debris generated on the thicker coatings is larger than that generated on the thinner coatings. For a thicker coating, it is more difficult to be broken; the broken coating chips (debris) for a thicker coating are larger than those for the thinner coatings. The difference in the residual stresses of the coatings of different thicknesses could also affect the size of debris. The AFM image shows that the silicon substrate was damaged by plowing, associated with the plastic flow of materials. At and after the critical load, small and uniform debris is observed and the amount of debris increases with increasing normal load.

Part D | 26.3

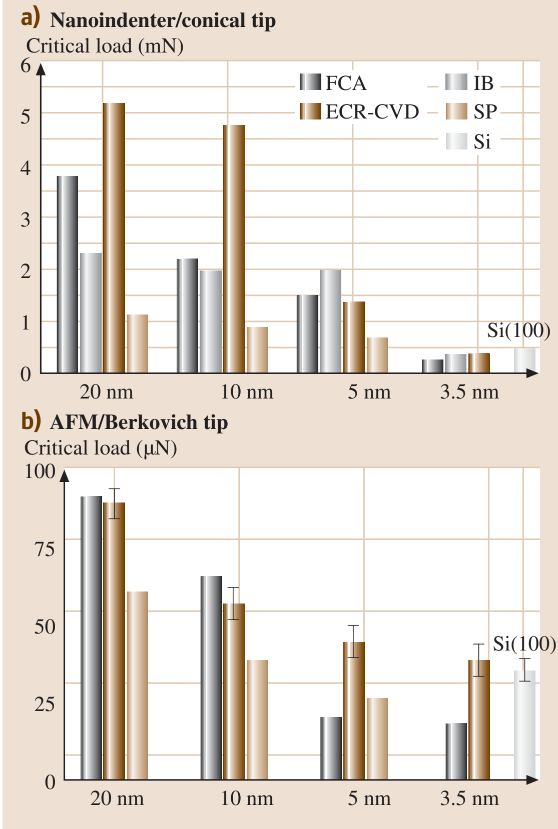

Fig. 26.20a,b Critical loads estimated from the coefficient of friction profiles from (a) nanoindenter and (b) AFM tests for various coatings of different thicknesses and Si(100) substrate

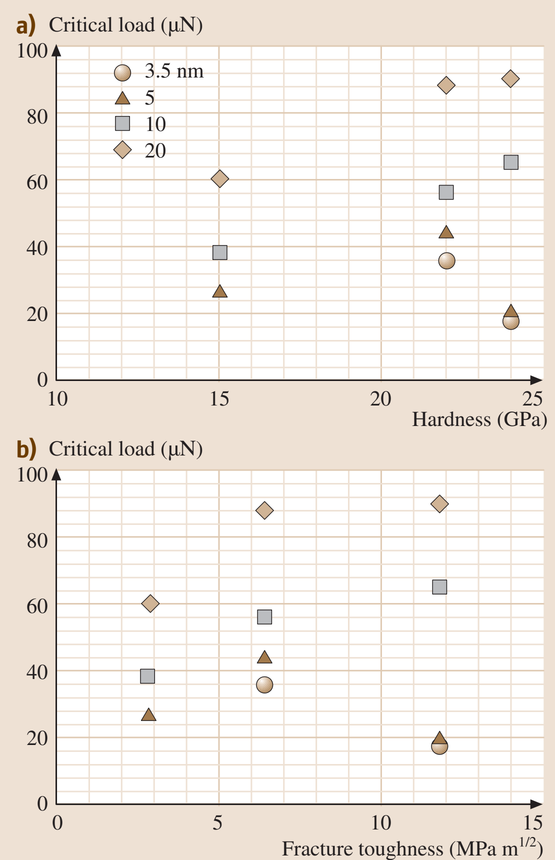

Fig. 26.21a,b Measured critical loads estimated from the coefficient of friction profiles from AFM tests as a function of (a) coating hardness and (b) fracture toughness. Coating hardness and fracture toughness values were obtained using a nanoindenter on 100-nm-thick coatings (Table 26.5)

Since at the critical load, the damage mechanism appears to be the onset of plowing, higher hardness and fracture toughness of a coating will therefore result in a higher load required for deformation and hence a higher critical load. Figure 26.21 shows critical loads of the various coatings, obtained with AFM tests, as a function of the coating hardness and fracture toughness (from Table 26.5). It can be seen that, in general, higher coating hardness and fracture toughness result in a higher critical load. The only exceptions are the FCA coatings at 5- and 3.5-nm coating thickness, which show the lowest critical loads despite their high hardness and fracture toughness. The brittleness of the thinner FCA coatings may be one reason for their low critical loads. The mechanical properties of coatings that are less than 10 nm thick are unknown. The FCA process may result in coatings with low hardness at such low thickness due to differences in coating stoichiometry and structure compared to the coatings of higher thickness. Also, at these thicknesses stresses at the coating-substrate interface may affect adhesion and load-carrying capacity of the coatings.

Based on the experimental results, a schematic of scratch damage mechanisms of the DLC coatings used in this study is shown in Fig. 26.22. Below the critical load, if a coating has a good combination of strength and fracture toughness, plowing associated with the plastic flow of materials is responsible for the damage of coating (Fig. 26.22a). Whereas if a coating has a lower fracture toughness, cracking could occur during plowing, asso-

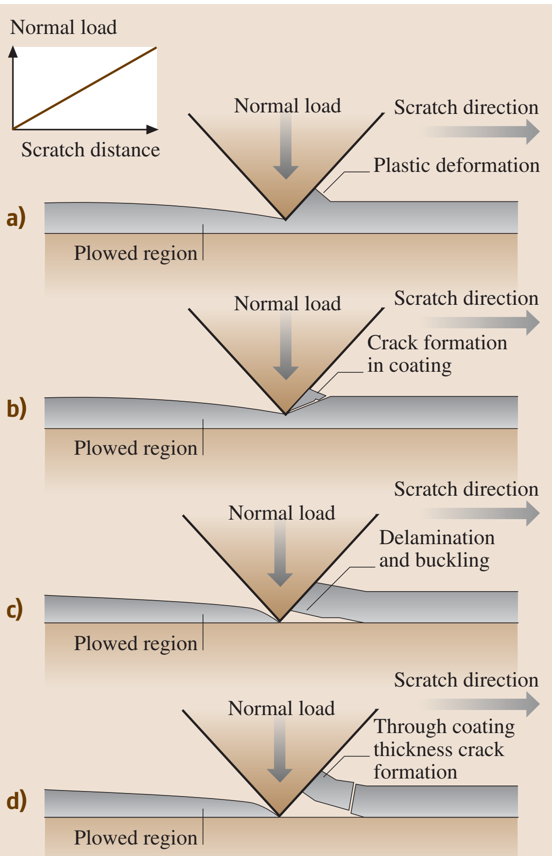

Fig. 26.22a–d Schematic of scratch damage mechanisms of the DLC coatings: **(a)** plowing associated with the plastic flow of materials, **(b)** plowing associated with the formation of small debris, **(c)** delamination and buckling at the critical load, and **(d)** breakdown via through coating thickness cracking at and after the critical load [26.48]

ciated with the formation of small debris (Fig. 26.22b). When normal load increases up to the critical load, delamination or buckling will occur at the coating/substrate interface (Fig. 26.22c). A further increase in normal load will result in the breakdown of coating via through coating thickness cracking, as shown in Fig. 26.22d. Therefore, adhesion strength plays a crucial role in the determination of critical load. If a coating has stronger adhesive strength with the substrate, the coating is more difficult to delaminate, which will result in a higher critical load. The interfacial and residual stresses of a coating could greatly affect the delamination and buckling [26.1]. The coating with higher interfacial and residual stresses is more easily delaminated and buckled, which will result in a low critical load. It has been reported earlier that the FCA coatings have higher residual stresses than the other coatings [26.47]. Interfacial stresses play a more important role when a coating gets thinner. A large mismatch in elastic modulus between the FCA coatings and the silicon substrate may cause large interfacial stresses. This may be why the thinner FCA coatings show relatively low critical loads compared with the thicker FCA coatings, even though the FCA coatings have a higher hardness and elastic modulus. The brittleness of the thinner FCA coatings may be another reason for the lower critical loads. The strength and fracture toughness of a coating also affect the critical load. Higher strength and fracture toughness will make the coating more difficult to be broken after delamination and buckling. The high scratch resistance/adhesion of FCA coatings is attributed to an atomic intermixing at the coating-substrate interface because of high kinetic energy (2 keV) plasma formed during the cathodic arc deposition process [26.57]. The atomic intermixing at the interface provides a graded compositional transition between the coating and the substrate materials. In all other coatings used in this study, the kinetic energy of the plasma was insufficient for atomic intermixing.

Gupta and *Bhushan* [26.12, 47] and *Li* and *Bhushan* [26.48,49] measured scratch resistance of DLC coatings deposited on Al_2O_3-TiC, Ni-Zn ferrite, and single-crystal silicon substrates. For good adhesion of DLC coating to other substrates, in most cases, an interlayer of silicon is required except for cathodic arc deposited coatings. The best adhesion with cathodic arc carbon coating is obtained on electrically conducting substrates such as Al_2O_3-TiC and silicon, as compared to Ni-Zn ferrite.

Microwear

Microwear studies can be conducted using an AFM [26.23]. For microwear studies, a three-sided pyramidal single-crystal natural diamond tip with an apex angle of about 80° and a tip radius of about 100 nm is used at relatively high loads of 1–150 μN. The diamond tip is mounted on a stainless steel cantilever beam with a normal stiffness of about 30 N/m. The sample is generally scanned in a direction orthogonal to the long axis of the cantilever beam (typically at a rate of 0.5 Hz). The tip is mounted on the beam such that one of its edges is orthogonal to the beam axis. In wear studies, typically an area of 2 μm × 2 μm is scanned for a selected number of cycles.

Fig. 26.23a,b AFM images of wear marks on **(a)** bare Si(100), and **(b)** all 10-nm-thick DLC coatings [26.50]

Microwear studies of various types of DLC coatings have been conducted [26.50, 102, 103]. Fig. 26.23a shows a wear mark on uncoated Si(100). Wear occurs uniformly and material is removed layer by layer via plowing from the first cycle, resulting in the constant friction force seen during the wear (Fig. 26.24a). Figure 26.23b shows AFM images of the wear marks on all 10 nm coatings. It is seen that coatings wear nonuniformly. Coating failure is sudden and accompanied by a sudden rise in the friction force (Fig. 26.24b). Figure 26.24 shows the wear depth of Si(100) substrate and various DLC coatings at two different loads. FCA and ECR-CVD, 20-nm-thick coatings show excellent wear resistance up to 80 μN, the load that is required for the IB 20 nm coating to fail. In these tests, "failure" of a coating results when the wear depth exceeds the quoted coating thickness. The SP 20 nm coating fails at the much lower load of 35 μN. At 60 μN, the coating hardly provides any protection. Moving on to the 10 nm coatings, ECR-CVD coating requires about 45 cycles at 60 μN to fail as compared to IB and FCA, which fail at 45 μN. The FCA coating exhibits slight roughening in the wear track after the first few cycles, which leads to an increase in the friction force. The SP coating continues to exhibit poor resistance, failing at 20 μN. For the 5 nm coatings, the load required to fail the coatings continues to decrease. But IB and ECR-CVD still provide adequate protection as compared to bare Si(100) in that order, failing at 35 μN compared to FCA at 25 μN and SP at 20 μN. Almost all the 20, 10, and 5 nm coatings provide better wear resistance than bare silicon. At 3.5 nm, FCA coating

Fig. 26.24a,b Wear data of **(a)** bare Si(100) and **(b)** all DLC coatings. Coating thickness is constant along each row in **(b)**. Both wear depth and coefficient of friction during wear for a given cycle are plotted [26.50]

provides no wear resistance, failing almost instantly at 20 μN. The IB and ECR-CVD coating show good wear resistance at 20 μN compared to bare Si(100). But IB lasts only about 10 cycles and ECR-CVD about 3 cycles at 25 μN.

The wear tests highlight the differences in the coatings more vividly than the scratch tests. At higher thicknesses (10 and 20 nm), the ECR-CVD and FCA coatings appear to show the best wear resistance. This is probably due to higher hardness of the coatings (see Table 26.5). At 5 nm, IB coating appears to be the best. FCA coatings show poorer wear resistance with decreasing coating thickness. This suggests that the trends in hardness seen in Table 26.5 no longer hold at low thicknesses. SP coatings showed consistently poor wear resistance at all thicknesses. The IB 3.5 nm coating does provide reasonable wear protection at low loads.

26.3.3 Macroscale Tribological Characterization

So far, data on mechanical characterization and microscratch and microwear studies using a nanoindenter and an AFM have been presented. Mechanical properties affect tribological performance of the coatings, and microwear studies simulate a single asperity contact, which helps in developing a fundamental understanding of the wear process. These studies are useful in screening various candidates, as well as understanding the relationships between deposition conditions and properties of various samples. As a next step, macroscale friction and wear tests need to be conducted to measure tribological performance of the coatings.

Macroscale accelerated friction and wear tests to screen a large number of candidates and functional tests on selected candidates have been conducted. An accelerated test is designed to accelerate the wear process such that it does not change the failure mechanism. The accelerated friction and wear tests are generally conducted using a ball-on-flat tribometer under reciprocating motion [26.70]. Typically, a diamond tip with a 20 μm tip radius or a sapphire ball with a 3 mm diameter and surface finish of about 2 nm RMS is slid against the coated substrates at selected loads. Coefficient of friction is monitored during the tests.

Functional tests are conducted using an actual machine under close-to-actual operating conditions for which coatings are developed. Generally, the tests are accelerated somewhat to fail the interface in a short time.

Accelerated Friction and Wear Tests

Li and *Bhushan* [26.48] conducted accelerated friction and wear tests on DLC coatings deposited by various deposition techniques using a ball-on-flat tribometer.

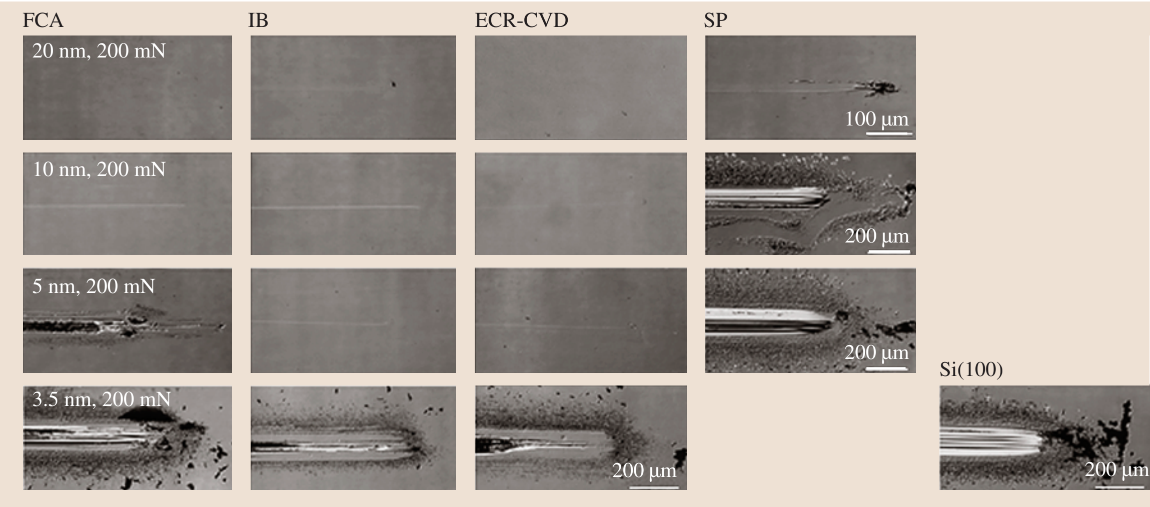

Fig. 26.25 Optical micrographs of wear tracks and debris formed on the various coatings of different thicknesses and silicon substrate when slid against a sapphire ball after sliding distance of 5 m. The end of the wear track is on the right-hand side of the image

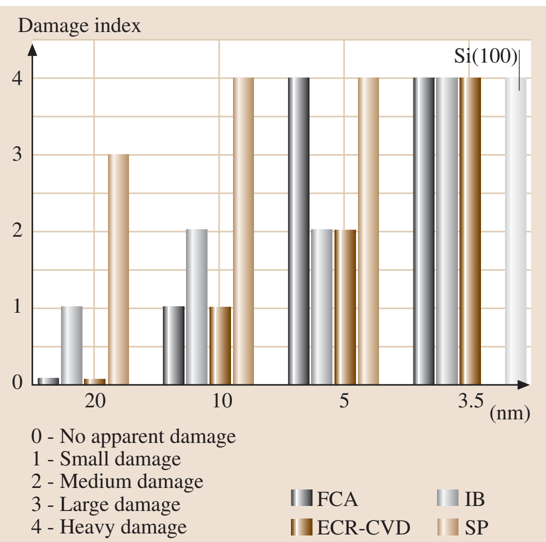

Fig. 26.26 Wear damage index bar chart of the various coatings of different thicknesses and Si(100) substrate based on optical examination of the wear tracks and debris

Average values of coefficient of friction are presented in Table 26.5. The optical micrographs of wear tracks and debris formed on all samples when slid against a sapphire ball after a sliding distance of 5 m are presented in Fig. 26.25. The normal load used for the 20- and 10-nm-thick coatings is 200 mN, and the normal load used for the 5- and 3.5-nm-thick coatings and silicon substrate is 150 mN.

Among the 20-nm-thick coatings, the SP coating exhibits a higher coefficient of friction of about 0.3 than the other coatings, which have comparable values of coefficient of friction of about 0.2. The optical micrographs show that the SP coating has a larger wear track and more debris than the IB coatings. No wear track and debris were found on the 20-nm-thick FCA and ECR-CVD coatings. The optical micrographs of 10-nm-thick coatings show that the SP coating was severely damaged, showing a large wear track with scratches and lots of debris. The FCA and ECR-CVD coatings show smaller wear tracks and less debris than the IB coatings.

For the 5-nm-thick coatings, the wear tracks and debris of the IB and ECR-CVD coatings are comparable. The bad wear resistance of the 5-nm-thick FCA coating is in good agreement with the low scratch critical load, which may be due to the higher interfacial and residual stresses as well as brittleness of the coating.

At 3.5 nm, all coatings exhibit wear. The FCA coating provides no wear resistance, failing instantly like the silicon substrate. Large block-like debris is observed on the sides of the wear track of the FCA coating. This indicates that large region delamination and buckling occurred during sliding, resulting in large block-like debris. This block-like debris, in turn, scratched the coating, making the coating damage even more severe. The IB and ECR-CVD coatings are able to provide some protection against wear at 3.5 nm.

In order to better evaluate the wear resistance of various coatings, based on the optical examination of the wear tracks and debris after tests, the wear damage index bar chart of the various coatings of different thicknesses and an uncoated silicon substrate is presented in Fig. 26.26. Among the 20- and 10-nm-thick coatings, the SP coatings show the worst damage, followed by FCA/ECR-CVD. At 5 nm, the FCA and SP coatings show the worst damage, followed by IB and ECR-CVD coatings. All 3.5-nm-thick coatings show the same heavy damage as the uncoated silicon substrate.

The wear damage mechanisms of thick and thin DLC coatings studied are believed to be as illustrated in Fig. 26.27. At the early stages of sliding, deformation zone and Hertzian and wear fatigue cracks formed beneath the surface extend within the coating on subsequent sliding [26.1]. Formation of fatigue cracks depend on the hardness and subsequent cycles. These are controlled by the sp^3-to-sp^2 ratio. For thicker coating, the cracks generally do not penetrate the coating. For a thinner coating, the cracks easily propagate down to the interface with the aid of the interfacial stresses and get diverted along the interface just enough to cause local delamination of the coating. When this happens, the coating experiences excessive plowing. At this point, the coating fails catastrophically, resulting in a sudden rise

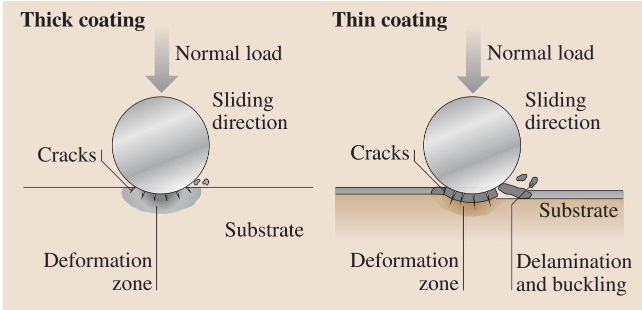

Fig. 26.27 Schematic of wear damage mechanisms of thick and thin DLC coatings [26.48]

in the coefficient of friction. All 3.5-nm-thick coatings failed much quicker than the thicker coatings. It appears that these thin coatings have very low load-carrying capacity and, therefore, the substrate undergoes deformation almost immediately. This generates stresses at the interface that weaken the coating adhesion and lead to delamination of the coating. Another reason may be that the thickness is insufficient to produce a coating comprised of the DLC structure. Instead, the bulk may be made up of a matrix characteristic of the interface region where atomic mixing occurs with the substrate and/or any interlayer used. This would also result in poor wear resistance and silicon-like behavior of the coating, especially in the case of FCA coatings, which show the worst performance at 3.5 nm. In contrast to the other coatings, all SP coatings show the worst wear performance at any thickness (Fig. 26.25). This may be due to their poor mechanical properties, such as lower hardness and scratch resistance, compared to the other coatings.

Comparison of Figs. 26.20 and 26.26 shows a very good correlation between the wear damage and scratch critical loads. Less wear damage corresponds to higher scratch critical load. Based on the data, thicker coatings do show better scratch and wear resistance than thinner coatings. This is probably due to better load-carrying capacity of the thick coatings compared to the thinner ones. For a given coating thickness, higher hardness and fracture toughness and better adhesion strength are believed to be responsible for the superior wear performance.

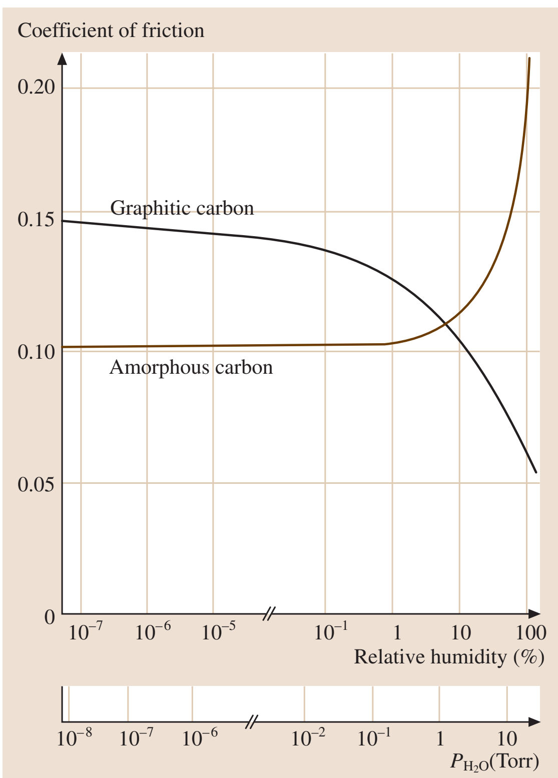

Fig. 26.28 Coefficient of friction as a function of relative humidity and water vapor partial pressure of RF-plasma deposited amorphous carbon coating and bulk graphitic carbon coating sliding against a steel ball

Effect of Environment

Friction and wear performance of amorphous carbon coatings are found to be strongly dependent on the water vapor content and partial gas pressure in the test environment. The friction data for an amorphous carbon film on the silicon substrate sliding against steel are presented as a function of the partial pressure of water vapor in Fig. 26.28 [26.1, 13, 69, 105, 106]. Friction increases dramatically above a relative humidity of about 40%. At high relative humidity, condensed water vapor forms meniscus bridges at the contacting asperities, and the meniscii result in an intrinsic attractive force that is responsible for an increase in friction. For completeness, the data for the coefficient of friction of bulk graphitic carbon are also presented in Fig. 26.28. Note that friction decreases with an increase in the relative humidity [26.107]. Graphitic carbon has a layered lattice crystal structure. Graphite absorbs po-

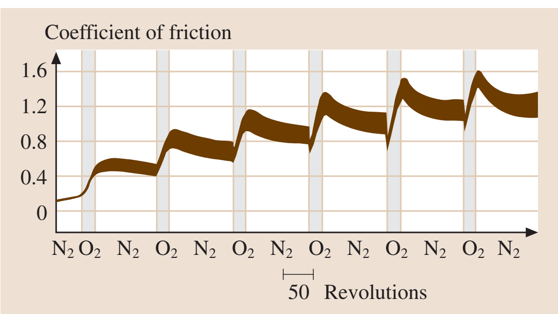

Fig. 26.29 Coefficient of friction as a function of sliding distance for a ceramic slider against a magnetic disk coated with 20-nm-thick DC magnetron sputtered DLC coating, measured at a speed of 0.06 m/s and 10 g load. The environment is alternated between oxygen and nitrogen gases [26.108]

lar gases (H_2O, O_2, CO_2, NH_3, etc.) at the edges of the crystallites, which weakens the interlayer bonding forces facilitating interlayer slip and results in lower friction [26.1].

To better study the effect of environment for carbon coated magnetic disks, a number of tests have been conducted in controlled environments. *Marchon* et al. [26.108] conducted tests in alternating environments of oxygen and nitrogen gases, Fig. 26.29. The coefficient of friction increases as soon as oxygen is added to the test environment, whereas in a nitrogen environment the coefficient of friction reduces slightly. Tribochemical oxidation of the DLC coating in the oxidizing environment is responsible for an increase in the coefficient of friction, implying wear. *Dugger* et al. [26.109], *Strom* et al. [26.110], *Bhushan* and *Ruan* [26.111], and *Bhushan* et al. [26.71] conducted tests with DLC coated magnetic disks (with about 2-nm-thick perfluoropolyether lubricant film) in contact with Al_2O_3-TiC sliders, in different gaseous environments including a high vacuum of 2×10^{-7} Torr, Fig. 26.30. The wear lives are shortest in high vacuum and longest in most atmospheres of nitrogen and argon with the following order (from best to worst): argon or nitrogen, Ar + H_2O, ambient, Ar + O_2, and Ar + H_2O, vacuum. From this sequence of wear performance, we can see that having oxygen and water in an operating environment worsens wear performance of the coatings, but having nothing in it (vacuum) is the worst of all. Indeed, failure mechanisms differ in various environments. In high vacuum, intimate contact between disk and slider surfaces results in significant wear. In ambient air, Ar + O_2, and Ar + H_2O, tribochemical oxidation of the carbon overcoat is responsible for interface failure. For experiments performed in pure argon and nitrogen, mechanical shearing of the asperities cause the formation of debris, which is responsible for the formation of scratch marks on the carbon surface as could be observed with an optical microscope [26.71].

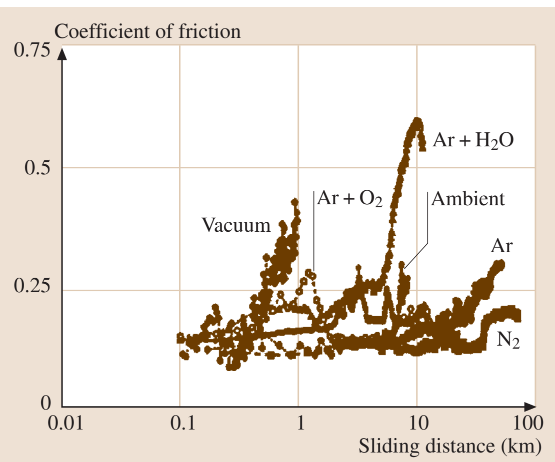

Fig. 26.30 Durability measured by sliding a Al_2O_3-TiC magnetic slider against a magnetic disk coated with 20-nm-thick DC sputtered amorphous carbon coating and 2-nm-thick perfluoropolyether film, measured at a speed of 0.75 m/s and 10 g load. Vacuum refers to 2×10^{-7} Torr [26.71]

Functional Tests

Magnetic thin-film heads made with Al_2O_3-TiC substrate are used in magnetic storage applications [26.13]. A multilayered thin-film pole-tip structure present on the head surface wears more rapidly than the much harder Al_2O_3-TiC substrate. Pole-tip recession (PTR) is a serious concern in magnetic storage [26.15–19, 112]. Two of the diamond-like carbon coatings superior in mechanical properties – ion beam and cathodic arc carbon – were deposited on the air bearing surfaces of Al_2O_3-TiC head sliders [26.15]. The functional tests were conducted by running a metal-particle (MP) tape in a computer tape drive. Average PTR as a function of sliding distance data are presented in Fig. 26.31. We note that PTR increases for the uncoated head, whereas for the coated heads there

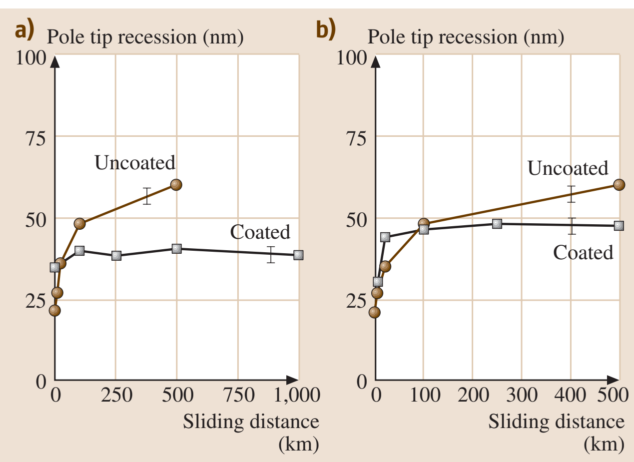

Fig. 26.31a,b Pole tip recession as a function of sliding distance measured with an AFM for **(a)** uncoated and 20-nm-thick ion beam carbon coated, and **(b)** uncoated and 20-nm-thick cathodic arc carbon coated Al_2O_3-TiC heads run against MP tapes [26.15]

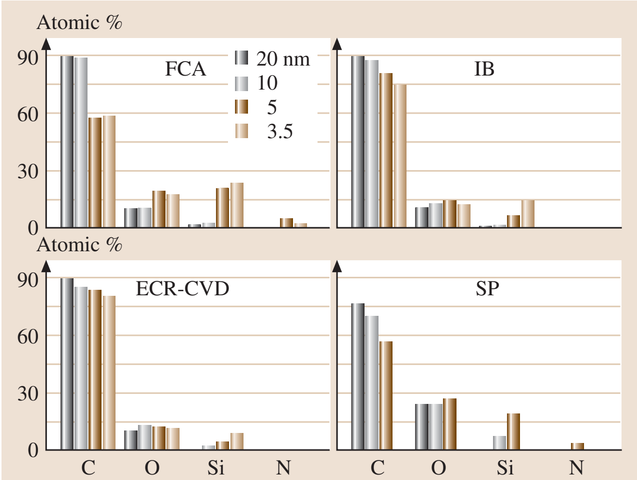

Fig. 26.32 Quantified XPS data for various DLC coatings on Si(100) substrate [26.50]. Atomic concentrations are shown

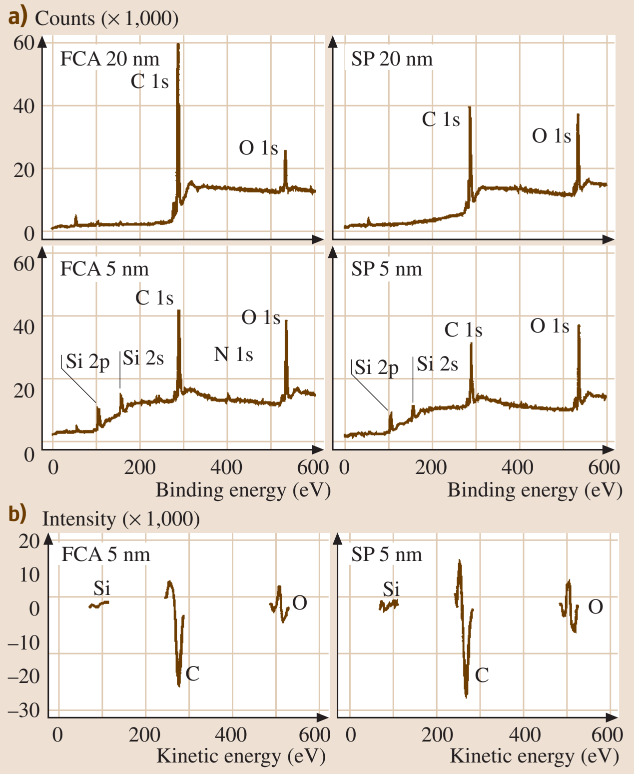

Fig. 26.33 (a) XPS spectra for FCA and SP coatings of 5 nm and 20 nm coating thicknesses on Si(100) substrate, and (b) AES spectra for FCA and SP coatings at 5 nm thickness on Si(100) substrate [26.50]

is a slight increase in PTR in early sliding followed by little change. Thus, coatings provide protection.

Micromechanical and accelerated and functional tribological data presented here clearly suggest that there is a good correlation between the scratch resistance and wear resistance measured using accelerated tests and functional tests. Thus, scratch tests can be successfully used to screen coatings for wear applications.

26.3.4 Coating Continuity Analysis

Ultrathin coatings less than 10 nm may not uniformly coat the sample surface. In other words, coating may be discontinuous and deposited in the form of islands on the microscale. A possible reason for poor wear protection and the nonuniform failure of the coatings may be due to poor coverage of the thin coatings on the substrate. Coating continuity can be studied by using surface analytical techniques such as Auger and/or XPS analyses. Any discontinuity with coating thickness less than the sampling depth of the instrument will detect locally the substrate species [26.49, 50, 102].

The results of XPS analysis on various coatings deposited on Si(100) substrates, over a 1.3 mm^2 region (single point measurement with spot diameter of 1,300 μm) are shown in Fig. 26.32. The sampling depth is about 2–3 nm. The poor SP coatings show much less carbon content (< 75% atomic concentration) as does the poor 5 nm and 3.5 nm FCA coatings (< 60%) compared to the IB and ECR-CVD coatings. Silicon is detected in all 5 nm coatings. From the data it is hard to say if the Si is from the substrate or from exposed regions due to coating discontinuity. Based on the sampling depth any Si detected in 3.5 nm coatings would likely be from the substrate. The other interesting observation is that all poor coatings (all SP and FCA 5 and 3.5 nm) show almost twice the oxygen content than that of the other coatings. Any oxygen present may be due to leaks in the deposition chamber and is present in the form of silicon oxides.

AES measurements averaged over a scan area of 900 μm^2 were conducted on FCA and SP 5 nm coatings at six different regions on each sample. Very little silicon was detected on this scale, and the detected peaks were characteristic of oxides. The oxygen levels were comparable to that seen for the good coatings by XPS. These contrast the XPS measurements at a larger scale, suggesting that the coating possesses discontinuities only at isolated areas and that the 5 nm coatings are generally continuous on the microscale. Figure 26.33 shows representative XPS and AES spectra of selected samples.

27. Self-Assembled Monolayers for Controlling Adhesion, Friction and Wear

Reliability of micro- and nanodevices, as well as magnetic storage devices require the use of lubricant films for the protection of sliding surfaces. To minimize high adhesion, friction, and because of small clearances in the devices, these films should be molecularly thick. Liquid films of low surface tension or certain hydrophobic solid films can be used. Ordered molecular assemblies with high hydrophobicity can be engineered using chemical grafting of various polymer molecules with suitable functional head groups, spacer chains and nonpolar surface terminal groups.

The classical approach to lubrication uses multi-molecular layers of liquid lubricants. Boundary lubricant films are formed by either physisorption, chemisorption, or chemical reaction. The physiosorbed films can be either monomolecularly or polymolecularly thick. The chemisorbed films are monomolecular, but stoichiometric films formed by chemical reaction can be multilayered. A good boundary lubricant should have a high degree of interaction between its molecules and the sliding surface. As a general rule, liquids are good lubricants when they are polar and thus able to grip on solid surfaces (or be adsorbed).

In this chapter, we focus on self-assembled monolayers (SAMs) for high hydrophobicity and/or low adhesion, friction, and wear. SAMs are produced by various organic precursors. We first present a primer to organic chemistry followed by an overview on suitable substrates, head groups, spacer chains, and end groups in the molecular chains and an overview of tribological properties of SAMs. The adhesion, friction, and wear properties of SAMs, having alkyl and biphenyl spacer chains with different surface terminal and head groups, are surveyed. The friction data are explained using a molecular spring model in which the local stiffness and intermolecular force govern its frictional performance. Based on the nanotribological studies of SAM films by AFM, they exhibit attractive hydrophobic and tribological properties.

Reliability of micro/nanodevices, also commonly referred to as micro/nanoelectromechanical systems (MEMS/NEMS), as well as magnetic storage devices (which include magnetic rigid disk drives, flexible disk drives, and tape drives) require the use of molecularly thick films for protection of sliding surfaces [27.1–8]. A solid or liquid film is generally necessary for acceptable tribological properties of sliding interfaces. However, a small quantity of high surface tension liquid present between smooth surfaces can substantially increase the adhesion, friction, and wear as a result of formation of menisci or adhesive bridges [27.9, 10]. It

becomes a major concern in micro/nanoscale devices operating at ultralow loads, as the liquid mediated adhesive force may be on the same order as the external load.

The source of the liquid film can be either preexisting film of liquid and/or capillary condensates of water vapor from the environment. If the liquid wets the surface ($0 \leq \theta < 90°$, where θ is the contact angle between the liquid-vapor interface and the liquid-solid interface for a liquid droplet sitting on a solid surface, Fig. 27.1a), the liquid surface is thereby constrained to lie parallel to the surface [27.11], and the complete liquid surface must therefore be concave in shape, Fig. 27.1b. Surface tension results in a pressure difference across any meniscus surface, referred to as capillary pressure or Laplace pressure, and is negative for a concave meniscus [27.9, 10]. The negative Laplace pressure results in an intrinsic attractive (adhesive) force, which depends on the interface roughness (local geometry of interacting asperities and number of asperities), the surface tension, and the contact angle. During sliding, frictional effects need to be overcome, not only because of external load, but also because of intrinsic adhesive force.

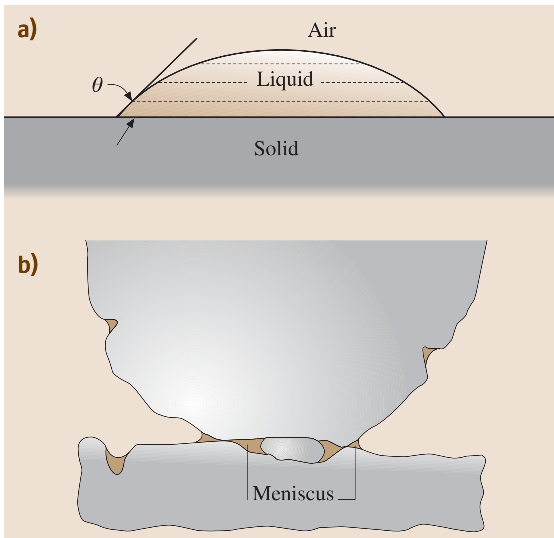

Fig. 27.1 (a) Schematic of a sessile-drop on a solid surface and the definition of contact angle, and **(b)** formation of meniscus bridges as a result of liquid present at an interface. The direct measurement of contact angle is most widely made from sessile-drops. The angle is generally measured by aligning a tangent with the drop profile at the point of contact with the solid surface using a telescope equipped with a goniometer eyepiece

Measured value of high static friction force contributed largely by liquid mediated adhesion (meniscus contribution) is generally referred to as "stiction". Basically, there are three ways to minimize the effect of liquid-mediated adhesion: increase in surface roughness, use of hydrophobic (water-fearing) rather than hydrophilic (water-loving) surfaces, and the use of a liquid with low surface tension [27.9, 10, 12, 13].

As an example, bulk silicon and polysilicon films used in the construction of micro/nanodevices can be dipped in hydrofluoric (HF) to make them hydrophobic (e.g., *Maboudian* [27.14]; *Scherge* and *Schaefer* [27.15]). In HF etching of silicon, hydrogen passivates the silicon surface by saturating the dangling bonds, and it results in a hydrogen-terminated silicon surface that is responsible for less adsorption of water. However, after exposure of the treated surface to the environment, it reoxidizes, which can adsorb water, and thus the surface again becomes hydrophilic.

The surfaces can also be treated or coated with a liquid with relatively low surface tension or a certain solid film to make them hydrophobic and/or to control adhesion, friction, and wear. The liquid lubricant film should be thin (about half of the composite roughness of the interface) to minimize liquid-mediated adhesion contribution [27.9, 10, 12, 13]. Thus, for ultra-smooth surfaces with RMS roughness on the order of a few nm, molecularly thick liquid films are required for liquid lubrication. The classical approach to lubrication uses freely supported multi-molecular layers of liquid lubricants [27.2, 4, 9, 10, 16–19]. Boundary lubricant films are formed by either physisorption, chemisorption, or chemical reaction. The physiosorbed films can be either monomolecularly or polymolecularly thick. The chemisorbed films are monomolecular, but stoichiometric films formed by chemical reaction can be multilayered. In general, stability and durability of surface films decrease in the following order: chemically reacted films, chemisorbed films, and physisorbed films. A good boundary lubricant should have a high degree of interaction between its molecules and the sliding surface. As a general rule, liquids are good lubricants when they are polar and thus able to grip on solid surfaces (or be adsorbed). Polar lubricants contain reactive functional end groups. Boundary lubrication properties are also dependent on the molecular conformation and lubricant spreading. It should be noted that the liquid films with a thickness on the order of a few nm, may be discontinuous and may deposit in an island form of nonuniform thickness with a lateral resolution on the nanometerscale.

Solid films are also commonly used for controlling hydrophobicity and/or adhesion, friction, and wear. Hydrophobic films have nonpolar surface terminal groups (to be described later) that repel water. These films have low surface energy (15–30 dyn/cm) and high contact angle ($\theta \geq 90°$), which minimize wetting (e.g., *Zisman* [27.20]; *Schrader* and *Loeb* [27.21]; *Neumann* and *Spelt* [27.22]). It should be noted that these films do not totally eliminate wetting. Multi-molecularly thick (few tenths of a nm) films of conventional solid-lubricants have been studied. *Hansma* et al. [27.23] reported the deposition of multi-molecularly thick, highly-oriented PTFE films from the melt or vapor phase or from solution by a mechanical deposition technique by dragging the polymer at controlled temperature, pressure, and speed against a smooth glass substrate. *Scandella* et al. [27.24] reported that the coefficient of nanoscale friction of MoS_2 platelets on mica, obtained by exfoliation of lithium intercalated MoS_2 in water, was a factor of 1.4 less than that of mica itself. However, MoS_2 is reactive to water and its friction and wear properties degrade with an increase in humidity [27.9, 10]. Amorphous diamond-like carbon (DLC) coatings can be produced with extremely high hardness and are commercially used as wear-resistant coatings [27.25, 26]. Their largest application is in magnetic storage devices [27.2]. Doping of the DLC matrix with elements like hydrogen, nitrogen, oxygen, silicon, and fluorine influences their hydrophobicity and tribological properties [27.25, 27, 28]. Nitrogen and oxygen reduce the contact angle (or increase the surface energy), due to the strong polarity that is formed when these elements are bonded to carbon. On the other hand, silicon and fluorine increase the contact angle ranging from 70–100° (or reduce the surface energy to 20–40 dyn/cm), making them hydrophobic [27.29, 30]. Nanocomposite coatings with a diamond-like carbon (a-C:H) network and a glass-like a-Si:O network are generally deposited using a plasma-enhanced chemical vapor deposition (PECVD) technique in which plasma is formed from a siloxane precursor using a hot filament. For a fluorinated DLC, CF_4 is added as the fluorocarbon source to an acetylene plasma. In addition, fluorination of DLC can be achieved by the post-deposition treatment of DLC coatings in a CF_4 plasma. Silicon- and fluorine-containing DLC coatings mainly reduce their polarity due to the loss of sp^2-bonded carbon (polarization potential of the involved π electrons) and dangling bonds of the DLC network. As silicon and fluorine are unable to form double bonds, they force carbon into a sp^3 bonding state [27.30]. Friction and wear properties of both silicon-containing and fluorinated DLC coatings have been reported to be superior to that of conventional DLC coatings [27.31,32]. However, DLC coatings require line of sight deposition process, which prevents deposition on complex geometries. Furthermore, it has been reported that some self-assembled monolayers (SAMs) are superior to DLC coatings in hydrophobicity and tribological performance [27.33].

Organized and dense molecular-scale layers of, preferably, long-chain organic molecules are known to be superior lubricants on both macro- and micro/nanoscales as compared with freely supported multi-molecular layers [27.4, 34–38]. Common techniques to produce molecular-scale organized layers are Langmuir–Blodgett (LB) deposition and chemical grafting of organic molecules to realize SAMs [27.39,40]. In the LB technique, organic molecules from suitable amphiphilic molecules are first organized at the air-water interface and then physisorbed on a solid surface to form mono- or multi-molecular layers [27.41]. In the case of SAMs, the functional groups of molecules chemisorb on a solid surface, which results in the spontaneous formation of robust, highly ordered, oriented, and dense monolayers [27.40]. In both cases, the organic molecules used have well distinguished amphiphilic properties (hydrophilic functional head and a hydrophobic aliphatic tail) so that an adsorption of such molecules on an active inorganic substrate leads to their firm attachment to the surface. Direct organization of SAMs on the solid surfaces allows coating in the tight areas such as the bearing and journal surfaces in an assembled bearing. The weak adhesion of classical LB films to the substrate surface restricts their lifetimes during sliding, whereas certain SAMs can be very durable [27.34]. As a result, SAMs are of great interest in tribological applications.

Much of the research in the application of SAMs has been carried out for the so-called soft lithographic technique [27.42, 43]. This is a non-photolithographic technique. Photolithography is based on a projection-printing system used for projection of an image from a mask to a thin-film photoresist and its resolution is limited by optical diffraction limits. In the soft lithography, an elastomeric stamp or mold is used to generate micropatterns of SAMs either by contact printing (known as microcontact printing or μCP [27.44]), by embossing (imprinting) [27.45], or by replica molding [27.46], which circumvents the diffraction limits of photolithography. The stamps are generally cast from photolithographically generated patterned masters, and the stamp material is gener-

ally polydimethylsiloxane (PDMS). In μCP, the ink is a SAM precursor to produce nm-thick resists with lines thinner than 100 nm. Although soft lithography requires little capital investment, it is doubtful that it would ever replace well established photolithography. However, μCP and embossing techniques may be used to produce microdevices that are a substantially cheaper and more flexible choice of material for construction than conventional photolithography (e.g., SAMs and non-SAM entities for μCP and elastomers for embossing).

Other applications for SAMs are in the areas of bio/chemical and optical sensors, for use as drug-delivery vehicles and in the construction of electronic components [27.39, 47]. Bio/chemical sensors require the use of highly sensitive organic layers with tailored biological properties that can be incorporated into electronic, optical, or electrochemical devices. Self-assembled microscopic vesicles are being developed to ferry potentially lifesaving drugs to cancer patients. By getting organic, metal, and phosphonate molecules (complexes of phosphorous and oxygen atoms) to assemble themselves into conductive materials, these can be produced as self-made sandwiches for use as electronic components. The application of interest here is an application requiring hydrophobicity and/or low friction and wear.

An overview of molecularly thick layers of liquid lubricants and conventional solid lubricant can be found in various references [27.2, 4, 9, 10, 18, 19, 25]. In this chapter, we focus on SAMs for high hydrophobicity and/or, low adhesion, friction, and wear. SAMs are produced by various organic precursors. We first present a primer to organic chemistry followed by an overview on suitable substrates, spacer chains, and end groups in the molecular chains, an overview of tribological properties of SAMs, and some concluding remarks.

27.1 A Primer to Organic Chemistry

All organic compounds contain the carbon (C) atom. Carbon, in combination with hydrogen, oxygen, nitrogen, and sulfur results in a large number of organic compounds. The atomic number of carbon is six, and its electron structure is $1s^2\,2s^2\,2p^2$. Two stable isotopes of carbon, ^{12}C and ^{13}C, exist. With four electrons in its outer shell, carbon forms four covalent bonds with each bond resulting from two atoms sharing a pair of electrons. The number of electron pairs that two atoms share determines whether or not the bond is single or multiple. In a single bond, only one pair of electrons is shared by the atoms. Carbon can also form multiple bonds by sharing two or three pairs of electrons between the atoms. For example, the double bond formed by sharing two electron pairs is stronger than a single bond, and it is shorter than a single bond. An organic compound is classified as saturated if it contains only the single bond and as unsaturated if the molecules possess one or more multiple carbon-carbon bonds.

27.1.1 Electronegativity/Polarity

When two different kinds of atoms share a pair of electrons a bond is formed in which electrons are shared unequally, one atom assumes a partial positive charge and the other a negative charge with respect to each other. This difference in charge occurs because the two atoms exert unequal attraction for the pair of shared electrons. The attractive force that an atom of an element has for shared electrons in a molecule or polyatomic ion is known as its electronegativity. Elements differ in their electronegativities. A scale of relative electronegatives, in which the most electronegative element, fluorine, is assigned a value of 4.0, was developed by Linus Pauling. The relative electronegativities of the elements in the periodic table can be found in most undergraduate chemistry textbooks (e.g., *Hein* et al. [27.48]). Relative electronegativity of the nonmetals is high compared to that of metals. Relative electronegativity of selected elements of interest with high values is presented in Table 27.1.

The polarity of a bond is determined by the difference in electronegativity values of the atoms forming the bond. If the electronegativities are the same, the bond is nonpolar and the electrons are shared equally. In this type of bond, there is no separation of positive and negative charge between atoms. If the atoms have greatly different electronegativities, the bond is very polar. A dipole is a molecule that is electrically asymmetrical, causing it to be oppositely charged at two points. As an example, both hydrogen and chlorine need one electron to form stable electron configurations. They share a pair of

Element	Relative electronegativity
F	4.0
O	3.5
N	3.0
Cl	3.0
C	2.5
S	2.5
P	2.1
H	2.1

Table 27.1 Relative electronegativity of selected elements

electrons in hydrogen chloride, HCl. Chlorine is more electronegative and, therefore, has a greater attraction for the shared electrons than hydrogen. As a result, the pair of electrons is displaced toward the chlorine atom, giving it a partial negative charge and leaving the hydrogen atom with a partial positive charge, Fig. 27.2. However, the entire molecule, HCl, is electrically neutral. The hydrogen atom with a partial positive charge (exposed proton on one end) can be easily attracted to the negative charge of other molecules, and this is responsible for the polarity of the molecule. A partial charge is usually indicated by δ, and the electronic structure of HClis given as:

$$\overset{\delta+}{\mathrm{H}}:\overset{\delta-}{\ddot{\underset{\cdot\cdot}{\mathrm{Cl}}}}: \ .$$

Similar to the HCl molecule, HF is polar, and both behave as a small dipole. On the other hand, methane

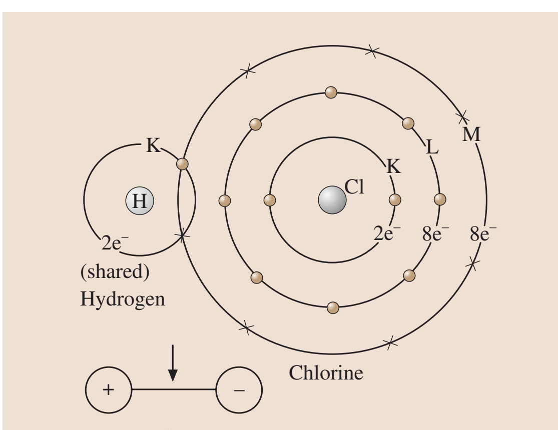

Fig. 27.2 Schematic representation of the formation of a polar HCl molecule

(CH_4), carbon tetrachloride (CCl_4), and carbon dioxide (CO_2) are nonpolar. In CH_4 and CCl_4, the four C−H and C−Cl polar bonds are identical, and because these bonds emanate from the center to the corners of a tetrahedron in the molecule, the effect of their polarities cancels out one another. CO_2 (O=C=O) is nonpolar, because carbon-oxygen dipoles cancel each other by acting in opposite directions. Symmetric molecules are generally nonpolar. Water (H−O−H) is a polar molecule. If the atoms in water were linear as in CO_2, two O−H dipoles would cancel each other, and the molecule would be nonpolar. However, water has a bent structure with an angle of 105° between the two bonds, which is responsible for the water being a polar molecule.

27.1.2 Classification and Structure of Organic Compounds

Tables 27.2–27.6 present selected organic compounds grouped into classes.

Hydrocarbons

Hydrocarbons are compounds that are composed entirely of carbon and hydrogen atoms bonded to each other by covalent bonds. Saturated hydrocarbons (alkanes) contain single bonds. Unsaturated hydrocarbons that contain a carbon-carbon double bond are called alkenes, and ones with a triple bond are called alkynes. Unsaturated hydrocarbons that contain an aromatic ring, e.g., benzene ring, are called aromatic hydrocarbons.

Saturated Hydrocarbons: Alkanes. The alkanes, also known as paraffins, are saturated hydrocarbons, straight- or branched-chain hydrocarbons with only single covalent bonds between the carbon atoms. The general molecular formula for alkanes is C_nH_{2n+2}, where n is the number of carbon atoms in the molecule. Each carbon atom is connected to four other atoms by four single covalent bonds. These bonds are separated by angles of 109.5° (the angle by lines drawn from the center of a regular tetrahedron to its corners). Alkane molecules contain only carbon-carbon and carbon-hydrogen bonds, which are symmetrically directed toward the corners of a tetrahedron. Therefore, alkane molecules are essentially nonpolar.

Common alkyl groups have the general formula C_nH_{2n+1} (one hydrogen atom less than the corresponding alkane). The missing H atom may be detached from any carbon in the alkane. The

Table 27.2 Names and formulas of selected hydrocarbons

Name	Formula
Saturated hydrocarbons	
Straight-chain alkanes	C_nH_{2n+2}
e.g., methane,	CH_4
ethane	C_2H_6 or CH_3CH_3
Alkyl groups	C_nH_{2n+1}
e.g., methyl,	$-CH_3$
ethyl	$-CH_2CH_3$
Unsaturated hydrocarbons	
Alkenes	$(CH_2)_n$
e.g., ethene,	C_2H_4 or $CH_2{=}CH_2$
propene	C_3H_6 or $CH_3CH{=}CH_2$
Alkynes	
e.g., acetylene	$HC{\equiv}CH$
Aromatic hydrocarbons	
e.g., benzene	(structural formula of benzene, C_6H_6: six C atoms in a ring with alternating double bonds, each bearing one H)

Table 27.3 Names and formulas of selected alcohols, ethers, phenols, and thiols

Name	Formula
Alcohols	$R-OH$
e.g., methanol,	CH_3OH
ethanol	CH_3CH_2OH
Ethers	$R-O-R'$
e.g., dimethyl ether,	CH_3-O-CH_3
diethyl ether	$CH_3CH_2-O-CH_2CH_3$
Phenols	C_6H_5OH or (benzene ring with OH)
Thiols	$-SH$
e.g., methanethiol	CH_3SH

The letters R- and R′- represent an alkyl group. The R- groups in ethers can be the same or different and can be alkyl or aromatic (Ar) groups.

name of the group is formed from the name of the corresponding alkane by replacing -ane with -yl ending. Some examples are shown in Table 27.2.

Unsaturated Hydrocarbons. Unsaturated hydrocarbons consist of three families of compounds that contain fewer hydrogen atoms than the alkane with the corresponding number of carbon atoms and contain multiple bonds

Springer Handbook *of* Nanotechnology
B. Bhushan • © Springer 2004

between carbon atoms. These include alkenes (with carbon-carbon double bonds), alkynes (with carbon-carbon triple bonds), and aromatic compounds (with benzene rings that are arranged in a six-member ring with one hydrogen atom bonded to each carbon atom and three carbon-carbon double bonds). Some examples are shown in Table 27.2.

Alcohols, Ethers, Phenols, and Thiols

Organic molecules with certain functional groups are synthesized for desirable properties. Alcohols, ethers, and phenols are derived from the structure of water by replacing the hydrogen atoms of water with alkyl groups (R) or aromatic (Ar) rings. For example, phenol is a class of compounds that have a hydroxy group attached to an aromatic ring (benzene ring). Organic compounds that contain the −SH group are analogs of alcohols and are known as thiols. Some examples are shown in Table 27.3.

Aldehydes and Ketones

Both aldehydes and ketones contain the carbonyl group, >C=O, a carbon-oxygen double bond. Aldehydes have at least one hydrogen atom bonded to the carbonyl group, whereas ketones have only an alkyl or aromatic group bonded to the carbonyl group. The general formula for the saturated homologous series of aldehydes and ketones is $C_nH_{2n}O$. Some examples are shown in Table 27.4.

Carboxyl Acids and Esters

The functional group of the carboxylic acids is known as a carboxyl group, represented as −COOH. Carboxylic acids can be either aliphatic (RCOOH) or aromatic (ArCOOH). The carboxylic acids with even numbers of carbon atoms, n, ranging from 4 to about 20 are called fatty acids (e.g., $n = 10$, 12, 14, 16 and 18 are called capric acid, lauric acid, myristic acid, palmitic acid, and stearic acid, respectively).

Esters are alcohol derivates of carboxylic acids. Their general formula is RCOOR′, where R may be a hydrogen, alkyl group, or aromatic group, and R′ may be an alkyl group or aromatic group but not a hydrogen. Esters are found in fats and oils. Some examples are shown in Table 27.5.

Table 27.4 Names and formulas of selected aldehydes and ketones

Name	Formula
Aldehydes	RCHO or R—C(=O)—H
	ArCHO or Ar—C(=O)—H
e.g., methanal or	HCHO
formaldehyde ethanal or acetaldehyde	CH_3CHO
Ketones	RCOR′ or R—C(=O)—R'
	RCOAr or R—C(=O)—Ar
	ArCOAr or Ar—C(=O)—Ar
e.g., butanone or methyl-ethyl ketone	$CH_3COCH_2CH_3$
The letters R and R′ represent alkyl groups, and Ar represents an aromatic group.	

Table 27.5 Names and formulas of selected carboxylic acids and esters

Name	Formula
Carboxylic acid*	RCOOH or R—C(=O)—OH
	ArCOOH or Ar—C(=O)—OH
e.g., methanoic acid (formic acid),	HCOOH
ethanoic acid (acetic acid),	CH_3COOH
octadecanoic acid (stearic acid)	$CH_3(CH_2)_{16}COOH$
Esters**	RCOOR′ or R—C(=O)—O—R' (R—C(=O): acid; O—R': alcohol)
e.g., methyl propanoate	$CH_3CH_2COOCH_3$

* The letter R represents an alkyl group and Ar represents an aromatic group.
** The letter R represents hydrogen, an alkyl group, or an aromatic group and R′ represents an alkyl group or aromatic group

Table 27.6 Names and formulas of selected organic nitrogen compounds (amides and amines)

Name	Formula
Amides	$RCONH_2$ or R—C(=O)—NH_2
e.g., methanamide (formamide),	$HCONH_2$
ethanamide (acetamide)	CH_3CONH_2
Amines	RNH_2 or R—N(H)(H)
	R_2NH
	R_3N
e.g., methylamine,	CH_3NH_2
ethylamine	$CH_3CH_2NH_2$

The letter R represents an alkyl group or aromatic group.

Amides and Amines

Amides and amines are organic compounds containing nitrogen. Amides are nitrogen derivates of carboxylic acids. The carbon atom of a carbonyl group is bonded directly to a nitrogen atom of a $-NH_2$, $-NHR$, or $-NR_2$ group. The characteristic structure of amide is $RCONH_2$.

An amine is a substituted ammonia molecule that has a general structure of RNH_2, R_2NH, or R_3N, where R is an alkyl or aromatic group. Some examples are shown in Table 27.6.

27.1.3 Polar and Nonpolar Groups

Table 27.7 summarizes polar and nonpolar groups commonly used in the construction of hydrophobic and hydrophilic molecules. Table 27.8 lists the relative polarity of selected polar groups [27.49]. Thiol, silane, carboxylic acid, and alcohol (hydroxyl) groups are the most commonly used polar anchor groups for their attachment to surfaces. Methyl and trifluoromethyl are commonly used end groups for hydrophobic film surfaces.

27.2 Self-Assembled Monolayers: Substrates, Head Groups, Spacer Chains, and End Groups

SAMs are formed as a result of spontaneous, self-organization of functionalized organic molecules onto the surfaces of appropriate substrates into stable, well-defined structures, Fig. 27.3. The final structure is close to or at thermodynamic equilibrium, and as a result, it tends to form spontaneously and rejects defects. SAMs consist of three building groups: a head group that binds strongly to a substrate, a surface terminal (tail) group that constitutes the outer surface of the film, and a spacer chain (backbone chain) that connects the head and surface terminal groups. The SAMs are named based on the surface terminal group followed by spacer chain and the head group (or type of compound formed at the surface). For a SAM to control hydrophobicity, adhesion, friction, and wear, it should be strongly adherent to the substrate, and the surface terminal group of the organic molecu-

lar chain should be nonpolar. For strong attachment of the organic molecules to the substrate, the head group of the molecular chain should contain a polar end group resulting in the exothermic process (energies on the order of tens of kcal/mol), i. e., it results in an apparent pinning of the head group to a specific site on the surface through a chemical bond. Furthermore, molecular structure and any crosslinking would have a significant effect on their friction and wear performance. The substrate surface should have a high surface energy (hydropolic), so that there will be a strong tendency for molecules to adsorb on the surface. The surface should be highly functional with polar groups and dangling bonds (generally unpaired electrons), so that they can react with organic molecules and provide a strong bond. Because of the exothermic head group–substrate interactions, molecules try to occupy every available binding site on the surface, and during this process they generally push together molecules that have already adsorbed. The process results in the formation of crystalline molecular assemblies. The interactions between molecular chains are van der Waals or electrostatic-type with energies on the order of a few (< 10) kcal/mol, exothermic. The molecular chains in SAMs are not perpendicular to the surface; the tilt angle depends on the anchor group, as well as on the substrate and the spacer group. For example, the tilt angle for alkanethiolate on Au is typically about 30–35° angle with respect to substrate normal.

SAMs are usually produced by immersing a substrate in a solution containing precursor (ligand) that is reactive to the substrate surface, or by exposing the substrate to a vapor of the reactive chemical species [27.39]. Table 27.9 lists selected systems that have been used for formation of SAMs [27.43]. The spacer chain of SAM is mostly an alkyl chain ($-C_nH_{2n+1}$), or made of a derivatized alkyl group. By attaching different terminal groups at the surface, the film surface can be made to attract or repel water. The commonly used surface terminal group of a hydrophobic film with low surface energy, in the case of a single alkyl chain, is a nonpolar methyl ($-CH_3$) or trifluoromethyl ($-CF_3$) group. For a hydrophilic film, the commonly used surface terminal groups are alcohol ($-OH$) or carboxylic acid ($-COOH$) groups. Surface active head groups most commonly used are thiol ($-SH$), silane (e.g., trichlorosilane or $-SiCl_3$), and carboxyl ($-COOH$) groups. The substrates most commonly used are gold, silver, platinum, copper, hydroxylated (activated) surfaces of SiO_2 on Si, Al_2O_3 on Al, glass, and hydrogen-terminated single-crystal silicon (H−Si). Hydroxylation of oxide surfaces is important to make them hydrophilic. Thermally grown silica can be activated through a sulfochromic treatment. The sample is dipped in a solution consisting of 100 mL of concentrated H_2SO_4, 5 mL of water, and 2 g of potassium

Table 27.9 Selected substrates and precursors that have commonly been used for formation of SAMs

Substrate	Precursor	Binding with substrate
Au	RSH (thiol)	RS−Au
Au	ArSH (thiol)	ArS−Au
Au	RSSR′ (disulfide)	RS−Au
Au	RSR′ (sulfide)	
Si/SiO_2, glass	$RSiCl_3$ (trichlorosilane)	Si−O−Si (Siloxane)
Si/Si−H	RCOOH (carboxyl)	R−Si
Metal oxides (e.g., Al_2O_3, SnO_2, TiO_2)	RCOOH (carboxyl)	RCOO− ... MO_n

R represents alkane (C_nH_{2n+2}) and Ar represents aromatic hydrocarbon. It consists of various surface active head groups and mostly with methyl terminal group

bichromate for 3–15 min [27.34]. The sample is then rinsed with flowing pure water. This results in a surface with silanol groups (−Si−OH) that is hydrophilic, Fig. 27.4. Bulk silicon, polysilicon film, or SiO_2 film surfaces can also be treated to produce activated hydrophilic silica surface by immersion in about three parts H_2SO_4 and one part H_2O_2 at temperatures ranging from ambient to 80 °C. For organic molecules to pack together and provide a better ordering, a substrate for given molecules should be selected such that the cross-sectional diameter of the spacer chains of the molecule is equal to or smaller than the distance between the anchor groups attached to the substrate. As an example, epitaxial Au film on glass, mica, or single-crystal silicon, produced by e-beam evaporation, is commonly used because it can be deposited on smooth surfaces as a film that is atomically flat and defect free. For the case of alkanethiolate film, the advantage of Au substrate over SiO_2 substrate is that it results in better ordering, because the cross-sectional diameter of the alkane molecule is slightly smaller than the distance between sulfur atoms attached to the Au substrate (∼ 0.53 nm). The thickness of the film can be controlled by varying the length of the hydrocarbon chain, and the surface properties of the film can be modified by the terminal group.

Some of the SAMs have been widely reported. SAMs of long-chain fatty acids, $C_nH_{2n+1}COOH$ or $(CH_3)(CH_2)_nCOOH$ ($n = 10, 12, 14$ or 16), on glass or alumina have been used in films studies since the 1950s [27.16, 20]. Probably the most studied SAMs to date are n-alkanethiolate monolayers $CH_3(CH_2)_nS-$, prepared from adsorption of alkanethiol $-(CH_2)_nSH$ solution onto an Au film (n-alkyl and n-alkane are used interchangeably) [27.35–37, 43] and n-alkylsiloxane monolayers produced by adsorption of n-alkyltrichlorosilane $-(CH_2)_nSiCl_3$ solution onto hydroxylated Si/SiO_2 substrate [27.50] with siloxane (Si−O−Si) binding, Fig. 27.5. *Jung* et al. [27.51] have produced organosulfur monolayers – decanethiol $(CH_3)(CH_2)_9SH$, and didecyl $CH_3(CH_2)_9-S-(CH_2)_9CH_3$ on Au films. *Geyer* et al. [27.52], *Bhushan* and *Liu* [27.35], *Liu* et al. [27.36], and *Liu* and Bhushan [27.37] have produced monolayers of 1,1′-biphenyl-4-thiol (BPT) on Au surface, where the spacer chain of the film consists of two phenyl rings with a hydrogen end group. *Bhushan* and *Liu* [27.35] and *Liu* and *Bhushan* [27.37] have also reported monolayers of 4,4′-dihydroxybiphenyl on Si surface.

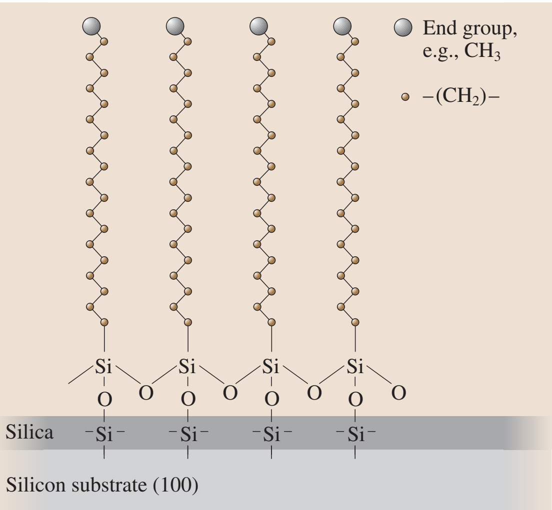

Fig. 27.5 Schematics of a methyl-terminated, n-alkylsiloxane monolayer on Si/SiO_2

27.3 Tribological Properties of SAMs

The basis for molecular design and tailoring of SAMs must start from a complete knowledge of the interrelationships between the molecular structure and tribological properties of SAMs, as well as a deep understanding of the adhesion, friction, and wear mechanisms of SAMs at the molecular level. Friction and wear properties of SAMs have been studied on macro- and nanoscales. Macroscale tests are conducted using a so-called pin-on-disk tribotester apparatus in which a ball specimen slides against a lubricated flat specimen [27.9, 10]. Nanoscale tests are conducted using an atomic force/friction force microscope (AFM/FFM) [27.4, 9, 10]. In the AFM/FFM experiments, a sharp tip of radius ranging from about 5–50 nm slides against a SAM specimen. A Si_3N_4 tip is commonly used for friction studies and a natural diamond tip is commonly used for scratch, wear, and indentation studies.

In early studies, the effect of chain length of the carbon atoms of fatty acid monolayers on the coefficient of friction and wear on the macroscale was studied by *Bowden* and *Tabor* [27.16] and *Zisman* [27.20]. *Zisman*

reported that for the monolayers deposited on a glass surface sliding against a stainless steel surface, there is a steady decrease in friction with increasing chain length. At a significantly long chain length, the coefficient of friction reaches a lower limit, Fig. 27.6. He further reported that monolayers having a chain length below 12 carbon atoms behave as liquids (poor durability), those with chain length of 12–15 carbon atoms behave like a plastic solid (medium durability), whereas those with chain lengths above 15 carbon atoms behave like a crystalline solid (high durability). Investigations by *Ruhe* et al. [27.53] indicated that the lifetime of the alkylsilane monolayer coating on a silicon surface increases greatly with an increase in the chain length of the alkyl substituent. *DePalma* and *Tillman* [27.54] showed that a monolayer of n-octadecyltrichlorosilane (n-$C_{18}H_{37}SiCl_3$, OTS) is an effective lubricant on silicon, followed by n-undecyltrichlorosilane (n-$C_{11}H_{23}SiCl_3$, UTS) and (tridecafluoro-1,1,2,2-tetrahydrooct-1-yl) trichlorosilane (n-$C_6F_{13}CH_2CH_2SiCl_3$, FTS). *Ando* et al. [27.55] suggested that γ-(N,N-dioctadecylsuccinylamino) propyltriethoxysilane monolayer is a candidate lubricant. The film exhibited a low coefficient of kinetic friction of 0.1, without stick-slip. However, tests in all these investigations were carried out using a pin-on-disk tribotester under relatively large normal loads up to 0.15 N. Thus, the relevance of these tests is questionable for micro/nanodevice application.

With the development of AFM techniques, researchers have successfully characterized the nanotribological properties of self-assembled monolayers [27.1, 4, 34–38]. Studies by *Bhushan* et al. [27.34] showed that C_{18} alkylsiloxane films exhibit the lowest coefficient of friction and can withstand a much higher normal load during sliding compared to LB films, soft Au films, and hard SiO_2 coatings.

McDermott et al. [27.56] studied the effect of length of alkyl chains on the frictional properties of methyl-terminated n-alkylthiolate $CH_3(CH_2)_nS-$ films chemisorbed on Au(111) using an AFM. They reported that the longer chain monolayers exhibit a markedly lower friction and a reduced propensity to wear than shorter chain monolayers, Fig. 27.7. These results are in good agreement with the macroscale results by *Zisman* [27.20]. They also conducted infrared reflection spectroscopy to measure the bandwidth of the methylene stretching mode (ν_a (CH_2)), which exhibits a qualitative correlation with the packing density of the chains. They found that the chain structures of monolayers prepared with longer chain lengths are more ordered and more densely packed in comparison to those of monolayers prepared with shorter chain lengths. They further reported that the ability of the longer chain monolayers to retain molecular-scale order during shear leads to a lower observed friction. Monolayers with a chain length of more than 12 carbon atoms, preferably 18 or more, are desirable for tribological applications. (Incidentally, the monolayer with 18 carbon atoms, octadecanethiol films, are commonly studied.)

Xiao et al. [27.57] and *Lio* et al. [27.58] also studied the effect of the length of the alkyl chains on the frictional properties of n-alkanethiolate films on gold and n-alkylsilane films on mica. Friction was found to be particularly high with short chains of less than eight carbon atoms. Thiols and silanes exhibit a similar friction force for the same n when $n > 11$; while for $n < 11$, silanes exhibit higher friction, larger than that for thiols by a factor of about 3 for $n = 6$. The increase in friction was attributed to the large number of dissipative modes in the less ordered chains that occurs when going from a thiol to a silane anchor or when decreasing n. Longer chains ($n > 11$), stabilized by van der Waals attraction, form more compact and rigid layers and act as better lubricants. *Schonherr* and *Vancso* [27.59] also correlated the magnitude of friction with the order of the alkane chains. The disorder of the short-chain hydrocarbon disulfides SAMs was found to result in a significant increase in the magnitude of friction.

Fluorinated carbon (fluorocarbon) molecules are commonly used for lubrication [27.2, 9, 10]. *Kim* et al. [27.60, 61] studied the influence of methyl-, isopropyl-, and trifluoromethyl-terminated alkanethiols on the friction properties of SAMs. They reported a factor of three increases in the friction in going from the methyl-terminated SAM to the trifluoromethyl-terminated SAM. They suggested that fluorinated monolayers exhibit higher frictional properties due to tighter packing at the interface, which arises from the larger van der Waals radii of the fluorine atoms. Subsequent steric and rotational factors between adjacent terminal groups give rise to long-range multi-molecular interactions in the plane of the $-CF_3$ groups. When these energetic barriers are overcome in the film structure, more energy is imparted to the film during sliding and results in higher friction for the fluorinated films.

Tsukruk et al. [27.62] and *Lee* et al. [27.63] studied the nanotribological properties of C_{60}-terminated alkyltrichlorosilanes and alkanedisulfides self-assembled monolayers. Both of their studies observed that the frictional forces of the C_{60}-terminated films are higher than those on normal methyl-terminated SAMs. However, *Tsukruk* et al. [27.62] reported that the C_{60}-terminated alkyltrichlorosilanes SAMs exhibit high wear resistance. *Tsukruk* and *Bliznyuk* [27.64] also studied the adhesion and friction between a Si sample and Si_3N_4 tip, in which both surfaces were modified by $-CH_3$, $-NH_2$, and $-SO_3H$ terminated silane-based SAMs. Various polymer molecules for the backbone were used. They reported that a very broad maximum adhesive force in the pH range of from 4 to 8 with a minimum adhesion at pH > 9 and pH < 3 were observed for all of the studied mating surfaces. This observation can be understood by considering a balance of electrostatic and van der Waals interaction between composite surfaces with multiple isoelectric points. The friction coefficient of NH_2/NH_2 and SO_3H/SO_3H mating SAMs is very high in aqueous solutions. Cappings of NH_2 modified surfaces (3-aminopropyltriethoxysilane) with rigid and soft polymer layers resulted in a significant reduction in adhesion to a level lower than that of untreated surfaces [27.65]. *Fujihira* et al. [27.66] studied the influence of surface terminal groups of SAMs and functional tip on adhesive force. It was found that the adhesive forces measured in air increase in the order of CH_3/CH_3, $CH_3/COOH$, and COOH/COOH.

Bhushan and *Liu* [27.35], *Liu* et al. [27.36], and *Liu* and *Bhushan* [27.37, 38] have studied the influence of spacer chains, surface terminal groups, and head groups on adhesion, friction, and wear properties of SAMs. They have explained the friction mechanisms using a molecular spring model in which local stiffness and the intermolecular forces govern the friction properties. They studied the influence of relative humidity, temperature, and velocity on adhesion and friction. They also investigated the wear mechanisms of SAMs by a continuous microscratch AFM technique.

To date, the nanotribological properties of alkyltrichlorosilanes, alkanethiols, and biphenyl thiol SAMs have been widely studied. In this chapter, we review, in some detail, the nanotribological properties of five kinds of SAMs, having alkyl and biphenyl spacer chains with different surface terminal groups ($-CH_3$, $-COOH$, and $-OH$), and head groups ($-SH$ and $-OH$), which have been investigated by AFM at various operating conditions, Fig. 27.8 [27.35–38]. Hexadecane thiol (HDT), 1,1′-biphenyl-4-thiol (BPT) and crosslinked BPT (BPTC), and 16-mercaptohexadecanoic acid thiol (MHA) were deposited on Au(111) substrates. A 4,4′-dihydroxybiphenyl (DHBp) film was deposited on a hydrogenated Si(111) substrate. Figure 27.8 shows that HDT and MHA have the same head groups and spacers, but different surface terminal groups; their surface terminals are $-CH_3$ and $-COOH$, respectively. BPT and DHBp have the same spacers, but the head and surface terminal groups of DHBp are $-OH$ instead of $-SH$ and $-CH$ in BPT. Crosslinked BPTC was produced by irradiation of BPT monolayers with low energy electrons.

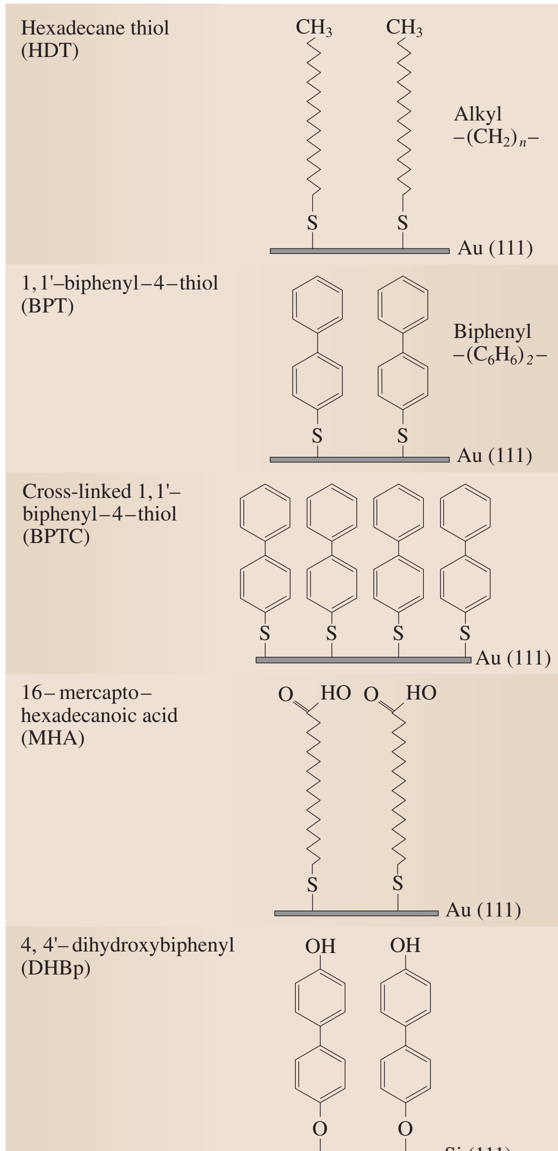

Fig. 27.8 Schematics of the structures of HDT, BPT, MHA, DHBp, and BPTC SAMs [27.35]

27.3.1 Surface Roughness and Friction Images of SAMs Films

Surface height and friction force images of SAMs were recorded simultaneously on an area of $1\,\mu m \times 1\,\mu m$ by an AFM, Fig. 27.9 [27.35]. The topography of Au(111) film and SAMs deposited on Au(111) substrates appear to be granular. A good correlation between the surface height and the corresponding friction force images was observed. It was noticed that the friction force changed with surface height in the same direction (upwards and downwards) in both trace and retrace friction profiles of the friction loop. Thus, the change in friction force corresponds to transitions in surface slope [27.4, 35, 36, 67]. Figure 27.9 also indicates that the topography and friction images of Si(111) and DHBp/Si(111) are very similar; they exhibit featureless surfaces and their friction force images do not show any abrupt changes.

For further analysis presented later in this chapter, the roughness, thickness, tilt angles, and spacer chain lengths of Si(111), Au(111), and various SAMs are listed in Table 27.10 [27.35]. The roughness values of BPT and MHA are very close to that of Au(111). But the roughness of BPTC is lower than that of Au(111) and BPT; this is caused by electron irradiation. Table 27.10 indicates that the roughness values of HDT and DHBp are much higher than their substrate roughness of Au(111) and Si(111), respectively. This is caused by local aggregation of organic compounds on the substrates during SAMs deposition. Table 27.10 also indicates that the thickness of biphenyl thiol SAMs is generally thinner than the alkylthiol, which is responsible for shorter spacer chain in biphenyl thiol.

27.3.2 Adhesion, Friction, and Work of Adhesion

The average values and standard deviation of the adhesive force and coefficients of friction measured by contact mode AFM are presented in Fig. 27.10 [27.35]. Based on the data, the adhesive force and coefficient of friction of SAMs are less than their corresponding substrates. Among various films, HDT exhibits the lowest values. The ranking of adhesive forces F_a is in the following order: $F_{a\text{-Au}} > F_{a\text{-Si}} > F_{a\text{-DHBp}} \approx F_{a\text{-MHA}} > F_{a\text{-BPT}} > F_{a\text{-BPTC}} > F_{a\text{-HDT}}$. And the ranking of the coefficients of friction μ is in the following order: $\mu_{\text{Si}} > \mu_{\text{Au}} > \mu_{\text{DHBp}} > \mu_{\text{BPTC}} > \mu_{\text{BPT}} \approx \mu_{\text{MHA}} > \mu_{\text{HDT}}$. The ranking of various SAMs for adhesive force and coefficient of friction is similar. It suggests that alkylthiol and biphenyl SAMs can be used as effective molecular lubricants for micro/nanodevices fabricated from silicon.

In micro/nano scale contact, liquid capillary condensation is one of the factors that influence adhesion and friction. In the case of a sphere in contact with a flat surface, the attractive Laplace force caused by water

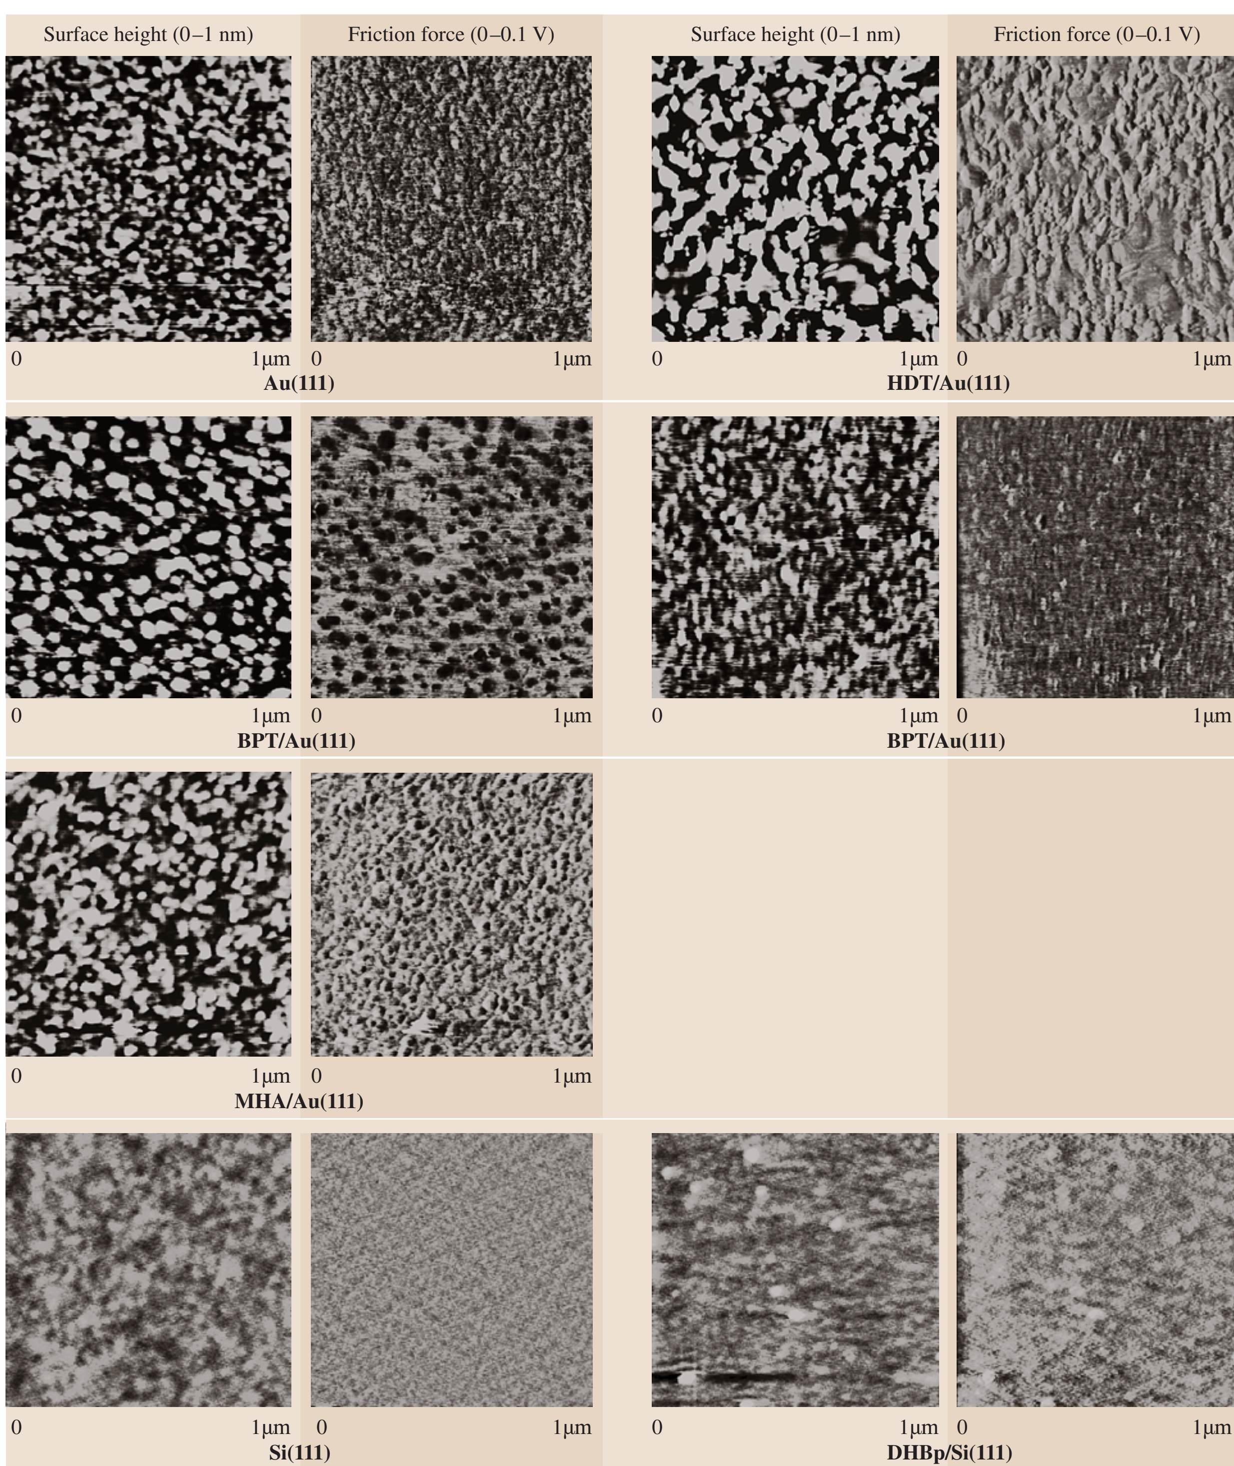

Fig. 27.9 AFM gray-scale surface height and friction force images of Au(111), Si(111), and various SAMs [27.35]

Table 27.10 The R_a roughness, thickness, tilt angles, and spacer chain lengths of SAMs

Samples	R_a roughness[1] (nm)	Thickness[2] (nm)	Tilt angle[2] (deg.)	Spacer length[3] (nm)
Si(111)	0.07			
Au(111)	0.37			
HDT	0.92	1.89	30	1.91
BPT	0.36	1.25	15	0.89
BPTC	0.14	1.14	25	0.89
MHA	0.37	2.01	30	1.91
DHBp	0.25	1.13	–	0.89

[1] Measured by an AFM with 1 μm × 1 μm scan size using a Si_3N_4 tip under 3.3 nN normal load.
[2] The thickness and tilt angles of BPT, BPTC, and DHBp are reported by *Geyer* et al. [27.52]. The thickness and tilt angles of HDT and MHA are reported by *Ulman* [27.40].
[3] The spacer chain lengths of alkylthiols were calculated by the method reported by *Miura* et al. [27.68]. The spacer chain lengths of biphenyl thiols were calculated by the data reported by *Ratajczak-Sitarz* et al. [27.69].

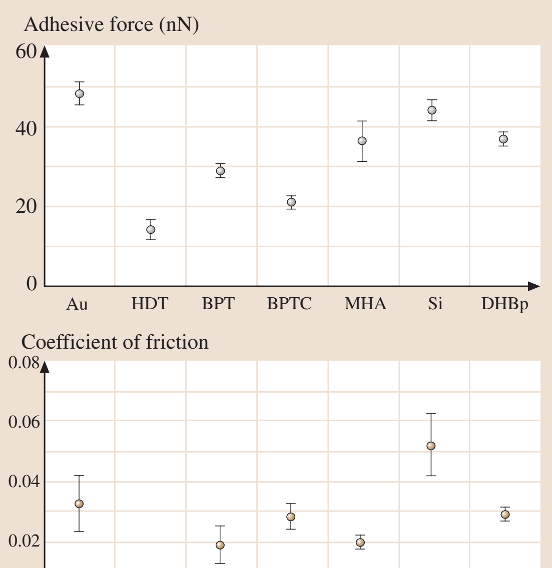

Fig. 27.10 Adhesive forces and coefficients of friction of Au(111), Si(111), and various SAMs [27.35]

capillary is:

$$F_L = 2\pi R\gamma_{la}(\cos\theta_1 + \cos\theta_2) , \tag{27.1}$$

where R is the radius of the sphere, γ_{la} is the surface tension of the liquid against air, θ_1 and θ_2 are the contact angles between liquid and flat and spherical surfaces, respectively [27.9, 10]. In an AFM adhesive study, the tip-flat sample contact is just like a sphere in contact with a flat surface and the liquid is water. Since a single tip was used in the adhesion measurements, $\cos\theta_2$ can be treated as a constant. Therefore,

$$\begin{aligned} F_L &= 2\pi R\gamma_{la}(1+\cos\theta_1) - 2\pi R\gamma_{la}(1-\cos\theta_2) \\ &= 2\pi R\gamma_{la}(1+\cos\theta_1) - C , \end{aligned} \tag{27.2}$$

where C is a constant.

Based on the following Young-Dupre equation, work of adhesion W_a (the work required to pull apart the unit area of the solid-liquid interface) can be written as [27.70]

$$W_a = \gamma_{la}(1+\cos\theta_1) . \tag{27.3}$$

It indicates that W_a is determined by the contact angle of SAMs, i.e., is influenced by the surface chemistry properties (polarization and hydrophobicity) of SAMs. By substituting (27.3) into (27.2), F_L can be expressed as

$$F_L = 2\pi R W_a - C . \tag{27.4}$$

When the influence on the adhesive force of other factors, such as van der Waals force, is very small, then adhesive force $F_a \approx F_L$. Thus the adhesive force F_a should be proportional to work of adhesion W_a.

Contact angle is a measure of the wettability of a solid by a liquid and determines the W_a value. The value of the contact angle changes with time. If the droplet expands, the contact angle is referred to as the advancing contact angle. The contact angles of distilled water on Si(111), Au(111), and SAMs were meas-

ured using a contact angle goniometer [27.35]. After dropping water on the sample surfaces, the dynamic advancing contact angle (DACA) was measured with a frequency of 60 s for spontaneous spreading for at least 420 s. The DACA as a function of time data is given in Fig. 27.11a. It indicates that there is a linear relationship between DACA and rest time. As stated by many authors, the static advancing contact angle (SACA) (at $t = 0$) should be used for surface characterization [27.71–73]. This SACA can be obtained by simple extrapolation of the data in Fig. 27.11a to $t = 0$. The SACA of Si(111), Au(111), and SAMs is summarized in Fig. 27.11b. For water, $\gamma_{la} = 72.6\,\mathrm{mJ/m^2}$ at 22 °C, and by using (27.3), the W_a data are obtained and presented in Fig. 27.11c. The W_a can be ranked in the following order: $W_{a\text{-Si}}(117.0) > W_{a\text{-DHBp}}(98.8) \approx W_{a\text{-MHA}}(101.8) \approx W_{a\text{-Au}}(97.1) > W_{a\text{-BPT}}(86.8) > W_{a\text{-BPTC}}(82.1) > W_{a\text{-HDT}}(61.4)$. Excluding $W_{a\text{-Au}}$, this order exactly matches the order of adhesion force in Fig. 27.10. The relationship between F_a and W_a is summarized in Fig. 27.12 [27.35]. It indicates that the adhesive force F_a (nN) increases with work of adhesion W_a (mJ/m^2) by the following linear relationship:

$$F_a = 0.57 W_a - 22\,. \tag{27.5}$$

These experimental results agree well with the modeling prediction presented earlier in (27.4). It proves that on the nanoscale at ambient condition the adhesive force of SAMs is mainly influenced by the water capillary force. Comparing the results of Figure 27.12 with Figure 27.8, it is found that MHA and DHBp, which have polar surface terminal groups (−COOH and −OH), lead to larger W_a and eventually larger adhesive forces. Though both HDT and BPT do not have polar surface groups, the surface terminal of HDT has a symmetrical structure, which causes a smaller electrostatic attractive

The uncertainty associated with the average contact angle is within ±2°. The insert schematic in **(a)** shows the contact angle of the water droplet on the sample surface [27.35]

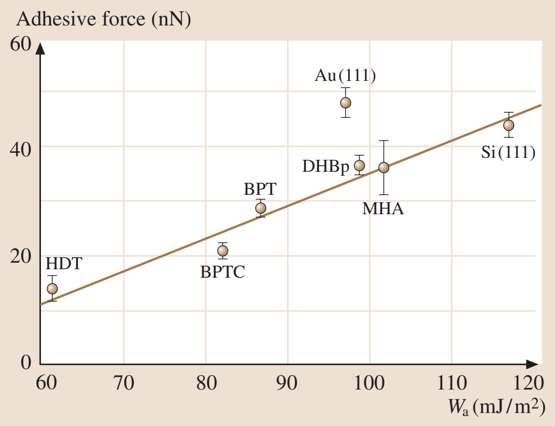

Fig. 27.12 Relationship between the adhesive forces and work of adhesion of different specimen [27.35]

force and yields smaller adhesive force than BPT. It is believed that the easy attachment of Au on the tip should be one of the reasons that cause the large adhesive force, which do not fit the linear relationship described by (27.5).

27.3.3 Stiffness, Molecular Spring Model, and Micropatterned SAMs

Next, the friction mechanisms of SAMs are examined. Monte Carlo simulation of the mechanical relaxation of $CH_3(CH_2)_{15}SH$ self-assembled monolayer performed by *Siepman* and *McDonald* [27.74] indicated that SAMs compress and respond nearly elastically to microindentation of an AFM tip under a critical normal load.

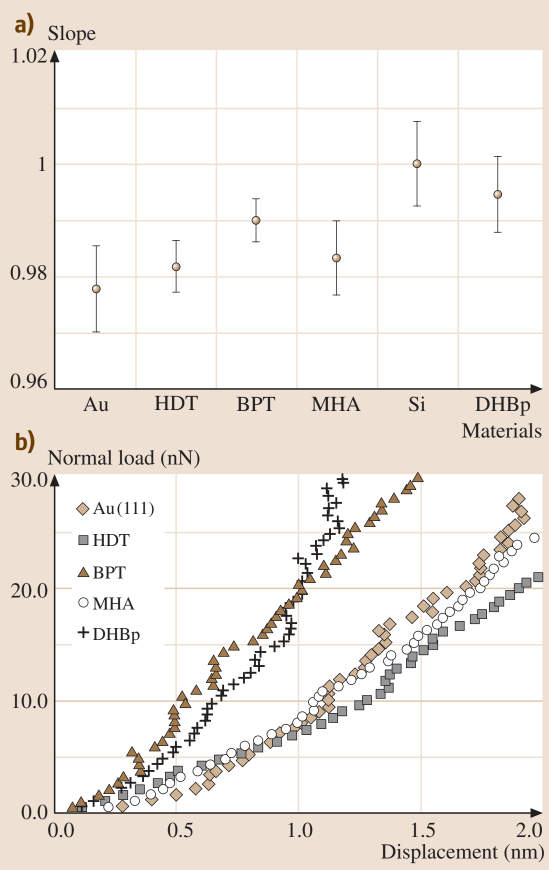

Fig. 27.13 **(a)** Slopes of cantilever deflection versus piezo displacement measured by force distance calibration mode AFM, and **(b)** normal load versus displacement curves of Au(111), Si(111), and various SAMs

Compression can lead to major changes in the mean molecular tilt (i. e., orientation), but the original structure is recovered as the normal load is removed.

To study the difference in the stiffness of various films, the stiffness properties were measured by an AFM in force-distance calibration mode, as well as in force modulation mode [27.4, 37]. Figure 27.13a shows the slope of cantilever deflection versus piezo movement obtained in the force-distance calibration mode. For an infinite hard material, since the surface can not be compressed, the cantilever deflection should equal the piezo movement distance, which means the slope of the cantilever deflection versus piezo movement equals 1. For a soft material, the surface can be compressed, causing a reduced cantilever deflection, and the slopes are smaller than 1. In this study the cantilever has been initially calibrated to slope = 1 against a clean, rigid Si(111) surface. Figure 27.13a indicates that the slopes of all of the SAMs are less than 1, which suggests that all of the SAMs can be compressed by a Si_3N_4 tip during the loading process. The slope value of SAMs can be ranked in the following order: $S_{DHBp} > S_{BPT} > S_{MHA} \approx S_{HDT}$. This order reflects the influence of molecular structure on the compression properties of SAMs. Since BPT and DHBp have rigid benzene structure, they are more difficult to compress than HDT and MHA. Figure 27.13b shows the variation of the displacement with normal load during indentation mode. It also clearly indicates that SAMs can be compressed. At a given normal load, long carbon chain structure SAMs such as HDT and MHA are easy to compress compared to rigid benzene-ring structure SAMs such as BPT and DHBp. *Garcia-Parajo* et al. [27.75] have also reported the compression and relaxation of octadecyltrichlorosilane (OTS) film in their loading and unloading tests.

In order to explain the frictional difference of SAMs, based on the friction and stiffness measurements by AFM and the Monte Carlo simulation, a molecular spring model is presented in Fig. 27.14. It is believed that the self-assembled molecules on a substrate are just like assembled molecular springs anchored to the substrates [27.35]. A Si_3N_4 tip sliding on the surface of SAMs is like a tip sliding on the top of "molecular springs or brush". The molecular spring assembly has compliant features and can experience compression and orientation under normal load. The orientation of the "molecular springs or brush" reduces the shearing force at the interface, which, in turn, reduces the friction force. The possibility of orientation is determined by the spring constant of a single molecule (local stiffness), as well as the interaction between the neighboring

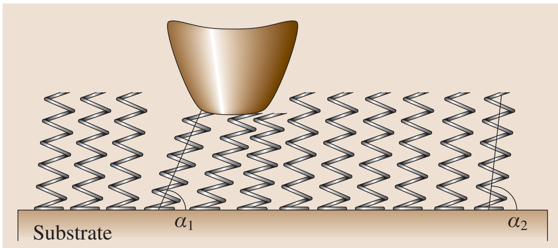

Fig. 27.14 Molecular spring model of SAMs. In this figure, $\alpha_1 < \alpha_2$, which is caused by the orientation under the normal load applied by an AFM tip. The orientation of the molecular springs reduces the shearing force at the interface, which, in turn, reduces the friction force. The molecular spring constant, as well as the inter-molecular forces can determine the magnitude of the coefficients of friction of SAMs. In this figure, the size of the tip and molecular springs are not drawn exactly to scale [27.35]

molecules, which can be reflected by packing density or packing energy. It should be noted that the orientation can lead to conformational defects along the molecular chains, which lead to energy dissipation. In the study of BPT by AFM, it was found that after the first several scans, the friction force is significantly reduced, but the surface height does not show any apparent change. This suggests that the molecular orientation can be facilitated by initial sliding and is reversible [27.38].

Based on the stiffness measurement results presented in Fig. 27.13 and the view of molecular structures in Fig. 27.14, biphenyl is a more rigid structure due to the contribution of two rigid benzene rings. Therefore, the spring constant of BPT is larger than that of HDT. The hydrogen (H^+) in a biphenyl chain has an electrostatic attractive force with the π electrons in the neighboring benzene ring. Thus, the intermolecular force between biphenyl chains is stronger than that for alkyl chains. The larger spring constant of BPT and stronger intermolecular force require a larger external force to allow it to orient, thus causing higher coefficient of friction. For MHA and DHBp, their basic chain structures are very close to HDT and BPT, respectively. But their surface terminals are different. The polar −COOH and −OH external functional groups in MHA and DHBp increase the adhesive force, thus leading to higher friction force than HDT and BPT, respectively. The crosslinking of BPT leads to a larger packing energy for BPTC. Therefore, it requires a larger external force to allow BPTC orientation, i. e., the coefficient of BPTC is higher than BPT.

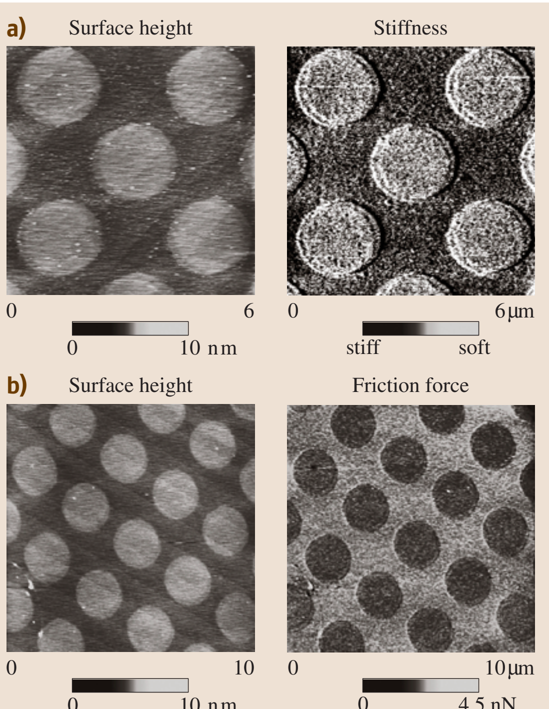

Fig. 27.15 **(a)** AFM gray-scale surface height and stiffness images, and **(b)** AFM gray-scale surface height and friction force images of micropatterned BDCS [27.37]

An elegant way to demonstrate the influence of molecular stiffness on friction is to investigate SAMs with different structures on the same wafer. For this purpose, a micropatterned SAM was prepared. First, the biphenyldimethylchlorosilane (BDCS) was deposited on silicon by the typical self-assembly method [27.37]. Then the film was partially crosslinked using mask technique by low energy electron irradiation. Finally, the micropatterned BDCS films were realized that had the as-deposited and crosslinked coatings on the same wafer. The local stiffness properties of these micropatterned samples were investigated by force modulation AFM technique [27.76]. The variation in the deflection amplitude provides a measure of the relative local stiffness of the surface. Surface height, stiffness, and friction images of the micropatterned biphenyldimethylchlorosilane (BDCS) specimen are obtained and presented in Fig. 27.15 [27.37]. The circular areas correspond to the as-deposited film, and the remaining area to the crosslinked film. Figure 27.15a indicates that crosslinking caused by the low energy electron irradiation leads

to about a 0.5 nm decrease of the surface height of BDCS films. The corresponding stiffness images indicate that the crosslinked area has a higher stiffness than the as-deposited area. Figure 27.15b indicates that the as-deposited area (higher surface height area) has lower friction force. Obviously, the data of the micropatterned sample prove that the local stiffness of SAMs has an influence on their friction performance. Higher stiffness leads to larger friction force. These results provide a strong proof of the suggested molecular spring model.

In summary, it has been found that SAMs exhibit compliance and can experience compression and orientation under normal load. The orientation of SAMs reduces the shear stress at the interface; therefore SAMs can serve as good lubricants. The molecular spring constant (local stiffness), as well as the intermolecular forces can influence the magnitude of the coefficients of friction of SAMs.

27.3.4 Influence of Humidity, Temperature, and Velocity on Adhesion and Friction

The influence of relative humidity on adhesion and friction was studied in an environmentally controlled chamber at 22 °C [27.35]. The results are presented in Fig. 27.16. It shows that for Si(111), Au(111), DHBp and MHA, the adhesive and friction forces increase with relative humidity. For BPT and BPTC, the adhesive force only slightly increases with relative humidity when the relative humidity is higher than 40%, but it is very interesting that their friction decreases in the same range. For HDT, in the testing range, the adhesive and friction force are not sensitive to changes in relative humidity.

It has already been shown that the adhesive force is linearly related to the W_a value of the surfaces in Fig. 27.12. DHBp and MHA have polar surface terminals and larger W_a value. This must therefore lead to the larger adhesive forces in higher relative humidity, which, in turn, increase the friction force. In comparison, HDT has a nonpolar $-CH_3$ surface terminal and a very small W_a value. Thus, the adhesive force and friction force of HDT are not sensitive to the change of humidity. The W_a values of BPT and BPTC are between Si(111) and HDT (see Fig. 27.11c); therefore their adhesive forces show a slight increase when RH > 40%. The fact that BPT and BPTC show lower friction force when RH > 40% suggests that a thin adsorbed water layer can act as a lubricant [27.35, 37]. The reason why the adsorbed water layer acts as a lubricant may be related to the thickness of the absorbed layer.

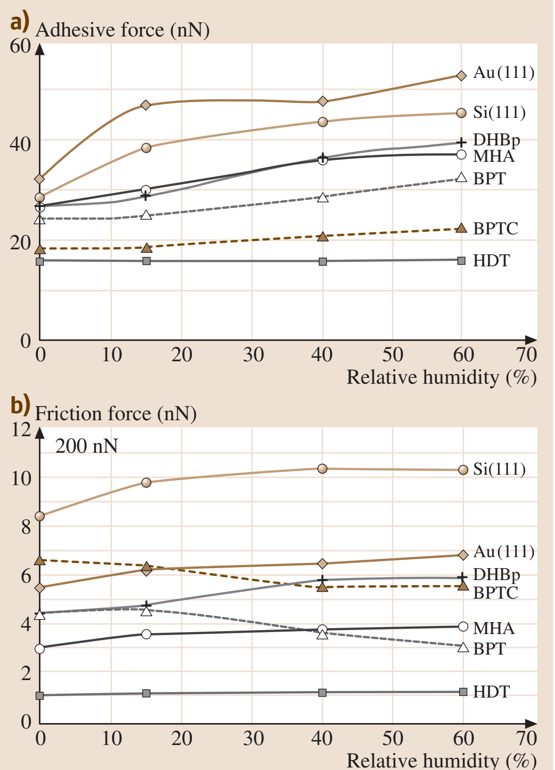

Fig. 27.16a,b The influence of relative humidity on the **(a)** adhesive force and **(b)** friction forces at 200 nN of Si(111), Au(111), and various SAMs [27.35]

Results of the influence of temperature on adhesion and friction of Si(111) and two selected typical SAMs – HDT and BPT – are presented in Fig. 27.17 [27.37]. The friction data are presented at various normal loads. In all cases, the normal load does not change the general trends. The data show that for Si(111), once the temperature is higher than 75 °C, the adhesive force decreases with temperature. The friction force of silicon decreases slightly with temperature from room temperature to 100 °C; once the temperature is higher than 100 °C, the friction force shows an apparent decrease. It is believed that desorption of the adsorbed water layer on Si(111) and the reduction of surface tension of water at high temperature are responsible for the decrease in adhesion and friction [27.77]. For HDT, in the testing range (22 °C–125 °C) its adhesion and friction show very slight change with temperature. For BPT, its adhesive force initially increases with temperature from 22 °C–75 °C, but when the temperature is higher than

Fig. 27.17a,b The influence of temperature on **(a)** adhesive forces and **(b)** friction forces of Si(111), HDT, and BPT [27.37]

Compound type	Molecular formula	Melting points (°C) [27.77]
Linear carbon chain	$CH_3(CH_2)_{14}CH_2OH$	50

	$2\text{-}HO{-}C_6H_4C_6H_5$	58–60

Table 27.11 Melting point of typical organic compounds similar to HDT and BPT SAMs

Fig. 27.18 The influence of velocity on friction forces of Si(111) and SAMs [27.37]

75 °C, the adhesive force remains steady within the experimental error. The variations in the friction force with temperature for BPT exhibit the maximum value, and the corresponding critical temperature is related to the normal load. The reason why BPT shows maximum friction force is believed to be caused by the melting of film at high temperature. When the temperature is below the melting point, an increase of temperature leads to the softening of SAM, which increases the real contact area and, consequently, the friction force. Once the temperature is higher than the melting point, the lubrication regime is changed from boundary lubrication in a solid

SAM to liquid lubrication in the melted SAM, and therefore the friction force is decreased. To date, the melting points of HDT and BPT SAMs are unknown. But from the literature [27.77], the melting points of typical linear carbon chain and benzene ring compounds are presented in Table 27.11. It is found that the reported melting of the benzene ring compounds is somewhat close to the frictional transition temperature of BPT measured by AFM. For HDT, their very compliant carbon chain can serve as an excellent lubricant even in solid state (i. e., at or near room temperature), so clear temperature effect is not observed as in the case of HDT.

Figure 27.18 shows the influence of velocity on the friction force of SAMs at different normal loads [27.37]. In all cases, normal load does not change the general trends. It is shown that for a silicon wafer, cleaned by Piranha solution just before the friction test, the friction force decreases linearly with increasing velocity. But for Si(111) without cleaning just before the AFM test, the friction force decreases only at high velocity. It is believed that this difference is caused by the adsorbed water and/or contamination on the surface during storage. Figure 27.18 also indicates that the velocity effects of SAMs depend on the molecular structures of SAMs. For SAMs that have compliant long carbon spacer chains, such as HDT and MHA, the friction force increases at high velocity, while for SAMs that have rigid biphenyl chains, such as BPT, BPTC, and DHBp, the friction force changes in the opposite way. The mechanisms responsible for the variation of the friction forces of SAMs with velocity are believed to be related to the viscoelastic properties of SAMs.

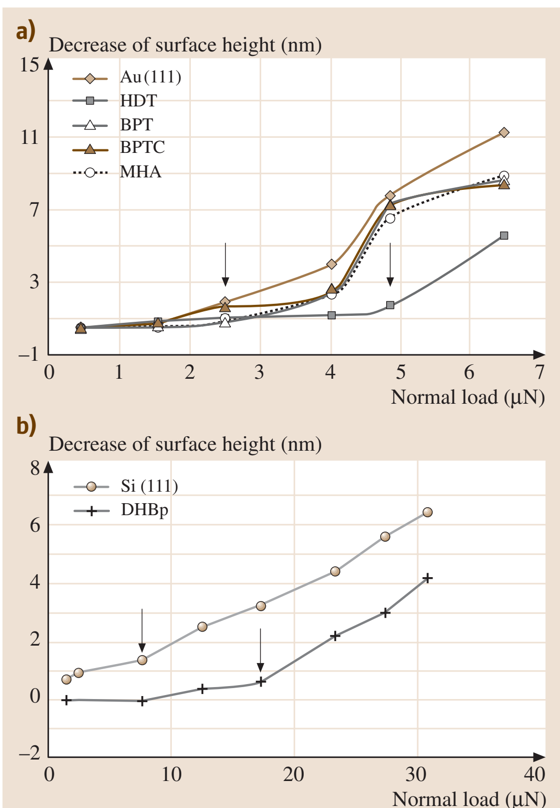

Fig. 27.19a,b Wear depth as a function of normal load after one scan cycle [27.35]. **(a)** on Au(111) and SAMs deposited on Au(111)/Si(111) **(b)** on Si(111) and DHPp deposited on Si(111)

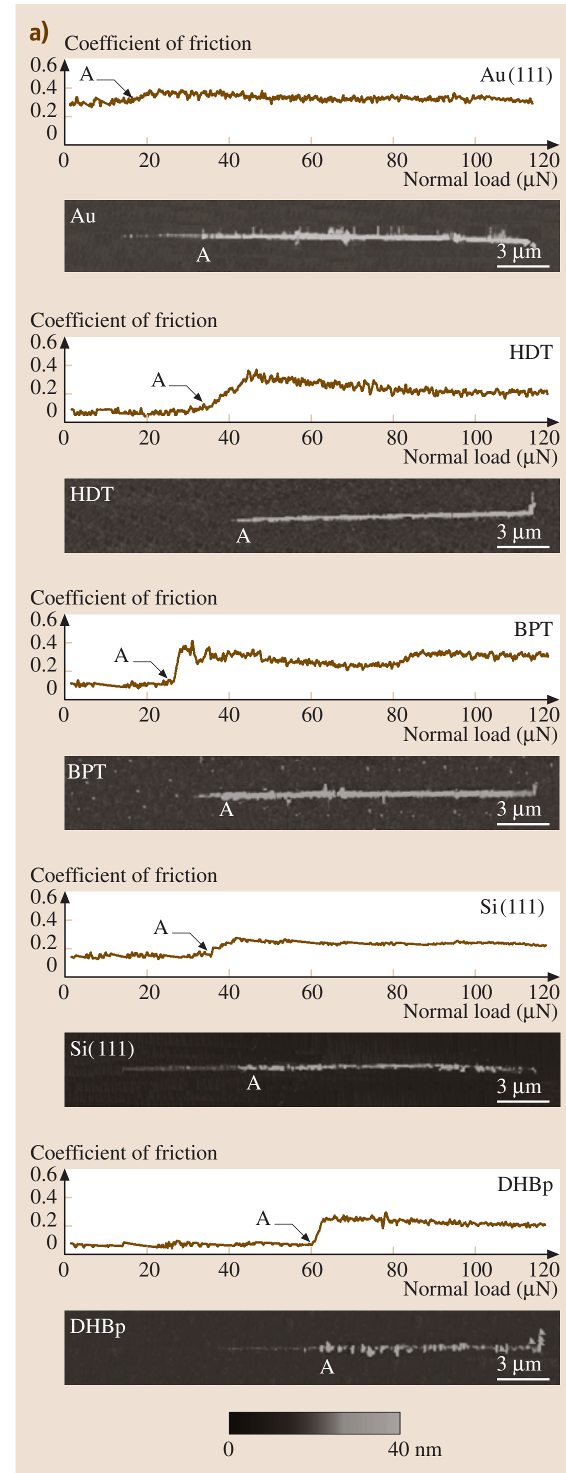
27.3.5 Wear and Scratch Resistance of SAMs

Wear resistance was studied on an area of 1 µm × 1 µm using a diamond tip in an AFM. The variation of wear depth with normal loads is presented in Fig. 27.19 [27.35]. It clearly shows that in the whole testing range, DHBp on Si(111) exhibits much better wear resistance compared to Si(111), Au(111), and other SAMs that were deposited on the Au(111) substrate. For the SAMs deposited on Au(111), HDT exhibits the best wear resistance. For all of the tested SAMs, in the wear depth as a function of normal load curves, there appears a critical normal load, which is marked by arrows in Fig. 27.19. When the normal load is smaller than the critical normal load, the monolayer only shows slight height change in the scan areas. When the normal load is higher than the critical value, the height change of SAMs increase dramatically. Relocation and accumulation of BPT molecules have been observed during the initial several scans, which lead to the formation of a larger terrace. Wear studies of a single BPT terrace indicate that the wear life of BPT increases exponentially with terrace size [27.36, 37].

Scratch resistances of Si(111), Au(111), and SAMs were studied by a continuous AFM microscratch technique. Figure 27.20a shows coefficient of friction profiles as a function of increasing normal load and corresponding tapping mode AFM surface height images of the scratches captured on Si(111), Au(111), and SAMs [27.37]. Figure 27.20a indicates that there is an abrupt increase in the coefficients of friction for all of the tested samples. The normal load associated with this event is termed the critical load (indicated by the arrows labeled "A"). At the initial stages of the scratch, all the samples exhibit a low coefficient of friction, indicating that the friction force is dominated by the shear com-



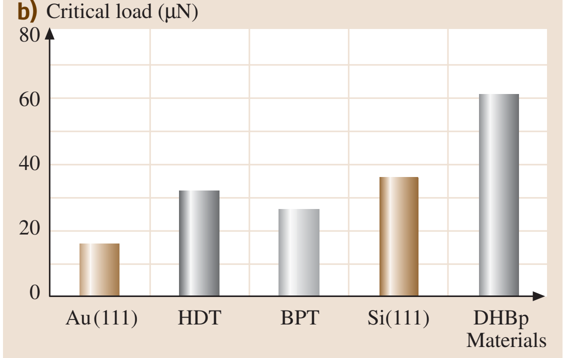


Fig. 27.20 **(a)** Coefficient of friction profiles during scratch as a function of normal load and corresponding AFM surface height images, and **(b)** critical loads estimated from the coefficient of friction profile and AFM images for Au(111), HDT/Au(111), BPT/Au(111), Si(111), and DHBp/Si(111) [27.37]

ponent. This is in agreement with analysis of the AFM images, which shows negligible damage on the surfaces prior to the critical load. At the critical load, a clear groove is formed, accompanied by the formation of material pileup at the sides of the scratch. This suggests that the initial damage that occurs at the critical load is due to ploughing associated with plastic deformation, which causes a sharp rise in the coefficient of friction. Beyond the critical load, debris can be seen in addition to material pile-up at the sides of the scratch. Figure 27.20b summarizes the critical loads for the various samples obtained in this study. It clearly indicates that all SAMs can increase the critical load of the corresponding substrate. DHBp, which is deposited on Si(111), shows superior scratch resistance in all of the tested samples.

Mechanisms responsible for a sudden drop in the decrease in surface height with an increase in load during wear and scratch tests need to be understood. *Barrena* et al. [27.78] observed that the height of self-assembled alkylsilanes decrease in discrete amounts with normal load. This step-like behavior is due to the discrete molecular tilts, which are dictated by the geometrical requirements of the close packing of molecules. Only certain angles are allowed due to the zigzag arrangement of the carbon atoms. The relative height of the monolayer under pressure can be calculated by the following equation:

$$\left(\frac{h}{L}\right) = \left[1 + \left(\frac{na}{d}\right)^2\right]^{-\frac{1}{2}} , \qquad (27.6)$$

Table 27.12 Calculated $\left[1+\left(\frac{na}{d}\right)^2\right]^{-1/2}$ and measured $\left(\frac{h}{L}\right)$ relative heights of HDT and MHA self-assembled monolayers [27.35]

Steps (n)	Calculated[1] $\left[1+\left(\frac{na}{d}\right)^2\right]^{-1/2}$	Measured[2] $\left(\frac{h}{L}\right)$ HDT	MHA
1	0.883		
2	0.685	0.674[3]	0.643[3]
3	0.531	0.532[3]	0.552[3]
4	0.425	0.416[3]	
5	0.352	0.354[3]	
6	0.299		

[1] Calculations are based on the assumption that the molecules tilt in discrete steps (n) upon compression with a diamond AFM tip [27.78].
[2] Measured values are the mean values of three tests.
[3] These measured values correspond to the normal loads of 0.50 µN, 1.57 µN, 2.53 µN, and 4.03 µN, respectively.

where L is the total length of the molecule, h is the height of the SAMs in the tilt configuration (monolayer thickness), a is the distance between alternate carbon atoms in the molecule, d is the separation of the molecules, and n is the step number. For HDT and MHA, only the head groups are different in their work and this study. The spacer carbon chains in alkanethiol and alkylsilane are exactly the same. So the same a (0.25 nm) and d (0.47 nm) values are used in the calculation for HDT and MHA. The calculated and measured relative heights of HDT and MHA are listed in Table 27.12. When the normal loads are smaller than the critical values in Fig. 27.19, the measured relative height values of HDT and MHA are very close to the calculated values. This means that HDT and MHA underwent step tilting below critical normal loads.

Table 27.13 Calculated L_0 and measured residual film thickness for SAMs under critical load

	L_0^1 (nm)	Residual thickness[2] (nm)
HDT	0.24	0.25
BPT	0.39	0.42
BPTC	0.33	0.38
MHA	0.36	0.29
DHBp	–	0.52

[1] Calculated by the equation of $h = b\cos(\alpha)n + L_0$ [27.68]
[2] Measured by AFM using diamond tip under critical normal load. All of the data are the mean values of three tests

The residual SAMs thickness after wear under critical normal load was measured by profiling the worn film using AFM. The results are listed in Table 27.13. For an alkanethiol monolayer, the relationship between the monolayer thickness h and intercept length L_0 can be expressed as (see Fig. 27.21):

$$h = b\cos(\alpha)n + L_0 , \quad (27.7)$$

where b is the length of the projection of the C–C bond onto the main chain axis ($b = 0.127$ nm for alkanethiol), n is the chain length defined by $CH_3(CH_2)_nSH$, and α is the tilt angle [27.68]. For BPT and BPTC, based on the same principle and using the bond lengths reported in reference [27.69], the L_0 values are also calculated, Table 27.13. It indicates that the measured residual thickness values of SAMs under critical load are very close to the calculated intercept length L_0 values. It means that under the critical normal load, the Si_3N_4 tip approaches the interface and SAMs wear severely away from the substrate. This is due to the interface chemical adsorption bond strength (HS–Au and Si–O) being generally smaller than the other chemical bond strengths in SAMs

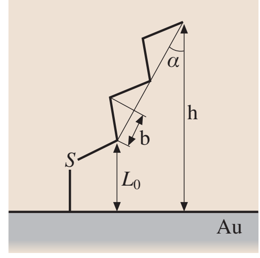

Fig. 27.21 Illustration of the relationship between the components of the equation $h = b\cos(\alpha)n + L_0$ [27.35]

Table 27.14 Bond strengths of the chemical bonds in SAMs [27.35]

SAMs	Bond	Bond strength[1] (kJ/mol)
Thiol on Au	S−Au	184 [27.58]
Hydroxyl on Si	O−Si	242.7 [27.79]
HDT	$H-CH_2$	464.8
	H−CH	421.7
	CH_3-t-C_4H_9	425.9±8
	t-C_4H_9−SH	286.2±6.3
MHA	O=CO	532.2±0.4
	$H-OCOC_2H_5$	445.2±8
	$HO-OCH_2C(CH_3)$	193.7±7.9
	$C_6H_5CH_2-COOH$	280
BPT	CH_3-CH_3	376.0±2.1
	$H_2C=CH_2$	733±8
	C_6H_5-SH	361.9±8
DHBp	C_6H_5-OH	361.9±8

[1] Most of the data are cited from [27.77], except where indicated. For MHA and DHBp, the bonds that are common as in HDT and DHBp are not repeated

spacer chains (see Table 27.14). Based on this discussion, it is believed that the reason why DHBp has the best wear resistance is due to the rigid biphenyl ring structure (compared to linear carbon chain in alkylthiol), the hard Si(111) substrate (compared to Au(111) substrate), and the strong interface Si−O bond strength (compared to the weak S−Au bond strength in the other SAMs, see Table 27.14).

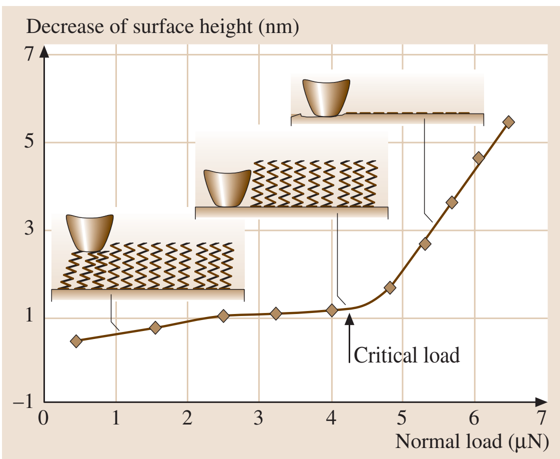

Fig. 27.22 Illustration of the wear mechanisms of SAMs with increasing normal load [27.37]

According to the wear and scratch results reported here and the above discussion, the transition of the wear mechanisms of SAMs with increasing normal load is illustrated in Fig. 27.22. Below the critical normal load, SAMs undergo step orientation, at the critical load SAMs wear away from the substrate due to the weak interface bond strengths, while above the critical normal load severe wear takes place on the substrate. In order to improve wear resistance, the interface bond must be enhanced; a rigid spacer chain and a hard substrate are also preferred.

27.4 Closure

Exposure of devices to humid environments results in condensates of water vapor from the environment. Condensed water, or a preexisting film of liquid, forms concave meniscus bridges between the mating surfaces. The negative Laplace pressure present in the meniscus results in an adhesive force that depends on the interface roughness, surface tension, and contact angle. The adhesive force can be significant in an interface with ultra-smooth surfaces, and it can be on the same order as the external load if the latter is small, such as in micro/nanodevices. Surfaces with high hydrophobicity can be produced by surface treatment. In many applications, hydrophobic films are expected to provide low adhesion, friction, and wear. To minimize high adhesion, friction, and/or because of small clearances in micro/nanodevices, these films should be molecularly thick. Liquid films of low surface tension or certain hydrophobic solid films can be used. Ordered molecular assemblies with high hydrophobicity can be engineered using chemical grafting of various polymer molecules with suitable functional head groups and nonpolar surface terminal groups.

The adhesion, friction, and wear properties of SAMs, having alkyl and biphenyl spacer chains with different surface terminal groups ($-CH_3$, −COOH, and −OH) and head groups (−SH and −OH), studied using an AFM, are reported in this chapter. It is found that the adhesive force varies linearly with the W_a value of SAMs, which indicates that capillary condensation of water plays an important role to the adhesion of SAMs on

nanoscale at ambient conditions. It has been found that HDT exhibits the smallest adhesive force and friction force, because of low W_a of $-CH_3$ surface terminal groups, and high-compliance long carbon spacer chain. The friction data are explained using a molecular spring model, in which the local stiffness and intermolecular force governs its frictional performance. The results of the stiffness and friction characterization of the micropatterned sample with different structures support this model. The influence of relative humidity on adhesion and friction of SAMs is dominated by the thickness of the adsorbed water layer. At higher humidity, water can either increase friction through increased adhesion by meniscus effect in the contact zone or reduce friction through an enhanced water-lubricating effect. In the case of Si(111), the desorption of the adsorbed water layer and reduction of surface tension of water with increasing temperature reduce the adhesive force and friction force. The increase of temperature does not show an apparent influence on HDT, but strongly influences the adhesion and friction properties of BPT, which are believed to be related to its melting. The effect of velocity on friction properties of SAMs depends on their molecular structures. For alkylthiol SAMs, their friction is increased by increasing velocity, while for biphenyl SAMs it changes in the opposite way. The mechanism responsible for the variation of the friction forces of SAMs with velocity is believed to be related to their viscoelastic properties. Wear and continuous microscratch tests show that among the SAMs on Au(111), HDT exhibits the best wear resistance. DHBp on Si(111), due to its rigid biphenyl spacer chains, strong interface bonds, and a hard substrate, has the best wear resistance among all of the tested samples. For all of the SAMs, the wear depth as a function of normal load curves shows critical normal loads. Below the critical normal load SAMs undergo step orientation, at the critical load SAMs wear away from the substrate due to the weak interface bond strengths, while above the critical normal load severe wear take place on the substrate.

Based on the nanotribological studies of SAM films by AFM, they exhibit attractive hydrophobic and tribological properties. SAM films should find many tribological applications, including in micro/nanodevices.

28. Nanoscale Boundary Lubrication Studies

Boundary films are formed by physisorption, chemisorption, and chemical reaction. With physisorption, no exchange of electrons takes place between the molecules of the adsorbate and those of the adsorbant. The physisorption process typically involves van der Waals forces, which are relatively weak. In chemisorption, there is an actual sharing of electrons or electron interchange between the chemisorbed species and the solid surface. The solid surfaces bond very strongly to the adsorption species through covalent bonds. Chemically reacted films are formed by the chemical reaction of a solid surface with the environment. The physisorbed film can be either monomolecularly or polymolecularly thick. The chemisorbed films are monomolecular, but stoichiometric films formed by chemical reaction can have a large film thickness. In general, the stability and durability of surface films decrease in the following order: chemically reacted films, chemisorbed films, and physisorbed films. A good boundary lubricant should have a high degree of interaction between its molecules and the sliding surface. As a general rule, liquids are good lubricants when they are polar and, thus, able to grip solid surfaces (or be adsorbed). In this chapter, we focus on PFPEs. We first introduce details of the commonly used PFPE lubricants; then present a summary of nanodeformation, molecular conformation, and lubricant spreading studies; followed by an overview of nanotribological properties of polar and nonpolar PFPEs studied by atomic force microscopy (AFM) and some concluding remarks.

Boundary films are formed by physisorption, chemisorption, and chemical reaction. With physisorption, no exchange of electrons takes place between the molecules of the adsorbate and those of the adsorbant. The physisorption process typically involves van der Waals forces, which are relatively weak. In chemisorption, there is an actual sharing of electrons or electron interchange between the chemisorbed species and the solid surface. The solid surfaces bond very strongly to the adsorption species through covalent bonds. Chemically reacted films are formed by the chemical reaction of a solid surface with the environment. The physisorbed film can be either monomolecularly or polymolecularly thick. The chemisorbed films are monomolecular, but stoichiometric films formed by chemical reaction can have a large film thickness. In general, the stability and durability of surface films decrease in the following order: chemically reacted films, chemisorbed films, and physisorbed films. A good boundary lubricant should have a high degree of interaction between its molecules and the sliding surface. As a general rule, liquids are good lubricants when they are polar and, thus, able to grip solid surfaces (or be adsorbed). Polar lubricants contain reactive functional groups with low ionization potential, or groups having high polarizability [28.1–3]. Boundary lubrication properties of lubricants are also dependent upon the molecular conformation and lubricant spreading [28.4–7].

Self-assembled monolayers (SAMs), Langmuir–Blodgett (LB) films, and perfluoropolyether (PFPE) films can be used as boundary lubricants [28.2, 3, 8–10].

PFPE films are commonly used for lubrication of magnetic rigid disks and metal evaporated magnetic tapes to reduce friction and wear of a head-medium interface [28.10]. PFPEs are well suited for this application because of the following properties: low surface tension and low contact angle, which allow easy spreading on surfaces and provide a hydrophobic property; chemical and thermal stability, which minimizes degradation under use; low vapor pressure,which provides low outgassing; high adhesion to substrate via organofunctional bonds; and good lubricity, which reduces the interfacial friction and wear [28.10–12]. While the structure of the lubricants employed at the head-medium interface has not changed substantially over the past decade, the thickness of the PFPE film used to lubricate the disk has steadily decreased from multilayer thicknesses to the sub-monolayer thickness regime [28.11, 13]. Molecularly thick PFPE films are also being considered for lubrication purposes of the evolving microelectromechanical systems (MEMS) industry [28.14]. It is well-known that the properties of molecularly thick liquid films confined to solid surfaces can be dramatically different from those of the corresponding bulk liquid. In order to efficiently develop lubrication systems that meet the requirements of the advanced rigid disk drive and MEMS industries, the impact of thinning the PFPE lubricants on the resulting of nanotribology should be fully understood [28.15, 16]. It is also important to understand lubricant-substrate interfacial interactions and the influence of the operating environment on the nanotribological performance of molecularly thick PFPEs.

An overview of nanotribological properties of SAMs and LB films can be found in many references such as [28.17]. In this chapter, we focus on PFPEs. We first introduce details of the commonly used PFPE lubricants; then present a summary of nanodeformation, molecular conformation, and lubricant spreading studies; followed by an overview of nanotribological properties of polar and nonpolar PFPEs studied by atomic force microscopy (AFM) and some concluding remarks.

28.1 Lubricants Details

Properties of two commonly used PFPE lubricants (Z-15 and Z-DOL) are reviewed here. Their molecular structures are shown schematically in Fig. 28.1. Z-15 has nonpolar $-CF_3$ end groups, whereas Z-DOL is a polar lubricant with hydroxyl ($-OH$) end groups. Their typical properties are summarized in Table 28.1. It shows that Z-15 and Z-DOL almost have the same density and surface tension. But Z-15 has larger molecular weight and higher viscosity. Both have low surface tension, low vapor pressure, low evaporation weight loss, and good oxidative stability [28.10, 12]. Generally, single-crystal Si(100) wafer with a native oxide layer was used as a substrate for deposition of molecularly thick lubricant films

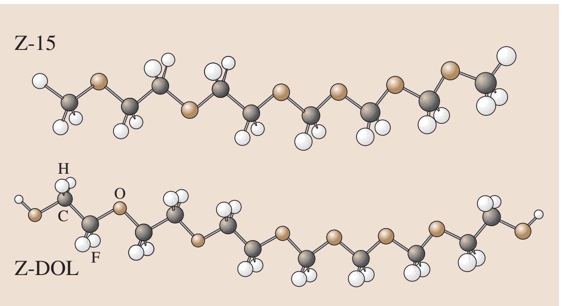

Fig. 28.1 Schematics of the molecular structures of Z-15 and Z-DOL. In this figure the m/n value, shown in Table 28.1, equals 2/3

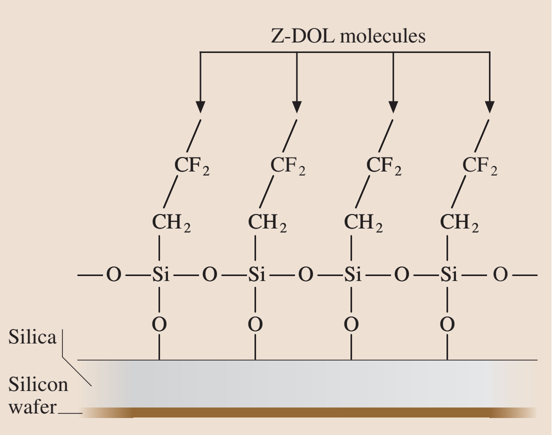

Fig. 28.2 Schematic of Z-DOL molecules that are chemically bonded on Si(100) substrate surface (which has native oxide) after thermal treatment at 150 °C for 30 min

for nanotribological characterization. Z-15 and Z-DOL films can be deposited directly on the Si(100) wafer by dip coating technique. The clean silicon wafer is vertically submerged into a dilute solution of lubricant in hydrocarbon solvent (HT-70) for a certain time. The silicon wafers are vertically pulled up from the solution with a motorized stage at a constant speed for deposition of desired thicknesses of Z-15 and Z-DOL lubricants. The lubricant film thickness obtained in dip coating is a function of the concentration and pulling-up speed, among other factors. The Z-DOL film is bonded to the silicon substrate by heating the as-deposited Z-DOL samples in an oven at 150 °C for about 30 s. The native oxide layer of Si(100) wafer reacts with the −OH groups of the lubricants during thermal treatment [28.18–21]. Subsequently, fluorocarbon solvent (FC-72) washing of the thermal treated specimen removes loosely absorbed species, leaving chemically bonded phase on the substrate. The chemical bonding between Z-DOL molecules and silicon substrate is illustrated in Fig. 28.2. The bonded and washed Z-DOL film is referred to as Z-DOL(BW) in this chapter. The as-deposited Z-15 and Z-DOL films are mobile phase lubricants (i. e., liquid-like lubricant), whereas the Z-DOL(BW) films are fully bonded soft solid phase (i. e., solid-like) lubricants. This will be further discussed in the next section.

28.2 Nanodeformation, Molecular Conformation, and Lubricant Spreading

Nanodeformation behavior of Z-DOL lubricants was studied using an AFM by *Blackman* et al. [28.22,23]. Before bringing a tungsten tip into contact with a molecular overlayer, it was brought into contact with a bare clean-silicon surface, Fig. 28.3. As the sample approaches the tip, the force initially is zero, but at point A the force suddenly becomes attractive (top curve), which increases until at point B, where the sample and tip come into intimate contact and the force becomes repulsive. As the sample is retracted, a pull-off force of 5×10^{-8} N (point D) is required to overcome adhesion between the tungsten tip and the silicon surface. When an AFM tip is brought into contact with an unbonded Z-DOL film, a sudden jump into adhesive contact is also observed. A much larger pull-off force is required to overcome the adhesion. The adhesion is initiated by the formation of a lubricant meniscus surrounding the tip. This suggests that the unbonded Z-DOL lubricant shows liquid-like behavior. However, when the tip was brought into contact with a lubricant film, which was firmly bonded to the surface, the liquid-like behavior disappears. The initial attractive force (point A) is no longer sudden, as with the liquid film, but, rather, gradually increases as the tip penetrates the film.

According to *Blackman* et al. [28.22, 23], if the substrate and tip were infinitely hard with no compliance and/or deformation in the tip and sample supports, the line for B to C would be vertical with an infinite slope. The tangent to the force-distance curve at a given point is referred to as the stiffness at that point and was determined by fitting a least-squares line through the nearby data points. For silicon, the deformation is reversible (elastic), since the retracting (outgoing) portion of the curve (C to D) follows the extending (ingoing) portion (B to C). For bonded lubricant film, at the point where slope of the force changes gradually from attractive to repulsive, the stiffness changes gradually, indicating compression of the molecular film. As the load is increased, the slope of the repulsive force eventually approaches that of the bare surface. The bonded film was found to respond elastically up to the highest loads of 5 µN that could be applied. Thus, bonded lubricant behaves as a soft polymer solid.

Figure 28.4 illustrates two extremes for the conformation on a surface of a linear liquid polymer without any reactive end groups and at submonolayer coverages [28.4, 6]. At one extreme, the molecules lie flat on the surface, reaching no more than their chain diameter δ above the surface. This would be the case if a strong attractive interaction exists between the molecules and the solid. On the other extreme, when a weak attraction exists between polymer segments and the solid, the molecules adopt conformation close to that of the molecules in the bulk, with the microscopic thickness equal to about the radius of gyration R_g. *Mate* and *Novotny* [28.6] used AFM to study conformation of 0.5–1.3 nm-thick Z-15 molecules on clean Si(100) surfaces. They found that the thickness measured by AFM is thicker than that measured by ellipsometry with the offset ranging from 3–5 nm. They found that the offset was the same for very thin submonolayer coverages. If the coverage is submonolayer and inadequate to make a liquid film, the relevant thickness is then the height (h_e) of the molecules extended above the solid surface. The offset should be equal to $2h_e$, assum-

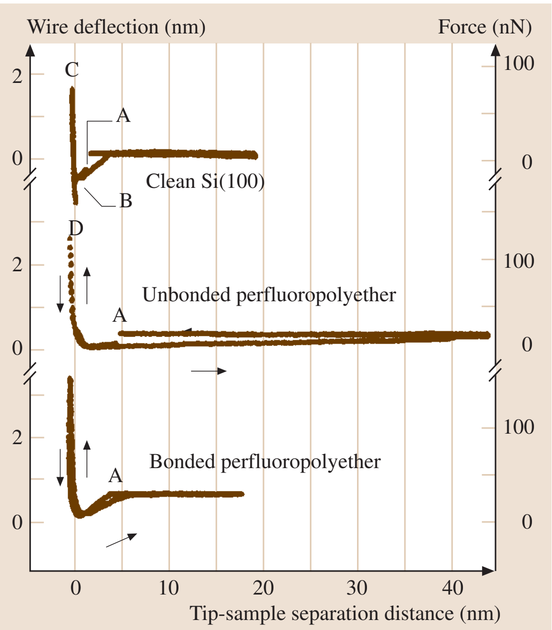

Fig. 28.3 Wire deflection (normal load) as a function of tip-sample separation distance curves comparing the behavior of clean Si(100) surface to a surface lubricated with free and unbonded PFPE lubricant, and a surface where the PFPE lubricant film was thermally bonded to the surface [28.22]

ing that the molecules extend the same height above both the tip and silicon surfaces. They therefore concluded that the molecules do not extend more than 1.5–2.5 nm above a solid or liquid surface, much smaller than the radius of gyration of the lubricants ranging between 3.2 and 7.3 nm, and to the approximate cross-sectional diameter of 0.6–0.7 nm for the linear polymer chain. Consequently, the height that the molecules extend above the surface is considerably less than the diameter of gyration of the molecules and only a few molecular diameters in height, implying that the physisorbed molecules on a solid surface have an extended, flat conformation. They also determined the disjoining pressure of these liquid films from AFM measurements of the distance needed to break the liquid meniscus that forms between the solid surface and the AFM tip. (Also see [28.7].) For a monolayer thickness of about 0.7 nm, the disjoining pressure is about 5 MPa, indicating strong attractive interaction between the liquid molecules and the solid surface. The disjoining pressure decreases with increasing film thickness in a manner consistent with a strong attractive van der Waals interaction between the liquid molecules and the solid surface.

Rheological characterization shows that the flow activation energy of PFPE lubricants is weakly dependent on chain length and is strongly dependent on the functional end groups [28.25]. PFPE lubricant films that contain polar end groups have lower mobility than those with nonpolar end groups of similar chain length [28.26]. The mobility of PFPE also depends on the surface chemical properties of the substrate. The spreading of Z-DOL on amorphous carbon surface has been studied as a function of hydrogen or nitrogen content in the carbon film, using scanning microellipsometry [28.24]. The diffusion coefficient data presented in Fig. 28.5 is thickness-dependent. It shows that the surface mobility of Z-DOL increased as the hydrogen content increased, but decreased as nitrogen content increased. The enhancement of Z-DOL surface mobility by hydrogenation may be understood from the fact that the interactions between Z-DOL molecules and the carbon surface can be significantly weakened, due to a reduction of the number of high-energy binding sites on the carbon surface. The stronger interactions between the Z-DOL molecules and carbon surface, as nitrogen content in the carbon coating increases, leads to the lowering of Z-DOL surface mobility.

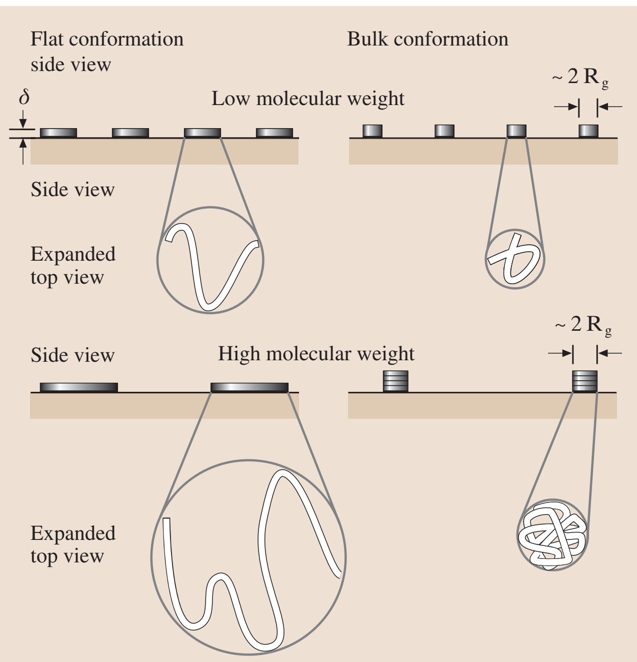

Fig. 28.4 Schematic representation of two extreme liquid conformations at the surface of the solid for low and high molecular weights at low surface coverage. δ is the cross-sectional diameter of the liquid chain, and R_g is the radius of gyration of the molecules in the bulk [28.6]

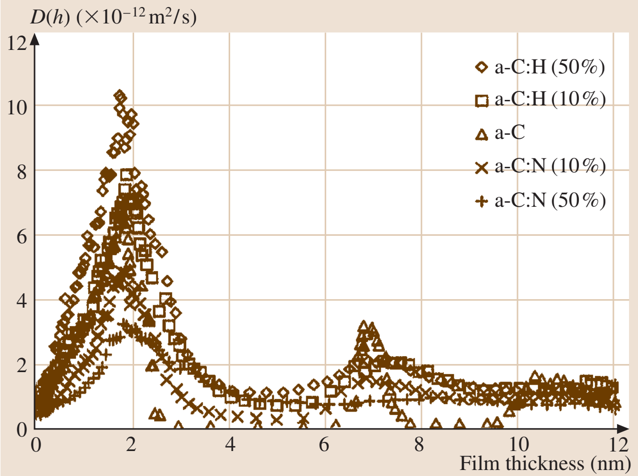

Fig. 28.5 Diffusion coefficient $D(h)$ as a function of lubricant film thickness for Z-DOL on different carbon films [28.24]

Molecularly thick films may be sheared at very high shear rates, on the order of 10^8–10^9 s^{-1} during sliding, such as during magnetic disk drive operation. During such shear, lubricant stability is critical to the protection of the interface. For proper lubricant selection, viscosity at high shear rates and associated shear thinning need to be understood. Viscosity measurements of eight different types of PFPE films show that all eight lubricants display Newtonian behavior and their viscosity remains constant at a shear rate up to 10^7 s^{-1} [28.27, 28].

28.3 Boundary Lubrication Studies

With the development of AFM techniques, studies have been carried out to investigate the nanotribological performance of PFPEs. *Mate* [28.29, 30], *O'Shea* et al. [28.31, 32], *Bhushan* et al. [28.15, 33], *Koinkar* and *Bhushan* [28.20, 34], *Bhushan* and *Sundararajan* [28.35], *Bhushan* and *Dandavate* [28.36], and *Liu* and *Bhushan* [28.21] used an AFM to provide insight into how PFPE lubricants function at the molecular level. *Mate* [28.29, 30] conducted friction experiments on bonded and unbonded Z-DOL and found that the coefficient of friction of the unbonded Z-DOL is about two times larger than the bonded Z-DOL (also see [28.31, 32]). *Koinkar* and *Bhushan* [28.20, 34] and *Liu* and *Bhushan* [28.21] studied the friction and wear performance of a Si(100) sample lubricated with Z-15, Z-DOL, and Z-DOL(BW) lubricants. They found that using Z-DOL(BW) could significantly improve the adhesion, friction, and wear performance of Si(100). They also discussed the lubrication mechanisms on the molecular level. *Bhushan* and *Sundararajan* [28.35] and *Bhushan* and *Dandavate* [28.36] studied the effect of tip radius and relative humidity on the adhesion and friction properties of Si(100) coated with Z-DOL(BW).

In this section, we review, in some detail, the adhesion, friction, and wear properties of two kinds of typical PFPE lubricants of Z-15 and Z-DOL at various operating conditions (rest time, velocity, relative humidity, temperature, and tip radius). The experiments were carried out using a commercial AFM system with pyramidal Si_3N_4 and diamond tips. An environmentally controlled chamber and a thermal stage were used to perform relative humidity and temperature effect studies.

28.3.1 Friction and Adhesion

To investigate the friction properties of Z-15 and Z-DOL(BW) films on Si(100), the friction force versus normal load curves were measured by making friction measurements at increasing normal loads [28.21]. The representative results of Si(100), Z-15, and Z-DOL(BW) are shown in Fig. 28.6. An approximately linear response of all three samples is observed in the load range of 5–130 nN. The friction force of solid-like Z-DOL(BW) is consistently smaller than that for Si(100), but the friction force of liquid-like Z-15 lubricant is higher than that of Si(100). *Sundararajan* and *Bhushan* [28.37] have studied the static friction force of silicon micromotors lubricated with Z-DOL by AFM. They also found that liquid-like lubricants of Z-DOL significantly increase the static friction force, whereas solid-like Z-DOL(BW) coating can dramatically reduce the static friction force. This is in good agreement with the results of *Liu* and *Bhushan* [28.21]. In Fig. 28.6, the nonzero value of the friction force signal at zero external load is due to the adhesive forces. It is well-known that the following relationship exists between the friction force F and external

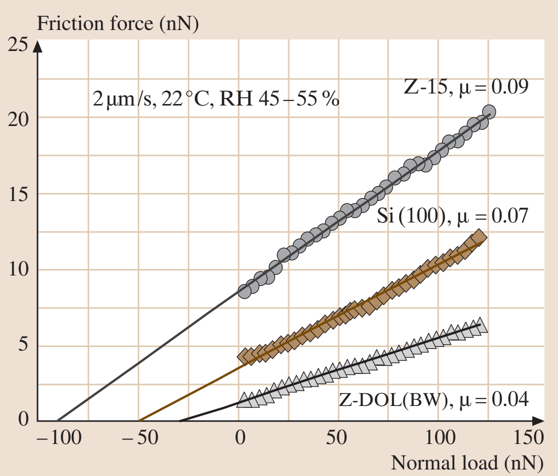

Fig. 28.6 Friction force versus normal load curves for Si(100), 2.8-nm-thick Z-15 film, and 2.3-nm-thick Z-DOL(BW) film at 2 µm/s, and in ambient air sliding against a Si_3N_4 tip. Based on these curves, coefficient of friction μ and adhesion force of W_a can be calculated [28.21]

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

normal load W [28.2, 3]

$$F = \mu(W + W_a) , \quad (28.1)$$

where μ is the coefficient of friction and W_a is the adhesive force. Based on this equation and the data in Fig. 28.6, we can calculate the μ and W_a values. The coefficients of friction of Si(100), Z-15, and Z-DOL are 0.07, 0.09, and 0.04, respectively. Based on (28.1), the adhesive force values are obtained from the horizontal intercepts of the friction force versus normal load curves at a zero value of friction force. Adhesive force values of Si(100), Z-15, and Z-DOL are 52 nN, 91 nN, and 34 nN, respectively.

The adhesive forces of these samples were also measured using a force calibration plot (FCP) technique. In this technique, the tip is brought into contact with the sample and the maximum force, needed to pull the tip and sample apart, is measured as the adhesive force. Figure 28.7 shows the typical FCP curves of Si(100), Z-15, and Z-DOL(BW) [28.21]. As the tip approaches the sample within a few nanometers (A), an attractive force exists between the tip and the sample surfaces. The tip is pulled toward the sample, and contact occurs at point B on the graph. The adsorption of water molecules and/or presence of liquid lubricant molecules on the sample surface can also accelerate this so-called "snap-in", due to the formation of meniscus of the water and/or liquid lubricant around the tip. From this point on, the tip is in contact with surface, and as the piezo extends further, the cantilever is further deflected. This is represented by the slope portion of the curve. As the piezo retracts, at point C the tip goes beyond the zero deflection (flat) line, because of the attractive forces, into the adhesive force regime. At point D, the tip snaps free of the adhesive forces and is again in free air. The adhesive force (pull-off force) is determined by multiplying the cantilever spring constant (0.58 N/m) by the horizontal distance between points C and D, which corresponds to the maximum cantilever deflection toward the samples before the tip is disengaged. Incidentally, the horizontal shift between the loading and unloading curves results from the hysteresis of the PZT tube.

The adhesive forces of Si(100), Z-15, and Z-DOL(BW) measured by FCP and friction force versus normal load plot are summarized in Fig. 28.8 [28.21]. The results measured by these two methods are in good agreement. Figure 28.8 shows that the presence of mobile Z-15 lubricant film increases the adhesive force as compared to that of Si(100). In contrast, the presence of solid phase Z-DOL(BW) film reduces the adhesive force as compared to that of Si(100). This result is in good agreement with the results of *Blackman* et al. [28.22] and *Bhushan* and *Ruan* [28.38]. Sources of adhesive forces between the tip and the sample surfaces are van der Waals attraction and long-range meniscus force [28.2, 3, 16]. Relative magnitudes of the forces from the two sources are dependent on various factors, including the distance between the tip and the sample surface, their surface roughness, their hydrophobicity, and relative humidity [28.39]. For most surfaces with some roughness, meniscus contribution dominates at moderate to high humidities.

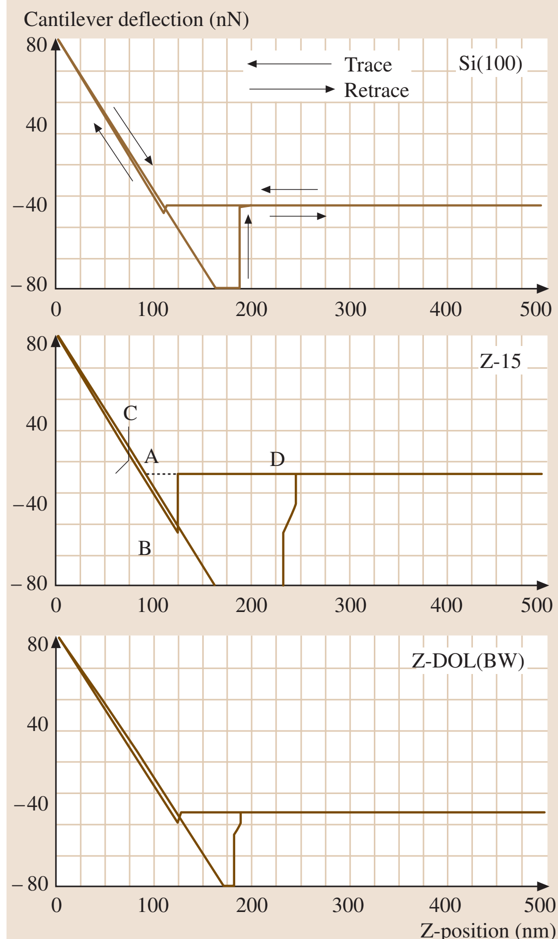

Fig. 28.7 Typical force calibration plots of Si(100), 2.8-nm-thick Z-15 film, and 2.3-nm-thick Z-DOL(BW) film in ambient air. The adhesive forces can be calculated from the horizontal distance between points C and D, and the cantilever spring constant of 0.58 N/m [28.21]

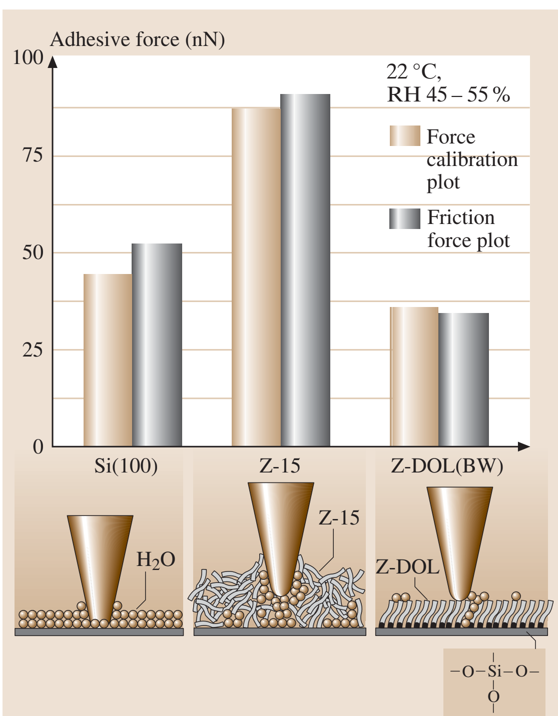

Fig. 28.8 Summary of the adhesive forces of Si(100), 2.8-nm-thick Z-15 film, and 2.3-nm-thick Z-DOL(BW) film measured by force calibration plots and friction force versus normal load plots in ambient air. The schematic (*bottom*) shows the effect of meniscus formed between the AFM tip and the sample surface on the adhesive and friction forces [28.21]

The schematic (bottom) in Fig. 28.8 shows relative size and sources of meniscus. The native oxide layer (SiO_2) on the top of Si(100) wafer exhibits hydrophilic properties, and some water molecules can be adsorbed on this surface. The condensed water will form meniscus as the tip approaches the sample surface. In the case of a sphere (such as a single-asperity AFM tip) in contact with a flat surface, the attractive Laplace force (F_L) caused by capillary is:

$$F_L = 2\pi R\gamma_{la}(\cos\theta_1 + \cos\theta_2)\,, \tag{28.2}$$

where R is the radius of the sphere, γ_{la} is the surface tension of the liquid against air, θ_1 and θ_2 are the contact angles between liquid and flat and spherical surfaces, respectively [28.2, 3, 40]. As the surface tension value of Z-15 (24 dyn/cm) is smaller than that of water (72 dyn/cm), the larger adhesive force in Z-15 cannot only be caused by the Z-15 meniscus. The nonpolarized Z-15 liquid does not have complete coverage and strong bonding with Si(100). In the ambient environment, the condensed water molecules will permeate through the liquid Z-15 lubricant film and compete with the lubricant molecules present on the substrate. The interaction of the liquid lubricant with the substrate is weakened, and a boundary layer of the liquid lubricant forms puddles [28.20, 34]. This dewetting allows water molecules to be adsorbed on the Si(100) surface as aggregates along with Z-15 molecules. And both of them can form meniscus while the tip approaches the surface. In addition, as the Z-15 film is pretty soft compared to the solid Si(100) surface, penetration of the tip in the film occurs while pushing the tip down. This leads to a large area of the tip involved to form the meniscus at the tip-liquid (water aggregates along with Z-15) interface. These two factors of the liquid-like Z-15 film result in higher adhesive force. It should also be noted that Z-15 has a higher viscosity compared to that of water. Therefore, Z-15 film provides higher resistance to sliding motion and results in a larger coefficient of friction. In the case of Z-DOL(BW) film, both of the active groups of Z-DOL molecules are strongly bonded on Si(100) substrate through the thermal and washing treatment. Thus, the Z-DOL(BW) film has relatively low free surface energy and cannot be displaced readily by water molecules or readily adsorb water molecules. Thus, the use of Z-DOL(BW) can reduce the adhesive force. We further note that the bonded Z-DOL molecules can be orientated under stress (behaves as a soft polymer solid), which facilitates sliding and reduces coefficient of friction.

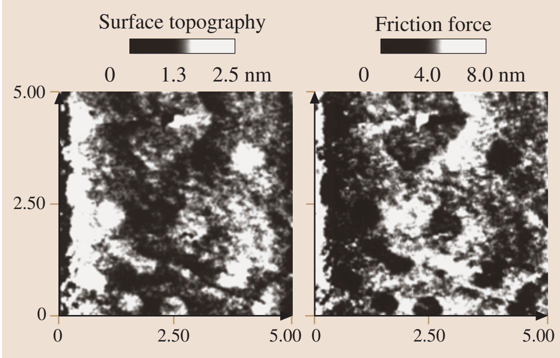

Fig. 28.9 Gray-scale plots of the surface topography and friction force obtained simultaneously for unbonded 2.3-nm-thick Demnum-type PFPE lubricant film on silicon [28.20]

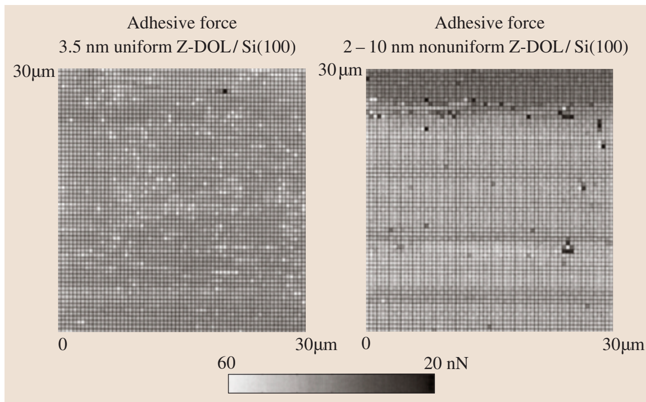

Fig. 28.10 Gray-scale plots of the adhesive force distribution of a uniformly coated, 3.5-nm-thick unbonded Z-DOL film on silicon and 3- to 10-nm-thick unbonded Z-DOL film on silicon that was deliberately coated nonuniformly by vibrating the sample during the coating process [28.36]

These studies suggest that if the lubricant films exist as liquid-like, such as Z-15 films, they easily form meniscus (by themselves and the adsorbed water molecules), and thus have higher adhesive force and higher friction force. Whereas if the lubricant film exists in solid-like phase, such as Z-DOL(BW) films, they are hydrophobic with low adhesion and friction.

In order to study the uniformity of lubricant film and its influence on friction and adhesion, friction force mapping and adhesive force mapping of PFPE have been carried out by *Koinkar* and *Bhushan* [28.34] and *Bhushan* and *Dandavate* [28.36], respectively. Figure 28.9 shows gray-scale plots of surface topography and friction force images obtained simultaneously for unbonded Demnum-type PFPE lubricant film on silicon [28.34]. The friction force plot shows well distinguished low and high friction regions corresponding roughly to high and low surface height regions in the topography image (thick and thin lubricant regions). A uniformly lubricated sample does not show such a variation in friction. Figure 28.10 shows the gray-scale plots of the adhesive force distribution for silicon samples coated uniformly and nonuniformly with Z-DOL lubricant. It can be clearly seen that there exists a region that has an adhesive force distinctly different from the other region for the nonuniformly coated sample. This implies that the liquid film thickness is nonuniform, giving rise to a difference in the meniscus forces.

28.3.2 Rest Time Effect

It is well-known that in the computer rigid disk drive, the stiction force increases rapidly with an increase in rest time between the head and magnetic medium disk [28.10, 11]. Considering that the stiction and friction are

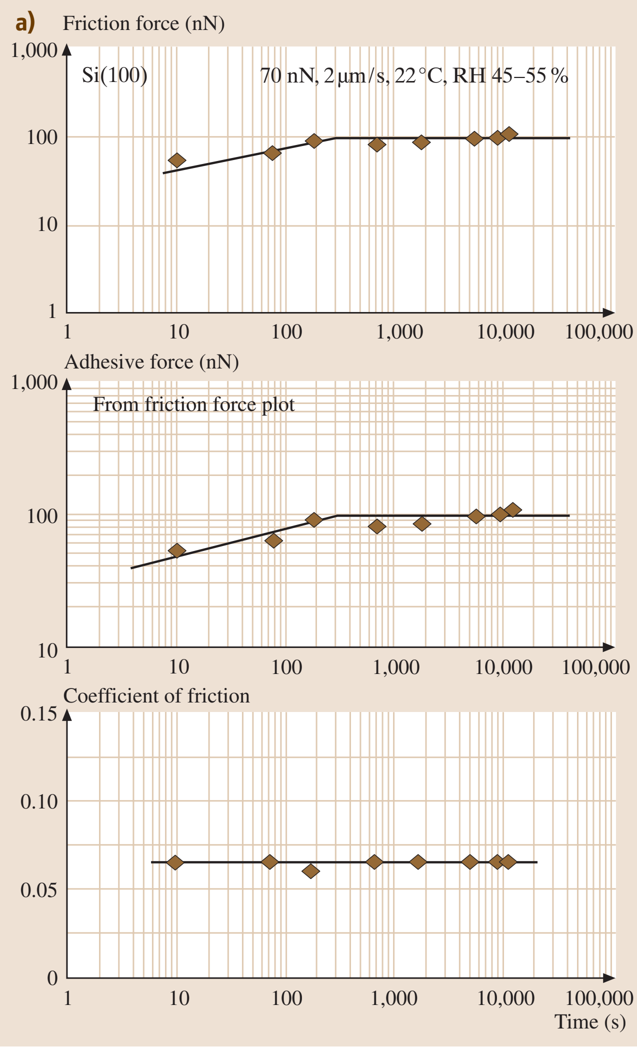

Fig. 28.11 **(a)** Rest time effect on friction force, adhesive force, and coefficient of friction of Si(100). **(b)** (*see next page*) Summary of the rest time effect on friction force, adhesive force, and coefficient of friction of Si(100), 2.8-nm-thick Z-15 film, and 2.3-nm-thick Z-DOL(BW) film. Fig. 28.11b

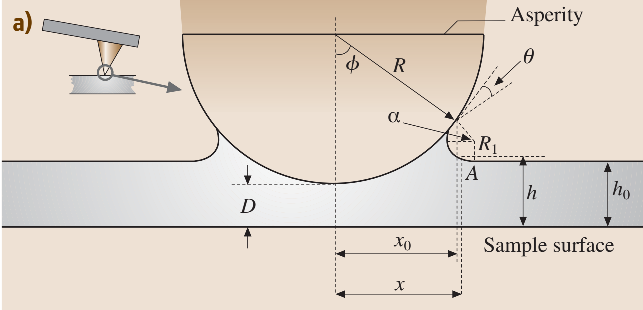

Fig. 28.12a

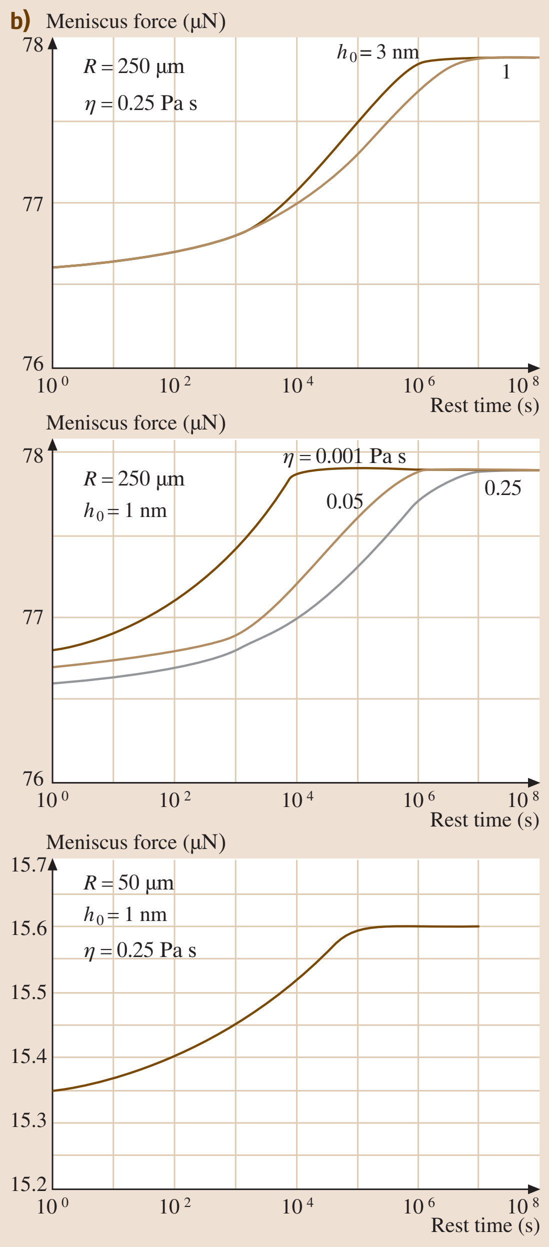

Fig. 28.12 **(a)** Schematic of a single asperity in contact with a smooth flat surface in the presence of a continuous liquid film when ϕ is large. **(b)** Results of the single asperity model. Effect of viscosity of the liquid, radius of the asperity, and film thickness is studied with respect to the time-dependent meniscus force [28.41]

two of the major issues that lead to the failure of computer rigid disk drives and MEMS, it is very important to find out if the rest time effect also exists on the nanoscale. First, the rest time effect on the friction force, adhesive force, and coefficient of Si(100) sliding against Si_3N_4 tip was studied, Fig. 28.11a [28.21]. It was found that the friction and adhesive forces logarithmically increase up to a certain equilibrium time after which they remain constant. Figure 28.11a also shows that the rest time does not affect the coefficient of friction. These results suggest that the rest time can result in growth of the meniscus, which causes a higher adhesive force, and in turn, a higher friction force. But in the whole testing range the friction mechanisms do not change with the rest time. Similar studies were also performed on Z-15 and Z-DOL(BW) films. The results are summarized in Fig. 28.11b [28.21]. It is seen that similar time effect has been observed on Z-15 film, but not on Z-DOL(BW) film.

AFM tip in contact with a flat sample surface is generally believed to represent a single asperity contact. Therefore, a Si_3N_4 tip in contact with Si(100) or Z-15/Si(100) can be modeled as a sphere in contact with a flat surface covered by a layer of liquid (adsorbed water and/or liquid lubricant), Fig. 28.12a. Meniscus forms around the contacting asperity and grows with time until equilibrium occurs [28.41]. The meniscus force, which is the product of meniscus pressure and meniscus area, depends on the flow of liquid phase toward the contact zone. The flow of the liquid toward the contact zone is governed by the capillary pressure P_c, which draws liquid into the meniscus, and the disjoining pressure Π, which tends to draw the liquid away from the meniscus. Based on the Young and Laplace equation, the capillary pressure, P_c, is:

$$P_c = 2K\gamma \,, \tag{28.3}$$

where $2K$ is the mean meniscus curvature ($= K_1 + K_2$, where K_1 and K_2 are the curvatures of the meniscus in the contact plane and perpendicular to the contact plane) and γ is the surface tension of the liquid. *Mate* and *Novotny* [28.6] have shown that the disjoining pressure decreases rapidly with increasing liquid film thickness in a manner consistent with a strong van der Waals attraction. The disjoining pressure, Π, for these liquid films can be expressed as:

$$\Pi = \frac{A}{6\pi h^3} \,, \tag{28.4}$$

where A is the Hamaker constant and h is the liquid film thickness. The driving forces that cause the lubricant flow that results in an increase in the meniscus force are the disjoining pressure gradient, due to a gradient in film thickness, and capillary pressure gradient, due to curved liquid-air interface. The driving pressure, P, can then be written as:

$$P = -2K\gamma - \Pi \,. \tag{28.5}$$

Based on these three basic relationships, the following differential equation has been derived by *Chilamakuri* and *Bhushan* [28.41], which can describe the meniscus at time t:

$$2\pi x_0 \left(D + \frac{x_0^2}{2R} - h_0 \right) \frac{dx_0}{dt} = \frac{2\pi h_0^3 \gamma}{3\eta} \frac{(1+\cos\theta)}{D + a - h_0} - \frac{A x_0}{3\eta h} \cot\alpha \,, \tag{28.6}$$

where η is the viscosity of the liquid and a is given as

$$a = R(1-\cos\phi) \sim \frac{R\phi^2}{2} \sim \frac{x_0^2}{2R} \,. \tag{28.7}$$

The differential equation (28.4) was solved numerically using Newton's iteration method. The meniscus force at any time t less than the equilibrium time is proportional to the meniscus area and meniscus pressure ($2K\gamma$), and it is given by

$$f_m(t) = 2\pi R\gamma(1+\cos\theta) \left(\frac{x_0}{(x_0)_{eq}} \right)^2 \left(\frac{K}{K_{eq}} \right) \,, \tag{28.8}$$

where $(x_0)_{eq}$ is the value of x_0 at the equilibrium time

$$\left[(x_0)_{eq}\right]^2 = 2R \left[\frac{-6\pi h_0^3 \gamma(1+\cos\theta)}{A} + (h_0 - D) \right] . \tag{28.9}$$

This modeling work (at the microscale) showed that the meniscus force initially increases logarithmically with the rest time up to a certain equilibrium time after which it remains constant. Equilibrium time decreases with an increase in liquid film thickness, a decrease in viscosity, and a decrease in the tip radius, Fig. 28.12b. This early numerical modeling work and the data at the nanoscale in Fig. 28.11a are in good agreement.

28.3.3 Velocity Effect

To investigate the velocity effect on friction and adhesion, the friction force versus normal load relationships of Si(100), Z-15, and Z-DOL(BW) at different velocities were measured, Fig. 28.13 [28.21]. Based on these data,

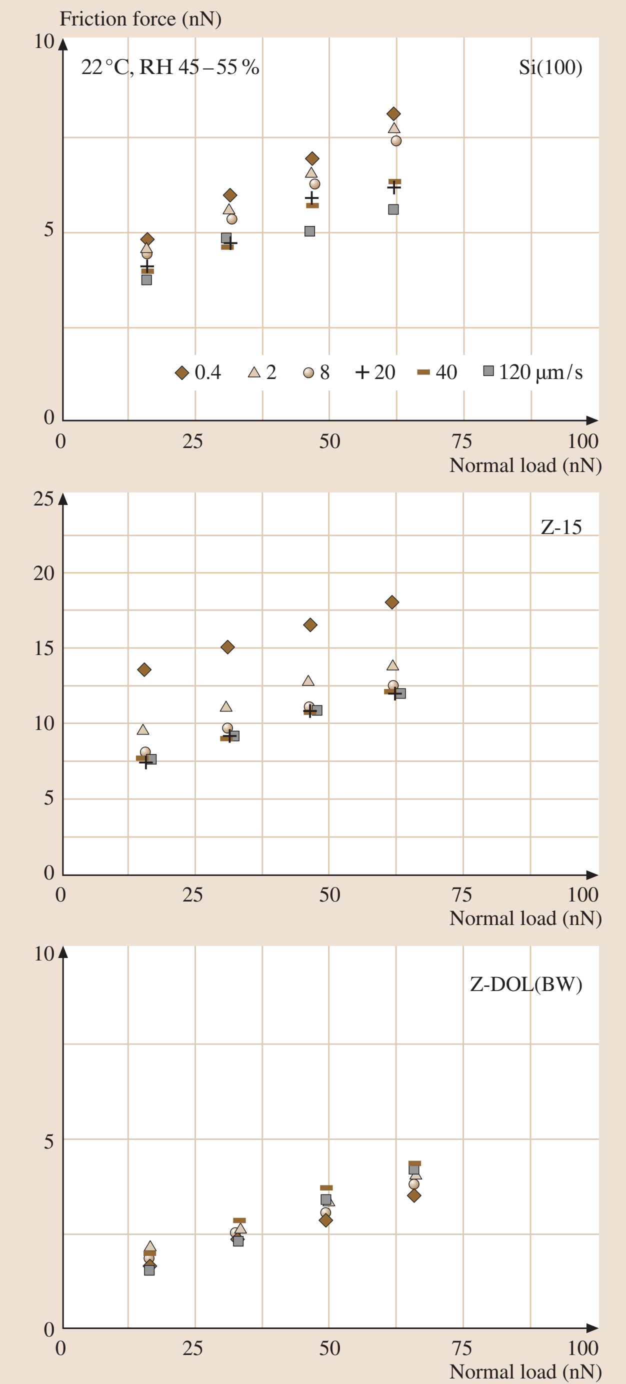

Fig. 28.13 Friction forces versus normal load data of Si(100), 2.8-nm-thick Z-15 film, and 2.3-nm-thick Z-DOL(BW) film at various velocities in ambient air [28.21]

the adhesive force and coefficient of friction values can be calculated by (28.1). The variation of friction force, adhesive force, and coefficient of friction of Si(100), Z-15, and Z-DOL(BW) as a function of velocity are summarized in Fig. 28.14. It indicates that for silicon wafer, the friction force decreases logarithmically with increasing velocity. For Z-15, the friction force decreases with increasing velocity up to 10 µm/s, after which it remains almost constant. The velocity has a much smaller effect on the friction force of Z-DOL(BW); it reduced slightly only at very high velocity. Figure 28.14 also indicates that the adhesive force of Si(100) is increased when the velocity is higher than 10 µm/s. The adhesive force of Z-15 is reduced dramatically with a velocity increase up to 20 µm/s, after which it is reduced slightly. And the adhesive force of Z-DOL(BW) also decreases at high velocity. In the testing range of velocity, only the coefficient of friction of Si(100) decreases with velocity, but the coefficients of friction of Z-15 and Z-DOL(BW) almost remain constant. This implies that the friction mechanisms of Z-15 and Z-DOL(BW) do not change with the variation of velocity.

The mechanisms of the effect of velocity on the adhesion and friction are explained based on the schematics shown in Fig. 28.14 (right). For Si(100), tribochemical reaction plays a major role. Although at high velocity the meniscus is broken and does not have enough time to rebuild, the contact stresses and high velocity lead to tribochemical reactions of Si(100) wafer and Si_3N_4 tip, which have native oxide (SiO_2) layers with water molecules. The following reactions occur:

$$SiO_2 + 2H_2O = Si(OH)_4 \quad (28.10)$$

$$Si_3N_4 + 16H_2O = 3Si(OH)_4 + 4NH_4OH\,. \quad (28.11)$$

The $Si(OH)_4$ is removed and continuously replenished during sliding. The $Si(OH)_4$ layer between the tip and Si(100) surface is known to be of low shear strength and causes a decrease in friction force and coefficient of friction in the lateral direction [28.42–46]. The chemical bonds of Si−OH between the tip and Si(100) surface induce large adhesive force in the normal direction. For Z-15 film, at high velocity the meniscus formed by condensed water and Z-15 molecules is broken and does not have enough time to rebuild. Therefore, the adhesive force and, consequently, friction force is reduced. For Z-DOL(BW) film, the surface can adsorb few water molecules in ambient condition, and at high velocity these molecules are displaced, which is responsible for a slight decrease in friction force and adhesive force. Even at high velocity range, the friction mechanisms for Z-15 and Z-DOL(BW) films still are shearing of the vis-

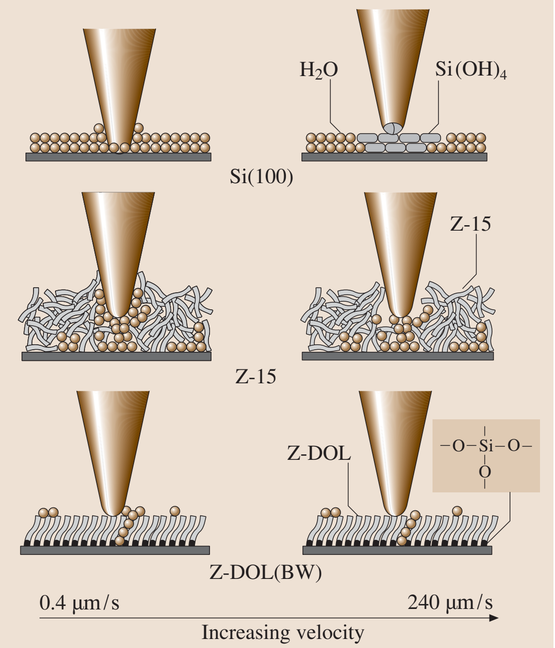

Fig. 28.14 The influence of velocity on the friction force, adhesive force, and coefficient of friction of Si(100), 2.8-nm-thick Z-15 film, and 2.3-nm-thick Z-DOL(BW) film at 70 nN, in ambient air. The schematic (*right*) shows the change of surface composition (by tribochemical reaction) and change of meniscus with increasing velocity [28.21]

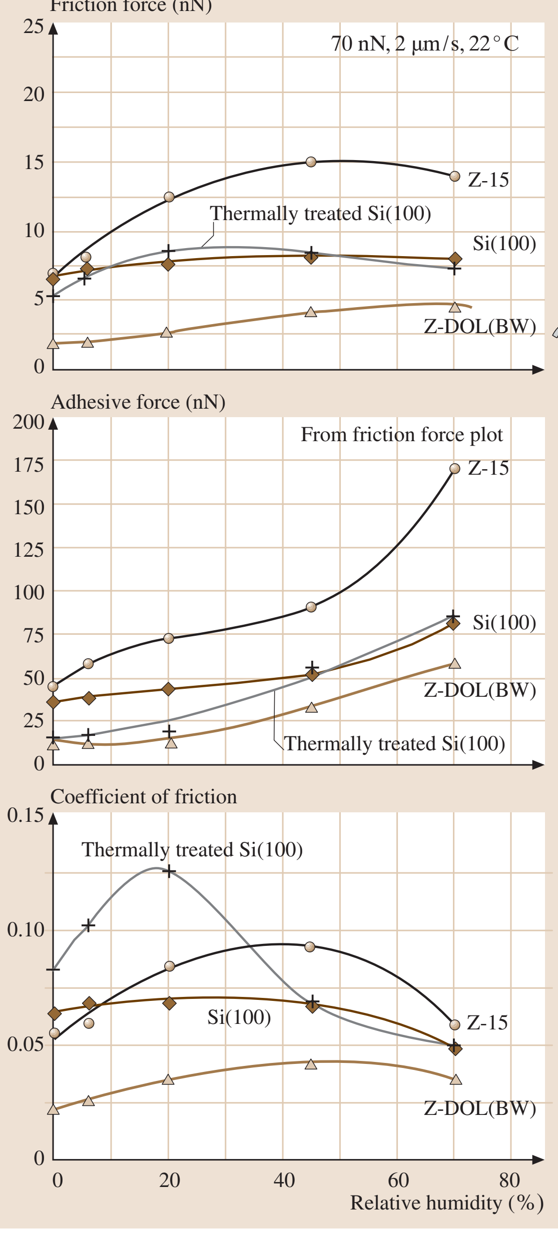
cous liquid and molecular orientation, respectively. Thus the coefficients of friction of Z-15 and Z-DOL(BW) do not change with velocity.

Koinkar and *Bhushan* [28.20, 34] have suggested that in the case of samples with mobile films, such as condensed water and Z-15 films, alignment of liquid molecules (shear thinning) is responsible for the drop in friction force with an increase in scanning velocity. This could be another reason for the decrease in friction force with velocity for Si(100) and Z-15 film in this study.

28.3.4 Relative Humidity and Temperature Effect

The influence of relative humidity on friction and adhesion was studied in an environmentally controlled chamber. The friction force was measured by making measurements at increasing relative humidity, the results are presented in Fig. 28.15 [28.21]. It shows that for Si(100) and Z-15 film, the friction force increases with a relative humidity increase up to RH 45%, and then it shows a slight decrease with a further increase in relative humidity. Z-DOL(BW) has a smaller friction force than Si(100) and Z-15 in the whole testing range. And its friction force shows a relatively apparent increase when the relative humidity is higher than RH 45%. For Si(100), Z-15, and Z-DOL(BW), adhesive



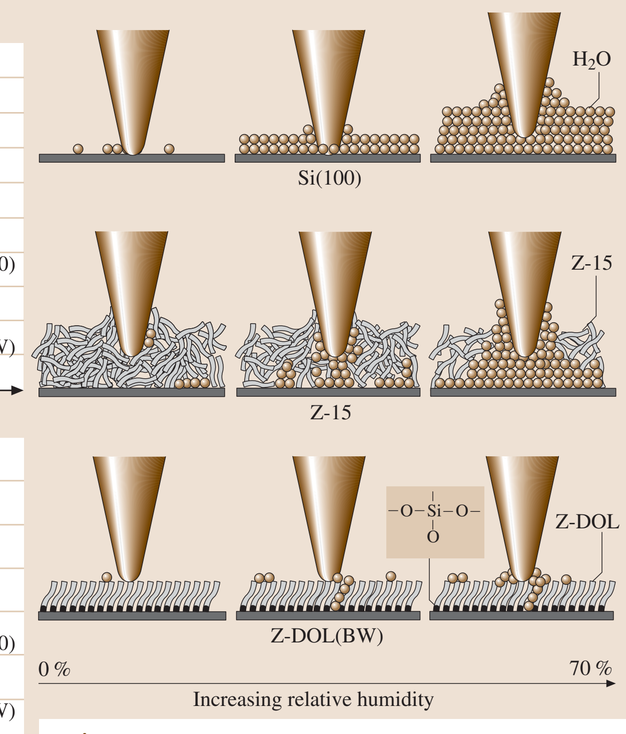


Fig. 28.15 The influence of relative humidity (RH) on the friction force, adhesive force, and coefficient of friction of Si(100), 2.8-nm-thick Z-15 film, and 2.3-nm-thick Z-DOL(BW) film at 70 nN, 2 µm/s, and in 22 °C air. Schematic (*right*) shows the change of meniscus with increasing relative humidity. In this figure, the thermally treated Si(100) represents the Si(100) wafer that was baked at 150 °C for 1 hour in an oven (in order to remove the adsorbed water) just before it was placed in the 0% RH chamber [28.21]

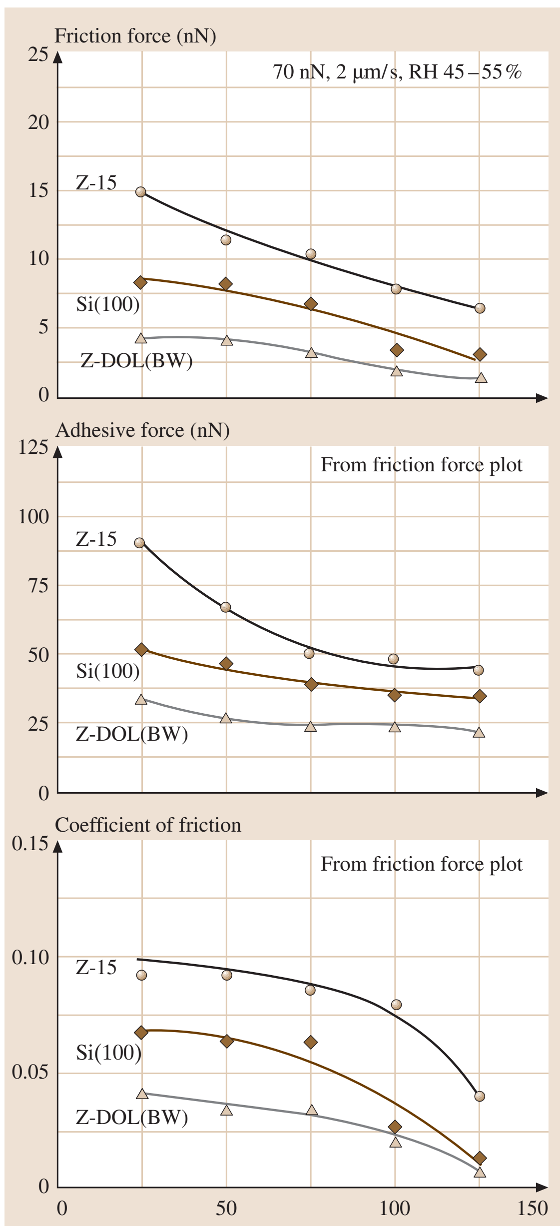
forces increase with relative humidity. And their coefficients of friction increase with a relative humidity up to RH 45%, after which they decrease with a further increase of the relative humidity. It is also observed that the humidity effect on Si(100) really depends on the history of the Si(100) sample. As the surface of Si(100) wafer readily adsorbs water in air, without any pre-treatment the Si(100) used in our study almost reaches its saturate stage of adsorbing water and is responsible for less effect during increasing relative humidity. However, once the Si(100) wafer was thermally treated by baking at 150 °C for 1 hour, a bigger effect was observed.

The schematic (right) in Fig. 28.15 shows that because its high free surface energy Si(100) can adsorb more water molecules with increasing relative humidity. As discussed earlier, for Z-15 film in a humid environment, condensed water competes with the lubricant film present on the sample surface. Obviously, more water molecules can also be adsorbed on a Z-15 surface with increasing relative humidity. The more adsorbed water



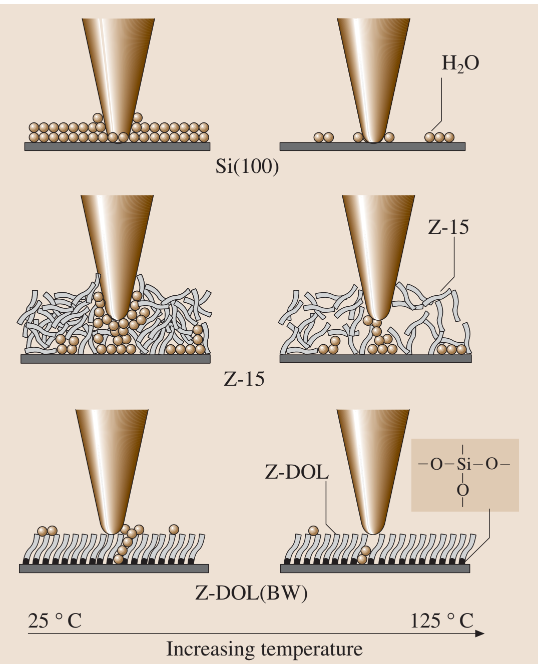


Fig. 28.16 The influence of temperature on the friction force, adhesive force, and coefficient of friction of Si(100), 2.8-nm-thick Z-15 film, and 2.3-nm-thick Z-DOL(BW) film at 70 nN, at 2 μm/s, and in RH 40–50 % air. The schematic (*right*) shows that at high temperature, desorption of water decreases the adhesive forces. And the reduced viscosity of Z-15 leads to the decrease of coefficient of friction. High temperature facilitates orientation of molecules in Z-DOL(BW) film, which results in lower coefficient of friction [28.21]

molecules in the case of Si(100), along with lubricant molecules in Z-15 film, form a bigger water meniscus, which leads to an increase of friction force, adhesive force, and coefficient of friction of Si(100) and Z-15 with humidity. But at very high humidity of RH 70%, large quantities of adsorbed water can form a continuous water layer that separates the tip and sample surface, and acts as a kind of lubricant, which causes a decrease in the friction force and coefficient of friction. For Z-DOL(BW) film, because of its hydrophobic surface properties, water molecules can only be adsorbed at high humidity (≥ RH 45%), which causes an increase in the adhesive force and friction force.

The effect of temperature on friction and adhesion was studied using a thermal stage attached to the AFM. The friction force was measured at increasing temperature from 22–125 °C. The results are presented in Fig. 28.16 [28.21]. It shows that the increasing temperature causes a decrease of friction force, adhesive force, and coefficient of friction of Si(100), Z-15, and Z-DOL(BW). The schematic (right) in Fig. 28.16 indicates that at high temperature, desorption of water leads

to the decrease of friction force, adhesive force, and coefficient of friction for all of the samples. Besides that, the reduction of surface tension of water also contributes to the decrease of friction and adhesion. For Z-15 film, the reduction of viscosity at high temperature has an additional contribution to the decrease of friction. In the case of Z-DOL(BW) film, molecules are more easily oriented at high temperature, which may also be responsible for the low friction.

Using a surface force apparatus, *Yoshizawa* and *Israelachvili* [28.47, 48] have shown that a change in the velocity or temperature induces phase transformation (from crystalline solid-like to amorphous, then to liquid-like) in surfactant monolayers, which are responsible for the observed changes in the friction force. Stick-slip is observed in a low velocity regime of a few μm/s, and adhesion and friction first increase followed by a decrease in the temperature range of 0–50 °C. Stick-slip at low velocity and adhesion and friction curves peaking at some particular temperature (observed in their study), have not been observed in the AFM study. It suggests that the phase transformation may not happen in this study, because PFPEs generally have very good thermal stability [28.10, 12].

As a brief summary, the influence of velocity, relative humidity, and temperature on the friction force of Z-15 film is presented in Fig. 28.17. The changing trends are also addressed in this figure.

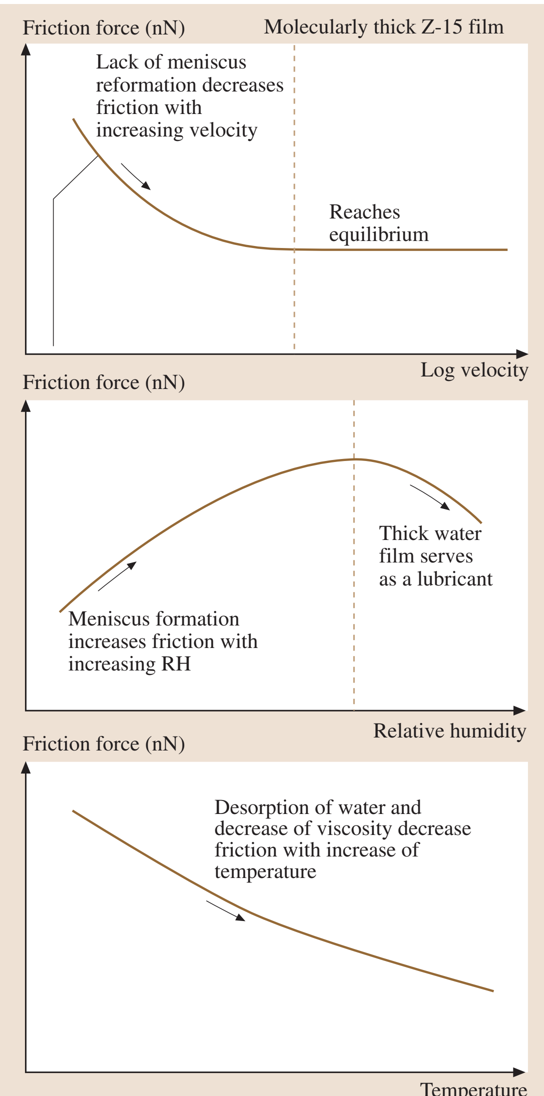

Fig. 28.17 Schematic shows the change of friction force of molecularly thick Z-15 films with log velocity, relative humidity, and temperature [28.21]

28.3.5 Tip Radius Effect

The tip radius and relative humidity affect adhesion and friction for dry and lubricated surfaces [28.35, 36]. Figure 28.18a shows the variation of single point adhesive force measurements as a function of tip radius on a Si(100) sample for several humidities. The adhesive force data are also plotted as a function of relative humidity for various tip radii. Figure 28.18a indicates that the tip radius has little effect on the adhesive forces at low humidities, but the adhesive force increases with tip radius at high humidity. Adhesive force also increases with an increase in humidity for all tips. The trend in adhesive forces as a function of tip radii and relative humidity, in Fig. 28.18a, can be explained by the presence of meniscus forces, which arise from capillary condensation of water vapor from the environment. If enough liquid is present to form a meniscus bridge, the meniscus force should increase with an increase in tip radius based on (28.2). This observation suggests that thickness of the liquid film at low humidities is insufficient to form continuous meniscus bridges and to affect adhesive forces in the case of all tips.

Figure 28.18a also shows the variation in coefficient of friction as a function of tip radius at a given humidity and as a function of relative humidity for a given tip radius on the Si(100) sample. It can be observed that for RH 0%, the coefficient of friction is about the same for the tip radii except for the largest tip, which shows

Fig. 28.18a,b Adhesive force and coefficient of friction as a function of tip radius at several humidities and as a function of relative humidity at several tip radii on **(a)** Si(100) and **(b)** 0.5-nm Z-DOL(BW) films [28.35]

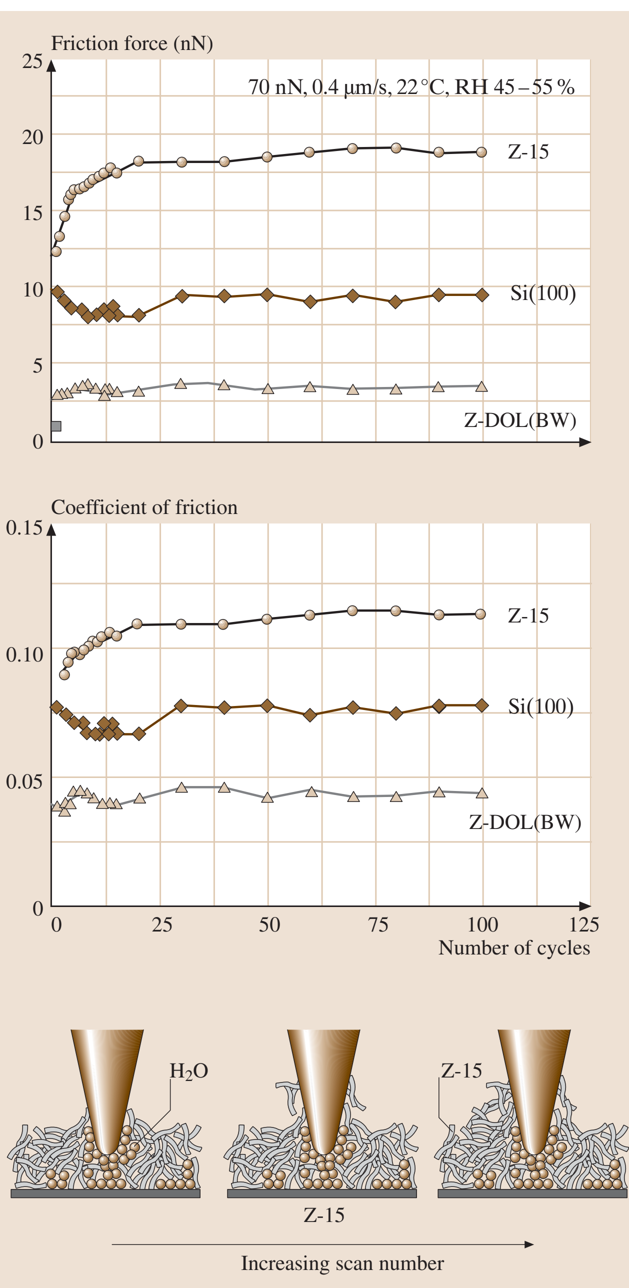

Fig. 28.19 Friction force and coefficient of friction versus number of sliding cycles for Si(100), 2.8-nm-thick Z-15 film, and 2.3-nm-thick Z-DOL(BW) film at 70 nN, 0.8 µm/s, and in ambient air. Schematic (*bottom*) shows that some liquid Z-15 molecules can be attached on the tip. The molecular interaction between the attached molecules on the tip with the Z-15 molecules in the film results in an increase of the friction force with multiple scanning [28.21]

a higher value. At all other humidities, the trend consistently shows that the coefficient of friction increases with tip radius. An increase in friction with tip radius at low to moderate humidities arises from increased contact area (i. e., higher van der Waals forces) and higher values of shear forces required for a larger contact area. At high humidities, similar to adhesive force data, an increase with tip radius occurs due to of both contact area and meniscus effects. It can be seen that for all tips, the coefficient of friction increases with humidity to about RH 45%, beyond which it starts to decrease. This is attributed to the fact that at higher humidities, the adsorbed water film on the surface acts as a lubricant between the two surfaces [28.21]. Thus the interface is changed at higher humidities, resulting in lower shear strength and, hence, lower friction force and coefficient of friction.

Figure 28.18b shows adhesive forces as a function of tip radius and relative humidity on Si(100) coated with 0.5-nm-thick Z-DOL(BW) film. Adhesive forces for all the tips with the Z-DOL(BW) lubricated sample are much lower than those experienced on unlubricated Si(100), shown in Fig. 28.18a. The data also show that even at a monolayer thickness of the lubricant there is very little variation in adhesive forces with tip radius at a given humidity. For a given tip radius, the variation in adhesive forces with relative humidity indicates that these forces slightly increase from RH 0% to RH 45%, but remain more or less the same with a further increase in humidity. This is seen even with the largest tip, which indicates that the lubricant is indeed hydrophobic; there is some meniscus formation at humidities higher than RH 0%, but the formation is very minimal and does not increase appreciably even up to RH 65%. Figure 28.18b also shows coefficient of friction for various tips at different humidities for the Z-DOL(BW) lubricated sample. Again, all the values obtained with the lubricated sample are much lower than the values obtained on unlubricated Si(100), shown in Fig. 28.18a. The coefficient of friction increases with tip radius for all humidities, as was seen on unlubricated Si(100), due to an increase in the contact area. Similar to the adhesive forces, there is an increase in friction from RH 0% to RH 45%, due to a contribution from an increased number of menisci bridges. But thereafter there is very little additional water film forming, due to the hydropho-

bicity of the Z-DOL(BW) layer, and, consequentially, the coefficient of friction does not change appreciably, even with the largest tip. These findings show that even a monolayer of Z-DOL(BW) offers good hydrophobic performance of the surface.

28.3.6 Wear Study

To study the durability of lubricant films at the nanoscale, the friction of Si(100), Z-15, and Z-DOL(BW) as a function of the number of scanning cycles was measured, Fig. 28.19 [28.21]. As observed earlier, friction force and coefficient of friction of Z-15 is higher than that of Si(100), and Z-DOL(BW) has the lowest values. During cycling, friction force and coefficient of friction of Si(100) show a slight variation during the initial few cycles then remain constant. This is related to the removal of the top adsorbed layer. In the case of Z-15 film, the friction force and coefficient of friction show an increase during the initial few cycles and then approach higher and stable values. This is believed to be caused by the attachment of the Z-15 molecules onto the tip. The molecular interaction between these attached molecules to the tip and molecules on the film surface is responsible for an increase in the friction. But after several scans, this molecular interaction reaches the equilibrium, and after that, friction force and coefficient of friction remain constant. In the case of Z-DOL(BW) film, the friction force and coefficient of friction start out low and remain low during the entire test for 100 cycles. It suggests that Z-DOL(BW) molecules do not get attached or displaced as readily as Z-15.

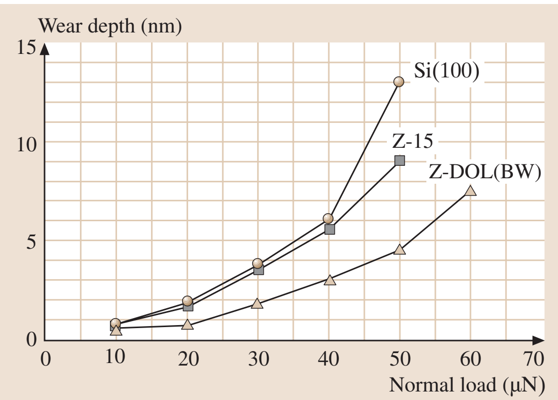

Fig. 28.20 Wear depth as a function of normal load using a diamond tip for Si(100), 2.9-nm-thick Z-15 film, and 2.3-nm-thick Z-DOL(BW) after one cycle [28.20]

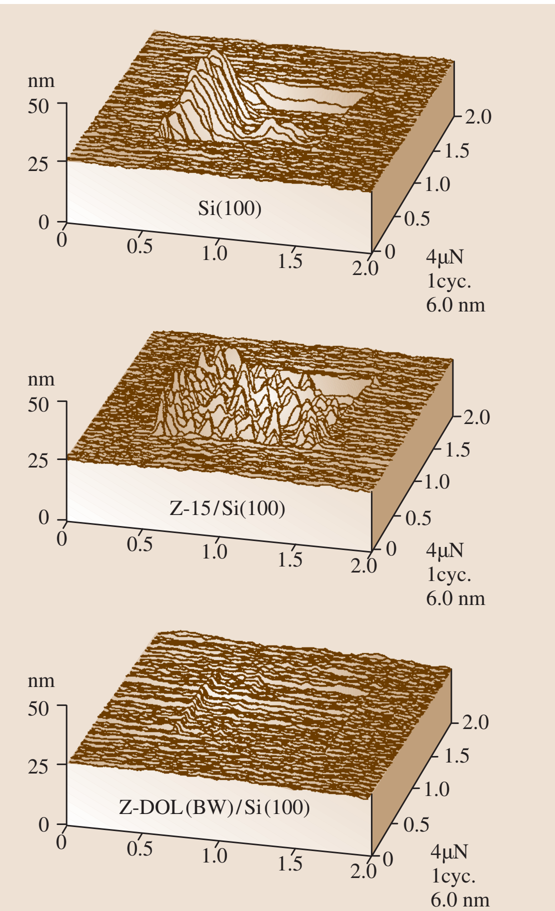

Fig. 28.21 Wear profiles for Si(100), 2.9-nm-thick Z-15 film, and 2.3-nm-thick Z-DOL(BW) film after wear studies using a diamond tip. Normal force used and wear depths are listed in the figure [28.20]

Koinkar and *Bhushan* [28.20, 34] conducted wear studies using a diamond tip at high loads. Figure 28.20 shows the plots of wear depth as a function of normal force, and Fig. 28.21 shows the wear profiles of the worn samples at 40 μN normal load. The 2.3-nm-thick Z-DOL(BW) lubricated sample exhibits better wear resistance than unlubricated and 2.9-nm-thick Z-15 lubricated silicon samples. Wear resistance of a Z-15 lubricated sample is little better than that of unlubricated sample. The Z-15 lubricated sample shows debris inside the wear track. Since the Z-15 is a liquid lubricant, debris generated is held by the lubricant and they become sticky. The debris moves inside the wear track

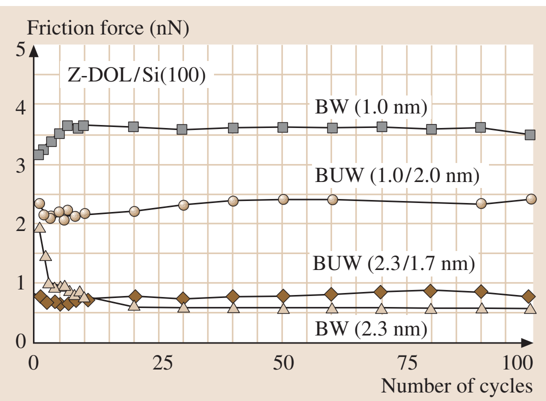

Fig. 28.22 Friction force as a function of number of cycles using a Si_3N_4 tip at a normal load of 300 nN for Z-DOL(BW) and Z-DOL(BUW) films with different film thicknesses [28.34]

and does damage, Fig. 28.20. These results suggest that using Z-DOL(BW) can improve the wear resistance of substrate.

To study the effect of the degree of chemical bonding, the durability tests were conducted on both fully bonded and partially bonded Z-DOL films. Durability results for Z-DOL(BW) and Z-DOL bonded and unwashed (Z-DOL(BUW), a partially bonded film that contains both bonded and mobile phase lubricants) with different film thicknesses are shown in Fig. 28.22 [28.34]. Thicker films, such as Z-DOL(BUW), with a thickness of 4.0 nm (bonded/mobile = 2.3 nm/1.7 nm) exhibit behavior similar to 2.3-nm-thick Z-DOL(BW) film. Figure 28.22 also indicates that Z-DOL(BW) and Z-DOL(BUW) films with a thinner film thickness exhibit a higher friction value. Comparing 1.0-nm-thick Z-DOL(BW) with 3.0-nm-thick Z-DOL(BUW) (bonded/mobile = 1.0 nm/2.0 nm), the Z-DOL(BUW) film exhibits a lower and stable friction value. This is because the mobile phase on a surface acts as a source of lubricant replenishment. A similar conclusion has also been reported by *Ruhe* et al. [28.19], *Bhushan* and *Zhao* [28.13], and *Eapen* et al. [28.49]. All of them indicate that using partially bonded Z-DOL films can dramatically reduce the friction and improve the wear life.

28.4 Closure

Nanodeformation study has shown that fully bonded Z-DOL lubricants behave as soft polymer solids, while the unbonded lubricants behave liquid-like. AFM studies have shown that the physisorbed nonpolar molecules on a solid surface have an extended, flat conformation. The spreading property of PFPE is strongly dependent on the molecular end groups and substrate chemistry.

Using solid-like Z-DOL(BW) film can reduce the friction and adhesion of Si(100), while using liquid-like lubricant of Z-15 shows a negative effect. Si(100) and Z-15 film show apparent time effect. The friction and adhesion forces increase as a result of growth of meniscus up to an equilibrium time, after which they remain constant. Using Z-DOL(BW) film can prevent time effects. High velocity leads to the rupture of meniscus and prevents its reformation, which leads to a decrease of friction and adhesive forces of Z-15 and Z-DOL(BW). The influence of relative humidity on the friction and adhesion is dominated by the amount of the adsorbed water molecules. Increasing humidity can either increase friction through increased adhesion by water meniscus, or reduce friction through an enhanced water-lubricating effect. Increasing temperature leads to desorption of water layer, decrease of water surface tension, decrease of viscosity, and easier orientation of the Z-DOL(BW) molecules. These changes cause a decrease of friction force and adhesion at high temperature. During cycling tests, the molecular interaction between the attached Z-15 molecules to the tip and the Z-15 molecules on the film surface causes the initial rise of friction. Wear tests show that Z-DOL(BW) can improve the wear resistance of silicon. Partially bonded PFPE film appears to be more durable than fully bonded films.

These results suggest that partially/fully bonded films are good lubricants for devices operating in different environments and under varying conditions.

29. Kinetics and Energetics in Nanolubrication

Lubrication, one of human kind's oldest engineering disciplines, in the 19th century gained from Reynolds' classical hydrodynamic description a theoretical base unmatched by most of the theories developed in tribology to date. In the 20th century, however, increasing demands on lubricants shifted the attention from bulk film to ultrathin film lubrication. Finite size limitations imposed constraints on the lubrication process that were not considered in bulk phenomenological treatments introduced by Reynolds. At this point, as is common in many engineering applications, empiricism took over. Functional relationships derived from the classical theories were tweaked to accommodate the new situation of reduced scales by introducing "effective" or "apparent" properties.

With the inception of nanorheological tools of complementary nature in the later decades of the 20th century (e.g., the surface forces apparatus and scanning force microscopy), tribology entered the realm of nanoscience. Through an increasing confidence in experimental findings on the nanoscale, kinetic and energetic theories incorporated interfacial and molecular constraints.

The very fundamentals have been challenged in recent years. Researchers have realized that bulk perceptions, such as "solid" and "liquid" are defied on the nanoscale. The reduction in dimensionality of the nanoscale imposes constraints that bring into question the use of classical statistical mechanics of decoupled events. The diffusive description of lubrication is failing in a system that is thermodynamically not well-equilibrated.

The challenge any nanotechnological endeavor encounters is the development of a theoretical framework based on an appropriate statistics. In tribology this is met with spectral descriptions of the dynamic sliding process. Statistical kernels are being developed for probability density functions to explain anomalous transport processes that involve long-range spatial or temporal correlations. With such theoretical developments founded in nanorheological experiments, a more realistic foundation will be laid to describe the behavior of lubricants in the confined geometries of the nanometer length scale.

Strong reasons have come to support a growing probability, and it can finally be said the certainty, in favor of the hypothesis of the atomists. (Jean Baptiste Perrin – Nobel Lecture, December 11, 1926)

Since technology is driving lubricant films to molecular thickness, kinetic friction and its dependence on the sliding parameters – especially the sliding velocity – have become of great interest. The complexity of the frictional resistance in lubricated sliding is illustrated in Fig. 29.1 with a *Stribeck Curve*. Various regimes of lubrication can be identified in the Stribeck curve. They express to what degree the hydrodynamic pressure is involved in the lubrication process. In the ultra-low speed regime, called the *boundary lubrication regime*, no hydrodynamic pressure is built up in the lubricant. Consequently the load is carried by contact asperities coated with adsorbed lubricant molecules. If the speed is raised, a hydrodynamic pressure builds that leads to a *mixed lubrication*, in which the load is carried by both asperities and hydrodynamic pressure. At even higher speeds, elastic contributions of the solid surfaces have to be considered paired with hydrodynamic pressure effects (elastohydrodynamic lubrication), until only *hydrodynamic lubrication* matters. Hence, the Stribeck curve combines various aspects of lubrication. The curve cannot be discussed without considering the lubricant thickness and the different models of asperity contact sliding.

In one of the first comprehensive physical models of "dry" friction, Bowden and Tabor introduced a plastic asperity model, in which the material's yield stress and adhesive properties play an important role [29.1]. Considering this model, which depends on surface energies and mechanical yield properties paired with all the properties that come along with a surface adsorbent lubricant, one can hardly grasp the difficulty level involved in describing the frictional kinetics in lubrication.

Past and current engineering challenges in lubrication have been met with great and complex empiricism. The theoretical modeling of lubrication junctions generally involved only bulk property considerations with inadequately known adsorption mechanisms. The complexity of today's lubricants, most of them, such as motor oil, a product of empirical design over many years, increased exponentially, making it very difficult to meet future challenges. The problem of empiricism is that conventional laws and perceptions are unchallenged. *Effective* quantities are invented (e.g., effective viscosity), exponential fitting parameters are introduced (e.g., Kohlrausch relaxation parameter), and terminologies such as *solid* and *liquid* are taken as granted. Progress based on empiricism is only incremental and rarely revolutionary.

One of the reasons for empiricism is a lack of access to a system with fewer and better controlled parameters. In lubrication sliding that challenge has been addressed over the last two decades with the inception of the surface forces apparatus (SFA) by *Tabor* et al. [29.2] and scanning force microscopy (SFM) by *Binnig* et al. [29.3]. These two instrumental methods allow lubrication studies where roughness effects can be neglected, surface energies controlled, and wear from wearless friction distinguished. Lubricant properties can be studied at nearly mathematically described boundaries, atomistic friction events can be recorded, and fundamental models that have been considered to be mere Gedanken Experiments, such as the *Tomlinson model of friction*, can be verified. In the wake of these nanoscopic tools, exciting new theoretical lubrication and friction models have appeared.

This chapter considers these recent experimental and theoretical developments with a particular focus on sliding speed and real or apparent changes in the lubricant material properties. We will discuss kinetics and energetics in the "simplified" world of nanolubrication, in which our conventional perception is challenged. After a brief review of some of the classical lubrication concepts (hydrodynamic lubrication and boundary lubrication), we will turn our attention to a thermal activation model of friction, functional behavior of lubricated friction with velocity, and models based on small non-conforming contacts. We will critically discuss the limitation of the underlying Gaussian statistics, introduce fractal dynamics in lubrication, and will end our discussion with metastable lubricant systems.

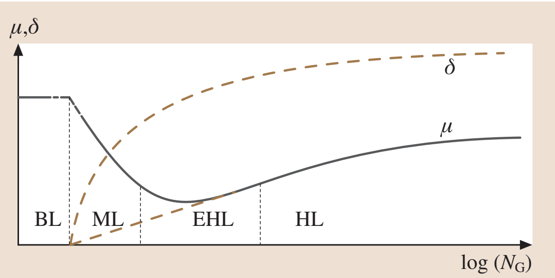

Fig. 29.1 Stribeck Curve (schematic) relates the fluid lubricant thickness, δ, and the friction coefficient μ to the Gumbel Number $N_G = \eta\omega P^{-1}$; i.e., the product of the liquid bulk viscosity, η, the sliding speed (or more precisely the shaft frequency), ω, and the inverse of the normal pressure, P. 29.1 Background: From Bulk to Molecular Lubrication

29.1.1 Hydrodynamic Lubrication and Relaxation

In the classical theories of tribology by da Vinci, Amonton, and Coulomb, not much attention was given to the dependence of kinetic friction on the sliding velocity. This clearly changed in the 19th century during the first industrial revolution, at which time lubricants became increasingly important, for instance, in ball and journal bearings. It was *Petrov* [29.4], *Tower* [29.5], and *Reynolds* [29.6] who established that the liquid viscous shear properties determine the frictional kinetics. *Reynolds* [29.6] combined the pressure-gradient determined *Poisseuille flow* with the bearing surface induced *Couette flow* assuming, based on Petrov's law [29.4], a no-slip condition at the interface between lubricant and solid. This led to the widely used linear relationship between friction and velocity. Reynolds' hydrodynamic theory of lubrication can be applied to steady state sliding at constant relative velocity and to transient decay sliding (sliding is stopped from an initial velocity v and a corresponding shear stress τ_0), which leads to the classical Debye exponential relaxation behavior, i. e.:

$$\tau = \tau_0 \exp\left(\frac{-D}{A\eta}t\right) ; \quad \tau_0 \propto \frac{v\eta}{D} . \tag{29.1}$$

D is the lubricant thickness, A the area of the slider, and η the viscosity of the fluid. We will later see that this classical exponential relaxation behavior, obtained in a thermodynamically well-mixed three dimensional medium, is distorted when the liquid film thickness is reduced to molecular dimensions.

29.1.2 Boundary Lubrication

Reynolds hydrodynamic description of lubrication was found to work well for thick lubricant films but to break down for thinner films. One manifestation is that for films on the order of ten molecular diameters, the stress in the film does not allow the tension to return to zero. It was also found that the motion in the steady state sliding regime was disrupted, exhibiting a stick–slip-like slider motion [29.7]). Consequently, this non-Newtonian behavior was treated with a modified viscosity parameter (effective viscosity), which was composed of the pressure, temperature, and rate of shear.

The term *Boundary Lubrication* is used to describe a lubricant that is reduced in thickness to molecular dimension and effectively reduces friction between two opposing solid surfaces. *Hardy* et al. [29.8] recognized that molecular properties such as molecular weight and molecular arrangement, are governing the frictional force. This confined concept of lubrication, often visualized by two highly ordered opposing films with shear taking place somewhere in between the two layers, contains many of the rate dependent manifestations of frictional sliding; e.g., stick–slip, ultra-low friction, transitions from high to low friction, phase transitions, dissipation due to dislocations (e.g., gauche and cis-transformations), and memory effects.

Boundary lubrication was found to be in many respects unique [29.9]. In macroscopic experiments, which involved rough surfaces, friction–velocity plots resembled logarithmic functions at moderate speeds. No static stiction force peaks were observed in boundary lubricants close to zero speed. On the contrary, retractive slips could be observed upon halting, constituting a static friction coefficient exceeded by the dynamic friction coefficient [29.9]. These unique manifestations of boundary lubrication were discussed in terms of a lubricated asperity–junction mechanism, which associated "an increase in the coefficient of friction with a decrease in the adsorptive coverage of the rubbing surfaces by the lubricant substance" [29.9]. It was argued that in the course of the sliding process of a macroscopic slider, more adsorbed lubricant is expected to exist within the interfacial area than outside the contact zone. This would lead upon halting to a relaxation process of the elastic restraints on the slider, causing the slider to a retractively slip.

29.1.3 Stick Slip and Collective Phenomena

Based on numerous friction experiments at the initiation of sliding with rough macroscopic contact, it was argued that the distinction between static and kinetic friction is not categorical but rather a manifestation of the apparatus [29.9]. This was a widely held opinion prior to *Briscoe*'s et al. [29.10] molecularly smooth monolayer SFA experiments of aliphatic carboxylic acids and their soaps. Briscoe found that the character of sliding motion (continuous vs. discontinuous), depends not only on the apparatus but also on the properties (chemistry) of the monolayer. As in the rough boundary layer experiments discussed above, Briscoe's molecularly smooth monolayer experiments exhibited logarithmic-like friction–velocity behaviors.

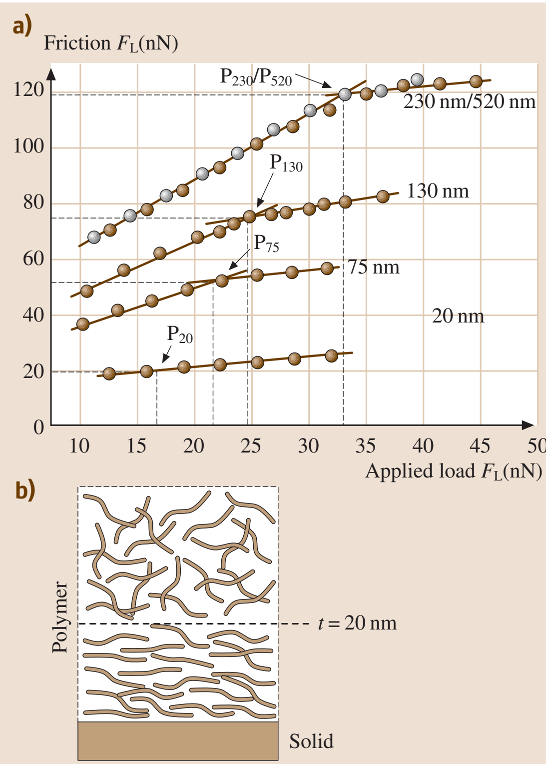

Fig. 29.2 (a) SFM friction measurements at a speed 1 μm/s: Cooperative molecular response of polyethylene co-propylene to frictional shear forces as a function of the applied load. P_t (t corresponds to the thickness of the polymer film) represents the critical activation load at which collective sliding is energetically more favorable than local plastic yielding. Adapted from [29.11]. **(b)** Sketch of the degree of disentanglement in the vicinity to the solid substrate surface

It was *Israelachvili* et al. [29.7] who, based on SFA experiments and computer simulations, provided a molecular picture of the stick–slip behavior caused by the lubricant material. The major achievement of this work was to draw our attention to the molecular structure of the lubricant, which is often different from the bulk and unstable during the sliding motion. It was recognized that bulk rheology failed to describe the lubrication process. Finally addressed in the Israelachvili study were in-plane structuring of simple liquids caused by compression forces and "freezing–melting" transitions due to shear.

The simple concept of a freezing–melting transition is based on a common perception of the two distinctive parts of a stick–slip occurrence: the solid (Hookian)-like sticking part and the liquid (Newtonian)-like slipping part. But a deformation of a solid can be both, coordinated or uncoordinated, and thus can exhibit both solid-like and liquid-like behavior. For instance, most of the plastic yielding processes are uncoordinated. On the other hand, slipping within a solid, along a crystal plane in a thermally activated strain-release process for instance, is a highly coordinated molecular process [29.12].

Similar arguments can be made for a liquid. For example, stick–slip behaviors were observed in more complex fluidic systems by *Reiter* et al. [29.13], who compared a molecularly "wet" lubricant film with a "dry" self-assembled monolayer lubricant. They concluded that sliding in liquid films is the result of slippage along an interface. In other words, the degree of molecular cooperation determined the frictional resistance.

The concept of local-*versus*-cooperative yield to shear is briefly illustrated here with a frictional-load study of a molecularly entangled polymer melt obtained in a SFM study of *Buenviaje* et al. [29.11]. Each of the curves presented in Fig. 29.2a represents a polymer film of polyethylene co-propylene of distinctly different degree of entanglement. Films of thickness above 230 nm exhibit the strongest entanglement strength. Films of 20 nm thickness or thinner are fully disentangled. The reason for the film thickness-dependent entanglement strength is given by the substrate distance-dependent shear strength during the spin coating process of the thin films. For entangled films SFM friction studies exhibit a critical applied load (identified by P_t, and the thickness t) that separates two friction regimes: One identified by a high friction coefficient and the other by a low friction coefficient. At loads below P_t the friction coefficients are high, indicating plastic yielding during sliding. In these plastic regimes of sliding, molecular cooperation is low, leading to high local shear stresses compensated by local yielding of the material. Above the critical load, the friction coefficient drops, independent of the film thickness, to a low value of 3.0, corresponding to the value obtained from the fully disentangled film. Note that the polymer molecules in the 20-nm-thick film experience high substrate tangential stresses during the spin coating process. Hence the disentangled polymer molecules can be considered to be aligned preferentially along the substrate surface as sketched in Fig. 29.2b. This leads to a decrease of the structural entropy the closer the material is to the solid substrate surface. Considering the matching friction coefficient

of 0.3 above P_t for thicker films, we can assume that any entangled film above a critical load exhibits a similar molecular collective response toward shear as the 20 nm film during spin coating. The critical load and its related pressure represent a barrier that has to be overcome before a collective phenomenon is activated.

29.2 Thermal Activation Model of Lubricated Friction

With the discussion of shear in entangled polymer systems we have introduced structural entropy as one of the key players that affect frictional resistance in lubricants. We found that the structural entropy was affected by the load of the slider, which introduces an activation barrier in the form of a critical pressure. The terminology used here resembles the one of the Eyring theory of molecular liquid transport [29.14].

Eyring discussed a pure liquid at rest in terms of a thermal activation model. The individual liquid molecules experience a "cage-like" barrier that hinders molecular free motion, because of the close packing in liquids. To escape from the cage an activation barrier needs to be surmounted. In Eyring's model, two processes are considered in order to overcome the potential barrier: (i) shear stresses and (ii) thermal fluctuations. The potential barrier in the thermal activation model is depicted in Fig. 29.3 indicating the barrier modification by the applied pressure force P, and shear stress τ. *Briscoe* et al. [29.10] picked up on this idea to interpret the frictional behavior observed on molecularly smooth monolayer systems. Starting from the overall barrier height $E = Q + P\Omega - \tau\phi$ that is repeatedly overcome during a discontinuous sliding motion, using a Boltzmann distribution to determine the average time for single molecular barrier-hopping, and assuming a regular series of barriers and a high stress limit ($\tau\Phi/kT > 1$), the following shear strength versus velocity v relationship was derived [29.10]:

$$\tau = \frac{k_B T}{\phi} \ln\left(\frac{v}{v_0}\right) + \frac{1}{\phi}(Q + P\Omega) \ . \tag{29.2}$$

The barrier height, E, is composed of the process activation energy Q, the compression energy $P\Omega$, where P is the pressure acting on the volume of the junction Ω, and the shear energy $\tau\phi$, where τ is the shear strength acting on the stress activation volume ϕ. T represents the absolute temperature. The stress activation volume ϕ can be conceived as a process coherence volume and interpreted as the size of the moving segment in the unit shear process, whether it is a part of a molecule or a dislocation line. The most critical parameter in (29.2), v_0, is a characteristic velocity related to the frequency of the process and to a jump distance (discussed further below).

From (29.2) the following iso-relationships can be directly deduced [29.10]:

$$\tau = \tau_0 + \alpha P \ ; \quad \tau_0 = \frac{1}{\phi}\left(k_B T \ln\left(\frac{v}{v_0}\right) + Q\right) \ ;$$
$$\alpha = \frac{\Omega}{\phi} \ ; \text{at constant } v, T \ , \tag{29.3a}$$
$$\tau = \tau_1 - \beta T \ ; \quad \tau_1 = \frac{1}{\phi}(Q + P\Omega) \ ;$$
$$\beta = -\frac{k}{\phi} \ln\left(\frac{v}{v_0}\right) \ , \quad \text{at constant } P, v \ , \tag{29.3b}$$
$$\tau = \tau_2 + \theta \ln v \ ; \quad \tau_2 = \frac{1}{\phi}(Q + P\Omega - kT \ln v_0) \ ;$$
$$\theta = \frac{kt}{\phi} \ , \quad \text{at constant } P, T \ . \tag{29.3c}$$

Thus Eyring's model predicts a linear relationship of friction (the product of the shear strength and the active process area) in pressure and temperature and a logarithmic relationship in velocity.

Eyring's model has been verified in lubrication experiments of solid (soap-like) lubricants by Briscoe and liquid lubricants by *He* et al. [29.15] within

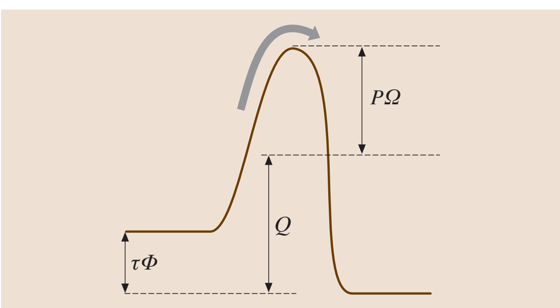

Fig. 29.3 Potential barrier in a lubricant based on Eyring's thermodynamic "cage-model." The normal pressure P and the shear stress τ are modifying the barrier height Q. Modified from [29.10]

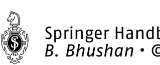

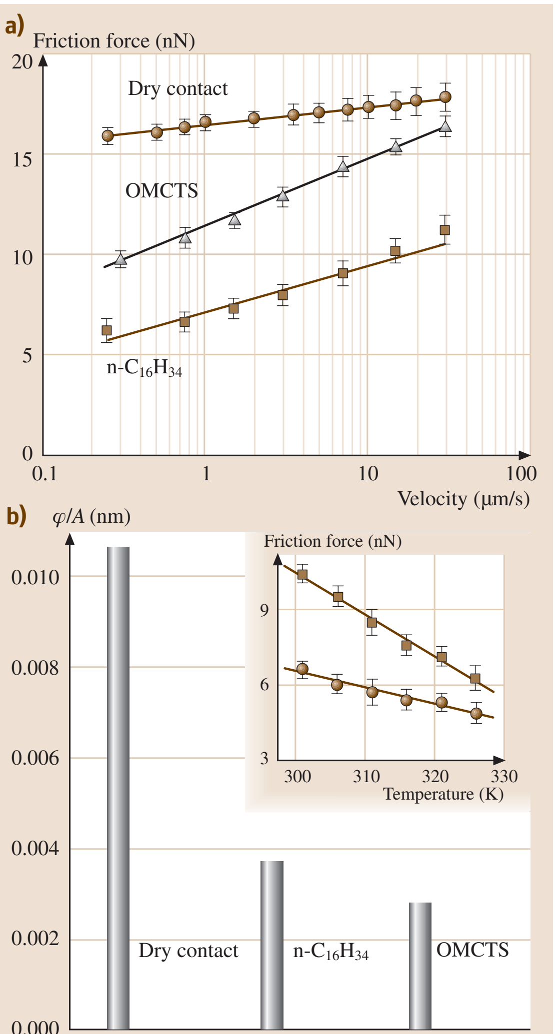

Fig. 29.4 **(a)** Logarithmic $F_F(v)$-plots. $F_F(v) = F_0 + \alpha \ln(v[\mu m/s])$: ● "dry" contact (18% relative humidity) with $F_0 = 16.4$ nN and $\alpha = 0.91$ nN, △ OMCTS lubricated with $F_0 = 11.3$ nN and $\alpha = 3.4$ nN, and ■ n-hexadecane (n-$C_{16}H_{34}$) lubricated with $F_0 = 7.1$ nN and $\alpha = 2.5$ nN. The measurements were obtained with rectangular SFM cantilevers (0.4–0.8 N/m) at 100 nN load and 21 °C, both feedback-controlled. **(b)** Stress activation length, ϕ/A. (A area of contact) for OMCTS, n-hexadecane and dry contact. The *inset* provides a linear relationship between friction and temperature at a velocity of 1 µm/s and a normal load of 100 nN. Adapted from [29.15]

three logarithmic decades of velocities. While *Briscoe* et al. [29.10] employed a SFA that confines and pressurizes the film over several square microns, He et al. used a SFM system in which the contact is on the order of the lubricant molecular dimension.

He et al. determined the degree of interfacial structuring and its effect on lubrication of n-hexadecane and octamethylcyclotetrasiloxane (OMCTS). For spherically shaped OMCTS molecules, only an interfacial "monolayer" was found; in contrast, a 2-nm-thick entropically cooled layer was detected for n-hexadecane in the boundary regime to an ultra-smooth silicon wafer. SFM measurements of the two lubricants (with similar chemical affinity to silicon) identified the molecular shape of n-hexadecane responsible for augmented interfacial structuring. Consequently, interfacial liquid structuring was found to reduce lubricated friction, Fig. 29.4. Again as reasoned above, these results can be discussed in terms of a collective phenomenon, i.e., in terms of increased molecular coordination in n-hexadecane versus OMCTS.

29.3 Functional Behavior of Lubricated Friction

Friction-rate experiments are well suited to evaluate the rheological nature of interfacial liquids. In classical theories, such as the Reynolds' hydrodynamic theory discussed above, drag forces in lubricated sliding over thick liquid films were found to depend linearly on the rate of sliding and on the viscosity of the bulk fluid. In high-pressure lubrication, described by the elastohydrodynamic lubrication theory [29.16, 17], it was found that the linear relationship between friction and velocity can be retained by adjusting the (apparent) viscosity by introducing an *apparent viscosity term*. Qualitatively, the same linear relationship has been observed for highly confined simple liquids between ultrasmooth mica surfaces such as alkanes [29.18]. Note that the lubricated contact area in SFA experiments is on the micron-scale. It significantly exceeds the size of the confined molecules. For small and unbranched molecules, such as simple alkanes, it is possible that the confined material undergoes a pressure-induced phase reconstruction, which leads to material properties that deviate

significantly from the bulk. Larger and more complex (branched) molecules are less likely to exhibit pressure-induced phase reconstruction due to internal constraints and poor mixing within the contact area. This was shown by *Drummond* et al. [29.19] in SFA shear experiments. They found that the linear friction–velocity dependence does not apply for branched hydrocarbon lubricants. Also Drummond discussed "molecular lubrication" in terms of a logarithmic friction–velocity relationship, which is in accordance with the above-discussed thermal activation model, the solid lubricant SFA study by *Briscoe* et al. [29.10], and the liquid lubricant SFM study by *He* et al. [29.15].

Common to the three studies by *Briscoe*, *He*, and *Drummond* is that they operate on a single material phase that is disrupted or relaxed over a very specific lateral length scale. In the Eyring model, the length scale is deduced by assuming a regular series of barriers, separated by a *virtual jump distance*. The distance is embedded in v_0, the characteristic velocity, which is the product of the jump distance and the frequency of the process. *Briscoe* et al. [29.10] used the lattice constant of the highly oriented monolayers as the virtual jump distance. It was assumed that the process frequency was related to the vibrational frequency of the molecules ($10^{11}\ s^{-1}$), neglecting sliding velocity, temperature, and pressure effects. *He* et al. [29.15] assumed a jump distance of 0.2 nm and considered frequencies between a perfectly structured alkane layer (10^{11} Hz) and the bulk fluid (10^{13}–10^{15} Hz, estimated from infrared absorption data for typical covalent bonds). With these assumptions *He* determined total "jump-energies" of $4–8\times10^{-20}$ J. *Briscoe* and *He* pointed out that a friction–velocity study alone provides only a qualitative measure of the microscopic origin of friction. Additional measurements have to be conducted that quantitatively address jump distances and frequencies.

The issue of the jump distance has been addressed by *Overney* et al. [29.20] in a SFM study on a highly ordered lubricant model system. This study avoided two levels of difficulties *Briscoe* et al. [29.10] and *He* et al. [29.15] encountered: (a) large contact areas of SFA studies, and (b) complex rheology with unknown structure parameters as in liquid lubricant studies. It involved contact dimensions on the order of $1\ nm^2$, and the crystalline form a bilayer model-lipid-lubricant with in-plane lattice spacings of 0.6 and 1.1 nm. The study mainly focused on the effect of the depth of the corrugation potential (barrier height) on the static and dynamic friction force. This is illustrated in Fig. 29.5 in the form of stick–slip amplitude plotted as a function of the drag direction (i.e., sliding with respect to the anisotropic row-like film structure). Relevant to our discussion about jump distance in lubrication events is Overney's discussion about the sliding speed and its effect on the slip distance. They demonstrated that within sliding speeds of 36 nm/s to 100 nm/s, the jump distance corresponded to the lattice spacing. At higher velocities, however, they could observe jumps over multiples of lattice distances and found the jump length distribution to become increasingly stochastic. They proposed molecular (or atomistic) friction as a white-noise driven system, which obeys a Gaussian fluctuation–dissipation relation. Hence, based on this finding one should consider discussing kinetic friction in terms of a statistical fluctuation model and understand the jump distance as a statistical quantity.

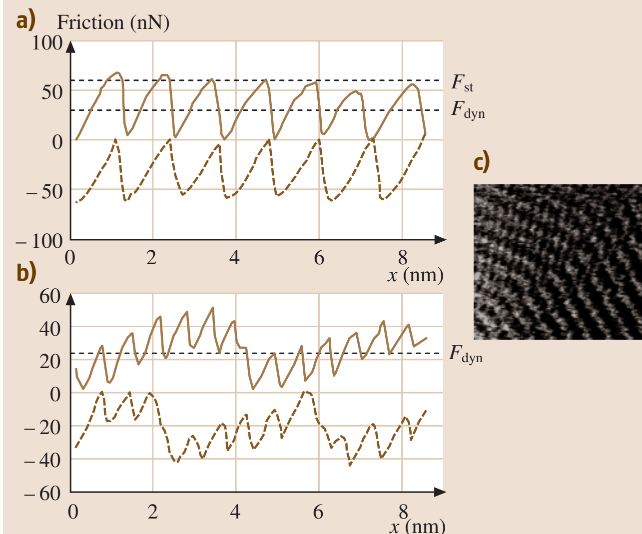

Fig. 29.5 SFM molecular stick-slip measurements of a bilayer lipid system (5-(4'-N,N-dihexadecylamino)benzylidene barbituric acid). **(a)** High amplitude frictional stick-slip behavior is observed for scans perpendicular to molecular rows as imaged in **(c)**. F_{st}, static friction, is assigned to the maximum force occurrence. The average value corresponds to the dynamic friction value, F_{dyn}, determined on large-scale micrometer scans. **(b)** A 30° out of row direction scan leads to decreased frictional stick-slip behavior due to smaller molecular corrugations. **(c)** $12\times12\ nm^2$ SFM lateral force image of a highly structured lipid bilayer. Two crystalline domains with a boundary are imaged. The anisotropic row-like structure is responsible for directional dependent friction forces. The molecular corrugation between the rows is larger than the molecular corrugation in between a single row. **(a)** and **(b)** are adapted from [29.20] and **(c)** from [29.21].

29.4 Thermodynamical Models Based on Small and Nonconforming Contacts

The SFM approach simulates a single asperity contact with a very high compliance, provided by a microfabricated and etched ultra-sharp tip and a typically soft cantilever spring. From a realistic, tribological perspective, the SFM approach is targeted toward the study of the intrinsic lubricant properties of a thin film in close vicinity to the solid substrate. The small contact area on the order of the lubricant's molecular dimension allows discussing SFM results in terms of a thermodynamic equilibrium. The area is insufficient in reorganizing the lubricant molecules coherently, to cause an apparent material phase-transition, or to generate a metastable situation as observed in SFA experiments (see below). SFM is therefore not appropriate to reflect on tribological issues involving large area confinement effects.

In our prior molecular discussion of friction above, we introduced for solid and liquid lubrication a thermal activation model, the *Eyring model*, which employed a regular series of potential barriers. Note that the concept applies for a solid lubricant of an inherent, highly ordered structure (e.g., [29.10]), but also for a liquid system in which the series of potentials is built up and overcome in the course of the shear process (e.g., [29.15]).

Gnecco et al. [29.22] showed in a ultrahigh vacuum study on sodium chloride that the concept of the Eyring model also applies for dry SFM friction studies. Thus a molecular theory of lubricated friction involving a molecular contact could be derived from a very simplistic model of an apparent sinusoidal-corrugated surface over which a cantilever tip is pulled. In a first attempt one could assume that the corresponding wave length of the shear process corresponds to the apparent lattice spacing of the corrugated surface. With such a simple attempt it is, however, assumed that there is no noise, such as thermal noise, existing in the system, and thus the driven tip leaves the total potential well when the barrier vanishes at the instability point. In the presence of noise, the transition to sliding can be expected to occur before the top of the barrier is reached. Such barrier-hopping fluctuations have been theoretically discussed by *Sang* et al. [29.23] and *Dudko* et al. [29.24].

The relationship between thermal fluctuations and velocity must be handled thoughtfully. *Sang* et al. [29.23] pointed out that in previous considerations of thermal fluctuations by *Heslot* et al. [29.25], the fluctuations were proportionally related to the velocity, which led to a friction force that is logarithmically dependent on the velocity. In Heslot's *linear creep model*, the barrier height is proportional to the frictional force. *Sang* argued that if one considered an absorbing boundary condition (i. e., an elastic deformation of the overall potential which is accomplished by shifting the x-axis) the barrier height becomes proportional to a 3/2-power law in the friction force. *Sang*'s extended linear creep model resembles a *ramped creep model* and leads analytically to a logarithmic distorted dynamic friction-*versus*-velocity relationship; i. e.,

$$F = F_c - \Delta F \left|\ln v^*\right|^{2/3} . \qquad (29.4)$$

In (29.4) v^* represents a dimensionless velocity, $\Delta F \propto T^{2/3}$, and F_c is an experimentally determined constant (by plotting F versus $T^{2/3}$ for a fixed ratio $T/v = 1\,\mathrm{K/(nm/sec)}$) that contains the critical position of the cantilever support. The same relationship of friction with velocity was also derived for the maximum spring force by *Dudko* et al. [29.24]. ΔF and v^* in (29.4) were derived as follows by *Sang*:

$$v^* = 2\left(\frac{v\beta\omega_0^2 U_0}{k_B T\,\lambda}\right)\frac{\Omega_k^2}{\left(1-\Omega_k^4\right)^{1/2}} ;$$

$$\Omega_k = \frac{\omega_0}{2\pi\omega_k} ;$$

$$\omega_0 = \sqrt{\frac{M\lambda^2}{U_0}} ; \quad \omega_k = \sqrt{\frac{M}{k}} , \qquad (29.5a)$$

$$\Delta F = \frac{\pi U_0}{\lambda}\left(\frac{3}{2}\frac{k_B T}{U_0}\right)^{\frac{2}{3}}\left(\frac{\left(1-\Omega_k^4\right)^{\frac{1}{6}}}{1+\Omega_k^2}\right) . \qquad (29.5b)$$

In (29.5a,b) v is the velocity of the cantilever stage, β is the microscopic friction coefficient or dissipation (damping) factor, ω_0 is the frequency of the small oscillations of the tip in the minima of the periodic potential, λ is the lattice constant, U_0 is the surface barrier potential height, M and k represent the mass and the spring constant of the cantilever, respectively, and $2\pi\Omega_k$ represents the ratio of ω_0 with the intrinsic cantilever resonance frequency ω_k.

Sang's and *Dudko*'s model was experimentally confirmed by *Sills* and *Overney* [29.26] on an unstructured amorphous surface of atactic polystyrene, Fig. 29.6. *Dudko* determined that the typically used weak spring constants in SFM measurements are responsible for

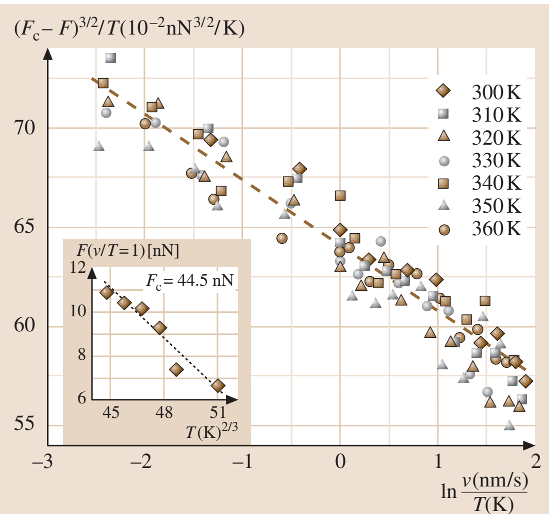

Fig. 29.6 Collapse of SFM friction data obtained on atactic polystyrene using the ramped creep scaling model. The regression parameters from the linear fit (*dashed line*) are $-2.158\times10^{-2}\,\mathrm{N}^{3/2}\,\mathrm{s/m}$ and $40.186\times10^{-2}\,\mathrm{nN}^{-3/2}/\mathrm{K}$ ($R^2 = 0.9124$). Lower *inset*: the constant F_c is determined from the intercept of the friction force F versus $T^{2/3}$ for a fixed ratio $T/v = 1\,\mathrm{K/(nm/s)}$: $F_c = 44.5\,\mathrm{nN}$. (Adapted from *Sills* and *Overney* [29.26])

the more pronounced logarithmic behavior of friction in velocity as found by *Gnecco* et al. [29.22] and *He* et al. [29.15]. The ramped creep model is also supported by numerical solutions of the Langevin equation.

The Langevin equation combines the equation of motion (including the sinusoidal potential and perfect cantilever oscillator in the total potential energy E) with the thermal noise in the form of the random force, $\xi(t)$, i.e.,

$$M\ddot{x} + M\beta\dot{x} + \frac{\partial E(x,t)}{\partial x} = \xi(t)\,, \tag{29.6}$$

$$\text{where } E(x,t) = \frac{k}{2}\left(R(t)-x\right)^2 - U_0\left(\frac{2\pi x}{\lambda}\right).$$

Equation (29.6) was solved numerically by both *Sang* et al. [29.23] and *Dudko* et al. [29.24] independently, assuming a Gaussian fluctuation–dissipation relation, $\langle\xi(t)\xi(t')\rangle = 2M\beta k_b T\delta(t-t')$ to express the random force. *Sang* confirmed the *ramped creep model*, and *Dudko* showed that a force reconstruction approach from the density of states (accumulated from the corresponding Fokker–Planck equation) is equivalent to the Langevin equation. From the dynamic spectral analysis, it could be concluded that the locked states (states within the potential wells) contribute mostly to the potential component of the friction force that dominates at low driving velocities, and sliding states contribute to viscous friction dominating at high driving velocities [29.24].

It should be noted that all of the above results considered an overdamped SFM system with respect to the driven spring (i.e., $\beta^2 > 4\,\mathrm{kM}$), and an underdamped system with respect to the periodic potential (i.e., $\beta^2 < 4(M\omega)^2$). This aspect will be further addressed below in our discussion of metastable lubricant systems in large conforming contacts.

29.5 Limitation of the Gaussian Statistics – The Fractal Space

The spectral description of dynamic processes involving probability density functions has recently been the focus of numerous theoretical papers that treat various statistical kernels [29.27–30]. *Dudko*'s et al. [29.24] Fokker–Planck discussion of kinetic friction and *Luedtke*'s et al. [29.27] Lévy flight model of slip diffusion of adsorbed nanoclusters are two examples in which statistical methods are applied to describe diffusive properties relevant to the kinetics in tribology.

Currently most models used to describe tribological processes assume Gaussian statistics (e.g., [29.23], and [29.24]). One of the limitations of a Gaussian statistics is that there are no correlations between statistical incidences. In other words, the Gaussian dynamic system is without memory. This is important to remember as the Eyring model discussed above, with its equally spaced potential barriers, used a Gaussian statistics. Simple "inert" lubricants, such as short chain alkanes embedded between silicon wavers, are described satisfactorily with such a statistics; however, confined complex liquids are not, including branched molecules, polymers, and generally chemically interactive and entropically confined systems (e.g., perfluropolyether lubricants as discussed below).

Confined complex liquids, for instance, easily exhibit strongly interacting glass-like behavior. The dynamic and stress relaxation behaviors in glasses, frequently discussed only as a low interacting system with

Arrhenius laws (Gaussian statistics), are often distorted from processes described by independently occurring microscopic processes. For instance, deviations from the Debye exponential relaxation as introduced in (29.1) are expressed in the form of an *extended exponential* Kohlrausch relaxation function over time t; i. e.,

$$F(t) \equiv \left[\frac{X(t)-X(\infty)}{X(0)-X(\infty)}\right] = \mathrm{e}^{-\left(\frac{t}{\tau}\right)^b}; \quad 0 < b < 1 , \tag{29.7}$$

where X is the property that is relaxed. The exponent b, the Kohlrausch exponent, can theoretically be determined if one assumes that the process occurs in series, representing a well-determined microscopic origin that correlates the various degrees of freedom [29.31]. This approach is borrowed from magnetic spin models such as the *Ising spin model* [29.32]. The idea is that a given molecular motion is dependent on the availability of other degrees of freedom of mobile neighboring structural units. Finite relaxation times, t_{max}, are gradually obtained with increasing spin levels (ergodic limit).

As mentioned above, the models by *Dudko* et al. [29.24] and *Sang* et al. [29.23] assumed Gaussian statistics. To illustrate how a diffusion process can deviate from Gaussian statistics, we introduce a simplified version of the Langevin equation, i. e.,

$$\ddot{x} = -\eta\dot{x} + \varsigma(t) \tag{29.8}$$

with the coordinate x, the dissipation (or dampening) parameter η, and the random acceleration $\zeta(t)$. Assuming Gaussian statistics, the mean squared displacement is

$$\left\langle x^2(t)\right\rangle = 2k_{\mathrm{B}}T\eta t = 2Dt , \tag{29.9}$$

where $D = \eta kT$ defines the diffusion constant [29.33]). It was already realized at the time of Smoluchovski at the beginning of the 20th century that a diffusive description of a dynamic process demands a thermodynamically well-equilibrated or mixed system. Especially in a confined tribological system that involves a third medium (e.g., a lubricant), it can be expected that the Markovian nature of the underlying stochastic process could be disturbed. Consequently, for a monolayer lubricant that is chemically interacting, a nonlinear relationship of the mean squared displacement in time can be expected. Manifestations of anomalous transport are long-range spatial or temporal correlations. Two extreme limits can be distinguished: (a) processes with strong temporal relations ("fractal time") [29.29], and (b) systems that exhibit long jumps ("Lévy flights") [29.30].

29.6 Fractal Mobility in Reactive Lubrication

The importance of the underlying kinetics is illustrated by ultra-thin wetting lubricants. The spreading of "completely wetting" polymer liquids on solid surfaces has revealed unexpected spatial and temporal features when examined at the molecular level. The spreading profile is typically characterized by the appearance of a precursor film of monomolecular thickness extending over macroscopic distances and, in many cases, a terracing (also on the order of molecular dimensions) of the fluid remaining in the reservoir [29.34]. These spatial features have been shown to be consistent with a Poiseuille-like flow in which the disjoining pressure gradients with film thickness drive the spreading process [29.35]. The temporal evolution of the spreading profile in this film thickness regime is, however, found to universally scale as $t^{1/2}$ even at short times [29.34]. That the spreading dynamics are reflective of a diffusive transport mechanism and not of a pressure driven "liquid" flow suggests that interfacial confinement substantially alters the mobility of molecularly thin polymer fluids [29.36].

The molecular mobility is of fundamental importance for monolayer lubrication purposes, such as in magnetic storage devices. It has, for instance, been shown that for low surface energy hydroxyl-terminated perfluoropolyether (PFPE-OH) films, the lubricant exhibits spatially terraced flow profiles indicative of film layering [29.35] and spreading dynamics that are diffusive in nature [29.37, 38]. In magnetic storage devices the hydroxylated chain ends of molecularly thin PFPE-OH films interact with the solid surface, an amorphous carbon surface, via the formation of hydrogen-bonds with the polar, carbon-oxygen functionalities located on the carbon surface. The bonding of the PFPE-OH polymer to carbon is predicated on the ability of the PFPE backbone to deliver spatially the hydroxyl end-group to within a sufficiently close distance to the surface active sites. Kinetic measurements probing the bonding of the PFPE-OH polymer to the carbon reveal two distinctive kinetic behaviors, as illustrated in Fig. 29.7 at two representative temperatures: 50 °C and 90 °C for the

© Springer 2004

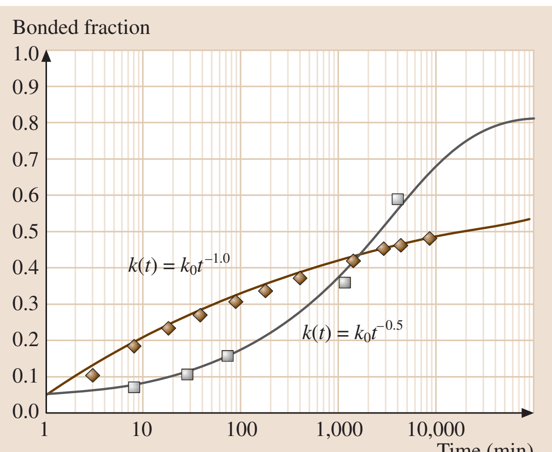

Fig. 29.7 Representative kinetic data for the bonding of PFPE-OH (tradename: Fomblin ZDOL) to amorphous carbon at $T = 50\,°\mathrm{C}$ and $T = 90\,°\mathrm{C}$. *Solid lines* represent fits using a rate coefficient of the form, $k(t) = k_0 t^{-\alpha}$ with $\alpha = 0.5$ for $T = 50\,°\mathrm{C}$ and $\alpha = 1.0$ for $T = 90\,°\mathrm{C}$

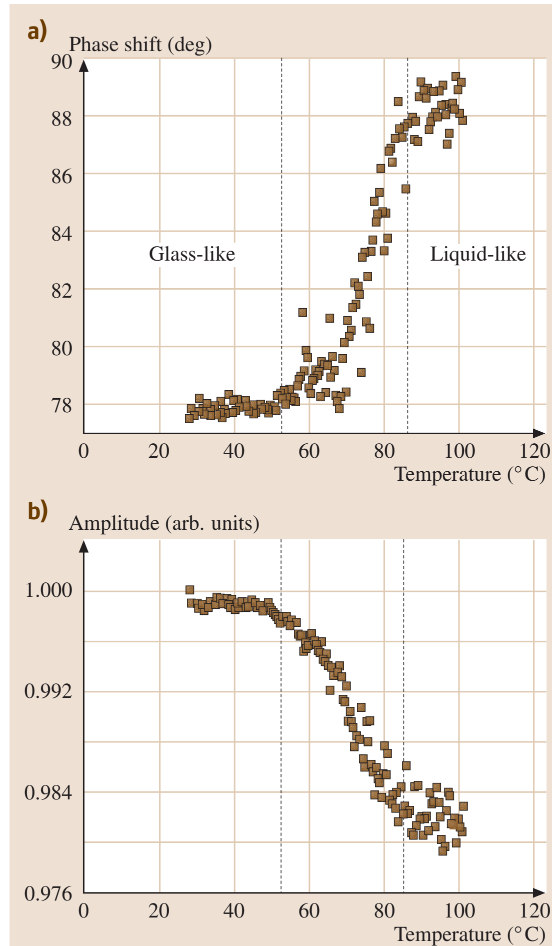

Fig. 29.8a,b Shear-modulated SFM experiments performed on a $10.7 \pm 0.5\,\mathrm{Å}$ Fomblin Zdol film: **(a)** phase shift response between disturbance and response, and **(b)** contact stiffness response vs. temperature

two temperature regimes below 56 °C and above 85 °C. Below 56 °C the kinetics are described with a time-dependent (fractal time dependent) rate coefficient of the form

$$k(t) = k_0 t^{-1/2} \qquad (29.10)$$

and at temperatures above 85 °C with the form

$$k(t) = k_0 t^{-1.0} \,. \qquad (29.11)$$

The initial bonding rate constants, k_0, increased abruptly as the temperature rose above 50 °C.

The bonding kinetics in the low-temperature regime is characteristic of a diffusion-limited reaction occurring from a glass-like state of the molecularly thin PFPE-OH film [29.39]. The mobility of the PFPE chain in the glass-like state is limited by the propagation of holes or packets of free volume, which facilitate configurational rearrangements of the chain. The onset of changes in the bonding kinetics at nominally $T > 56°$ signifies a fundamental change in the mobility of the molecularly thin PFPE-OH film. Specifically, the transition in the fractal time dependence suggests that delivery of the hydroxyl moiety to the surface is no longer limited by hole diffusion, and the increase in the initial rate constant indicates an enhancement in the backbone flexibility. These results are consistent with a transition in the film from a glass-like to a liquid-like state in which the enhanced PFPE-OH segmental mobility results from rotations about the ether oxygen linkages in the chain that become increasingly facile. The time dependence observed in the high-temperature rate coefficients, $k(t) = k_0 t^{-1.0}$ is characteristic of a process occurring from a confined liquid-like state in which the activation energy increases as the extent of the reaction increases.

The impact of this transition in the molecular mobility on tribology can be illustrated with sinusoidally modulated shear force experiments [29.40, 41]. In brief, a molecularly thin ($10.7 \pm 0.5\,\mathrm{Å}$) PFPE-OH film is subjected to a local shear stress by means of a sinusoidal

force applied *laterally* to a SFM probe (at constant load) where the modulation amplitude is initially set below that required to initiate sliding between the tip and the sample. The amplitude and phase-shift responses are measures of the contact stiffness and the effective viscous dampening, respectively. From Fig. 29.8 it can be inferred that the SFM-measured nanorheological properties of the PFPE-OH film exhibit the changes discussed above in the molecular mobility. Thus kinetic and rheological data suggest that the thermal transition observed is due to the formation of a two-dimensional (2-D) glass. The "glass transition" results from the preferential "freezing out" of the out-of-plane torsional motions of the energetically confined PFPE backbone. The confinement-induced solidification in the molecularly thin precursor film will significantly impact the lubrication properties and challenge thermodynamic, well-equilibrated models of lubrication as introduced above.

29.7 Metastable Lubricant Systems in Large Conforming Contacts

It is important to note that in an experiment of thermal activation, the critical time of the experiment t_{exp} decides the system response with its finite relaxation time $t_{\max}$. If $t_{\mathrm{exp}} > t_{\max}$, the system behaves in an ergodic manner, and thermodynamic laws apply for interpreting lubrication results. On the contrary, if $t_{\mathrm{exp}} < t_{\max}$ the thermal evolution cannot be described by classical statistical thermodynamics. A metastable configuration is generated. The experimental time depends strongly on the contact area, the parameter that most differs between SFA and SFM measurements. SFA experiments involve large micron-scale contacts while SFM measurements are conducted with contacts on the nanoscale

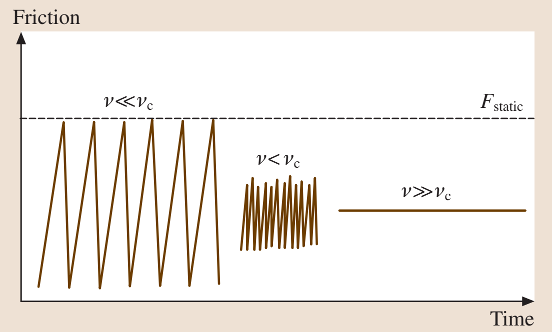

Fig. 29.9 Dynamic states of friction for an underdamped spring system

Because of the large contact area, SFA experiments are very susceptible to generating unequilibrated metastable lubricant configurations. The SFA study by *Yoshizawa* et al. [29.42], in which distinctively different *dynamic states of friction* were introduced, could be interpreted as such. To date there are three velocity regimes used to describe the dynamic state of friction for a system that is "underdamped" [29.43]. In an underdamped system, realized by a stiff spring compared to the friction constant, the characteristic slip time is comparable or smaller than the response time of the mechanical system. One distinguishes three velocity regimes, as depicted in Fig. 29.9. The three regimes distinguish themselves by a single discriminator, v_{c}, a material, pressure and temperature dependent critical velocity. The regimes are described as

1. highly regular with high amplitude stick–slip for $v \ll v_{\mathrm{c}}$,
2. intermittent stochastic stick–slip for $v < v_{\mathrm{c}}$, and
3. smooth low friction sliding for $v > v_{\mathrm{c}}$.

Various models have been suggested to describe the different dynamic states, including melting freezing transition [29.44], chain adsorption on substrates [29.45], and embedded particle [29.43]. Until the embedded particle model by Rozman was introduced, the SFA approach seemed to be the tool of choice to investigate metastable lubricant configurations. Rozman's single particle model alerts us, however, to drawing unambiguous conclusions on the dynamical structure of a molecular system embedded between two plates and driven by an underdamped system. In Rozman's simple theoretical model, sketched in Fig. 29.10, a single particle is embedded between two corrugated

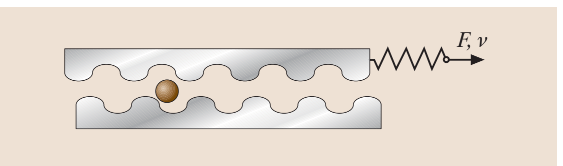

Fig. 29.10 Model of single particle embedded in a two-wave potential driven at constant force, F, and velocity v

Springer Handbook *of* Nanotechnology
B. Bhushan • © Springer 2004

surfaces (*two-wave potential*). The top plate is pulled at constant velocity by a linear spring, and the plate motion is monitored. Interestingly, the plate exhibits exactly the same dynamic state of frictional motion as introduced above with the three regimes, which were attributed to a rate-dependent configurational change of the lubricant.

Finally it shall be noted that the slip relaxation pattern depends condition under which the stick–slip motion is being studied. In an *overdamped* system, i. e., a system in which the spring constant is weak compared to the friction constant, *Rozman* et al. [29.46] found that one can control the experimentally observed relaxation pattern of the slip by controlling the spring constant.

29.8 Conclusion

Starting from a classical tribological Master Curve, the Stribeck curve, with its complex description of lubrication for thin lubricants, we launched a discussion of molecular lubrication pulling together disparate approaches to studying friction. We found that phenomenological descriptions of lubrication, such as the Reynolds' theory, were kept alive for ultra-thin lubricants by "adjusting" material properties, such as the viscosity. This is a common engineering approach to introduce "effective" or "apparent" properties, if tested models fail to describe new situations.

In the case of molecular lubrication, significant progress has been made in the last ten years. Two instrumental techniques have in particular contributed to this progress: the SFA and the SFM. The contributions of these two techniques have been complementary. While the SFA has tested lubricants under pressure constraints with large contacts in respect to the size of the trapped molecules, the SFM has probed the degree of collective mobility with disturbances in the size of the molecules themselves.

One feature common to interpreting lubrication results, and which was discussed here in detail, is the problem of finding the appropriate underlying statistics to describe the lubrication process. Most of the current molecular models that have been used to describe molecular friction and lubrication assumed a Gaussian statistics. Only recently has it been recognized important to consider statistics that embrace long-range spatial or temporal correlations. In the near future, it can be expected that the next leap in an improved fundamental understanding of kinetics and energetics in nanolubrication will come from interpretations that are challenging the Markovian nature of the underlying stochastic process.

30. Nanotechnology for Data Storage Applications

Nanotechnology

This chapter considers atomic force microscopy (AFM) as an enabling technology for data storage applications, considering already existing technologies such as hard disk drives (HDD), optical disk drives (ODD) and Flash Memories that currently dominate the nonvolatile data storage market, together with future devices based on magnetoresistive and phase change effects. The issue at hand is the question of whether the novel AFM-based storage, dubbed "Probe Storage", can offer a competing approach to the currently available technologies by playing the role of a disruptive technology. Probe Storage will be contrasted to HDD and ODD who are purely mechanical, as they are based on a rotating disk that uses just a single probe to address billions of bits of data, and nonvolatile RAM that has no moving parts yet requires billions of interconnects. In particular, capacity, areal density, transfer rate, form factor and cost of various data storage devices will be discussed and the unique opportunity offered by Probe Storage in employing massive parallelism will be outlined. It will be shown that Probe Storage bridges the gap between HDD, ODD and other nonvolatile RAM, drawing from the strength of each one of these and adding a significant attribute neither of these has; namely, the possibility of addressing a very large number of nanoscale bits of data in parallel. This chapter differs from the other chapters in this book in that it addresses the important issue of whether a given scientific effort, namely, Probe Storage, is mature enough to evolve into a commercially viable technology. The answer seems to indicate that there indeed is a huge niche in the data storage arena that such a technology is uniquely qualified to fill, which is large enough to justify a major investment in research and development. Indeed, as other chapters indicate, such an effort is developing at a rapid pace, with hopes of having a viable product within a few years.

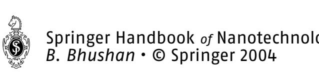
This chapter will differ from the other chapters in this handbook in that it addresses the important issue of whether a given scientific effort is mature enough to evolve into a commercially viable technology. Specifically, we consider scanning probe microscopy (SPM), consisting of scanning tunneling microscopy (STM) [30.1–3] and atomic force microscopy (AFM) with all their variants, as a means for storing and retrieving nanoscale bits of data to and from a substrate. Indeed, many studies have already been published in which researchers demonstrated the feasibility of using SPM techniques that hold promise for realistic applications [30.4]. However, in approaching a topic from a practical point of view, that is, whether it has the ingredients that will spawn a commercial product, it is imperative to obtain a clear view of the status of competing technologies. The commercially available technologies that will concern us here entail two classes of devices, one consisting of hard disk drives (HDD) and optical disk drives (ODD), and the other consisting of Non-Volatile Random Access Memories (NVRAM) based on charge trapping (Flash Memory) that currently dominate the data storage market. The latter may soon be supplemented by magnetoresistive RAM (MRAM) and phase change RAM (PC-RAM). For brevity, we will refer to the first class as HDD and the one as NVRAM.

It is commonly thought that nanotechnology is a breakthrough technology that is a quantum leap beyond existing technologies in its capabilities. In reality, however, nanotechnology is in many cases just a limiting



case to the already commercially available technologies. The latter may progress at such a high rate that the distinction between what is considered "conventional" and "nano" becomes blurred. A case in point is data storage in which distances and times are already specified by nanometers and nanoseconds. For example, the head of an HDD in a PC's hard disk flies across the storage medium (platter) at a speed of 10 m/s ($\sim$ 22 miles per h) at a height of $\sim$ 10 nm, reading and writing bits of data on a nanosecond time scale. Also, both giant magnetoresistance (GMR) devices that read magnetic data in an HDD and transistors belonging to NVRAM devices use nanoscale structures, one employing spintronic effects and the other tunneling junctions between pairs of transistors, where quantum laws of physics have to be used to describe their operation.

The issue at hand is, therefore, whether novel nanotechnologies can offer a competing approach to currently available technologies by playing the role of a "disruptive technology". This term has been coined in the high-tech industry to describe a situation where, figuratively speaking, a discovery developed in a basement can lead to a development of a new device that has the potential of becoming a commercial alternative to a commonly used one. Such a disruption of the success of a commercially established technology by a product developed by a new start-up, for example, has been witnessed more and more frequently in recent years. One would even venture to assume that the support companies give to research groups at universities can be attributed to their concern about a possible disruption of their own technology.

The important issue here is the question of what nanotechnology can offer to an already mature field such as data storage. As will be discussed later, HDD and NVRAM are worlds apart in technology. HDD is purely mechanical, as it is based on a rotating disk that uses just a single probe (head) to address billions of bits of data. NVRAM, on the other hand, has no moving parts yet requires billions of probes, i. e., interconnects, positioned at the intersection of horizontal and vertical interconnects with one probe for every bit of data. Another distinction between HDD and NVRAM is the time it takes to access a random bit of data. For an HDD the random access time is 10 ms (75 ms for ODD), while for NVRAM it is less than one µs. Clearly, NVRAM beats HDD (and ODD) in the random access arena, if that is the criteria for performance. On the other hand, the rate at which an HDD can read data sequentially is rather impressive. The current performance of an HDD stands at 436 Mb/s and 22 Mb/s for ODD, comparable to what NVRAM can offer, being of the order of 10 MByte/s. Another playing field in the battle between HDD and NVRAM performance concerns capacity and areal density of bits of data. Here, capacity measures the total number of bytes of data, while areal density measures the number of bits per square inch. The first addresses the ever growing need for storing larger and larger amounts of data, say, for high-definition TV applications, while the latter is related to what is commonly called the form factor, namely, the physical size of a storage device. The form factor is intimately connected to portability, as more and more hand-held devices have restrictions on the physical size of each of its components. Note also that a major consideration in comparing HDD and NVRAM is cost, a topic that will be addressed later.

As discussed before, both HDD and ODD use just a single probe that addresses all the bits of data on a platter where data is stored. NVRAM, on the other hand, has to resort to a grid of interconnects that contacts each bit of information individually. Such a grid, in which each bit is interfaced with one "word line" and one "bit line", occupies expensive real estate across a storage device, and, even more importantly, it requires that the interconnects be on the order of the bits of data they address. As long as these bits have dimensions on the order of, say, 1 µm, one is able to use conventional lithography for the fabrication of the interconnects. However, when the bits of data shrink to, say, 25 nm in size, interconnects are no longer a viable option due to lithographic limitations. HDD and ODD, in contrast, require no interconnects, so this limitation on the size of bits is not a concern. However, there are many other problems that arise as one tries to push the size of the stored bits to nanoscale dimensions, as will be discussed later.

By now we have touched on the heart of the challenge that nanotechnology-based storage faces if it is to compete with HDD and NVRAM in both performance and cost. Practically, one should restate this issue and ask a more modest question, namely, what niche nanotechnology will fill in consumer data-storage applications. To address this question, one notes that nanotechnology is concerned with the ability to miniaturize and characterize nanometer-sized structures. For data storage, the question is how to address nanoscale data bits rapidly without having to resort to the use of too many interconnects.

A possible solution to this challenge emerged from a brilliant idea developed at IBM and Stanford laboratories, as part of their scanning probe microscopy research [30.5–9].

A conventional AFM employs a single cantilever with a sharp tip at its end to raster scan a sample and its minute deflections, due to protrusion on the surface, generate a map of the surface topography. Under ideal conditions one can even obtain atomically resolved images. The IBM-Stanford group demonstrated that it is possible to employ a large number of such cantilevers and operate them in parallel. Such an operation provides a faster means of obtaining images of different parts of a sample simultaneously. These cantilever arrays are often referred to as types of microelectromechanical systems (MEMS), or if they are small enough, nanoelectromechanical systems (NEMS).

One can view this breakthrough concept as an enabling technology for data storage applications in that it bridges the gap between HDD and NVRAM technologies, drawing from the strength of each. To appreciate this concept, consider a medium whose area is sectioned into a thousand squares, each containing one million bits of data. Each square is addressed by its own interconnect whose width can now be as wide as a thousand bits of data. Consider now a square structure consisting of one thousand cantilevers whose tips are aligned such that each one addresses its own square. Such an arrangement, known as probe storage, and dubbed "millipede" by IBM, has some attributes belonging to an HDD, some attributes belonging to NVRAM, and potentially one significant attribute neither of these has: the possibility of addressing nanoscale bits of data. While random access is faster than that of a HDD, it is slower than that of NVRAM.

In this chapter, we will address the issues mentioned in the introduction with an emphasis on a comparison between existing and future development of conventional technologies and nanotechnologies. We will not address more futuristic approaches such as DNA and molecular electronics for data storage applications – fascinating topics on their own merit, yet deemed too far in the future for our more "technological" approach.

30.1 Current Status of Commercial Data Storage Devices

Before describing the current status of commercial storage devices, it is worthwhile to reiterate definitions and cover some new key features associated with HDD [30.10]. A schematic of a hard disk drive, shown in Fig. 30.1, is configured into sectors, each having radial tracks; there are typically 58,000 tracks per in. for HDD and 34,000 tracks per in. for ODD, 562 kbits per in. for HDD, and 100 kbits per in. for ODD. In 1993, a HDD head was flying above the storage media at a typical height of 100 nm, which dropped to 10 nm in 2002, and is expected to drop to 4 nm in 2004.

Hard Disk Drives and Optical Disk Drives

The time it takes the read-write head to get to a random bit along a track is called latency, while the time it takes the head to get to a random sector is called seek time. The time to get to any random bit is called access time. From 1990 to 2002 this time decreased linearly from 20 ms to 8 ms, and is expected to decrease to 4 ms by 2004.

Transfer time is the time it takes to transfer a given number of bits from the hard drive to a given destination in a computer. The total number of bits per unit area, usually given in bpsi (bits per square inch), is called areal density. The total number of bytes in a storage device is called capacity.

The physical size of a storage device and its price are paramount factors in its commercial viability. Disk drives are usually divided into magnetic and optical, although a combination of both is currently advanced by several companies and research groups around the world. A magnetic hard drive (HDD) has a higher capacity, lower cost, and higher performance than an optical hard drive (ODD), but its disk is not removable. The ODD, on the other hand, has a removable disk that can be mass produced by parallel replication (stamping), making it cheaper for large-scale distribution. Also, an ODD is configured to operate in such a way that the head reads data sequentially, while HDD is optimized for random access operation. Note that units of bits are usually denoted by a lower case "b" and used for areal density and transfer rate, while units of bytes are usually denoted by an upper case "B" and used for capacity. A note in passing: Areas are, oddly enough, expressed in square inches, and the holy grail for areal density is denoted by 1 tbpsi (one terabit per square inch).

Now, a crucial question when assessing the viability of a promised technology concerns the demand for the commercial product in question. Figure 30.2 estimates that a grand total of 2.12 million terabytes of information were produced in 1999 [30.11]. The breakdown is 83 terabytes for optical, 240 terabytes for paper, 427,000 terabytes for film, and 1.6 million terabytes for magnetic data storage. PC disk drives take the first place in demand: 700,000 terabytes of data!

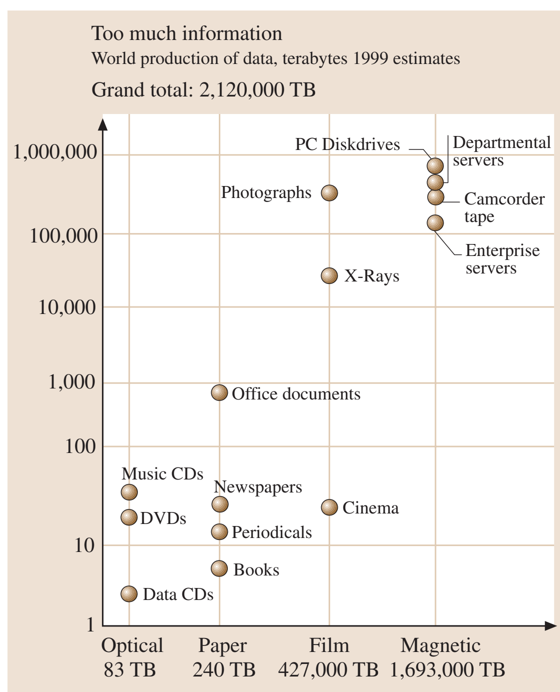

Fig. 30.2 World production of data in 1999 estimates

To appreciate the economic impact of the HDD storage drive industry (NVRAM will be discussed later), consider Fig. 30.3, which is current to 2002 [30.10]. Here, one observes that the industry shipped 528 million units with a value of $ 35.5 billion, 58% of the value consisting of HDD and 27% of ODD, while the numbers shipped are almost evenly divided between HDD, ODD, and floppies. Based on Fig. 30.3, one would think that such a huge market would involve a large number of companies competing with each other in price and performance.

However, as shown in Fig. 30.4, the cut-throat competition among various companies gave rise to the disappearance of many of them and mergers between the others [30.12]. Note that the number of disk drive manufacturers dropped from 62 in 1985 to only seven in 2002, while merchant components suppliers dropped from 28 to eight during that period! For example, Maxtor and Quantum merged, IBM sold its disk drive division to Hitachi, and Fujitsu exited desktop HDD altogether. In 2002, Seagate shipped 1,959,000 terabytes of storage, 10.2 million enterprise drives, 1.2 million 15,000 rpm drives, and 44.8 million personal storage devices. And they expect that there will be migration to smaller form factors and increased areal density in all segments of the

industry and that mobility will be become increasingly important.

A projection of HDD areal density on a logarithmic scale is shown in Fig. 30.5 [30.13]. Whereas in 1990 the areal density was only 1 gigabit per sq. in., it reached 100 gigabits per square inch in 2002 and is projected to reach 1 Tbpsi in 2006. One wonders whether it will take nanotechnology to get to 50 Tbpsi in 2017, as the figure suggests. As quoted from a Seagate presentation, "in traditional applications, areal density has grown faster than consumption, moving to a single platter society in PC's that enables smaller form factors. In non-traditional markets, new applications drive capacity growth, especially with video content." [30.12].

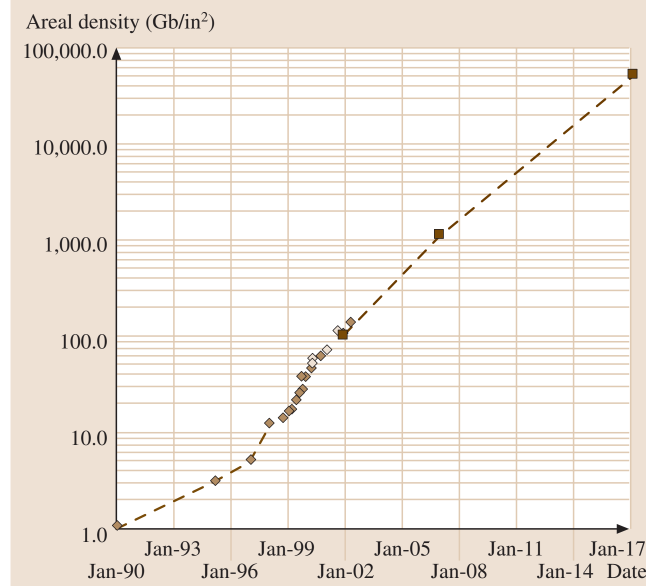

Fig. 30.5 Projected areal density for hard disk drives [30.13]

Table 30.1 [30.10] presents several key parameters characterizing HDD and ODD that should serve as a reality check for the potential viability of any nanotechnology approach that aims to act as a disruptive technology. Thus any new concept should be judged against this current status of HDD and ODD and, as described later, NVRAM. Note that in contrast to these impressive parameters associated with HDD and ODD, seek time is limited to 10 ms and 75 ms, respectively.

A comparison of the perceived limits to HDD and ODD performance are presented in Table 30.2 [30.10]. For magnetic disk drives, the limit to areal density is the superparamagnetic effect in which too small a magnetic domain can be thermally excited into an opposite direction, losing the reliability of the stored data. Ways and means for approaching this limit and maintaining reliability will be discussed later. For optical data storage, the conventional limit is clearly the spot size of the focused laser beam. However, near-field methods are currently being developed to circumvent this limit. As far as speed goes, switching times for magnetic domains is around 1 ns, while for laser-induced thermal effects it is ten times slower.

The current and projected relationship between areal density and data rate for several technologies are

shown in Fig. 30.6 [30.5]. These technologies consist of CD-ROM, magneto-optical, magnetic disks, magnetic tape, SIL, holography, and thermo-mechanical AFM. According to this projection, magnetic disks are in the forefront of technology and are expected to have the same areal density as that of the probe storage concept, yet have a much faster data rate. The latter technology, as predicted in this figure, will grow from a data rate of only 1 Mb/s to more than 10 Mb/s, accompanied by an increase in areal density from 10 gigabits per sq. in. to hundreds of gigabits per sq. in. More about the probe storage concept will be discussed later.

Fig. 30.6 Projected areal density vs. data rate for several technologies

30.1.1 Non-Volatile Random Access Memory

Demand for Flash Memory has been growing rapidly over the last few years, driven by the rapid expansion of several markets, including mobile communications and portable media devices (notably cameras and MP3 players). Flash Memory is by now the fastest growing segment of the memory market. Figure 30.7 [30.14] shows the total value of the Flash Memory market year by year. It can be seen that the market is increasing by nearly a factor of ten every five years and up to 100% every year. The market is projected to reach $ 23 billion by 2003, up from $ 2.5 billion in 1998. The reasons for this dramatic growth are depicted in Fig. 30.8 [30.14], which shows the demand by industry sector and the growth in these areas. By far the biggest driver of demand for Flash Memory is consumer electronics and, in particular, cellular phones, which account for nearly half the market and are growing at a compounded annual growth rate of 120%.

Flash Memory

Flash Memory, the most common non-volatile, programmable memory device, uses rows and columns of interconnects that address each data cell. At the intersection of these are two transistors, which comprise the Flash Memory cell, as shown in Fig. 30.9. Each cell is addressed by a network of interconnects, where the common connection to the transistor gates is called the word

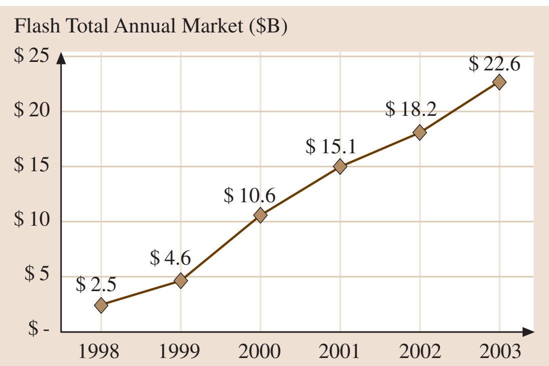

Fig. 30.7 Total value of the flash memory market, 1998–2003. The market has been growing rapidly over the last few years, and is now the fastest growing sector of the memory market

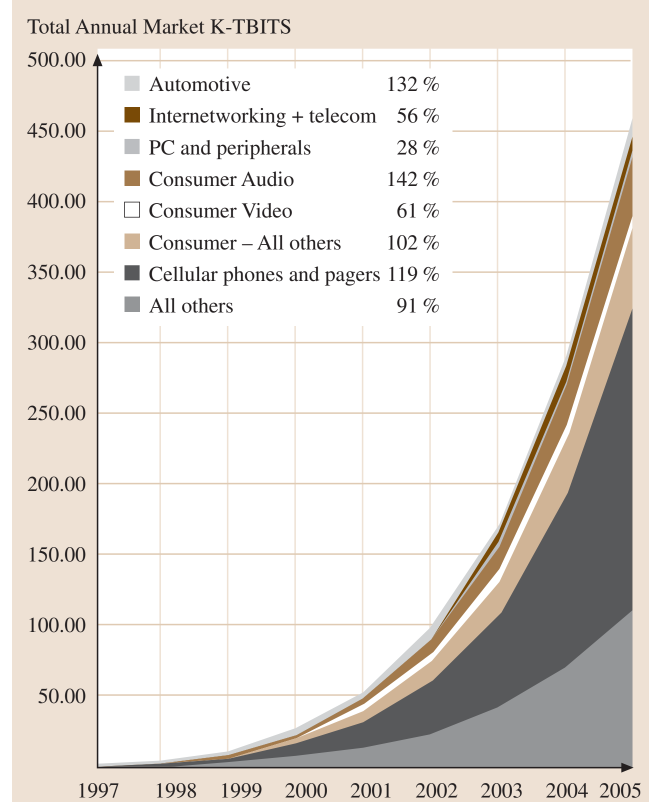

Fig. 30.8 Market segments that are driving the demand for flash memory where cellular phones are leading the demand

line and the common connection to the drain is called the bit line. Every cell in the memory array can be accessed by activating a unique combination of these lines. Here, the floating gate is linked to a word line via a second gate that serves as a control gate. The floating gate potential is altered by Fowler–Nordheim tunneling of electrons, an effect that takes place when the applied bias needed for switching is larger than the work function of the relevant electrode. The electrons arrive from the column, or bit line, and enter the floating gate from which they drain to the ground. A cell sensor monitors the flow of electrons through the gate. A value of 1 is assigned when the current is greater than a given threshold value, and 0 if it is below that value. Approximately 30,000 electrons are stored in the gate to make a 1 and 5,000 for a 0. The memory of the device derives from the very long storage time (tens of years) of the tunneling electrons in the gate capacitor. For the data to have a lifetime of ten years, the electrons can leak at a rate of no more than five a day. Flash memory can only be rewritten a limited number of times (10^{5-6}), as electrons get permanently trapped in the gate over time, impairing device efficiency. Memory devices using this technology are SmartMedia, CompactFlash cards, and Memory Sticks, for example, that read and write memory in 256- or 512-byte increments, enhancing their speed of operation. A Flash Memory device, in contrast to a hard disk drive, is noiseless, has no moving parts, is lighter and smaller, and, above all, has access times orders of magnitude faster than HDD. SmartMedia cards, which serve as solid-state floppy disk cards, were originally developed by Toshiba. They are currently available in a capacity of 128 Mbytes and higher and measure roughly 45 mm × 37 mm × 1 mm. In comparison to a HDD, however, SmartMedia cards are much more expensive. Note that a single storage cell occupies roughly 0.1 μm^2, a size limited by the complexity of its physical structure and width of the addressing interconnects.

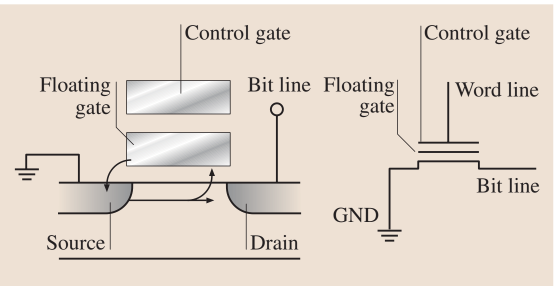

Fig. 30.9 Schematics diagram of a typical Flash Memory cell

Part E | 30.1

Magnetoresistive Random-Access Memory

Figure 30.10 [30.15] is a schematic diagram of a magnetoresistive random-access memory (MRAM) that acts as a non-volatile storage device. As with Flash Memory, there are word lines and bit lines at the intersection of which is a cell with a switchable property. Whereas with Flash Memory the electric potential of a storage cell is modified by electron tunneling, here it is the magnetic domain orientation that is switched by the current flowing through the electrodes. Passage of electrons through the magnetic domain of the cell depends on the state of polarization of the spins of the injected electrodes, much the same as the operation of giant magnetoresistance elements used to read data in a hard disk drive. In contrast to HDD and Flash Memory, MRAM is still in a stage of development and, as such, is not yet commercially available. One of its main attributes is its high speed of programming, which is faster than that of Flash Memory. The main challenges confronting MRAM technology are: (i) the size of the cell is still too large, (ii) the power consumption required during the write mode is still too high, and (iii) there are manufacturing difficulties associated with high temperature steps that may damage the magnetic layers.

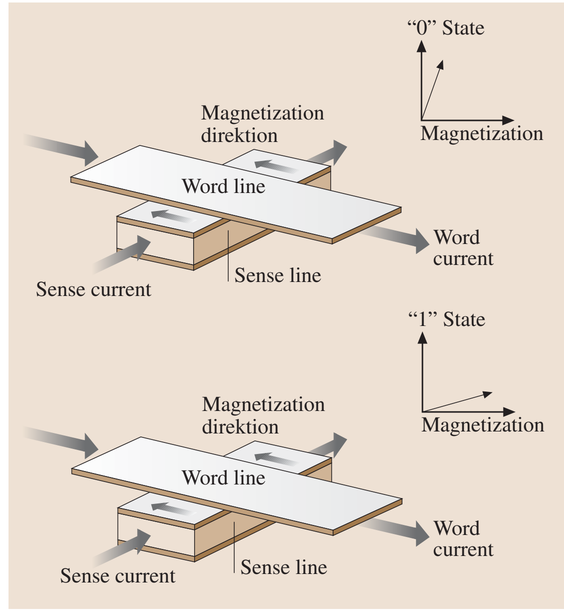

Fig. 30.10 A diagram of a MRAM cell

To exemplify the status of this technology, note that Motorola demonstrated a 1-Mbit MRAM test chip using a 0.6-μm process, yielding a cell size of 7.2 μm^2. Projections are that using a 0.18-μm process will shrink the cell size to about 0.7 μm^2, and thus be competitive with Flash Memory. Also, Sony demonstrated an MRAM test chip using a 0.35-μm process that yielded a cell size of 5.8 μm^2. Other companies like IBM, which is partnering with Infineon, are also active in MRAM research.

Phase-Change Random-Access Memory

Phase-change random-access memory is a technology that uses a chalcogenide as the data storage material in the memory cell. The medium is similar to the switchable material used in rewritable CDs. It is being pioneered by Ovonyx, in association with Intel. A schematic diagram of an Ovonyx Unified Memory (OUM) is shown in Fig. 30.11 [30.16]. The OUM is an example of a phase-change random-access memory that operates much as the Flash Memory and MRAM, as far as the electrodes are concerned, except that the memory bit cell consists of a chalcogenide material that undergoes a phase change. Upon passing current from the word line to the bit line, the chalcogenide, a GeTeSb alloy, changes its phase reversibly between amorphous and crystalline states, depending on the temperature it is heated to and the rate of cooling. This change in phase is accompanied by a several orders of magnitude change in conductivity, which makes it possible to obtain a high reading signal-to-noise ratio. Similar to Flash Memory and MRAM, the OUM requires a protective shield from the environment for reliable operation over a long period. We shall come back to this issue later.

30.2 Opportunities Offered by Nanotechnology for Data Storage

We have by now summarized the two mainstream commercial data storage devices, HDD and NVRAM, and the two near-term candidates for future commercial success, the MRAM and PC-RAM devices. As stated before, the technology utilized by these devices should be used as a measure against which novel nanotechnology approaches are judged. Note that even if a promising novel nanotechnology-based device comes into being, it will take time to bring it into maturity, and during that period, the state-of-the-art of HDD, Flash Memory, MRAM, and PC-RAM will steadily improve. One could state that we have here a competition on the "run" that will be decided based on the following four criteria: (i) capacity, (i) cell size, which translates to areal density or form factor, (iii) access time, and (iv) price, where each technology is looking for its own business niche.

Nanotechnology offers two unique opportunities to solve the problem of how to miniaturize storage devices. The first opportunity entails the use of a variety of chemical and physical processes to fabricate memory media capable of supporting nanoscale features that have reversible properties, be it magnetic, electric, or phase change. Such media should satisfy the first and second criteria, namely, a large data storage capacity and a small form factor. The second opportunity derives from the ability of scanning probe microscopy, the champion of nanotechnology, to characterize and modify structures down to atomic dimensions. Here, the use of a large number of probes operating in parallel should satisfy the third criterion, namely, fast access times. Also, because the fabrication of multiple cantilevers lends itself rather readily to mass production using currently available photolithographic processes, it should satisfy the fourth criterion: low cost.

In the next section, we describe how probe storage can be realized as a data storage technology that may find a commercially viable niche. It will be useful to divide this section into three parts, each one describing different aspects of what is known as probe storage. The first part, titled "Motors", will deal with the question of how one can access a large number of nanoscale memory cells using parallel and sequential processes. The second part, denoted by "Heads", will describe methods for reading and writing each individual memory cell using different SPM techniques. The third part, called "Media and Experimental Results", will describe the properties of different media applicable to data storage that have or can be used for probe storage.

30.2.1 Motors

This section considers two possible geometric configurations of data storage devices that operate in parallel. One consists of a rotating cylinder and an array of cantilevers positioned in an axial direction, as shown in Fig. 30.12, and the other is a 2-D, all-MEMS configuration, as shown in Fig. 30.13 [30.17]. Very little work has been done in the first, "mixed" configuration, and we will, therefore, present only a short survey of this work. Most of the section will be dedicated to the all-MEMS configuration, on which massive work has been proposed, tested, and published.

Cylinder

A cylindrical ROM media for optical data storage is currently being explored as an alternative to DVD devices, using an adhesive tape film as the recordable medium [30.18]. The purpose of the study is to find out whether this geometry will result in a smaller form factor

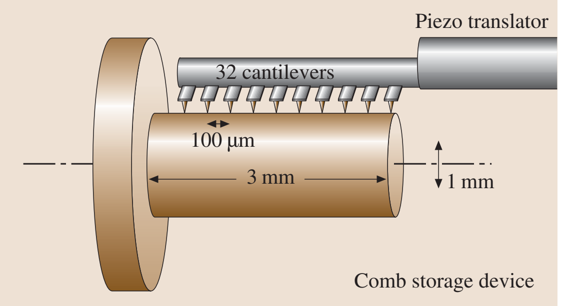

Fig. 30.12 A schematic diagram of a comb storage device

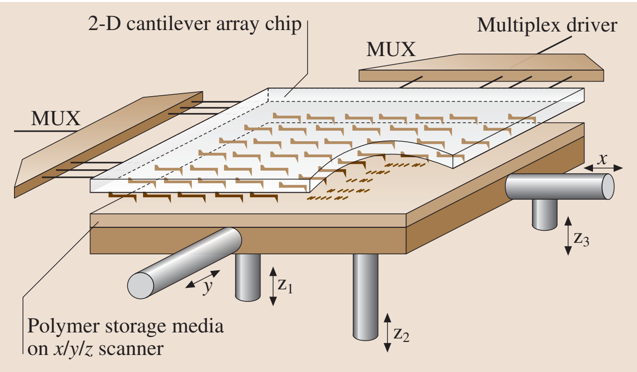

Fig. 30.13 A schematic diagram of a MEMS storage device

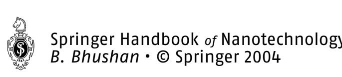

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

and reduced vibrations relative to a commercial DVD. These authors find that this geometry offers a larger writing area than that of a disk. For example, consider a disk with inner and outer radii of r and R, respectively, and a cylinder with the same radius and a height of h. For equal areas, the height of the cylinder is given by $h = (R^2 - r^2)/2R$. Therefore, for $r = 2.5$ mm and $R = 15$ mm, one obtains $h = 7.3$ mm. As a result, a cylinder with $R = h = 15$ mm offers more than twice the area of a disk. Such a device presents an interesting opportunity that the authors are currently pursuing. Figure 30.12 is an artist's concept of a possible geometry where a linear array of 32 cantilevers with their tips is mounted along the axis of a rotating cylinder. This array, which resembles a comb, is mounted on a piezoelectric actuator that can move the minute array very fast across a distance that equals the gap between adjacent cantilever tips. Let the cylinder circumference be divided into 32 sectors, each containing data bits arranged as circular tracks within each sector. As the cylinder rotates, each of the 32 tips reads independently a single track. Using the piezoelectric actuator, one can now move all the tips such that they read the next 32 tracks. Consider the particular geometry presented in Fig. 30.12, where the diameter of the cylinder is 1 mm, its length 3 mm, the distance between tips 100 μm, and a cylinder rotation rate of 10,020 rpm.

A crude assessment of the possible performance of such a device indicates promising values for the capacity, latency, access time, and transfer rate [30.19].

Note that while the rotational rates of these devices are expected to be similar to those of a HDD, one can conceive of MEMS-derived motors increasing the rotation rate. For example, a micro-engine with a diameter of 64 μm driven electrostatically at 300,000 rpm has recently been investigated [30.20]. The purpose here was to study the out-of-plane displacement and tilts about the rotating hub. Optical methods have been developed to characterize the operation of this device, together with a model that takes into account the various parameters relating to its operation. One wonders whether a combination of this MEMS technology with a disk or cylindrical recordable medium is a viable option for reducing latency and decreasing access time for data storage applications.

Probe Storage

The next section provides a detailed description of a probe storage device, so here we will only outline briefly the main principles of its operation [30.8, 9, 21–26]. Consider a typical schematic of a MEMS-based storage presented in Fig. 30.13, [30.17] where the cantilevers are laid out on a "sled" in both the x and y directions. The sled is translated, typically by electrostatic actuators, over the medium surface. This means that, unlike in conventional hard disks, the sectors are laid out adjacent to each other.

There are two possible architectures to this arrangement, one in which the media is moved relative to the tips and one in which the media is fixed and the tips are moved. The moving-tips model is very space inefficient, allowing only about 1% of the media area to be used for data storage, and, therefore, making it unviable in comparison to other storage technologies. In this configuration, the media is suspended by springs over the tips with actuators that control their positioning. In contrast, however, a typical design for a moving media model could have 10,000 tips in a 1 cm^2 area with a bit size of 50 nm^2. This geometry allows 30–50% of the area of the media to be utilized. Allowing for overheads such as error correction, this gives a storage capacity of 4 Gb/cm^2.

The disadvantage of this scheme is the greater mass that needs to be moved, resulting in large seek times. There is a settling time associated with each movement of the system, as the springs cause the sled to oscillate around its final position before coming to rest.

As shown in Fig. 30.14, the media is divided into $M \times N$ rectangular regions, each of which is accessible only by a single tip. The major advantage of this is that the data can be "striped" across multiple regions, dramatically increasing read times, as one seek operation is sufficient to read many bits.

The notation to address each bit is of the form $\langle x, y, tip \rangle$, where x and y are the horizontal and vertical coordinates of the bit within a rectangular region accessible by *tip*. A tip track is the data for which $\langle x, tip \rangle$ is the same, i. e., a vertical column within a rectangular region. By analogy with hard disk architecture, all data with identical x form a cylinder, accessible without moving the sled in the x direction. Cylinders are divided into tracks, which are accessible by the currently active tips, as not all tips can be active simultaneously for power considerations.

As mentioned, a benefit of this architecture is that data tracks are striped across tip tracks. This is depicted in Fig. 30.14 [30.23], where each data sector is mapped across several tip tracks. Sectors 1 and 2 can be read in parallel by activating tips 1–4 and moving them vertically downwards.

Simulated device performance for a prototype sled with parameters given in Table 30.3 is shown in Ta-

Table 30.3 A table of probe storage operating parameters

Sled mobility in x and y	100 µm
Bit cell width (area)	50 nm (0.0025 µm^2)
Number of tips	6,400
Simultaneously active tips	1,280
Tip sector length	80 bits (8 bytes)
Servo overhead	10 bits per tip sector
Device capacity (per sled)	2.1 GByte
Sled acceleration	114.8 m/s^2
Per-tip data rate	400 kbit/s
Settling time constants	1
Sled resonant frequency	220 Hz
Spring factor	75%

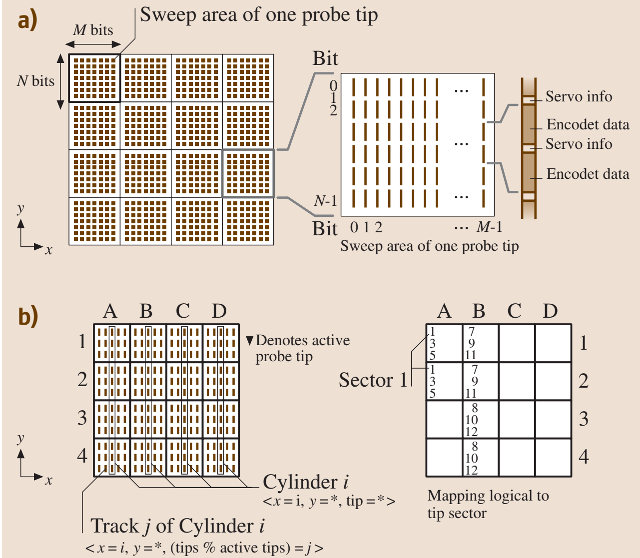

Fig. 30.14 A schematic diagram of a probe storage data organization

ble 30.4. Note that an important breakthrough in MEMS technology has recently been reported in which over one million cantilevers per sq. cm have been fabricated by anisotropic etching of silicon [30.27]. The cantilevers, which had tips at their end, measured a few micrometers in length, had spring constants of a few N/m, resonance frequencies around 10 MHz, and Q factors of 5 in air. Significantly, the resonance frequencies within the same row deviated only by 0.01%. Cantilevers as short as 100 nm and as thin as 20 nm were also fabricated, demonstrating the latitude that this technology offers. Also reported was the fabrication of a large number of cantilevers operating at frequencies up to 1 GHz with Q factors up to 8,000 [30.28]. These results will no doubt play a pivotal role in MEMS-related data storage technology for which mass parallelism combined with superfast sensors offer an important advantage.

Table 30.4 Probe storage projected performance

Average service time	1.49 ms (0.25)
Maximum service time	4.51 ms
Average seek time	1.27 ms (0.25)
Maximum seek time	1.66 ms
Average x seek time	1.24 ms (0.21)
Maximum x seek time	1.66 ms
Average y seek time	0.90 ms (0.31)
Maximum y seek time	1.62 ms
Settling time	0.72 ms
Average per request turnaround time	0.20 ms (0.20)
Maximum per request turnaround time	1.34 ms

Table 30.4 [30.22] takes into account the physical performance of the device, including the acceleration of the actuators, settling time, etc. One observes that the results of the model compare favorably to current hard disk technology, having access times that are approximately six times faster. Note that recent results by the IBM group imply a potential bit areal densities of 400 Gbpsi [30.29].

30.2.2 Sensors

As stated before, the key problem associated with densely packed nanoscale data bits is how to address them, realizing that no interconnects of this small size exist. Clearly, the only known method is to utilize MEMS technology where sharp tips are used to read, write, and rewrite the data bits. Although such a technology is attractive, one has to realize that the number of physical phenomena available for effecting such an interaction is quite limited.

There are, in principle, three modes for interfacing, or sensing nanoscale data bits. In the first mode, denoted as contact mode, a sharp tip is constantly in contact with the medium on which the bits are written. Here, the apex of the tip has to be comparable in size to that of the bit. The second mode involves such a tip in close proximity to the bit without actually touching it. The third mode, dubbed the noncontact mode, is a combination of the

other two modes. Here, the tip vibrates in close proximity to the media in such a way that on each cycle it touches or taps its surface for a short period. This mode is referred to as the tapping mode [30.30], which turns out to have several advantages relative to the other two modes. In either mode one can use an electric current within the tip to heat up a data bit, inject a current into it, or impose an electric field across it.

For the noncontact mode, one can use field emission from a sharp tip that is positioned several nanometers away from a sample, or use a tunneling current when the tip is within a fraction of a nanometer away from the sample. The current can then be used to heat a data bit and probe its conductivity as a means for data storage and retrieval. Yet both of these are accompanied with electronic noise when operating in ambient, thus requiring vacuum for a more steady operation. Note that a tunneling current is so sensitive to a tip-sample gap that a change of 0.1 nm in gap size will change the tunneling current by one order of magnitude. One can, therefore, rule out such a technique, as its restrictions on media flatness are too strenuous. In spite of some inherent difficulties, field emission maintained its position as a viable technology for data storage applications. A schematic diagram of the operation of a device based on this technology is shown in Fig. 30.15 [30.31].

Here, a multiplicity of stationary tips is positioned in close proximity to a conducting medium, such as a chalcogenide, and a controlled current emission for each tip is used to transform its phase reversibly from crystalline to amorphous. Either the tips or the media are raster scanned across each other such that, as with the probe storage device, one can address a large number of data bits. Both tips and media are placed under a mild vacuum that has to be maintained at all times.

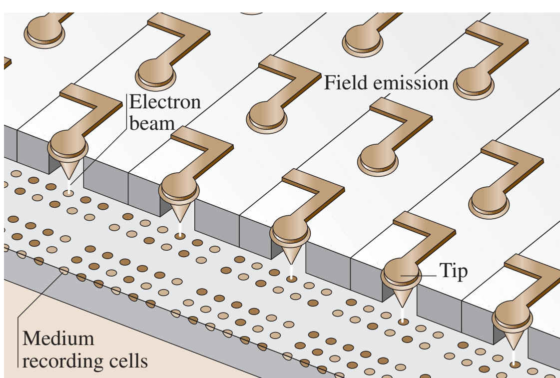

Fig. 30.15 A schematic diagram of field-emission tips

Although writing bits may be utilized efficiently, reading them back, namely, measuring their conductivity is a nontrivial task that requires further investigation. Along these lines, one may employ a MEMS-based approach and use conducting tips that are in direct contact with a conducting medium.

A different approach to locally heating a sample that does not require direct tip-sample contact, vacuum conditions, or conducting media, is to have a heating element embedded inside each tip. In spite of the fact that each tip has a complex structure, as shown in Fig. 30.16b, it was found possible to fabricate a 64×64 2-D array that raster scans a polymer medium. Heating a data bit and pressing a sharp tip into it generates a nanoscale pit that is estimated to persist for years. Sensing the pit for readout is accomplished by monitoring the heat

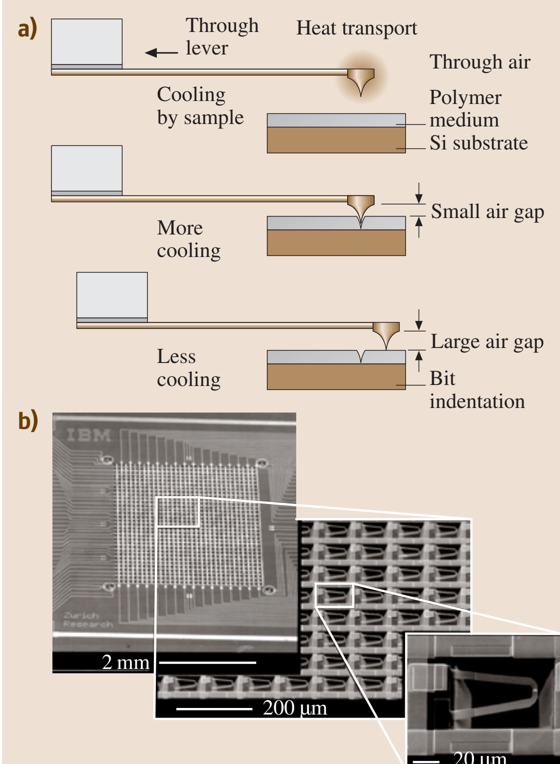

Fig. 30.16 **(a)** A schematic diagram of a cantilever with a heating and heat-sensing tip. Indentations are inscribed into a polymeric medium by means of a heated tip. The bits are read by sensing the increased heat loss in an indentation due to the greater surface area in contact. **(b)** Details of the tip structure

dissipation of the heated tip as a function of the media topography. When the tip is across a smooth surface, it is exposed mostly to air. When the tip is sunk into a pit, it is surrounded partially by the polymer material. Thus, the difference in heat conductivity between these two cases serves as a measure of the state of the polymer, whether it is smooth or dimpled. A key difficulty with this technology has been the erase mechanism, which is currently being addressed [30.29].

In the noncontact mode, the tip is vibrated at a distance such that the tip never touches the surface directly. However, the tip senses the surface of the sample indirectly through force gradients that modify the resonance frequency of the cantilever. This mode can be useful in magnetic recording if one attaches a small magnet to the tip and uses it to both modify and sense magnetic domains. This mode, however, is slow, as the tip has to vibrate many times during the sensing of a single data bit and, therefore, can be ruled out as a candidate for data storage.

We shall now consider the tapping mode that has three main advantages to the contact mode. First, the tip-sample contact time is reduced by almost two orders of magnitude, thus minimizing tip-media wear. The second advantage is that it touches the media in a much gentler way and, therefore, does not twist or bend. The third advantage is that the tip jumps between points of contacts, which constitute the data bits, so it is less prone to crash due to media roughness. If one uses the tapping mode with a conducting tip and taps on a conducting substrate, it is possible to follow the motion of the vibrating cantilever by monitoring the time the tip makes contact with the sample. This method makes it easy to control a feedback system that keeps the motion of the cantilever under control, provided the contact is good enough. The problem one encounters using this mode, however, is that such an operation is usually chaotic and, therefore, difficult to control. If one were to overcome this problem, this mode would be fast enough relative to the noncontact mode to be considered a viable method for data storage.

We will now consider the theory and experimental results of the tapping mode by first treating it as a grazing impact oscillator (GIO) for which one can obtain closed-form expressions connecting all of its parameters [30.32]. The GIO consists of a cantilever driven at a constant frequency and an amplitude by an external force. The vibrating cantilever is then brought into close proximity to the surface of a sample until its tip starts impacting the surface. At this point the amplitude of vibration of the GIO changes, together with the relative phase between the driver and the tip. Let the amplitude of vibration of the driver be denoted by a and the spring constant and quality factor of the cantilever be denoted by k_0 and Q, respectively. On impact, the GIO acquires amplitudes of vibration A and effective spring constant k_{eff}, establishing a new value for the input power and phase:

$$A = \frac{aQ}{\sqrt{Q^2\left(1-\frac{k}{k_0}\right)^2+\frac{k}{k_0}}}\,, \tag{30.1a}$$

$$\theta = \tan^{-1}\left(\frac{\sqrt{k/k_0}}{Q(1-k/k_0)}\right)\,, \tag{30.1b}$$

$$k = k_0\left[\sqrt{\left(\frac{a}{AA}\right)^2+\frac{1}{4}\left(\frac{1}{Q^4}-\frac{4}{Q^2}\right)} - \frac{1}{2Q^2}+1\right]\,. \tag{30.1c}$$

Equation (30.1) shows the relationship among the various parameters governing the operation of the GIO in a closed form, making it possible to model the effect that impacting has on the tapping cantilever. Figure 30.17a shows that on bringing the vibrating cantilever closer to the surface, its amplitude of vibration decreases and its effective spring constant increases. Figure 30.17b shows the phase of the vibrating cantilever as a function of the amplitude of vibration. Figure 30.17c and d depict the input power as a function of the amplitude of vibration of the cantilever and of its phase, respectively. The double-

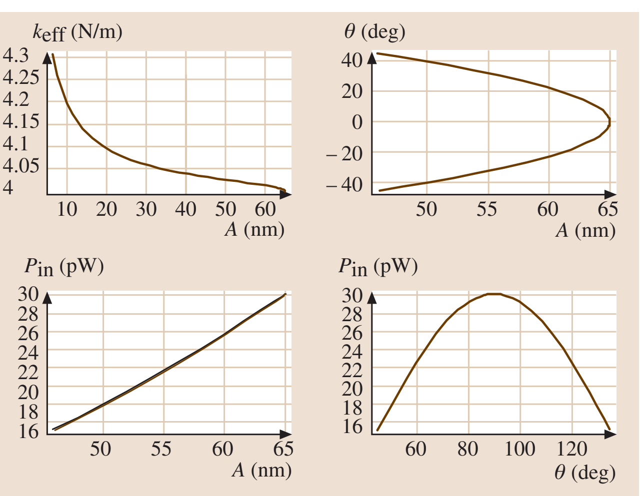

Fig. 30.17 Calculated tapping behavior. Modeling of the relationships among the amplitude A, effective spring constant k_{eff}, input power P_{in}, and phase ϕ

Part E | 30.2

valued functions express the fact that one can operate either below or above the original resonance frequency of the cantilever.

This simplified model of a tapping mode neglects many effects such as indentation of the surface on impact and adhesion and other interface tip-sample forces. For our purpose, however, we will neglect these effects and explore the feasibility of using the tapping mode for data storage applications. The idea here is to have the tip jump from one pixel, or bit of stored data on the surface of a sample to another pixel without touching the surface in between. And while briefly touching the surface, the tip, which is conducting, will inject a pulse of current into the pixel and modify its conductivity [30.33]. Upon returning to the same pixel, the tip could monitor the conductivity of that particular pixel.

Considering the fact that the tapping mode involves a driven, damped oscillator, it is apparent that the motion of the cantilever traces a chaotic trajectory, necessitating an averaging process. For most imaging or nanofabrication purposes, such an averaging, combined with an appropriate image processing procedure, can indeed yield images with nanometer resolution. For data storage applications, however, it is desirable to have non-chaotic, reproducible interactions for every single tap because one could not afford an averaging procedure.

There are two key issues regarding the requirement that each tap produce a controlled interaction. The first concerns the identification of conditions under which (i) chaotic motion of the cantilever is minimized and (ii) good tip-sample contact is established. The second issue concerns the means by which one can observe these individual interactions. The difficulty in measuring tip-sample interactions during an individual tap stems from the fact that most of the time the tip is far away from the sample, and only during a small fraction of a cycle does it actually sense the presence of the sample. Also, it is the nature of the tapping mode of operation that the tip approaches the sample at a relatively small velocity, which is the reason why it acts as a grazing impact oscillator in the first place. One can choose the electrical contact between tip and sample as the measuring tool for the reproducibility of the interaction for individual taps. This choice is clearly compatible with storage modalities in which current injection into storage media gives rise to writing and reading of phase-change data.

The use of all-metal cantilevers tapping on a gold substrate was recently demonstrated, whereby carefully chosen parameters enable the generation and observation of individual current pulses [30.34]. These pulses were generated by applying a short bias pulse during the tip-sample contact time. Each current pulse, lasting up to 20 μs, could produce a current of ∼ 10 μA in a nm^2 region yielding a current density of 10^{13} A/m^2. This density is large enough to be applicable for phase-change. The cantilever was fabricated from a rectangular PtIr wire whose length, width, and thickness were 1,200 μm, 100 μm, and 50 μm, respectively. One side of the cantilever was attached to a driving bimorph, and the other side etched to produce a tip whose apex radius was estimated to be 70 nm. The spring constant, resonance frequency, amplitude of vibration, and quality factor of the cantilever were 300 N/m, 13 kHz, 100 nm, and 100, respectively. The all-metal cantilever ensured good conductivity and could withstand a large number of

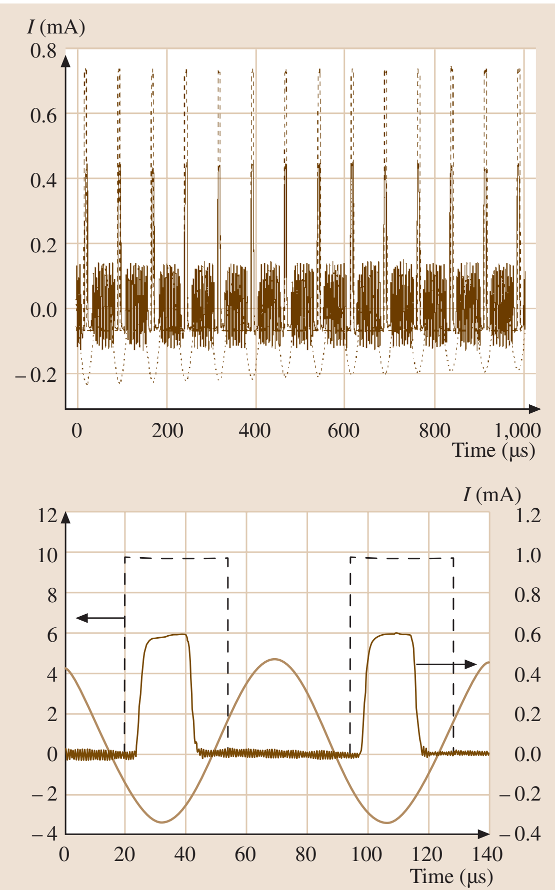

Fig. 30.18 **(a)** A typical current pulse train (*solid line*) obtained with pulsed voltage bias in phase with the cantilever's lowest position and the associated cantilever motion (*dotted line*), **(b)** two current pulses (*solid line*), bias voltage pulses (*dashed line*), and cantilever motion (*dotted line*)

tapping impacts without degrading and had a shiny surface that acted as a good mirror for the optical deflection technique.

The experimental results yielded long trains of individually injected current pulses. Figure 30.18 (left-hand side) shows 14 non-averaged experimental current pulses (solid line) and their associated cantilever motion (dashed line) with a background of instrumental noise [30.34]. The current pulses demonstrate the reproducibility of the conductance established during each tap. Figure 30.18 [30.34] (right-hand side) shows two averaged current pulses (solid line) with their input bias pulses (dashed line) and the associated cantilever motion (dotted line). Note that the tip-sample contact time is revealed by the duration of the current pulse, which is shorter than the duration of the applied bias pulse. Here, the amplitude of the bias pulse was 10 mV, its duration was 40 μs, and the timing of its application relative to the motion of the cantilever was provided by the output of the atomic force microscope photodiode. The current pulses, with a magnitude of 0.5 mA, are much larger than the tunneling current occurring while the tip is within a fraction of a nanometer from the surface. Also, the displacement current, due to the motion of the cantilever and the time varying nature of the applied bias, is expected to be much smaller than the observed current pulses. The contact conductance

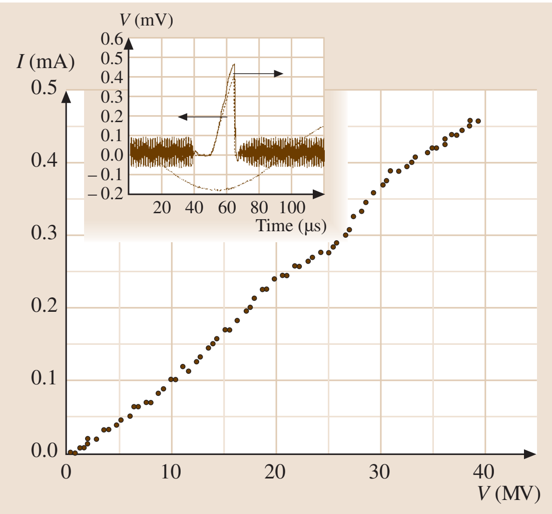

Fig. 30.19 An I–V curve taken with an individual ramped input voltage pulse demonstrating an ohmic contact. *Insert:* The current pulse (*solid line*), ramped input bias voltage (*dashed line*), and cantilever motion (*dotted line*)

is shown in Fig. 30.19, where a linear relation between voltage and current implies a good ohmic contact. These results demonstrate that it is possible to minimize the chaotic behavior of a tapping cantilever and obtain reproducible conductance on each individual tap. The next step is to use the tapping mode in conjunction with current injection to write and read data bits on conducting media.

30.2.3 Media and Experimental Results

This section summarizes several typical experimental results using different data storage media, electric charging, electric domain orientation, magnetic domain orientation, chemical modification, and phase change in chalcogenides and organic films.

Electric Charging

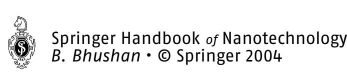
Quate's group at Stanford has studied charge trapping in a silicon nitride/silicon dioxide/silicon system using a scanning capacitance microscope [30.6]. The charge trapping in this system has been used for many years for non-volatilesemiconductor memory. Using chemical vapor deposition, 500 Å of silicon nitride was deposited onto a silicon wafer with a 50 Å oxide coating. By selectively storing charge into the substrate, they were able to write bits as small as 0.02 μm^2. Using this method, they were able to write the founding document of the Swiss Confederation onto a 120 μm^2 area, corresponding to 256 kilobits of information that yields a data density of 10 Gbpsi.

Electric Domains

Hidaka et al. have demonstrated the possibility of ultra-high density charge storage in a ferroelectric film, $PbZr_{1-x}Ti_xO_3$ [30.35]. They show that a change in the topography of the film can be introduced by domain reorientation induced by the application of a 10 V pulse with a duration of 100 μs. This is due to the piezoelectric effect caused by domain structures. Data bits as small as 40 nm were written this way. This result implies a data density of approximately 300 Gbpsi, suggesting that this medium is a good candidate for high-density data storage.

Thin Oxide Films

IBM Research in Switzerland has demonstrated reproducible switching in thin oxide perovskite films [30.36]. By constructing metal-insulator-metal capacitor-like devices, with $SrZr0_3$ as the insulator, they were able to observe an order of magnitude increase in the leakage



current of the device at a threshold voltage of −0.5 V. This process is perfectly reversible, and the leakage current can be restored to its initial state upon application of a positive voltage. The switching occurs very rapidly, taking less than 100 ns to change from one conductivity state to another. Interestingly, the magnitude of the transition depends on the voltage applied, suggesting the possibility of storing multiple bits in one pixel.

Magnetic Domains

Sun et al. have demonstrated a novel way to overcome the limitations of media currently used for magnetic data storage [30.37]. By reducing iron and platinum-containing compounds, they demonstrated the formation of large-scale self-ordered arrays of magnetic particles. Initial studies suggest that an assembly of magnetic particles as small as 4 nm can support stable magnetization transitions at room temperature. By using the particles in these arrays as bits, the possibility of terabit-per-square-inch magnetic data storage could be realized.

Figure 30.20 shows transmission electron microscopy of these arrays that indicate a remarkable uniformity of particle size and large-scale periodicity. The figure also shows assemblies of these particles deposited onto a silicon oxide substrate under varying experimental conditions.

Chemical Modification

We have discussed the fact that the tapping mode is considerably less damaging to the tip and sample, as the tip spends less time contacting the sample and does not drag across it while raster scanning. For this purpose, diamond-coated cantilevers have been found useful for experiments in which wear is a problem. For sample oxidation purposes, the tip is first oscillated away from the sample with peak-to-peak amplitude of 10–15 nm, and then a feedback system reduces the amplitude to 7–10 nm by pressing the tip further into the sample. A 50 ms-long pulse with a 10–12 V magnitude is then applied to oxidize a thin Ti film. It was found that this technique produces much finer structures. Figure 30.21 [30.38] is a tapping mode AFM image of four dots created in such a way. The dots in this image have a diameter of less than 10 nm and a height of 3.5 nm above the surrounding Ti surface with a center separation of 20 nm. Around the dots there is what appears to be a lower ring of material with a channel in between. This experiment demonstrates that one can use the tapping mode to write fine pixels, albeit not to erase them.

Phase Change in Chalcogenides

Chalcogenides, the active material in rewritable CDs, have the advantage of being a well-characterized and understood bistable phase change material that has already had successful commercial data storage applications, i. e., CDRWs. Currently, NVRAM using chalcogenides as the active material is being pursued by an alliance of Ovonyx and Intel. Chalcogenides are materials that have an easily reversible stable change between amorphous and crystalline phases. To switch from the crystalline to the amorphous phase, the material is heated sufficiently, so that the material subsequently cools rapidly into the amorphous phase. The reverse change is achieved by heating the material above the glass transition temperature, so that it recrystallizes upon cooling. For commercial CDRWs, writing is done by means of laser light heating and reading is done by measuring the difference in reflectivity of the laser light from each of these two phases.

Scanning probe microscopy can be used to switch the phase of a chalcogenide material by the application of a pulse of current that heats the material as it passes through it [30.39]. The state of the material can be read typically by measuring the resistance of the sample. Figure 30.22 shows the two different states, amorphous and crystalline of the chalcogenides. The reversibility of this transition is remarkable, and has been shown to be stable over 10^{12} repeated read-write cycles. *Gotoh* et al. demonstrated this effect using conducting AFM tips, where a transition from the high resistance amorphous state to the lower resistance crystalline state was observed both the in topography and the conductivity of the sample. The change from amorphous to crystalline phases was confirmed by X-ray diffraction. Figure 30.23a and a′ show a conductance AFM image and a profile of the surface after the application of varying voltage pulses. The topography of the substrate is shown in Fig. 30.23b. Figure 30.23c and c′ show the equivalent conductance AFM images after the substrate has been scanned at a negative voltage, erasing the lower power marks on the substrate.

These materials have been further characterized by *Gidon* et al. [30.26], who showed that the resistivity of the film in its amorphous phase was $100\,\Omega\,cm^{-1}$, while that of the crystalline state was $0.1\,\Omega\,cm^{-1}$. They also show that a data bit requires a 200 ns pulse with a power of 50 μW, which translates to a total energy of 10 pJ.

Phase Change in Organics

Organics have proved important in a variety of electronic and optoelectronic applications such as light-emitting diodes, thin-film displays, transistors, photovoltaics, and

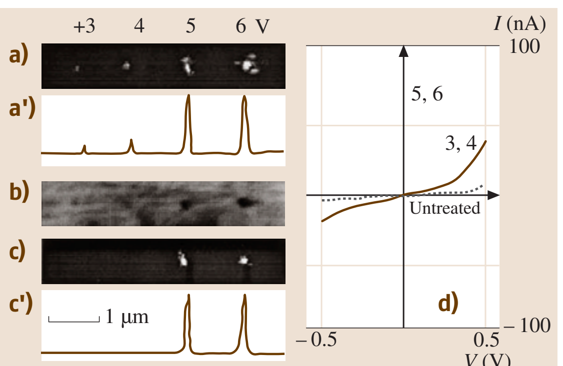

Fig. 30.23 Experimental results of phase change using an AFM tip **(a)**, **(a′)**, conducting AFM images after applying 100 ns pulses to the substrate, **(b)** topography AFM image of the substrate, **(c)**, **(c′)** conducting AFM images showing erasure after scanning the substrate with an applied bias of −1 V, **(d)** *I–V* curves of untreated (*dotted*) and treated (*solid*) regions

lasers. There are several advantages to organics for economic and manufacturing reasons, and a large body of research already exists in this field. As such, there is significant interest and motivation in finding data storage applications based on organic technology.

There has been much research recently into organic materials and systems capable of reversible switching and thus capable of being exploited for data storage applications. There are two broad categories of organics data storage; one where the active material (which can be homogenous or heterogeneous) has inherent bistability, and one where the bistability is a property of the device structure.

There are many different materials that have been investigated for data storage. The fundamental property is that it should have two states (electronic, morphological, or some other easily measured physical characteristic) that the material can exist in, and it should be stable indefinitely in either state. Furthermore, the material should be able to be easily and reversibly switched between these states, and this should be reproducible over many millions of cycles for it to be useful as a data storage medium.

Several groups have been working on reversible transitions in organic complexes suitable for switching by scanning probe techniques. Many complexes have been demonstrated to exhibit reversible switching, e.g., 3-nitrobenzal malonitrile (NBMN) and 1,4-phenylenediamine (pDA) [30.40], tetrathiofulvane (TTF) and *m*-nitrobenzylidene propanedinitrile (*m*-NBP) [30.41], and many other variants.

Li et al. [30.41] have studied organic films consisting of tetrathiofulvane (TTF), an electron donor, and *m*-nitrobenzylidene propanedinitrile (*m*-NBP), an electron acceptor. This complex demonstrates electrical bistability, which can be written and read by scanning tunneling microscopy.

The nature of the measurement means that it is difficult to ascertain whether this is due to solely conductive changes in the sample, or whether topographic modifications might also contribute. By applying pulses of 1 ms duration, bits of 1.2 nm diameter could be written. This implies an areal density of $\sim 10^{18}$ bits/in^2. This change was characterized electrically, and the resistance was measured as changing from $10^8\ \Omega$ to $10^3\ \Omega$ with a threshold switching voltage of 3.1 V. The proposed switching mechanism is charge transfer between the two film constituents. This change was stable over time and is reversible. This change is reversible, but only by heating for prolonged periods, making it unsuitable for applications as of yet.

Gao et al. have demonstrated stable, local, reversible nanoscale switching [30.40] using a charge transfer complex of 3-nitrobenzal malonitrile (NBMN) and 1,4-phenylenediamine (pDA). A 200-nm-thick film of this complex was deposited onto highly ordered pyrolitic graphite. Macroscopic electrical measurements demonstrate the bistability and switching of the material. Figure 30.24a shows the current-voltage characteristics of the sample in these two conductivity states. Initially, the material is in a low conductivity state, but upon reaching a certain threshold voltage, in this case 3.2 V, the material abruptly changes to a conductive state. The transition time is very abrupt, 80 ns, as shown in Fig. 30.24b.

Of further interest for data storage applications is that, having demonstrated reversible switching in macroscopic films, Gao et al. also showed that it was possible to switch these materials on the nanoscale using an STM

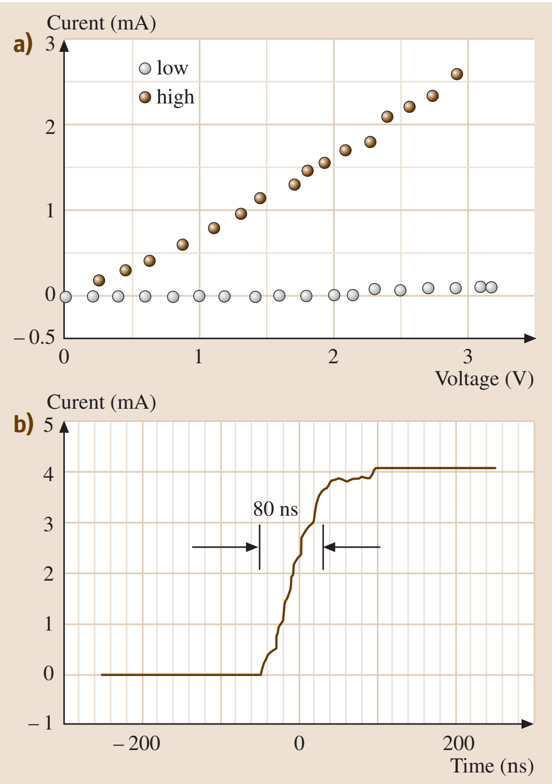

Fig. 30.24a,b Experimental results of bulk conductivity changes of organic films. **(a)** *I–V* curves of a 200-nm-thick film showing the two conductivity states. Switching voltage is 3.2 V. **(b)** Change in conductivity against time, showing a transition time of 80 ns

to apply pulses, i. e., to write bits, and also to measure conductivity, i. e., to read bits.

Figure 30.25a shows the local nanoscale film morphology of the sample. Figure 30.25b and c show patterns written on a sample by application of voltage pulses from the STM tip. Figure 30.25d demonstrates the erasure of a single bit from the pattern by application of a reverse-biased voltage pulse. Similar to the work of *Li* et al., the entire substrate could be erased by prolonged heating. Of much greater interest is the demonstration of individual bit erasure, achieved by applying reverse voltage pulses. The erasure is incomplete unless the pulse is reverse-biased, indicating that it is the combined effect of heating and electric field that erases the bits.

Several proposed mechanisms were investigated as the possible origin of this switching, including conformational switching and charge transfer. These could be discounted for reasons, including the stability and time scale of the switching. A more plausible hypothesis is a local phase transition from crystalline insulating regions to amorphous conducting regions. TEM and diffraction studies of the samples agree with this hypothesis. It should be pointed out that an alternative interpretation has been suggested by *Zhao* et al. [30.42]. The conductivity change could be due mainly to a change in the topography of the sample, reducing the tip-sample distance and, therefore, the tunneling distance, manifested as an apparent change in conductivity.

Ma et al. have developed a simple device structure that exhibits electrical bistability [30.43]. This device has a fairly simple structure consisting of alternating layers of aluminum and an organic compound, 2-amino-4,5-imidazoledicarbonitrile (AIDCN), as depicted in Fig. 30.26a. Several alternative organics (Alq3 and MEH-PPV) and metals (copper, silver, and gold) have been tried with varying degrees of success.

Figure 30.26b shows the current-voltage bistability of a device with structure Al/AIDCN (50 nm)/Al (20 nm)/AIDCN (50 nm)/Al. A first run shows an initially low current, followed by an abrupt and dramatic increase in the current of four orders of magnitude at 2 V. Subsequent repeated voltage runs (b) show that this transition is stable, being orders of magnitude higher than the initial measurement. The devices proved to be stable in this state over periods ranging from days to weeks.

Of further interest is that the device proved to be erasable by purely electrical means, the application of a −0.5 V pulse bringing the device back to its original state. This is denoted by c in Fig. 30.26b. Furthermore, the devices showed excellent stability over time, with over one million read-write-erase cycles being performed on the devices with excellent repeatability, as depicted in Fig. 30.26c. The origin of this bistability is unclear. It is clear that the central electrode is critical to the observed effect, as the bistability is only observed when the central electrode thickness is above a threshold value, 10 nm. Organics with high dielectric constants and low conductivity are believed to be important for device performance. The exact mechanism, however, is as yet unclear. Preliminary results on novel materials [30.44] have suggested the possibility of an all-organic variation of this concept, with an AFM tip switching between bistable states of the system.

30.3 Conclusion

Nanotechnology is perceived as a branch of science that deals with structures whose dimensions are measured in nanometers. Clearly, new phenomena become apparent when the number of atoms at the interface of such a structure becomes comparable to the number of atoms in its volume. As a result, nanotechnology evolved into a new kind of science that deals with the physics of small things. However, the suffix -technology here implies a far more reaching aspect than just a scientific curiosity; this branch of science should also be of some use. This poses a dilemma for researchers whose main interest is in understanding new phenomena, rather than in finding a use for them. Consider scanning probe microcopy, which is celebrating its twentieth birthday now with uncountable contributions to the science of measurement of surfaces and near-surface phenomena. Despite all the contributions scanning probe microscopy has made, it has always served as a tool for investigations, rather than as a practical device that can become a commercial commodity. And yet this is exactly what this chapter deals with. The challenge of converting scanning probe microscopy from a research tool into a probe storage device is daunting indeed and will require new ideas to make it happen. The danger associated with this challenge is that novel ideas developed by research groups are sometimes too immature to be measured against any existing technology, in general, and against data storage, in particular. One has to keep pursuing research opportunities whose outcomes are unknown and whose applications are unexpected with the hope that they will bring about good science and hopefully useful applications.

However, based on the technical breakthroughs delineated in this and the following chapter and judging from the history of data storage evolution, it seems plausible that probe storage will serve as a disruptive technology that replaces data storage devices in a particular market niche. These new devices should be non-volatile, have terabyte capacity with microsecond access times with gigabyte transfer rates, all for a cost that is highly competitive with current commercially available data storage devices.

31. The "Millipede" – A Nanotechnology-Based AFM Data-Storage System

The "millipede" concept presented here is a new approach for storing data at high speed and ultrahigh density. The interesting part is that millipede stores digital information in a completely different way from magnetic hard disks, optical disks, and transistor-based memory chips. The ultimate locality is provided by a tip, and high data rates are a result of massive parallel operation of such tips. As storage medium, polymer films are being considered, although the use of other media, in particular, magnetic materials, has not been ruled out. The current effort is focused on demonstrating the millipede concept with areal densities of up to 0.5–1 Tb/in^2 and parallel operation of very large 2-D (up to 64 × 64) AFM cantilever arrays with integrated tips and write/read/erase functionality. The fabrication and integration of such a large number of mechanical devices (cantilever beams) will lead to what we envision as the VLSI age of micro- and nanomechanics.

In this chapter, the millipede concept for a MEMS-based storage device is described in detail. In particular, various aspects pertaining to AFM thermomechanical read/write/erase functions, 2-D array fabrication and characteristics, *x*/*y*/*z* microscanner design, polymer media properties, read channel modeling, servo control and synchronization, as well as modulation coding techniques suitable for probe-based data-storage devices are discussed.

In the twenty-first century, the nanometer will probably play a role similar to the one played by the micrometer in the twentieth century. The nanometer scale will presumably also pervade the field of data storage, although there is so far no obvious way in conventional magnetic, optical, or transistor-based storage to achieve the nanometer scale in all three dimensions. After decades of spectacular progress, those mature technologies have entered the homestretch; imposing physical limitations loom before them.

One promising method involves the use of patterned magnetic media for which the ideal write/read concept still needs to be demonstrated. The biggest challenge, however, is to pattern the magnetic disk in a cost-effective way. If such approaches are successful, the basis for large-capacity storage in the twenty-first century might still be magnetism.

Other proposals call for totally different media and techniques such as local probes, near-field optics, magnetic super-resolution or holographic methods. In general, when an existing technology is about to reach its limits in the course of its evolution and alternatives are emerging in parallel, two things usually happen: First, the existing and well-established technology is explored further and every effort is made to push its limits to the utmost in order to get the maximum return on the consid-

erable investments made. Then, when all possibilities for improvement have been exhausted, the technology may still survive for certain niche applications, but the emerging technology will take over, opening new perspectives and new directions.

In many fields today we are witnessing the transition of structures from the micrometer to the nanometer scale, a dimension that nature has long been using to build the finest devices with a high degree of local functionality. Many of the techniques we use today are not suitable for the nanometer age; some will require minor or major modifications, others will be partially or entirely replaced. It is certainly difficult to predict which techniques will fall into which category. In key information technology areas, such as nano-electronics and data storage, it is not yet obvious which technologies and materials will be used in the future.

In any case, for an emerging technology to be seriously considered as a candidate to replace an existing technology that is approaching its inherent limits, it must provide a long-term perspective. For instance, the silicon microelectronics and storage industries are huge and have exacted correspondingly enormous investments, which makes them long-term oriented by nature. The consequence for storage is that any novel technology with higher areal storage density than today's magnetic recording [31.1, 2] should have long-term potential for further scaling, preferably down to the nanometer or even atomic scale.

The only available tool known today that is simple and yet provides this very long-term perspective is the nanometer-sharp tip. The simple tip is a very reliable tool that concentrates on one functionality: the ultimate local confinement of interaction. Techniques that use nanometer-sharp tips for imaging and investigating the structure of materials down to the atomic scale, such as the atomic force microscope (AFM) and the scanning tunneling microscope (STM) [31.3, 4], are suitable for the development of ultrahigh-density storage devices.

In the early 1990s, Mamin and Rugar at the IBM Almaden Research Center pioneered the capability of using an AFM tip for writing and readback of topographic features for data storage. In one of their schemes [31.5], writing and reading were demonstrated with a single AFM tip in contact with a rotating polycarbonate substrate. The writing was performed thermomechanically by heating the tip. In this way, storage densities of up to 30 Gb/in^2 were achieved, constituting a significant advance over the densities of that time. Later refinements included increasing readback speeds to attain a data rate of 10 Mb/s [31.6] and the implementation of track servoing [31.7].

When using single tips in AFM or STM operation for storage, one has to deal with their fundamental data-rate limitations. At present, the mechanical resonant frequencies of the AFM cantilevers limit the data rates of a single cantilever to a few Mb/s for AFM data storage [31.8, 9]. The feedback speed and low tunneling currents limit STM-based storage approaches to even lower data rates.

Currently a single AFM operates at best on the microsecond time scale. Conventional magnetic storage, however, operates at best on the nanosecond time scale, making it clear that AFM data rates have to be improved by at least three orders of magnitude to be competitive with current and future magnetic recording. One solution for substantially increasing the data rates achievable by tip-based storage devices is to employ micro-electro-mechanical system (MEMS) arrays of cantilevers operating in parallel, with each cantilever performing write/read/erase operations in an individual storage field. It is our conviction that very large-scale integrated (VLSI) micro/nanomechanics will greatly complement future micro- and nanoelectronics (integrated or hybrid) and may generate hitherto inconceivable applications of VLSI-MEMS.

Various efforts are under way to develop MEMS-based storage devices. For example, a MEMS-actuated magnetic-probe-based storage device capable of storing 2 GB of data on 2 cm^2 of die area and whose fabrication is compatible with a standard integrated circuit manufacturing process is described by *Carley* et al. [31.10]. In their device, a magnetic storage medium is positioned in the x/y plane, and writing is achieved magnetically by using an array of probe tips, each tip being actuated in the z-direction. Another concept is the atomic resolution storage described by *Gibson* et al. [31.11], who employ electron field emitters to change the state of a phase-change medium in a bit-wise fashion from polycrystalline to amorphous or vice versa. Reading is done with lower currents by detecting either back-scattered electrons or changes in the semiconductor properties in the media.

The "millipede" concept presented here is a new approach for storing data at high speed and ultrahigh density. The interesting part is that millipede stores digital information in a completely different way from magnetic hard disks, optical disks, and transistor-based memory chips. The ultimate locality is provided by a tip, and high data rates are a result of massive parallel operation of such tips. As storage medium, polymer films are being considered, although the use of other

media, in particular, magnetic materials, has not been ruled out. Our current effort is focused on demonstrating the millipede concept with areal densities of up to 0.5–1 Tb/in^2 and parallel operation of very large 2-D (up to 64×64) AFM cantilever arrays with integrated tips and write/read/erase functionality. The fabrication and integration of such a large number of mechanical devices (cantilever beams) will lead to what we envision as the VLSI age of micro- and nanomechanics.

In this chapter, the millipede concept for a MEMS-based storage device is described in detail. In particular, various aspects pertaining to AFM thermomechanical read/write/erase functions, 2-D array fabrication and characteristics, *x*/*y*/*z* microscanner design, polymer media properties, read channel modeling, servo control and synchronization, as well as modulation coding techniques suitable for probe-based data-storage devices are discussed.

31.1 The Millipede Concept

A 2-D AFM cantilever array storage technique [31.13–15], internally called the millipede, is illustrated in Fig. 31.1. Information is stored as sequences of indentations and no indentations written on nanometer-thick polymer films using the array of AFM cantilevers. The presence and absence of indentations will also be referred to as logical marks. Each cantilever performs write/read/erase operations over an individual storage field with an area on the order of 100×100 μm^2. Write/read operations depend on a mechanical parallel *x*/*y* scanning of either the entire cantilever array chip or the storage medium. The tip-medium contact is maintained and controlled globally, i. e., not on an individual cantilever basis, by using a feedback control in the *z*-direction for the entire chip, which greatly simplifies the system. This basic concept of the entire chip approach/leveling has been tested and demonstrated for the first time by parallel imaging with a 5×5 array chip [31.16, 17]. These parallel imaging results have shown that all 25 cantilever tips have approached the substrate within less than 1 μm of *z*-actuation, which indicates that overall chip tip-apex height control to within 500 nm is feasible. The stringent requirement for tip-apex uniformity over the entire chip is determined by the uniform force required to reduce tip and medium wear due to large force variations resulting from large tip-height nonuniformities [31.7]. Moreover, as the entire array is tracked without individual lateral cantilever positioning, thermal expansion of the array chip has to be small or well controlled. Thermal expansion considerations are a strong argument for a 2-D instead of a 1-D array arrangement.

Efficient parallel operations of large 2-D arrays can be achieved by a row/column time-multiplexed addressing scheme similar to that implemented in DRAMs. In the case of the millipede, the multiplexing scheme is used to address the array column by column with full parallel write/read operation within one column [31.18]. In particular, readback signal samples are obtained by applying an electrical read pulse to the cantilevers in a column of the array, low-pass filtering the cantilever response signals, and finally sampling the filter output signals. This process is repeated sequentially until all columns of the array have been addressed, and then restarted from the first column. The time between two pulses applied to the cantilevers of the same column corresponds to the time it takes for a cantilever to move from one logical mark position to the next. An alternative approach is to access all or a subset of the cantilevers simultaneously without resorting to the row/column multiplexing scheme. Clearly, the latter scheme yields higher data rates, whereas the former leads to lower implementation complexity of the channel electronics.

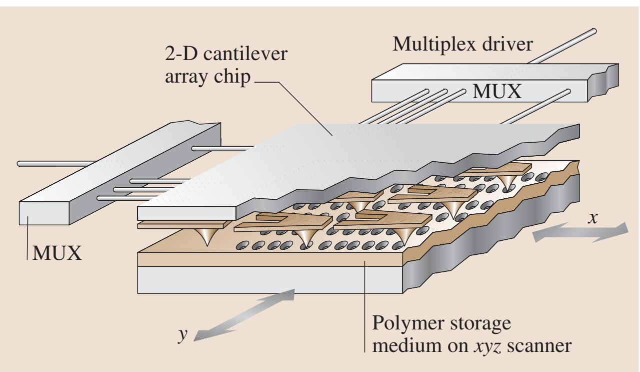

Fig. 31.1 The millipede concept (after [31.12])

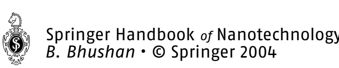

31.2 Thermomechanical AFM Data Storage

In recent years, AFM thermomechanical recording in polymer storage media has undergone extensive modifications mainly with respect to the integration of sensors and heaters designed to enhance simplicity and to increase data rate and storage density. Thermomechanical writing in polycarbonate films and optical readback was first investigated and demonstrated by Mamin and Rugar (1992). Using heater cantilevers, thermomechanical recording at 30 Gb/in^2 storage density and data rates of a few Mb/s for reading and 100 kb/s for writing have been demonstrated [31.5, 6, 19]. Although the storage density of 30 Gb/in^2 obtained originally was not overwhelming, the results were encouraging enough to consider using polymer films to achieve density improvements. The current millipede storage approach is based on a new thermomechanical write/read process in nanometer-thick polymer films.

Thermomechanical writing is achieved by applying a local force through the cantilever/tip to the polymer layer and simultaneously softening the polymer layer by local heating. Initially, the heat transfer from the tip to the polymer through the small contact area is very poor, but it improves as the contact area increases. This means that the tip must be heated to a relatively high temperature of about 400 °C to initiate softening. Once softening has been initiated, the tip is pressed into the polymer, and hence the indentation size is increased. Rough estimates [31.20, 21] indicate that at the beginning of the writing process only about 0.2% of the heating power is used in the very small contact zone (10–40 nm^2) to soften the polymer locally, whereas about 80% is lost through the cantilever legs to the chip body and about 20% is radiated from the heater platform through the air gap to the medium/substrate. After softening has started and the contact area has increased, the heating power available for generating the indentations increases at least ten times to reach 2% or more of the total heating power.

With this highly nonlinear heat-transfer mechanism it is very difficult to achieve small tip penetration and hence small bit sizes, as well as to control and reproduce the thermomechanical writing process. This situation can be improved if the thermal conductivity of the substrate is increased and if the depth of tip penetration is limited. We have explored the use of very thin polymer layers deposited on Si substrates to improve these characteristics [31.22, 23], as illustrated in Fig. 31.2. The hard Si substrate prevents the tip from penetrating farther than the film thickness, and it enables more rapid transport of heat away from the heated region, as Si is a much better conductor of heat than the polymer. Using coated Si substrates with a 50-nm film of polymethylmethacrylate (PMMA), we have achieved indentation sizes of between 10 and 50 nm. However, increased tip wear has occurred, probably caused by contact between the Si tip and the Si substrate during writing. Therefore, a 70-nm layer of crosslinked photoresist (SU-8) was introduced between the Si substrate and the PMMA film to act as a softer penetration stop that avoids tip wear, but remains thermally stable.

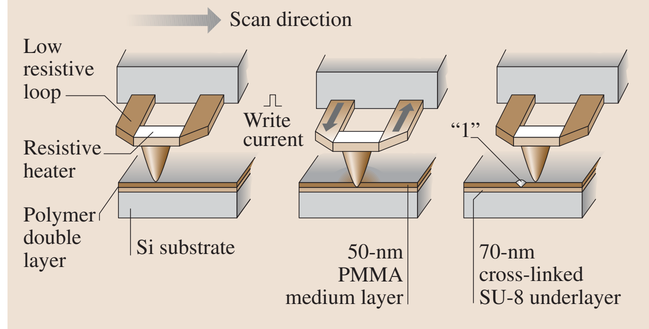

Fig. 31.2 New storage medium used for writing small bits. A thin, writable PMMA layer is deposited on a Si substrate separated by a cross-linked film of epoxy photoresist (after [31.15])

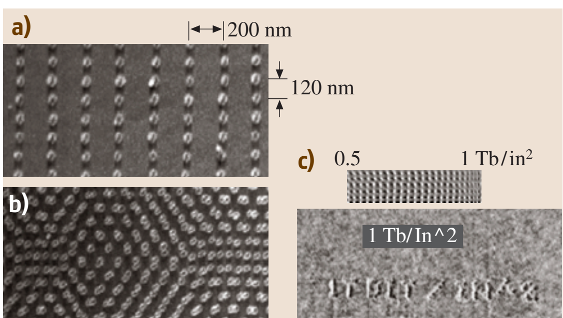

Fig. 31.3a–c Series of 40-nm indentations formed in a uniform array with **(a)** 120-nm pitch and **(b)** variable pitch (≥ 40 nm), resulting in areal densities of up to 400 Gb/in^2. Images obtained with a thermal readback technique. **(c)** Ultra-high-density bit writing with areal densities approaching 1 Tb/in^2. The scale is the same for all three images (from [31.15] © 2002 IEEE)

Using this layered storage medium, indentations 40 nm in diameter have been written as shown in Fig. 31.3. These experiments were performed using a 1-µm-thick, 70-µm-long, two-legged Si cantilever [31.19]. The cantilever legs are made highly conducting by high-dose ion implantation, whereas the heater region remains low-doped. Electrical pulses 2 µs in duration were applied to the cantilever with a period of 50 µs. Figure 31.3a demonstrates that 40-nm bits can be written with 120-nm pitch or, as shown in Fig. 31.3b, very close to each other without merging, implying a potential areal density of 400 Gb/in^2. Figure 31.3c shows recent results from a single-lever experiment, where indentations are spaced as closely as 25 nm apart, resulting in areal densities of up to 1 Tb/in^2, although with a somewhat degraded write/read quality.

Imaging and reading are performed by a new thermomechanical sensing concept [31.24]. To read the written information, the heater cantilever originally used for writing is given the additional function of a thermal readback sensor by exploiting its temperature-dependent resistance. In general, the resistance increases nonlinearly with heating power/temperature from room temperature to a peak value at 500–700 °C. The peak temperature is determined by the doping concentration of the heater platform, which ranges from 1×10^{17} to 2×10^{18} at/cm^3. Above the peak temperature, the resistance drops as the number of intrinsic carriers increases due to thermal excitation [31.25]. For sensing, the resistor is operated at about 350 °C, a temperature that is not high enough to soften the polymer as in the case of writing. The principle of thermal sensing is based on the fact that the thermal conductance between the heater platform and the storage substrate changes according to the distance between them. The medium between the heater platform and the storage substrate, in our case air, transports heat from the cantilever to the substrate. When the distance between cantilever and storage substrate is reduced as the tip moves into an indentation, the heat transport through the air becomes more efficient. As a result, the evolution of the heater temperature differs in response to a pulse applied to the cantilever. In particular, the maximum value achieved by the heater temperature is higher in the absence of an indentation. As the value of the variable resistance depends on the temperature of the cantilever, the maximum value achieved by the resistance will be lower as the tip moves into an indentation. Therefore, during the read process, the cantilever resistance reaches different values depending on whether the tip moves into an indentation (logical bit "1") or over a region without an indentation (logical bit "0"). Figure 31.4 illustrates this concept.

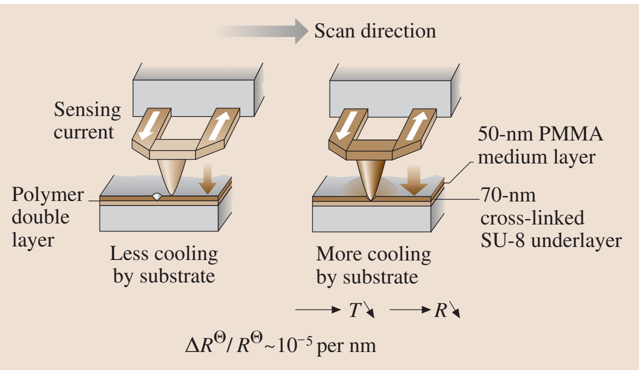

Fig. 31.4 Principle of AFM thermal sensing. The tip of the heater cantilever is continuously heated by a dc power supply while the cantilever is being scanned and the heater resistivity measured (after [31.15])

Under typical operating conditions, the sensitivity of thermomechanical sensing is even greater than that of piezoresistive-strain sensing, which is not surprising because thermal effects in semiconductors are stronger than strain effects. The good sensitivity is demonstrated by the images of the 40-nm-sized indentations in Fig. 31.3, which were obtained using the described thermal-sensing technique.

The thermomechanical cantilever sensor, which transforms temperature into an electrical signal that carries information, is the electrical equivalent, to a first degree of approximation, of a variable resistance. A detection circuit must, therefore, sense a voltage that depends on the value of the cantilever resistance to decide whether a "1" or a "0" is written. The relative variation of thermal resistance is on the order of 10^{-5}/nm. Hence a written "1" typically produces a relative change of the cantilever thermal resistance $\Delta R^{\Theta}/R^{\Theta}$ of about 10^{-4} to 5×10^{-4}. Note that the relative change of the cantilever electrical resistance is of the same order of magnitude. Thus, one of the most critical issues in detecting the presence or absence of an indentation is the high resolution required to extract the signal that contains the information about the logical bit being "1" or "0". The signal carrying the information can be regarded as a small signal superimposed on a very large offset signal. The large offset problem can be mitigated by subtracting a suitable reference signal [31.12, 26, 27].

31.3 Array Design, Technology, and Fabrication

Encouraged by the results of the 5×5 cantilever array [31.16, 17], a 32×32 array chip was designed and fabricated [31.18]. With the findings from the fabrication and operation of the 5×5 array and the very dense thermomechanical writing/reading in thin polymers with single cantilevers, some important changes of the chip functionality and fabrication processes were made. The major differences are (1) surface micromachining to form cantilevers at the wafer surface, (2) all-silicon cantilevers, (3) thermal instead of piezoresistive sensing, and (4) first- and second-level wiring with an insulating layer for a multiplexed row/column-addressing scheme.

As the heater platform functions as a read/write element and no individual cantilever actuation is required, the basic array cantilever cell becomes a simple two-terminal device addressed by a multiplexed x/y wiring, as shown in Fig. 31.5. The cell area and x/y cantilever pitch are $92 \times 92\,\mu m^2$, which results in a total array size of less than $3 \times 3\,mm^2$ for the 1,024 cantilevers. The cantilevers are fabricated entirely of silicon for good thermal and mechanical stability. They consist of a heater platform with the tip on top, legs acting as soft mechanical springs, and electrical connections to the heater. They are highly doped to minimize interconnect resistance and to replace the metal wiring on the cantilever in order to eliminate electromigration and parasitic z-actuation of the cantilever due to a bimorph effect. The resistive ratio between the heater and the silicon interconnect sections should be as high as possible; currently the resistance of the highly doped interconnections is $\sim 400\,\Omega$ and that of the heater platform is $5\,k\Omega$ (at 3 V reading bias).

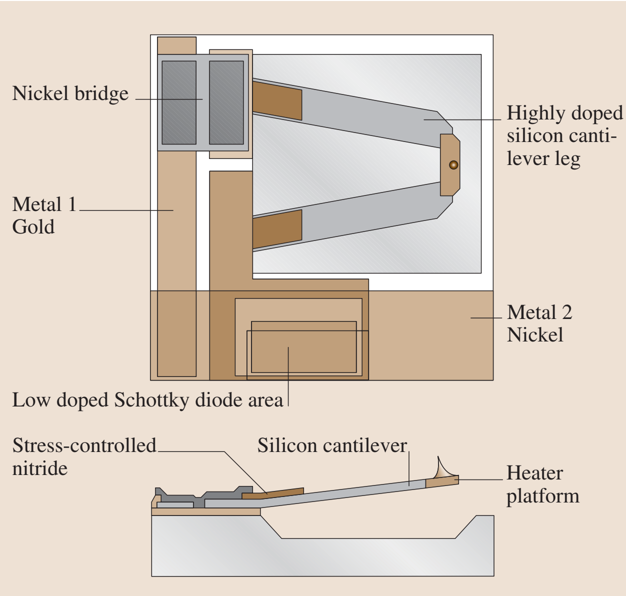

Fig. 31.5 Layout and cross section of one cantilever cell (after [31.28])

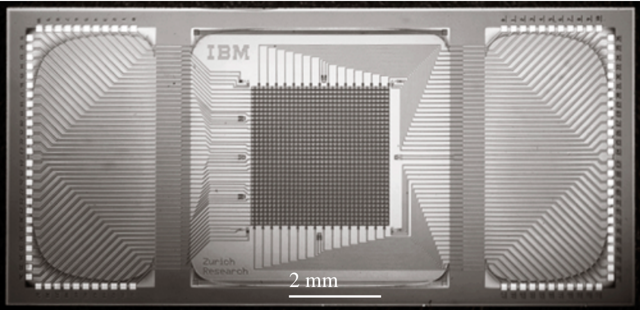

Fig. 31.6 Photograph of fabricated chip ($14 \times 7\,mm^2$). The 32×32 cantilever array is located at the center with bond pads distributed on either side (from [31.28] © 1999 IEEE)

The cantilever mass has to be minimized to obtain soft, high-resonant-frequency cantilevers. Soft cantilevers are required for a low loading force in order to eliminate or reduce tip and medium wear, whereas a high resonant frequency allows high-speed scanning. In addition, sufficiently wide cantilever legs are required for a small thermal time constant, which is partly determined by cooling via the cantilever legs [31.19]. These design considerations led to an array cantilever with 50-μm-long, 10-μm-wide and 0.5-μm-thick legs, and a 5-μm-wide, 10-μm-long and 0.5-μm-thick heater platform. Such a cantilever has a stiffness of $\sim 1\,N/m$ and a resonant frequency of $\sim 200\,kHz$. The heater time constant is a few microseconds, which should allow a multiplexing rate of up to 100 kHz.

The tip height should be as small as possible because the heater platform sensitivity depends strongly on the platform-to-medium distance. This contradicts the requirement of a large gap between the chip surface and the storage medium to ensure that only the tips, and not the chip surface, make contact with the medium. Instead of making the tips longer, we purposely bent the cantilevers a few micrometers out of the chip plane by depositing a stress-controlled plasma-enhanced chemical vapor deposition (PECVD) silicon-nitride layer at the base of the cantilever (see Fig. 31.5). This bending as well as the tip height must be well controlled in order

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

to maintain an equal loading force for all cantilevers of an array.

Cantilevers are released from the crystalline Si substrate by surface micromachining using either plasma or wet chemical etching to form a cavity underneath the cantilever. Compared to a bulk-micromachined through-wafer cantilever-release process, as was done for our 5×5 array [31.16, 17], the surface micromachining technique allows an even higher array density and yields better mechanical chip stability and heat sinking. As mentioned above, the entire array is tracked without individual lateral cantilever positioning, therefore thermal expansion of the array chip has to be small or well controlled. For a 3×3-mm^2 silicon array area and 10-nm tip-position accuracy, the temperature difference between array chip and medium substrate has to be controlled to about 1 °C. This is ensured by four temperature sensors in the corners of the array and heater elements on each side of the array.

The photograph in Fig. 31.6 shows a fabricated chip with the 32×32 array located in the center (3×3 mm^2) and the electrical wiring interconnecting the array with the bonding pads at the chip periphery. Figure 31.7 shows the 32×32 array section of the chip with the independent approach/heat sensors in the four corners and the heaters on each side of the array, as well as zoomed scanning electron micrographs (SEMs) of an array section, a single cantilever, and a tip apex. The tip height is 1.7 µm and the apex radius is smaller than 20 nm, which is achieved by oxidation sharpening [31.29]. The cantilevers are connected to the column and row address lines using integrated Schottky diodes in series with the cantilevers. The diode is operated in reverse bias (high resistance) if the cantilever is not addressed, thereby greatly reducing cross talk between cantilevers. More details about the array fabrication are given in [31.28, 30].

31.4 Array Characterization

The array's independent cantilevers, which are located in the four corners of the array and used for approaching and leveling the chip and storage medium, serve to initially characterize the interconnected array cantilevers. Additional cantilever test structures are distributed over the wafer; they are equivalent to but independent of the array cantilevers. Figure 31.8 shows an I/V curve of such a cantilever; note the nonlinearity of the resistance. In the low-power part of the curve, the resistance increases as a function of heating power, whereas in the high-power regime, it decreases.

In the low-power, low-temperature regime, silicon mobility is affected by phonon scattering, which depends on temperature, whereas at higher power, the intrinsic temperature of the semiconductor is reached, which results in a resistivity drop owing to the increasing number of carriers [31.25]. Depending on the heater-platform doping concentration of 1×10^{17} to 2×10^{18} at/cm^3, our calculations estimate a resistance maximum at a temperature of 500 to 700 °C, respectively.

The cantilevers within the array are electrically isolated from one another by integrated Schottky diodes. As every parasitic path in the array to the cantilever addressed contains a reverse-biased diode, the cross talk current is drastically reduced, as shown in Fig. 31.9. Thus, the current response of an addressed cantilever in an array is nearly independent of the size of the array, as demonstrated by the I/V curves in Fig. 31.9. Hence, the power applied to address a cantilever is not shunted by other cantilevers, and the reading sensitivity is not degraded – not even for very large arrays (32×32). The introduction of the electrical isolation using integrated

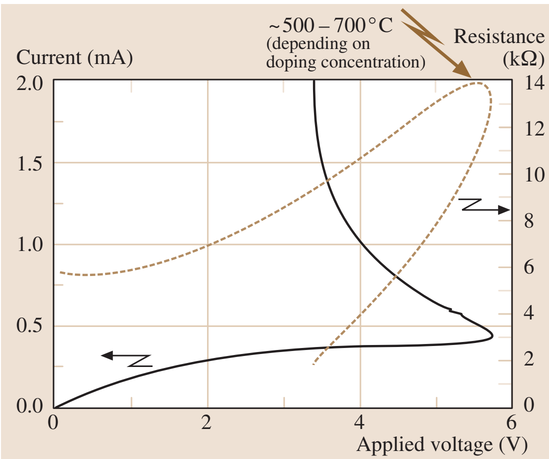

Fig. 31.8 I/V curve of one cantilever. The curve is nonlinear owing to the heating of the platform as the power and temperature are increased. For doping concentrations between 1×10^{17} and 2×10^{18} at/cm^3, the maximum temperature varies between 500 and 700 °C (after [31.30])

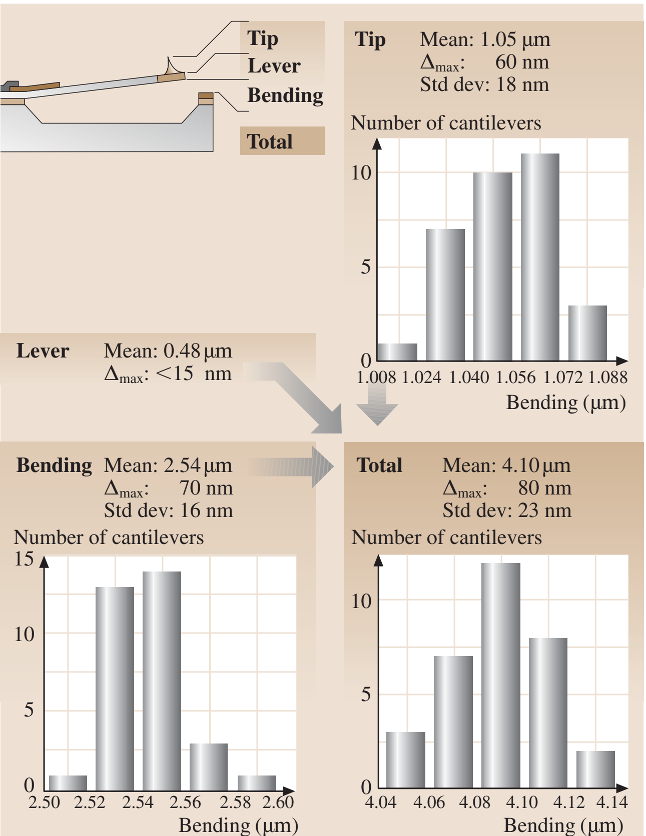

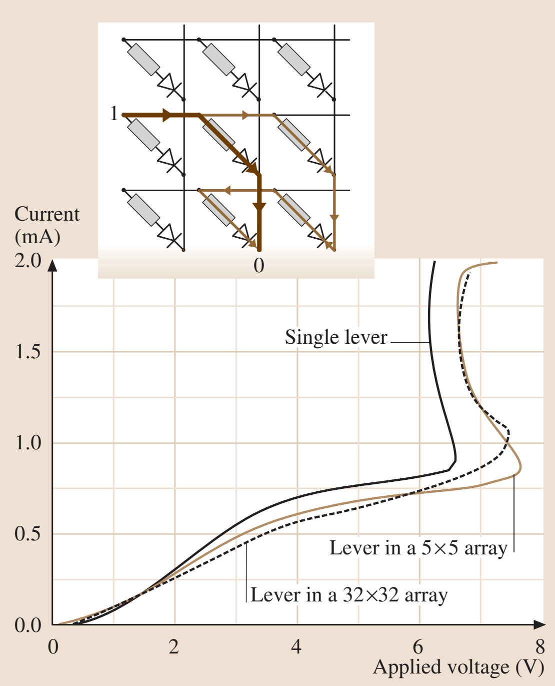

Fig. 31.9 Comparison of the I/V curve of an independent cantilever (*solid black line*) with the current response when addressing a cantilever in a 5×5 (*solid brown line*) or a 32×32 (*dashed line*) array with a Schottky diode serially connected to the cantilever. Little change is observed in the I/V curve between the different cases. Inset: sketch of the direct path (*bold line*) and a parasitic path (*thin line*) in a cantilever-diode array. In the parasitic path there is always one diode in reverse bias that reduces the parasitic current (after [31.30])

Schottky diodes turned out to be crucial for the successful operation of interconnected cantilever arrays with a simple time-multiplexed addressing scheme.

The tip-apex height uniformity within an array is very important because it determines the force of each cantilever while in contact with the medium and hence influences write/read performance, as well as medium and tip wear. Wear investigations suggest that a tip-apex height uniformity across the chip of less than 500 nm

Fig. 31.10 Tip-apex height uniformity across one cantilever row of the array with individual contributions from the tip height and cantilever bending. (© 2000 International Business Machines Corporation; after [31.18])

is required [31.7], with the exact number depending on the spring constant of the cantilever. In the case of the millipede, the tip-apex height is determined by the tip height and the cantilever bending. Figure 31.10 shows the tip-apex height uniformity of one row of the array (32 tips) due to tip height and cantilever bending. It demonstrates that our uniformity is on the order of 100 nm, thus meeting the requirements.

31.5 *x*/*y*/*z* Medium Microscanner

A key issue for the millipede concept is the need for a low-cost, miniaturized scanner with $x/y/z$ motion capabilities and a lateral scanning range on the order of 100 μm. Multiple-probe systems arranged as 1-D or 2-D arrays [31.18] must also be able to control, by means of tilt capabilities, the parallelism between the probe array and the sample [31.18, 32].

We have developed a microscanner with these properties based on electromagnetic actuation. It consists of a mobile platform supported by springs and containing integrated planar coils positioned over a set of miniature permanent magnets [31.33]. A suitable arrangement of the coils and magnets allows us, by electrically addressing the various coils, to apply magnetically induced forces to the platform and drive it in the x, y, z, and tilt directions. Our first silicon/copper-based version of this device has proved the validity of the concept [31.34], and variations of it have since been used elsewhere [31.35]. However, the undamped copper spring system gave rise to excessive cross talk and ringing when driven in an open loop, and its layout limited the compactness of the overall device.

We investigate a modified microscanner that uses flexible rubber posts as a spring system and a copper-epoxy-based mobile platform, Fig. 31.11. The platform is made of a thick, epoxy-based SU-8 resist [31.36], in which the copper coils are embedded. The posts are made of polydimethylsiloxane (PDMS, Sylgard 184 silicon elastomer, Dow Corning, Midland, MI) and are fastened at the corners of the platform and at the ground plate, providing an optimally compact device by sharing the space below the platform with the magnets. The shape of the posts allows their lateral and longitudinal stiffness to be adjusted, and the dissipative rubber-like properties of PDMS provide damping to avoid platform ringing and to suppress nonlinearities.

Figure 31.12 shows the layout of the platform, which is scaled laterally, so that the long segments of the "racetrack" coils used for in-plane actuation coincide with commercially available 24 mm^2 SmCo magnets. The thickness of the device is determined by that of the magnets (1 mm), the clearance between magnet and platform (500 μm), and the thickness of the platform itself, which is 250 μm and determined mainly by the aspect ratio achievable in SU-8 resist during the exposure of the coil plating mold. The resulting device volume is approximately $15 \times 15 \times 1.6\ mm^3$.

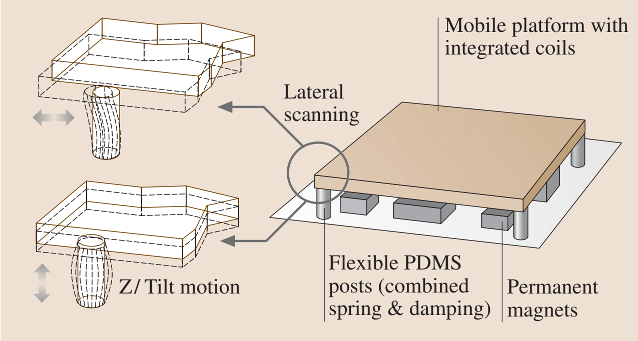

Fig. 31.11 Microscanner concept using a mobile platform and flexible posts (after [31.31])

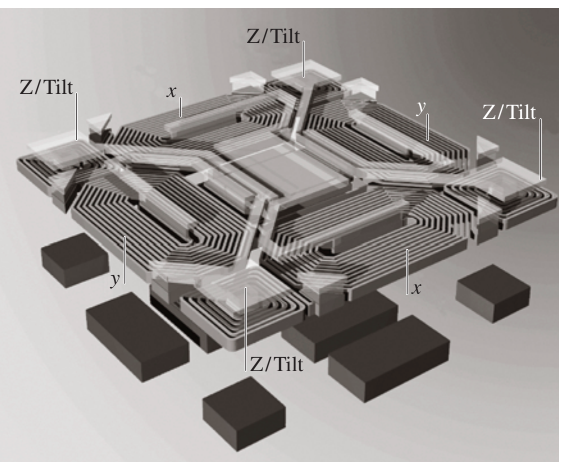

Fig. 31.12 Arrangement of the coils, the interconnects, and the permanent magnets, as well as the various motions addressed by the corresponding coils (from [31.15] © 2002 IEEE)

The SmCo magnets produce a measured magnetic field intensity of ∼ 0.14 T at the mid-thickness of the coils. The effective coil length is 320 mm, yielding an expected force $F_{x,y}$ of 45 µN per mA of drive current.

The principal design issue of the spring system is the ratio of its stiffnesses for in-plane and out-of-plane motion. Whereas for many scanning probe applications the required z-axis range need not be much larger than a few microns, it is necessary to ensure that the z-axis retraction of the platform due to the shortening of the posts as they take on an S-shape at large in-plane deflections can be compensated for at acceptable z-coil current levels. Various PDMS post shapes have been investigated to optimize and trade off the various requirements. Satisfactory performance was found for simple O-shapes [31.31].

The fabrication of the scanner, Fig. 31.13, starts on a silicon wafer with a seed layer and a lithographically patterned 200-µm-thick SU-8 layer, in which copper is electroplated to form the coils (Fig. 31.13a). The coils typically have 20 turns, with a pitch of 100 µm and a spacing of 20 µm. Special care was taken in the resist processing and platform design to achieve the necessary aspect ratio and to overcome adhesion and stress problems of SU-8. A second SU-8 layer, which serves as an insulator, is patterned with via holes, and another seed layer is then deposited (Fig. 31.13b). Next, an interconnect level is formed using a Novolac-type resist mask and a second copper-electroplating step (Fig. 31.13c). After stripping the resist, the silicon wafer is dissolved by a sequence of wet and dry etching, and the exposed seed layers are sputtered away to prevent shorts (Fig. 31.13d).

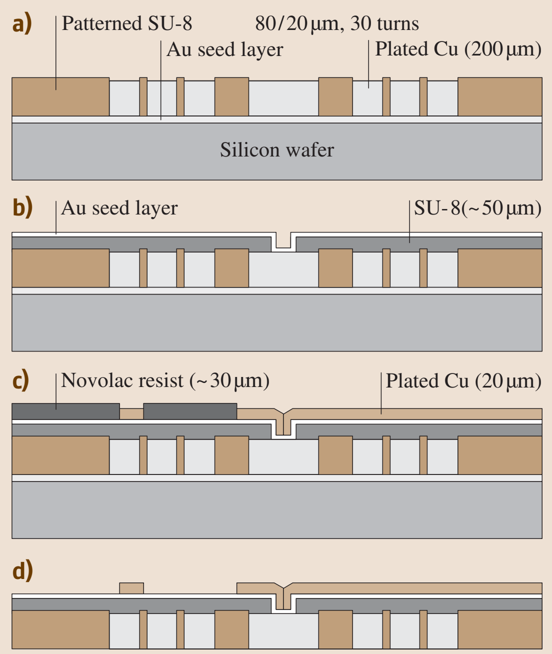

Fig. 31.13a–d Cross section of the platform fabrication process. **(a)** Coils are electroplated through an SU-8 resist mask, which is retained as the body of the platform; **(b)** an insulator layer is deposited; **(c)** interconnects are electroplated; **(d)** the platform is released from the silicon substrate (after [31.31])

The motion of the scanner was characterized using a microvision strobe technique [31.37]. The results presented below are based on O-type PDMS ports. Frequency response curves for in-plane motion (Fig. 31.14) show broad peaks (characteristic of a large degree of damping) at frequency values that are consistent with expectations based on the measured mass of the platform (0.253 mg). The amplitude response (Fig. 31.15) displays the excellent linearity of the spring system for displacement amplitudes up to 80 µm (160-µm displacement range). Based on these near-DC (10 Hz) responses (∼ 1.4 µm/mA) and a measured circuit resistance of 1.9 Ω, the power necessary for a 50-µm displacement amplitude is approximately equal to 2.5 mW.

Owing to limitations of the measurement technique, it was not possible to measure out-of-plane displacements greater than 0.5 µm. However, the small-

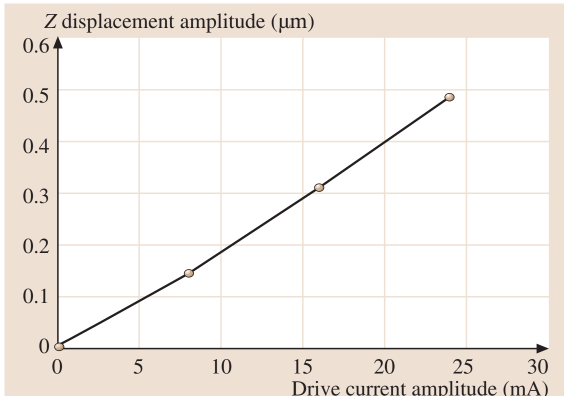

Fig. 31.16 Out-of-plane amplitude response for an ac drive current at 3 Hz. The drive current is the total for all four corner coils, which are driven in phase (after [31.31])

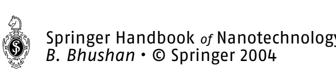
amplitude response for z-motion when all four corner coils are driven in-phase also displays good linearity over the range that can be measured (Fig. 31.16).

The electromagnetic scanner performs reliably and as predicted in terms of the scan range, device volume, and power requirements, achieving overall displacement ranges of 100 µm with approximately 3 mW of power. The potential access time in the 100-µm storage field is on the order of a few milliseconds. By being potentially cheap to manufacture, the integrated scanner presents a good alternative actuation system for many scanning probe applications.

31.6 First Write/Read Results with the 32×32 Array Chip

We have built a prototype that includes all the basic building blocks of the millipede concept (see Fig. 31.1) [31.38]. A 3×3-mm^2 silicon substrate is spin-coated with the SU-8/PMMA polymer medium, as described in Sect. 31.3. This storage medium is attached to the $x/y/z$ microscanner and approaching device. The magnetic z-approaching actuators bring the medium into contact with the tips of the array chip. The z-distance between the medium and the millipede chip is controlled by the approaching sensors in the corners of the array. The signals from these cantilevers are used to determine the forces on the z-actuators and, hence, the forces of the cantilever while it is in contact with the medium. This sensing/actuation feedback loop continues to operate during x/y scanning of the medium. The PC-controlled write/read scheme addresses the 32 cantilevers of one row in parallel. Writing is performed by connecting the addressed row for 20 µs to a high negative voltage and simultaneously applying data inputs ("0" or "1") to the 32 column lines. The data input is a high positive voltage for a "1" and ground for a "0". This row-enabling and column-addressing scheme supplies a heater current to all cantilevers, but only those cantilevers with high positive voltage generate an indentation ("1"). Those grounded are not hot enough to form an indentation and thus write a "0". When the scan stage has moved to the next logical mark position, the process is repeated, and this is continued until the line scan is finished. In the read process, the selected row line is connected to a moderate negative voltage, and the column lines are grounded via a protection resistor of about 10 kΩ, which keeps the cantilevers warm. During scanning, the voltages across the resistors are measured. Depending on the topography of the recording surface, the degree of cooling of each cantilever varies, thus changing the resistance and voltage across the series resistor and allowing written data to be read back.

The results of writing and reading in this fashion can be seen in Fig. 31.17, which shows 1,024 images corresponding to the 1,024 storage fields and associ-



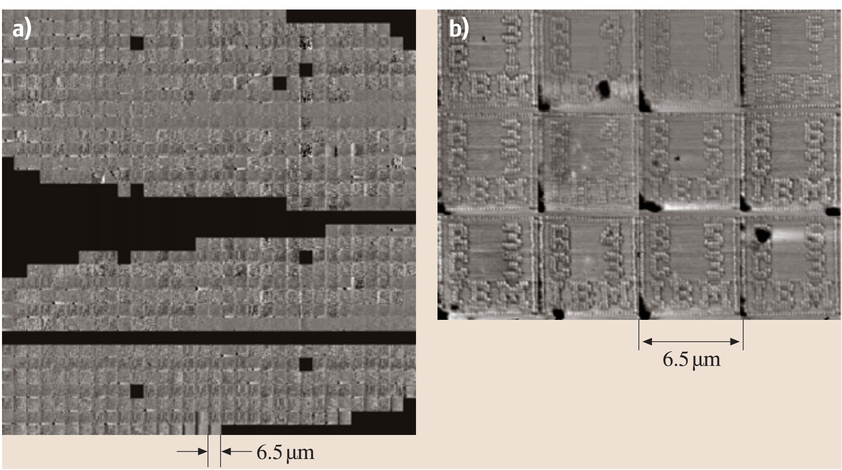


Fig. 31.17 **(a)** 1,024 images, each one obtained from a cantilever of the 2-D array. **(b)** Enlarged view of typical images from **(a)**. The numbers in the images indicate the row and column of each lever (from [31.38])

ated cantilevers. Of the 1,024 levers, 834 were able to write and read data back, i. e., a success rate of more than 80%. The sequence is as follows. First, a bit pattern is written simultaneously by each of the levers in row 1, then read back simultaneously, followed by row 2, etc. through row 32. The data sent to the levers is different, each lever writing its own row and column number in the array. The bit pattern consists of 64×64 bits, where odd-numbered bits are always set to 0. In this case, the area used is $6.5 \times 6.5\,\mu m^2$. The readback image is a grey-scale bit map of 128×128 pixels. The distance between levers is 92 µm, so the images in Fig. 31.17 are also 92 µm apart. The areal density of the written information shown in Fig. 31.17 corresponds to 15–30 Gb/in^2, depending on the coding scheme adopted. More recently, an areal density of 150–200 Gb/in^2, at an array yield of about 60%, has been demonstrated.

Those levers that did not read back failed for one of four reasons: (i) a defective chip connector rendered an entire column unusable, (ii) a point defect occurred, meaning that a single lever or tip was broken, (iii) there was a nonuniformity of the tip contact due to tip/lever variability or storage substrate bowing due to mounting, (iv) there were thermal drifts. The latter two reasons were the most likely and major failure sources. At present, there is clearly a tradeoff between the number of working levers and the density, which will most likely be resolved by a better substrate/chip mounting technique and lower thermal drifts.

The writing and readback rates achieved with this system are 1 kb/s per lever, thus, the total data rate is about 32 kb/s. This rate is limited by the rate at which data can be transferred over the PC ISA bus, not by a fundamental time limitation of the read/write process.

31.7 Polymer Medium

The polymer storage medium plays a crucial role in millipede-like thermomechanical storage systems. The thin-film multilayer structure with PMMA as active layer (see Fig. 31.2) is not the only possible choice, considering the almost unlimited range of polymer materials available. The ideal medium should be easily deformable for writing, yet indentations should be stable against tip wear and thermal degradation. Finally, one would also like to be able to erase and rewrite data repeatedly. In order to be able to address all important aspects properly, some understanding of the basic physical mechanism of thermomechanical writing and erasing is required.

31.7.1 Writing Mechanism

In a *gedanken* experiment we visualize writing of an indentation as the motion of a rigid body (the tip) in a viscous medium (the polymer melt). Let us initially assume

that the polymer, i. e., PMMA, behaves like a simple liquid after it has been heated above the glass-transition temperature in a small volume around the tip. As viscous drag forces must not exceed the loading force applied to the tip during indentation, we can estimate an upper bound for the viscosity ζ of the polymer melt using Stokes's equation:

$$F = 6\pi\zeta\varrho v\,. \qquad (31.1)$$

In actual indentation formation, the tip loading force is on the order of $F = 50\,\text{nN}$ and the radius of curvature at the apex of the tip is typically $\varrho = 20\,\text{nm}$. Assuming a depth of the indentation of, say, $h = 50\,\text{nm}$ and a heat pulse of $\tau_h = 10\,\mu\text{s}$ duration, the mean velocity during indentation formation is on the order of $v = h/\tau_h = 5\,\text{mm/s}$. Note that thermal relaxation times are on the order of microseconds [31.20, 21] and, hence, the heating time can be equated to the time it takes to form an indentation. With these parameters we obtain $\zeta < 25\,\text{Pa s}$, whereas typical values for the shear viscosity of PMMA are at least seven orders of magnitude larger even at temperatures well above the glass-transition point [31.39].

This apparent contradiction can be resolved by considering that polymer properties are strongly dependent on the time scale of observation. At time scales on the order of 1 ms and below, entanglement motion is in effect frozen in and the PMMA molecules form a relatively static network. Deformation of the PMMA now proceeds by means of uncorrelated deformations of short molecular segments, rather than by a flow mechanism involving the coordinated motion of entire molecular chains. The price one has to pay is that elastic stress builds up in the molecular network as a result of the deformation (the polymer is in a so-called rubbery state). On the other hand, corresponding relaxation times are orders of magnitude smaller, giving rise to an effective viscosity at millipede time scales on the order of 10 Pa s [31.39], as required by our simple argument (see (31.1)). Note that, unlike normal viscosity, this high-frequency viscosity is basically independent of the detailed molecular structure of the PMMA, i. e., chain length, tacticity, polydispersity, etc. In fact, we can even expect that similar high-frequency viscous properties can be found in a large class of other polymer materials, which makes thermomechanical writing a rather robust process in terms of material selection.

We have argued above that elastic stress builds up in the polymer film during the formation of an indentation, creating a corresponding reaction force on the tip on the order of $F_r \sim 2\pi G\varrho^2$, where G denotes the elastic shear modulus of the polymer [31.40]. An important property for millipede operation is that the shear modulus drops by several orders of magnitude in the glass-transition regime, i. e., for PMMA from $\sim 1\,\text{GPa}$ below Θ_g to ~ 0.5–$1\,\text{MPa}$ above Θ_g, where Θ_g denotes the glass-transition temperature [31.39]. The bulk modulus, on the other hand, retains its low-temperature value of several GPa. Hence, in this elastic regime, formation of an indentation above Θ_g constitutes a volume-preserving deformation. For proper indentation formation, the tip load must be balanced between the extremes of the elastic reaction force F_r for temperatures below and above Θ_g, i. e., $F \ll 2.5\,\mu\text{N}$ for PMMA to prevent indentation of the polymer in the cold state and $F \gg 2.5\,\text{nN}$ to overcome the elastic reaction force in the hot state. Unlike the deformation of a simple liquid, the indentation represents a metastable state of the entire deformed volume, which is under elastic tension. Recovery of the unstressed initial state is prevented by rapid quenching of the indentation below the glass temperature with the tip in place. As a result, the deformation is frozen in, because below Θ_g motion of molecular-chain segments is, in effect, inhibited (see Fig. 31.18).

This mechanism also allows indentations to be erased locally – it suffices to heat the deformed volume locally above Θ_g, whereupon the indented volume reverts to its unstressed flat state driven by internal elastic stress. In addition, erasing is promoted by surface tension forces, which give rise to a restoring surface pressure on the order of $\gamma(\pi/\varrho)^2 h \approx 25\,\text{MPa}$, where $\gamma \sim 0.02\,\text{N/m}$ denotes the polymer-air surface tension.

One question immediately arises from these speculations: If the polymer behavior can be determined from the macroscopic characteristics of the shear modulus as a function of time, temperature, and pressure, can the time-temperature superposition principle also be applied in this case? The time-temperature superposition principle is a powerful concept of polymer physics [31.41]. It basically states that the time scale and the temperature are interdependent variables that determine the polymer behavior such as the shear modulus. A simple transformation can be used to translate time-dependent into temperature-dependent data and vice versa. It is not clear, however, whether this principle can be applied in our case, i. e., under such extreme conditions (high pressures, short time scales, and nanometer-sized volumes, which are clearly below the radius of gyration of individual polymer molecules).

To test this, we varied the heating time, the heating temperature, and the loading force in indentation-writing experiments on a standard PMMA sample. The results

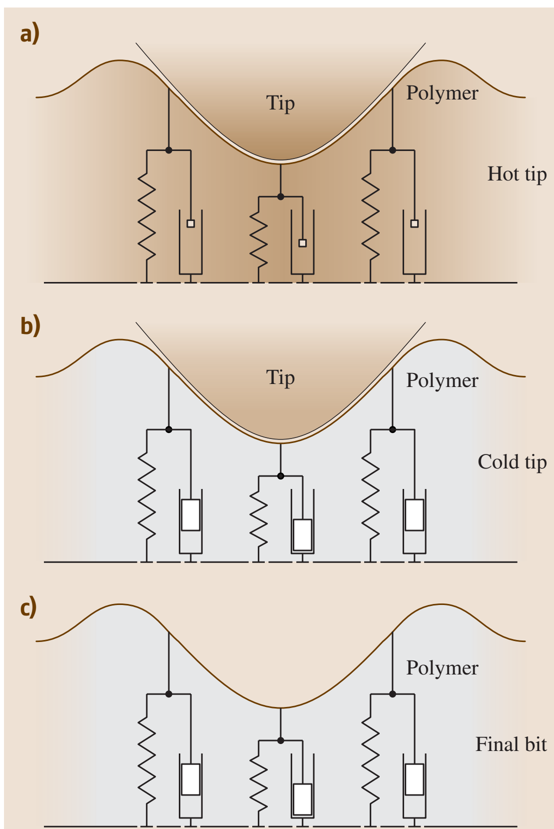

Fig. 31.18a–c Viscoelastic model of indentation writing. **(a)** The hot tip heats a small volume of polymer material to more than Θ_g. The shear modulus of the polymer drops drastically from GPa to MPa, which in turn allows the tip to indent the polymer. In response, elastic stress (represented as compression springs) builds up in the polymer. In addition, viscous forces (represented as pistons) associated with the relaxation time for the local deformation of molecular segments limit the indentation speed. **(b)** At the end of the writing process, the temperature is quenched on a microsecond time scale to room temperature: The stressed configuration of the polymer is frozen-in (represented by the locked pistons). **(c)** The final indentation corresponds to a metastable configuration. The original unstressed flat state of the polymer can be recovered by heating the indentation volume to more than Θ_g, which unlocks the compressed springs (after [31.15])

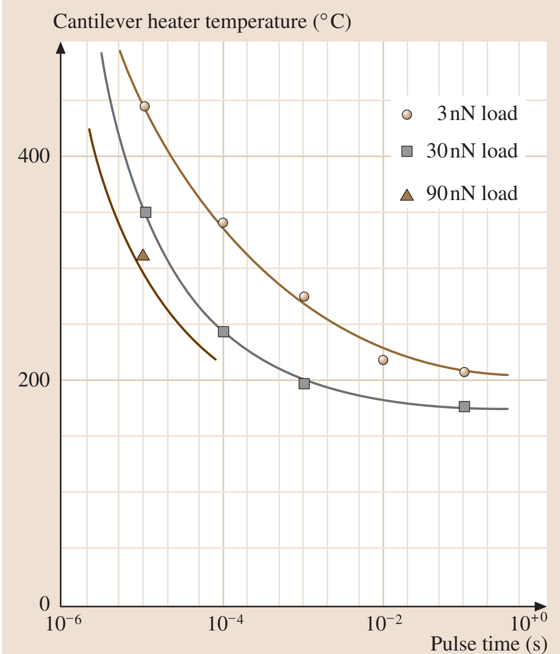

Fig. 31.19 Indentation-writing threshold measurements. The load was controlled by pushing the cantilever/tip into the sample with a controlled displacement and a known spring constant of the cantilever. When a certain threshold is reached, the indentations become visible in subsequent imaging scans (see also Fig. 31.21). The *solid lines* are guides to the eye. Curves of similar shape would be expected from the time-temperature superposition principle (after [31.15])

are summarized in Fig. 31.19. The minimum heater temperature at which the formation of an indentation starts for a given heating-pulse length and loading force was determined. This so-called threshold temperature is plotted against the heating-pulse length. A careful calibration of the heater temperature has to be done to allow a comparison of the data. The heater temperature was determined by assuming proportionality between temperature and electrical power dissipated in the heater resistor at the end of the heating pulse when the tip has reached its maximum temperature. An absolute temperature scale is established using two well-defined reference points. One is room temperature, corresponding to zero electrical power. The other is provided by the point of turnover from positive to negative differential resistance (see Fig. 31.8), which corresponds to a heater temperature of approximately 550 °C. The general shape of the measured threshold temperature versus heating time curves indeed shows the characteristics of time-temperature superposition. In particular, the curves

are identical up to a load-dependent shift with respect to the time axis. Moreover, we observe that the time it takes to form an indentation at constant heater temperature is inversely proportional to the tip load. This property is exactly what one would expect if internal friction (owing to the high-frequency viscosity) is the rate-limiting step in forming an indentation (see (31.1)).

The time it takes to heat the indentation volume of polymer material higher than the glass-transition temperature is another potentially rate-limiting step. Here, the spreading resistance of the heat flow in the polymer and the thermal contact resistance are the most critical parameters. Simulations suggest [31.20, 21] that equilibration of temperature in the polymer occurs within less than 1 µs. Very little is known, however, about the thermal coupling efficiency across the tip-polymer interface. We have several indications that the heat transfer between tip and sample plays a crucial role, one of them being the asymptotic heater temperature for long writing times, which according to the graph in Fig. 31.19 is approximately 200 °C. The exact temperature of the polymer is unknown. However, the polymer temperature should approach the glass-transition temperature (around 120 °C for PMMA) asymptotically. Hence, the temperature drop between heater and polymer medium is substantial. Part of the temperature difference is due to a temperature drop along the tip, which according to heat-flow simulations [31.20, 21] is expected to be on the order of 30 °C at most. Therefore, a significant temperature gradient must exist in the tip-polymer contact zone. Further experiments on the heat transfer from tip to surface are needed to clarify this point.

We also find that the heat transfer for a nonspherical tip is anisotropic. As shown in Fig. 31.20, in the case of a pyramid-shaped tip, the indentation not only exhibits sharp edges, but also the region around the indentation, where polymer material is piled up, is anisotropic. The pile-up characteristics will be discussed in detail below. At this point we take it as an indication of the relevance of the heat transfer to the measurements.

One of the most striking conclusions of our model of the indentation-writing process is that it should in principle work for most polymer materials. The general behavior of the mechanical properties as a function of temperature and frequency is similar for all polymers [31.41]. The glass-transition temperature Θ_g would then be one of the main parameters that determines the threshold writing temperature.

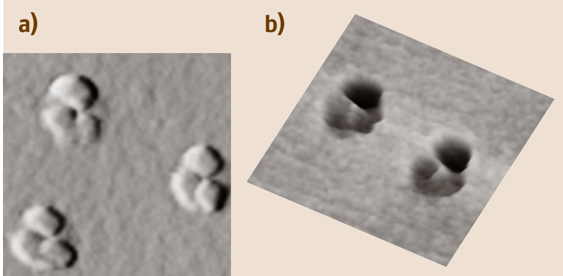

Fig. 31.20a,b Topographic image of individual indentations. **(a)** The region around the actual indentations clearly shows the threefold symmetry of the tip, here a three-sided pyramid. **(b)** The indentations themselves exhibit sharp edges, as can be seen from the inverted 3-D image. Image size is $2\times2\,\mu m^2$ (from [31.15] © 2002 IEEE)

A verification of this was found experimentally by comparing various polymer films. The samples were prepared in the same way as the PMMA samples discussed above [31.18]: by spin-casting thin films (10–30 nm) onto a silicon wafer with a photo-resist buffer. Then, threshold measurements were done by applying heat pulses with increasing current (or temperature) to the tip while the load and the heating time were held constant (load about 10 nN and heating time 10 µs). Examples of such measurements are shown in Fig. 31.21, where the increasing size and depth of indentations can be seen for different heater temperatures. A threshold can be defined based on such data and compared with the glass-transition temperature of these materials. The results show a clear correlation between the threshold heater temperature and the glass-transition temperature (see Fig. 31.22).

With our simple viscoelastic model of writing we are able to formulate a set of requirements that potential candidate materials for millipede data storage have to fulfill. First, the material should ideally exhibit a well-defined glass-transition point with a large drop of the shear modulus at Θ_g. Second, a rather high value of Θ_g (on the order of 150 °C) is preferred to facilitate thermal read back of the data without destroying the information. We have investigated a number of materials to explore the Θ_g parameter space. The fact that all polymer types tested are suitable for forming small indentations leaves us free to choose which polymer type to optimize in terms of the technical requirements for a device such as lifetime of indentations, polymer endurance of the read and write process, power consumption, etc. These are subjects of ongoing research.

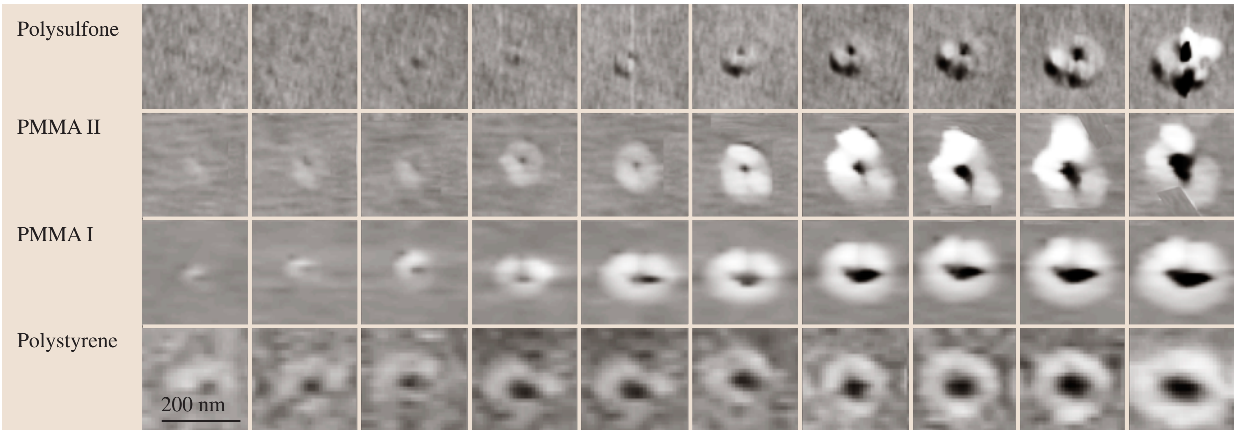

Fig. 31.21 Written indentations for different polymer materials. The heating pulse length was 10 μs, the load about 10 nN. The grey scale is the same for all images. The heater temperatures for the indentation on the left-hand side are 445, 400, 365, and 275 °C for the polymers Polysulfone, PMMA II (anionically polymerized PMMA, $M \approx 26$ k), PMMA I (Polymer Standard Service, Germany, $M \approx 500$ k), and Polystyrene, respectively. The temperature increase between events on the horizontal axis is 14, 22, 20, and 9 °C, respectively (from [31.15] © 2002 IEEE)

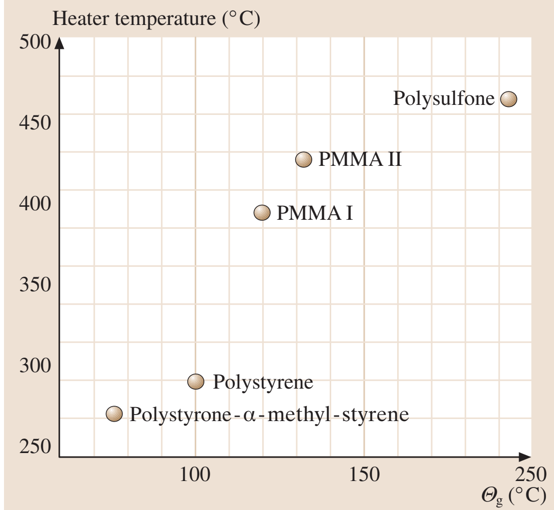

Fig. 31.22 The heater temperature threshold for writing indentations with the same parameters as in Fig. 31.21 is plotted against the glass-transition temperature for these polymers, including poly-α-methyl-styrene (after [31.15])

31.7.2 Erasing Mechanism

It is worthwhile to look at the detailed shapes of the written indentations. The polymer material around an indentation appears piled up as can be seen, for example, in Fig. 31.20. This is not only material that was pushed aside during indentation formation as a result of volume conservation. Rather, the flash heating by the tip and subsequent rapid cooling result in an increase of the specific volume of the polymer. This phenomenon, that the specific volume of a polymer can be increased by rapidly cooling a sample through the glass transition [31.41], is well-known. Our system allows a cooling time on the order of microseconds, which is much faster than the highest rates that can be achieved with standard polymer-analysis tools. However, a quantitative measurement of the specific volume change cannot be easily performed with our type of experiments. On the other hand, the pile-up effect serves as a convenient threshold thermometer. The outer perimeter of the pile-ups surrounding the indentations corresponds to the Θ_g isotherm, and the temperature in the enclosed area has certainly reached values greater than Θ_g during the indentation process. Based on our viscoelastic model, one would thus conclude that previously written indentations that overlap with the piled up region of a subsequently written indentation should be erased.

That this pile-up effect actually works against the formation of an indentation can clearly be seen in the line scans of a series of indentations written in Polysulfone (Fig. 31.23). Here, the heating of the tip was accompanied by a rather high normal force. The force was high enough to create a small indentation, even if the tip was too cold to modify the polymer (Fig. 31.23a).

Then, with increasing tip heating, the indentations initially fill up in the piled up region (Fig. 31.23b) before they finally become deeper (Fig. 31.23c).

The pile-up phenomenon turns out to be particularly beneficial for data-storage applications. The following example demonstrates the effect. If we look at the sequence of images in Fig. 31.24, taken on a standard PMMA sample, we find that the piled up regions can overlap each other without disturbing the indentations. However, if the piled up region of an individual writing event extends over the indented area of a previously written "1", the depth of the corresponding indentation decreases markedly (Fig. 31.24d). This can be used for erasing written data. On the other hand, if the pitch between two successive indentations is decreased even further, this erasing process will no longer work. Instead, a broader indentation is formed, as shown in Fig. 31.24e. Hence, to exclude mutual interference, the minimum pitch between successive indentations, which we denote by minimum-indentation pitch (BP_{min}), must be larger than the radius of the piled up area around an indentation.

In the example shown in Fig. 31.24, the temperature chosen was so high that the ring around the indentations was very large, whereas the depth of the indentation was limited by the stop layer underneath the PMMA material. Clearly, the temperature was too high here to form small indentations, the minimum pitch of which is around 250 nm. However, by carefully optimizing all parameters it is possible to achieve areal densities of up to 1 Tb/in^2, as demonstrated in Fig. 31.3c.

The new erasing scheme based on this volume effect switches from writing to erasing merely by decreasing the pitch of writing indentations. This can be done in a very controlled fashion, as shown in Fig. 31.25, where individual lines or predefined subareas are erased. Hence, this new erasing scheme can be made to work in a way that is controlled on the scale of individual indentations. Compared with earlier global erasing schemes [31.23], this simplifies erasing significantly.

31.7.3 Overwriting Mechanism

Overwriting data on some part of the storage medium can be achieved by first erasing the entire area and then writing the desired data on the erased surface. Although this process works well, it is time-consuming and dissipates a significant amount of power. In a millipede-based storage device, where data rate and power consumption are at a premium, such a two-step overwriting mech-

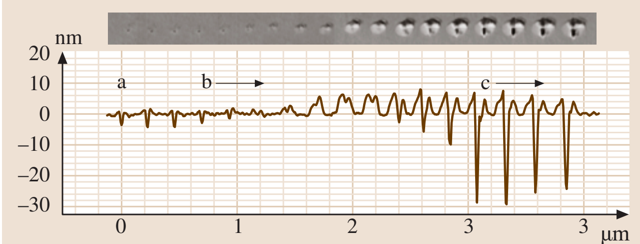

Fig. 31.23 Section through a series of indentations similar to Fig. 31.21. Here, a load of about 200 nN was applied before a heating pulse of 10-µs length was fired. The temperature of the heater at the end of the pulse has been increased from 430 to 610 °C in steps of about 10.6 °C. (a) The load was sufficient to form a plastic indentation even if the polymer was not heated enough to come near the glass transition. (b) With increasing heater temperature, the polymer swells. This eliminates the indentation, thus erasing previously written "cold" marks. (c) As this process continues, the thermomechanical formation of indentations begins to dominate until, finally, normal thermomechanical indentation writing occurs (after [31.15])

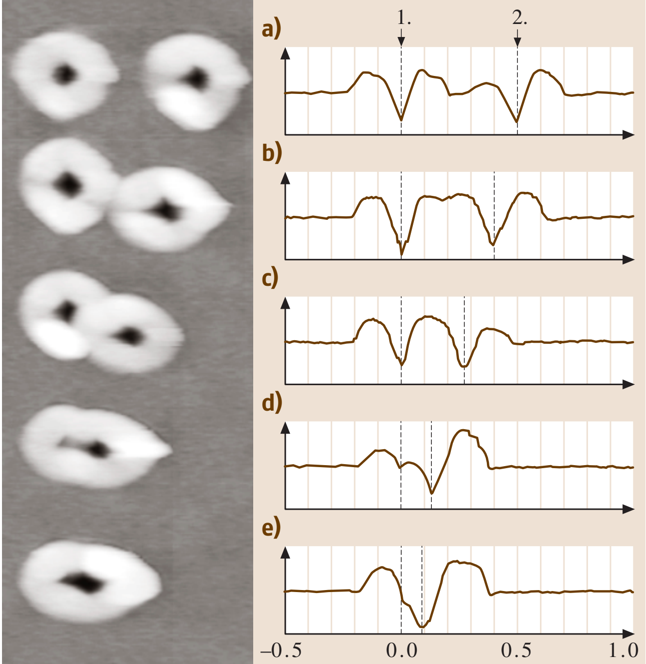

Fig. 31.24a–e Indentations in a PMMA film at several distances. The depth of the indentations is ∼ 15 nm, roughly the same as the thickness of the PMMA layer. The indentations on the left-hand side were written first, then a second series of indentations was made with decreasing distance from the first series going from **(a)** to **(e)** (after [31.15])

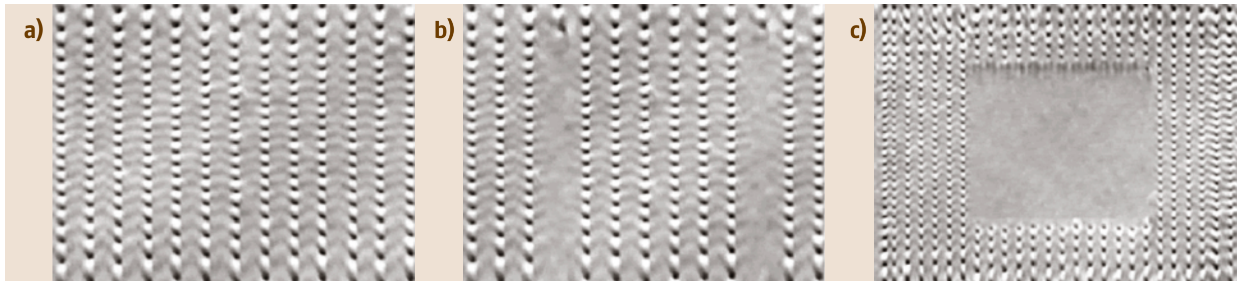

Fig. 31.25a–c Demonstration of the new erasing scheme: **(a)** A bit pattern recorded with variable pitch in the vertical axis (fast scan axis) and constant pitch in the horizontal direction (slow scan axis) was prepared. **(b)** Then two of the lines were erased by decreasing the pitch in the vertical direction by a factor of three, showing that the erasing scheme works for individual lines. One can also erase entire fields of indentations without destroying indentations at the edges of the fields. This is demonstrated in **(c)**, where a field has been erased from an indentation field similar to the one shown in **(a)**. The distance between the lines is 70 nm (from [31.15] © 2002 IEEE)

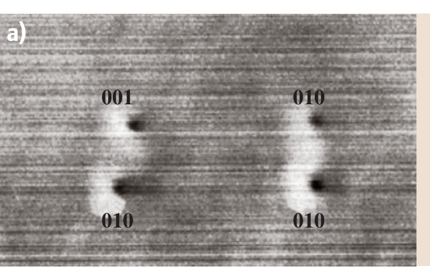
anism may be impractical. Instead, a one-step, direct overwriting process similar to those applied in magnetic hard-disk drives and rewritable optical drives is desired.

As discussed above, switching from writing to erasing may be achieved by decreasing the pitch of writing. It has been found experimentally that erasing can be performed effectively by halving the pitch of writing successive indentations, which is denoted as BP, provided the condition BP $\approx$ BP_{min} is satisfied. This suggests that the basic distance unit for combined write-erase operations should be BP/2. Written indentations are spaced n units apart, where $n \geq 2$. Let us recall that the presence of an indentation corresponds to a logical bit "1" and the absence of an indentation to a logical bit "0". Logical bits are then stored in the medium at the points of a regular lattice with minimum distance between points equal to BP/2 in the on-track direction, with successive "1"s separated by at least one "0". This condition is necessary in order to avoid mutual interference between successive "1"s. It is also the basis for an important category of codes known as (d, k) codes, which are described in Sect. 31.9.3. Coding can thus be used to enable direct data overwriting in an elegant way. Direct overwriting requires the simultaneous realization of two conditions: If previously written "1"s exist where "0"s are to be written, then these "1"s have to be *erased*. On the other hand, if "0"s exist where "1"s are to be written, then these "1"s have to be *written*. Writing an indentation is performed thermomechanically as described above. Erasing an existing indentation is done by writing another indentation next to it, at a distance of BP/2 units. However, as this operation creates a new indentation shifted by BP/2 with respect to the one erased, the erasing process must be performed repeatedly until the newly created indentation lies at a position corresponding to a "1" in the new data pattern. The basic principle of erasing is illustrated in Fig. 31.26a and b. The figures show how the four bit strings 001, 010, 100, and 101 are modified into the string 010. Figure 31.27 depicts the results of a rewriting experiment; the top track shows a prestored sequence, which is to be overwritten by another sequence, shown on the bottom track for comparison. The result of direct



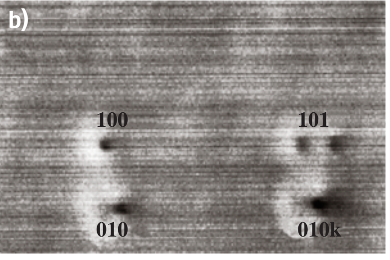


Fig. 31.26a,b Bit strings **(a)** 001 and 010, and **(b)** 100 and 101, overwritten to 010

overwriting of the prestored sequence is shown on the middle track.

Comparison with the sequence on the bottom track, which is written on a clean surface, illustrates the effectiveness of the proposed procedure. Although the write/read quality of overwritten data is somewhat inferior to that of data written on a clean storage surface, detection of the newly written sequence is not affected. However, repeated overwriting may further degrade the quality of stored data. As the extent and rate of degradation are important characteristics of a storage system, this remains an area of ongoing investigation.

Fig. 31.27 Experimental result of overwriting a bit sequence

31.8 Read Channel Model

Let us now consider the readback channel for a single cantilever that is scanning a storage field where bits are written as indentations or absence of indentations in the storage medium. As discussed above, a cantilever is modeled as a variable resistor that depends on the temperature at the cantilever tip. The model of the read channel, used for the design and analysis of the detection system, is illustrated in Fig. 31.28 [31.12, 26, 27].

To evaluate the evolution of the temperature of a heated cantilever during the read process, we resort to a simple RC-equivalent thermal circuit, illustrated in Fig. 31.29, where $(1+\eta_x)R^{\Theta}$ and C^{Θ} denote the thermal resistance and capacitance, respectively. The parameter $\eta_x = \Delta R^{\Theta}(x)/R^{\Theta}$ indicates the relative variation of thermal resistance that results from the small change in air-gap width between the cantilever and the storage medium. The subscript x indicates the distance in the direction of scanning from the initial point. Therefore, the parameter η_x will assume the largest absolute value when the tip of the cantilever is located at the center of an indentation. The heating power that is dissipated in the cantilever heater region is expressed as

$$P^e[t, \Theta(t,x)] = \frac{V_C^2(t)}{R^e[\Theta(t,x)]} , \tag{31.2}$$

where $V_C(t)$ is the voltage across the cantilever, $\Theta(t,x)$ is the cantilever temperature, and $R^e[\Theta(t,x)]$ is the temperature-dependent cantilever resistance.

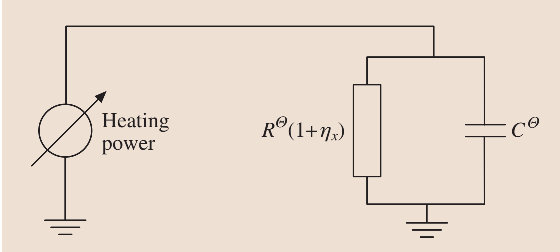

Fig. 31.29 RC-equivalent thermal model of the heat transfer process (after [31.12])

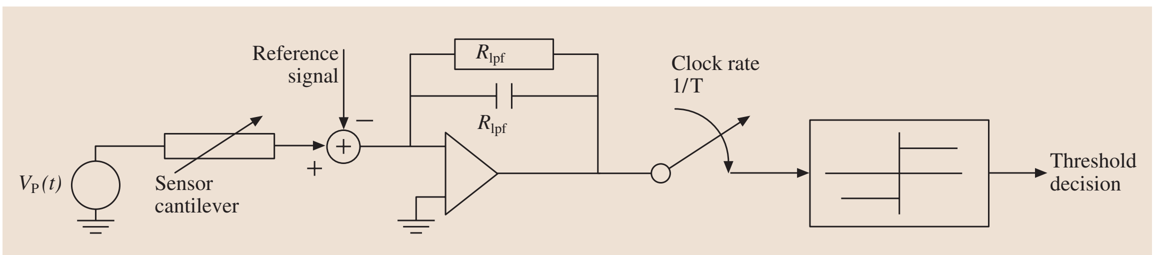

Fig. 31.28 Block diagram of the detection circuit

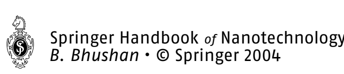

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

As the heat-transfer process depends on the value of thermal resistance and on the read pulse waveform, the cantilever temperature $\Theta(t, x)$ depends on time t and distance x. However, because the time it takes for the cantilever to move from the center of one logical mark to the next is greater than the duration of a read pulse, we assume that $\Theta(t, x)$ does not vary significantly as a function of x while a read pulse is being applied, and that it decays to the ambient temperature Θ_0 before the next pulse is applied. Therefore, the evolution of the cantilever temperature in response to a pulse applied at time $t_0 = x_0/v$ at a certain distance x_0 from the initial point of scanning and for a certain constant velocity v of the scanner obeys a differential equation expressed as

$$\Theta'(t, x_0) + \frac{1}{(1+\eta_{x_0})R^{\Theta}C^{\Theta}}\left[\Theta(t, x_0) - \Theta_0\right] = \frac{1}{C^{\Theta}}\frac{V_{\mathrm{C}}^2(t)}{R^e[\Theta(t, x_0)]}, \quad (31.3)$$

where $\Theta'(t, x_0)$ denotes the derivative of $\Theta(t, x_0)$ with respect to time.

With reference to the block diagram of the read channel illustrated in Fig. 31.28, the source generates the read pulse $V_{\mathrm{P}}(t)$ applied to the cantilever. Clearly, because of the virtual ground at the operational amplifier input, the voltage $V_{\mathrm{C}}(t)$ across the cantilever variable resistance is equal to $\mathrm{V}_{\mathrm{P}}(t)$. Furthermore, the active low-pass RC detector filter, where R_{lpf} and C_{lpf} denote the resistance and capacitance of the low-pass filter, respectively, is realized using an ideal operational amplifier that exhibits infinite input impedance, zero output impedance, and infinite frequency-independent gain. Therefore, the readback signal $V_o(t, x_0)$ obtained at the low-pass filter output in response to the applied voltage $V_{\mathrm{P}}(t) = A\,\mathrm{rect}\left[(t - T_0)/\tau\right]$, where

$$\mathrm{rect}\left(\frac{t}{\tau}\right) = \begin{cases} 1 & \text{if } 0 \le t \le \tau \\ 0 & \text{otherwise} \end{cases}, \quad (31.4)$$

and A denotes the pulse amplitude, obeys the differential equation

$$V_o'(t, x_0) = \frac{1}{R_{\mathrm{lpf}}C_{\mathrm{lpf}}}\left[-V_o(t, x_0) + \frac{R_{\mathrm{lpf}}}{R^e\left[\Theta(t, x_0)\right]}V_P(t)\right]. \quad (31.5)$$

As the voltage at the output of the low-pass filter depends on the value of the variable resistance $R^e[\Theta(t, x_0)]$, the readback signal is determined by solving jointly the differential equations (31.3) and (31.5), with initial conditions $\Theta(t_0, x_0) = \Theta_0$ and $V_o(t_0, x_0) = 0$. For example, a comparison between experimental and synthetic readback signals is shown in Figs. 31.30 and 31.31 for a time constant of the low-pass filter $\tau_{\mathrm{lpf}} = 1.18\,\mu\mathrm{s}$ and two values of the duration of the applied rectangular pulse. For a given cantilever design the function $R^e(\Theta)$ is determined experimentally. Finally, the parameters R^{Θ} and C^{Θ} used in the simple readback channel model are obtained via simulated annealing, where the cost function is given by the mean-square error between experimental and synthetic signals at the low-pass filter output.

Assuming that ideal control of the scanner is performed such that the time of application of a read pulse corresponds either to the cantilever located at the center of an indentation for detecting a "1" bit, or away from an indentation for detecting a "0" bit, two possible responses are obtained at the output of the low-pass filter as solutions of (31.3) and (31.5), which we denote as $V_{o,1}(t, x_0)$ and $V_{o,0}(t, x_0)$, respectively. By sampling the readback signal at the instant $t_s = t_0 + \tau$, simple threshold detection may in principle be applied to detect a written bit, where the value of the threshold is given by

$$V_{\mathrm{Th}} = \frac{1}{2}\left[V_{o,1}(t_s, x_0) + V_{o,0}(t_s, x_0)\right]. \quad (31.6)$$

As mentioned in Sect. 31.2, one of the most critical issues in detecting the presence or absence of an indentation is the high resolution required to extract the small signal $V_{o,1}(t_s, x_0) - V_{o,0}(t_s, x_0)$ that contains the information about the bit being "1" or "0" superimposed on the offset signal $V_{o,0}(t, x_0)$. As illustrated in Fig. 31.28, this problem can be solved by subtracting a suitable reference signal $V_{o,\mathrm{ref}}(t, x_0)$ from the readback signal. The readback signal is thus given by

$$\tilde{V}_o(t, x_0) = V_o(t, x_0) - V_{o,\mathrm{ref}}(t, x_0), \quad (31.7)$$

and the threshold is set at $\tilde{V}_{\mathrm{Th}} = \frac{1}{2}\left[V_{o,1}(t_s, x_0) - V_{o,0}(t_s, x_0)\right]$. A VLSI implementation of the detection scheme analyzed here is presented in [31.42].

Now consider read pulses of duration τ that are periodically applied at instants $t_n = nT$, where $1/T$ denotes the symbol rate. Assuming that the response of the previous pulse has vanished as a new pulse is applied and that the temperature of the cantilever has approached the ambient temperature, i. e., $V_o(t_n, x_n) = 0$ and $\Theta(t_n, x_n) = \Theta_0$, then the analysis presented above still holds. In particular, the readback signal samples ob-

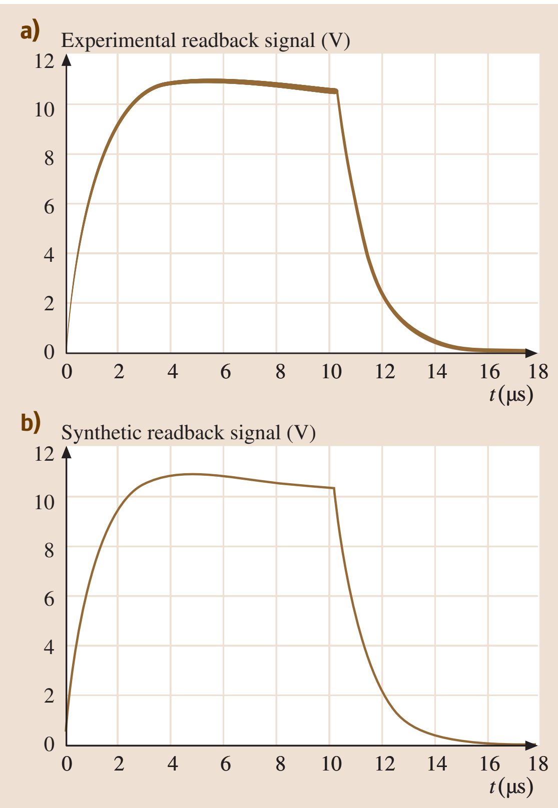

Fig. 31.30 **(a)** Experimental and **(b)** synthetic readback signal for $\tau = 10.25\,\mu$s (after [31.12])

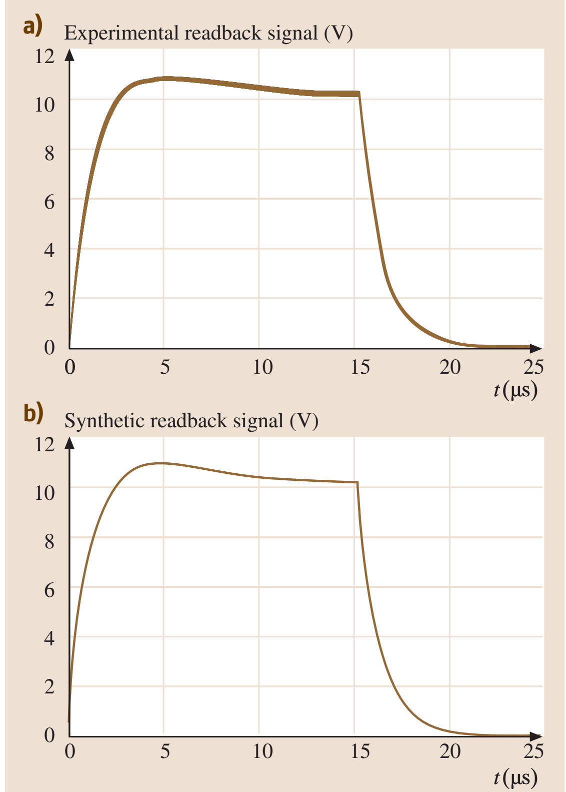

Fig. 31.31 **(a)** Experimental and **(b)** synthetic readback signal for $\tau = 15.25\,\mu$s (after [31.12])

tained in response to N pulses applied to the cantilever for detecting a sequence of N binary written symbols are expressed as

$$s(t_{s,n}) = \tilde{V}_o(t_{s,n}, x_n), \quad t_{s,n} = nT + \tau,$$
$$n = 0, \ldots, N-1\,, \tag{31.8}$$

where $\tilde{V}_o(t, x_n)$ is given by (31.7) for pulses applied at time t_n and at distance $x_n = nT\upsilon$, $n = 0, \ldots, N-1$ from the initial point of scanning. Note that the functions $V_o(t, x_n)$ and $V_{o,\text{ref}}(t, x_n)$ in (31.7) are ideally given by the solution of the differential equations (31.3) and (31.5) for $\eta_x = \Delta R^\Theta(x_n)/R^\Theta$ and $\eta_x = 0$, respectively.

The readback signal (31.7) at the output of the low-pass filter is observed in the presence of additive noise. Therefore, the readback signal for the detection of the n-th binary symbol is given by

$$r(t_{s,n}) = s(t_{s,n}) + w(t_{s,n})\,, \tag{31.9}$$

where $w(t)$ denotes the noise signal. The components of the noise signal that must be taken into account are thermal noise (Johnson's noise) from the sensor, which reaches a temperature of about $\Theta_1 = 350\,°$C during the read process, as well as from front-end analog circuitry. However, note that besides thermal noise, medium-related noise also affects the overall system performance.

Based on the above analysis, the response to a pulse applied to the cantilever at a distance x from some initial point can be calculated given the parameter $\eta_x = \Delta R^\Theta(x)/R^\Theta$. Recall that the value of η_x is proportional to the distance of the cantilever from the storage medium at the current location of the tip. Therefore, during tip displacement due to scanner motion, η_x is modulated from the topographical features of the storage surface such as written indentations, rings, and dust particles. This indicates that the modeling of the readback signal is a two-step process. First,

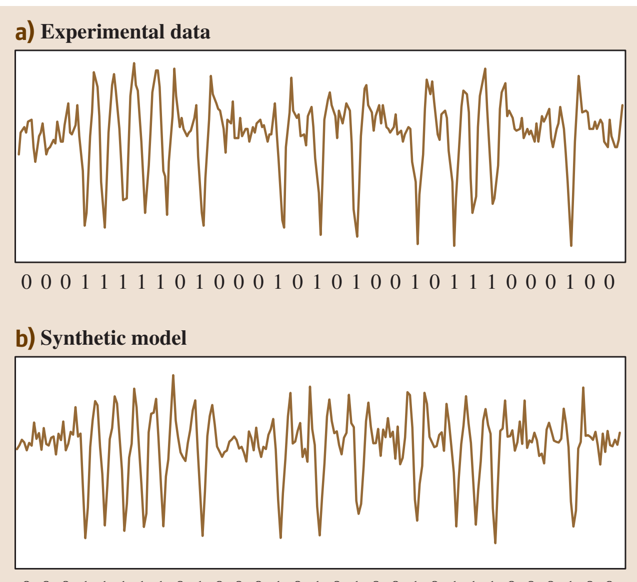

Fig. 31.32a,b Comparison between **(a)** the readback signal obtained experimentally along a data track and **(b)** the readback signal obtained by the synthetic model (after [31.12])

a model for the storage surface topography is developed, which directlyand then the above procedure is used to calculate the readback signal samples in response to pulses applied at selected points in the particular storage area.

In the absence of any imperfections during the manufacturing and the writing process, the storage surface would consist of completely flat regions interrupted by uniformly shaped indentations, possibly surrounded by polymer rings. A 1-D cross section of an indentation along the scanning direction is modeled by a function with one main lobe and two side lobes, one on each side of the main lobe, the magnitude and the extent of which can be varied independently. The side lobes are of opposite sign than the main lobe and simulate the polymer rings around written indentations. By varying their magnitude and extent while keeping the total extent of the pulse fixed, one can simulate indentations/rings of varying width and asymmetric ring formation, phenomena that are caused by different recording conditions. In practice, however, no polymer surface is entirely flat and indentation shapes are far from uniform. The deviation of indentations from uniformity is simulated by scaling the amplitude of each pulse shape by a random number drawn from a Gaussian distribution with unit mean and adjustable variance. The surface roughness is in turn simulated by adding white Gaussian noise to the height of every point in the area of interest. Note that surface roughness is a medium-related effect and manifests itself in the readback signal as a noise process, which is, however, of a very different nature than thermal noise. The advantage of the adopted two-step model is that it naturally decouples these unrelated noise sources, as well as the write and the read processes.

Figure 31.32 illustrates the experimental and synthetic readback signals obtained along a data track. The waveforms shown in Fig. 31.32 have been obtained by applying pulses at the oversampling rate of q/T, where q denotes the oversampling factor. For a more detailed comparison between model and actual signals, Figs. 31.33 and 31.34 illustrate 3-D views of isolated indentations from experimental and synthetic readback

Part E | 31.8

signals, respectively. The dark regions in the center of both figures correspond to the indentation centers, whereas dark regions around them are due to rings. Note also the irregular height of the surrounding surface, which is attributed to the roughness of the storage medium.

31.9 System Aspects

In this section, we describe various aspects of a storage system based on our millipede concept. Each cantilever can write data to and read data from a dedicated area of the polymer surface, called a *storage field*. As mentioned above, in each storage field the presence (absence) of an indentation corresponds to a logical “1” (“0”). All indentations are nominally of equal depth and size. The logical marks are placed at a fixed horizontal distance from each other along a data track. We refer to this distance, measured from one logical mark center to the next, as the *bit pitch* (BP). The vertical (cross-track) distance between logical mark centers, the *track pitch* (TP), is also fixed. To read and write data the polymer medium is moved under the (stationary) cantilever array at a constant velocity.

A robust way to achieve synchronization and servo control in an x/y-actuated large 2-D array is by reserving a small number of storage fields exclusively for timing recovery and servo-control purposes, as illustrated in Fig. 31.35. Because of the large number of levers in the millipede, this solution is advantageous in terms of overhead compared with the alternative of timing and servo information being embedded in all data fields.

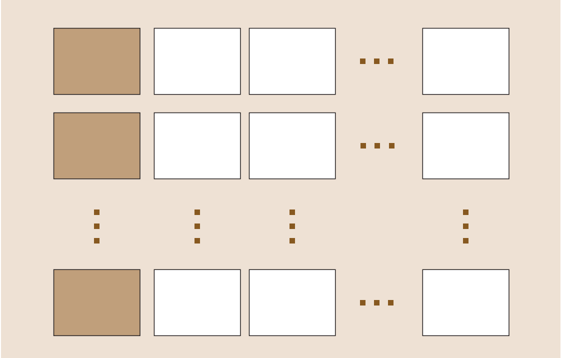

Fig. 31.35 Layout of data and servo/timing fields. *Dark boxes* represent dedicated servo/timing fields, *white boxes* represent data fields

31.9.1 PES Generation for the Servo Loop

With logical marks as densely spaced as in the millipede, accurate track following becomes a critical issue. Track following means controlling the position of each tip such that the tip is always positioned over the center of a desired track during reading. During writing, the tip position should be such that the written marks are aligned in a predefined way. In electromechanical systems, track following is performed in a servo loop, which is driven by an appropriate error signal called position-error signal (PES). Ideally, its magnitude is a direct estimate of the vertical (cross-track) distance of the tip from the closest track centerline, and its polarity indicates the direction of this offset.

Several approaches exist to generate a PES for AFM-based storage devices [31.9]. However, based on the results reported, none of these methods can achieve the track-following accuracy required for the millipede system. The quality of the PES directly affects the stability and robustness of the associated tracking servo loop [31.43].

We describe a method for generating a uniquely decodable PES for the millipede system [31.12, 27]. The method is based on the concept of *bursts* that are vertically displaced with respect to each other, arranged in such a way as to produce two signals in quadrature, which can be combined to provide a robust PES. This concept is borrowed from magnetic recording [31.43]. However, servo marks, as opposed to magnetic transitions, are placed in bursts labeled A and B for the in-phase signal and C and D for the quadrature signal. The centers of servo marks in burst B are vertically offset from mark centers in burst A by d' units of length. This amount of vertical spacing is related to the diameter of the written marks. The same principle applies to marks in the quadrature bursts C and D, with the additional condition that mark centers in burst C are offset by $d'/2$ units from mark centers in A in the cross-track direction. The latter condition is required in order to generate a quadrature signal. The configuration of servo bursts is illustrated in Fig. 31.36 for a case where $\mathrm{TP} = 3d'/2$. Al-

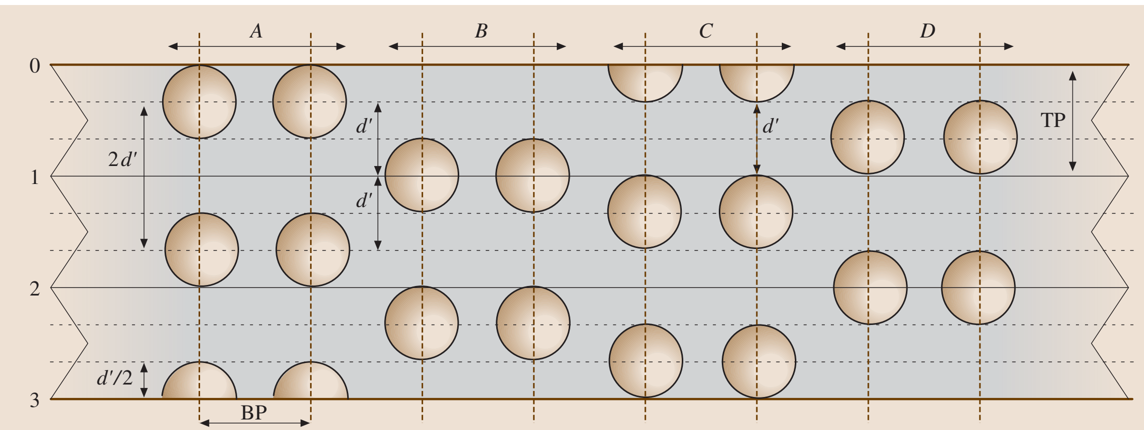

Fig. 31.36 Servo burst configuration (after [31.12])

though each burst typically consists of many marks to enable averaging of the corresponding readout signals, only two marks per burst are shown here to simplify the presentation. The solid horizontal lines depict track centerlines, and circles represent written marks, which are modeled here as perfect conical indentations on the polymer storage surface.

To illustrate the principle of PES generation, let us assume that marks in all bursts are spaced BP units apart in the longitudinal direction, and that sampling occurs exactly at mark centers, so that timing is perfect. The assumption of perfect timing is made only for the purpose of illustration. In actual operation, sampling is performed with the aid of a timing recovery loop, as described in Sect. 31.9.2. Referring to Fig. 31.36, let us further assume that the cantilever/tip is located on the line labeled "0" and moves vertically toward line "3" in a line crossing the centers of the left-most marks in burst A (shown as a brown dashed line). The tip moves from the edge of the top mark toward its center, then toward its bottom edge, then to a blank space, again to a mark, and so on. The readout signal magnitude decreases linearly with the distance from the mark center and reaches a constant, background level value at a distance greater than the mark radius from the mark center, according to the adopted (conical mark) model. To synthesize the in-phase signal, the readout signal is also captured as the tip (conceptually) moves in a vertical line crossing the mark centers of burst B (brown dashed line in Fig. 31.36). The in-phase signal is then formed as the difference $\bar{A}-\bar{B}$, where $\bar{A}$ and $\bar{B}$ stand for the measured signal amplitudes in bursts A and B, respectively. This signal is represented by the line labeled "I" in Fig. 31.37. It has zero-crossings at integer multiples of d', which do not generally correspond to track centers because we set $\mathrm{TP}=3d'/2$ in this example. Therefore, the I-signal is not a valid PES in itself. This is why the quadrature (Q) signal becomes necessary in this case. The Q-signal is generated from the servo readback signals of bursts C and D as $\bar{C}-\bar{D}$ and is also shown in Fig. 31.37 (Q-curve). Note that it exhibits zero-crossings at points where the I-signal has local extrema.

A certain combination of the two signals (I and Q), shown as solid lines in Fig. 31.37, has zero-crossings at all track center locations and constant (absolute) slope, which qualifies it as a valid PES. However, this PES exhibits zero-crossings at all integer multiples of $d'/2$. For our example of $\mathrm{TP}=3d'/2$, three such zero-crossings exist in an area of width equal to TP around any track centerline. This fact, however, does not hamper unique position decoding. At even-numbered tracks, it is the zero of the *in-phase* signal that indicates the track center. The zeros of the quadrature signal, in turn, can be uniquely mapped into a position estimate by examining the polarity of the in-phase signal at the corresponding positions. This holds for any value of the combined PES within an area

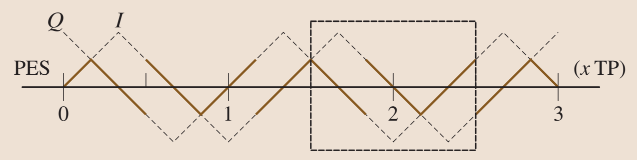

Fig. 31.37 Ideal position-error signal (after [31.12])

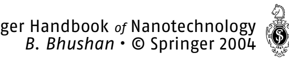

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

of width equal to TP around each current track centerline. The signals exchange roles for odd-numbered tracks. The current track number, which is known a priori from the seek operation, is used to determine the mode of operation for the position demodulation procedure.

The principle of PES generation based on servo marks has been verified experimentally. For this purpose, A, B, C, and D bursts were written by an AFM cantilever/tip on an appropriate polymer medium consisting of a polymer coating on a silicon substrate. The bit pitch was set to 42 nm, and the track pitch was taken to be approximately equal to d', the cross-track distance between A (C) and B (D) bursts. An image created by reading the written pattern with the same cantilever is shown in Fig. 31.38. Shaded areas indicate indentations. The readout signal from the cantilever was also used for servo demodulation, as described above. The resulting in-phase and quadrature signals are shown in Fig. 31.39. The track centerlines are indicated by vertical dotted lines in the graph.

It can be observed that the zero-crossings of the in-phase signal are closely aligned with the track centerlines, as well as with the minima and maxima of the quadrature signal, as required for unique position decoding across all possible cross-track positions, at least in cases where $\text{TP} \neq d'$. Moreover, the PES slope is nearly linear along a cross-track width of one track pitch around each track center, as $\text{TP} \approx d'$ in this case, although deviations from the ideal signal shape exist. These deviations occur mainly because written indentations do not have perfect conical shapes, and also because of medium noise due to the roughness of the recording medium. Nevertheless, the experimentally generated error signals indicate that the proposed concept is valid and promising. Specifically, the results indicate that servo self-writing is feasible, that servo demodulation is almost identical to data readout and can be performed by any cantilever without special provisions, and that the PES generated closely approximates the desirable features described above.

31.9.2 Timing Recovery

Similar to obtaining servo information based on using dedicated servo fields, we employ separate dedicated clock fields for recovery of timing information [31.12, 26, 27]. The concept is to have continuous access to a pilot signal for synchronization after initial phase acquisition and gain estimation. The recovered clock is then distributed to all remaining storage fields to allow reliable detection of random data. Initial phase acquisition is obtained by a robust correlation algorithm, gain estimation is based on averaging of the readback signal obtained from a predefined stored pattern, and tracking of the optimum sampling phase is achieved by a second-order digital loop.

At the beginning of the read process, several signal parameters have to be estimated prior to data detection. Besides the clock phase and frequency, it is necessary to

estimate the gain of the overall read channel. To solve the problem of initial estimation of signal parameters prior to data detection, the sequence written in the clock field consists of a preamble, followed by a pattern of all "1"s for tracking the optimum sampling phase during the detection of random data. The transition between the preamble and the pattern of all "1"s must be detected reliably, as it indicates the start of data records to the remaining storage fields. Assuming that the initial frequency offset is within a small, predetermined range, usually 1,000 parts-per-million (PPM), we distinguish the tasks needed for timing recovery as follows: (i) acquisition of the optimum sampling phase; (ii) estimation of the overall channel gain needed for threshold detection; (iii) detection of the transition between the preamble and the pattern of all "1"s; and (iv) tracking of the optimum sampling phase.

At the beginning of the acquisition process, an estimate of the optimum sampling phase is obtained by resorting to a correlation method. We rely on the knowledge of the preamble and of an ideal reference-channel impulse response, which closely resembles the actual impulse response (see Sect. 31.9). The channel output samples obtained at the oversampling rate q/T are first processed by removing the dc-offset, then averaging is performed to reduce the noise level, and finally the resulting sequence is correlated with the reference impulse response to determine the phase estimate.

After determining the estimate of the optimum sampling phase, an estimate of the overall channel gain is obtained by averaging the amplitude of the channel output samples at the optimum sampling instants. The gain estimate is obtained from an initial segment of the preamble corresponding to an "all 1" binary pattern. As mentioned above, it is necessary that the end of the preamble is indicated by a "sync" pattern, which marks the transition between acquisition mode and tracking mode. Detection of the sync pattern is also based on a robust correlation method. After the sync pattern, an "all 1" pattern, as in the case of robust phase acquisition and gain estimation, is employed for tracking. The "all 1" pattern corresponds to regularly spaced indentations, which convey reliable timing information.

Tracking of the optimum sampling phase is achieved by the second-order loop configuration shown in Fig. 31.40. Assuming data detection is performed at instants that correspond to integer multiples of the oversampling factor q, the deviation of the sampling phase from the optimum sampling phase is estimated as

$$\Delta\tau_n = r(t_{s,nq+1}) - r(t_{s,nq-1}) . \qquad (31.10)$$

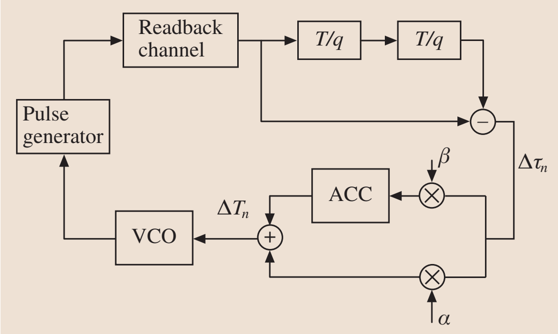

Fig. 31.40 Second-order loop for tracking the optimum sampling phase (after [31.12])

This estimate of the phase deviation is input to a second-order loop filter, which provides an output given by

$$\Delta T_n = u_n + \alpha\,\Delta\tau_n , \qquad (31.11)$$

where the discrete-time integrator is recursively updated as

$$u_{n+1} = u_n + \beta\,\Delta\tau_n . \qquad (31.12)$$

The loop-filter output then determines the control signal for a voltage-controlled oscillator (VCO).

Note that a similar concept for timing recovery can also be applied if no separate clock field is available. In this case, the timing information is extracted from the random user data on each storage field.

31.9.3 Considerations on Capacity and Data Rate

The ultimate locality provided by nanometer-sharp tips represents the pathway to the high areal densities that will be needed in the foreseeable future. The intrinsic nonlinear interactions between closely spaced indentations, however, may limit the minimum distance between successive indentations and, hence, the areal density. The storage capacity of a millipede-based storage device can be further increased by applying modulation or constrained codes [31.12].

With modulation coding, a desired constraint is imposed on the data-input sequence, so that the encoded data stream satisfies certain properties in the time or frequency domain. These codes are very important in digital recording devices and have become ubiquitous in all data-storage applications. The particular class

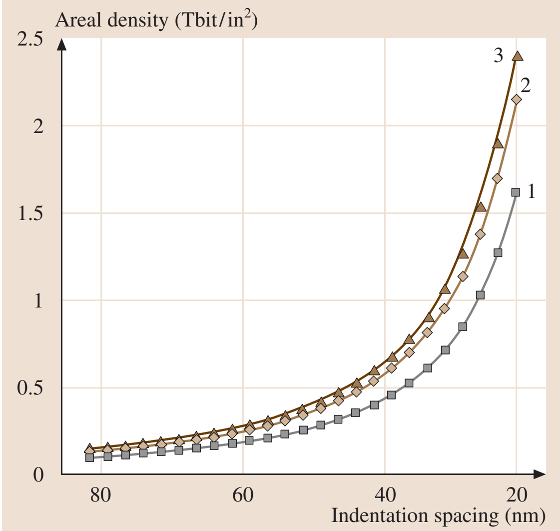

Fig. 31.41 Areal density versus indentation spacing. Curve 1: $d=0$; curve 2: $d=1$; and curve 3: $d=2$

of codes that imposes restrictions on the number of consecutive "1"s and "0"s in the encoded data sequence, generally known as run-length-limited (RLL) (d, k) codes [31.44], can be used to facilitate overwriting and also increase the effective areal density of a millipede-based storage device. The code parameters d and k are nonnegative integers with $k > d$, where d and k indicate the minimum and maximum number of "0"s between two successive "1"s, respectively. In the past, the precoded (RLL) (d, k) codes were mainly used for spreading the magnetic transitions further apart via the d-constraint, thereby minimizing intersymbol interference and nonlinear distortion, and for preventing loss of clock synchronization via the k-constraint. In optical recording, precoded RLL codes are primarily used for increasing the shortest pit length in order to improve the reliability of bit detection, as well as for limiting the number of identical symbols, so that useful timing information can be extracted from the readback signal.

For the millipede application, where dedicated clock fields are used, the k-constraint does not really play an important role and, therefore, can, in principle, be set to infinity, thereby facilitating the code design process. In a precoderless RLL code design, where the presence or absence of an indentation represents a "1" or "0", respectively, the d-constraint is instrumental in limiting the interference between successive indentations, as well as in increasing the effective areal density of the storage device. In particular, the quantity $(d+1)R$, where R denotes the rate of the (d, k) code, is a direct measure of the increase in linear recording density. Clearly, the packing density can be made larger by increasing d. On the other hand, large values of d lead to codes with very low rate, which implies high recording symbol rates, thus rendering these codes impractical for storage systems that are limited by the clock speed. The choice of $d=1$ and $k \geq 6$ guarantees the existence of a code with rate $R=2/3$. Use of $(d=1, k \geq 6)$ modulation coding reduces the bit distance by half while maintaining the pitch between "1"s constant, thereby

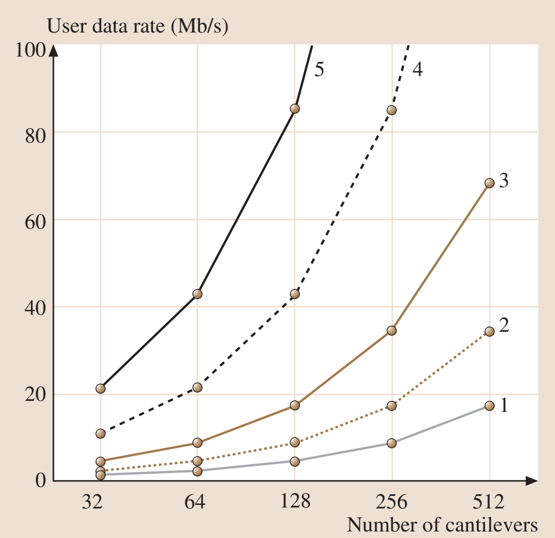

Fig. 31.42 User data rate versus number of active cantilevers for the $(d=1, k \geq 6)$ coding scheme. Curve 1: $T = 20\,\mu s$; curve 2: $T = 10\,\mu s$; curve 3: $T = 5\,\mu s$; curve 4: $T = 2\,\mu s$; and curve 5: $T = 1\,\mu s$ (after [31.12])

Table 31.1 Areal density and storage capacity (after [31.12] with permission © 2003 IEEE)

Coding	Linear density (kb/in)	Track density (kt/in)	Areal density (Gb/in^2)	Capacity (Gb)
Uncoded	847	847	717	1.21
$(d=1, k \geq 6)$	1,129	847	956	1.61
$(d=2, k > 6)$	1,269	847	1,075	1.81

increasing the linear density by a factor of 4/3. Similarly, the choice of $d=2$ and $k>6$ guarantees the existence of a code with rate $R=1/2$. Use of ($d=2$, $k>6$) modulation coding reduces the bit distance to a third while maintaining the pitch between "1"s constant, thereby increasing the linear density by a factor of 3/2. Figure 31.41 shows the areal density as a function of the indentation spacing for an uncoded system, as well as for systems coded with ($d=1$, $k \geq 6$) and ($d=2$, $k>6$), where coding is applied only in the on-track direction.

Table 31.1 shows the achievable areal densities and storage capacities for a 32×32 cantilever array with 1,024 storage fields, each having an area of $100\times100\,\mu\text{m}^2$, resulting in a total storage area of $3.2\times3.2\,\text{mm}^2$. The indentation pitch and the track pitch are set equal to 30 nm. Finally, for the computation of the storage capacity an overall efficiency of 85% has been assumed, taking into account the redundancy of the outer error-correction coding, as well as the presence of dedicated servo and clock fields.

Figure 31.42 shows the user data rate as a function of the total number of cantilevers accessed simultaneously, for various symbol rates and a ($d=1$, $k\geq6$) modulation coding scheme. For example, for a 32×32 cantilever array, a system designed to access a maximum of 256 cantilevers every $T=5\,\mu\text{s}$ provides a user data rate of 34.1 Mb/s. Alternatively, by resorting to the row/column multiplexing scheme with $T=80\,\mu\text{s}$ a data rate of 8.5 Mb/s is achieved.

31.10 Conclusions

A very large 2-D array of AFM probes has been operated for the first time in a multiplexed/parallel fashion, and write/read/erase operations in a thin polymer medium have been successfully demonstrated at densities of or significantly higher than those achieved with current magnetic storage systems.

The millipede has the potential to achieve ultrahigh storage areal densities on the order of $1\,\text{Tb/in}^2$ or higher. The high areal storage density, small form factor, and low power consumption render the millipede concept a very attractive candidate as a future storage technology for mobile applications, as it offers several Gigabytes of capacity at data rates of several Megabytes per second. Dedicated servo and timing fields allow reliable system operation with a very small overhead. The read channel model provides the methodology for analyzing system performance and assessing various aspects of the detection and servo/timing algorithms that are key to achieving the system reliability required by the applications envisaged.

Although the first high-density storage operations with the largest 2-D AFM array chip ever built have been demonstrated, there are a number of issues that need further investigation such as overall system reliability, including long-term stability of written indentations, tip and medium wear, limits of data rates, array and cantilever size, as well as trade-offs between data rate and power consumption.

32. Microactuators for Dual-Stage Servo Systems in Magnetic Disk Files

This chapter discusses the design and fabrication of electrostatic MEMS microactuators and the design of dual-stage servo systems in disk drives. It introduces fundamental requirements of disk drive servo systems, along with challenges posed by storage densities increases. It describes three potential dual-stage configurations and focuses on actuated slider assemblies using electrostatic MEMS microactuators. The authors discuss major electrostatic actuator design issues, such as linear versus rotary motion, electrostatic array configuration, and differential operation. Capacitive and piezoresistive elements may be used to sense relative slider position, while integrated gimbals and structural isolation may prove useful in improving performance. A detailed design example based on a translational, micromolded actuator illustrates several of these concepts and is accompanied by theoretical and experimental results.

The chapter continues to discuss MEMS microactuator fabrication. It describes several processes for obtaining appropriate electrostatic devices including micromolding, deep-reactive ion etching, and electroplating. The primary goal of these processes is to obtain very high-aspect ratio structures, which improve both actuation force and structural robustness. Other fabrication issues, such as electrical interconnect formation, material selection, and processing cost, are also considered. Actuated slider fabrication is compared to that of actuated suspension and actuated head assemblies; this includes instrumentation of a suspension with strain sensors to aid in vibration detection.

The section on controller design reviews dual-stage servo control design architectures and methodologies. The considerations for controller design of MEMS microactuator dual-stage servo systems are discussed. The details of control designs using a decoupled SISO design method and the robust multivariable design method of μ-synthesis are also presented. In the decoupled design, a self-tuning control algorithm has been developed to compensate for the variations in the microactuator's resonance mode. In the μ-synthesis design, robust controllers can be synthesized by using additive and parametric uncertainties to characterize the un-modeled dynamics of the VCM and the variations in the microactuator's resonance mode. Finally, the chapter also introduces a dual-stage short-span seek control scheme based on decoupled feed forward reference trajectories generations.

This chapter discusses the design and fabrication of electrostatic MEMS microactuators, and the design of dual-stage servo systems, in disk drives. The focus of the chapter is an actuated slider assembly using an electrostatic MEMS microactuator. We discuss major design issues, including linear versus rotary actuation, electrostatic array configuration, and integrated sensing capability. We describe several fabrication processes for obtaining the necessary devices, such as micromolding, deep-reactive ion etching, and electroplating. Dual-stage servo control design architectures and methodologies are then reviewed . We present in detail track-following controller designs based on a sensitivity function decoupling single-input-single-output design methodology and the robust μ-synthesis design methodology. Finally, we introduce a 2-DOF short span seek control design using a dual-stage actuator.

Since the first hard disk drive (HDD) was invented in the 1950s by IBM, disk drives' storage density has been following Moore's law, doubling roughly every 18 months. The current storage density is 10 million times larger than that of the first HDD [32.1]. Historically, increases in storage density have been achieved by almost equal increases in track density, the number of tracks encircling the disk, and bit density, the number of bits in each track. However, because of superparamagnetism limitations, future areal storage density increases in HDDs are predicted to be achieved mainly through an increase in track density [32.2].

Research in the HDD industry is now targeting an areal density of one terabit per square inch. For a predicted bit aspect ratio of 4 : 1, this translates to a linear bit density of 2 M bits per inch (BPI) and a radial track density of 500 K tracks per inch (TPI), which in turn implies a track width of 50 nm. A simple rule of thumb for servo design in HDDs is that three times the statistical standard deviation of the position error between the head and the center of the data track should be less than 1/10 of the track width. Thus, to achieve such a storage density, nanometer-level precision of the servo system will be required.

A disk drive stores data as magnetic patterns, forming bits, on one or more disks. The polarity of each bit is detected (read) or set (written) by an electromagnetic device known as the read/write head. The job of a disk drive's servo system is to position the read/write head over the bits to be read or written as they spin by on the disk. In a conventional disk drive, this is done by sweeping over the disk or disks a long arm consisting of a voice coil motor (VCM), an E-block, suspensions, and sliders, as shown in Figs. 32.1 and 32.2. A read/write head is fabricated on the edge of each slider (one for each disk surface). Each slider is supported by a suspension and flys over the surface of a disk on an air-bearing. The VCM actuates the suspensions and sliders about a pivot in the center of the E-block. We describe this operation in more detail in the following section.

The key to increasing HDD servo precision is to increase servo control bandwidth. However, the bandwidth of a traditional single-stage servo system as shown in Fig. 32.2 is limited by the multiple mechanical resonance modes of the pivot, the E-block, and the suspension between the VCM and the head. Nonlinear friction of the pivot bearing also limits achievable servo precision. Dual-stage actuation, with a second stage actuator placed between the VCM and the head, has been proposed as a solution that would increase servo bandwidth and precision.

Several different secondary actuation forces and configurations have been proposed, each having strengths and weaknesses given the requirements of HDDs. The dual-stage configurations can be categorized into three groups: actuated suspension, actuated slider, and actuated head. Within these, actuation forces include piezoelectric, electrostatic, and electromagnetic. In this chapter, we discuss design, fabrication and control of an electrostatic MEMS microactuator (MA) for actuated slider dual-stage positioning.

32.1 Design of the Electrostatic Microactuator

The servo system of a hard disk drive is the mechatronic device that locates and reads data on the disk. In essence, it is a large arm that sweeps across the surface of the disk. At the end of the arm is the read-write head, containing the magnetic reading and writing elements that transfer information to and from the disk.

32.1.1 Disk Drive Structural Requirements

This read-write head is contained in a box-like structure known as a slider. The slider has a contoured lower surface that acts as an air bearing between the head and the disk. The high-velocity airflow generated by

the spinning disk pushes up on the air-bearing surface, maintaining the slider and read-write head at a constant distance from the disk, despite unevenness of the disk, permitting reliable data reading and writing.

The arm over an HDD's disk has three primary stages: the voice-coil motor (VCM), the E-block, and the suspension. In a conventional disk drive, the VCM performs all positioning of the head, swinging it back and forth across the disk. The E-block lies between the VCM and the suspension and contains the pivot point. The suspension projects from the E-block over the disk as a thin flexible structure, generally narrowing to a point at the location of the slider.

For a disk drive servo to operate effectively, it must maintain the read-write head at a precise height above the disk surface and within a narrow range between the disk tracks arranged in concentric circles around the disk. It must also be able to seek from one track on the disk to another. Information about the track that the head is following is encoded in sectors radiating from center of the disk, allowing the head to identify its position and distance from the center of the track. To maintain a correct flying height, the suspension must be designed with an appropriate stiffness in the vertical direction to balance an air-bearing force corresponding to the slider design in use in the drive. Meanwhile, the suspension must be flexible to roll and pitch at the slider location to permit adaptation to unevenness of the disk surface. This is accomplished using a gimbal structure. The suspension as a whole, however, should not bend or twist during the operation, as this would misdirect the head away from the track it is following.

As data densities in HDDs increase and track widths diminish, single-stage, conventional servo systems become less able to position the head precisely. Because the VCM/E-block/suspension assembly is large and massive as a unit, the speed at which the head can be controlled is limited. Furthermore, the assembly tends to have a low natural frequency, which can accentuate vibration in the disk drive and cause off-track errors. At track densities in the future approaching one Terabit per square inch, the vibration induced in a disk drive by airflow alone is enough to force the head off-track.

A solution to these problems is to complement the VCM with a smaller, secondary actuator to form a dual-stage servo system. The VCM continues to provide rough positioning, while the second stage actuator does fine positioning and damps out vibration and other disturbances. The smaller second stage actuator can typically be designed to have a much higher natural frequency and less susceptibility to vibration than the VCM. Any actuator used in a dual-stage system should be inexpensive to build, require little power to operate, and preserve the stiffness properties described above necessary to preserve the flying height.

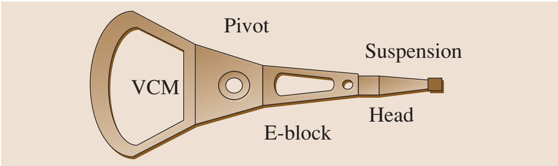

Fig. 32.2 VCM actuator in an HDD

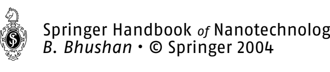
32.1.2 Dual-Stage Servo Configurations

In the past six years, much research work has been dedicated to the exploration of suitable secondary actuators for constructing dual-stage servo systems for HDDs. These dual-stage configurations can be categorized into three groups: "actuated suspension," "actuated slider," and "actuated head."

Actuated Suspension

In this approach, the suspension is redesigned to accommodate an active component, typically a piezoelectric material. This piezoelectric material stretches or flexes the suspension to position the slider and magnetic head. Piezoelectric material is an active actuation element that produces a large actuation force but small actuation stroke. In the "actuated-suspension" configuration, therefore, the piezoelectric actuators are usually implemented in a leverage mechanism that can convert small actuation displacements into large head displacements. Typically this is done by placing the piezoelectric



actuators away from the magnetic head (between the E-block and suspension) so that they can have a long leverage arm to gain mechanical amplification and produce a sufficient magnetic-head motion. The advantage of this approach is that the suspension can be fabricated by a conventional suspension-making process, and its dual-stage servo configuration is effective in attaining low frequency runout attenuation in the positioning servo loop. The major drawback of this approach is that the system is still susceptible to instabilities due to the excitation of suspension resonance modes. Thus, track-per-inch (TPI) servo performance can be increased but remains limited when compared to the alternative approaches. The actuated suspension approach, nonetheless is expected to be the first deployed in commercial HDDs [32.3, 4].

Actuated Slider

In this approach, a microactuator is placed between the slider and gimbal to position the slider/magnetic heads. The resulting servo bandwidth can be higher than the previous approach because the secondary actuation bypasses the mechanical resonances of the suspension. This approach uses existing sliders and microactuators that can be batch fabricated, and thus could be cost effective. However, the size and mass of the microactuator are significant relative to those of current sliders and may interfere with the slider flying stability. Current suspensions, therefore, need to be redesigned to adopt this secondary actuator. Suitable driving forces in this approach include electrostatic, electromagnetic, and piezoelectric [32.5–8]. To further reduce the assembly task of placing the microactuator in between gimbal structure and slider, some researchers have proposed microactuators that are either integrated with the gimbal structure [32.6] or the slider [32.9].

Actuated Head

In this approach, the slider is redesigned so that the microactuators can be placed inside the slider block and actuate the magnetic heads with respect to the rest of the slider body. As these microactuators are very small, they only slightly increase the slider weight and are thus capable of working with the current suspension assembly. Researchers have successfully demonstrated the integrated fabrication process for fabricating the electrostatic microactuators and magnetic heads within one piece of ceramic block (slider). The embedded electrostatic microactuator has its resonance close to 30 kHz and was able to position the magnetic heads relative to the rest of the slider body by 0.5 μm [32.10, 11]. Full-fledged integration of slider, actuator, and read/write head remains a challenge.

In this chapter, we focus on actuated slider configurations, as they involve a great deal of interesting microscale engineering. In particular, we will discuss electrostatic actuation, probably the most common method of implementing microactuation in microelectromechanical devices. Any such microactuator will exhibit certain features:

- a fixed base, which attaches to the suspension,
- a movable platform, upon which the slider rests,
- springs between the base and platform, flexible in the direction of desired motion, and stiff in all other directions, and
- an electrostatic actuation array that generates the force used to move the platform and slider.

Microactuators must also include a wiring scheme for transferring signals to and from the slider and often incorporate a structure for sensing the motion of the slider relative to the suspension. Electrostatic microactuators to be discussed in this chapter include HexSil and DRIE fabricated actuators from the University of California, Berkeley, and electroplating-formed actuators by IBM and the University of Tokyo.

Electromagnetic or piezoelectric force are alternatives to electrostatic actuation in the actuated-slider configuration. Electromagnetic microactuators use ferromagnetic films to produce force perpendicular to an applied electric field. This type of actuation has potentially low voltage requirements but requires special fabrication techniques to integrate the magnetic components into the assembly. A microactuator of this type for hard disk drives is under development at Seagate, with results as yet unpublished. Piezoelectric microactuators use a piezoelectric material, which expands or contracts in response to applied voltage, to move the slider. These actuators have simple fabrication, the patterning a piece of piezoelectric material to sit between the suspension and slider, but it is difficult to obtain an adequate range of motion. A short stroke from the piezoelectric piece must be leveraged into a much larger motion at the read/write head. A piezoelectric microactuator has been produced by TDK corporation with a 0.5 μm stroke length at 10 V, with a 10 V bias [32.12].

32.1.3 Electrostatic Microactuators: Comb-Drives vs. Parallel-Plates

Electrostatic microactuators have been studied as the secondary actuators in HDDs for their relative ease

of fabrication, particularly in the configurations of "actuated slider" and "actuated head," since the structural material needs only to be conductive rather than ferromagnetic or piezoelectric. Electrostatic force is generated by applying a voltage difference between the moving shuttle and a fixed stator element. Depending on the designated motion for the shuttle, electrostatic actuators are often categorized into two groups: comb-drives and parallel-plates, as illustrated in Fig. 32.3.

The magnitude of the electrostatic force generated equals the rate of change of energy that is retained within the finger-like structure and varied by shuttle motion. Therefore, the electrostatic force for comb-drive actuators, in which the designated shuttle motion moves along the x-direction, as shown in Fig. 32.3, equals

$$F_{\text{comb}} = \frac{\partial E}{\partial x} = \frac{\epsilon h}{2d} V^2 , \tag{32.1}$$

where ϵ is the permittivity of air, x is the overlap between two adjacent plates, h is plate thickness, and d is the gap between two parallel plates. Similarly, the electrostatic force for parallel-plates actuators is

$$F_{\text{parallel}} = \frac{\partial E}{\partial y} = \frac{\epsilon x h}{2d^2} V^2 , \tag{32.2}$$

where x is the finger overlap.

As indicated in (32.1) and (32.2), the electrostatic force for comb-drives actuators does not depend on the displacement of the moving shuttle and thus allows a long stroke while maintaining a constant electrostatic force. The electrostatic force for parallel-plates actuators, in contrast, is a nonlinear function of its shuttle motion ($\propto 1/d^2$), and the maximum stroke is limited by the nominal gap between shuttle and stator. A longer stroke is achieved with a larger gap, at the expense of lower electrostatic force. For applications that require small stroke but large force output, parallel-plates actuators are preferred since the output force from parallel-plates can be x/d times larger than the force from comb-drives. The following equation (32.3) is easily derived from (32.1) and (32.2).

$$\frac{F_{\text{parallel}}}{F_{\text{comb}}} = \frac{x}{d} . \tag{32.3}$$

A simplified second-order differential equation is often utilized to describe the dynamic response of an electrostatic microactuator

$$m\ddot{x}(t) + b\dot{x}(t) + K_{\text{m}}x(t) = F\,[V, x(t)] , \tag{32.4}$$

where m is the mass of the moving shuttle, b is the damping coefficient of the microactuator, K_{m} is the spring

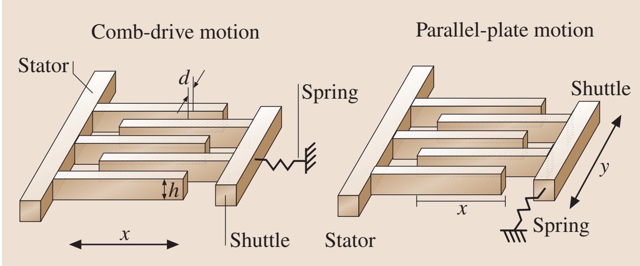


Fig. 32.3 Electrostatic microactuators. Comb-drives versus parallel-plates

constant of the mechanical spring that connects the moving shuttle to an anchor point, and F is the electrostatic force that can be obtained from (32.1) and (32.2).

Differential Drives

Because electrostatic force is always attractive, electrostatic microactuators need other features to actively control the direction of shuttle motion in servo applications, as opposed to relying on the restoring force from a mechanical spring. For this reason, the differential-drives approach, as shown in Fig. 32.4, is frequently adopted in electrostatic microactuator designs. Based on the differential-drive configuration, the simplified second-order differential equation (32.4) is rewritten as

$$\begin{aligned} m\ddot{x}(t)+b\dot{x}(t)+K_{\text{m}}x(t) &= F[V_{\text{bias}}+V_{\text{dr}}, x_o-x(t)]- \\ &\quad F[V_{\text{bias}}-V_{\text{dr}}, x_o+x(t)] , \end{aligned} \tag{32.5}$$

where x_0 is the nominal position of the moving shuttle. If the differential drive is operated at the bias voltage (V_{bias}) with a small perturbation voltage (V_{dr}), the nonlinear force input in (32.5) can be linearized with a first-order

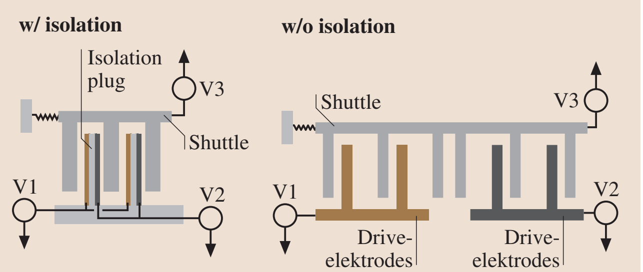

Fig. 32.4 Differential parallel-plates actuators and electrical-isolation features

approximation.

$$m\ddot{x}(t)+b\dot{x}(t)+(K_m-K_e)x(t)=K_v V_{dr} ,$$
$$K_e = 2\frac{\partial F}{\partial x}\,|_{V_{bias}} ,$$
$$K_v = 2\frac{\partial F}{\partial V_{dr}}\,|_{V_{bias}} . \quad (32.6)$$

Here K_e represents a softening electrostatic spring constant, and K_v represents the voltage-to-force gain. The electrostatic spring constant acts as a negative spring during the electrostatic microactuator operation, and its value varies with the bias voltage (V_{bias}). When the electrostatic spring constant K_e exceeds the spring constant K_m from the mechanical spring, the microactuator becomes unstable; this is often described as pull-in instability. As shown in (32.5) and (32.6), the differential configuration cancels the even order harmonics in voltage and thus linearizes the voltage–force relation to some extent. Furthermore, in parallel-plates actuators, the differential configuration reduces the nonlinearity in actuation voltage as well as in shuttle displacement.

Electrical Isolation

Because electrostatic actuation requires multiple voltage levels for actuation force and position sensing (as discussed in the following section), electrical isolation is another challenge for designing an electrostatic microactuator. Generally speaking, when multiple voltage levels are needed in MEMS devices, electrical isolation is achieved by breaking up the parts that need to be on different voltage level and anchoring them separately to a nonconductive substrate. This approach has many drawbacks, not only because it requires a substrate in a device but also because structures have to be mechanically separated to be electrically isolated. The electrical isolation problem is far more severe in parallel-plates microactuators than comb-drive microactuators since parallel-plates actuation generally requires different voltage levels for stator fingers pulling in opposite directions.

Figure 32.4 shows an example of how an electrical-isolation feature can be utilized to increase the actuation force output in a differential parallel-plates microactuator design. As shown in the figure, without the proper electrical isolation, drive-electrodes with different voltage potentials have to be placed in separate groups and result in the same voltage difference between drive-electrodes and shuttle on both sides of each shuttle finger [32.5, 6]. Since electrostatic forces are always attractive, gaps on two sides of the interlaced structure cannot be made equal, otherwise the forces on two sides of a shuttle finger will be equal and the shuttle's movement direction will be uncontrollable. With such electrical-isolation features as the "isolation plug," shown on the left in Fig. 32.4, gaps of the interlaced structure can be the same width, since different voltages can be applied on the two sides of the shuttle fingers. As shown in Fig. 32.4, the design with integrated electrical-isolation features is more compact than without isolation features. Consequently, more finger structures can fit in the same amount of space, and the actuation voltage can be reduced.

32.1.4 Position Sensing

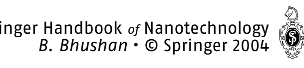
Most proposed HDD dual-stage servo controllers utilize only the position of the magnetic head relative to the center of data track, known in the industry as the position error signal, or PES, for closed-loop track following control. These systems have a single-input-multi-output (SIMO) control architecture. In some instances, however, it is also possible to measure the relative position error signal (RPES) of the magnetic head relative to the VCM. In this case, the control architecture is multi-input-multi-output (MIMO). As shown in [32.13], RPES can be used in a MIMO controller to damp out the second stage actuator's resonance mode and enhance the overall robustness of the servo system.

Capacitive position sensing and piezoresistive position sensing are two popular sensing mechanisms among electrostatic microactuator designs. Each of these sensing mechanisms is discussed in more detail in the following sections.

Capacitive Position Sensing

Capacitive position sensing is based on shuttle movement causing a capacitance change between the moving shuttle and fixed stators. By measuring the change in capacitance, it is possible to determine the shuttle location relative to the fixed stator. The output voltage (V_o) for both differential drives in Fig. 32.5 equals $2\delta C/C_i V_s$. The capacitance change due to shuttle movement (dC/dx) can be derived and the output voltage (V_o) for the comb-drives and parallel-plates can be formulated as a function of shuttle displacement.

$$V_{comb} = 2\frac{C_s}{C_i}\frac{\delta x}{x_0}V_s ,$$
$$V_{parallel} = 2\frac{C_s}{C_i}\frac{y_0\delta y}{y_0^2-\delta y^2}V_s ,$$
$$\approx 2\frac{C_s}{C_i}\frac{\delta y}{y_0}V_s , \quad (32.7)$$



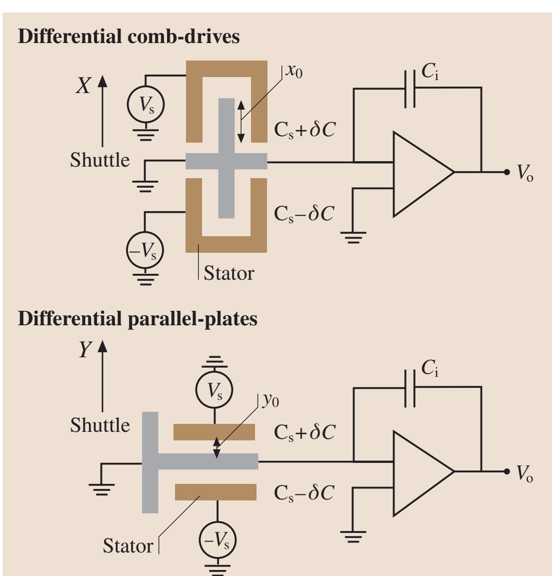


Fig. 32.5 Capacitive position sensing. Comb-drives versus parallel-plates motion

where x_0 is the nominal overlap for interlaced fingers and y_0 is the nominal gap between overlapped fingers, as shown in Fig. 32.5.

As indicated by (32.7), the voltage output for the comb-drives sensing structure, V_{comb}, is linear with shuttle displacement. On the other hand, the sensing configuration that makes use of parallel-plates motion has better sensitivity for detecting shuttle motion since y_0 is usually smaller than x_0. Although the nonlinearity in parallel-plates sensing can be linearized by the differential drive configuration to some extent, in a design example of 4 μm gap with 1 μm stroke, the linear model shown in (32.7) still produces 6% deviation from the nonlinear model.

Among electrostatic microactuators that use capacitive position sensing, the capacitance variation due to shuttle motion (dC/dx) is typically at the level of 100 fF/μm. In order to obtain 10 nm position sensing resolution, the capacitance sensing circuit must be able to detect capacitance variation of 1 fF in the presence of parasitic capacitance and offset/mismatches from op-amps, which can easily result in an output voltage orders of magnitude larger than the output voltage from the designated capacitance variation. In most capacitive position sensing, the limiting factor for the sensing resolution is not the thermal noise but the sensing circuit's design.

Here we introduce two basic capacitance sensing circuits suitable for high-resolution position sensing [32.14]. The concept of the "synchronous scheme," as shown in Fig. 32.6 I, is to reduce the impedance of sense capacitors as well as the offset and 1/f noises from op-amps by applying modulation techniques on the sense voltage (V_s). The R_{dc} resistor on the feedback loop sets the DC voltage level at the input nodes of the "charge integrator." The effect of the presence of parasitic capacitance (C_p) is nullified by the virtual ground condition from the op-amps. The major drawback of the synchronous scheme is that the DC-setting resistor (R_{dc}) has to be large to ensure the proper gain for the capacitance sensing [32.14], which introduces excessive thermal noise into the sensing circuit. In addition, a large resistor usually consumes a large die space in implementation.

A switched-capacitance scheme, as shown in Fig. 32.6 II, is one alternative that avoids the use of DC-setting resistor. The capacitance sensing period is broken into two phases: reset phase and sense phase. During the reset phase, input/output nodes of capacitors

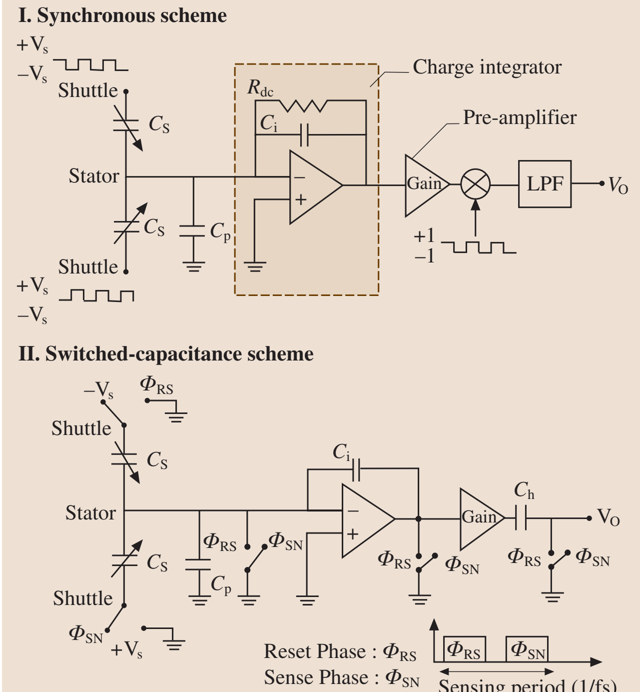

Fig. 32.6 Capacitive position sensing circuits. Synchronous scheme versus switched-capacitance scheme

and input voltage to op-amps are set to ground or reference level to ensure proper DC voltage for the charge integrator. During the sense phase, sense voltage $\pm V_s$ is applied to the sense capacitors, and the amount of charge proportional to the mismatch in the sense capacitors is integrated on the capacitor C_i, thus producing an output voltage proportional to the capacitance mismatch from the sense capacitors. This approach replaces the large DC-setting resistor by capacitors and switches and results in a much smaller die compared to the synchronous scheme. Furthermore, the switching technique allows more design flexibility for system integration and performance improvement because of the ability to allocate separate phases for various operations. The major drawback of this design is that it draws noise into sensing circuits from switches and sampling capacitor C_h. However, these noises can be compensated by dividing the sense phase into $2 \sim 3$ sub-sense phases [32.14], at the expense of a complicated circuit design.

Piezoresistive Sensing

Piezoresistive films have been widely used as strain-sensitive components in a variety of MEMS devices, including pressure sensors and vibration sensors. Generally speaking, piezoresistive sensing techniques require less complicated sensing circuits and perform better in a severe environment than other sensing techniques. When a piezoresistive film is subjected to stress, the film resistivity and dimensions change. The fractional change of resistance is proportional to the deformation of the piezoresistive film. For a small change of resistance, this relation can be expressed as,

$$\frac{\Delta R}{R} = K \cdot \epsilon \,, \qquad (32.8)$$

where R is resistance of the piezoresistive film, K is its gage factor and ϵ is strain. In microactuator designs, the piezoresistive film is usually applied to the spring structure that connects the moving shuttle to an anchor point. When the shuttle moves, it stretches the spring as well as the piezoresistive film, consequently, the piezoresistive film produces a deformation signal proportional to the shuttle displacements. As a result, piezoresistive sensing is easier to implement than capacitive position sensing, but the sensing resolution is usually less accurate due to higher thermal noises introduced by the resistance of the piezoresistive film.

Another application of piezoresistive sensing, aside from measuring relative slider position, is to detect vibration in the suspension itself. The idea is to sense airflow-induced vibration of the suspension and feed that information forward to an actuated slider to damp out motion at the head. Piezoresistors used for this purpose can be made from metal or semiconductor materials, arranged as a strip or series of strips oriented along the direction of vibration strain. It is important that these sensors observe all vibration modes that contribute to off-track error, so a number of optimization schemes for locating the sensors have been developed [32.15]. One method is to maximize the minimum eigenvalue of the observability matrix of the sensor or sensors. This ensures that all relevant modes are observed. Another method is to minimize a linear quadratic gaussian control problem over potential sensor locations [32.16]. This serves to determine an optimal placement from the perspective of a linear controller.

32.1.5 Electrostatic Microactuator Designs for Disk Drives

Various electrostatic microactuators have been designed for secondary actuation in HDDs. To incorporate an electrostatic microactuator into a HDD without altering much of current suspension configuration, many design constrains are imposed. In this section, we will first discuss some design issues and then present one specific design example.

Translational Microactuators versus Rotary Microactuators

Depending on the motion of the magnetic head actuated, microactuator designs are categorized into two groups: translational actuators and rotary actuators. Either type can be implemented by comb-drives [32.8, 17] or parallel-plates [32.5, 6, 18] actuation.

When employing a translational microactuator in a dual-stage HDD servo, previous research [32.13] has shown that a force coupling between the suspension and the translational microactuator exists, consisting of transmitted actuation force from the VCM and suspension vibration induced by windage. The force coupling from the VCM not only complicates the dual-stage servo controller but also imposes a design constraint on a translational microactuator design, in that the translational microactuator has to provide a large force output to counterbalance the coupling force. When the VCM makes a large movement, as in seeking a new data track, the microactuator may be overpowered. One solution is to pull the actuator to one side and lock it momentarily in place. Even then, the use of the two actuation-stages must be carefully coordinated to moderate the influence of the VCM on the microactuator. On the other

hand, the linear springs in the translational microactuator can also aid in damping out motion of the suspension. The portion of suspension vibration induced by windage mostly consists of high frequency excitation, so the resulting magnetic head's position error can be passively attenuated by low resonant frequency translational microactuators.

Generally speaking, rotary actuators are more difficult to design/analyze than translational actuators because of their nonuniform gap between shuttle and stator. Still, their different operating properties have both strengths and weaknesses. Unlike a translational actuator, no obvious force coupling is transmitted from the suspension to a rotary actuator, as the microactuator is nearly always attached to the end of suspension at the microactuator's center of rotation, which acts as a pivot point. With no mechanical coupling, the dual-stage servo system using a rotary microactuator does not suffer from the force coupling between VCM and microactuator seen in translational designs. However, the rotary microactuator has to compensate for the magnetic head's position error induced by suspension vibration without any passive attenuation of the vibration. Overall, a rotary acuator is likely to behave better than a translational microactuator during track seeking and worse during track following.

Gimballed Microactuator Design

Proper flying height and orientation of a slider and read-write head over a hard disk is maintained by the interaction of the suspension, the air bearing of the slider, and a gimbal structure. The gimbal structure is located at the tip of the suspension and holds the slider/microactuator in its center coupon. The dynamic characteristic requirements of gimbal structures are that they be flexible in pitch and roll motion but stiff in in-plane and out-of-plane bending motion. To meet all these requirements using only one piece of metal is a highly challenging task. For this reason, most commercially available suspension/gimbal designs consist of two to four pieces of steel, each with different thickness.

The goal of a gimballed microactuator design is to seamlessly integrate an actuator and gimbal into a one-piece structure, as shown in Fig. 32.7, to simplify both suspension design and HDD assembly. A full integrated suspension that includes suspension, gimbal, and microactuators in one part has also been proposed [32.19]. The dimple structure, existing in most current gimbal structures, is excluded from the gimballed microactuator design and electrical interconnects are in situ fabricated on the gimballed microactuator, replacing the flexible cable in current HDD suspension assembly.

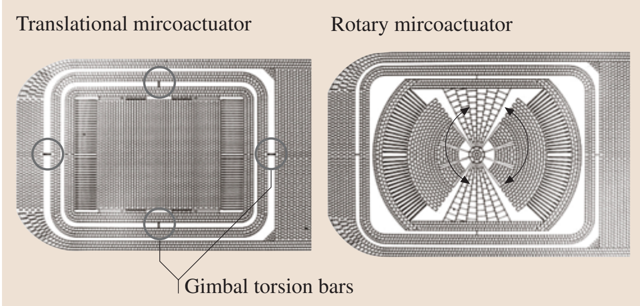

Fig. 32.7 Schematics of translational microactuator versus rotary microactuator. Courtesy from Lilac Muller

The dimple structure in current suspension assemblies provides out-of-plane stiffness while preserving the necessary torsional compliance in the gimbal structure. Without a dimple structure in the suspension assembly, the gimbal itself must provide high out-of-plane bending stiffness. Otherwise, it would unbalance the suspension pre-load, which is an overbend of the suspension that balances the upward air-bearing force on the suspension during operation. The electrical interconnects are implemented to transmit data between magnetic heads, located at the center coupon of the gimbal structure, and IC circuits located at the end of the suspension. The in situ fabricated electrical interconnects are inevitably passed through torsion bars of the gimbal and thus set a design constraint for the minimum width of torsional bars. Furthermore, both the gimbal structure and microactuator should be the same thickness to simplify the MEMS fabrication process.

To summarize the design constrains discussed above, the integrated gimbal structure has to meet performance requirements with a single, uniform piece of material that would previously have been achieved by two to four metal pieces with different thicknesses, while the minimum width of any torsion bars that may be used pre-determined. To solve this problem, *Muller* [32.6] proposed a T-shaped structure (a beam structure with overhang surface sheet) for the torsion bars, and *Chen* [32.19] proposed "double-flexured" torsion bars. Additionally, many suspension manufacturers have developed new gimbal structures for their suspensions designed specifically for use with MEMS microactuators, moving the gimbal location back to the suspension from the microactuator.

An Electrostatic Microactuator Design Example

Figure 32.8 shows a translational microactuator design suitable for the HDD dual-stage actuation by *Horsley* in 1998 [32.5]. The translational electrostatic microactuator dimensions are 2.2 mm × 2.0 mm × 0.045 mm and weight 67 µg. The dimensions of the pico-slider on the top are 1.2 mm × 1.0 mm × 0.3 mm and weight 1.6 mg. This microactuator design does not include "electrical-isolation" features, and thus the electrical isolation and electrical-interconnects were fabricated on a separate substrate and subsequently bonded to the microactuator. This microactuator uses parallel-plates for actuation force but does not have dedicated position sensing structures due to fabrication process limitations. Table 32.1 summarizes key parameters of this microactuator design.

Based on these parameters, the characteristics of this electrostatic microactuator can be estimated by the linear differential equation shown in (32.6).

Figure 32.9 shows the schematics of a circuit design by *Wongkomet* in 1998 [32.14], in which actuation driving voltage and capacitive position sensing were implemented for the electrostatic microactuator designed by Horsley. As mentioned before, the electrostatic microactuator design doesn't have dedicated structure for a position sensing; as a consequence, the input nodes for actuation and output nodes for capacitive position sensing have to share the same electrodes. Capacitors C_c and C_{c0}, shown in Fig. 32.9, are carefully designed to shield the high voltage presented in actuation circuit from sensing circuit, which is mostly low voltage, and thus enable driving/sensing circuit integration.

The driving circuit, shown in the left in Fig. 32.9, demonstrates how to generate the bias voltage (V_{bias}, ±40 V) and drive voltage (V_{dr}, −40–+40 V) from 0–5 V CMOS compatible circuits. The switches at the output of the charge pumps were synchronized with the switching period ϕ_{RS}. During the sense phases ϕ_{SN1} and ϕ_{SN2}, therefore, the switches are left open and thus no voltage fluctuation is seen by the sensing circuits. This arrangement was utilized to reduce feedthrough from the driving circuit to position sensing circuit.

The design target for the capacitive position sensing circuit was to achieve position sensing resolution of 10 nm, and this goal was approached by two main techniques implemented in the circuit: differential sensing and Correlated-Double-Sampling (CDS). The main

Table 32.1 Parameters of the electrostatic microactuator design by *Horsley* 1998 [32.5]

Parameters	Source*	Value
Nominal gap	D	10 µm
Structure thickness	D	45 µm
Rotor mass, m	I	44 µg
dC/dx	C	68 fF/µm
Actuation voltage, bias voltage	D	40 V
Actuation voltage, maximum driving voltage	D	±40 V
Voltage-to-force gain K_v	I	50 nN/V
Mechanical spring constant K_m	I	29 N/m
Electrostatic spring constant K_e	I	9.6 N/m
Damping coefficient, b	I	1.03×10^{-4} N/(m/s)
Voltage-to-position DC gain	M	0.05 µm/V
Resonance frequency, w_r	M	550 Hz

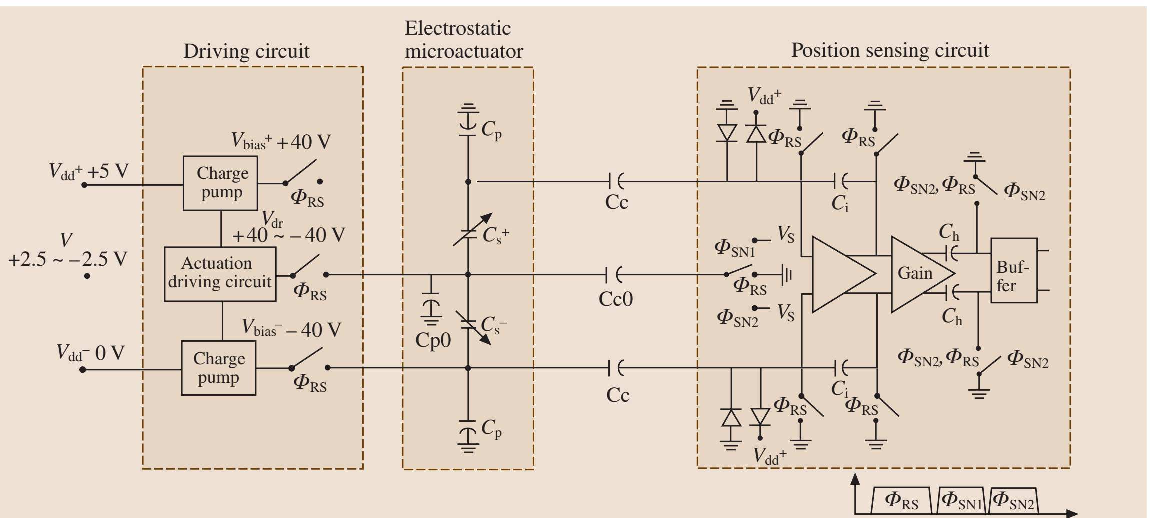

Fig. 32.9 A simplified schematic including driving and sensing circuits for the electrostatic microactuator. Courtesy from Wongkomet 1998

benefits of the differential sensing scheme are reduced noise coupling and feedthrough, elimination of even-order harmonics, and improvement of dynamic range by doubling the output swing. To adapt this differential sensing scheme in a differential parallel-plates electrostatic microactuator, a bias voltage (V_{bias}) was applied to the stator and the drive voltage (V_{dr}) was applied to the shuttle. The CDS technique, a modified capacitance sensing technique based on the switched-capacitance scheme, was implemented along with the differential sensing scheme to compensate for sensing noises including 1/f, KT/C, switch charge injection and offset from op-amps [32.14]. The concepts of CDS can be briefly described as follows: the sense period is broken into three phases: one reset phase, ϕ_{RS}, and two sense phases, ϕ_{SN1} and ϕ_{SN2}. During the ϕ_{RS} sense phase, the voltages for capacitors and input nodes to op-amps are set to the reference level of the DC-voltage setting for the charge integrator, same as for the switched-capacitance scheme discussed in Sect. 32.1.4. During the ϕ_{SN1} sense phase, a sensing voltage $-V_s$ is applied to the shuttle and results in a voltage difference, $\alpha(-V_s) + V_{error}$, across the sampling capacitor C_h, where α is the transfer function from sense voltage to the output voltage at the pre-amplifier, shown as *Gain* in the plot, and V_{error} is the voltage at the output node of pre-amplifier resulting from noise, leakage charge, and offset of op-amps. Lastly, during the ϕ_{SN2} sense phase, the sensing voltage is switched from $-V_s$ to V_s and the switch next to C_h is switched open. This results in a voltage output $\alpha(V_s) + V_{error}$ at the output node of the pre-amplifier and a voltage, $2\alpha(V_s)$, at the input node of the buffer. As a consequence, the voltage resulting from sensing error (V_{error}), which appears at the output node of pre-amplifier, disappears from the voltage-input node to the buffer. Switches utilized in

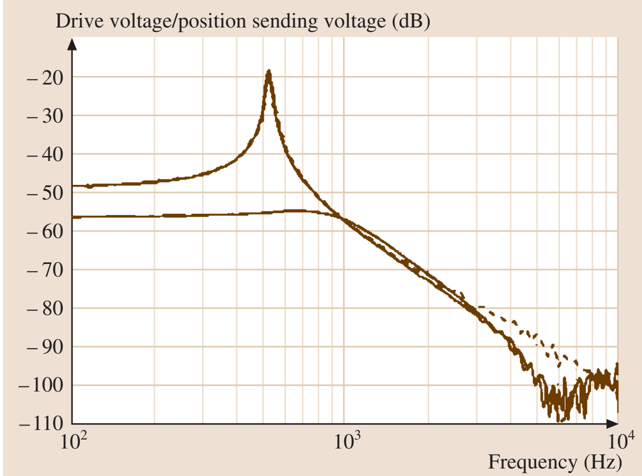

Fig. 32.10 Open-loop and closed-loop frequency response of the prototype microactuator with a pico-slider. The capacitive position measurement (*solid line*) is compared to the measurements from LDV (*dashed line*). Courtesy from Wongkomet

the circuit and their correspondent timing are shown in Fig. 32.9. Be aware that for presentation simplicity components in the pre-amplifier and buffer are not shown in detail in Fig. 32.9.

The frequency response, both open-loop and closed-loop with a PD controller, of the electrostatic microactuator measured by a capacitive position sensing circuit is shown in Fig. 32.10. The position measurements from an LDV are also shown in the same plot for comparison. The deviation between measurements from the different position sensing devices appears in the high frequency region of the plot and has been identified as the feedthrough from the capacitance sensing circuit. The effect from feedthrough was negligible at low frequency region but becomes significant and results in a deviation in magnitude for the transfer function of $-80\,\mathrm{dB} \sim -90\,\mathrm{dB}$ after 2 kHz. The feedthrough presented in the capacitance sensing circuits limited the position sensing resolution to the level of 10 nm.

32.2 Fabrication

While there are several approaches to building electrostatic microactuators suitable for hard disk drives, they all exhibit certain common features from a fabrication standpoint.

32.2.1 Basic Requirements

As we discussed earlier, nearly all electrostatic microactuators rely on a system of interlaced fingers or plates to provide actuation force. As a result, a method for producing arrays of these fingers or plates with narrow gaps between them is usually the central concern in developing a fabrication process. The resulting structure must then be strong enough to support both the slider on the microactuator and the microactuator on the suspension, particularly when loaded by the air-bearing that supports the slider above the hard drive's spinning disk. In addition, the design and fabrication process must include a way to perform electrical interconnection on the microactuator. This involves transferring signals to and from the actuator and slider and isolating the parts of the microactuator requiring different voltage levels.

Meanwhile, the microfabrication process is subject to certain basic constraints. The materials used in fabrication must either be thermally and chemically compatible with any processing steps that take place after their deposition or must somehow be protected during steps that would damage them. This often constrains the choice of materials, deposition techniques, and processing order for microdevices. Another concern is that the surface of the structure be planar within photoresist spinning capabilities and lithography depth-of-focus limits if patterning is to be performed. This can be a major challenge for disk drive microactuators, which are large in size and feature high-aspect ratio trenches compared to other MEMS devices.

32.2.2 Electrostatic Microactuator Fabrication Example

Section 32.1.5 described the design and operation of a translational electrostatic microactuator. This section examines the fabrication process by which that microactuator was built [32.5]. The process is a variation on a micro-molding process known as HexSil [32.20]. In a micro-molding process, a mold wafer defines the structure of the microactuator and may be reused many times like dies in macro-scale molding; in the HexSil version of the procedure, the mechanical parts of the microactuator are formed in the mold by polysilicon. A second wafer is used to create metallized, patterned target dies. Upon extraction from the mold, the HexSil structure is bonded to this target substrate, which is patterned to determine which sections of the HexSil structure are electrically connected.

Naturally, the mold wafer is the first item to be processed and is quite simple. It is a negative image of the desired structure, etched down into the wafer's surface, as shown in Fig. 32.11a. A deep but very straight etch is critical for successful fabrication and subsequent operation of the devices. If the trench is too badly bowed or is undercut, the finished devices will be stuck in the mold and difficult to release. On the other hand, a tall device will have a larger electrostatic array area, will generate more force, and be better able to support a slider while in a disk drive.

Fabrication of the HexSil structure forms the majority of the processing sequence Fig. 32.11b–g. HexSil fabrication begins by coating the surface of the mold wafer with a sacrificial silicon oxide. This layer, deposited by low-pressure chemical vapor deposition (LPCVD), must coat all surfaces of the mold, so that removal of the oxide at the end of the process will

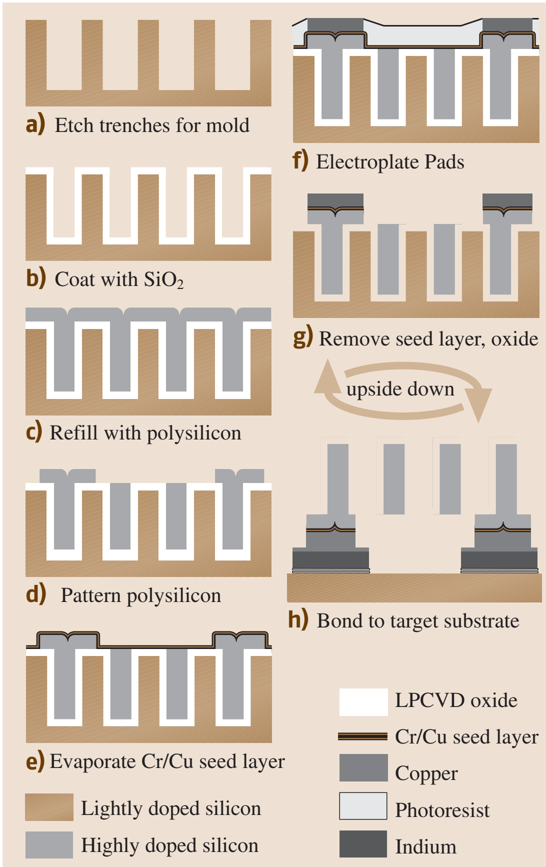

Fig. 32.11 Fabrication example 1: HexSil

leave the device completely free of the mold. This microactuator uses a 3 to 4 μm thick oxide layer to ensure clearance between the polysilicon structure and the trench walls during release. The mold is then refilled completely with LPCVD polysilicon, which will form the desired mechanical structure. Polysilicon is chosen for its conductivity and good conformality in refilling trenches. This also leaves a planar surface ready for photolithography to cover bonding locations. After the lithography step, the polysilicon deposited on top of wafer is removed, except where the bonding points were defined.

The structure is then prepared for bonding by forming a soldering surface. First a chrome/copper seed layer is evaporated on the surface of the wafer. The chrome promotes copper adhesion to the silicon, while the copper forms the starting point for electroplating. The seed layer is covered with photoresist, which is cleared only in the locations where contacts are desired. There, electroplating will produce a metal film, forming soldering points for the device to the target substrate that will form its base. In this case, copper is used as the plating material, thanks to its high conductivity and solderability. The device is released from the mold by ion milling away the thin seed layer, then dissolving the oxide lining with a hydroflouric (HF) acid wet etch. The free standing portion of the microactuator is thus ready for bonding to the target. The mold, meanwhile, may be used again after a simple cleaning step.

The target substrate may be prepared in several ways. The target shown above consists simply of indium solder bumps and interconnects on a patterned seed layer; this is known as a “plating bus” arrangement. The seed layer is used for the same reasons as on the HexSil structure, but in this case the seed layer is patterned immediately, with the unwanted portions removed by sputter etching. This provides isolation where desired without having to etch the seed layer after the indium is in place. Photoresist is spun again and patterned to uncover the remaining seed layer. A layer of indium is then electroplated everywhere the seed layer is visible. Indium acts as the solder when the two parts of the microactuator are pressed together, forming a cold weld to the copper at 200–300 MPa as shown in Fig. 32.11h, that was found suitable for hard disk requirements.

32.2.3 Electrostatic Microactuator Example Two

The high-aspect ratio microactuator described in this section is in development at the University of California, Berkeley, and demonstrates another way to create the features required of an actuated slider. The microactuator is translational, with parallel-plates actuation, and includes two of the design options described previously: integrated isolation plugs, as described in Sect. 32.1.3, and a capacative sensing array, as described in Sect. 32.1.4. A picture of the basic design is shown in Fig. 32.12; a central shuttle holding the slider is supported by four folded-flexure springs and driven by parallel-plates arrays.

Basic Process: Silicon-on-Insulator

Successful processing of the design is centered around the ability to etch very straight, narrow trenches using deep reactive ion etching (DRIE). DRIE is a special plasma etching sequence that uses polymerization of the sidewalls of a trench to keep the walls straight even at extreme aspect ratios. Deep, narrow trenches

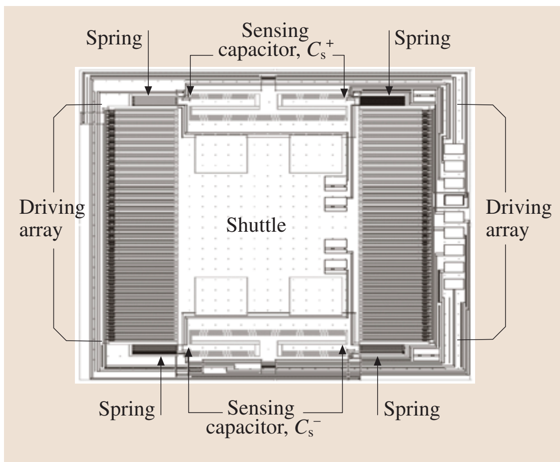

Fig. 32.12 Translational high-aspect ratio microactuator

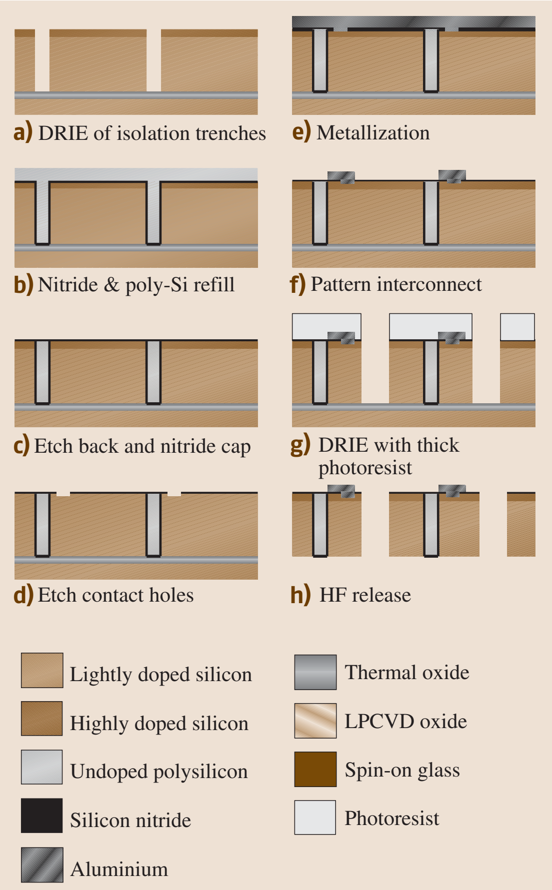

Fig. 32.13 Basic silicon-on-insulator fabrication process

make possible a microactuator with both closely packed electrostatic arrays and good mechanical strength. Conventional surface micromaching is used to produce the majority of the electrical interconnects.

The basic fabrication process uses a silicon-on-insulator (SOI) wafer to control DRIE trench depth. SOI wafers are very useful in microfabrication as they provide a layer of single-crystal silicon (the device layer) separated from the bulk of the wafer (the handle layer) by a thin layer of buried silicon oxide. This gives a very well controlled thickness to finished device but is very expensive. The microactuators described here are fabricated from an SOI wafer with a 100 μm device layer. A variation on the processing sequence and layout eliminates the need for SOI wafers and will be discussed in the following section.

The first stage of fabrication is creation of deep isolation trenches (see Fig. 32.13a–c). This procedure has been adapted to MEMS from integrated circuit processing for isolating thick MEMS structures [32.21]. The isolation pattern is formed by photolithography and etched by DRIE down to the buried oxide. With trenches only 2 μm wide, this corresponds to an aspect ratio of 50 : 1. The wafer surface and trenches are then coated with LPCVD silicon nitride, which acts as the electrical insulator. The trench is then refilled in its entirety with LPCVD polysilicon, which is a more conformal material better fills the trench than silicon nitride would alone; polysilicon also has much lower residual stresses than silicon nitride. The refill leaves a layer of polysilicon on the surface of the substrate, which must be etched or polished back to the silicon nitride. After etch-back, a second layer of LPCVD nitride completes isolation between regions.

Next, electrical interconnects are formed, as shown in Fig. 32.13d–f. Contact holes to the substrate are defined by photolithography and etched by reactive ion etching of the silicon nitride. Metal lines may then be patterned directly by photolithography or formed by lift-off. In a lift-off process, photoresist is deposited and patterned before the metal. The metal is then deposited vertically, so that the sidewalls of the resist are uncovered. Dissolving the resist allows the metal on top to float away, leaving behind the interconnect pattern. In the figures shown here, the interconnects are formed by evaporated aluminum, eliminating the need for electroplating and a seed layer. The ability to isolate portions of the substrate is useful for simplifying the interconnect layout, as one interconnect can cross another by

passing underneath it through an isolated portion of the substrate.

Finally, structural lithography is performed and a second etch by DRIE is done, as shown in Fig. 32.13g. These trenches will define the shape of the microactuator, and are larger, 4 μm wide, to allow sufficient rotor travel. After this etch step, the device layer on the SOI buried oxide consists of fully defined microactuators. When the buried oxide is removed by wet etching, the microactuator is released from the substrate Fig. 32.13h and, after removal of the photoresist that protected the device surface from HF during release, ready for operation. Thanks to the high-aspect ratios of DRIE and the efficient integrated isolation scheme, the microactuator can theoretically be operated with a DC bias voltage of 15 V on the rotor, and a dynamic stator voltages below 5 V. In practice, higher voltages are required due to the spreading of trench walls over the course of DRIE. A picture of the electrostatic structure, with the rotor fingers on the left and the stator fingers on the right, divided down the center by isolation trenches, is shown in Fig. 32.14.

Variation: Anisotropic Backside Release

An alternative fabrication approach is to build the microactuator from a regular silicon wafer ($\sim 550\,\mu$m thick), but then, since the microactuator shouldn't be more than 100 μm thick to fit in a HDD, etch away the backside of the wafer to obtain devices of that size. The main reason for using a silicon-only wafer is to reduce the need for expensive SOI wafers, which cost approximately ten times as much as single-material wafers. Another benefit is the elimination of the need for etch holes to reach the buried oxide layer, which increase vulnerability of microactuators to particle or moisture contamination. However, the thickness of the devices cannot be controlled as accurately as with the SOI process, and the processing sequence is more complicated.

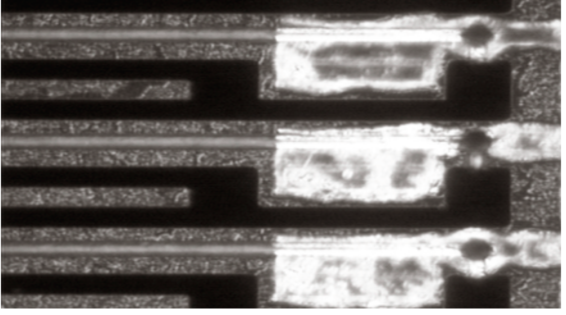

Fig. 32.14 Electrostatic driving array of microactuator from SOI

Control of backside etching is difficult, making it hard to obtain devices with uniform thickness across a wafer. A proposed solution is to use an anisotropic wet etchant during the backside etch step. Anisotropic etchants work very slowly on certain crystal planes of a single-crystal silicon wafer; a coating on trench sidewalls can protect fast-etching planes when the etchant reaches the trenches from the back, causing slow-etching crystal planes to begin coming together slowing the etch. The result is a nearly self-stopping etch with a V-shaped profile that prevents overetching even in the presence of nonuniformities in etch rate and trench depth across the wafer. The most common anisotropic etchants are potassium hydroxide (KOH) and tetramethyl ammonium hydroxide (TMAH). This release process is referred to here as an anisotropic backside release (ABR).

The key to a good release by this method is to achieve excellent protection of the top of the wafer and the deep trenches from the etchant, and this neccessitates changes in the process flow from that for an SOI wafer. Without a good protective film, the interconnects on the surface of the wafer could be destroyed, or the fast-etching planes might be attacked along the trench sidewalls. Of the etchants mentioned above, TMAH is preferred, due to high selectivity to both silicon oxide and nitride and, especially, thermally grown oxide, which can be used as protective films. However, growing thermal oxide and/or depositing high-quality nitride are high temperature processes not compatible with most metals, so the structural trenches must be etched and oxidized before forming the electrical interconnects. As shown in Fig. 32.15c–d, the isolation trenches are formed as before, but the structural trenches are patterned and etched in the very next step. A thermal oxide is then grown in the trenches to produce the protective oxide layer Fig. 32.15e.

To do lithography for the interconnects at this point, then, the surface of the wafer must be planarized. This is done by refilling the trenches with spin-on-glass. The spin-on-glass plugs the trenches nearly to the top and can be sacrificed along with the thermal oxide at the end of the process. Extra glass on the wafer surface can be removed by a quick HF dip or chemical mechanical polishing. The resulting surface is uneven, as shown in Fig. 32.15f, but a thick photoresist layer can be applied over the trenches evenly enough to accomplish contact and metal patterning lithographies. After metallization much the same as for the SOI wafer Fig. 32.15g, a final coating of etch resistant material is required to protect the metal during backside release, as shown in

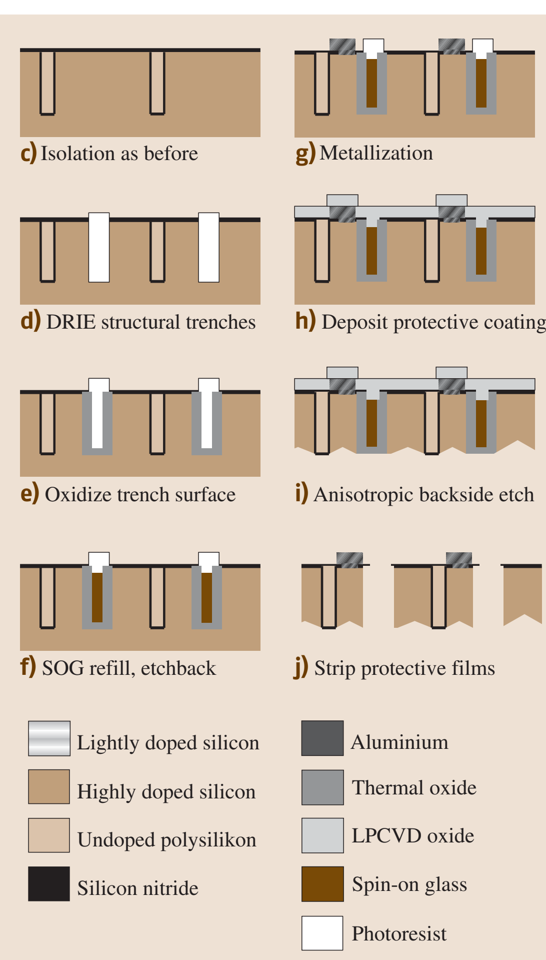

Fig. 32.15 Deep trench fabrication process adapted for backside release

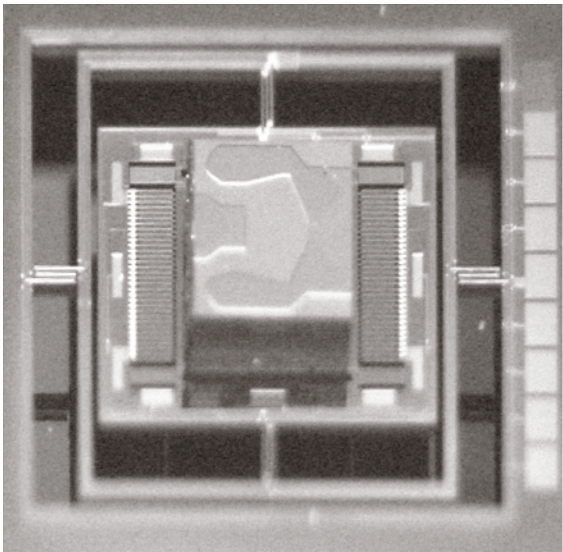

Fig. 32.16 Microactuator with integrated gimbal fabricated by ABR

Fig. 32.15h–j. After ABR, the backside of the device will be shaped by crystal planes, but the thickness of the device at the edge of DRIE features will be fixed. While a combination of silicon oxide and silicon nitride has been effective over a "metallization" of undoped polysilicon, an effective combination of true metal interconnects and protective films has yet to be found and is an ongoing area of research for improving the ABR process sequence.

A prototype microactuator with integrated gimbal fabricated using ABR is shown in Fig. 32.16. This prototype was operated with a 30 V DC bias and ±8 V AC driving voltage for ±1 μm displacement, while a larger version (shown in Fig. 32.12) was operated at 15 V bias and ±3 V driving. This layout and fabrication concept is currently being adjusted to fit a MEMS-ready suspension for more advanced testing.

32.2.4 Other Fabrication Processes

Where the DRIE-based process described above "digs" the microactuator out of a wafer, a procedure developed by IBM "grows" a microactuator with high-aspect ratio trenches on top of a wafer [32.22].

IBM Electroplated Microactuator

The microactuator is fabricated by a clever sequence of electroplating steps and sacrificial depositions. An oxide sacrificial film is first patterned then covered with a metal seed layer. When later removed, the sacrificial will have left a gap between the microactuator and substrate portions of the microactuator needed to move freely. A polymer, 40 μm thick, is spun onto the wafer and patterned with a reverse image of the main structural layer. Trenches are etched down to the sacrificial layer by plasma etching then refilled by electroplating, much like micro-molding. Another sacrificial polymer, photoresist this time, separates the top of the fixed portions of the structure from the platform upon which the slider will sit, while conveniently planarizing the surface for further lithography. The platform is created by two more electroplating steps on top of the parts of the

structure that will move freely. Removal of the sacrificial layers (photoresist, polymer, and oxide) releases the microactuator for use.

This process has been used to produce both rotary and linear microactuators and is comparatively advanced from a commercial standpoint. The resulting devices are thinner than those described in the previous example, but a similar aspect ratio (20 : 1) can be achieved. This procedure also has the benefits of being a low temperature process, which helps decrease processing cost and is compatible with the thin film magnetic head manufacturing process. Moreover, it includes an upper structure that covers the fingers, which improves device reliability by shielding the fingers from particles.

Additional fabrication details and dynamic testing results for the IBM design may be found in references [32.22] and [32.23]. Certain control results are described in Sect. 32.3.2.

Electroplated Microactuators with Fine Gaps

Finally, fabrication processes developed at the University of Tokyo demonstrate additional techniques for obtaining very small gaps between electrostatic fingers [32.24]. Similar to the IBM process, electrostatic fingers are electroplated, in this case by nickel, within a polymer pattern. The gap between closely spaced fingers, however, is then formed by a sacrificial metal. Photoresist is used to cover the fingers except for the surfaces where a small gap is desired; these are electroplated with sacrificial copper, making narrow, well-defined gaps possible, in perhaps the most reliable of the processes described here. Continuing with a second nickel electroplating step creates the interlaced fingers, which will also support the slider; the wafer is polished down to level the structure. Finally the copper, photoresist, and seed layer are etched away, leaving the free standing structure.

In another version of process, photoresist alone separates the stator and rotor fingers. In this case, a thin layer of photoresist is left where small gaps are desired, instead of growing a layer of copper. This method is dependent on excellent alignment but can eliminate the need for polishing after the second electroplating step.

32.2.5 Suspension-Level Fabrication Processes

The long, highly integrated fabrication processes required by actuated slider microactuators contrast greatly with the fabrication of actuated suspension microactuators.

PZT Actuated Suspensions

In most cases, actuated suspensions use piezoelectric (PZT) drivers cut or etched as single, homogeneous pieces and attached to the steel suspension. Nevertheless, microfabrication techniques can still be useful in suspension processing. For example, some recent suspensions have used thin film PZT deposited on a substrate by sputtering or spinning-on of a sol-gel for incorporation in a suspension. This is intended to produce a higher quality PZT films and begins to introduce MEMS-style processing techniques even into suspension-scale manufacturing [32.25, 26].

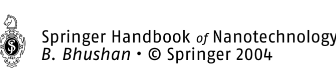
Integrated Silicon Suspension

Another area where silicon processing has been suggested for use on a suspension is the gimbal region, or even the entire suspension, as described in [32.19]. An integrated silicon suspension would incorporate aspects of both actuated suspension and actuated slider fabrication. Force is provided by four piezes of bulk PZT cut down to size, as in other actuated suspensions, but the rest of the suspension is fabricated from single-crystal silicon by bulk micromachining.

The fabrication process for the integrated suspension is the precursor to the ABR process used to fabricate the microactuator in Sect. 32.2.3. Layers of LPCVD silicon nitride and polysilicon are deposited on a bare silicon wafers. The polysilicon is doped by ion implantation and covered with a second layer of nitride. The outline of the suspension and any spaces within it are then lithographically patterned. After a reactive-ion nitride etch to reach the substrate, trenches are etched by DRIE. The trenches are then plugged with spin-on-polymer for further lithography. First, the top layer of polysilicon is patterned into piezoresisistive strips for sensing vibration. Second, a layer of photoresist is patterned for copper lift-off, to create metal interconnects. Last, the planarizing polymer is removed, and the entire surface is coated with silicon nitride. This final coating protects the top surface during an anisotropic backside wet etch, in this case by potassium hydroxide.

Instrumented Suspensions

Finally, microfabrication techniques may be useful for installing sensors on conventional steel suspensions. The concept is to deposit a dielectric and a piezoresistive material on the stainless steel sheet that will be formed into the central piece of the suspension and then to pattern piezoresistive layer directly by photolithography and etching to form strain gages. A second lithography may be used to add metal lines back to the E-block. Vi-



bration sensors on the suspension are very desirable for controlling slider position, and the use of thin-film deposition and photolithography permits the sensors to be located at the points most effective for detecting vibration. An example of a sensor formed by this method is shown in Fig. 32.17.

Fig. 32.17 Piezoresistive strain sensor on steel substrate

32.2.6 Actuated Head Fabrication

Several interesting fabrication processes have been proposed for another approach to creating a dual-stage disk drive servo: the actuated head. In an actuated head, the actuator is built into the slider and moves just the read/write head. This could potentially eliminate many of the mechanical limits of actuated suspensions or actuated sliders. Actuation techniques are typically similar to those of actuated sliders, with the key complication being the need to integrate an actuator fabrication process with a slider fabrication process. We discuss ways in which this might be done below.

One fabrication approach to actuating a read/write head is to enclose an electrostatic driving array inside a slider. The slider is built on a glass or silicon substrate, beginning with the air-bearing surface (ABS), followed by a microactuator, and then surrounded by the remainder of the slider. The ABS is formed by silicon oxide deposited over aluminum and tapered photoresist layers that give it a contoured shape. The majority of the ABS is then covered with photoresist, while a block in the center is plated with nickel and etched to form the electrostatic actuator. The electrostatic microactuator, in turn, is covered while the remainder of the slider body is electroplated. The slider may then be bonded to a suspension and the ABS surface released from the substrate by etching away the original aluminum and photoresist surface [32.9].

The sacrificial metal technique described in Sect. 32.2.4 is another possibility for building an electrostatic array onto a slider. It can be used to form small array with very narrow gaps, and the process is compatible with slider and head materials [32.27].

The third actuated-head process makes use of an SOI wafer and silicon based materials. For this structure, a 20 μm device layer is coated with silicon nitride. The nitride is patterned with contact holes for connections to the substrate and used as insulation over the rest of the device. A layer of molybdenum is sputter deposited to perform interconnections to both the head and the electrostatic array. This array is formed by DRIE to the buried oxide, using a lithographically patterned hard mask of tetraethylorthosilicate. The result is a simple, tiny, actuator that must be bonded to the edge of a slider after release from the SOI wafer [32.28].

32.3 Servo Control Design of MEMS Microactuator Dual-Stage Servo Systems

The objective of disk drive servo control is to move the read/write head to the desired track as quickly as possible, referred to as track seek control, and, once on-track, position the head on the center of the track as precisely as possible, referred to as track-following control, so that data can be read/written quickly and reliably. The implementation of the servo controller relies on the position error signal (PES), which is obtained by reading the position information encoded on the disk's data tracks.

32.3.1 Introduction to Disk Drive Servo Control

The position error is also called track mis-registration (TMR) in the disk drive industry. Major TMR sources in the track-following mode include spindle runout, disk fluttering, bias force, external vibration/shock disturbance, arm and suspension vibrations due to air turbulence, PES noise, written-in repeatable runout, and residual vibration due to seek/settling [32.29]. These sources can be categorized as runout, r, input disturbance, d, and measurement noise, n, by the locations they are injected into the control system, as shown in Fig. 32.18. In Fig. 32.18, $G_P(s)$ and $G_C(s)$ represent the disk drive actuator and the controller, respectively; r and x_p represent track runout and head position, respectively.

From Fig. 32.18, the PES can be written as

$$\mathrm{PES} = S(s)r + S(s)G_P(s)d - S(s)n\,, \tag{32.9}$$

where $S(s)$ is the closed loop sensitivity function defined by

$$S(s) = \frac{1}{1+G_C(s)G_P(s)}\,. \tag{32.10}$$

The higher the bandwidth of the control system, the higher the attenuation of the sensitivity function $S(s)$ below the bandwidth. Thus, one of the most effective methods to reduce PES and increase servo precision is to increase the control system bandwidth.

Traditional disk drive servo systems utilize a single voice coil motor (VCM) to move the head. Multiple structural resonance modes of the E-block arm and the suspension located between the pivot and the head impose a major limitation on the achievable control bandwidth. A dual-stage servo system using a MEMS actuated-slider microactuator can achieve high bandwidth because the microactuator is located between the suspension and the slider, thus by-passing the pivot, E-block arm, and suspension resonance modes.

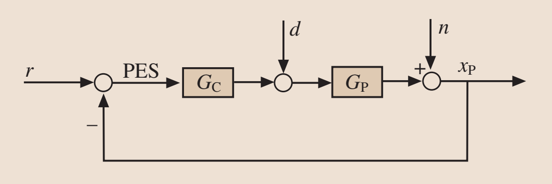


Fig. 32.18 Disk drive servo control

One basic task of dual-stage servo control design is to increase control bandwidth using the second stage actuator. Many design methodologies have been developed to accomplish this objective. In this section, we first review major dual-stage servo control design methodologies, and then we discuss design considerations for controller design of a MEMS microactuator dual-stage servo system. As design examples, the details of track-following control designs using a sensitivity function decoupling design method and the μ-synthesis design method are presented in Sect. 32.3.3. In Sect. 32.3.4, we introduce a short-span seek control scheme using a dual-stage actuator based on decoupled feed forward reference trajectories generations.

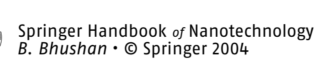
32.3.2 Overview of Dual-Stage Servo Control Design Methodologies

Various control design architectures and methodologies have been developed for dual-stage servo control design. They can be largely classified into two categories: those based on decoupled or sequential single-input-single-output (SISO) designs, and those based on modern optimal design methodologies, such as LQG, LQG/LTR, H_∞, and μ-synthesis, in which the dual-stage controllers are obtained simultaneously.

Two constraints must be considered in dual-stage servo control design. First, the contribution from each actuator must be properly allocated. Usually the first stage actuator, or the coarse actuator, has a large moving range but a low bandwidth while the second stage actuator, or the fine actuator, has a high bandwidth but small moving range. Second, the destructive effect, in which the two actuators fight each other by moving in opposite directions, must be avoided.

Classical SISO Design Methodologies

Several architectures and design methodologies have been proposed to transform the dual-stage control design problem into decoupled or sequential multiple SISO compensators design problems, for example, master–slave design, decoupled design [32.30], PQ method [32.31], and direct parallel design [32.32]. Figures 32.19 to 32.22 shows the block diagrams of dual-stage controller designs using these methods. In these figures, G_1 and G_2 represent the coarse actuator (VCM) and fine actuator (microactuator) respectively; x_1 is the position of the coarse actuator; x_r is the position of the fine actuator relative to the coarse actuator; x_p is the total position output; r is the reference input (runout), and PES is the position error, $e = r - x_\mathrm{p}$.



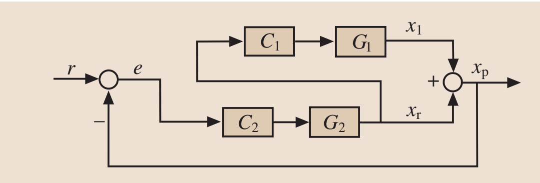


Fig. 32.19 Master–slave design structure

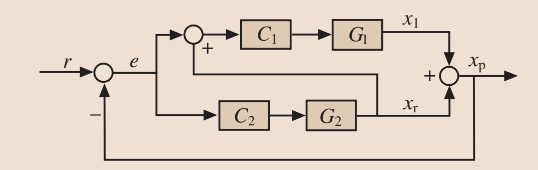

Fig. 32.20 Decoupled control design structure

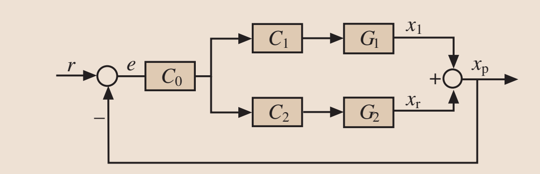

Fig. 32.21 PQ control design structure

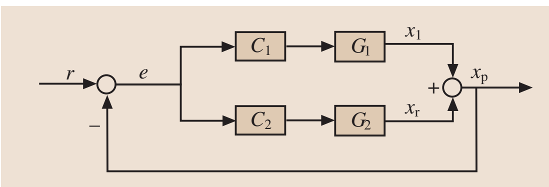

Fig. 32.22 Parallel control design structure

Master–slave Design. In a traditional master–slave structure, the absolute position error is fed to the fine actuator, and output of the fine actuator is fed to the coarse actuator, as shown in Fig. 32.19. The position error will be compensated by the high bandwidth fine actuator. The coarse actuator will follow the fine actuator to prevent its saturation.

Decoupled Design. Figure 32.20 shows the decoupled design structure [32.30], which is similar to the master–slave structure. A summation of the fine actuator output and the position of the coarse actuator, is fed the coarse actuator. A very nice feature of this structure is that the control system is decoupled into two independent control loops, and the total sensitivity function is the product of the sensitivity functions of each of the control loops [32.13]. Thus the two compensators C_1 and C_2 can be designed independently. Decoupled design is also referred to as decoupled master–slave design, or sensitivity function decoupling design. In Sect. 32.3.3, we will discuss details of a track-following controller for MEMS microactuator dual-stage servo system designed using this method.

Both the master–slave and the decoupled designs use the relative position of the fine actuator, x_r. If a relative position sensor is unavailable, x_r can be estimated using a model of the fine actuator.

PQ Design Method. The PQ method is another innovative design technique for control design of dual-input, single-output system [32.31]. A block diagram of a dual-stage control design using this method is shown in Fig. 32.21.

In PQ design, P is defined by

$$P = \frac{G_1}{G_2}\,, \tag{32.11}$$

and a dual-stage controller can be designed in two steps. The first involves the design of an auxiliary compensator Q for plant P, which is defined by

$$Q = \frac{C_1}{C_2}\,. \tag{32.12}$$

Q is designed to parameterize the relative contribution of the coarse and fine actuators. The 0 dB crossover frequency and phase margin of the open loop transfer function PQ are the design parameters in the design of Q. At frequencies below the 0 dB crossover frequency of PQ, the output is dominated by the coarse actuator, while at frequencies above the 0 dB crossover frequency, the output is dominated by the fine actuator. At the 0 dB crossover frequency, the contributions from the two actuators are equal. A large phase margin of PQ will ensure that the two actuators will not fight each other when their outputs are close in magnitude, thus avoiding any destructive effects.

The second step in the PQ design methodology is to design a compensator C_0 for SISO plant PQ such that the bandwidth (crossover frequency), gain margin, phase margin, and error rejection requirements of the overall control system are satisfied.

Direct Parallel Design. It is also possible to design the dual-stage controller directly using a parallel structure, as shown in Fig. 32.22, by imposing some design constraints and by sequential loop closing [32.32].

The two constraints for parallel design in terms of the PES open loop transfer functions are [32.32]:

$$C_1(s)G_1(s) + C_2(s)G_2(s) \rightarrow C_2(s)G_2(s) , \quad (32.13)$$

at high frequencies and

$$|C_1(s)G_1(s) + C_2(s)G_2(s)| \gg |C_2(s)G_2(s)| , \quad (32.14)$$

at low frequencies. The first constraint implies that open loop frequency response of the dual-stage control system at high frequencies approximately equals that of the fine actuator control loop. Thus the compensator $C_2(s)$ can be first designed independently as a SISO design problem to satisfy the bandwidth, gain margin, and phase margin requirements of the dual-stage control system. The second constraint ensures that the fine actuator will not be saturated. Compensator $C_1(s)$ can then be designed for the SISO plant model with the fine actuator control loop closed, such that the low frequency constraint and overall stability requirement are satisfied. This model is defined by:

$$G(s) = \frac{G_1(s)}{1 + C_2(s)G_2(s)} . \quad (32.15)$$

A dual-stage controller for a MEMS dual-stage actuator servo system has been designed using this method and implemented at IBM. An open loop gain crossover frequency of 2.39 kHz with gain margin 5.6 dB and phase margin 33° was obtained. In experimental testing, a 1-σ TMR of 0.024 μm has been achieved [32.32].

Modern MIMO Design Methodologies

Since the dual-stage actuator servo system is a MIMO system, it is natural to utilize modern MIMO optimal design methodologies, such as LQG, LQG/LTR, H_∞, and μ-synthesis, to design the dual-stage controller. Usually MIMO optimal designs are based on the parallel structure shown in Fig. 32.22, augmented with noise/disturbances models and other weighting functions to specify the control design performance objectives.

Linear quadratic Gaussian (LQG) control combines a Kalman filter and optimal state feedback control based on the separation principle. However, the Kalman filter weakens the desirable robustness properties of the optimal state feedback control. Linear quadratic Gaussian/loop-transfer recovery (LQG/LTR) control recovers robustness by a Kalman filter redesign process. Examples of dual-stage control designs using LQG and LQG/LTR have been reported in [32.33–35].

The LQG design methodology minimizes the H_2 norm of the control system, while the H_∞ design methodology minimizes the H_∞ norm of the control system. μ-synthesis design methodology is based on the H_∞ design and accounts for plant model uncertainties during the controller synthesis process with guaranteed robustness. Examples of dual-stage control designs based on the H_∞ and μ-synthesis design methodologies have been reported in [32.33, 36, 37]. A control design using μ-synthesis for the MEMS microactuator dual-stage servo system will be presented in Sect. 32.3.3

Other advanced control theories also have been applied to dual-stage servo control designs, such as sliding mode control [32.38] and neural networks [32.39].

32.3.3 Track-Following Controller Design for a MEMS Microactuator Dual-Stage Servo System

MEMS microactuators for dual-stage servo application are usually designed to have a single flexure resonance mode between 1–2 kHz [32.8,40]. This resonance mode is usually very lightly damped and can have a ±15% variations due to the differences in the fabrication processes. Since the uncertain resonance frequency is relatively low and close to the open loop gain crossover frequency of the control system, robustness to these variations must be considered in the controller design.

Controller Design Considerations for MEMS Microactuator Dual-stage Servo System

Capacitive sensing can be utilized in MEMS microactuators to measure the position of the microactuator relative to the VCM actuator [32.14, 40]. However, this requires additional sensing electronics and wires to and from the head gimbal assembly (HGA), which result in additional fabrication and assembly costs. Thus, whether or not a relative position sensor will be used in MEMS dual-stage servo systems is still an open question. If the microactuator's resonance mode is lightly damped, it is susceptible to airflow turbulence and external disturbances. The relative position signal can be utilized to damp the microactuator's resonance mode. Dual-stage control can be classified as MIMO or SIMO designs according to the availability of the relative position signal.

Given the fact that the inertia of the MEMS microactuator is very small compared to that of the VCM, the effect of the motion of the microactuator on the VCM can be neglected. By feeding the control input of the VCM to the input of the microactuator with a proper gain, we can cancel the coupling effect of the VCM on the microactuator [32.13]. Thus the dual-stage control model can

be decoupled as the sum of the outputs of the VCM and the microactuator, as shown in Fig. 32.23, in which G_V, G_M are the VCM and microactuator models respectively, and x_p is the absolute position of the read/write head, which equals the absolute position of the VCM, x_v, and the position of the microactuator relative to the VCM, RPES.

Decoupled Track-Following Control Design and Self-Tuning Control

Figure 32.24 shows a block diagram used for decoupled control design of a MEMS microactuator dual-stage servo systems [32.13].

Sensitivity Function Decoupling Design Methodology. The part enclosed in the dashed box on the upper-right corner is the dual-stage plant model shown in Fig. 32.23. In the figure, G_V and G_M are the VCM and microactuator models, respectively; x_P is the absolute position of the read/write head; x_v is the absolute position of the VCM actuator; and RPES is the position of the microactuator relative to the VCM; r represents the track runout, and PES is the position error signal of the head relative to the data track.

The decoupling control approach, originally introduced in [32.30], utilizes the PES and RPES signals to generate the position error of the VCM relative to the data track center, labeled as $VPES$,

$$VPES = \text{PES} + \text{RPES} = r - x_v \,, \quad (32.16)$$

and this signal is fed to the VCM loop compensator.

As shown in the block diagram, three compensators need to be designed: the VCM loop compensator K_V; the microactuator PES loop compensator K_M; and the microactuator RPES minor loop compensator $K_{MM} = K_{RR}/K_{RS}$ is used to damp the microactuator's flexure resonance mode and place the closed loop poles of the microactuator RPES loop at appropriate locations. The damped microactuator closed loop transfer function G_R, shown in the lower-middle dashed box, is defined by

$$G_R = \frac{G_M}{K_{RS} + G_M K_{RR}} \,. \quad (32.17)$$

The total dual-stage open loop transfer function from r to x_P, G_T, is

$$G_T = K_V G_V + K_M G_R + K_M G_R K_V G_V \,. \quad (32.18)$$

It can be shown that the block diagram in Fig. 32.24 is equivalent to the sensitivity block diagram shown in Fig. 32.25, and the total closed loop sensitivity function from r to PES equals the product of the VCM and microactuator loop sensitivities, S_V and S_M, respectively:

$$S_T = \frac{1}{1 + G_T} = S_V S_M \,, \quad (32.19)$$

where

$$S_V = \frac{1}{1 + K_V G_V} \,, \; S_M = \frac{1}{1 + K_M G_R} \,. \quad (32.20)$$

Thus the dual-stage servo control design can be decoupled into two independent designs: the VCM loop and the microactuator loop designs. The VCM loop sensitivity can be designed using traditional single-stage servo design methodologies. The microactuator loop sensitivity is designed to expand the bandwidth and increase the attenuation of low frequency runout and disturbances.

Closed Loop Sensitivity Design by Pole Placement. For a typical sampled second order system with the discrete time transfer function

$$G\left(q^{-1}\right)=\frac{q^{-1}B_o\left(q^{-1}\right)}{A_o\left(q^{-1}\right)}\,, \tag{32.21}$$

where q^{-1} is one step delay operator; $B_o\left(q^{-1}\right)$ is the plant zero polynomial, and $A_o\left(q^{-1}\right)=1+a_1q^{-1}+a_2q^{-2}$ is the plant pole polynomial. The closed loop sensitivity function can be designed by pole placement, solving the following Diophantine equation [32.41]:

$$A_c\left(q^{-1}\right)=A_o\left(q^{-1}\right)S\left(q^{-1}\right)+q^{-1}B_o\left(q^{-1}\right)R\left(q^{-1}\right)\,, \tag{32.22}$$

where $A_c\left(q^{-1}\right)$ is the desired closed loop characteristic polynomial. The closed loop sensitivity function, G_S, is

$$G_S\left(q^{-1}\right)=\frac{A_o\left(q^{-1}\right)S\left(q^{-1}\right)}{A_c\left(q^{-1}\right)}\,, \tag{32.23}$$

and the discrete time controller $C\left(q^{-1}\right)$ is

$$C\left(q^{-1}\right)=\frac{R\left(q^{-1}\right)}{S\left(q^{-1}\right)}\,. \tag{32.24}$$

$A_c\left(q^{-1}\right)$ can be chosen such that the required bandwidth and system response are satisfied. Usually it is more intuitive to describe it with its continuous time equivalent parameters: the damping ratio, ζ, and the natural frequency, ω_n. The damping ratio is directly related to the phase margin of the open loop transfer function. For a typical design, it can be chosen to be equal to or greater than one, in order to ensure adequate phase margin. ω_n is related to the control system's bandwidth, which is limited by sampling frequency and time delay, or the high frequency structural dynamics of the system.

Dual-Stage Sensitivity Function Design. The compensators in the dual-stage servo system depicted in Fig. 32.24 can be designed by a two-step design process, as illustrated in Fig. 32.26.

First, the VCM loop compensator K_V is designed to attain a desired VCM closed loop sensitivity S_V, as shown in the top part of Fig. 32.26. Its bandwidth, ω_{VC} in Fig. 32.26, is generally limited by the E-block and suspension resonance modes. The design of this compensator can be accomplished using conventional SISO frequency shaping techniques.

The second step of the design process involves the design of the microactuator loop compensators to attain

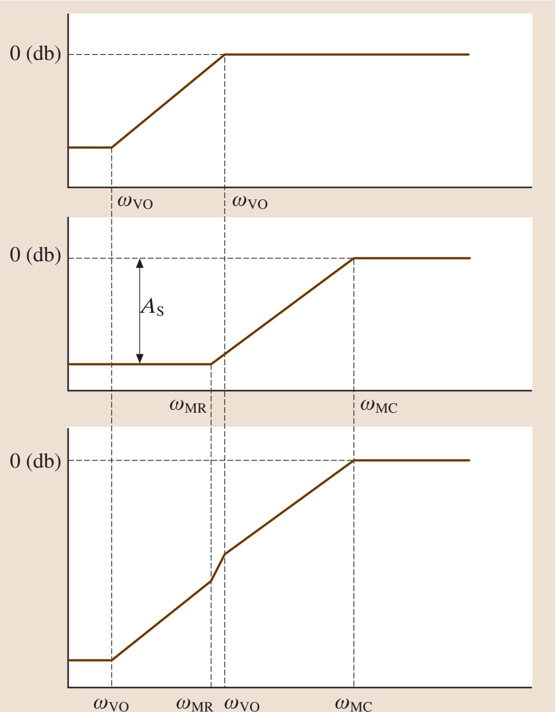

Fig. 32.26 Illustration of dual-stage sensitivity S_T design

additional attenuation S_M, as shown in the middle part of Fig. 32.26. This step is itself accomplished in two steps. First, the minor RPES loop compensator, K_{RR}/K_{RS}, is determined in order to damp the microactuator resonance mode and place the poles of G_R, or equivalently ω_{MR} in Fig. 32.26, at desired locations. The compensator can be obtained by solving a Diophantine equation by pole placement as discussed in the previous subsection. The poles of G_R will become the zeros of the microactuator loop sensitivity function, S_M.

Finally, the PES loop compensator K_M is designed to place the poles, or equivalently. ω_{MC} in Fig. 32.26, of the microactuator loop closed loop sensitivity S_M. ω_{MC} is limited by the PES sampling frequency and computational time delay [32.42].

The total dual-stage sensitivity is shown in the bottom part of Fig. 32.26. For a given ω_{MC}, the additional attenuation A_S, provided by the microactuator loop, will be determined by ω_{MR}. In our proposed procedure, the initial value of ω_{MR} can be chosen to be the same as ω_{VC}. It is then adjusted so the desired attenuation and phase margin requirements of the overall dual-stage system are satisfied. Decreasing ω_{MR} increases the low frequency

attenuation of the closed loop sensitivity function S_T but also generally reduces the phase margin of open loop transfer function G_T.

For SIMO design when the RPES is not available, the microactuator model can be used as an open loop observer to estimate the RPES. The combination of the open loop observer and the minor loop compensator is equivalent to a notch filter.

Self-Tuning Control to Compensate Variations in the Microactuator's Resonance Mode. An adaptive control scheme can be combined with the decoupled discrete time pole placement design methodology described above to compensate variations in the microactuator's resonance mode by tuning the microactuator RPES inner loop compensator.

A block diagram for the microactuator inner loop self-tuning control is shown in Fig. 32.27. The parameter adaptation algorithm (PAA) is a direct self-tuning algorithm, based on the microactuator inner loop pole placement design.

Consider the microactuator open loop transfer function in (32.21). Since the microactuator's resonance mode is lightly damped, the zero of the microactuator's discrete time transfer function is very close to 1 ($z_o \approx 1$). Thus it is possible to factor out the "known" term $(1+z_o q^{-1})$ from the Diophantine equation (32.22). The resulting RPES minor-loop closed loop dynamics is given by

$$A_c\left(q^{-1}\right) y(k) = q^{-1} b_0 \left(1+z_o q^{-1}\right) \times\left[K_{RS}\left(q^{-1}\right) u_M(k) + K_{RR}\left(q^{-1}\right) y(k)\right] ,$$

where u_M is the control input to the microactuator; y denotes the position of the microactuator relative to the VCM, i.e. $y = $ RPES. Defining:

$$S\left(q^{-1}\right) = b_0 K_{RS}\left(q^{-1}\right) = s_0 + s_1 q^{-1} , \quad (32.25)$$

$$R\left(q^{-1}\right) = b_0 K_{RR}\left(q^{-1}\right) = r_0 + r_1 q^{-1} , \quad (32.26)$$

the regressor vector, $\phi(k)$ and filtered regressor vector, $\phi_f(k)$,

$$\phi(k) = \left[u_M(k)\ u_M(k-1)\ y(k)\ y(k-1)\right] , \quad (32.27)$$

$$A_c\left(q^{-1}\right)\phi_f(k) = \left(1+z_o q^{-1}\right)\phi(k) , \quad (32.28)$$

and the controller parameter vector $\theta = [s_0\ s_1\ r_0\ r_1]^T$, the closed loop RPES dynamics (32.25) can be rewritten as

$$y(k) = \theta^T \phi_f(k-1) . \quad (32.29)$$

From (32.29), the controller parameter vector estimate $\hat{\theta}(k) = [\hat{s}_0(k)\ \hat{s}_1(k)\ \hat{r}_0(k)\ \hat{r}_1(k)]^T$ can be updated using a standard recursive least square algorithm (RLS) [32.41]:

$$\hat{\theta}(k) = \hat{\theta}(k-1) + P(k)\phi_f(k)e^o(k) , \quad (32.30)$$

$$e^o(k) = y(k) - \hat{\theta}^T(k-1)\phi_f(k-1) , \quad (32.31)$$

$$P(k) = \left[P(k-1) - \frac{P(k-1)\phi_f(k-1)\phi_f^T(k-1)P(k-1)}{1+\phi_f^T(k-1)P(k-1)\phi_f(k-1)}\right] , \quad (32.32)$$

The control law is

$$\hat{S}\left(k, q^{-1}\right) u_M(k) = \hat{S}_o(k) u_M(k) - \hat{R}\left(k, q^{-1}\right) y(k) , \quad (32.33)$$

with

$$\hat{S}\left(k, q^{-1}\right) = \hat{s}_0(k) + \hat{s}_1(k) q^{-1} , \quad (32.34)$$

$$\hat{R}\left(k, q^{-1}\right) = \hat{r}_0(k) + \hat{r}_1(k) q^{-1} , \quad (32.35)$$

and $u_M(k)$ being the output of the microactuator fixed outer loop compensator K_M, $u_M(k)$ being the control input to the microactuator.

Dual-Stage Track-Following Control Design Using μ-Synthesis

The structured singular value, μ, is a measure of how big a perturbation to a system needs to be to make the sys-

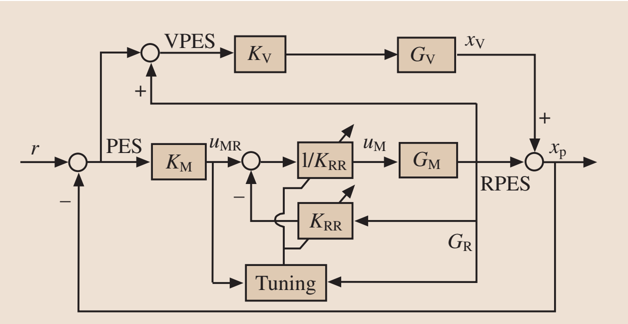

Fig. 32.27 Self-tuning control of the microactuator

Part E | 32.3

tem unstable. By incorporating a fictitious uncertainty block, robust performance in terms of the H_∞ norm of the closed loop transfer function can be related to the value of μ. μ-synthesis is a robust optimal controller design technique that attempts to minimize μ through an iterative process [32.43].

Design Methodology. For controller design using μ-synthesis, the model uncertainties are represented using linear fractional transformations (LFT). Disturbances and outputs are weighted to characterize the real plant environment and the performance requirements. A block diagram used for dual-stage μ-synthesis controller design is shown in Fig. 32.28.

In the block diagram, two model uncertainties, δ_1 and δ_2, are considered. δ_1 is an additive uncertainty used to describe the VCM unmodeled dynamics. δ_2 represents the parametric uncertainty in the stiffness of the microactuator.

Disturbance signals accounted for in the model include the track runout r, input disturbances to the VCM d_{VCM}, input disturbances to the microactuator d_{MA}, PES sensor noise n_{PES}, and the $RPES$ sensor noise n_{RPES}. These disturbance signals are generated by passing normalized signals $\overline{r}$, $\overline{d_{\mathrm{VCM}}}$, $\overline{d_{\mathrm{MA}}}$, $\overline{n_{PES}}$, and $\overline{n_{RPES}}$ through weighting functions W_r, $W_{d\mathrm{VCM}}$, $W_{d\mathrm{MA}}$, W_{nPES}, and W_{nRPES}, respectively, which can be either constants or frequency shaping filters. These weights are selected by the designer so that disturbances are modeled with sufficient fidelity.

The output signals in the synthesis model are head position error signal, PES, the microactuator relative position signal, $RPES$, the VCM control input u_{VCM}, and the microactuator control input u_{MA}. These signals are multiplied by scaling factors, W_{PES}, W_{RPES}, $W_{u\mathrm{VCM}}$, and $W_{u\mathrm{MA}}$, respectively, to produce the weighted performance signals $\overline{PES}$, $\overline{RPES}$, $\overline{u_{\mathrm{VCM}}}$, $\overline{u_{\mathrm{MA}}}$. The scaling factors are selected to characterize the performance requirements.

Given a set of input and output weights and plant uncertainties, if the synthesized controller achieves

$$\mu \le \beta\,, \tag{32.36}$$

the closed loop transfer function, $\overline{T}$, from the normalized disturbances

$$\overline{d} = \left[\overline{r}\ \overline{d_{\mathrm{VCM}}}\ \overline{d_{\mathrm{MA}}}\ \overline{n_{\mathrm{PES}}}\ \overline{n_{\mathrm{RPES}}}\right], \tag{32.37}$$

to the weighted performance signals

$$\overline{e} = \left[\overline{\mathrm{PES}}\ \overline{\mathrm{RPES}}\ \overline{u_{\mathrm{VCM}}}\ \overline{u_{\mathrm{MA}}}\right], \tag{32.38}$$

will have infinity norm

$$\left\|\overline{T}\right\|_\infty \le \beta\,, \tag{32.39}$$

for perturbations

$$\|\Delta\|_\infty = \left\|\begin{bmatrix}\delta_1 & 0\\ 0 & \delta_2\end{bmatrix}\right\|_\infty \le \frac{1}{\beta}\,. \tag{32.40}$$

The interpretation of H_∞ as the RMS gain of the sinusoidal signals to help understand the design is as follows. Assume that each element $\overline{d_i}$ of the disturbance

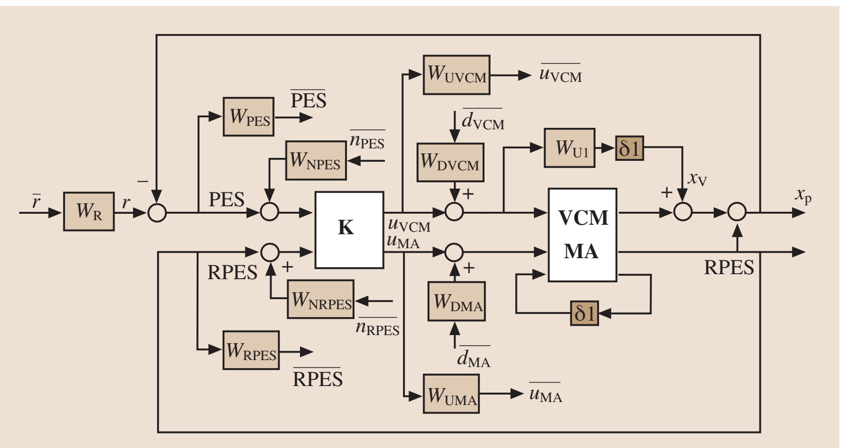

Fig. 32.28 μ-synthesis design block diagram

input vector in (32.37) is a sinusoid of the form

$$\overline{d_i}(t) = D_i \sin(\omega_i t + \psi_i)\,, \tag{32.41}$$

such that

$$\sum_{i=1}^{5} D_i^2 \le 1\,. \tag{32.42}$$

Then the steady state response of output in (32.38) will also be a sinusoid of the form

$$\overline{e_i}(t) = E_i \sin(\omega_i t + \phi_i)\,, \tag{32.43}$$

and

$$\sum_{i=1}^{4} E_i^2 \le \beta\,, \tag{32.44}$$

under the perturbations defined in (32.40).

Weighting Functions for μ-Synthesis Design. Performance weights are chosen based on limits that the error signals should not exceed. The limit on the PES is based on a rule of thumb commonly used in the disk drive industry which states that the position error of the head should not exceed 1/10 of a track width during track following. RPES is limited by the stroke limit of the microactuator. Thus,

$$W_{\text{PES}} = \frac{10}{\text{track width}}\,; \quad W_{\text{RPES}} = \frac{1}{\text{stroke limit}}\,. \tag{32.45}$$

Weights on control inputs are based on the control input saturations.

$$W_{U\text{VCM}} = \frac{1}{(i_{\text{V}})_{\max}}\,; \quad W_{U\text{MA}} = \frac{1}{(v_{\text{M}})_{\max}}\,, \tag{32.46}$$

where $(i_{\text{V}})_{\max}$ and $(v_{\text{M}})_{\max}$ are the maximum drive current of the VCM and the maximum drive voltage of the microactuator, respectively.

The weights for PES noise, n_{PES}, and the disturbance to the VCM, $w_{d\text{VCM}}$, were determined by extrapolating the PES decomposition results presented in [32.29]. The weight of the RPES sensing noise, n_{RPES}, is assumed to be 8 nm [32.14]. The disturbance weight, $w_{d\text{MA}}$, is assumed to be 0.1 V in the design.

The runout weighting function is a low pass filter that captures the combined effects of track runout, mechanical vibrations, and bias force disturbance to PES,

$$W_{\text{r}} = \frac{2\times10^{-8}(s+2\pi\times10)^2}{(s+2\pi\times1000)^2}\,. \tag{32.47}$$

The combination of W_{PES} and W_{r} determines the closed loop sensitivity function from r to PES, $S(s)$, of the dual-stage system. If the designed control system achieves a peak μ value of β, we have

$$\left\| W_{\text{PES}} S(s) W_{\text{r}} \right\|_{\infty} \le \beta\,. \tag{32.48}$$

If $\beta = 1$, the magnitude of bode plot of $S(s)$ lies below that of $1/W_{\text{PES}} W_{\text{r}}$.

For SIMO design, the controller to be synthesized has only one input. In the synthesis model, RPES is not fed to the controller K, and RPES noise n_{rpes} and its weights W_{nRPES} are not used.

Design and Simulation Results

Figure 32.29 shows the Bode plots of the open loop transfer functions from r to $x_{\text{p}}p$ and the closed loop sensitivity functions of the two designs, respectively. Sampling frequency was chosen to be 20 kHz in both designs.

For the decoupled MIMO design, the gain crossover frequency, gain margin, phase margin of the open loop system are 2,201 Hz, 9.1 dB, and 48.8°, respectively. For the decoupled SIMO design, they are 2,381 Hz, 8.7 dB, and 30.6°, respectively.

For μ-synthesis MIMO design, the gain crossover frequency, gain margin, phase margin of the open loop system are 2,050 Hz, 9.5 dB, 66.0°, respectively. For μ-synthesis SIMO design, they are 2,223 Hz, 2.9 dB, 32.0°, respectively.

The above controller designs have not been implemented on a MEMS microactuator dual-stage servo system. Controllers designed using both methods have been tested on a PZT actuated suspension dual-stage servo system, however, validating their effectiveness [32.44].

Figure 32.30 shows the simulation of control parameters adaptation for the self-tuning controller, when the real microactuator resonance frequency is 1.2 times its nominal value. The controller parameters converge to their desired values. Similar responses were obtained when the real resonance frequency is 0.8 times the nominal value.

32.3.4 Dual-Stage Seek Control Design

Because the inertia of a microactuator is much smaller than that of the VCM, it can produce a larger acceleration and move faster than the VCM. The motion range of a microactuator is usually limited to a few micrometers, however. Thus the performance improvement in seek control made possible by using

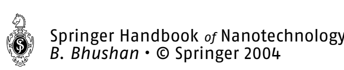
Fig. 32.29 **(a)** Open loop Bode plot of the decoupled design; **(b)** open loop Bode plot of the μ-synthesis design; **(c)** closed loop sensitivity Bode plot of the decoupled design; **(d)** closed loop sensitivity Bode plot of the μ-synthesis design

dual-stage actuation will mainly be in short distance seeks.

Two degree-of-freedom (DOF) position control has been a very popular control technique in short distance seeks. A 2-DOF control technique utilizing decoupled feed forward reference trajectories has been developed for short span seek control using a PZT actuated suspension dual-stage servo system [32.45]. The same technique can also be applied to seek control of MEMS microactuator dual-stage servo system.

Figure 32.31 shows a block diagram for dual-stage short span seek control design using this method. In the figure, x_{V}^{d} and x_{R}^{d} are the desired seek trajectories of the VCM and the microactuator respectively. K_{VF} and K_{RF} are Zero Phase Error Tracking Feed Forward Controllers (ZPETFFC) generated using with the VCM model G_{V} and the damped microactuator model G_{R} [32.46].

To minimize the residual vibration after seek operation, minimum jerk seek trajectories were applied to both the VCM and the microactuator. These can be generated



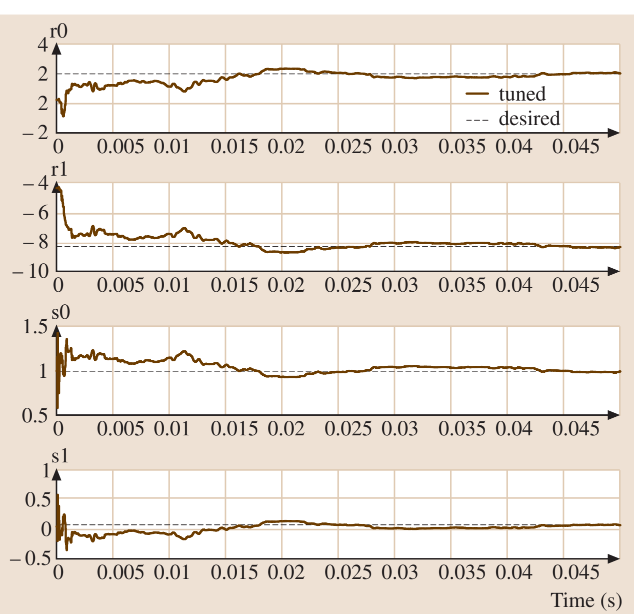


Fig. 32.30 Control parameters adaptation response

by [32.47]

$$x_{\mathrm{V}}^{d}(t)=60\,d_s\left[\frac{1}{10}\left(\frac{t}{T_{\mathrm{V}}}\right)^5-\frac{1}{4}\left(\frac{t}{T_{\mathrm{V}}}\right)^4+\frac{1}{6}\left(\frac{t}{T_{\mathrm{V}}}\right)^3\right], \tag{32.49}$$

$$x_{\mathrm{R}}^{d}=\begin{cases}60\,\left(d_s-x_{\mathrm{V}}^{d}(T)\right) & \\ \times\left[\frac{1}{10}\left(\frac{t}{T}\right)^5-\frac{1}{4}\left(\frac{t}{T}\right)^4+\frac{1}{6}\left(\frac{t}{T}\right)^3\right] & t\le T\,,\\ d_s-x_{\mathrm{V}}^{d}(t) & t>T\end{cases} \tag{32.50}$$

where d_s is the distance of the head from the target track; T is the time when the head reaches the target track if dual-stage actuator is used, while T_{V} is the time when the head reaches the target track if only VCM is used. T_{V} and T can be chosen based on the control force saturation and seek performance requirements.

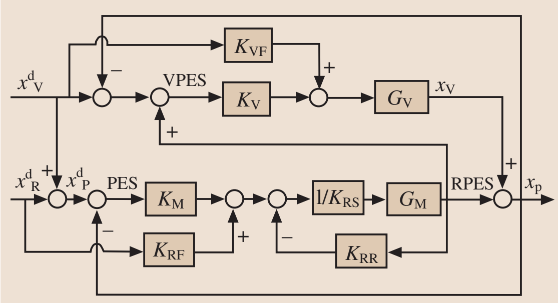

Fig. 32.31 Dual-stage seek control design

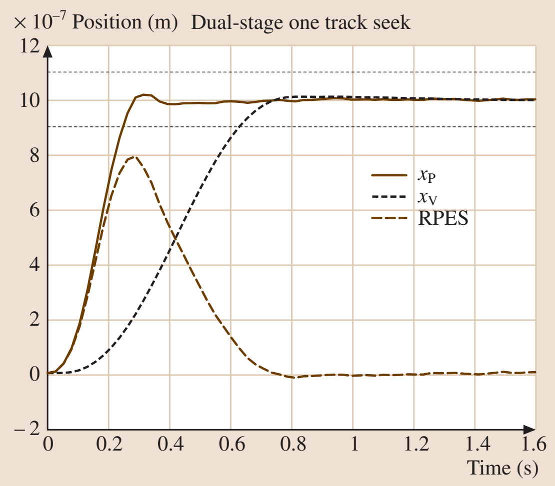

Fig. 32.32 Dual-stage short span seek response

Figure 32.32 shows the 1 µm seek responses of the dual-stage actuator for the MIMO design. Overshoot was eliminated, and no obvious residual vibrations occured. The seek time using the dual-stage actuator is about 0.25 ms, compared to a seek time of about 0.7 ms if only the VCM is used.

32.4 Conclusions and Outlook

In order to increase hard disk drive storage density, high bandwidth dual-stage servo systems are necessary to suppress disturbances and increase servo precision. Various prototype MEMS microactuators have been designed and fabricated to provide a dual-stage actuation system. The most common approach for these prototypes is to use electrostatic driving arrays produced by MEMS fabrication methods.

MEMS microactuators provide a potentially high performance and low cost solution for achieving the servo requirements for extremely high HDD storage density. Simulations and experiments show that many

MEMS microactuator features, such as integrated silicon gimbals and capacitive relative position sensing arrays, can meet important requirements for operation of HDDs. The use of structural electrical-isolation in the microactuator design could considerably reduce microactuator driving voltages, while processes that avoid the use of silicon-on-insulator wafers or high-temperature processing steps could reduce manufacturing costs. High bandwidth dual-stage track-following controllers have been designed using both a decoupled SISO design method and robust μ-synthesis design method, among others. In addition, short-span seeking control using a 2-DOF control structure with decoupled feed forward trajectory generation can greatly reduce the short span seek time.

Research remains to be done in the areas of system integration, reliability, and performance enhancement for this technology to be utilized in commercial products. Cost and reliability are probably the most important obstacles to commercial implementation of actuated slider dual-stage servo systems at this time. Streamlining of microactuator fabrication processes or development of a process compatible with that of the slider and head fabrication could reduce manufacturing costs, which are not quite yet economical. Meanwhile, dynamic behavior and reliability of the microactuator under disturbances from airflow, head-disk interaction, and particle presence are being experimentally studied by industry.

Further in the future, to achieve nanometer servo precision, third-generation dual-stage servo systems will have to employ an actuated head approach. Research in this area has just started, with the key problem being how to combine microactuator fabrication with read/write head fabrication. Another area of research is the use of MEMS technology to incorporate additional sensors, such as accelerometers and strain gauge vibration sensors, to suppress the TMR due to airflow and external disturbances excited structural vibrations. New robust, adaptive MIMO control architectures and algorithms must be developed for such a multisensing and multiactuation servo system.

Besides the application of MEMS microactuators in dual-stage servo control of traditional rotating media magnetic HDDs, recent advances in MEMS and nanotechnology have made possible the development of a new class of miniaturized ultra-high density storage devices that use probe arrays for recording and reading data. This new architecture abandons the traditional rotating media and flying slider paradigm in favor of parallel x-y scanning of entire probe arrays over a storage medium. The probe arrays and/or the media are moved with electrostatic or electromagnetic microactuators that generate x-y in-plane relative motion, as well as z-axis out-of-plane relative motion. One example of this new generation of storage devices is IBM's "millipede," which utilizes atomic force microscopy (AFM) recording technology [32.48]. Data is recorded on a polymer media by tiny depressions melted by a thermomechanical process by the AFM tips. 400 Gb/in.^{2} bit patterns have been demonstrated using thermal probes.

By any of the paths above, MEMS and nanotechnology will become a basic enabling technology for the development of future data storage devices, offering the capabilities of small size, low power consumption, ultra-high densities, low cost, and high performance.

33. Micro/Nanotribology of MEMS/NEMS Materials and Devices

The field of MEMS/NEMS has expanded considerably over the last decade. The length scale and large surface-to-volume ratio of the devices result in very high retarding forces such as adhesion and friction that seriously undermine the performance and reliability of the devices. These tribological phenomena need to be studied and understood at the micro- to nanoscales. In addition, materials for MEMS/NEMS must exhibit good microscale tribological properties. There is a need to develop lubricants and identify lubrication methods that are suitable for MEMS/NEMS. Using AFM-based techniques, researchers have conducted micro/nanotribological studies of materials and lubricants for use in MEMS/NEMS. In addition, component level testing has also been carried out to aid in better understanding the observed tribological phenomena in MEMS/NEMS.

Macroscale and microscale tribological studies of silicon and polysilicon films have been performed. The effects of doping and oxide films and environment on the tribological properties of these popular MEMS/NEMS materials have also been studied. SiC film is found to be a good tribological material for use in high-temperature MEMS/NEMS devices. Hexadecane thiol self-assembled monolayers and bonded perfluoropolyether lubricants appear to be well suited for lubrication of microdevices under a range of environmental conditions. DLC coatings can also be used for low friction and wear. Surface roughness measurements of micromachined polysilicon surfaces have been made using an AFM. The roughness distribution on surfaces is strongly dependent on the fabrication process. Roughness should be optimized for low adhesion, friction, and wear. Adhesion and friction of microstructures can be measured using novel apparatuses. Adhesion and friction measurements on silicon-on-silicon confirm AFM measurements that hexadecane thiol and bonded perfluoropolyether films exhibit superior adhesion and friction properties. Static friction force measurements of micromotors have been performed using an AFM. The forces are found to vary considerably with humidity. A bonded layer of perfluoropolyether lubricant is found to satisfactorily reduce the friction forces in the micromotor.

AFM/FFM-based techniques can be satisfactorily used to study and evaluate micro/nanoscale tribological phenomena related to MEMS/NEMS devices.

This chapter presents a review of macro- and micro/nanoscale tribological studies of materials and lubrication studies for MEMS/NEMS and component-level studies of stiction phenomena in MEMS/NEMS devices.

Microelectromechanical systems (MEMS) refer to microscopic devices that have a characteristic length of less than 1 mm but more than 1 µm and combine electrical and mechanical components. Nanoelectromechanical systems (NEMS) refer to nanoscopic devices that have a characteristic length of less than 1 µm and combine electrical and mechanical components. In mesoscale devices, if the functional components are on the micro- or nanoscale, they may be referred to as MEMS or NEMS, respectively. To put the dimensions and masses in perspective, see Fig. 33.1 and Table 33.1. The acronym MEMS originated in the United States. The term commonly used in Europe and Japan is micro/nanodevices, which is used in a much broader sense. MEMS/NEMS terms are also now used in a broad sense. A micro/nanosystem, a term commonly used in Europe, is referred to as an intelligent miniaturized system comprising sensing, processing, and/or actuating functions.

Fabrication techniques include top-down methods, in which one builds down from the large to the small, and the bottom-up methods, in which one builds up from the small to the large. Top-down methods include micro/nanomachining methods and methods based on lithography, as well as nonlithographic miniaturization for MEMS and NEMS fabrication. In the bottom-up methods, also referred to as nanochemistry, the devices and systems are assembled from their elemental constituents for NEMS fabrication, much like the way nature uses proteins and other macromolecules to

Fig. 33.1 Dimensions of MEMS and NEMS in perspective. An example of molecular dynamic simulations of carbon-nanotube-based gear is obtained from [33.1], quantum-dot transistor is obtained from [33.2], and DMD is obtained from [33.3]

Table 33.1 Dimensions and masses in perspective

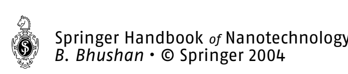
A Dimensions in Perspective	
NEMS characteristic length	< 1,000 nm
MEMS characteristic length	< 1 mm and > 1 µm
Individual atoms	typically fraction of a nm in diameter
DNA molecules	∼ 2.5 nm wide
Molecular gear	∼ 50 nm
Biological cells	in the range of thousands of nm in diameter
Human hair	∼ 75,000 nm in diameter
B Masses in Perspective	
NEMS built with cross sections of about 10 nm	as low as 10^{-20} N
Micromachine silicon structure	as low as 1 nN
Water droplet	∼ 10 µN
Eyelash	∼ 100 nN

construct complex biological systems. The bottom-up approach has the potential to go far beyond the limits of top-down technology by producing nanoscale features through synthesis and subsequent assembly. Furthermore, the bottom-up approach offers the potential to produce structures with enhanced and/or completely new functions. It allows the combination of materials with distinct chemical composition, structure, and morphology.

MEMS and emerging NEMS are expected to have a major impact on our lives, comparable to that of semiconductor technology, information technology, or cellular and molecular biology [33.4, 5]. MEMS/NEMS are used in mechanical, information/communication, chemical, and biological applications. The MEMS industry in 2000 was worth about $15 billion and, with a projected 10–20% annual growth rate, is expected to be more than $100 billion by the end of this decade [33.6]. Growth of Si MEMS may slow down and non-silicon MEMS may pick up during this decade. The NEMS industry is expected to expand in this decade, mostly in biomedical applications, as well as in nanoelectronics or molecular electronics. The NEMS industry was worth about $100 million in 2002 and integrated NEMS are expected to be more than $25 billion by the end of this decade. Due to the enabling nature of these systems, and because of the significant impact they can have on both commercial and defense applications, industry, as well as the federal government have taken a special interest in seeing growth nurtured in this field. Micro- and nanosystems are the next logical step in the "silicon revolution."

33.1 Introduction to MEMS

The advances in silicon photolithographic process technology beginning in the 1960s led to the development of MEMS in the early 1980s. More recently, lithographic processes have been developed to process nonsilicon materials. The lithographic processes are being complemented with non-lithographic processes for fabrication of components or devices made from plastics or ceramics. Using these fabrication processes, researchers have fabricated a wide variety of miniaturized devices, including Si-based devices, chemical and biological sensors and actuators, and miniature non-silicon structures (e.g., devices made from plastics or ceramics) with dimensions in the range of a couple to a few thousand microns (see e.g., [33.7–15]). MEMS for mechanical applications include acceleration, pressure, flow, gas sensors, linear and rotary actuators, and other microstructures or microcomponents such as electric motors, gear trains, gas turbine engines, nozzles, fluid pumps, fluid



valves, switches, grippers, and tweezers. MEMS for chemical applications include chemical sensors and various analytical instruments. Microoptoelectromechanical systems, or MOEMS, include micromirror arrays and fiber optic connectors. BIOMEMS include biochips. Radio frequency MEMS or RF-MEMS include inductors, capacitors, and antennas. High-aspect-ratio MEMS (HARMEMS) have also been introduced.

The fabrication techniques for MEMS devices include lithographic and non-lithographic techniques. The lithographic techniques fall into three basic categories: bulk micromachining, surface micromachining, and LIGA (a German acronym for Lithographie Galvanoformung Abformung), a German term for lithography, electroforming, and plastic molding. The first two approaches, bulk and surface micromachining, use planar photolithographic fabrication processes developed for semiconductor devices in producing two-dimensional (2-D) structures [33.10, 15–17]. The various steps involved in these two fabrication processes are shown schematically in Fig. 33.2. Bulk micromachining employs anisotropic etching to remove sections through the thickness of a single-crystal silicon wafer, typically 250 to 500 μm thick. Bulk micromachining is a proven high-volume production process and is routinely used to fabricate microstructures such as accelerometers, pressure sensors, and flow sensors. In surface micromachining, structural and sacrificial films are alternatively deposited, patterned and etched to produce a freestanding structure. These films are typically made of low-pressure chemical vapor deposition (LPCVD) polysilicon film with 2 to 20 μm thickness. Surface micromachining is used to produce sensors, actuators, and complex microdevices such as micromirror arrays, motors, gears, and grippers.

The LIGA process is based on the combined use of X-ray lithography, electroforming, and molding processes. The steps involved in the LIGA process are shown schematically in Fig. 33.3. LIGA is used to produce high-aspect-ratio MEMS (HARMEMS) devices that are up to 1 mm in height and only a few microns in width or length [33.18]. The LIGA process yields very sturdy 3-D structures due to their increased thickness. One of the limitations of silicon microfabrication processes originally used for fabrication of MEMS devices is the lack of suitable materials that can be processed. With LIGA, a variety of non-silicon materials such as metals, ceramics, and polymers can be processed. Nonlithographic micromachining processes, primarily in Europe and Japan, are also being used for fabrication of millimeter-scale devices using direct material microcutting or micromechanical machining (such as microturning, micromilling, and microdrilling), or removal by energy beams (such as microspark erosion, focused ion beam, laser ablation, and laser polymerization) [33.19, 20]. Hybrid technologies, including LIGA and high-precision micromachining techniques, have been used to produce miniaturized motors, gears, actuators, and connectors [33.21–24]. These millimeter-scale devices may find more immediate applications.

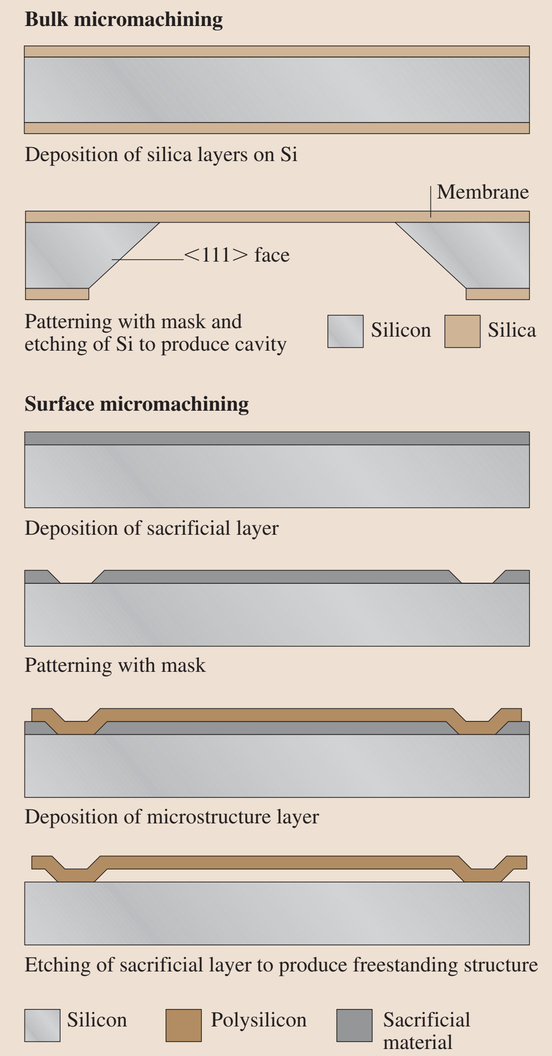


Fig. 33.2 Schematics of process steps involved in bulk micromachining and surface micromachining fabrication of MEMS

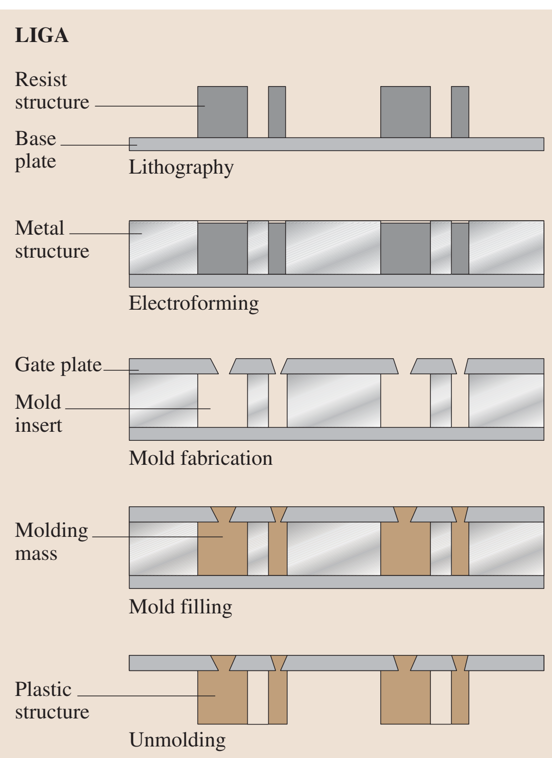

Fig. 33.3 Schematic of process steps involved in LIGA fabrication of MEMS

A microfabrication technique, so-called "soft lithography," is a nonlithographic technique [33.25, 26] in which an elastomeric stamp or mold is used to generate micropatterns by replica molding [33.27], embossing (imprinting) [33.28], or by contact printing (known as microcontact printing or μCP) [33.29]. Replica molding is commonly used for mass-produced, disposable plastic microcomponents, for example, microfluidic chips, generally made of poly(dimethylsiloxane) (PDMS) and polymethyl methacrylate (PMMA). The elastomeric stamps are generally cast from photolithographically generated micropatterned masters. This technique is substantially cheaper and more flexible in choice of materials for construction than conventional photolithography.

To assemble microsystems, microrobots are used. Microrobotics include building blocks such as steering links, microgrippers, conveyor system, and locomotive robots [33.13].

A variety of MEMS devices have been produced and some are commercially used [33.8, 10–12, 14, 15]. A variety of sensors are used in industrial, consumer, defense, and biomedical applications. Various microstructures or microcomponents are used in micro-instruments and other industrial applications such as micromirror arrays. Two of the largest "killer" industrial applications are accelerometers (about 85 million units in 2002) and digital micromirror devices (about $400 million in sales in 2001). Integrated capacitive-type, silicon accelerometers have been used in airbag deployment in automobiles since 1991 [33.30, 31]. Accelerometer technology was about a billion-dollar-a-year industry in 2001 dominated by Analog Devices, followed by Motorola and Bosch. Commercial digital light processing (DLP) equipments, using digital micromirror devices (DMD), were launched in 1996 by Texas Instruments for digital projection displays in portable and home theater projectors, as well as table top and projection TVs [33.32–34]. More than 1.5 million projectors were sold before 2002. Other major industrial applications include pressure sensors, inkjet printer heads and optical switches. Silicon-based piezoresistive pressure sensors for manifold absolute pressure sensing for engines were launched in 1991 by NovaSensor, and their annual sales were about 25 million units in 2002. Capacitive pressure sensors for tire pressure measurements were launched by Motorola. Annual sales of inkjet printer heads with microscale functional components were about 400 million units in 2002. Other applications of MEMS devices include chemical sensors, gas sensors, infrared detectors and focal plane arrays for earth observation, space science, and missile defense applications, pico-satellites for space applications, and many hydraulic, pneumatic, and other consumer products. MEMS devices are also being pursued in magnetic storage systems [33.35], where they are being developed for super-compact and ultrahigh-recording-density magnetic disk drives. Several integrated head/suspension microdevices have been fabricated for contact recording applications [33.36, 37]. High-bandwidth servo-controlled microactuators have been fabricated for ultrahigh-track-density applications that serve as the fine-position control element of a two-stage, coarse/fine servo system, coupled with a conventional actuator [33.38–40].

BIOMEMS are used increasingly in commercial and defense applications (e.g., [33.8, 41–44]). Applications of BIOMEMS include biofluidic chips (microfluidic chips or bioflips or simply biochips) for chemical and biochemical analyses (biosensors) in medical diagnostics (e.g., DNA, RNA, proteins, cells, blood pressure and assays, and toxin identification) and implantable pharmaceutical drug delivery. The biosensors, also referred

to as lab-on-a-chip, integrate sample handling, separation, detection, and data analysis onto one platform. Biosensors are designed to either detect a single or class of (bio)chemicals or system-level analytical capabilities for a broad range of (bio)chemical species known as micro total analysis systems (μTAS). The chips rely on microfluidics and involve manipulation of tiny amounts of fluids in microchannels using microvalves. The chips consist of several basic components, including microfluidic channels and reservoirs, microvalves, micropumps, flow sensors, and biosensors. The test fluid is injected into the chip generally using an external pump or a syringe for analyses. Some chips have been designed with an integrated electrostatically actuated diaphragm-type micropump. Micropumps both with and without valves are used. The sample, which can have volume measured in nanoliters, flows through microfluidic channels via an electric potential and capillary action using microvalves (having various designs, including membrane type) for various analyses. The fluid is preprocessed and then analyzed using a biosensor. For a review on micropumps and microvalves, see [33.11, 45, 46]. Silicon-based disposable blood-pressure sensor chips were introduced in the early 1990s by NovaSensor for blood pressure monitoring (about 20 million units in 2002). A blood sugar monitor, referred to as GlucoWatch, was introduced in 2002. It automatically checks blood sugar every 10 min by detecting glucose through the skin, without having to draw blood. If glucose is out of the acceptable range, it sounds an alarm so the diabetic can address the problem quickly. A variety of biosensors, many using plastic substrates, are manufactured by various companies, including ACLARA, Agilent Technologies, Calipertech, and I-STAT.

After the tragedy of Sept. 11, 2001, concern over biological and chemical warfare has led to the development of handheld units with bio- and chemical sensors for detection of biological germs, chemical or nerve agents, and mustard agents, and chemical precursors to protect subways, airports, water supply, and population at large [33.47].

Other BIOMEMS applications include minimal invasive surgery, including endoscopic surgery, laser angioplasty, and microscopic surgery. Implantable artificial organs can also be produced.

Micro-instruments and micromanipulators are used to move, position, probe, pattern, and characterize nanoscale objects and nanoscale features. Miniaturized analytical equipment include gas chromatography and mass spectrometry. Other instruments include micro-STM, where STM stands for scanning tunneling microscope.

In some cases, MEMS devices are used primarily for their miniature size. While in others, as in the case of air bags, they are used because of their low-cost manufacturing techniques, since semiconductor-processing costs have reduced drastically over the last decade, allowing the use of MEMS in many fields.

33.2 Introduction to NEMS

NEMS are produced by nanomachining in a typical top-down approach (from large to small) and bottom-up approach (from small to large) largely relying on nanochemistry [33.48–53]. The top-down approach relies on fabrication methods, including advanced integrated-circuit (IC) lithographic methods – electron-beam lithography and STM writing by removing material atom by atom. The bottom-up approach includes chemical synthesis, the spontaneous "self-assembly" of molecular clusters (molecular self-assembly) from simple reagents in solution, or biological molecules (e.g., DNA) as building blocks to produce 3-D nanostructures, quantum dots (nanocrystals) of arbitrary diameter (about $10–10^5$ atoms), molecular beam epitaxy (MBE) and organometallic vapor phase epitaxy (OMVPE) to create specialized crystals one atomic or molecular layer at a time, and manipulation of individual atoms by an atomic force microscope or atom optics. The self-assembly must be encoded. That is, one must be able to precisely assemble one object next to another to form a designed pattern. A variety of nonequilibrium plasma chemistry techniques are also used to produce layered nanocomposites, nanotubes, and nanoparticles. The NEMS field, in addition to fabrication of nanosystems, has provided the impetus to develop experimental and computation tools.

Examples of NEMS include nanocomponents, nanodevices, nanosystems, and nanomaterials such as microcantilevers with integrated sharp nanotips for STM and atomic force microscopy (AFM), AFM array (millipede) for data storage, AFM tips for nanolithography, dip-pen nanolithography for printing molecules,

biological (DNA) motors, molecular gears, molecularly thick films (e.g., in giant magnetoresistive or GMR heads, and magnetic media), nanoparticles (e.g., nanomagnetic particles in magnetic media), nanowires, carbon nanotubes, quantum wires (QWRs), quantum boxes (QBs), and quantum transistors. BIONEMS include nanobiosensors – a microarray of silicon nanowires, roughly a few nm in size, to selectively bind and detect even a single biological molecule such as DNA or protein by using nanoelectronics to detect the slight electrical charge caused by such binding, or a microarray of carbon nanotubes to electrically detect glucose, implantable drug-delivery devices – e.g., micro/nanoparticles with drug molecules encapsulated in functionized shells for a site-specific targeting applications and a silicon capsule with a nanoporous membrane filled with drugs for long-term delivery – , nanodevices for sequencing single molecules of DNA in the Human Genome Project, cellular growth using carbon nanotubes for spinal cord repair, nanotubes for nanostructured materials for various applications such as spinal fusion devices, organ growth, and growth of artificial tissues using nanofibers.

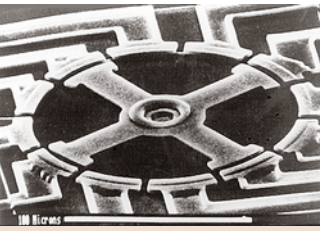
Nanoelectronics can be used to build computer memory using individual molecules or nanotubes to store bits of information, molecular switches, molecular or nanotube transistors, nanotube flat-panel displays, nanotube integrated circuits, fast logic gates, switches, nanoscopic lasers, and nanotubes as electrodes in fuel cells.

33.3 Tribological Issues in MEMS/NEMS

Tribological issues are important in MEMS/NEMS requiring intended and/or unintended relative motion. In MEMS/NEMS, various forces associated with the device scale down with size. When the length of the machine decreases from 1 mm to 1 µm, the area decreases by a factor of a million and the volume decreases by a factor of a billion. As a result, surface forces such as adhesion, friction, meniscus forces, viscous drag forces, and surface tension that are proportional to area become a thousand times larger than the forces proportional to the volume such as inertial and electromagnetic forces. In addition to the consequence of a large surface-to-volume ratio, since MEMS/NEMS are designed for small tolerances, physical contact becomes more likely, which makes them particularly vulnerable to adhesion between adjacent components. Since the start-up forces and torques involved in MEMS/NEMS operation available to overcome retarding forces are small, the increase in resistive forces such as adhesion and friction become a serious tribological concern that limits the life and reliability of MEMS/NEMS [33.10]. A large lateral force required to initiate relative motion between two surfaces, large static friction, is referred to as "stiction," which has been studied extensively in tribology of magnetic storage systems [33.35, 54, 55]. A large normal force required to separate two surfaces is also referred to as stiction. Adhesion, friction/stiction (static friction), wear, and surface contamination affect MEMS/NEMS performance and in some cases, can even prevent devices from working. Some examples of devices that experience tribological problems follow.

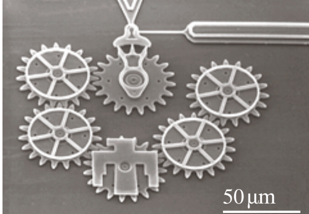
33.3.1 MEMS

Figure 33.4a shows examples of several microcomponents that can encounter the aforementioned tribological problems. The polysilicon electrostatic micromotor has 12 stators and a four-pole rotor and is produced by surface micromachining. The rotor diameter is 120 µm and the air gap between the rotor and stator is 2 µm [33.56]. It is capable of continuous rotation up to speeds of 100,000 RPM. The intermittent contact at the rotor-stator interface and physical contact at the rotor-hub flange interface result in wear issues, and high stiction between the contacting surfaces limits the repeatability of operation, or may even prevent the operation altogether. Next, a bulk micromachined silicon stator/rotor pair is shown with bladed rotor and nozzle guide vanes on the stator with dimensions less than a mm [33.57]. These are being developed for high-temperature microgas turbine generators with an operating speed up to 1 million RPM. Erosion of blades and vanes and wear of bearings used in the turbine generators are some of the concerns. Next, is an SEM micrograph of a surface micromachined polysilicon six-gear chain from Sandia National Lab. (For more examples of previous versions, see [33.58, 59].) As an example of non-silicon components, a milligear system produced using the LIGA process for a DC brushless permanent magnet millimotor (diameter = 1.9 mm, length = 5.5 mm) with an integrated milligear box [33.21–23] is also shown. The gears are made of metal (electroplated Ni-Fe), but can also be made from injected polymer materials (e.g.,



Electrostatic micromoter (*Tai* et al., [33.56])

Microturbine bladed rotor and nozzle guide vanes on the stator (*Spearing* and *Chen*, [33.57])



Six gear chain (www.sandia.gov)

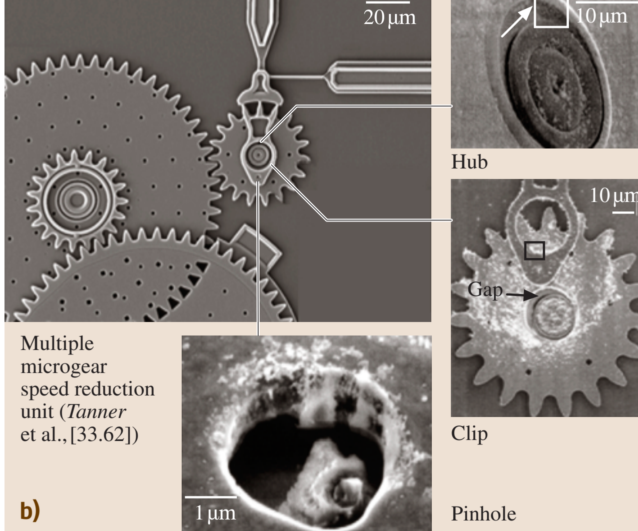
a) Low-pressure flow modulator with electrostatically actuated microvalves (*Robertson* and *Wise*, [33.60])



Multiple microgear speed reduction unit (*Tanner* et al., [33.62])

b)

Fig. 33.4a,b Examples of MEMS devices and components that experience tribological problems: **(a)** several micro-component and **(b)** a polysilicon, multiple microgear speed reduction unit

Polyoxy-methylene, or POM) using the LIGA process. Even though the torque transmitted at the gear teeth is small, on the order of a fraction of a nNm, because of small dimensions of gear teeth, the bending stresses are large where the teeth mesh. Tooth breakage and wear at the contact of gear teeth are concerns. Next, in a micromachined flow modulator, several micromachined flow channels are integrated in series with electrostatically actuated microvalves [33.60]. The flow channels lead to a central gas outlet hole drilled in the glass substrate. Gas enters the device through a bulk micromachined gas inlet hole in the silicon cap. After passing through an open microvalve, the gas flows parallel to the glass substrate through flow channels and exits the device through an outlet. The normally open valve structure consists of a freestanding double-end-clamped beam, which is positioned beneath the gas inlet orifice. When deflected electrostatically upwards, the beam seals against the inlet orifice, and the valve is closed. In these microvalves used for flow control, the mating valve surfaces should be smooth enough to seal while maintaining a minimum roughness to ensure low adhesion [33.54, 55, 61]. High adhesion (stiction) is a major issue.

Figure 33.4b shows a polysilicon, multiple microgear speed reduction unit and its components after laboratory wear tests conducted in air [33.62]. These units have been developed for an electrostatically driven microactuator (microengine) developed at Sandia National Lab for operation in the kHz frequency range. Wear of various components is clearly observed in the figure. Humidity was shown to be a strong factor in the wear of rubbing surfaces. In order to improve the wear characteristics of rubbing surfaces, 20-nm-thick tungsten (W) coating using chemical vapor deposition (CVD) technique was used [33.63]. Tungsten-coated microengines tested for reliability showed improved wear characteristics with longer lifetimes than polysilicon microengines.

Commercially available MEMS devices also exhibit tribological problems. Figure 33.5 shows an integrated capacitive-type silicon accelerometer fabricated using surface micromachining by Analog Devices, a couple of mm in dimension, which is used for the deployment of airbags in automotives and more recently for

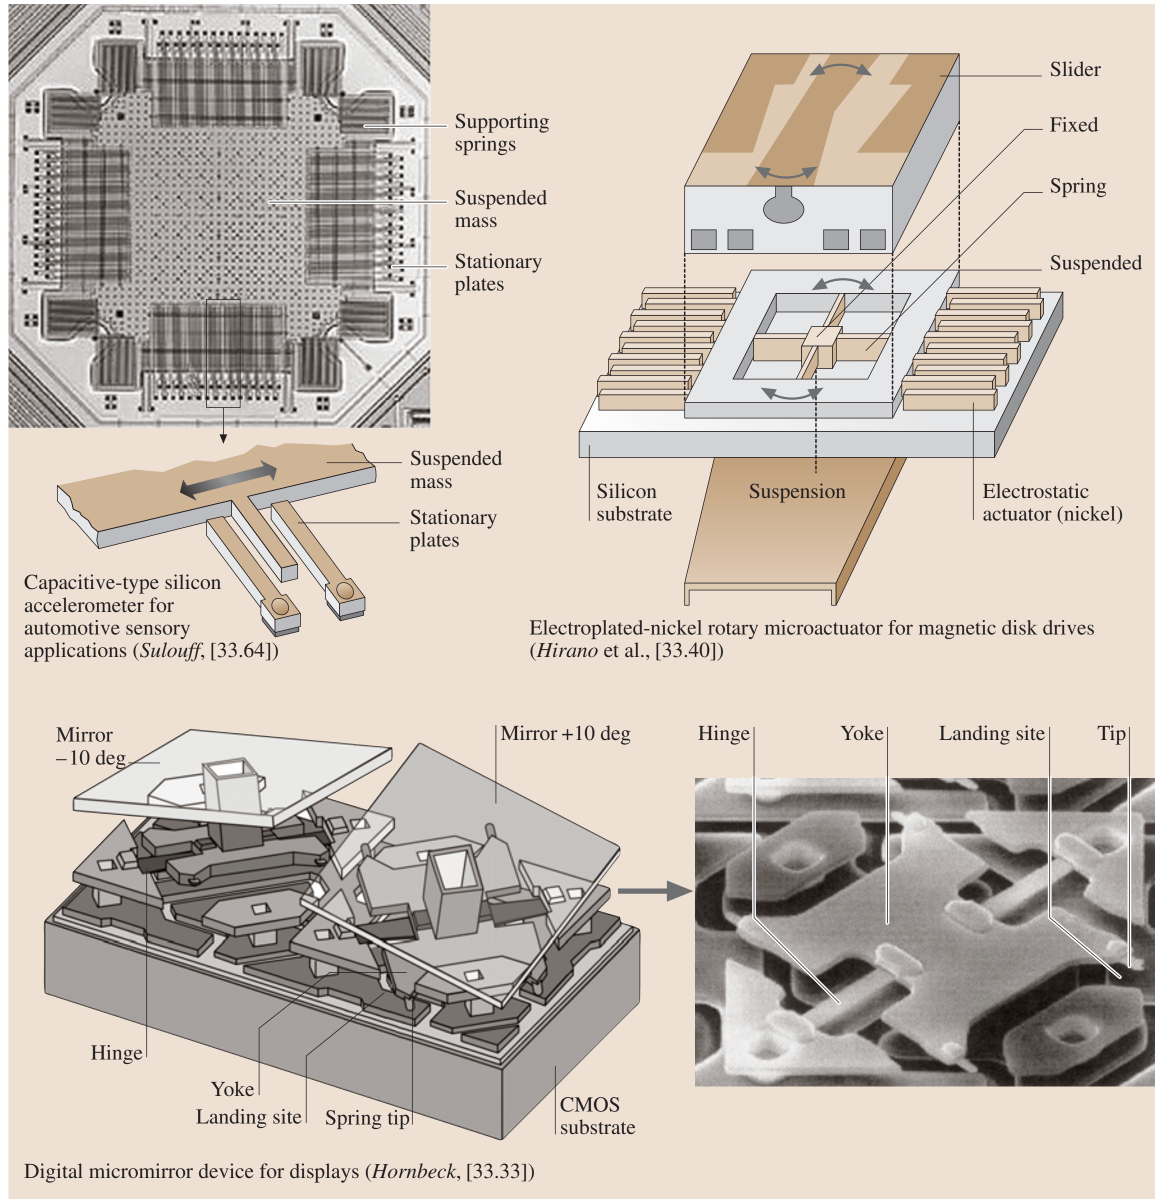


Fig. 33.5 Examples of commercial use MEMS devices that experience tribological problems

the consumer electronics market [33.30, 64, 65]. These accelerometers are now being developed for many other applications such as vehicle stability, rollover control, and gyro sensor applications. The central suspended beam mass (about 0.7 μg) is supported on the four corners by spring structures. The central beam has interdigitated, cantilevered electrode fingers (about 125 μm long and 3 μm thick) on all four sides that alternate with those of the stationary electrode fingers, as shown, with about a 1.3 μm gap. Lateral motion of the central beam causes a change in the capacitance between these electrodes, which is used to measure the acceleration. Here stiction between the adjacent electrodes, as well as stiction of the beam structure with the under-

lying substrate are detrimental to the operation of the sensor [33.30, 64]. Wear during unintended contacts of these polysilicon fingers is also a problem. A molecularly thick diphenyl siloxane lubricant film with high resistance to temperature and oxidation, applied by a vapor deposition process is used on the electrodes to reduce stiction and wear.

Figure 33.5 also shows two digital micromirror device (DMD) pixels used in digital light processing (DLP) technology for digital projection displays in portable and home theater projectors, as well as table-top and projection TVs [33.32–34]. The entire array (chip set) consists of a large number of rotatable aluminum micromirrors (digital light switches) that are fabricated on top of a CMOS static random access memory integrated circuit. The surface micromachined array consists of half of a million to more than two million of these independently controlled, reflective micromirrors (mirror size on the order of 14 μm square and 15 μm pitch) that flip backward and forward at a frequency on the order of 5,000 times per s. For the binary operation, a micromirror/yoke structure mounted on torsional hinges is rotated ±10° (with respect to the horizontal plane) as a result of electrostatic attraction between the micromirror structure and the underlying memory cell and is limited by a mechanical stop. Contact between cantilevered spring tips at the end of the yoke (four present on each yoke) with the underlying stationary landing sites is required for true digital (binary) operation. Stiction and wear during a contact between aluminum alloy spring tips and landing sites, hinge memory (metal creep at high operating temperatures), hinge fatigue, shock and vibration failure, and sensitivity to particles in the chip package and operating environment are some of the important issues affecting the reliable operation of a micromirror device [33.66–68]. Perfluorodecanoic acid (PFDA) self-assembled monolayers are used on the tip and landing sites to reduce stiction and wear. The spring tip is employed in order to use the spring stored energy to pop up the tip during pull-off. A lifetime estimate of over 100,000 operating hours with no degradation in image quality is the norm.

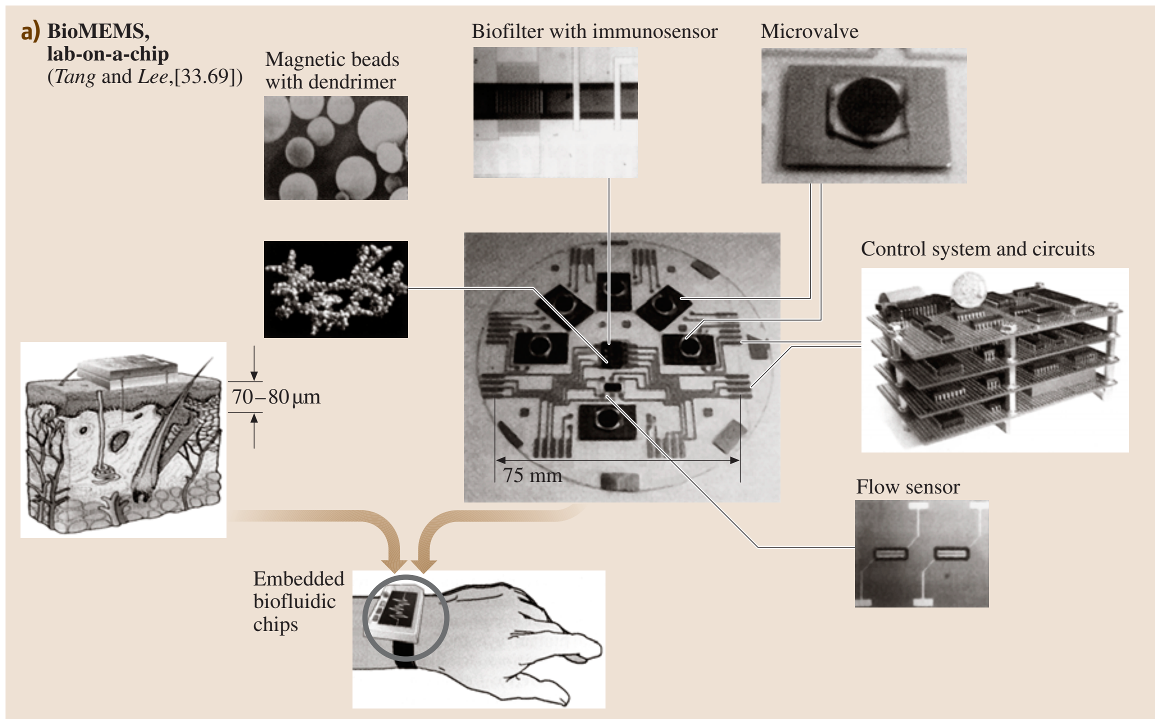

Fig. 33.6a,b Schematics of **(a)** a MEMS-based biofluidic chip, commonly known as disposable lab-on-a-chip, and **(b)** (*see next page*) a NEMS-based submicroscopic drug-delivery device, and an intravascular micro/nanoparticles for search-and-destroy diseased blood cells

A third MEMS device, shown in Fig. 33.5, is an electrostatically driven rotary microactuator for a magnetic disk drive surface-micromachined by a multilayer electroplating method [33.40]. This high-bandwidth servo-controlled microactuator, located between a slider and a suspension, is being developed for ultrahigh-track-density applications, which serves as the fine-position and high-bandwidth control element of a two-stage, coarse/fine servo system when coupled with a conventional actuator [33.38–40]. A slider is placed on top of the central block of a microactuator, which gives rotational motion to the slider. The bottom of the silicon substrate is attached to the suspension. The radial flexure beams in the central block give the rotational freedom of motion to the suspended mass (slider), and the electrostatic actuator drives the suspended mass. Actuation is accomplished via interdigitated, cantilevered electrode fingers, which are alternatingly attached to the central body of the moving part and to the stationary substrate to form pairs. A voltage applied across these electrodes results in an electrostatic force, which rotates the central block. The inter-electrode gap width is about 2 μm. Any unintended contacts between the moving and stationary electroplated-nickel electrodes may result in wear and stiction.

An example of disposable plastic lab-on-a-chip using microfluidics and BIOMEMS technologies is shown in Fig. 33.6a [33.69]. This biofluidic chip integrates multiple fluidic components on a microfluidic motherboard that can be worn like a wristwatch. It enables the unobstructive assessment of a human's medical condition through continuous blood sampling. It can be used for the analysis of a number of different compounds, including lactate, glucose, carbon dioxide, and oxygen levels in the blood and for the detection of infectious diseases. The test fluid is injected into the microchannels using a micropump, and the flow is regulated using microvalves. A magnetic bead approach is used for identification of target biomolecules based on sandwich immunoassay and electrochemical detection. Adhesion in micropumps and microvalves involving moving parts and adhesion of fluid in microchannels are some of the tribological issues. In both active and passive microvalves, the main wear mechanism appears to be erosion, corrosion, and fatigue. As the magnetic bead particulates are pumped through the microfluidic system, they could erode the valve material. Also, several different reagents are used to perform the necessary analyses. The interaction of these reagents with the valve material could cause corrosive wear. Finally, because the valves are continuously being activated, fatigue failure becomes a concern.

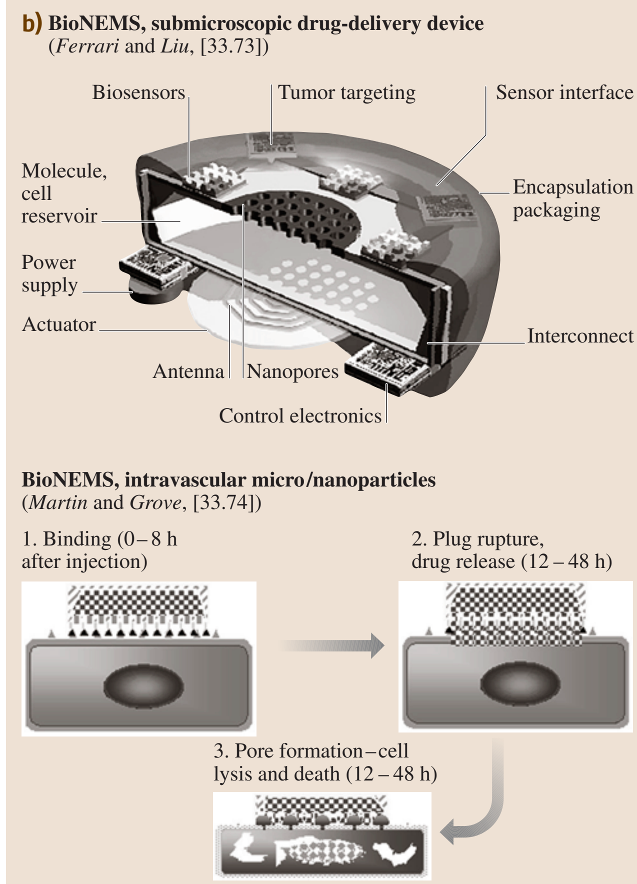

Fig. 33.6b

Stiction/friction and wear clearly limit the lifetimes and compromise the performance and reliability of microdevices. Figure 33.7 summarizes tribological problems encountered in some of the MEMS devices and components just discussed. In addition, tribological issues are present in the processes used for fabrication of MEMS/NEMS. For example, in surface micromachining, the suspended structures can sometimes collapse and permanently adhere to the underlying substrate due to meniscus effects during the final rinse and dry process, as shown in Fig. 33.7 [33.70]. Adhesion is caused by water molecules adsorbed on the adhering surfaces and/or because of formation of adhesive bonds by silica residues that remain on the surfaces after the water has evaporated. This so called release stiction is overcome

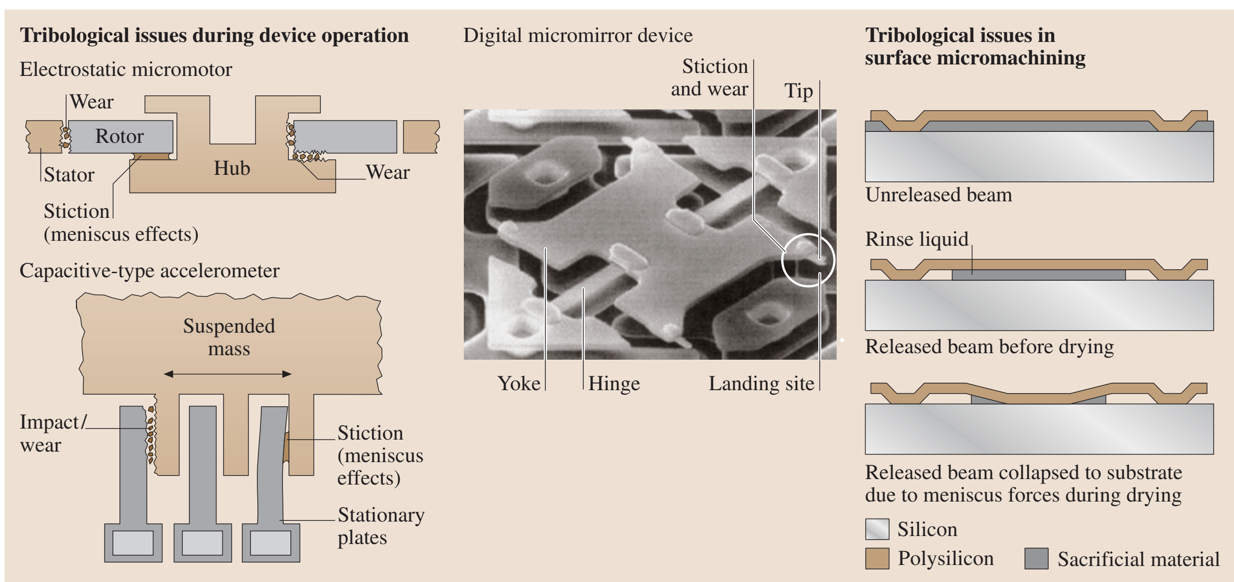

Fig. 33.7 Summary of tribological issues in MEMS device operation and fabrication via surface micromachining

by using dry release methods (e.g., CO_2 critical point drying or sublimation methods [33.71]).

33.3.2 NEMS

Figure 33.8 shows an AFM-based nanoscale data storage system for ultrahigh density magnetic recording that experiences tribological problems [33.72]. The system uses arrays of several thousand silicon microcantilevers ("millipede") for thermomechanical recording and playback on an about 40-nm-thick polymer (PMMA) medium with a harder Si substrate. The cantilevers are integrated with integrated tip heaters that have tips of nanoscale dimensions. Thermomechanical recording is a combination of applying a local force to the polymer layer, and softening it by local heating. The tip heated to about 400 °C is brought in contact with the polymer for recording. Imaging and reading are done using the heater cantilever, originally used for recording, as a thermal read-back sensor by exploiting its temperature-dependent resistance. The principle of thermal sensing is based on the fact that the thermal conductivity between the heater and the storage substrate changes according to the spacing between them. When the spacing between the heater and sample is reduced as the tip moves into a bit, the heater's temperature and hence its resistance will decrease. Thus, changes in temperature of the continuously heated resistor are monitored while the cantilever is scanned over data bits, providing a means of detecting the bits. Erasing for subsequent rewriting is carried out by thermal reflow of the storage field by heating the medium to 150 °C for a few seconds. The smoothness of the reflown medium allows multiple rewriting of the same storage field. Bit sizes ranging between 10 and 50 nm have been achieved by using a 32×32 (1024) array write/read chip (3 mm×3 mm). It has been reported that tip wear occurs through the contact between tip and Si substrate during writing. Tip wear is considered a major factor in device reliability.

Figure 33.6b shows two examples of BIONEMS [33.73, 74]. The figure shows a conceptual model of a submicroscopic drug delivery device with the ability to localize in the areas of need. It is a silicon capsule with a nanoporous membrane filled with drugs for long-term delivery. It uses a nanomembrane with pores as small as 6 nm that are used as flux regulators for the long-term release of drugs. The nanomembrane also protects therapeutic substances from attack by the body's immune system. The figure also shows a conceptual model of an intravascular drug delivery device – micro/nanoparticle used for search-and-destroy disease cells. With the lateral dimensions of 1 μm or less, the particle is smaller than any blood cells. These particles can be injected into the blood stream and travel freely through the circulatory system. In order to direct these drug-delivery micro/nanoparticles to cancer sites, their external sur-

faces are chemically modified to carry molecules that have lock-and-key binding specificity with molecules that support a growing cancer mass. As soon as the particles dock on the cells, a compound is released that forms a pore on the membrane of the cells, which leads to cell death and ultimately to that of the cancer mass that was nourished by the blood vessel. Adhesion between micro/nanodevices and disease cells is required.

33.3.3 Tribological Needs

The MEMS/NEMS need to be designed to perform expected functions typically in the ms to ps range. Expected life of the devices for high speed contacts can vary from a few hundred thousand to many billions of cycles, e.g., over a hundred billion cycles for DMDs, which puts serious requirements on materials [33.10, 62, 75–78]. Most mechanical properties are known to be scale-dependent [33.79]. The properties of nanoscale structures need to be measured [33.80]. Tribology is an important factor affecting the performance and reliability of MEMS/NEMS [33.10, 49, 81]. There is a need for developing a fundamental understanding of adhesion, friction/stiction, wear, and the roles of surface contamination and environment [33.10]. MEMS/NEMS materials need to exhibit good mechanical and tribological properties on the micro/nanoscale. There is a need to develop lubricants and identify lubrication methods that are suitable for MEMS/NEMS. Component-level studies are required to provide a better understanding of the tribological phenomena occurring in MEMS/NEMS. The emergence of micro/nanotribology and atomic force microscopy-based techniques has provided researchers with a viable approach to address these problems [33.49, 82]. This chapter presents a review of macro- and micro/nanoscale tribological studies of materials and lubrication studies for MEMS/NEMS and component-level studies of stiction phenomena in MEMS/NEMS devices.

33.4 Tribological Studies of Silicon and Related Materials

Materials of most interest for planar fabrication processes using silicon as the structural material are undoped and boron-doped (p^+-type) single-crystal silicon for bulk micromachining and phosphorus (n^+-type) doped and undoped LPCVD polysilicon films for surface micromachining. Silicon-based devices lack high-temperature capabilities with respect to both mechanical and electrical properties. Researchers have been pursuing SiC as a material for high-temperature microsensor and microactuator applications, for some time [33.83, 84]. SiC is a likely candidate for such applications, since it has long been used in high temperature electronics, high frequency and high power devices. SiC can also be desirable for high-frequency micromechanical resonators, in the GHz range, because of its high modulus of elasticity and, consequently, high resonant frequency. Table 33.2 compares selected bulk properties of SiC and Si(100). Researchers have found low cost techniques of producing single-crystal 3C-SiC (cubic or β-SiC) films via epitaxial growth on large-area silicon substrates for bulk micromachining [33.85] and polycrystalline 3C-SiC films on polysilicon and silicon dioxide layers for surface micromachining of SiC [33.86].

Table 33.2 Selected bulk properties[a] of 3C (β- or cubic) SiC and Si(100)

Sample	Density (kg/m^3)	Hardness (GPa)	Elastic modulus (GPa)	Fracture toughness ($MPa\,m^{1/2}$)	Thermal conductivity[b] (W/m K)	Coeff. of thermal expansion[b] ($\times10^{-6}/°C$)	Melting point (°C)	Band gap (eV)
β-SiC	3,210	23.5–26.5	440	4.6	85–260	4.5–6	2,830	2.3
Si(100)	2,330	9 –10	130	0.95	155	2 –4.5	1,410	1.1

[a] Unless stated otherwise, data shown were obtained from [33.87]

[b] Obtained from [33.88]

As will be shown, bare silicon exhibits inadequate tribological performance and needs to be coated with a solid and/or liquid overcoat or surface treated (e.g., oxidation and ion implantation, commonly used in semiconductor manufacturing), which exhibit lower friction and wear. SiC films exhibit good tribological performance. Both macroscale and microscale tribological properties of virgin and treated/coated silicon, polysilicon films, and SiC are presented next.

33.4.1 Tribological Properties of Silicon and the Effect of Ion Implantation

Friction and wear of single-crystalline and polycrystalline silicon samples, as well as the effect of ion implantation with various doses of C^+, B^+, N_2^+, and Ar^+ ion species at 200 keV energy to improve their friction and wear properties have been studied [33.89–91]. The coefficient of macroscale friction and wear factor of virgin single-crystal silicon and C^+-implanted silicon samples as a function of ion dose are presented in Fig. 33.9 [33.89]. The macroscale friction and wear tests were conducted using a ball-on-flat tribometer. Each data bar represents the average value of four to six measurements. The coefficient of friction and wear factor for bare silicon are very high and decrease drastically with ion dose. Silicon samples bombarded above the ion dose of 10^{17} C^+ cm^{-2} exhibit extremely low values of coefficients of friction (typically 0.03 to 0.06 in air) and wear factor (reduced by as much as four orders of magnitude). *Gupta* et al. [33.89] reported that a decrease in coefficient of friction and wear factor of silicon as a result of C^+ ion bombardment occurred because of formation of silicon carbide, rather than amorphization of silicon. *Gupta* et al. [33.90] also reported an improvement in friction and wear with B^+ ion implantation.

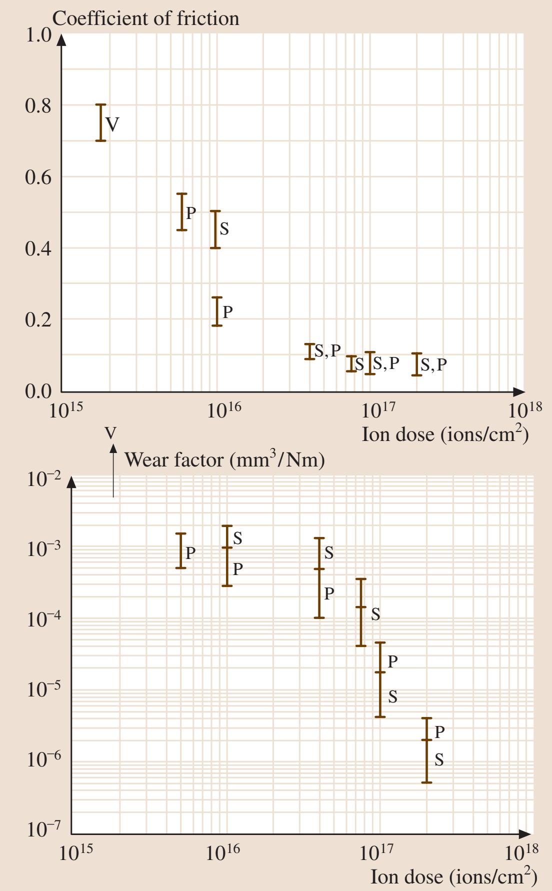

Fig. 33.9 Influence of ion doses on the coefficient of friction and wear factor on C^+ ion bombarded single-crystal and polycrystalline silicon slid against an alumina ball. V corresponds to virgin single-crystal silicon, while S and P denote tests that correspond to doped single- and polycrystalline silicon, respectively [33.89]

Table 33.3 Surface roughness and micro- and macroscale coefficients of friction of selected samples

Material	RMS roughness (nm)	Coefficient of microscale friction[a]	Coefficient of macroscale friction[b]
Si(111)	0.11	0.03	0.33
C^+-implanted Si(111)	0.33	0.02	0.18

[a] Versus Si_3N_4 tip, tip radius of 50 nm in the load range of 10–150 nN (2.5–6.1 GPa) at a scanning speed of 5 µm/s over a scan area of 1 µm × 1 µm in an AFM

[b] Versus Si_3N_4 ball, ball radius of 3 mm at a normal load of 0.1 N (0.3 GPa) at an average sliding speed of 0.8 mm/s using a tribometer

Microscale friction measurements were performed using an atomic force/friction force microscope (AFM/FFM) [33.49]. Table 33.3 shows values of surface roughness and coefficients of macroscale and microscale friction for virgin and doped silicon. There is a decrease in coefficients of microscale and macroscale friction values as a result of ion implantation. When measured for small contact areas and very low loads used in microscale studies, the indentation hardness and elastic modulus are higher than at the macroscale. This, added to the effect of the small apparent area of contact reducing the number of trapped particles on the interface, results in less plowing contribution and lower friction in the case of microscale friction measurements. Results of microscale wear resistance studies of ion-implanted silicon samples studied using a diamond tip in an AFM [33.92] are shown in Fig. 33.10a, b. For tests conducted at various loads on Si(111) and C^+-implanted Si(111), it is noted that wear resistance of an implanted sample is slightly poorer than that of virgin silicon up to about 80 µN. Above 80 µN, the wear resistance of implanted Si improves. As one continues to run tests at 40 µN for a larger number of cycles, the implanted sample exhibits higher wear resistance than the unimplanted sample. Damage from the implantation in the top layer results in poorer wear resistance. However, the implanted zone at the subsurface is more wear resistant than the virgin silicon.

Hardness values of virgin and C^+-implanted Si(111) at various indentation depths (normal loads) are presented in Fig. 33.10c [33.92]. The hardness at a small indentation depth of 2.5 nm is 16.6 GPa and drops

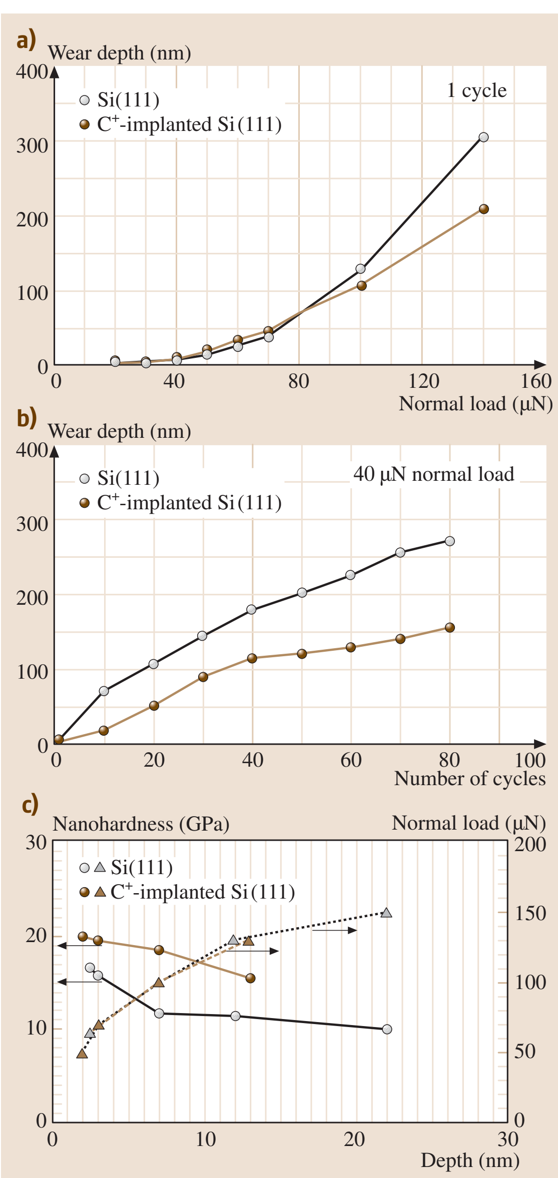

Fig. 33.10a–c Wear depth as a function of **(a)** load (after one cycle), and **(b)** cycles (normal load = 40 mN) for Si(111) and C^+-implanted Si(111). **(c)** Nanohardness and normal load as a function of indentation depth for virgin and C^+-implanted Si(111) [33.92]

to a value of 11.7 GPa at a depth of 7 nm and a normal load of 100 µN. Higher hardness values obtained in low-load indentation may arise from the observed pressure-induced phase transformation during the nanoindentation [33.93, 94]. An additional increase in the hardness at an even lower indentation depth of 2.5 nm reported here may arise from the contribution of complex chemical films (not from native oxide films) present on the silicon surface. At small volumes there is a lower probability of encountering material defects (dislocations, etc.). Furthermore, according to the strain gradient plasticity theory advanced by *Fleck* et al. [33.95], large strain gradients inherent in small indentations lead to the accumulation of geometrically necessary dislocations that cause enhanced hardening. These are some of the plausible explanations for an increase in hardness at smaller volumes. If the silicon material were to be used at very light loads such as in microsystems, the high hardness of surface films would protect the surface until it is worn.

From Fig. 33.10c, hardness values of C^+-implanted Si(111) at a normal load of 50 µN is 20.0 GPa with an indentation depth of about 2 nm, which is comparable to the hardness value of 19.5 GPa at 70 µN, whereas measured hardness value for virgin silicon at an indentation depth of about 7 nm (normal load of 100 µN) is only about 11.7 GPa. Thus, ion implantation with C^+ results in an increase in hardness in silicon. Note that the surface layer of the implanted zone is much harder compared to the subsurface and may be brittle, leading to higher wear on the surface. The subsurface of the implanted zone is harder than the virgin silicon, resulting in higher wear resistance, which is also observed in the results of the macroscale tests conducted at high loads.

33.4.2 Effect of Oxide Films on Tribological Properties of Silicon

Macroscale friction and wear experiments have been performed using a magnetic disk drive with bare, oxidized, and implanted pins sliding against amorphous-carbon coated magnetic disks lubricated with a thin layer of perfluoropolyether lubricant [33.96–99]. Representative profiles of the variation of the coefficient of friction with a number of sliding cycles for Al_2O_3-TiC slider and bare and dry-oxidized silicon pins are shown in Fig. 33.11. For bare Si(111), after an initial increase, the coefficient of friction drops to a steady state value of 0.1 following the increase, as seen in Fig. 33.11.

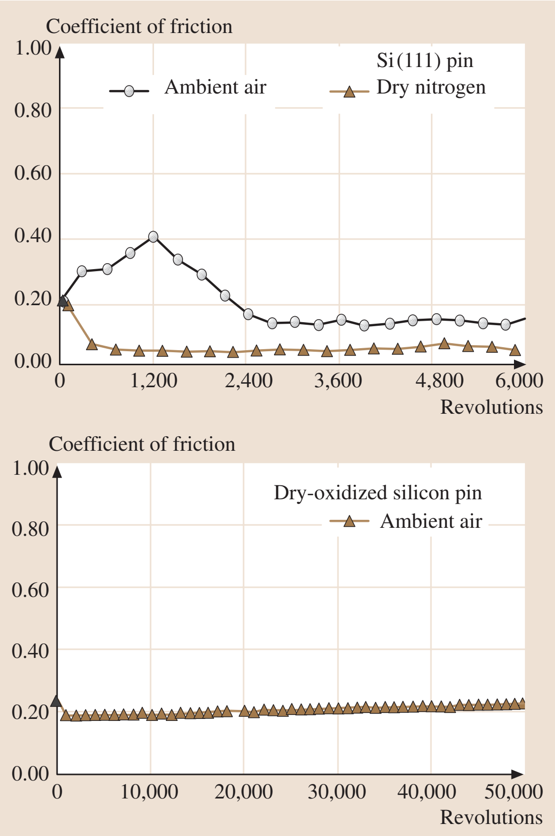

Fig. 33.11 Coefficient of friction as a function of number of sliding revolutions in ambient air for Si(111) pin in ambient air and dry nitrogen and dry-oxidized silicon pin in ambient air [33.96]

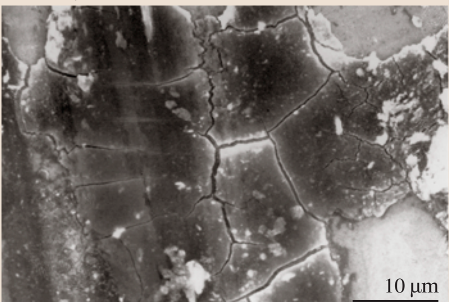
The rise in the coefficient of friction for the Si(111) pin is associated with the transfer of amorphous carbon from the disk to the pin and the oxidation-enhanced fracture of pin material followed by tribochemical oxidation of the transfer film, while the drop is associated with the formation of a transfer coating on the pin, as shown in Fig. 33.12. Dry-oxidized Si(111) exhibits excellent characteristics, and no significant increase was observed over 50,000 cycles (Fig. 33.11). This behavior has been attributed to the chemical passivity of the oxide and lack of transfer of DLC from the disk to the pin. The behavior of PECVD-oxide (data are not presented here) was comparable to that of dry oxide, but for the wet oxide there was some variation in the coefficient of friction (0.26 to 0.4). The difference between dry and wet oxide was attributed to increased

Ambient air, 6,000 cycles



Dry nitrogen, 15,000 cycles

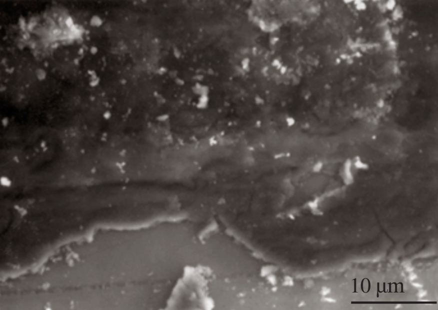


Fig. 33.12 Scanning electron micrographs of Si(111) after sliding against a magnetic disk in a rigid disk drive in ambient air for 6,000 cycles and in dry nitrogen after 15,000 cycles

porosity of the wet oxide [33.96]. Since tribochemical oxidation was determined to be a significant factor, experiments were conducted in dry nitrogen [33.97, 98]. The variation of the coefficient of friction for a silicon pin sliding against a thin-film disk in dry nitrogen is shown in Fig. 33.11. It is seen that in a dry nitrogen environment, the coefficient of friction of Si(111) sliding against a disk decreased from an initial value of about 0.2 to 0.05 with continued sliding. Based on SEM and chemical analysis, this behavior has been attributed to the formation of a smooth amorphous-carbon/lubricant transfer patch and suppression of oxidation in a dry nitrogen environment. Based on macroscale tests using disk drives, it was found that the friction and wear performance of bare silicon is not adequate. With dry-oxidized or PECVD SiO_2-coated silicon, no significant friction increase or interfacial degradation was observed in ambient air.

Table 33.4 and Fig. 33.13 show surface roughness, microscale friction and scratch data, and nanoindentation hardness for various silicon samples [33.92]. Scratch experiments were performed using a diamond tip in an AFM. Results on polysilicon samples are also shown for comparison. Coefficients of microscale friction values for all the samples are about the same. These samples could be scratched at 10 µN load. Scratch depth increased with normal load. Crystalline orientation of silicon has little influence on

Table 33.4 RMS, microfriction, microscratching/microwear, and nanoindentation hardness data for various virgin, coated, and treated silicon samples

Material	RMS roughness[a] (nm)	Coefficient of microscale friction[b]	Scratch depth[c] at 40 µN (nm)	Wear depth[c] at 40 µN (nm)	Nanohardness[c] at 100 µN (GPa)
Si(111)	0.11	0.03	20	27	11.7
Si(110)	0.09	0.04	20		
Si(100)	0.12	0.03	25		
Polysilicon	1.07	0.04	18		
Polysilicon (lapped)	0.16	0.05	18	25	12.5

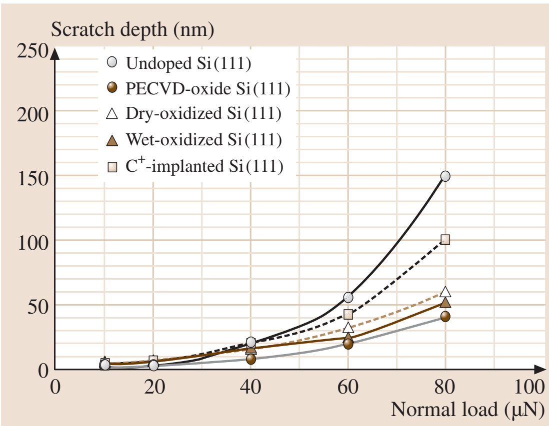

Fig. 33.13 Scratch depth as a function of normal load after 10 cycles for various silicon samples: virgin, treated, and coated [33.92]

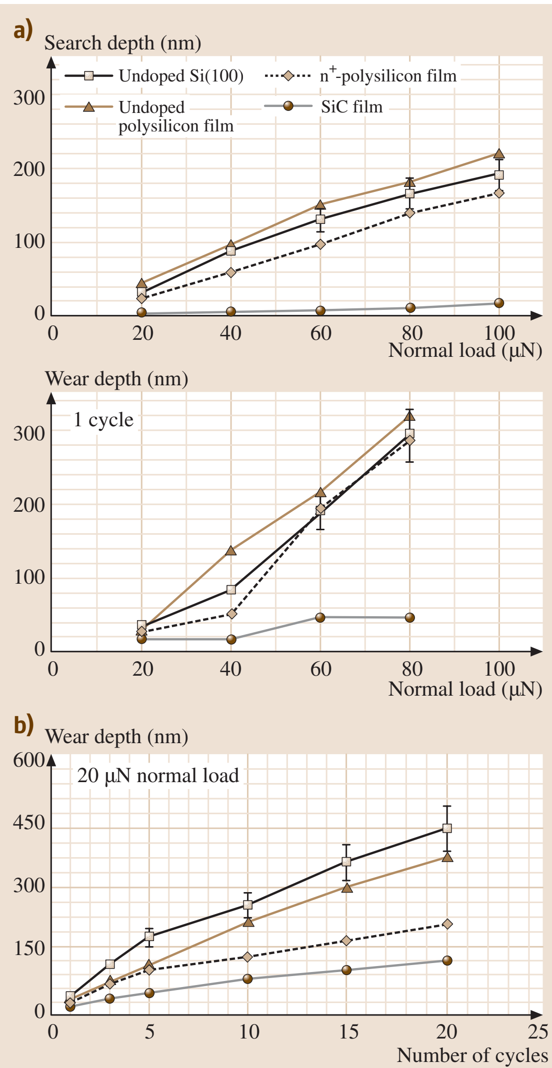

Fig. 33.14 **(a)** Scratch depths for 10 cycles as a function of normal load and **(b)** wear depths as a function of normal load and as a function of number of cycles for various samples [33.10]

scratch resistance, because natural oxidation of silicon in ambient masks the expected effect of crystallographic orientation. PECVD-oxide samples showed the best scratch resistance, followed by dry-oxidized, wet-oxidized, and ion-implanted samples. Ion implantation with C^+ does not appear to improve scratch resistance.

Wear data on the silicon samples are also presented in Table 33.1 [33.92]. PECVD-oxide samples showed superior wear resistance followed by dry-oxidized, wet-oxidized, and ion-implanted samples. This agrees with the trends seen in scratch resistance. In PECVD, ion bombardment during deposition improves the coating properties such as suppression of columnar growth, freedom from pinhole, decrease in crystalline size, and increase in density, hardness, and substrate-coating adhesion. These effects may help in improving the mechanical integrity of the sample surface. Coatings and treatments improved nanohardness of silicon. Note that dry-oxidized and PECVD films are harder than wet-oxidized films, as these films may be porous. High hardness of oxidized films may be responsible for measured high scratch/wear resistance.

33.4.3 Tribological Properties of Polysilicon Films and SiC Film

Studies have also been conducted on undoped polysilicon film, heavily doped (n^+-type) polysilicon film, heavily doped (p^+-type) single-crystal Si(100), and 3C-SiC (cubic or β-SiC) film [33.10, 100, 101]. The polysilicon films studied here are different from the ones discussed previously.

Table 33.5 presents a summary of the tribological studies conducted on polysilicon and SiC films. Values for single-crystal silicon are shown for comparison. Polishing of the as-deposited polysilicon and SiC films drastically affects the roughness, as the values reduce by two orders of magnitude. Si(100) appears to be

Table 33.5 Summary of micro/nanotribological properties of the sample materials

[g] Measured using microindenter with Vickers indenter at a normal load of 0.5 N

the smoothest followed by polished undoped polysilicon and SiC films, which have comparable roughness. The doped polysilicon film shows higher roughness than the undoped sample, which is attributed to the doping process. Polished SiC film shows the lowest friction followed by polished and undoped polysilicon film, which strongly supports the candidacy of SiC films for use in MEMS/NEMS devices. Macroscale friction measurements indicate that SiC film exhibits one of the lowest friction values as compared to the other samples. The doped polysilicon sample shows low friction on the macroscale as compared to the undoped polysilicon sample, possibly due to the doping effect.

Figure 33.14a shows a plot of scratch depth vs. normal load for various samples [33.10, 100]. Scratch depth increases with increasing normal load. Figure 33.15 shows AFM 3-D maps and averaged 2-D profiles of the scratch marks on the various samples. It is observed that scratch depth increases almost linearly with the normal load. Si(100) and the doped and undoped polysilicon films show similar scratch resistance. It is clear from the data that the SiC film is much more scratch resistant than the other samples. Figure 33.14b shows results from microscale wear tests on the various films. For all the materials, the wear depth increases almost linearly with increasing number of cycles. This suggests that the material is removed layer by layer in all the materials. Here also SiC film exhibits lower wear depths than the other samples. Doped polysilicon film wears less than the undoped film. Higher fracture toughness and hardness of SiC compared to Si(100) are responsible for its lower wear. Also the higher thermal conductivity of SiC (see Table 33.2) compared to the other materials leads to lower interface temperatures, which generally results in less degradation of the surface [33.35, 54, 55]. Doping of the polysilicon does not affect the scratch/wear resistance and hardness much. The measurements made on the doped sample are affected by the presence of grain boundaries. These studies indicate that SiC film exhibits desirable tribological properties for use in MEMS devices. Recently, researchers have fabricated SiC micromotors and have reported satisfactory operation at high temperatures [33.102].

Fig. 33.15 AFM 3-D maps and averaged 2-D profiles of scratch marks on various samples [33.10]

33.5 Lubrication Studies for MEMS/NEMS

Several studies of liquid perfluoropolyether (PFPE) lubricant films, self-assembled monolayers (SAMs), and hard diamond-like carbon (DLC) coatings have been carried out for the purpose of minimizing adhesion, friction, and wear [33.49, 66, 99, 103–108]. Many variations of these films are hydrophobic (low surface tension and high contact angle) and have low shear strength, which provide low adhesion, friction, and wear. Relevant details are presented here.

33.5.1 Perfluoropolyether Lubricants

The classical approach to lubrication uses freely supported multimolecular layers of liquid lubricants [33.49, 54, 55]. The liquid lubricants are sometimes chemically bonded to improve their wear resistance. Partially chemically bonded, molecularly thick perfluoropolyether (PFPE) lubricants are widely used for lubrication of magnetic storage media [33.35] and are suitable for MEMS/NEMS devices.

Adhesion, friction, and durability experiments have been performed on virgin Si(100) surfaces and silicon surfaces lubricated with two commonly used PFPE lubricants – Z-15 (with -CF_3 nonpolar end groups) and Z-DOL (with -OH polar end groups) [33.49, 103, 105, 106]. Z-DOL film was thermally bonded at 150 °C for 30 min and an unbonded fraction was removed by a solvent (BW) [33.35]. The thicknesses of Z-15 and Z-DOL (BW) films were 2.8 nm and 2.3 nm, respectively. Nanoscale measurements were made using an AFM. The adhesive forces of Si(100), Z-15 and Z-DOL (BW) measured by force calibration plot and friction force versus normal load plot are summarized in Fig. 33.16. The results measured by these two methods are in good agreement. Figure 33.16 shows that the presence of mobile Z-15 lubricant film increases the adhesive force compared to that of Si(100) by meniscus formation [33.54, 55, 109]. The presence of solid phase Z-DOL (BW) film reduces the adhesive force compared to that of Si(100) due to the absence of mobile liquid. The schematic (bottom) in Fig. 33.16 shows the relative size and sources of meniscus. It is well-known that the native oxide layer (SiO_2) on the top of Si(100) wafer exhibits hydrophilic properties, and some water molecules can be adsorbed on this surface. The condensed water will form meniscus as the tip approaches the sample surface. The larger adhesive force in Z-15 is not only caused by the Z-15 meniscus. The nonpolarized Z-15 liquid does not have good wettability and strong bonding with Si(100). In the ambient environment, the condensed water molecules from the environment permeate through the liquid Z-15 lubricant film and compete with the lubricant molecules presented on the substrate. The interaction of the liquid lubricant with the substrate is weakened, and a boundary layer of the liquid lubricant forms puddles [33.105, 106]. This dewetting allows water molecules to be adsorbed on the Si(100) surface as aggregates, along with Z-15 molecules. And both of them can form meniscus while the tip approaches the surface. Thus, the dewetting of liquid Z-15 film results in higher adhesive force and poorer lubrication performance. In addition, as the Z-15 film is pretty soft compared to the solid Si(100) surface, penetration of the tip in the film occurs while pushing the tip downwards. This leads to the large area of the tip involved

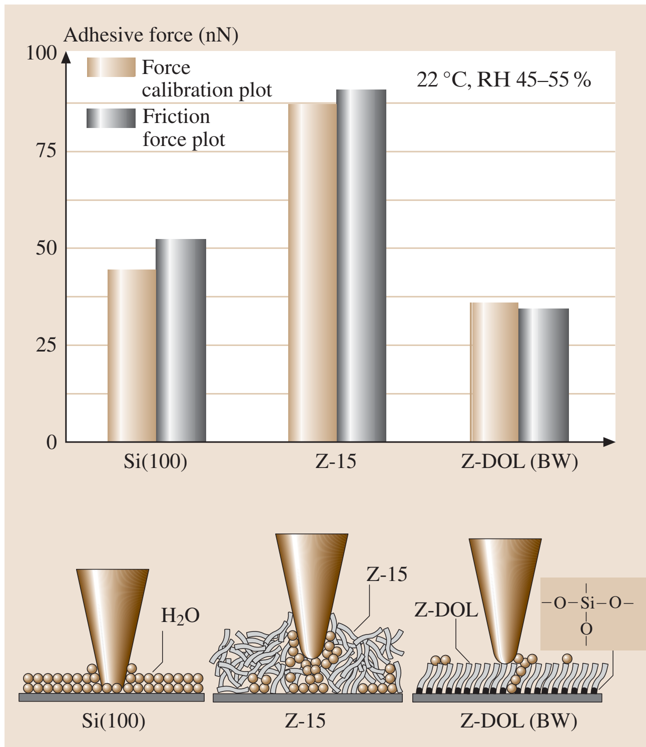

Fig. 33.16 Summary of the adhesive forces of Si(100) and Z-15 and Z-DOL (BW) films measured by force calibration plots and friction force versus normal load plots in ambient air. The schematic (*bottom*) showing the effect of meniscus, formed between the AFM tip and the surface sample, on the adhesive and friction forces [33.103]

to form the meniscus at the tip-liquid (mixture of Z-15 and water) interface. It should also be noted that Z-15 has a higher viscosity compared to water, and therefore, Z-15 film provides higher resistance to motion and coefficient of friction. In the case of Z-DOL (BW) film, the active groups of Z-DOL molecules are mostly bonded on Si(100) substrate, thus the Z-DOL (BW) film has low free surface energy and cannot be displaced readily by water molecules, or readily adsorb water molecules. Thus, the use of Z-DOL (BW) can reduce the adhesive force.

To study the relative humidity effect on friction and adhesion, the variations of friction force, adhesive force, and coefficient of friction of Si(100), Z-15, and Z-DOL (BW) as a function of relative humidity are shown in Fig. 33.17. It shows that for Si(100) and Z-15 film, the friction force increases with a relative humidity increase of up to 45% and then slightly decreases with a further increase in relative humidity. Z-DOL (BW) has a smaller friction force than Si(100) and Z-15 in the whole testing range. And its friction force shows a relative apparent increase when the relative humidity is higher than 45%. For Si(100), Z-15, and Z-DOL (BW), the adhesive forces increase with relative humidity. And their coefficients of friction increase with a relative humidity up to 45%, after which they decrease with a further increase in relative humidity. It is also observed that the humidity effect on Si(100) really depends on the history of the Si(100) sample. As the surface of Si(100) wafer readily adsorbs water in air, without any pre-treatment the Si(100) used in our study almost reaches its saturated stage of adsorbed water and is responsible for less effect during increasing relative humidity. However, once the Si(100) wafer was thermally treated by baking at 150 °C for 1 h, a bigger effect was observed.

The schematic (right) in Fig. 33.17 shows that Si(100), because its high free-surface energy, can adsorb more water molecules with increasing relative humidity. As discussed earlier, for the Z-15 film in the humid environment, the condensed water from the humid environment competes with the lubricant film present on the sample surface, and interaction of the liquid lubricant film with the silicon substrate is weakened, and a boundary layer of the liquid lubricant forms puddles. This dewetting allows water molecules to be adsorbed on the Si(100) substrate mixed with Z-15 molecules [33.105, 106]. Obviously, more water molecules can be adsorbed on Z-15 surface while increasing relative humidity. The more adsorbed water molecules in the case of Si(100), along with lubricant molecules in Z-15 film case, form bigger water meniscus, which leads to an increase in friction force, adhesive force, and coefficient of friction of Si(100) and Z-15 with humidity. But at a very high humidity of 70%, large quantities of adsorbed water can form a continuous water layer that separates the tip and sample surface and acts as a kind of lubricant, which causes a decrease in the friction force and coefficient of friction. For Z-DOL (BW) film, because of its hydrophobic surface properties, water molecules can be adsorbed at a humidity higher than 45% and cause an increase in the adhesive and friction forces.

To study the durability of lubricant films at the nanoscale, the friction of Si(100), Z-15, and Z-DOL (BW) as a function of the number of scanning cycles are shown in Fig. 33.18. As observed earlier, friction force and coefficient of friction of Z-15 is higher than that of Si(100) with the lowest values for Z-DOL (BW). During cycling, friction force and coefficient of friction of Si(100) show a slight decrease during the initial few cycles, then remain constant. This is related to the removal of the top adsorbed layer. In the case of Z-15 film, the friction force and coefficient of friction show an increase during the initial few cycles and then approach higher and stable values. This is believed to be caused by the attachment of the Z-15 molecules onto the tip. The molecular interaction between these attached molecules and molecules on the film surface is responsible for an increase in friction. But after several scans, this molecular interaction reaches the equilibrium, and after that, friction force and coefficient of friction remain constant. In the case of Z-DOL (BW) film, the friction force and coefficient of friction start out low and remain low during the entire test for 100 cycles, suggesting that Z-DOL (BW) molecules do not get attached or displaced as readily as Z-15.

33.5.2 Self-Assembled Monolayers (SAMs)

A preferred method of lubrication of MEMS/NEMS is by the deposition of organized and dense molecular-scale layers of long-chain molecules, as they have been shown to be superior lubricants [33.54, 55, 104, 107, 108, 110, 111]. Two common methods of producing monolayers are the Langmuir–Blodgett (L-B) deposition and self-assembled monolayers (SAMs) by chemical grafting of molecules. L-B films are physically bonded to the substrate by weak van der Waals forces, while SAMs are bonded covalently to the substrate and provide high durability.

SAMs can be formed spontaneously by the immersion of an appropriate substrate into a solution of an

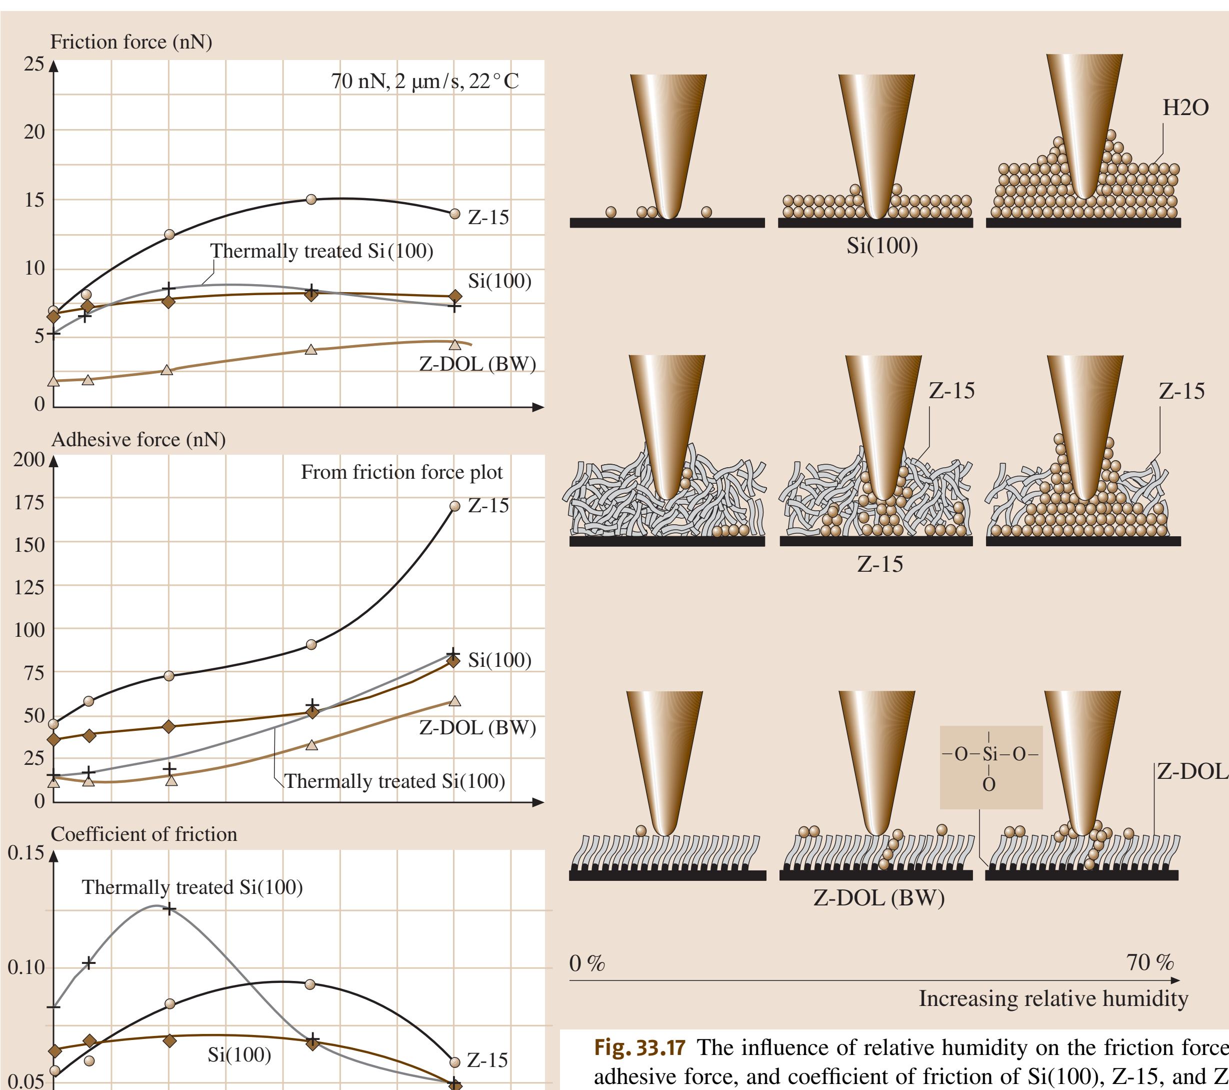

Fig. 33.17 The influence of relative humidity on the friction force, adhesive force, and coefficient of friction of Si(100), Z-15, and Z-DOL (BW) films at 70 nN, 2 µm/s, and in 22 °C air. Schematic (*right*) shows the change of meniscus with increasing relative humidity. In this figure, the thermally treated Si(100) represents the Si(100) wafer that was baked at 150 °C for 1 h in an oven (in order to remove the adsorbed water) just before it was placed in the 0% RH chamber [33.103]

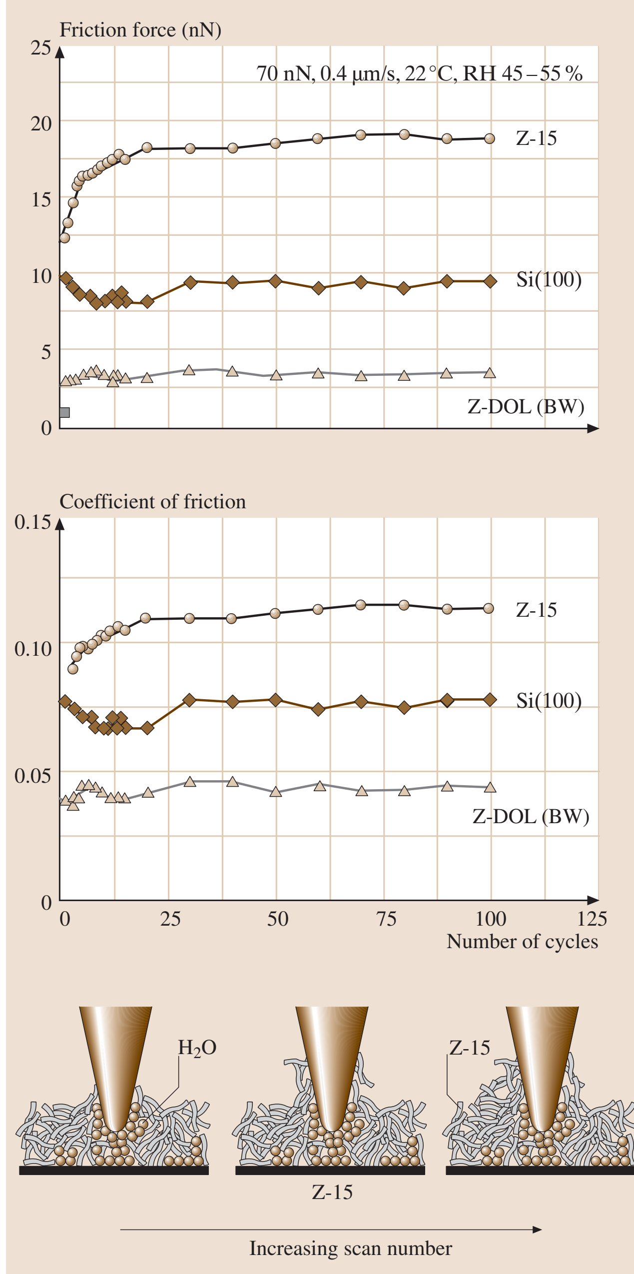

Fig. 33.18 Friction force and coefficient of friction versus number of sliding cycles for Si(100) and Z-15 and Z-DOL (BW) films at 70 nN, 0.4 µm/s, and in ambient air. Schematic (*bottom*) shows that some liquid Z-15 molecules can be attached onto the tip. The molecular interaction between the attached molecules with the Z-15 molecules in the film results in an increase of the friction force with multi-scanning [33.103]

active surfactant in an organic solvent. SAMs offer the flexibility and advantage of molecular tailoring to obtain a variety of different tribological and mechanical properties. For example, researchers have shown that by changing the head groups, tail groups, chain lengths, or types of bonds within a chain, varying degrees of friction, adhesion and/or compliance can be obtained (e.g., [33.107, 108]). These studies indicate that the basis for molecular design and tailoring of SAMs must include a complete understanding of the interrelationships between the molecular structure and tribological properties of SAMs, as well as a deep understanding of the friction and wear mechanisms of SAMs at the molecular level.

Bhushan and *Liu* [33.107] and *Liu* and *Bhushan* [33.108] studied nanotribological properties of four different kinds of alkylthiol and biphenyl thiol monolayers with different surface terminals, spacer chains, and head groups using AFM/FFM techniques. These monolayers, along with a schematic of their structures and substrates, are listed in Fig. 33.19. Surface roughness, adhesion, and microscale friction studies were carried out using an AFM/FFM. The average values and standard deviation of the adhesive force and coefficient of microscale friction for the various SAMs are summarized in Fig. 33.20. It shows that SAMs can reduce the adhesive and friction forces. Alkylthiol and biphenyl thiol SAMs can be used as effective molecular lubricants for MEMS/NEMS fabricated from silicon. In order to explain the frictional differences in SAMs, a molecular spring model is presented in Fig. 33.21. It is suggested that the chemically adsorbed self-assembled molecules on a substrate are just like assembled molecular springs anchored to the substrate. An AFM tip sliding on the surface of a SAM is like a tip sliding on the top of "molecular springs or brush." The molecular assembly has compliant features and can experience orientation and compression under load. The orientation of the molecular springs under normal load reduces the shearing force at the interface, which, in turn, reduces the friction force. The possibility of orientation is determined by the spring constant of a single molecule (local stiffness), as well as the interaction between the neighboring molecules, which is reflected by the packing density or packing energy. It is noted that HDT exhibits the lowest adhesive and friction forces. Based on local stiffness measurements [33.108] and the view of molecular structures, biphenyl is a more rigid structure due to the contribution by two benzene rings. Therefore, the spring constant of BPT is larger than that of HDT. A more compliant film (HDT) exhibits lower friction force than a rigid film (BPT/BPTC).

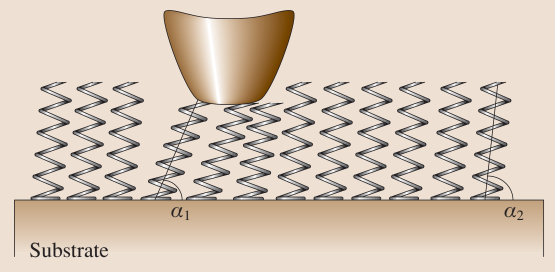

Fig. 33.21 Molecular spring model of SAMs. In this figure, $\alpha_1 < \alpha_2$, which is caused by the further orientation under the normal load applied by an asperity tip [33.107]

Crosslinking of chains in BPTC resulted in higher coefficient of friction. It should be noted that the orientation can lead to conformational defects along the molecular chains that lead to energy dissipation.

The influence of relative humidity on adhesion and friction was studied in an environmentally controlled chamber. The results are given in Fig. 33.22, which show that for Si(111), Au(111), and DHBp, the adhesive and frictional forces increase with relative humidity. For BPT and BPTC (cross-linked BPT), the adhesive forces slightly increase with relative humidity when the relative humidity is higher than 40%, but it is very interesting that their coefficients of friction decrease slightly in the same range. For HDT, over the testing range, the adhesive and friction force do not seem to be sensitive to the change in relative humidity. The influence of relative humidity on adhesive and frictional forces can be mainly understood by comparing their surface terminal polarization properties and work of adhesion. Meniscus forces are related linearly to the works of adhesion of a surface, which in

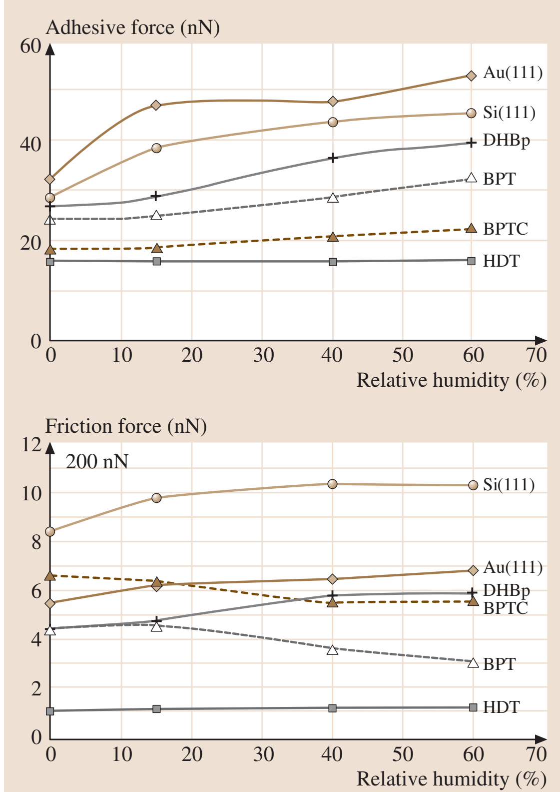

Fig. 33.22 The influence of relative humidity on the adhesive and friction forces at 200 nN of various SAMs studied [33.107]

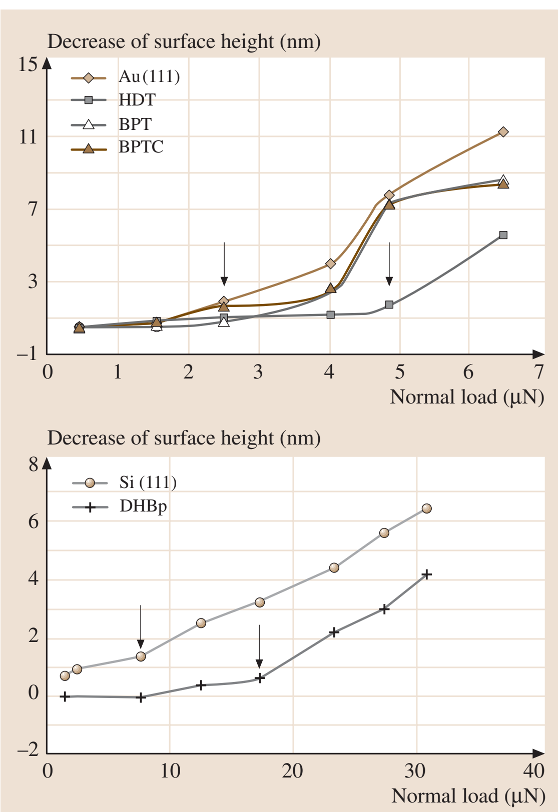

Fig. 33.23 Wear depth as a function of normal load for various SAMs [33.107]

the case of SAMs, is dependent on the surface terminals. Polar surface terminals such as DHBp on Si(111) result in higher work of adhesion and hence higher adhesive forces. Larger adhesive forces result in higher friction forces. Nonpolar surface terminals (HDT) have very small work of adhesion and hence low adhesive and friction forces. In higher humidity, water capillary condensation can either increase friction through increased adhesion in the contact zone, or reduce friction through an enhanced water-lubricating effect.

Figure 33.23 shows results of microscale wear tests on SAMs using a diamond tip in an AFM. DHBp on Si(111) shows the best wear resistance. For the SAMs deposited on gold substrate, HDT exhibits the best wear resistance. Scratch tests corroborated the wear results. The wear resistance of SAMs is influenced by the interfacial bond strength, the molecular structure of the spacers, and the substrate hardness. Based on the wear data, the SAMs with high-compliance long carbon chains, in addition to low friction, exhibit the best wear resistance [33.107, 108]. In wear experiments, the wear depth as a function of normal load curves shows critical normal load (Fig. 33.23). Below the critical normal load, SAMs undergo orientation. At the critical load, SAMs wear away from the substrate due to weak interfacial bond strength, while above the critical normal load, severe wear takes place on the substrate, Fig. 33.24.

According to these results, it is suggested that a dual SAM with a compliant layer on a stiff layer, deposited on hydrogenated silicon, may have optimized tribological performance for MEMS/NEMS applications.

33.5.3 Hard Diamond-like Carbon (DLC) Coatings

Hard amorphous carbon (a-C), commonly known as DLC (implying high hardness), coatings are deposited by a variety of deposition techniques including

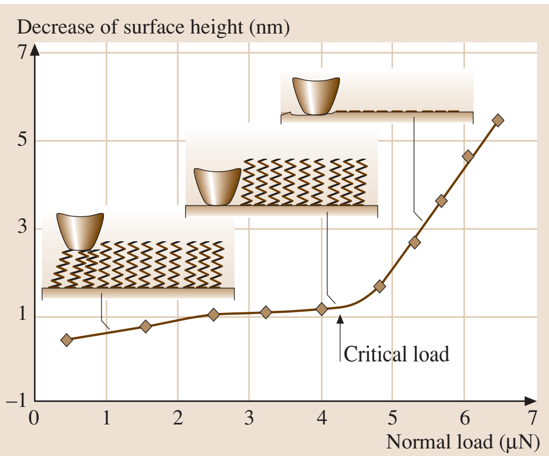

Fig. 33.24 Illustration of the wear mechanism of SAMs with increasing normal load [33.108]

filtered cathodic arc, ion beam, electron cyclotron resonance chemical vapor deposition (ECR-CVD), plasma-enhanced chemical vapor deposition (PECVD), and sputtering [33.83, 99]. These coatings are used in a wide range of applications, including tribological, optical, electronic, and biomedical applications. Ultrathin coatings (3.5 to 10 nm thick) are employed to protect against wear and corrosion in magnetic storage applications (thin-film rigid disks, metal evaporated tapes) and thin-film read/write head (Gillette Mach 3 razor blades, glass windows, and sunglasses). The coatings exhibit low friction, high hardness and wear resistance, chemical inertness to both acids and alkalis, lack of magnetic response, and optical band gap ranging from zero to a few eV, depending on the deposition technique and its conditions. Selected data on DLC coatings relevant for MEMS/NEMS applications are presented in a following section on adhesion measurements.

33.6 Component-Level Studies

33.6.1 Surface Roughness Studies of Micromotor Components

Most of the friction forces resisting motion in the micromotor are concentrated near the rotor-hub interface, where continuous physical contact occurs. Surface roughness of the surfaces usually has a strong influence on the friction characteristics on the micro/nanoscale. A catalog of roughness measurements on various components of a MEMS device does not exist in the literature. Using an AFM, measurements on various component surfaces was made for the first time by *Sundararajan* and *Bhushan* [33.112].

Table 33.6 shows various surface roughness parameters obtained from 5×5 μm scans of the various component surfaces of several unlubricated micromotors using the AFM in tapping mode. A surface with a Gaussian height distribution should have a skewness of zero and kurtosis of three. Although the rotor and stator top surfaces exhibit comparable roughness pa-

rameters, the underside of the rotors exhibits lower RMS roughness and peak-to-valley distance values. More importantly, the rotor underside shows negative skewness and lower kurtosis than the topsides both of which are conducive to high real area of contact and hence high friction [33.54, 55]. The rotor underside also exhibits higher coefficient of microscale friction than the rotor topside and stator, as shown in Table 33.6. Figure 33.25 shows representative surface height maps of the various surfaces of a micromotor measured using the AFM in tapping mode. The rotor underside exhibits varying topography from the outer edge to the middle and inner edge. At the outer edges, the topography shows smaller circular asperities, similar to the topside. The middle and inner regions show deep pits with fine edges that may have been created by the etchants used for etching the sacrificial layer. It is known that etching can affect the surface roughness of surfaces in surface micromachining. The residence time of the etchant near the inner region is high, responsible for larger pits. Figure 33.26 shows roughness of the surface directly beneath the rotors (the base polysilicon layer). There appears to be a difference in the roughness between the portion of this surface that was initially underneath the rotor (region B) during fabrication and the portion that was away from the rotor and hence always exposed (region A). The former region shows lower roughness than the latter region. This suggests that the surfaces at the rotor-hub interface that come into contact at the end of the fabrication process exhibit large real areas of contact that result in high friction.

33.6.2 Adhesion Measurements

Surface force apparatus (SFA) and AFMs are used to measure adhesion between two surfaces on micro- to nanoscales. In the SFA, the adhesion of liquid films sandwiched between two curved and smooth surfaces is measured. In an AFM, as discussed earlier, adhesion between a sharp tip and the surface of interest is measured. To measure adhesion between two beams in the mesoscopic length scale, a cantilever beam array (CBA) technique is used [33.113, 115–117]. The technique utilizes an array of micromachined polysilicon beams (for Si MEMS applications) anchored to the substrate at one end and with different lengths parallel to the surface. It relies on the peeling and detachment of cantilever beams. Change in free energy, or reversible work done to separate unit areas of two surfaces from contact is called work of adhesion. To measure the work of adhesion, electrostatic actuation is used to bring all beams in contact with the substrate, Fig. 33.27 [33.113, 117]. Once the actuation force is removed, the beams begin to peel themselves off the substrate, which can be observed with an optical interference microscope. For beams shorter than a characteristic length, the so-called detachment length, their stiffness is sufficient to completely free them from the substrate underneath. Beams larger than the detachment length remain adhered. The beams at the transition region start to detach and remain attached to the substrate just at the tips. For this case, by equating the elastic energy stored within the beam and the beam-substrate interfacial energy, the work of adhesion, W_{ad}, can be calculated by the following equation [33.117]:

$$W_{ad} = \frac{3Ed^2t^3}{8l_d^4} , \qquad (33.1)$$

where E is the Young's modulus of the beam, d is the spacing between the undeflected beam and the substrate, t is the beam thickness, and l_d is the detachment length. The technique has been used to screen methods for adhesion reduction in polysilicon microstructures.

To measure adhesion, friction, and wear between two microcomponents, a microtriboapparatus has been used. Figure 33.28 shows a schematic of a microtriboapparatus capable of adopting MEMS components [33.114]. In this apparatus, an upper specimen mounted on a soft cantilever beam comes in contact with a lower specimen mounted on a lower specimen holder. The apparatus consists of two piezos (x- and z-piezos), and four fiber optic sensors (x- and z-displacement sensors, and x- and z-force sensors). For adhesion and friction studies, z- and x-piezos are used to bring the upper and lower specimens in contact and to apply a relative motion in the lateral direction, respectively. The x- and z-displacement sensors are used to measure the lateral position of the

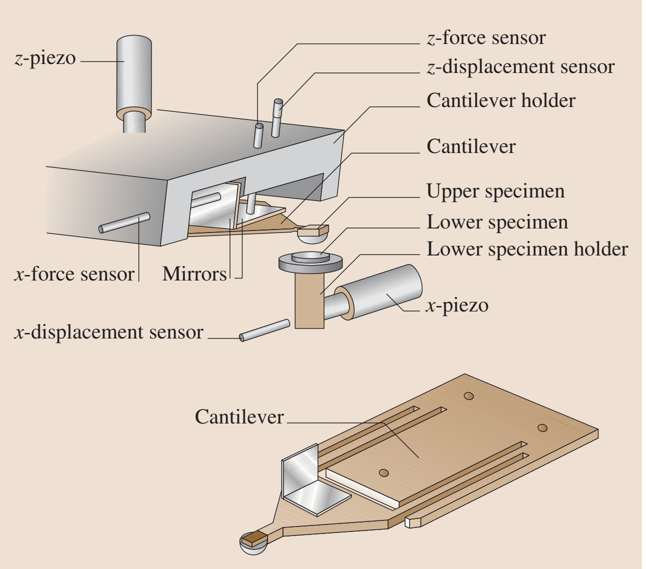

Fig. 33.28 Schematic of the microtriboapparatus, including specially designed cantilever (with two perpendicular mirrors attached on the end), lower specimen holder, two piezos (x- and z-piezos), and four fiber optic sensors (x- and z-displacement sensors and x- and z-force sensors) [33.114]

lower specimen and vertical position of the upper specimen, respectively. The x- and z-force sensors are used to measure friction force and normal load/adhesive force between these two specimens, respectively, by monitoring the deflection of the cantilever.

As most of the MEMS/NEMS devices are fabricated from silicon, the study of silicon-on-silicon contacts is important. This contact was simulated by a flat single-crystal Si(100) wafer (phosphorus doped) specimen sliding against a single crystal Si(100) ball (1 mm in diameter, 5×10^{17} atoms/cm^3 boron doped) mounted on a stainless steel cantilever [33.114, 118]. Both of them have a native oxide layer on their surfaces. The other materials studied were 10-nm-thick DLC deposited by filtered cathodic arc deposition on Si(100), 2.3-nm-thick chemically bonded PFPE (Z-DOL, BW) on Si(100), and hexadecane thiol (HDT) monolayer on evaporated Au(111) film to investigate their anti-adhesion performance.

It is well-known that in the computer rigid disk drives, the adhesive force increases rapidly with an increase in rest time between a magnetic head and a magnetic disk [33.35]. Considering that adhesion and friction are the major issues that lead to the failure of MEMS/NEMS devices, the rest time effect on microscale on Si(100), DLC, PFPE, and HDT was studied, and the results are summarized in Fig. 33.29a. It is found that the adhesive force of Si(100) increases logarithmically with the rest time to a certain equilibrium time ($t = 1{,}000$ s), after which it remains constant. Figure 33.29a also shows that the adhesive force of DLC, PFPE, and HDT does not change with rest time. Single-asperity contact modeling of the dependence of meniscus force on the rest time has been carried out by *Chilamakuri* and *Bhushan* [33.119], and the modeling results (Fig. 33.29b) verify experimental observations. Due to the presence of thin film adsorbed water on Si(100), meniscus forms around the contacting asperities and grows with time until equilibrium occurs, which causes the rest time effect on its adhesive force. The adhesive forces of DLC, PFPE, and HDT do not change with rest time, which suggests that either water meniscus is not present on their surfaces, or it does not increase with time.

The measured adhesive forces of Si(100), DLC, PFPE, and HDT at rest time of 1 s are summarized in Fig. 33.30. It shows that the presence of solid films of DLC, PFPE, and HDT greatly reduces the adhesive force of Si(100), whereas HDT film has the lowest adhesive force. It is well-known that the native oxide layer (SiO_2) on the top of Si(100) wafer exhibits hydrophilic properties, and water molecules produced by capillary condensation of water vapor from the environment can be adsorbed easily on this surface. The condensed water will form meniscus as the upper specimen approaches the lower specimen surface. The meniscus force is a major contributor to the adhesive force. In the case of DLC, PFPE, and HDT, the films are found to be hydrophobic based on contact angle measurements, and the amount of condensed water vapor is low compared to that on Si(100). It should be noted that the measured adhesive force is generally higher than that measured in AFM,

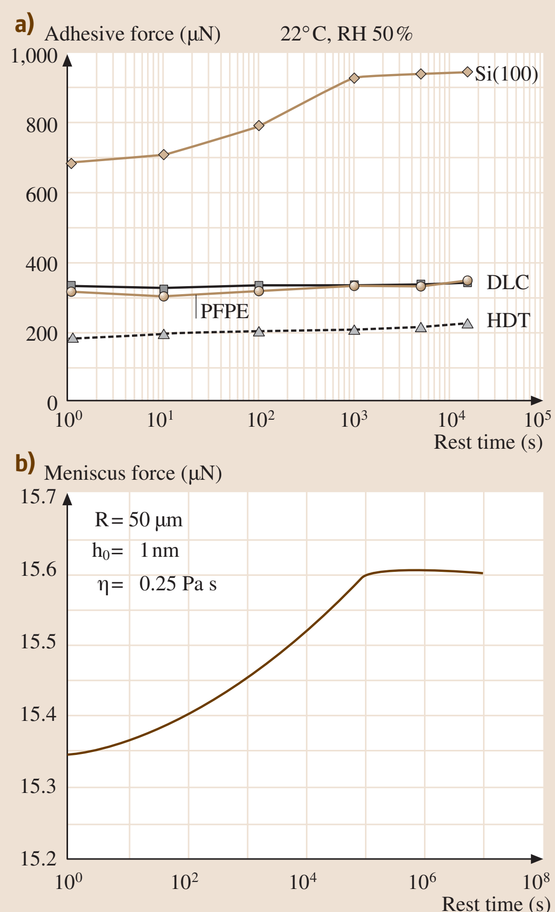

Fig. 33.29 (a) The influence of rest time on the adhesive force of Si(100), DLC, chemically bonded PFPE, and HDT, and **(b)** single asperity contact modeling results of the rest time effect on the meniscus force for an asperity of R in contact with a flat surface with a water-film thickness of h_0 and absolute viscosity of η_0 [33.119]

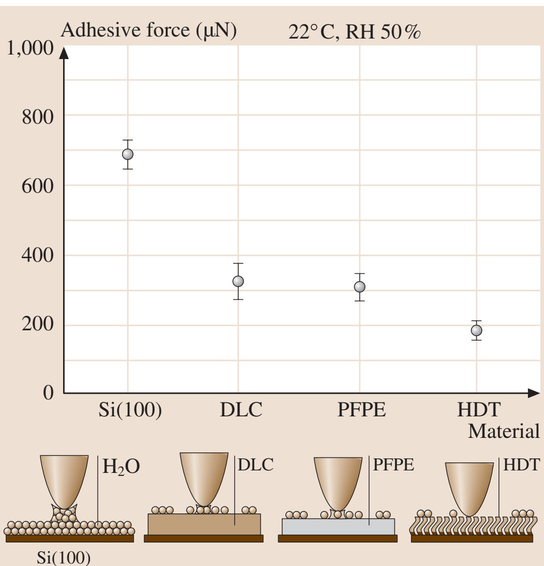

Fig. 33.30 Adhesive forces of Si(100), DLC, chemically bonded PFPE, and HDT at ambient conditions and a schematic showing the relative size of water meniscus on different specimens

because the larger radius of the Si(100) ball compared to that of an AFM tip induces larger meniscus and van der Waals forces.

To investigate the velocity effect on friction, the friction force as a function of velocity was measured and is summarized in Fig. 33.31a. It indicates that for Si(100) the friction force initially decreases with increasing velocity until equilibrium occurs. Figure 33.31a also indicates that the velocity almost has no effect on the friction properties of DLC, PFPE, and HDT. This implies that the friction mechanisms of DLC, PFPE, and HDT do not change with the variation in velocity. For Si(100), at high velocity, the meniscus is broken and does not have enough time to rebuild. In addition, it is believed that tribochemical reaction plays an important role. The high velocity leads to tribochemical reactions of Si(100), which has native oxide SiO_2, with water molecules to form a $Si(OH)_4$ film. This film is removed and continuously replenished during sliding. The $Si(OH)_4$ layer at the sliding surface is known to be of low shear strength. The breaking of the water meniscus and the formation of a $Si(OH)_4$ layer result in a decrease in friction force of Si(100). For DLC, PFPE, and HDT, surfaces exhibit hydrophobic properties and can only adsorb a few water molecules in ambient conditions. The above mentioned meniscus breaking and tribochemical reaction mechanisms do not exist for these films. Therefore, their friction force does not change with velocity.

The influence of relative humidity was studied in an environmentally controlled chamber. The adhesive and friction forces were measured at increasing relative humidity, and the results are summarized in Fig. 33.31b. The figure shows that for Si(100), the adhesive force increases with relative humidity, but the adhesive forces of DLC and PFPE only show slight increases when humidity is higher than 45%, while the adhesive force of HDT does not change with humidity. Figure 33.31b also shows that for Si(100), the friction force increases with a relative humidity increase up to 45%, and then it shows a slight decrease with a further increase in the relative humidity. For PFPE, there is an increase in the friction force when humidity is higher than 45%. In the whole testing range, relative humidity does not have any apparent influence on the friction properties of DLC and HDT. In the case of Si(100), the initial increase of relative humidity up to 45% causes more adsorbed water molecules and forms bigger water meniscus, which leads to an increase of friction force. But at a very high humidity of 65%, large quantities of adsorbed water can form a continuous water layer that separates the tip and sample surfaces and acts as a kind of lubricant, which causes a decrease in the friction force. For PFPE, dewetting of lubricant film at humidity larger than 45% results in an increase in the adhesive and friction forces. DLC and HDT surfaces show hydrophobic properties, and increasing relative humidity does not play much of a role in their friction forces.

The influence of temperature was studied using a heated stage. The adhesive force and friction force were measured at increasing temperatures from 22 °C to 125 °C. The results are presented in Fig. 33.31c. It shows that once the temperature is higher than 50 °C, increasing temperature causes a significant decrease in adhesive and friction forces of Si(100) and a slight decrease in the cases of DLC and PFPE. But the adhesion and friction forces of HDT do not show any apparent change with test temperature. At high temperature, desorption of water, and reduction of surface tension of water lead to the decrease of adhesive and friction forces of Si(100), DLC, and PFPE. However, in the case of HDT film, as only a few water molecules are adsorbed on the surface, the above mentioned mechanisms do not play a big role. Therefore, the adhesive and friction forces of HDT do not show any apparent change with temperature. Figure 33.31 shows that in the whole ve-

Fig. 33.31a–c The influence of **(a)** sliding velocity on the friction forces, **(b)** relative humidity on the adhesive and friction forces, and **(c)** temperature on the adhesive and friction forces of Si(100), DLC, chemically bonded PFPE, and HDT

locity, relative humidity, and temperature test range, the adhesive forces and friction forces of DLC, PFPE, and HDT are always smaller than that of Si(100), whereas HDT has the smallest value.

To summarize, several methods can be used to reduce adhesion in microstructures. MEMS surfaces can be coated with hydrophobic coatings such as PFPEs, SAMs, and passivated DLC coatings. It should be noted that other methods to reduce adhesion include the formation of dimples on the contact surfaces to reduce contact area [33.10, 54, 55, 116, 117]. Furthermore, an increase in hydrophobicity of the solid surfaces (high contact angle approaching 180°) can be achieved by using surfaces with suitable roughness, in addition to lowering their surface energy [33.120, 121]. The hydrophobicity of surfaces is dependent on a subtle interplay between surface chemistry and mesoscopic topography. The self-cleaning mechanism, or so-called "Lotus-effect", is closely related to the ultra-hydrophobic properties of these biological surfaces, which usually show micro-sculptures in specific dimensions.

33.6.3 Static Friction Force (Stiction) Measurements in MEMS

In MEMS devices involving parts in relative motion to each other, such as micromotors, large friction forces become the limiting factor to their successful operation and reliability. It is generally known that most micromotors cannot be rotated as manufactured and require some form of lubrication. It is therefore critical to determine the friction forces present in such MEMS devices. To measure in situ the static friction of a rotor-bearing interface in a micromotor, *Tai* and *Muller* [33.122] measured the starting torque (voltage) and pausing position for different starting positions under a constant-bias voltage. A friction-torque model was used to obtain the coefficient of static friction. To measure the in situ kinetic friction of the turbine and gear structures, *Gabriel* et al. [33.123] used a laser-based measurement system to monitor the steady-state spins and decelerations. *Lim* et al. [33.124] designed and fabricated a polysilicon microstructure to in situ measure

the static friction of various films. The microstructure consisted of a shuttle suspended above the underlying electrode by a folded beam suspension. A known normal force was applied, and lateral force was measured to obtain the coefficient of static friction. *Beerschwinger* et al. developed a cantilever-deflection rig to measure friction of LIGA-processed micromotors [33.125, 126]. Table 33.7 presents static friction coefficients of various MEMS devices evaluated by various researchers. Most of these techniques employ indirect methods to determine the friction forces, or involve fabrication of complex structures.

A novel technique to measure the static friction force (stiction) encountered in surface micromachined polysilicon micromotors using an AFM has been developed by *Sundararajan* and *Bhushan* [33.112]. Continuous physical contact occurs during rotor movement (rotation) in the micromotors between the rotor and lower hub flange. In addition, contact occurs at other locations between the rotor and the hub surfaces and between the rotor and the stator. Friction forces will be present at these contact regions during motor operation. Although the actual distribution of these forces is not known, they can be expected to be concentrated near the hub, where there is continuous contact. If we, therefore, represent the static friction force of the micromotor as a single force F_s acting at point P_1 (as shown in Fig. 33.32a), then the magnitude of the frictional torque about the center of the motor (O) that must be overcome before rotor movement can be initiated is:

$$T_s = F_s l_1 \,, \tag{33.2}$$

where l_1 is the distance OP_1, which is assumed to be the average distance from the center at which the friction force F_s occurs. Now consider an AFM tip moving against a rotor arm in a direction perpendicular to the long axis of the cantilever beam (the rotor arm edge closest to the tip is parallel to the long axis of the cantilever beam), as shown in Fig. 33.32a. When the tip encounters the rotor at point P_2, the tip will twist, generating a lateral force between the tip and the rotor (event A in Fig. 33.32b). This reaction force will generate a torque about the center of the motor. Since the tip is trying to move farther in the direction shown, the tip will continue to twist to a maximum value at which the lateral force between the tip and the rotor becomes high enough such that the resultant torque T_f about the center of the motor equals the static friction torque T_s. At this point, the ro-

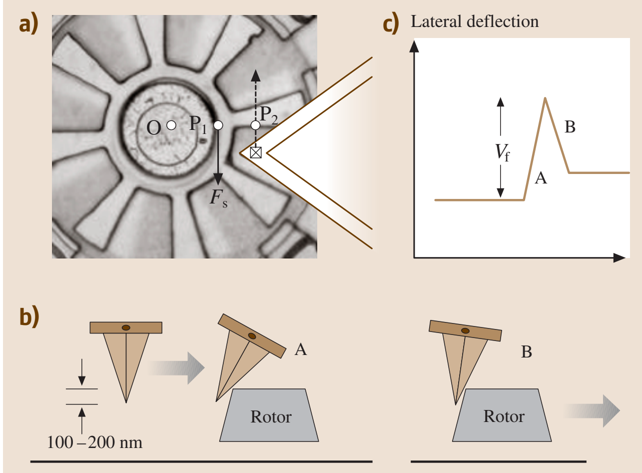

Fig. 33.32 **(a)** Schematic of the technique used to measure the force, F_s, required to initiate rotor movement using an AFM/FFM. **(b)** As the tip is pushed against the rotor, the lateral deflection experienced by the rotor due to the twisting of the tip prior to rotor movement is a measure of static friction force, F_s, of the rotors. **(c)** Schematic of lateral deflection expected from the above mentioned experiment. The peak V_f is related to the state of the rotor [33.112]

Table 33.7 Published data on coefficient of static friction measurements of MEMS devices and structures

Reference	Test method	Device/structure	Material pairs	Environment	Coefficient of static friction
[33.122]	Starting voltage	IC-processed micromotor	$PolySi/Si_3N_4$	Air	0.20–0.40
[33.124]	Electrostatic loading	Comb-drive microstructure	PolySi/PolySi $PolySi/Si_3N_4$	Air	4.9 ± 1.0 2.5 ± 0.5
[33.127]	Pull-off force	Silicon microbeams	SiO_2/SiO_2	Air	2.1 ± 0.8
[33.126]	Cantilever/fiber deflection rig	LIGA micromotors	Ni/Alumina	Air	0.6–1.2

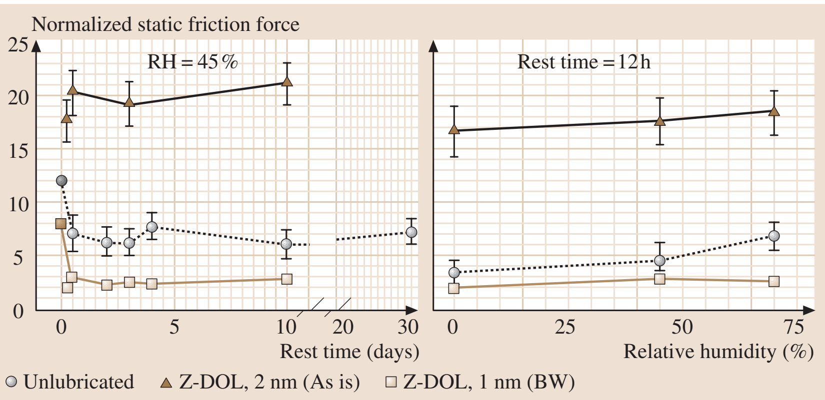

Fig. 33.33 Static friction force values of unlubricated motors and motors lubricated using PFPE lubricants, normalized over the rotor weight, as a function of rest time and relative humidity. Rest time is defined as the time elapsed between a given experiment and the first experiment in which motor movement was recorded (time 0). The motors were allowed to sit at a particular humidity for 12 h prior to measurements [33.112]

tor will begin to rotate, and the twist of the cantilever decreases sharply (event B in Fig. 33.32b). The twist of the cantilever is measured in the AFM as a change in the lateral deflection signal (in volts), which is the underlying concept of friction force microscopy (FFM). The change in the lateral deflection signal corresponding to the above mentioned events as the tip approaches the rotor is shown schematically in Fig. 33.32b. The value of the peak V_f is a measure of the force exerted on the rotor by the tip just before the static friction torque is matched and the rotor begins to rotate.

Using this technique, the viability of PFPE lubricants for micromotors has been investigated and the effect of humidity on the friction forces of unlubricated and lubricated devices was studied as well. Figure 33.33 shows static friction forces normalized over the weight of the rotor of unlubricated and lubricated micromotors as a function of rest time and relative humidity. Rest time here is defined as the time elapsed between the first experiment conducted on a given motor (solid symbol at time zero) and subsequent experiments (open symbols). Each open symbol data point is an average of six measurements. It can be seen that for the unlubricated motor and the motor lubricated with a bonded layer of Z-DOL (BW), the static friction force is highest for the first experiment and then drops to an almost constant level. In the case of the motor with an as-is mobile layer of Z-DOL, the values remain very high up to 10 days after lubrication. In all cases, there is negligible difference in the static friction force at 0% and 45% RH. At 70% RH, the unlubricated motor exhibits a substantial increase in the static friction force, while the motor with bonded Z-DOL shows no increase in static friction force due to the hydrophobicity of the lubricant layer. The motor with an as-is mobile layer of the lubricant shows consistently high values of static friction force that vary little with humidity.

33.6.4 Mechanisms Associated with Observed Stiction Phenomena in Micromotors

Figure 33.34 summarizes static friction force data for two motors, M1 and M2, along with schematics of the meniscus effects for the unlubricated and lubricated surfaces. Capillary condensation of water vapor from the environment results in the formation of meniscus bridges between contacting and near-contacting asperities of two surfaces in close proximity to each other, as shown in Fig. 33.34. For unlubricated surfaces, more menisci are formed at higher humidity, resulting in a higher friction force between the surfaces. The formation of meniscus bridges is supported by the fact that the static friction force for unlubricated motors increases at high humidity (Fig. 33.34). Solid bridging may occur near the rotor-hub interface due to silica residues after the first etching process. In addition, the drying process after the final etch can result in liquid bridging formed by the drying liquid due to meniscus force at these areas [33.54,55,113,116]. The initial static friction force therefore will be quite high, as evidenced by the solid data points in Fig. 33.34. Once the first movement of the rotor permanently breaks these solid and liquid bridges, the static friction force of the motors will drop (as seen in Fig. 33.34) to a value dictated predominantly by the adhesive energies of rotor and hub surfaces, the real area of contact between these surfaces and meniscus forces due to water vapor in the air, at which point, the effect of lubricant films can be observed. Lubrication with a mobile layer, even a thin one, results in very high static friction forces

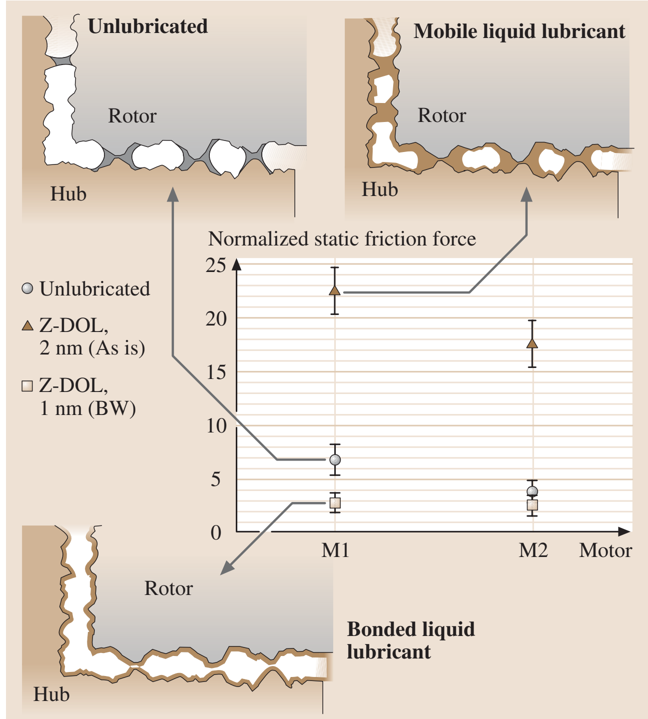

Fig. 33.34 Summary of effect of liquid and solid lubricants on static friction force of micromotors. Despite the hydrophobicity of the lubricant used (Z-DOL), a mobile liquid lubricant (Z-DOL as is) leads to very high static friction force due to increased meniscus forces, whereas a solid-like lubricant (bonded Z-DOL, BW) appears to provide some amount of reduction in static friction force

due to meniscus effects of the lubricant liquid itself at and near the contact regions. It should be noted that a motor submerged in a liquid lubricant would result in a fully flooded lubrication regime. In this case, there is no meniscus contribution and only the viscous contribution to the friction forces would be relevant. However, submerging the device in a lubricant may not be a practical method. A solid-like hydrophobic lubricant layer (such as bonded Z-DOL) results in favorable friction characteristics of the motor. The hydrophobic nature of the lubricant inhibits meniscus formation between the contact surfaces and maintains low friction even at high humidity (Fig. 33.34). This suggests that solid-like hydrophobic lubricants are ideal for lubrication of MEMS, while mobile lubricants result in increased values of static friction force.

34. Mechanical Properties of Micromachined Structures

To be able to accurately design structures and make reliability predictions, in any field it is necessary first to know the mechanical properties of the materials that make up the structural components. In the fields of microelectromechanical systems (MEMS) and nanoelectromechanical systems (NEMS), the devices are necessarily very small. The processing techniques and microstructures of the materials in these devices may differ significantly from bulk structures. Also, the surface-area-to-volume ratio in these structures is much higher than in bulk samples, and so the surface properties become much more important. In short, it cannot be assumed that mechanical properties measured using bulk specimens will apply to the same materials when used in MEMS and NEMS. This chapter will review the techniques that have been used to determine the mechanical properties of micromachined structures, especially residual stress, strength, and Young's modulus. The experimental measurements that have been performed will then be summarized, in particular the values obtained for polycrystalline silicon (polysilicon).

34.1 Measuring Mechanical Properties of Films on Substrates

In order to determine accurately the mechanical properties of very small structures, it is necessary to test specimens made from the same materials, processed in the same way, and of the same approximate size. Not surprisingly it is often difficult to handle specimens this small. One solution is to test the properties of films remaining on substrates. Micro- and nanomachined structures are typically fabricated from films that are initially deposited onto a substrate, are subsequently patterned and etched into the appropriate shapes, and then finally released from the substrate. If the testing is performed on the continuous film, before patterning and release, the substrate can be used as an effective "handle" for the specimen (in this case, the film). Of course since the films are adhered to the substrate, the types of tests possible are severely limited.

34.1.1 Residual Stress Measurements

One common measurement easily performed on films attached to substrates is residual film stress. The curvature of the substrate is measured before and after film deposition. Curvature can be measured in a number of ways. The most common technique is to scan a laser across the surface (or scan the substrate beneath the laser) and detect the angle of the reflected signal. Alternatively, profilometry, optical interferometry, or even atomic force microscopy can be used. As expected, tools that map a surface or perform multiple linear scans can give more accurate readings than tools that measure only a single scan.

Assuming that the film is thin compared to the substrate, the average residual stress in the film, σ_f, is given

by the Stoney equation,

$$\sigma_f = \frac{1}{6}\frac{E_s}{(1-\nu_s)}\frac{t_s^2}{t_f}\left(\frac{1}{R_1}-\frac{1}{R_2}\right), \quad (34.1)$$

where the subscripts f and s refer to the film and substrate, respectively; t is thickness, E is Young's modulus, ν is Poisson's ratio, and R is radius of curvature before (R_1) and after (R_2) film deposition [34.2]. For the typical (100)-oriented silicon substrate, $E/(1-\nu)$ (also known as the biaxial modulus) is equal to 180.5 GPa, independent of in-plane rotation [34.3]. This investigation can be performed on the as-deposited film or after any subsequent annealing step, provided no changes occur to the substrate.

This measurement will reveal the average residual stress of the film. Typically, however, the residual stresses of deposited films will vary through the film thickness. One way to detect this, using substrate curvature techniques, is to etch away a fraction of the film and repeat the curvature measurement. This can be iterated any number of times to obtain a residual stress profile for the film [34.4]. Alternatively, tools have been designed to measure the substrate curvature during the deposition process itself, to obtain information on how the stresses evolve [34.5].

An additional feature of some of these tools is the ability to heat the substrates while performing the stress measurement. An example of the results obtained in such an experiment is shown in Fig. 34.1 [34.1], for an aluminum film on a silicon substrate. The slope of the heating curve gives the difference in thermal expansion between the film and the substrate. When the heating curve changes slope and becomes nearly horizontal, the yield strength of the film has been reached.

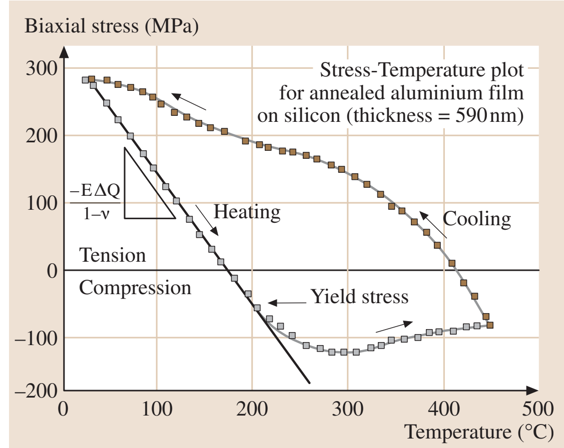

Fig. 34.1 Typical results for residual stress as a function of temperature for an aluminum film on a silicon substrate [34.1]. The stresses were determined by measuring the curvature of the substrate before and after film deposition, using the reflected signal of a laser scanned across the substrate surface

34.1.2 Mechanical Measurements Using Nanoindentation

Aside from residual stress, it is difficult to measure mechanical properties of films adhered to substrates without the measurement being affected by the presence of the substrate. Recent developments in nanoindentation equipment have allowed this technique to be used in some cases. With specially designed tools, indentation can be performed using very low loads. If the films being investigated are thick and rigid enough, measurements can be made that are not influenced by the presence of the substrate. Of course, this can be verified by depositing the same film onto different substrates. By continuously monitoring the displacement as well as the load during indentation, a variety of properties can be measured, including hardness and Young's modulus [34.6]. This area is covered in more detail in a separate chapter.

For brittle materials, cracks can be generated by indentation, and strength information can be gathered. But the exact stress fields created during the indentation process are not exactly known, and, therefore, quantitative values for strength are difficult to determine. Anisotropic etching of single crystal silicon has been done to create 30-μm-tall structures that were then indented to examine fracture toughness [34.7], however this is not possible with most materials.

34.2 Micromachined Structures for Measuring Mechanical Properties

Certainly the most direct way to measure the mechanical properties of small structures is to fabricate structures that would be conducive to such tests. Fabrication techniques are sufficiently advanced that virtually any design can be realized, at least in two dimensions. Two basic types of devices are used for mechanical property testing: "passive" structures and "active" structures.

34.2.1 Passive Structures

As mentioned previously, the main difficulty in testing very small specimens is in handling. One way to circumvent this problem is by using passive structures. These structures are designed to act as soon as they are released from the substrate and to provide whatever information they are designed to supply without further manipulation. For all of these passive structures, the forces acting on them come from the structural materials' own internal residual stresses. For devices on the micron scale or smaller, gravitational forces can be neglected, and therefore internal stresses are the only source of actuation force.

Stress Measurements

Since the internal residual stresses act upon the passive devices when they are released, it is natural to design a device that can be used to measure residual stresses. One such device, a rotating microstrain gauge, is shown in Fig. 34.2. There are many different microstrain gauge designs, but all operate under the same principle. In Fig. 34.2a, the large pads, labeled A, will remain anchored to the substrate when the rest of the device is released. Upon release, the device will expand or contract in order to relieve its internal residual stresses. A structure under tension will contract, and a structure under compression will expand. For the structure in Fig. 34.2, a compressive stress will cause the legs to lengthen. Since the two opposing legs are not attached to the central beam at the same point but are offset, they will cause the central beam to rotate when they expand. The device in Fig. 34.2 contains two independent gauges that point to one another. At the ends of the two central beams are two parts of a Vernier scale. By observing this scale, one can measure the rotation of the beams.

If the connections between the legs and the central beams were simple pin connections, the strain, ε, of the legs (the fraction of expansion or contraction) could be determined simply by the measured rotation and the geometry of the device, namely

$$\varepsilon = \frac{d_{\text{beam}} d_{\text{offset}}}{2 L_{\text{central}} L_{\text{leg}}} , \quad (34.2)$$

where d_{beam} is the lateral deflection of the end of one central beam, d_{offset} is the distance between the connections of the opposing legs, L_{central} is the length of the central beam (measured to the center point between the leg connections), and L_{leg} is the length of the leg. But since the entire device was fabricated from a single polysilicon film, this cannot be the case; there must be some bending occurring at the connections. As a result, to get an accurate determination of the strain relieved upon release, finite element analysis (FEA) of the struc-

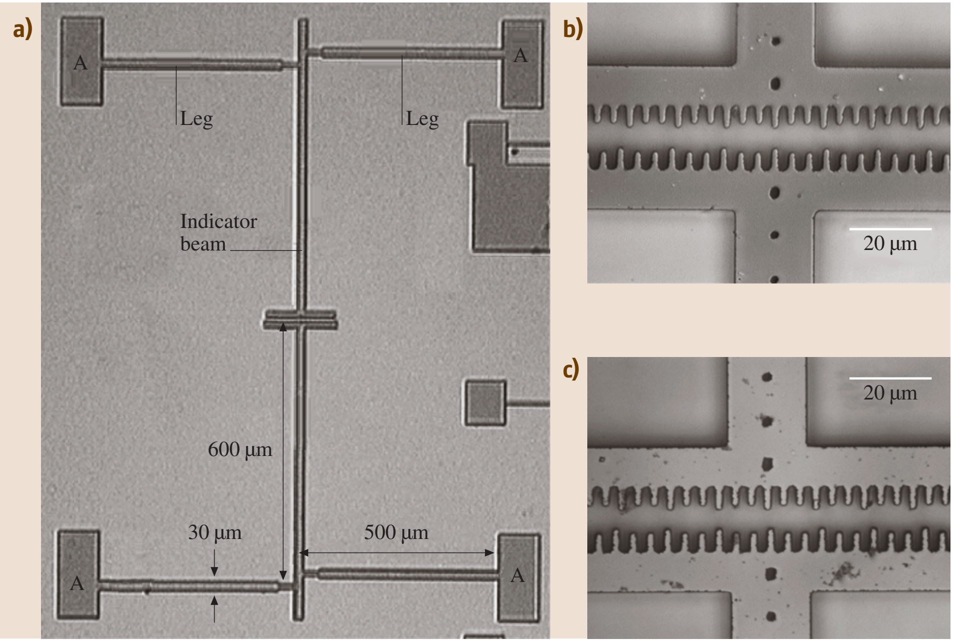

Fig. 34.2 **(a)** Microstrain gauge fabricated from polysilicon. **(b)** shows a close-up of the Vernier scale before release, and **(c)** shows the same area after release

ture must be performed. This is a common situation for microdevices. FEA is a powerful tool in determining the displacements and stresses of nonideal geometries. One drawback is that Young's modulus of the material must be known in order to do the FEA as well as to convert the measured strain into a stress value. But Young's moduli for many micromachined materials are known or can be measured using other techniques.

Other devices, besides rotating strain gauges, are designed to measure residual stresses. One of the most simple is a doubly clamped beam, a long, narrow beam of constant width and thickness that is anchored to the substrate at both ends. If the beam contains a tensile stress, it will remain straight. But if the beam contains a compressive stress, it will buckle if its length exceeds a critical value, l_{cr}, according to the Euler buckling criterion [34.8],

$$\varepsilon_r = -\frac{\pi^2}{3}\left(\frac{h}{l_{cr}}\right)^2 , \tag{34.3}$$

where ε_r is the residual strain in the beam, and h is the width or thickness of the beam, whichever is less. To determine the residual strain, a series of doubly clamped beams are fabricated of varying lengths. In this way, the critical length, l_{cr}, for buckling can be deduced after release. One problem with this technique is that during the release process, any turbulence in the solution will lead to enhanced buckling of beams, and a low value for l_{cr} will be obtained.

For films with tensile stresses, a similar analysis can be done using ring-and-beam structures, also called Guckel rings after their inventor, Henry Guckel. A schematic of this design is shown in Fig. 34.3 [34.8]. A tensile stress in the outer ring will cause it to contract. This will lead to a compressive stress in the central beam, even though the material was originally tensile before release. The amount of compression in the central beam can be determined analytically from the geometry of the device and the residual strain of the material. Again, by changing the length of the central beam, the l_{cr} will be determined, and then the residual strain can be deduced.

Stress Gradient Measurements

For structures fabricated from thin deposited films, the stress gradient can be just as important as the stress itself. Figure 34.4 shows a portion of a silicon microactuator. The device is designed to be completely planar; however, stress gradients in the film cause the structures to bend. This figure illustrates the importance of characterizing and controlling stress gradients, and it also demonstrates that the easiest structure for measuring stress gradients is a simple cantilever beam. By measuring the end deflection δ, of a cantilever beam of length l, and thickness t, the stress gradient, $\mathrm{d}\sigma/\mathrm{d}t$ is determined by [34.9]

$$\frac{\mathrm{d}\sigma}{\mathrm{d}t} = \frac{2\delta}{l^2}\frac{E}{1-\nu} . \tag{34.4}$$

The magnitude of the end deflection can be measured by microscopy, optical interferometry, or any other technique.

Another useful structure for measuring stress gradients is a spiral. For this structure, the end of the spiral not anchored to the substrate will move out-of-plane. Also

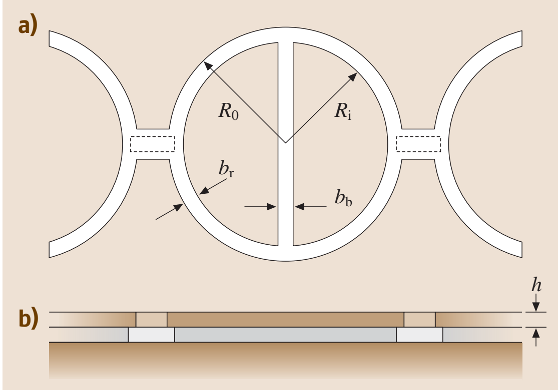

Fig. 34.3a,b Schematic **(a)** top view and **(b)** side view of Guckel ring structures [34.8]. The *dashed lines* in **(a)** indicate the anchors

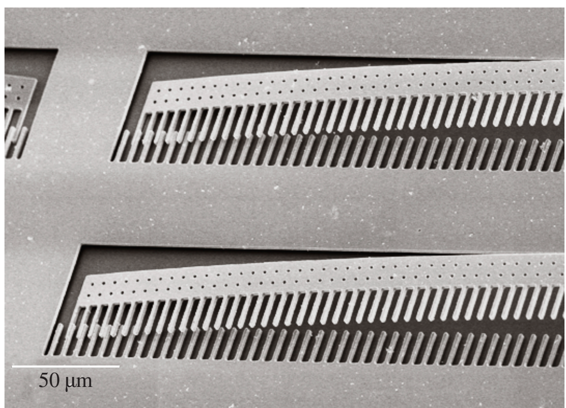

Fig. 34.4 Scanning electron micrograph (SEM) of a portion of a silicon microactuator. Residual stress gradients in the silicon cause the structure to bend

the diameter of the spiral will contract, and the free end of the spiral will rotate when released [34.10].

Strength and Fracture Toughness Measurements

As mentioned above, if a doubly clamped beam contains a tensile stress, it will remain taut when released because it cannot relieve any of its stress by contracting. This tensile stress can be thought of as a tensile load being applied at the ends of the beam. If this tensile load exceeds the tensile strength of the material, the beam will break. Since the tensile stress can be measured, as discussed in the Sect. 34.2.1, this technique can be used to gather information on the strength of materials. Figure 34.5 shows two different beam designs that have been used to measure strength. The device shown in Fig. 34.5a was fabricated from a tensile polysilicon film [34.11]. Different beams were designed with varying lengths of the wider regions (marked l_1 in the figure). In this manner, the load applied to the narrow center beam was varied, even though the entire film contained a uniform residual tensile stress. For l_1 greater than a critical value, the narrow center beam fractured, giving a measurement for the tensile strength of polysilicon.

The design shown in Fig. 34.5b was fabricated from a tensile Si_xN_y film [34.12]. As seen in the figure, a stress concentration was designed into the beam, to ensure the fracture strength would be exceeded. In this case, a notch was etched into one side of the beam. Since the stress concentration is not symmetric with regard to the beam axis, this results in a large bending moment at that position, and the test measures the bend strength of the material. Again, like the beams shown in Fig. 34.5a, the geometry of various beams fabricated from the same film were varied, to vary the maximum stress seen at the notch. By seeing which beams fracture at the stress concentration after release, the strength can be determined.

Through a similar technique but by using an atomically sharp pre-crack instead of a stress concentration, the fracture toughness of a material can be determined. Sharp pre-cracks can be introduced into micromachined structures before release by placing a Vickers indent on the substrate, near the device; the radial crack formed by the indent will propagate into the overlying structure [34.14]. Accordingly, the beam with a sharp pre-crack, shown in Fig. 34.6, was fabricated using polysilicon [34.13]. Due to the stochastic nature of indentation, the initial pre-crack length will vary from beam to beam. Because of this, even though the geometry of the beams remains identical, the stress intensity, K, at the pre-crack tip will vary. Upon release, only those pre-cracks whose K exceeds the fracture toughness of the material, K_{Ic}, will propagate, and in this way upper and lower bounds for K_{Ic} for the material can be determined.

For all of the beams discussed in this section, finite element analysis is required to determine the stress concentrations and stress intensities. Even though approximate analytical solutions may exist for these designs, the actual fabricated structure will not have idealized geometries. For example, corners will never be perfectly sharp, and cracks will never be perfectly straight. This

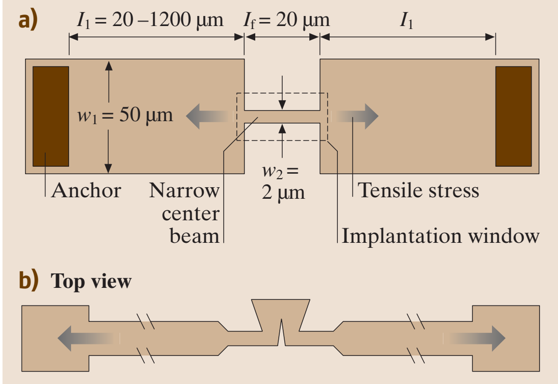

Fig. 34.5a,b Schematic designs of doubly clamped beams with stress concentrations for measuring strength. (a) was fabricated from polysilicon [34.11], and (b) was fabricated from Si_xN_y [34.12]

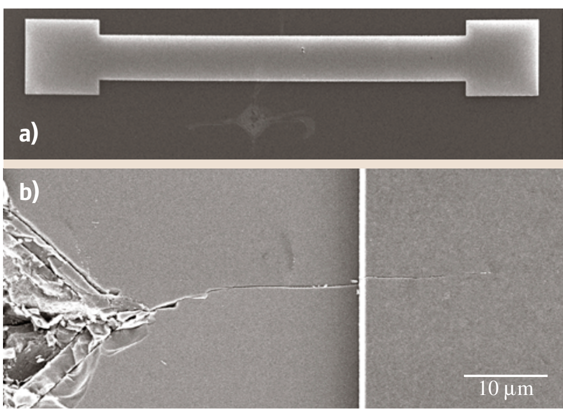

Fig. 34.6 (a) SEM of a 500 µm long polysilicon beam with a Vickers indent placed near its center; (b) higher magnification SEM of the area near the indent showing the pre-crack traveling from the substrate into the beam [34.13]

reinforces the idea that FEA is a powerful tool in determining mechanical properties of very small structures.

34.2.2 Active Structures

As discussed above, it is very convenient to design structures that act upon release to provide information on the mechanical properties of the structural materials. This is not always possible, however. For example, those passive devices just discussed rely on residual stresses to create the changes (rotation or fracture) that occur upon release, but many materials do not contain high residual stresses as deposited, or the processing scheme of the device precludes the generation of residual stresses. Also, some mechanical properties, such as fatigue resistance, require motion in order to be studied. Active devices are therefore used. These are acted upon by a force (the source of this force can be integrated into the device itself or can be external to the device) in order to create a change, and by the response to the force, the mechanical properties are studied.

Young's Modulus Measurements

Young's modulus, E, is a material property critical to any structural device design. It describes the elastic response of a material and relates stress, σ, and strain, ε, by

$$\sigma = E\varepsilon \,. \tag{34.5}$$

In bulk samples, E is often measured by loading a specimen in tension and measuring displacement as a function of stress for a given length. While this is considerably more difficult for small structures, such as those fabricated from thin deposited films, it can be achieved with careful experimental techniques. Figure 34.7 shows the schematic of one such measurement system [34.15]. The fringe detectors in the figure detect the reflected laser signal from two gold lines deposited onto the polysilicon specimen, which act as gage markers. In this manner, the strain in the specimen during loading can be monitored. Besides gold lines, Vickers indents placed in a nickel specimen can also serve as gage markers [34.16], or a speckle interferometry technique [34.17] can be used to determine strain in the specimen. Once the stress-versus-strain behavior is measured, the slope of the curve is equal to E.

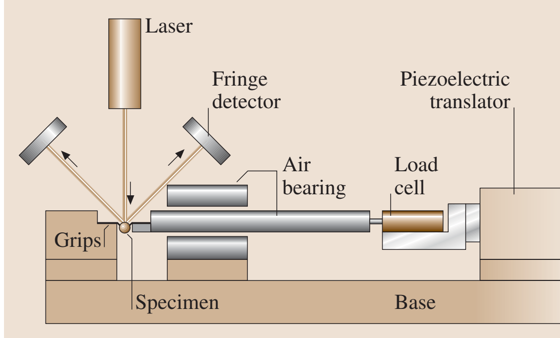

Fig. 34.7 Schematic of a measurement system for tensile loading of micromachined specimens [34.15]

In addition to the tensile test, Young's modulus can be determined by other measures of stress-strain behavior. As seen in Fig. 34.8, a cantilever beam can be bent by pushing on the free end with a nanoindenter [34.18]. The nanoindenter can monitor the force applied and the displacement, and simple beam theory can convert the displacement into strain to obtain E. A similar technique, shown schematically in Fig. 34.9 [34.19], involves pulling downward on a cantilever beam by means of an electrostatic force. An electrode is fabricated into the substrate beneath the cantilever beam, and a voltage is applied between the beam and the bottom electrode. The force acting on the beam is equal to the electrostatic force corrected to include the effects of fringing fields acting on the sides of the beam, namely

$$F(x) = \frac{\varepsilon_0}{2}\left(\frac{V}{g+z(x)}\right)^2\left(1+\frac{0.65[g+z(x)]}{w}\right) \,, \tag{34.6}$$

where $F(x)$ is the electrostatic force at x, ε_0 is the dielectric constant of air, g is the gap between the beam and the bottom electrode, $z(x)$ is the out-of-plane deflection of the beam, w is the beam width, and V is the applied voltage [34.19]. In this work, the deflection of the beam as a function of position is measured using optical interferometry. These measurements combine to give stress-strain behavior for the cantilever beam. An extension of this technique uses doubly clamped beams instead of cantilever beams. In this case, the deflection of the beam at a given electrostatic force depends on the residual stress in the material as well as Young's modulus. This method can also be used, therefore, to measure residual stresses in doubly clamped beams.

Another device possible to fabricate from a thin film and also possible to use for investigating stress-strain behavior is a suspended membrane, seen in Fig. 34.10 [34.20]. As shown in the schematic figure, the membrane is exposed to an elevated pressure on one side, causing it to bulge in the opposite direction. The deflection of the membrane is measured by optical or other techniques and related to the strain in the mem-

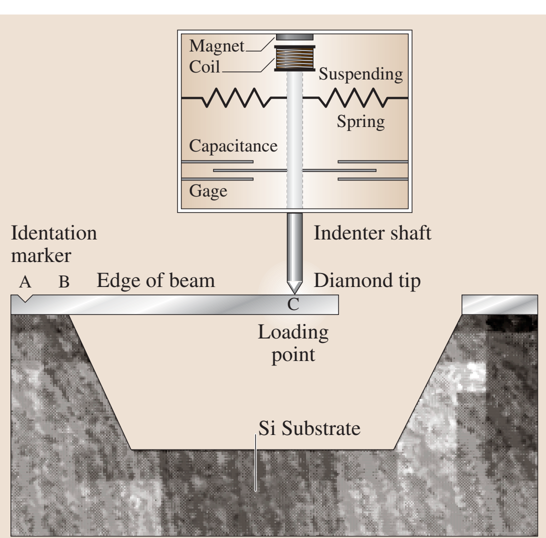

Fig. 34.8 Schematic of a nanoindenter loading mechanism pushing on the end of a cantilever beam [34.18]

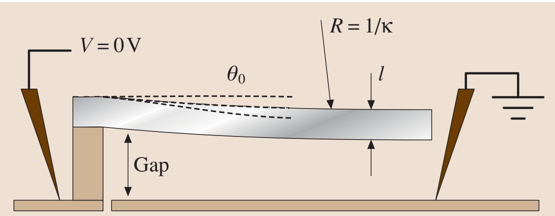

Fig. 34.9 Schematic of a cantilever beam bending test using an electrostatic voltage to pull the beam toward the substrate [34.19]

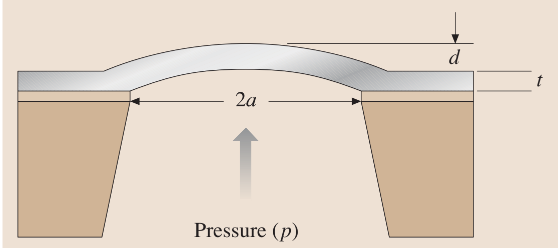

Fig. 34.10 Schematic cross section of a microfabricated membrane [34.20]

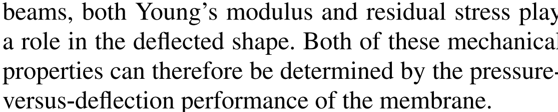
brane. These membranes can be fabricated in any shape, typically square or circular. Both analytical solutions and finite element analyses have been done to relate the deflection to the strain. Like the doubly clamped



beams, both Young's modulus and residual stress play a role in the deflected shape. Both of these mechanical properties can therefore be determined by the pressure-versus-deflection performance of the membrane.

Another measurement besides stress-strain behavior that can reveal Young's modulus of a material is the determination of the natural resonance frequency. For a cantilever, the resonance frequency, f_r, for free undamped vibration is given by

$$f_r = \frac{\lambda_i^2 t}{4\pi l^2}\left(\frac{E}{3\rho}\right)^{1/2} , \qquad (34.7)$$

where ρ, l, and t are density, length, and thickness of the cantilever; λ_i is the eigenvalue, where i is an integer that describes the resonance mode number; for the first mode $\lambda_1 = 1.875$ [34.22]. By measuring f_r and knowing the geometry and density, therefore, E can be determined. The cantilever can be vibrated by a number of techniques, including a laser, loudspeaker, or piezoelectric shaker. The frequency that produces the highest amplitude of vibration is the resonance frequency.

A micromachined device that uses an electrostatic comb drive and an AC signal to generate the vibration of the structure is known as a lateral resonator [34.23]. One example is shown in Fig. 34.11 [34.21]. When a voltage is applied across either set of interdigitated comb fingers shown in Fig. 34.11, an electrostatic attraction will be generated due to the increase in capacitance as the overlap between the comb fingers increases. The force,

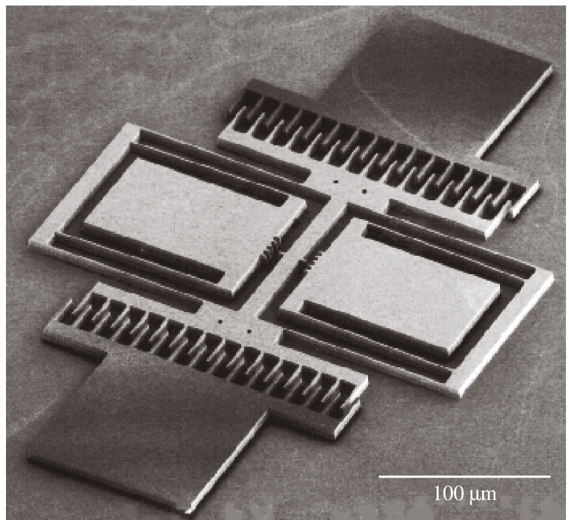


Fig. 34.11 SEM of a polysilicon lateral resonator [34.21]

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

F, generated by the comb drive is given by

$$F = \frac{1}{2}\frac{\partial C}{\partial x}V^2 = n\varepsilon\frac{h}{g}V^2 , \quad (34.8)$$

where C is capacitance, x is distance traveled by one comb-drive toward the other, n is the number of pairs of comb fingers in one drive, ε is the permittivity of the fluid between the fingers, h is the height of the fingers, g is the gap spacing between the fingers, and V is the applied voltage [34.23]. When an AC voltage at the resonance frequency is applied across either of the two comb drives, the central portion of the device will vibrate. In fact, since force depends on the square of the voltage for electrostatic actuation, for a time, t, dependent drive voltage, $v_D(t)$, of

$$v_D(t) = V_P + v_d \sin(\omega t) , \quad (34.9)$$

where V_P is the DC bias and v_d is the AC drive amplitude, the time dependent portion of the force will scale with

$$2\omega V_P v_d \cos(\omega t) + \omega v_d^2 \sin(2\omega t) \quad (34.10)$$

[34.23]. Therefore, if an AC drive signal is used with no DC bias, at resonance, the frequency of the AC drive signal will be one half the resonance frequency. For this device, the resonance frequency, f_r, will be

$$f_r = \frac{1}{2\pi}\left(\frac{k_{sys}}{M}\right)^{1/2} , \quad (34.11)$$

where k_{sys} is the spring constant of the support beams and M is the mass of the portion of the device that vibrates. The spring constant is given by

$$k_{sys} = 24EI/L^3 , \quad (34.12)$$

$$I = \frac{hw^3}{12} , \quad (34.13)$$

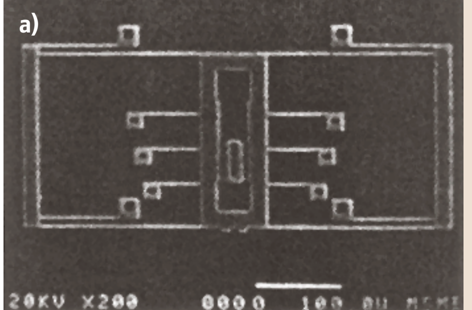
where I is the moment of inertia of the beams, and L, h, and w are the length, thickness, and width of the beams. By combining these equations and measuring f_r, therefore, E can be determined.

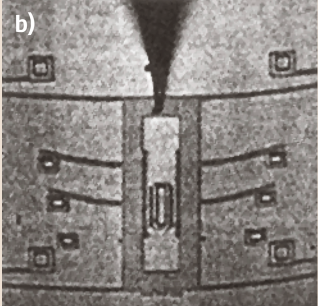
One distinct advantage of the lateral resonator technique and the electrostatically pulled cantilever technique for measuring Young's modulus is that they require no external loading sources. Portions of the devices are electrically contacted, and a voltage is applied. For the pure tension tests, such as shown in Fig. 34.7, the specimen must be attached to a loading system, which for the very small specimens discussed here, can be extremely difficult, and any misalignment or eccentricity in the test could lead to unreliable results. But the advantage of the externally loaded technique is that there are no limitations on the type of materials that can be tested. Conductivity is not a requirement, nor is any compatibility with electrical actuation.

Strength and Fracture Toughness Measurements

As one might expect, any of the techniques discussed in the previous section that strain specimens in order to measure Young's modulus can also be used to measure fracture strength. Simply, the load is increased until the specimen breaks. As long as either the load or the strain is measured at fracture, and the geometry of the specimen is known, the maximum stress required for fracture, σ_{crit}, can be determined, either through analytical analysis or FEA. Depending on the geometry of the test, σ_{crit} will represent the tensile or bend strength of the material.

If the available force is limited, or if it is desired to have a localized fracture site, stress concentrations can be added to the specimens. These are typically notches micromachined into the edges of specimens.





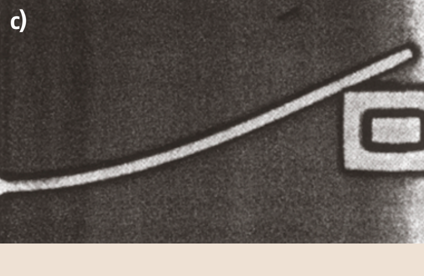


Fig. 34.12 **(a)** SEM of a device for measuring bend strength of polysilicon beams; **(b)** image of a test in process; **(c)** higher magnification view of one beam shortly before breaking [34.24]

Focused ion beams have also been used to carve stress concentrations into fracture specimens.

All of the external loading schemes, such as those shown in Figs. 34.7 and 34.8, have been used to measure fracture strength. Also, the electrostatically loaded doubly clamped beams can be pulled until they fracture. In this case, there is one complication. The electrostatic force is inversely proportional to the distance between the electrodes, and at a certain voltage, called the "pull-in voltage," the attraction between the beam and the substrate will become so great that the beam will immediately be pulled into contact with the bottom electrode. As long as the fracture takes place before the pull-in voltage is reached, the experiment will give valid results.

Other loading techniques have been used to generate fracture of microspecimens. Figure 34.12 [34.24] shows one device designed to be pushed by the end of a micromanipulated needle. The long beams that extend from the sides of the central shuttle come into contact with anchored posts, and, at a critical degree of bending, the beams will break off. Since the applied force cannot be measured in this technique, the experiment is optically monitored continuously during the test, and the image of the beams just before fracture is analyzed to determine σ_{crit}.

Another loading scheme that has been demonstrated for micromachined specimens utilizes scratch drive actuators to load the specimens [34.25]. These types of actuators work like inchworms, traveling across a substrate in discrete advances as an electrostatic force is repeatedly applied between the actuator and the substrate. The stepping motion can be made in the nm scale, depending on the frequency of the applied voltage, and so it can be an acceptable approximation to continuous loading. One advantage of this scheme is that very large forces can be generated by relatively small devices. The exact forces generated cannot be measured, so like the technique that used micromanipulated pushing, the test is continuously observed to determine the strain at fracture. Another advantage of this technique is that, like the lateral resonator and the electrically pulled cantilever, the loading takes place on-chip, and, therefore, the difficulties associated with attaching and aligning an external loading source are eliminated.

Another on-chip actuator used to load microspecimens is shown in Fig. 34.13, along with three different microspecimens [34.14]. Devices have been fabricated with each of the three microspecimens integrated with the same electrostatic comb-drive actuator. In all three cases, when a DC voltage is applied to the actuator, it moves downward, as oriented in Fig. 34.13. This pulls down on the left end of each of the three microspecimens, which are anchored on the right. The actuator contains 1,486 pairs of comb fingers. The maximum voltage that can be applied is limited by the breakdown

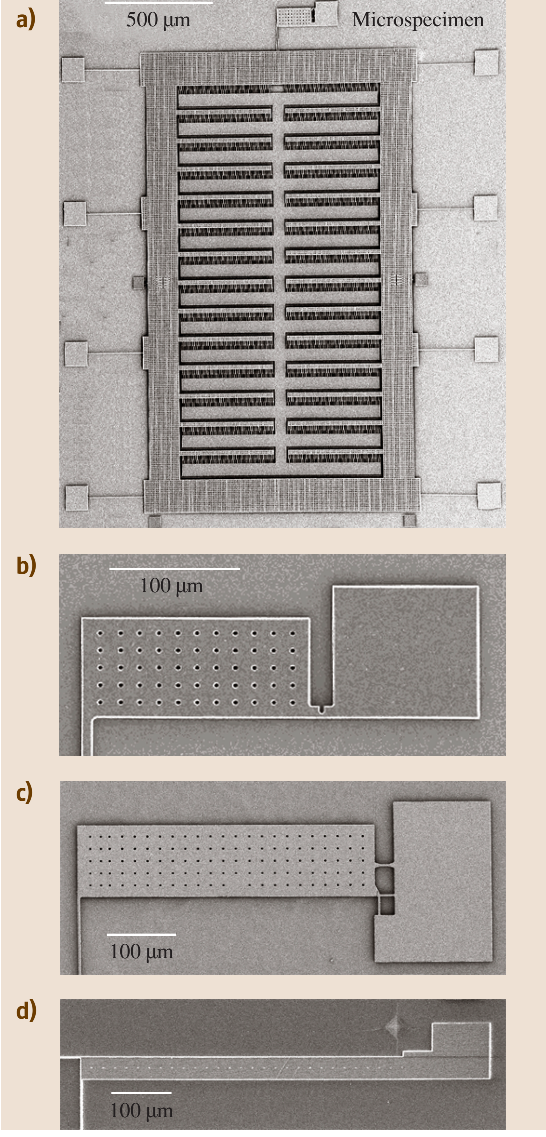

Fig. 34.13 (a) SEM of a micromachined device for conducting strength tests; the device consists of a large comb drive electrostatic actuator integrated with a microspecimen; **(b)–(d)** SEMs of various microspecimens for testing bend strength, tensile strength, and fracture toughness, respectively [34.14]

Part E | 34.2

voltage of the medium in which the test takes place. In air, that limits the voltage to less than 200 V. As a result, given a finger height of 4 μm and a gap of 2 μm, and using (34.8), the maximum force generated by this actuator is limited to about 1 mN. Standard optical photolithography has a minimum feature size of about 2 μm. As a result, the electrostatic actuator cannot generate sufficient force to perform a standard tensile test on MEMS structural materials such as polysilicon. The microspecimens shown in Fig. 34.13 are therefore designed such that the stress is amplified.

The specimen shown in Fig. 34.13b is designed to measure bend strength. It contains a micromachined notch with a root radius of 1 μm. When the actuator pulls downward on the left end of this specimen, the notch serve as a stress concentration, and when the stress at the notch root exceeds σ_{crit}, the specimen fractures. The specimen in Fig. 34.13c is designed to test tensile strength. When the left end of this specimen is pulled downward, a tensile stress is generated in the upper thin horizontal beam near the right end of the specimen. As the actuator continues to move downward, the tensile stress in this beam will exceed the tensile strength, causing fracture. Finally, the specimen in Fig. 34.13d is similar to that in Fig. 34.13b, except that the notch is replaced by a sharp pre-crack that was produced by the Vickers indent placed on the substrate near the specimen. When this specimen is loaded, a stress intensity, K, is generated at the crack tip. When the stress intensity exceeds a critical value, K_{Ic}, the crack propagates. K_{Ic} is also referred to as the fracture toughness.

The force generated by the electrostatic actuator can be calculated using (34.8). But (34.8) assumes a perfectly planar, two-dimensional device. In fact, when actuated, the electric fields extend out of the plane of the device, and so (34.8) is just an approximation. Instead, like many of the techniques discussed in this section, the test is continuously monitored, and the actuator displacement at the time of fracture is recorded. Then FEA is used to determine the magnitude of the stress or stress intensity seen by the specimen at the point of fracture.

Fatigue Measurements

A benefit of the electrostatic actuator shown in Fig. 34.13 is that, besides monotonic loading, it can generate cyclic loading. This allows the fatigue resistance of materials to be studied. Simply by using an AC signal instead of a DC voltage, the device can be driven at its resonant frequency. The amplitude of the resonance depends on the magnitude of the AC signal. This amplitude can be increased until the specimen breaks; this will investigate the low-cycle fatigue resistance. Otherwise the amplitude of resonance can be left constant at a level below that is required for fast fracture, and the device will resonate indefinitely until the specimen breaks; this will investigate high-cycle fatigue. It should be noted that the resonance frequency of such a device is about 10 kHz. Therefore, it is possible to stress a specimen over 10^9 cycles in less than a day. In addition to simple cyclic loading, if a DC bias is added to the AC signal, a mean stress can be superimposed on the cyclic load. In this way, nonsymmetric cyclic loading (either with a large tensile stress alternating with a small compressive stress, or vice versa) can be studied.

Another device that can be used to investigate fatigue resistance in MEMS materials is shown in Fig. 34.14 [34.26]. In this case, a large mass is attached to the end of a notched cantilever beam. The mass contains two comb drives on opposite ends. When an AC signal is applied to one comb drive, the device will res-

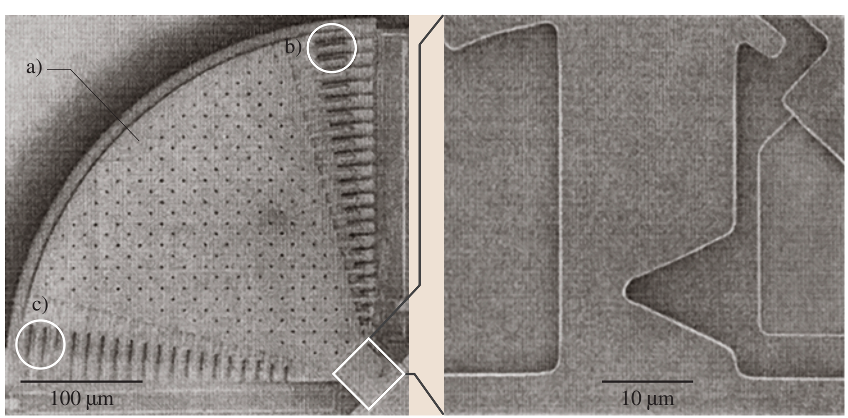

Fig. 34.14 SEM of a device for investigating fatigue; the image on the right is a higher magnification view of the notch near the base of the moving part of the structure [34.26] (a) mass, b) comb drive actuator, c) capacitive displacement sensor)

onate, cyclically loading the notch. The comb drive on the opposite side is used as a capacitive displacement sensor. This device contains many fewer comb fingers than the device shown in Fig. 34.13. As a result, it can apply cyclic loads by exploiting the resonance frequency of the device but cannot supply sufficient force to achieve monotonic loading.

Fatigue loading has also been studied using the same external loading techniques shown in Fig. 34.7. In this case, the frequency of the cyclic load is considerably lower, since the resonance frequency of the device is not being utilized. This leads to longer high-cycle testing times. Since the force is essentially unlimited, however, this technique allows a variety of frequencies to be studied to determine their effect on the fatigue behavior.

Fig. 34.16 Schematic cross section and top-view optical micrograph of a hinged-cantilever test structure for measuring friction in micromachined devices [34.28]

Friction Measurements

Friction is another property that has been studied in micromachined structures. To study friction, of course, two surfaces must be brought into contact with each other. This is usually avoided at all costs for these devices because of the risk of stiction. (Stiction is the term used when two surfaces that come into contact adhere so strongly that they cannot be separated.) Even so, a few devices have been designed to investigate friction. One of these is shown schematically in Fig. 34.15 [34.27]. It consists of a movable structure with a comb drive on one end and a cantilever beam on the other. Beneath the cantilever, on the substrate, is planar electrode. The device is moved to one side using the comb drive. Then a voltage is applied between the cantilever beam and the substrate electrode. The voltage on the comb drive is then released. The device would normally return to its original position, to relax the deflection in the truss suspensions, but the friction between the cantilever and the substrate electrode holds it in place. The voltage to the substrate electrode is slowly decreased until the device starts to slide. Knowing the electrostatic force generated by the

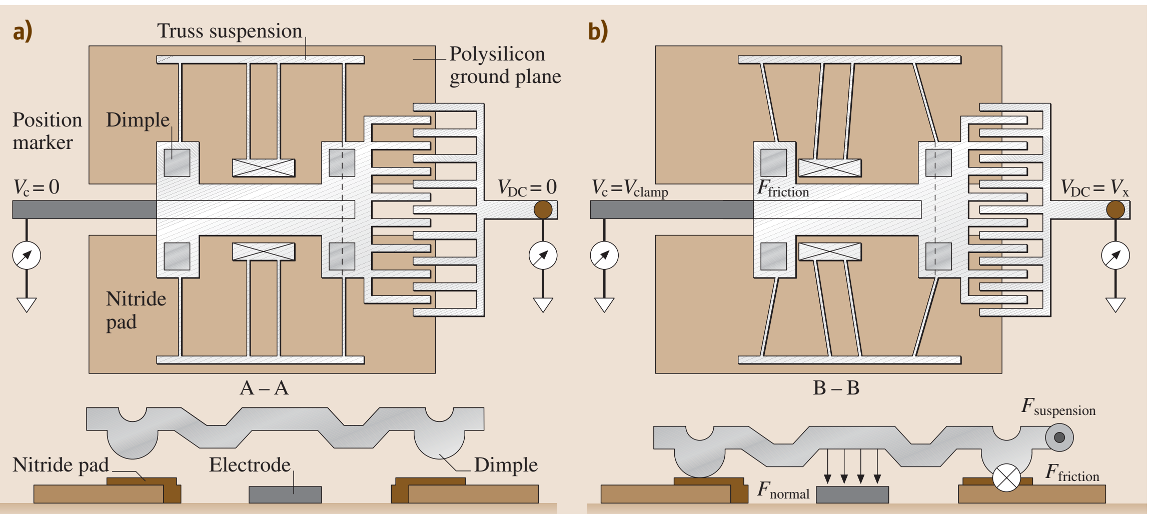

Fig. 34.15a,b Schematic drawings of a device used to study friction. **(a)** shows top and side views of the device in its original position, and **(b)** shows views of the device after it has been displaced using the comb drive and clamped using the substrate electrode [34.27]

substrate electrode and the stiffness of the truss suspensions, the static friction can be determined. For this device, bumps were fabricated on the bottoms of the cantilever beams. This limited the surface area that came into contact with the substrate and so lowered the risk of stiction.

Another device designed to study friction is shown in Fig. 34.16 [34.28]. This technique uses a hinged cantilever. The portion near the free end acts as the friction test structure, and the portion near the anchored end acts as the driver. The friction test structure is attracted to the substrate by means of electrostatic actuation, and when a second electrostatic actuator pulls down the driver, the friction test structure slips forward by a length proportional to the forces involved, including the frictional force. This distance, however, has a maximum of 30 nm, so all measurements must be exceedingly accurate in order to investigate a range of forces. This test structure can be used to determine the friction coefficients for surfaces with and without lubricating coatings.

34.3 Measurements of Mechanical Properties

All of the techniques discussed in Sects. 34.1 and 34.2 have been used to measure the mechanical properties of MEMS and NEMS materials. As a general rule, the results from the various techniques have agreed well with each other, and the argument becomes which of the measurement techniques is easiest and most reliable to perform. It is crucial to keep in mind, however, that certain properties, such as strength, are process dependent, and so the results taken at one laboratory will not necessarily match those taken from another. This will be discussed in more detail in Sect. 34.3.1.

34.3.1 Mechanical Properties of Polysilicon

In current MEMS technology, the most widely used structural material is polysilicon deposited by low-pressure chemical vapor deposition (LPCVD). One reason for the prevalence of polysilicon is the large body of processing knowledge for this material that has been developed by the integrated circuit community. Another reason, of course, is that polysilicon possesses a number of qualities beneficial for MEMS devices, particularly its high strength and Young's modulus. As a natural result, most of the mechanical properties investigations on MEMS materials have focused on polysilicon.

Residual Stresses in Polysilicon

The residual stresses of LPCVD polysilicon have been thoroughly characterized using both the wafer curvature technique, discussed in Sect. 34.1.1, and the microstrain gauges, discussed in Sect. 34.2.1. The results from both techniques give consistent values. Figure 34.17 summarizes the residual stress measurements as a function of deposition temperature taken from five different investigations at five different laboratories [34.29]. All five sets of data show the same trend. The stresses change from compressive at the lowest deposition temperatures to tensile at intermediate temperatures and back to compressive at the highest temperatures. The exact transition temperatures vary somewhat among the different investigations, probably due to differences in the deposition conditions: the silane or dichlorosilane pressure, the gas flow rate, the geometry of the deposition system, and the temperature uniformity. But in each data set the transitions are easily discernible. The origin of these residual stress changes lies with the microstructure of the LPCVD polysilicon films.

As with all deposited films, the microstructure of LPCVD polysilicon films is dependent on the deposition conditions. In general, the films are amorphous at

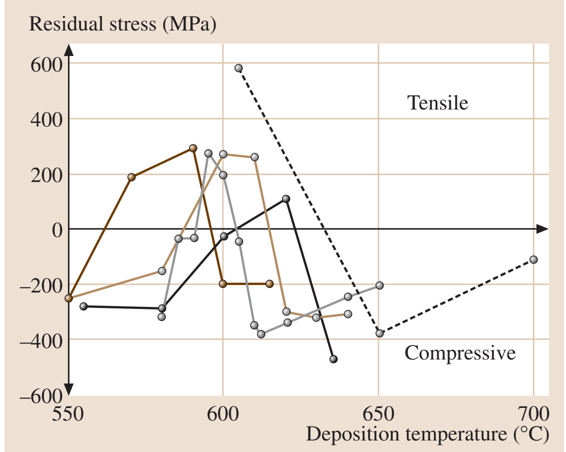

Fig. 34.17 Results for residual stress of LPCVD polysilicon films taken from five different investigations [34.29]. The data from each investigation are connected by a line

the lowest growth temperatures (lower than ~ 570 °C), display fine (~ 0.1 μm diameter) grains at intermediate temperatures (~ 570 °C to ~ 610 °C), and contain columnar (110)-textured grains with a thin fine-grained nucleation layer at the substrate interface at higher temperatures (~ 610 °C to ~ 700 °C) [34.29]. The fine-grained microstructure results from the homogeneous nucleation and growth of silicon grains within an as-deposited amorphous silicon film. In this regime, the deposition rate is just slightly faster than the crystallization rate. The as-deposited films will be crystalline near the substrate interface and amorphous at the free surface. (The amorphous fraction can be quickly crystallized by annealing above 610 °C.) The columnar microstructure seen at the higher growth temperatures results from the formation of crystalline silicon films as deposited, with growth being fastest in the ⟨110⟩ directions.

The origin of the tensile stress in the fine-grained polysilicon arises from the volume decrease that accompanies the crystallization of the as-deposited amorphous material. The origins of the compressive stresses in the amorphous and columnar films are less well understood. One proposed explanation for compressive stress generation during thin film growth postulates that an increase in the surface chemical potential is caused by the deposition of atoms from the vapor; the increase in surface chemical potential induces atoms to flow into newly formed grain boundaries, creating a compressive stress in the film [34.30].

Stress gradients are also typical of LPCVD polysilicon films. The partially amorphous films contain large stress gradients since they are essentially bilayers of compressive amorphous silicon on top of tensile fine-grained polysilicon. The fully crystalline films also exhibit stress gradients. The columnar compressive films are most highly stressed at the film-substrate interface, with the compressive stresses decreasing as the film thickness increases; the fine-grained films are less tensile at the film-substrate interface, with the tensile stresses increasing as the film thickness increases [34.29]. Both stress gradients are associated with microstructural variations. For the columnar films, the initial nucleation layer corresponds to a very high compressive stress, which decreases as the columnar morphology develops. For the fine-grained films, the region near the film-substrate interface has a slightly smaller average grain size, due to heterogeneous nucleation at the interface. This region displays a slightly lower tensile stress than the rest of the film, since the increased grain boundary area reduces the local density.

Young's Modulus of Polysilicon

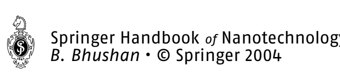
The Young's modulus of polysilicon films has been measured using all the techniques discussed in Sect. 34.2.2. A good review of the experimental results taken from bulge testing, tensile testing, beam bending, and lateral resonators are contained in [34.31]. All of the reported results are in reasonable agreement, varying from 130 to 175 GPa, though many values are reported with a relatively high experimental scatter. The main origin of the error in these results is the uncertainties involving the geometries of the small specimens used to make the measurements. For example, from (34.13), the Young's modulus determined by the lateral resonators depends on the cube of the tether beam width, typically about 2 μm. In general, the beam width and other dimensions can be measured with scanning electron microscopy to within about 0.1 μm; however, the width of the beams is not perfectly constant along the entire length or even through the thickness. These uncertainties in geometry lead to uncertainties in modulus.

In addition, the various experimental measurements lie close to the Voigt and Reuss bounds for Young's modulus calculated using the elastic stiffnesses and compliances for single crystal silicon [34.31]. This strongly implies that Young's modulus of micro- and nanomachined polysilicon structures will be the same as for bulk samples made from polysilicon. This is not unexpected, since Young's modulus is a material property. It is related to the interatomic interactions and should have no dependence on the geometry of the sample. It should be noted that polysilicon can display a preferred crystallographic orientation depending on the deposition conditions, and that this could affect the Young's modulus of the material, since the Young's modulus of silicon is not isotropic. But the anisotropy is fairly small for the cubic silicon.

A more recent investigation that utilized electrostatically actuated cantilevers and interferometric deflection detection yielded a Young's modulus of 164 GPa [34.19]. They found the grains in their polysilicon films to be randomly oriented and calculated the Voigt and Reuss bounds to be 163.4–164.4 GPa. This appears to be a very reliable value for randomly oriented polysilicon.

Fracture Toughness and Strength of Polysilicon

Using the device shown in Fig. 34.13a and the specimen shown in Fig. 34.13d, the fracture toughness, K_{Ic}, of polysilicon has been shown to be $1.0 \pm 0.1\,\mathrm{MPa\,m^{1/2}}$ [34.32]. Several different polysilicon microstructures were tested, including fine-grained,



columnar, and multilayered. Amorphous silicon was also investigated. All of the microstructures displayed the same K_{Ic}. This indicates that, like Young's modulus, fracture toughness is a material property, independent of the material microstructure or the geometry of the sample.

A tensile test, such as shown in Fig. 34.7 but using a sample with indentation-induced sharp pre-cracks, reveals a K_{Ic} of $0.86\,\mathrm{MPa\,m^{1/2}}$ [34.33]. The passive, residual stress loaded beams with sharp pre-cracks, shown in Fig. 34.6, gave a K_{Ic} of $0.81\,\mathrm{MPa\,m^{1/2}}$ [34.13].

Given that K_{Ic} is a material property for polysilicon, measured fracture strength, σ_{crit}, is related to K_{Ic} by

$$K_{Ic} = c\sigma_{crit}(\pi a)^{1/2} , \quad (34.14)$$

where a is the crack-initiating flaw size, and c is a constant of order unity. The value for c will depend on the exact size, shape, and orientation of the flaw; for a semicircular flaw, c is equal to 0.71 [34.34]. Therefore, any differences in the reported fracture strength of polysilicon will be the result of changes in a.

A good review of the experimental results available in the literature for polysilicon strength is contained in [34.35]. The tensile strength data vary from about 0.5 to 5 GPa. Like many brittle materials, the measured strength of polysilicon is found to obey Weibull statistics. This implies that the polysilicon samples contain a random distribution of flaws of various sizes, and that the failure of any particular specimen will occur at the largest flaw that experiences the highest stress. One consequence of this behavior is that, since larger specimens have a greater probability of containing larger flaws, they will exhibit decreased strengths. More specifically, it was found that the most important geometrical parameter is the surface area of the sidewalls of a polysilicon specimen [34.35]. The sidewalls, as opposed to the top and bottom surfaces, are those surfaces created by etching the polysilicon film. This is not surprising since LPCVD polysilicon films contain essentially no flaws within the bulk, and the top and bottom surfaces are typically very smooth.

As a result, the etching techniques used to create the structures will have a strong impact on the fracture strength of the material. For single-crystal silicon specimens it was found that the choice of etchant could change the observed tensile strength by a factor of two [34.36]. In addition, the bend strength of amorphous silicon was measured to be twice that of polysilicon for specimens processed identically [34.32]. It was found that the reactive ion etching used to fabricate the specimens produced much rougher sidewalls on the polysilicon than on the amorphous silicon.

Fatigue of Polysilicon

Fatigue failure involves fracture after a number of load cycles, when each individual load is not sufficient by itself to generate catastrophic cracking in the material. For ductile materials, such as metals, fatigue occurs due to accumulated damage at the site of maximum stress and involves local plasticity. As a brittle material, polysilicon would not be expected to be susceptible to cyclic fatigue. But fatigue has been observed for polysilicon tensile samples [34.33], polysilicon bend specimens with notches [34.26, 37], and polysilicon bend specimens with sharp cracks [34.38]. The exact origins of the fatigue behavior are still subject to debate. But some aspects of the experimental data are that the fatigue lifetime does not depend on the loading frequency [34.33], the fatigue behavior is affected by the ambient [34.13, 38], and the fatigue depends on the ratio of compressive to tensile stresses seen in the load cycle [34.13].

Friction of Polysilicon

The friction of polysilicon structures has been measured using the techniques described in Sect. 34.2.2. The measured coefficient of friction was found to vary from 4.9 [34.27] to 7.8 [34.28].

34.3.2 Mechanical Properties of Other Materials

As discussed above, of all the materials used for MEMS and NEMS, polysilicon has generated the most interest as well as the most research in mechanical properties characterization. But measurements have been taken on other materials, and these are summarized in this section.

As discussed in Sect. 34.2.2, one advantage of the externally loaded tension test, as shown in Fig. 34.7, is that essentially any material can be tested using this technique. As such, tensile strengths have been measured to be 0.6 to 1.9 GPa for SiO_2 [34.39] and 0.7 to 1.1 GPa for titanium [34.40]. The yield strength for electrodeposited nickel was found to vary from 370 to 900 MPa, depending on annealing temperature [34.16]. In addition, the yield strength was strongly affected by the current density during the electrodeposition process. Both the annealing and current density effects were correlated to changes in the microstructure of the material. Young's moduli were determined to be 100 GPa for

titanium [34.40] and 215 GPa for electrodeposited nickel [34.16].

The technique of bending cantilever beams, shown in Fig. 34.8, can also be performed on a variety of materials. The yield strength and Young's modulus of gold were found to be 260 MPa and 57 GPa, respectively, using this method [34.18]. Another technique that can be used with a number of materials is the membrane deflection method, shown in Fig. 34.10. A polyimide membrane gave a residual stress of 32 MPa, a Young's modulus of 3.0 GPa, and an ultimate strain of about four percent [34.20]. Membranes were also fabricated from polycrystalline SiC films with two different grain structures [34.41]. The film with (110)-texture columnar grains had a residual stress of 434 MPa and a Young's modulus of 349 GPa. The film with equiaxed (110)- and (111)-textured grains had a residual stress of 446 MPa and a Young's modulus of 456 GPa.

Other devices used for measuring mechanical properties require more complicated micromachining, namely patterning, etching, and release, in order to operate. These devices are more difficult to fabricate with materials not commonly used as MEMS structural materials. The following examples, however, demonstrate work in this area. The structure shown in Fig. 34.5b was fabricated from Si_xN_y and revealed a nominal fracture toughness of 1.8 MPa $m^{1/2}$ [34.12]. Lateral resonators of the type shown in Fig. 34.11 were processed using polycrystalline SiC, and Young's modulus was determined to be 426 GPa [34.42]. The device shown in Fig. 34.12 was fabricated from polycrystalline germanium and used to measure a bend strength of 1.5 GPa for unannealed Ge and 2.2 GPa for annealed Ge [34.43].

Thermo- and

35. Thermo- and Electromechanics of Thin-Film Microstructures

Applications using thin-film micromechanical structures for actuation and sensing require the coupling of energy between various physical domains. This chapter focuses on two important couplings: thermomechanics and electromechanics. Thermomechanical phenomena is considered in Sect. 35.1 where we describe broad aspects of the deformation characteristics and stress states that arise when dealing with a large class of thin-film microstructures. These include the origin of stresses in multiplayer films and their qualitative evolution through processing and release from the substrate. A basic framework is described for the analysis of the thermo mechanics of multiplayer films, emphasizing linear response. Issues of geometric and material no linearity are then taken up, and equal emphasis is put on the generality of the analysis approach and specific applications. As much as possible, we show comparisons between theoretical predictions and companion experimental results.

A common use of electro mechanics in microsystems involves the application of an electric potential between two electrodes where one is fixed and the other is connected to a deformable elastic structure. The electric potential produces an electric field and an associated electrostatic force that deforms the structure, and in turn alters the electrostatic force, resulting in fully-coupled nonlinear behavior. At some point an instability can occur where the deformable structure snaps into contact with the fixed electrode. This phenomena, called pull-in is often used for switching applications. In Sect. 35.2 we describe the basic electromechanical phenomena using a parallel-plate electrostatic actuator as a reference. We discuss many important phenomena including pull-in, external forcing, stabilization, time response, the effects of dielectric charging, and breakdown of gases in small gaps. We address these phenomena for a wide range of micro mechanical structures including cantilevered beams and plates, torsion ally suspended plates, and zipper actuators with curved electrodes.

Microsystems rely heavily on thin-film technology: the deposition, patterning, etching, and so on, of multiple film layers to yield micromechanical structures. We do not discuss fabrication techniques here but instead refer the interested reader to many excellent references that describe the fabrication of micromechanical structures by means of thin-film technology [35.1, 2] and, in particular, surface micromachining [35.3]. Regardless of the fabrication process flow, the end result is a thin-film microstructure that is connected to a substrate through one or more *sacrificial* film layers, which must be released to render it freestanding and thus useful. Figure 35.1a illustrates a simple, yet typical in terms of the microstructure and the materials involved, case: a cantilevered beam made of polycrystalline silicon (polysilicon) anchored to a silicon substrate and encased in an SiO_2 sacrificial layer. Also shown is a metal electrode used for electrostatic actuation of the cantilever after release. This is the state of affairs after the thin-film fabrication steps; we refer to it as the as-processed but unreleased condition. To render the beam freestanding, although anchored to the substrate at one end, the sacrificial material must be removed (Fig. 35.1b). For SiO_2, this is usually accomplished by etching in an HF solution, followed by drying. The latter step is important because during wet etching, strong (at the microscale) capillary forces can pull the beam into contact with the substrate. If the microstructure is too compliant, adhesive forces between the microstructure and the substrate can pin the beam to the substrate, rendering it useless. This phenomena is often referred to as stiction, and many recent references describe the phenomena, its impact regarding reliability, and practical ways to overcome it [35.4, 5]. For our purposes, we assume that the microstructure can be successfully released so that it is free from the substrate where desired and anchored where desired.

High stresses can develop in the film layers during processing, and these can vary significantly from layer to layer and even within a single layer. When the sacrificial layers are removed, the stresses redistribute, but at the expense of deformation. This can be detrimental in applications in which planarity is essential, or it can be used advantageously for actuation purposes. Indeed many applications are based on the use of thermally induced bending of bilayer beams and plates that arises due to the difference in thermal expansion coefficients between the film layers. An example is shown in Fig. 35.2 where a micromirror is suspended above the substrate by 2.0-μm-thick gold/polysilicon bilayer beams that position the mirror (or any desired device) and can then be electrostatically actuated to control the position of the micromirror. Upon release, microstructures are typically used for actuation and/or sensing functions. This requires the coupling of the mechanical behavior of the microstructure with various energy domains. These couplings include, among others, thermomechanics, electromechanics, electrothermomechanics, and magnetomechanics. The most common, and perhaps the most easily realizable, is electromechanics, specifically the coupling of electrostatics and mechanics. This coupling has been successfully demonstrated by many applications as both sensors and actuators.

This chapter focuses on the behavior of thin-film microstructures under the action of thermomechanical and electromechanical loadings. Section 35.1 is devoted to the development of stresses and deformation in multilayer thin-film microstructures when subjected to thermomechanical loading. It focuses heavily on linear thermoelastic behavior but describes important issues regarding geometric and material nonlinearity. Section 35.2 is devoted to the electromechanics of microstructures, emphasizing general approaches to modeling and then focusing on the behavior of typ-

ical classes of electromechanical microstructures. The treatment is certainly not exhaustive, but we hope it is detailed enough to provide the interested reader with an entry-level understanding of the basic phenomena and some guidance regarding where to turn to obtain more in-depth information.

35.1 Thermomechanics of Multilayer Thin-Film Microstructures

In this section we describe aspects of the deformation characteristics and stress states in multilayer thin-film microstructures. Deformation and stress states will be considered for microstructures that are both attached to a substrate and freestanding after release from the substrate. In the modeling formalism that we will describe, the substrate simply serves as another layer. We will refer to microstructures as beams and/or plates, depending on the relevant dimensions. At times we will use the terms loosely, but we will describe the difference of their deformation characteristics in detail. The remainder of this section will be organized as follows: Section 35.1.1 provides an overview of the basic phenomena including the origin of stresses in multilayer films and their qualitative evolution through processing and then release from the substrate. Section 35.1.2 outlines a general framework for the analysis of the thermomechanical behavior of multilayer thin films, emphasizing *linear* response. Issues of *geometric* and *material* nonlinearity are then briefly taken up in Sects. 35.1.3 and 35.1.4, respectively. Section 35.1.5 touches on a number of related and important issues that were not covered in the other sections.

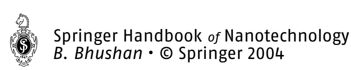
The objectives of this section are to describe the thermomechanical phenomena that arise when dealing with a large class of thin-film microstructures. A basic framework is described for analysis, and equal emphasis is put on the generality of the approach and specific applications. When possible, we show comparisons between theoretical predictions and companion experimental results. To this end, a specific material and geometric system must be chosen, and we use a gold/polysilicon multilayer for most of these cases. We note, though, that the phenomena discussed are not restricted to the gold/polysilicon system but arise in many multilayer film systems.

35.1.1 Basic Phenomena

During the multiple thin-film deposition and etching processes, many complicated mechanisms occur that result in straining of the film layers, and these generally differ from layer to layer. The requirement that the film layers maintain coherency at the interfaces between them means that these strains cannot occur freely, and thus they are constrained. This constraint leads to stresses in the layers and curvature of the multilayer film system; both can have significant practical implications. The mechanisms that lead to internal stresses include chemical reactions, lattice mismatch, and grain growth, among others, and are often called *intrinsic* stresses (see, for example [35.6]). The details of intrinsic stress development in thin films have been the subject of extensive study for both scientific and technological reasons, but they are beyond the scope of our study. In addition, stresses may arise due to thermal expansion mismatch between layers when subjected to a temperature change. Such stresses are often called *extrinsic* stresses. Now, in the unreleased configuration of Fig. 35.1a, a complicated stress distribution exists as a result of the intrinsic stresses. The release process to yield the configuration of Fig. 35.1b obviously alters the stress distribution as well as the state of deformation. In order to gain physical insight, the remainder of this section discusses rather qualitatively the nature of the stress states in the unreleased and released configurations. In subsequent sections details are given regarding analysis of these thermomechanical phenomena.

Transformation Strains, Misfit Strains, and Thin-Film Stresses

The important concepts here are most easily described in terms of a bilayer film system in which both layers are isotropic. Furthermore, they are easier to grasp in the context of a specific example, of which many would suffice. Once this understanding is in place, the generalization of the concepts to multilayer film systems follows naturally. To begin, we define a couple of terms. A *transformation strain* ε^* is a strain that occurs in a solid, but with no accompanying stress. It is thus an inelastic strain. In the literature a number of other terms are used to describe this concept including *stress-free strain* and *eigenstrain*. It can result, for example, from thermal expansion, a crystallographic phase transformation, or a variety of sources. When thermal expansion is the source, ε^* can be specified as $\varepsilon^* = \alpha T$ where



α is the thermal expansion coefficient of the material and T is the temperature change from a reference (usually stress-free) configuration. In general ε^* and α are second-order tensors. Stresses and deformation develop in bilayer film/substrate systems when, due to external or internal sources, each layer wants to undergo a *different* transformation strain, but the requirement of bonding of the films at the interface constrains each film to some degree. The source of the stress and deformation is then the difference in the transformation strains between the layers, i. e., $\Delta\varepsilon = \varepsilon_1^* - \varepsilon_2^*$ where ε_1^* and ε_2^* are the transformation strains of the two layers. For example, if a bilayer is subjected to a uniform temperature change T, then $\Delta\varepsilon = (\alpha_1 - \alpha_2)\,T = \Delta\alpha T$ where α_1 and α_2 are the thermal expansion coefficients of the two layers. $\Delta\varepsilon = \varepsilon_1^* - \varepsilon_2^*$ is termed the *misfit strain*. Its role as the direct source of deformation is obvious and clear for two-layer systems. The concept of misfit strain is not as direct for multilayer systems, and so we simply characterize the behavior in terms of the individual transformation strains of each layer.

It is important to understand the character of the stress distribution and deformation. To make the ideas concrete, consider the bilayer film system with planar dimensions (normal to the film thickness direction) that far exceed the total thickness. The two layers, denoted by 1 and 2, are perfectly bonded along the interface and have different isotropic thermal expansion coefficients and elastic moduli. The bilayer is initially flat, and each layer is stress free. Now assume the bilayer is subjected to a uniform temperature change T, which would lead to equibiaxial ($\varepsilon^* = \varepsilon_{xx}^* = \varepsilon_{yy}^*$, $\gamma_{xy}^* = 0$) transformation strains $\varepsilon_1^* = \alpha_1 T$ and $\varepsilon_2^* = \alpha_2 T$ in the two layers if they were not bonded. Because they are bonded, though, this results in the development of equibiaxial stresses ($\sigma = \sigma_{xx} = \sigma_{yy}, \sigma_{xy} = 0$) in the layers, a change of length in the planar directions (in-plane straining) and bending of the bilayer (curvature). This can be understood by the following thought experiment, which is often used in the calculation of film stresses. We will only use it, though, to explain the basics of the resulting deformation and will leave the actual calculations to the next section.

Consider the bilayer system shown schematically in Fig. 35.3a. The film layers are stress free and perfectly bonded. Our discussion will be in the context of biaxial transformation strains and stresses, but the ideas can be immediately applied to situations of uniaxial stress/strain behavior or plane stress or strain situations. We are interested in obtaining the deformation and stress state when the bilayer is subject to a uniform temperature

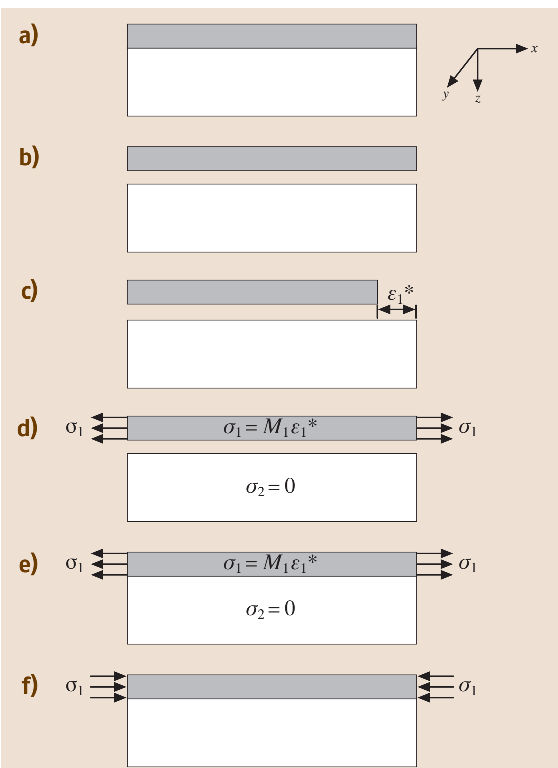


Fig. 35.3 Illustration showing the development of stresses and deformation in a bilayer film/substrate system

change T. Since the films are stress free in Fig. 35.3a, one can cut the bonds that connect the two layers and separate the films (Fig. 35.3b) without generating any stresses or deforming either layer. Now we (Fig. 35.3c) subject the layers to a uniform temperature change T; each layer will undergo its stress-free biaxial strain, $\varepsilon_1^* = \alpha_1 T$ and $\varepsilon_2^* = \alpha_2 T$ (for simplicity, Fig. 35.3c illustrates the deformation for the case where $\varepsilon_2^* = 0$, $T < 0$, and $\alpha_1 > 0$, but the ideas are the same for more general situations). Now the interfaces, which were originally in perfect registry, are no longer. To bring them into registry, a uniform stress must be applied to the film (Fig. 35.3d) by means of the application of forces along the film edge. At this stage the film is subjected to the uniform biaxial stress $\sigma_1 = M_1\varepsilon_1^*$, where M_1 is the biaxial modulus of the film (see Sect. 35.1.2), the substrate is still stress free, $\sigma_2 = 0$, and the layers are in perfect registry. They can then be reconnected (imagine reattaching the original bonds that were cut in Fig. 35.3b), without generating additional stresses or deforming the layers (Fig. 35.3e). The stress

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

state in Fig. 35.3e is the same as that in Fig. 35.3d, the only difference is that the films are now bonded. Now, to recover the solution for the bilayer subjected to a uniform temperature change T, we only have to remove the edge forces. This can be accomplished by applying forces of equal magnitude but opposite sign to the edges (Fig. 35.3f). The solution is then obtained as the superposition of the problems in Fig. 35.3e, which is trivial, and Fig. 35.3f, which is difficult in general. Instead of now trying to solve the problem in Fig. 35.3f, we will simply describe the character of the resulting deformation and stress state. Two aspects are important: the behavior near the free edge where the stress in Fig. 35.3f is applied, and the behavior far away from the free edge. One can appeal to St. Venant's principle to simplify the latter, but more involved analysis is required for the former (see for example [35.7]).

At a distance of ten or so film thicknesses away from the edges, the solution to the problem in Fig. 35.3f can be decomposed, as shown in Fig. 35.4. The uniform force distribution on the edges of the film (Fig. 35.4a) can be replaced by a concentrated force acting at the middle z-coordinate of the film thickness (Fig. 35.4b). The solution to this problem can then be obtained by the superposition of the two problems in Fig. 35.4c and 35.4d, the loadings of which are statically equivalent to that in Fig. 35.4b. That in Fig. 35.4c is a concentrated force applied at the as-yet-unknown neutral surface of the bilayer; it will lead to a uniform in-plane (x-y plane) straining of the bilayer. That in Fig. 35.4d is a moment of magnitude Pd, where d is the distance between the z-coordinates of the middle of the film and the neutral surface of the bilayer; it will lead to bending of the bilayer. If there were also a film on the bottom of the substrate so that the layered film was symmetric in material properties and geometry (film thicknesses) in the z-direction, then no moment would result, and the layered system would not bend but would only strain in-plane.

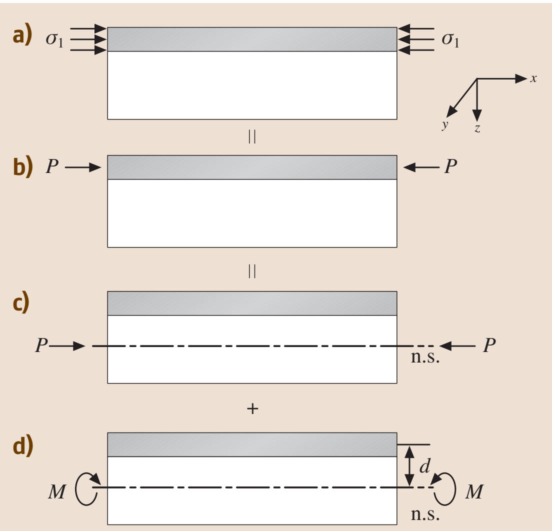

Fig. 35.4 Decomposition of the edge-loading problem into the superposition of a force and moment applied to the multilayer. Away from the edge, the force gives rise to uniform straining, and the moment gives rise to bending

It is probably obvious that very near the edge, the stress state is quite complicated. In fact, in the context of linear elasticity, a stress singularity generally exists at the intersection of the free edge and the interface between the two layers. This singular stress state is similar to that which exists at a crack tip, but the strength of the singularity differs depending on the mismatch in elastic constants of the materials [35.8, 9]. The region within which this stress state exists depends on the film thickness, and for very thin films it is often so small that it is insignificant. It has recently been shown, however, that in some cases it can be appreciable and in fact can be the primary source of failure [35.10]. As described in detail by *Hui* et al. [35.7], aside from the singular stresses, the stress state near the edges contains highly localized shear and normal stress (perpendicular to the interface) components. By St. Venant's principle these stress components decay over a rather short distance from the edge, but they can play a significant role in the durability of the film/substrate system as they can lead to delamination of the interface or cracking into one of the layers. The character of these stress components at the interface is shown qualitatively in Fig. 35.5. Note that in order to satisfy equilibrium, the normal stress (often called the peel stress) changes sign from tensile to compressive. Furthermore, since these stress components are highly localized at the edge, in the interior of the system the interface is free of normal or shear stresses. In this chapter we will not further consider these localized stresses but instead will concern ourselves with the stresses away from the edges and the companion deformation.

Our discussion has been based on the assumption that transformation strains are constant throughout the cross section of each film. In microsystems applications, though, films will often have transformation strains that vary through the thickness. This will lead to bending of the film after it is released from the substrate. Transformation strains that vary through the thickness, i. e.,

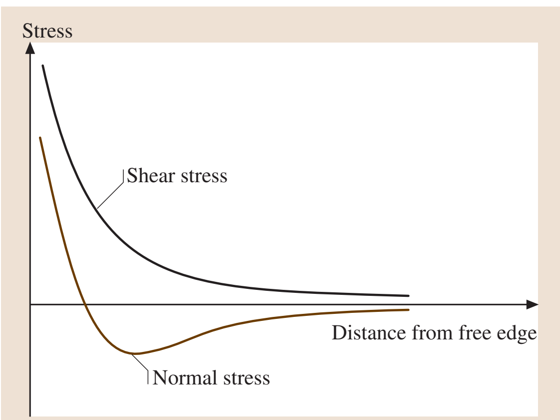

Fig. 35.5 Character of the normal and shear stress distribution at the film/substrate interface near the free edge

$\varepsilon^*(z)$, can be easily accommodated in the description of Fig. 35.3. It is altered in that now in Fig. 35.3c an in-plane strain results, the magnitude of which is given by the through-thickness average of $\varepsilon^*(z)$, but in addition, the film bends with constant curvature. Then, both a force (uniform stress) and moment (linearly varying stress) must be applied in Fig. 35.3d to flatten the film and lengthen it so that it is again in perfect registry with the substrate and can then be rebonded [35.11].

This description provides the starting point for understanding the effects of transformation strains on stresses and deformation in a multilayer thin-film system. It is an accurate picture of the state of affairs before release of a film from the substrate to yield a freestanding microstructure. In the next sections we will discuss the changes in the deformation that occur upon release as the constraint of the substrate is removed.

Single-Layer Beams

To keep things simple, in this and the following section we focus on *beams*, which have one nonzero normal stress component, that along the beam axis. In subsequent sections we will discuss the limitations of approximating such structures as beams and proceed with a more appropriate development in terms of *plates*. Consider the beam shown in Fig. 35.1. For simplicity we assume that the sacrificial material is much thinner than the substrate, has the same elastic moduli as the substrate, and so before release is mechanically equivalent to the substrate. In this way we can describe the stress distribution before release as that of a two-layer beam. To make the discussion more tangible, consider a specific but realistic case of a polysilicon beam on a silicon substrate. The top layer of thickness 1.5 µm is the polysilicon film, and the bottom layer of thickness 500 µm is the silicon substrate (including the very thin sacrificial layer that will be removed). Assume that the polysilicon film has an intrinsic mean stress S and a linear stress gradient β (we can easily consider a nonlinear stress gradient, but the simple linear gradient suffices to demonstrate the concepts involved). This intrinsic stress is interpreted as the stress state in the film if it were free, i. e., a transformation stress. It could be expressed in terms of a transformation strain $\varepsilon^*(z)$, but since reference is often made to thin-film stresses we will carry out this and the following example using this transformation stress rather than a transformation strain. We consider three cases to isolate the effects of the mean stress and the stress gradient: (a) $S = -10$ MPa, $\beta = 0$, (b) $S = 0$, $\beta = 0.8$ MPa/µm, and (c) $S = -10$ MPa, $\beta = 0.8$ MPa/µm. In all cases, the intrinsic stress in the substrate is zero.

In Table 35.1 we give calculated results using a simple beam theory (to be discussed in the following sections) for the three scenarios. Case (a) $S = -10$ MPa, $\beta = 0$ results in a slight contraction and a negative curvature (bent downward) of the film/substrate system prior to release. The compressive stress in the polysilicon beam is uniform but slightly lower than the value of S. The stress induced in the substrate is small and varies linearly through its thickness. It changes sign through the substrate, a necessary requirement to satisfy equilibrium. After release the stress is zero throughout the beam. To relax the stress, the beam extends (the midplane strain ε^0 is positive), but because $\beta = 0$ it does not bend. Case (b) $S = 0$ MPa, $\beta = 0.8$ MPa/µm results in a slight positive curvature (bent upward) but no extension or contraction of the film/substrate system prior to release. The mean compressive stress in the polysilicon beam is zero, and the gradient of the stress distribution through the film is decreased from the value of β. The stress induced in the substrate is again small and varies linearly through its thickness, changing sign. After release the stress is again zero throughout the beam. The beam does not extend or contract since $S = 0$, but it bends, assuming a curvature $\kappa = \beta/E$ where E is Young's modulus of polysilicon (see Sect. 35.1.2 for details regarding this result). Careful examination of Table 35.1 shows that the strain, curvature, and stress for case (c) $S = -10$ MPa, $\beta = 0.8$ MPa/µm can be obtained as the superposition of the results of cases (a) and (b). Specifically, after release the beam extends and bends.

Table 35.1 Stresses, curvature, and strains in a film/substrate system consisting of a 1.5-μm-thick polysilicon film and a 500-μm-thick silicon film. The elastic moduli of the film and the substrate are assumed equal, and the film has an intrinsic mean stress and stress gradient. The sign convention for curvature is that (−) indicates bending downward and (+) indicates bending upward

		(a) $S = -10$ MPa $\beta = 0$ MPa/μm		(b) $S = 0$ MPa $\beta = 0.8$ MPa/μm		(c) $S = -10$ MPa $\beta = 0.8$ MPa/μm	
		Unreleased	Released	Unreleased	Released	Unreleased	Released
	ε^0 (με)	0.0624	62.5	0	0	0.0624	62.5
	κ (m^{-1})	-7.5×10^{-4}	0	5.0×10^{-9}	5.0	-7.5×10^{-4}	5.0
σ (MPa)	Top	−9.96	0	0.2	0	−9.76	0
Polysilicon Film	Bottom	−9.96	0	−0.2	0	−10.16	0
σ (MPa)	Top	0.04	0	-2.0×10^{-7}	0	0.04	0
Silicon Substrate	Bottom	−0.02	0	2.0×10^{-7}	0	−0.02	0

These results illustrate the behavior of beams before and after release when they contain a mean stress and/or a linear stress gradient. The results also suggest natural means to attempt to measure the mean stress and the gradient. Test structures that are sensitive to length changes of beams after release can be used to characterize mean stress. For example, fracture of arrays of beams of varying width upon release can be used to estimate tensile stress, and fixed-fixed beams that buckle can be used to estimate compressive stress. The stress gradient in a beam can be determined by measuring its curvature after release. A survey of test structures suitable for these purposes can be found in [35.12].

Bilayer Beams

While stresses in single-layer microstructures are important for many applications, multilayer film microstructures abound in microsystems technology, and the development of stresses and deformation in them is also important. In order to convey the basic ideas, we consider an example of a two-layer beam fixed to a substrate in the same manner as that in the previous section. Specifically we consider the layered structure shown in the inset of Fig. 35.6: a polysilicon beam of thickness 1.5 μm attached to a silicon substrate of thickness 500 μm, covered with a gold film of thickness 0.5 μm. Photos of actual beams of this form are shown in Fig. 35.7 where the length of the longest beam shown is 600 μm, and the beams are 50 μm wide. Again we assume that the sacrificial material is very thin and has the same elastic moduli as the substrate, and so before release it is mechanically equivalent to the substrate. We assume that the polysilicon film has an intrinsic mean stress S and a linear stress gradient β as in the previous example, and that the gold film has an intrinsic mean stress but no stress gradient. We consider the reasonably typical stress states: $S = -10$ MPa and $\beta = 0.8$ MPa/μm in the polysilicon beam and $S = 50$ MPa in the gold film. The resulting curvature and stress distribution before and after release are shown in Fig. 35.6. They show that before release the stresses in the polysilicon and gold layer are nearly uniform, compared to the range of stresses throughout the layers. The multilayer experiences a positive curvature; recall that the system consisting of just the polysilicon

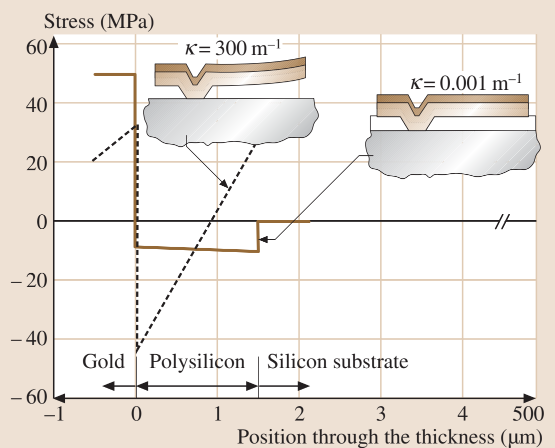

Fig. 35.6 Stress distribution through the thickness for a bilayer film consisting of a 0.5-μm-thick gold film on a 1.5-μm-thick polysilicon film subjected to an internal stresses and stress gradients. Stress distributions are shown before and after release from a 500-μm-thick silicon

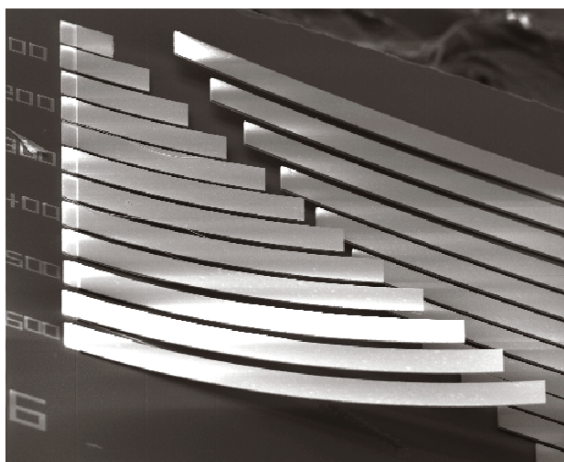

Fig. 35.7 Scanning electron microscope image of gold/polysilicon bilayer cantilever beams as released from the substrate. All beams have a 0.5-μm-thick gold film, but the beams on the *left* have a 1.5-μm-thick polysilicon film, and those on the *right* a 3.5-μm-thick polysilicon layer

film and the substrate experienced a negative curvature of about the same magnitude. Thus the tensile stress in the gold is significant enough to drive the curvature from negative (bending down) to positive (bending up).

After release from the substrate, the gold/polysilicon beam contracts and bends substantially to a curvature of about 300 m^{-1}. This should be compared with 5 m^{-1} for the polysilicon beam with a stress gradient. For a beam 300 μm long cantilevered from one end as shown in Fig. 35.6, this amounts to a tip deflection of about 13 μm. The stress states in both the gold and polysilicon are significantly altered upon release. Perhaps most significantly, large stress gradients exist through the thickness of each layer. Starting at the top of the gold film, the tensile stress increases through the gold thickness. Due to the discontinuity in elastic modulus and the residual stress and stress gradients, there is a jump in the stress of about −77 MPa at the gold/polysilicon interface. The stress is compressive at the top of the polysilicon film layer and increases linearly through the thickness of the polysilicon film, taking on its maximum tensile value at the bottom of the two-layer beam. In summary, the release process results in a reduction of the stress in the gold, an increase of the stress in the polysilicon, stress gradients in both layers, a small contraction, and a large curvature change.

These examples are meant to convey the basic phenomena and give a feel for the magnitudes of the quantities involved. The actual numerical results are based on calculations performed using a relatively simple multilayer beam theory and are reasonable estimates. Details regarding the analysis will be given in the following section, including a discussion of the suitability of the simple beam theory.

35.1.2 A General Framework for the Thermomechanics of Multilayer Films

Numerous studies have elucidated the basic thermomechanical response of multilayer material systems when subjected to temperature changes or other sources of transformation strains between the layers. These have come in the context of many technological applications, the most common being structural composite materials [35.13, 14] and thin film/substrate systems for microelectronics [35.15–22], which are directly applicable to the analysis of multilayer films.

The General Multilayer Film

When a layered film is subjected to transformation strains, two aspects of deformation play a primary role: straining of the midplane and bending. When the transverse deflections due to bending are of prime importance, as is often the case, one way to broadly characterize the deformation response, especially for plates with relatively large in-plane dimensions as compared to their thickness, is in terms of the average curvature developed as a function of the transformation strains. Formally the curvature is a second-rank tensor, and for the type of layered film problems considered here it can be wholly described by the two principal curvature components, e.g., in the x- and y- directions, κ_x and κ_y. The curvature is a pointwise quantity, meaning it varies from point to point over the in-plane dimensions of the plate. In terms of the average curvature variation as a function of misfit strain, three deformation regimes have been identified [35.16–19, 22, 23]. The first regime is a linear relation between the average curvature and temperature change where $\kappa_x = \kappa_y$, i. e., the average curvature is spherically symmetric (when the materials are isotropic). This symmetric deformation would not exist if the material properties were anisotropic. This deformation regime is characterized by both small transverse displacements and rotations, and so conventional thin-plate theory adequately describes the deformation. It is the subject of the analysis in this section. The second and third regimes, which arise due to geometric nonlinearity, will be taken up in Section 35.1.3.

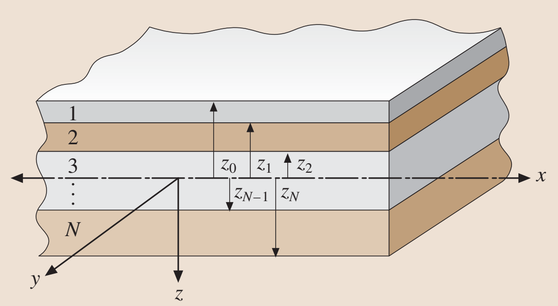

Fig. 35.8 Multilayer film system with a definition of the parameters involved in the analysis

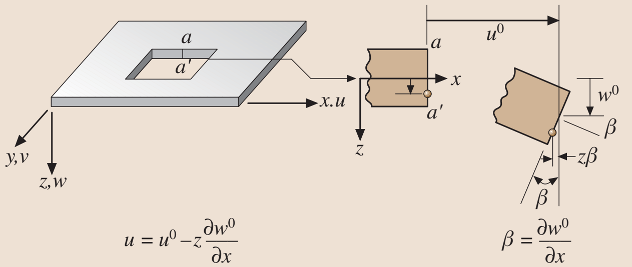

Fig. 35.9 Kinematics of the deformation of the thin-film multilayer

Figure 35.8 shows a schematic of the geometry considered in this study; a multilayer film microstructure with lateral dimensions that far exceed the total thickness. As such we ignore the effects of the free edges and focus on a representative point in the layered film that lies at least a distance of a few film thicknesses from the edge. The layers are numbered $1, 2, \dots, N$ where 1 is the top layer and N is the bottom layer. Each layer has a thickness t_i ($i = 1 \rightarrow N$), and the total thickness of the microstructure is t. Each of the film layers consists of an isotropic material with a Young's modulus E_i, Poisson's ratio, ν_i, and may undergo a transformation strain $\varepsilon_i^*(z)$, which may vary with position z through the film thickness. The source of $\varepsilon_i^*(z)$ may be arbitrary, and the effect of multiple sources can be considered as the sum of the individual ones. A common source, and one that we will focus on, is thermal expansion upon a uniform temperature change. In this case $\varepsilon_i^*(z) = \varepsilon_i^* = \alpha_i T$ where α_i is the thermal expansion coefficient and T is the temperature change from a reference state. In addition, each layer may contain an internal stress $\hat{\sigma}(z)$, which also may vary with position z through the thickness. For simplicity we focus our results on isotropic layers, but the framework is applicable to anisotropic behavior of each layer. As a result of the difference in stress-free strains and/or internal stresses between each layer, stresses are developed in the layers and the structure deforms; our intent is to compute these.

Analysis

The analysis presented here is somewhat standard in the treatment of laminated composite plates but has not been often used in the analysis of multilayer thin film problems for microelectronics and/or microelectromechanical systems. Detailed accounts of parts of the theory can be found in texts on composite materials (see for example [35.24,25]), and so only a brief account is presented here.

The displacements u and v at any point z through the thickness of the laminate are assumed to be described by the classical Kirchoff hypothesis. As illustrated in Fig. 35.9, the Kirchoff hypothesis states that after loads are applied to the layered film, the line a–a' which is initially straight and normal to the geometric midplane remains straight, normal to the deformed geometric midplane, and its length is unchanged. In other words, the normal does not deform but only translates and rotates. As a consequence of this assumption, the displacements of any point in the layered film are given by:

$$u = u^0 - z\frac{\partial w^0}{\partial x}$$
$$v = v^0 - z\frac{\partial w^0}{\partial y}$$
$$w = w^0 , \tag{35.1}$$

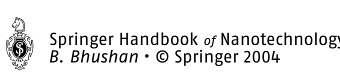
where u^0, v^0, and w^0 are the displacements of the geometric midplane at $z = 0$. Note that in addition to this explicit dependence of the displacements on z, they are generally functions of x and y.

The nonzero normal and shear strains are then:

$$\varepsilon_x = \frac{\partial u}{\partial x} = \frac{\partial u^0}{\partial x} - z\frac{\partial^2 w^0}{\partial x^2} = \varepsilon_x^0 + z\kappa_x$$
$$\varepsilon_y = \frac{\partial v}{\partial y} = \frac{\partial v^0}{\partial x} - z\frac{\partial^2 w^0}{\partial x^2} = \varepsilon_y^0 + z\kappa_y$$
$$\gamma_{xy} = \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} = \frac{\partial u^0}{\partial y} + \frac{\partial v^0}{\partial x} - 2z\frac{\partial^2 w^0}{\partial x \partial y}$$
$$= \gamma_{xy}^0 + z\kappa_{xy} \tag{35.2a}$$

or in matrix form:

$$\{\varepsilon\} = \left\{\varepsilon^0\right\} + z\,\{\kappa\} , \tag{35.2b}$$



B. Bhushan • © Springer 2004

where:

$$\{\varepsilon\}=\left\{\begin{array}{c}\varepsilon_x\\ \varepsilon_y\\ \gamma_{xy}\end{array}\right\}\ \left\{\varepsilon^0\right\}=\left\{\begin{array}{c}\varepsilon_x^0\\ \varepsilon_y^0\\ \gamma_{xy}^0\end{array}\right\}=\left\{\begin{array}{c}\dfrac{\partial u^0}{\partial x}\\ \dfrac{\partial v^0}{\partial y}\\ \dfrac{\partial u^0}{\partial y}+\dfrac{\partial v^0}{\partial x}\end{array}\right\}$$

$$\{\kappa\}=\left\{\begin{array}{c}\kappa_x\\ \kappa_y\\ \kappa_{xy}\end{array}\right\}=\left\{\begin{array}{c}-z\dfrac{\partial^2 w^0}{\partial x^2}\\ -z\dfrac{\partial^2 w^0}{\partial y^2}\\ -2z\dfrac{\partial^2 w^0}{\partial x\partial y}\end{array}\right\}. \tag{35.3}$$

In (35.3), $\left\{\varepsilon^0\right\}$ is the midplane strain and $\{\kappa\}$ is the midplane curvature. As with the displacements, $\left\{\varepsilon^0\right\}$ and $\{\kappa\}$ are generally functions of x and y.

The stress-strain relations for each layer are:

$$\left\{\begin{array}{c}\sigma_x(z)\\ \sigma_y(z)\\ \sigma_{xy}(z)\end{array}\right\}_k=\left[\begin{array}{ccc}Q_{11}&Q_{12}&Q_{16}\\ Q_{12}&Q_{22}&Q_{26}\\ Q_{16}&Q_{26}&Q_{66}\end{array}\right]_k \times\left[\left\{\begin{array}{c}\varepsilon_x\\ \varepsilon_y\\ \gamma_{xy}\end{array}\right\}-\left\{\begin{array}{c}\varepsilon_x^*(z)\\ \varepsilon_y^*(z)\\ \gamma_{xy}^*(z)\end{array}\right\}_k\right]+\left\{\begin{array}{c}\hat\sigma_x(z)\\ \hat\sigma_y(z)\\ \hat\sigma_{xy}(z)\end{array}\right\}_k \tag{35.4a}$$

or in compact form:

$$\{\sigma(z)\}_k=\left\{\overline{Q}\right\}_k\left[\{\varepsilon\}-\{\varepsilon(z)\}_k^*\right]+\left\{\hat\sigma(z)\right\}_k , \tag{35.4b}$$

where $k=1\rightarrow N$ denotes the layer number. Equation (35.4) is written in a global coordinate system for the layered structure, (x, y, z). As such, $\left[\bar{Q}\right]_k$ are the (generally anisotropic) elastic stiffness coefficients of the kth layer in the global coordinate system. They are obtained by transformation (see [35.24, 25], for example) of the stiffnesses, $[Q]_k$, from a natural coordinate system (x_1, x_2, x_3). For orthotropic materials the nonzero components of $[Q]$ for each layer are,

$$[Q]=\left[\begin{array}{ccc}\dfrac{E_1}{1-\nu_{12}\nu_{21}}&\dfrac{\nu_{12}E_2}{1-\nu_{12}\nu_{21}}&0\\ \dfrac{\nu_{21}E_1}{1-\nu_{12}\nu_{21}}&\dfrac{E_2}{1-\nu_{12}\nu_{21}}&0\\ 0&0&G_{12}\end{array}\right], \tag{35.5a}$$

where E_i, ν_{ij}, and G_{ij} are the orthotropic Young's moduli, Poisson's ratios, and the shear modulus, respectively, of the layer, in the local coordinate system. Note that $Q_{12}=Q_{21}$, and so the equality of these expressions in (35.5a) shows the reciprocal relationship between E_i and ν_{ij}; only three of the four are independent. For isotropic materials $\left[\bar{Q}\right]=[Q]$, and the nonzero components for each layer are:

$$\left[\bar{Q}\right]=[Q]=\left[\begin{array}{ccc}\dfrac{E}{1-\nu^2}&\dfrac{\nu E}{1-\nu^2}&0\\ \dfrac{\nu E}{1-\nu^2}&\dfrac{E}{1-\nu^2}&0\\ 0&0&G\end{array}\right] \tag{35.5b}$$

In (35.4) $\left\{\hat\sigma(z)\right\}_k$ is the residual internal stress in the layer and may be an arbitrary function of z, i. e., a stress gradient may exist within each layer; $\{\varepsilon\}$ is the total strain, $\{\varepsilon^*\}_k$ is the inelastic transformation strain, and the term in rectangular brackets is the elastic strain. The stresses and strains are all defined in the (x, y, z) coordinate system. Substituting (35.2) into (35.4) yields the stress distribution through the thickness:

$$\{\sigma(z)\}_k=\left\{\overline{Q}\right\}_k\left[\left\{\varepsilon^0\right\}+z\{\kappa\}-\left\{\varepsilon^*(z)\right\}_k\right] +\left\{\hat\sigma(z)\right\}_k . \tag{35.6}$$

For the layered film system we define a resultant force $\{N\}$ and moment $\{M\}$ per unit length as:

$$\left\{\begin{array}{c}N_x\\ N_y\\ N_{xy}\end{array}\right\}=\{N\}=\int_{-t/2}^{t/2}\{\sigma(z)\}_k\,\mathrm{d}z$$

$$\left\{\begin{array}{c}M_x\\ M_y\\ M_{xy}\end{array}\right\}=\{M\}=\int_{-t/2}^{t/2}\{\sigma(z)\}_k\,z\,\mathrm{d}z . \tag{35.7}$$

For example, N_x is the force in the x-direction per unit length in the y-direction. $\{N\}$ and $\{M\}$ have units of $[F/L]$, $[F\cdot L/L]$, respectively.

Substituting (35.6) into (35.7) and breaking the integrals through the thickness into sums of integrals over each layer yields:

$$\{N\}=[A]\left\{\varepsilon^0\right\}+[B]\{\kappa\}-\left\{N^\varepsilon\right\}+\left\{N^\sigma\right\}$$
$$\{M\}=[B]\left\{\varepsilon^0\right\}+[D]\{\kappa\}-\left\{M^\varepsilon\right\}+\left\{M^\sigma\right\} , \tag{35.8}$$

where:

$$[A] = \int_{-t/2}^{t/2} \{\overline{Q}\}_k \, dz = \sum_{k=1}^{N} \{\overline{Q}\}_k (z_k - z_{k-1})$$

$$[B] = \int_{-t/2}^{t/2} \{\overline{Q}\}_k \, z \, dz = \frac{1}{2} \sum_{k=1}^{N} \{\overline{Q}\}_k \left(z_k^2 - z_{k-1}^2\right)$$

$$[D] = \int_{-t/2}^{t/2} \{\overline{Q}\}_k \, z^2 \, dz = \frac{1}{3} \sum_{k=1}^{N} \{\overline{Q}\}_k \left(z_k^3 - z_{k-1}^3\right)$$

$$\left\{N^{\varepsilon}\right\} = \int_{-t/2}^{t/2} \{\overline{Q}\}_k \left\{\varepsilon^*(z)\right\}_k \, dz$$

$$\left\{N^{\sigma}\right\} = \int_{-t/2}^{t/2} \left\{\hat{\sigma}(z)\right\}_k \, dz$$

$$\left\{M^{\varepsilon}\right\} = \int_{-t/2}^{t/2} \{\overline{Q}\}_k \left\{\varepsilon^*(z)\right\}_k z \, dz$$

$$\left\{M^{\sigma}\right\} = \int_{-t/2}^{t/2} \left\{\hat{\sigma}(z)\right\}_k z \, dz \, . \quad (35.9)$$

In the terminology of laminated composite materials, $[A]$, $[B]$, and $[D]$ are the extensional, coupling, and bending constants and are functions of the elastic moduli of each layer and the arrangement of the layers through the thickness. $[A]$, $[B]$, and $[D]$ have units of $[F/L]$, $[F]$, and $[F \cdot L]$, respectively. Physically, $[A]$ describes the connection between in-plane forces and straining of the midplane, $[D]$ describes the connection between moments and curvature, and $[B]$ connects moments to midplane strain and forces to curvature. If both the geometry and material properties, including $\varepsilon^*(z)$ and $\hat{\sigma}(z)$, of the layered film system are symmetric about $z = 0$, then $[B] = [0]$ and there is no coupling between in-plane straining and bending. Note that $[A]$, $[B]$, and $[D]$ are 3×3 matrices, as are $\left[\overline{Q}\right]_k$, while all other terms a 3×1 column vectors of the form of (35.3) and (35.4).

Equation (35.8) can be written in compact form as:

$$\begin{Bmatrix} \{N\} \\ \{M\} \end{Bmatrix} = \begin{bmatrix} [A] & [B] \\ [B] & [D] \end{bmatrix} \begin{Bmatrix} \{\varepsilon^0\} \\ \{\kappa\} \end{Bmatrix} - \begin{Bmatrix} \{N^{\varepsilon}\} \\ \{M^{\varepsilon}\} \end{Bmatrix} + \begin{Bmatrix} \{N^{\sigma}\} \\ \{M^{\sigma}\} \end{Bmatrix} . \quad (35.10)$$

Equation (35.10) is most easily implemented in matrix form as a 6×6 system of equations that hold at each (x, y) coordinate. These are the constitutive equations for the layered film, incorporating the Kirchoff hypothesis and the strain-displacement relations. In order to completely describe the response of a layered film due to external or internal loads, (35.10) must be supplemented with the stress equilibrium equations and appropriate boundary conditions. In general the solution of these equations for a specified multilayer film geometry and loading is a complex undertaking and recourse is often taken to numerical methods such as the finite element method (FEM). Alternatively, the equations can be formulated using an energy approach that will be advantageous when we consider geometric nonlinearity in Section 35.1.3.

Fortunately, using this formulation we can solve a number of important problems simply using (35.10). For example, if there are no externally applied loads then $\{N\} = \{M\} = \{0\}$ and (35.10) can be inverted to yield:

$$\begin{Bmatrix} \{\varepsilon^0\} \\ \{\kappa\} \end{Bmatrix} = \begin{bmatrix} [A] & [B] \\ [B] & [D] \end{bmatrix}^{-1} \times \left\{ \begin{Bmatrix} \{N^{\varepsilon}\} \\ \{M^{\varepsilon}\} \end{Bmatrix} - \begin{Bmatrix} \{N^{\sigma}\} \\ \{M^{\sigma}\} \end{Bmatrix} \right\} . \quad (35.11)$$

Recall that all terms on the right-hand side are functions of the elastic moduli, the known transformation strains and stresses, and the geometrical arrangement of the layers. Once the midplane strain and curvature are computed using (35.11), the stress distribution in each layer can be computed using (35.6).

Special Cases

Here we apply (35.11) to yield some simple, yet important, results. Before doing so, it is useful to explicitly express the form of the transformation stress distribution $\left\{\hat{\sigma}(z)\right\}_k$. To this end we restrict $\left\{\hat{\sigma}(z)\right\}_k$ to be a linearly varying function through each layer. This can be written as:

$$\left\{\hat{\sigma}(z)\right\}_k = \{S\}_k - \{\beta\}_k \left(z - \frac{z_{k-1} + z_k}{2}\right) , \quad (35.12)$$

where $\{S\}_k$ is the average stress in layer k and $\{\beta\}_k$ is the stress gradient as shown in Fig. 35.10. For this form of the stress, $\{N^{\sigma}\}$ and $\{M^{\sigma}\}$ can be expressed

Part E | 35.1

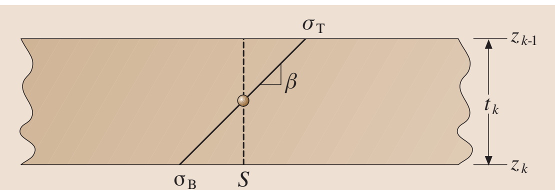


Fig. 35.10 Schematic showing a linear stress distribution characterized by a mean stress S and linear through-thickness stress gradient β

as:

$$\{N^\sigma\} = \sum_{k=1}^{N} \{S\}_k (z_k - z_{k-1})$$

$$\{M^\sigma\} = \frac{1}{2}\sum_{k=1}^{N} \{S\}_k \left(z_k^2 - z_{k-1}^2\right) - \frac{1}{12}\sum_{k=1}^{N} \{\beta\}_k \left(z_k^3 - z_{k-1}^3\right) . \quad (35.13)$$

Furthermore, it is useful to specify the form of $\{\varepsilon^*(z)\}$ when its source is thermal expansion during a uniform temperature change T from a reference temperature. In this case:

$$\{\varepsilon^*(z)\}_k = \{\varepsilon^*\}_k = \{\alpha\}_k T . \quad (35.14)$$

For this form of the stress-free strain, $\{N^\varepsilon\}$ and $\{M^\varepsilon\}$ can be expressed as:

$$N^\varepsilon = \int_{-t/2}^{t/2} \{\overline{Q}\}_k \{\alpha\}_k T \,\mathrm{d}z = \Delta T \sum_{k=1}^{N} \{\overline{Q}\}_k \{\alpha\}_k (z_k - z_{k-1})$$

$$M^\varepsilon = \int_{-t/2}^{t/2} \{\overline{Q}\}_k \{\alpha\}_k Tz \,\mathrm{d}z = \frac{\Delta T}{2}\sum_{k=1}^{N} \{\overline{Q}\}_k \{\alpha\}_k \left(z_k^2 - z_{k-1}^2\right) . \quad (35.15)$$

In all of the examples described in this section we will consider only cases in which all layers have elastic constants, thermal expansion properties, and misfit strains that are isotropic. As a result, $A_{16} = A_{26} = B_{16} = B_{26} = D_{16} = D_{26} = 0$. The ramifications of this are that the midplane shear strains $\gamma_{xy}^0 = 0$ and the twist curvatures $\kappa_{xy} = 0$. In addition, the midplane strains and curvatures are equibiaxial, i. e., $\varepsilon_x^0 = \varepsilon_y^0 = \varepsilon^0$ and $\kappa_x = \kappa_y = \kappa$. So in the remainder of this section this equibiaxial deformation state is understood, and we refer to it simply by ε^0 and κ. While this is the case in the examples presented in this section, it is not the case when material anisotropy exists, the film is patterned in lines instead of as a blanket, or large deflections occur which result in geometric nonlinearity. These issues will be discussed briefly in later sections.

Single-Layer Plate. Consider a single-layer film with an internal biaxial mean stress $S = S_{11} = S_{22}$ and stress gradient $\beta = \beta_{11} = \beta_{22}$ that is subjected to a uniform temperature change T. This scenario models the deformation of a film after release from a substrate when subjected to a temperature change where before release the film had an internal stress S, and stress gradient β. In this case, after significant manipulation (35.11), with (35.12) and (35.13), yields:

$$\kappa = \frac{\beta}{M} \quad (35.16)$$

$$\varepsilon^0 = -\frac{S}{M} + \alpha T , \quad (35.17)$$

where $M = \frac{E}{1-v}$ is the biaxial modulus. As previously discussed, after release there is straining due to S and $\varepsilon^* = \alpha T$, and the plate bends with a biaxial curvature κ. The result of (35.16), and especially the simplification that results for beams (simply obtained by setting $\nu = 0$ and interpreting κ and ε^0 as the uniaxial curvature and midplane strain in the direction of the beam length) is commonly used in conjunction with measurements of the curvature after release to determine the stress gradient in a film.

Bilayer Plate. Another simple yet practically important special case is that of two isotropic layers of thicknesses t_1 and t_2, subject only to a uniform temperature change T. In this case, (35.11), with (35.12) and (35.13), yields:

$$\kappa = \frac{6\Delta\alpha T}{t_2} hm \left(\frac{1+h}{1+2hm\left(2+3h+2h^2\right)+h^4m^2}\right) \quad (35.18)$$

$$\varepsilon^0 = T\left(\frac{\alpha_1 mh\left(1+3h+3h^2+mh^3\right)}{1+2hm\left(2+3h+2h^2\right)+h^4m^2} + \frac{\alpha_2\left[1+mh\left(3+3h+h^2\right)\right]}{1+2hm\left(2+3h+2h^2\right)+h^4m^2}\right) , \quad (35.19)$$

where $h = \frac{t_1}{t_2}$, $m = \frac{M_1}{M_2}$, and $M_k = \frac{E_k}{1-\nu_k}$ (here $k = 1, 2$ corresponds to layers 1 and 2) and $\Delta\alpha = \alpha_2 - \alpha_1$.

It is often convenient to define a nondimensional curvature $\hat{\kappa}$:

$$\hat{\kappa} = \frac{\kappa\, t_2}{6\Delta\alpha T} \quad (35.20)$$

Equation (35.18) can then be written as

$$\hat{\kappa} = \frac{hm\,(1+h)}{1+2hm\left(2+3h+2h^2\right)+h^4m^2} \,. \quad (35.21)$$

Two limiting values of (35.21) are of interest. The first is the case where there is no elastic mismatch between the layers, i. e., $m = 1$. In this case (35.21) simplifies to:

$$\hat{\kappa} = \frac{h}{(1+h)^3} \,. \quad (35.22)$$

The other is the *thin-film limit* where $t_1 \ll t_2$. Expanding (35.18) in powers of h and retaining only the lowest order term recovers *Stoney's* [35.26] well-known result:

$$\kappa = \frac{6\Delta\alpha T}{t_2} hm$$
$$\hat{\kappa} = hm \,. \quad (35.23)$$

In the thin film limit, (35.19) reduces to $\varepsilon^0 = \alpha_2 T$.

Figure 35.11 shows the normalized curvature $\hat{\kappa}$ as a function of the layer thickness ratio h for various ratios of the biaxial moduli, m. The curves from top to bottom are for $m = 10$, 0.66, and 0.1. $m = 10$ and 0.1 represent a stiff film on a compliant substrate and a compliant film on a stiff substrate, respectively. $m = 0.65$ represents a gold film on a polysilicon substrate. The solid curves are the exact results from (35.21) and the dashed curves are the Stoney's result for the thin-film limit, (35.23). In the latter case, $\hat{\kappa}$ varies linearly with h, with slope m. The results in Fig. 35.10 show how the range of applicability of Stoney's result depends on both h and m; the range decreases for increasing h and decreasing m. For most microstructure applications where the layer thicknesses are comparable ($h > 0.1$), Stoney's result is not accurate unless the film is much more compliant than the substrate. Thus physically, Stoney's result is accurate when the substrate stiffness controls the deformation, either because it is much thicker or has much higher elastic moduli than the film. Over the years many papers have discussed *corrections* to Stoney's result to increase the region of validity in terms of layer thicknesses and modulus mismatch. We emphasize, though, that (35.18) is valid for arbitrary layer thicknesses and modulus mismatch and is quite simple to use itself. We refer the reader interested in more details to [35.7, 18, 22].

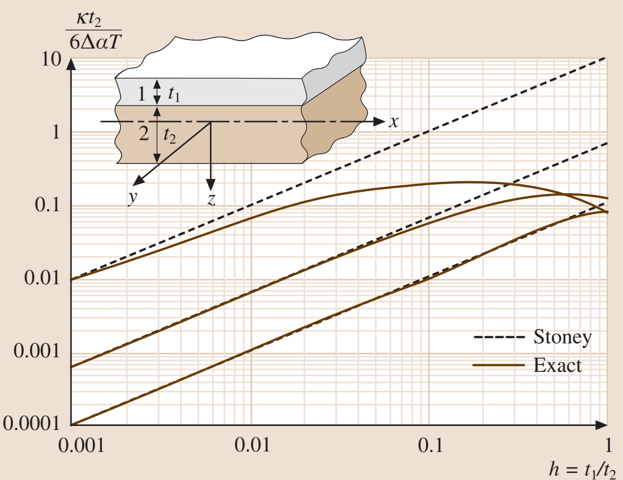

Fig. 35.11 Normalized curvature $\hat{\kappa}$ as a function of the film thickness ratio $h = t_1/t_2$ for three values of the biaxial modulus ratio, $m = M_1/M_2$. From *top* to *bottom*, the curves are for $m = 10$, 0.65 (gold/polysilicon), and 0.1. The *solid lines* are the exact solution, (35.21) and the *dashed lines* are Stoney's result in the thin-film limit, (35.23)

Equally important from a technological viewpoint is the equibiaxial stress distribution through the thickness $\sigma_x(z) = \sigma_y(z) = \sigma(z)$ obtained from (35.6):

$$\sigma(z)_k = M_k\left(\varepsilon^0 + z\kappa - \alpha_k T\right) \,, \quad (35.24)$$

where $k = 1, 2$ denotes the layer. In (35.24), κ and ε^0 are obtained from (35.18) and (35.19), respectively, and M_k and α_k are the values for the kth layer. In the thin-film limit the equibiaxial stress varies so little through the film thickness that it can be taken as constant, i. e., $\sigma_x = \sigma_y = \sigma$. This is the reason one often refers to the *stress* in a thin-film by a single number. In the thin film limit, the substrate (layer 2) thermal expansion dominates the deformation process, and so the film strains by an amount $\Delta\alpha T$, and the biaxial stress in the film is $\sigma_1 = M_1 \Delta\alpha T$, or in terms of the curvature:

$$\sigma_1 = \frac{M_2}{6}\frac{t_2^2}{t_1}\kappa \,. \quad (35.25)$$

Note that, as written, the thermoelastic properties of the film do not enter (35.25). We will discuss the practical ramifications of this shortly.

Figure 35.12 shows the stress distribution through the thickness of both layers for a negative unit temperature change, (35.24), as a function of $h = t_1/t_2$ for

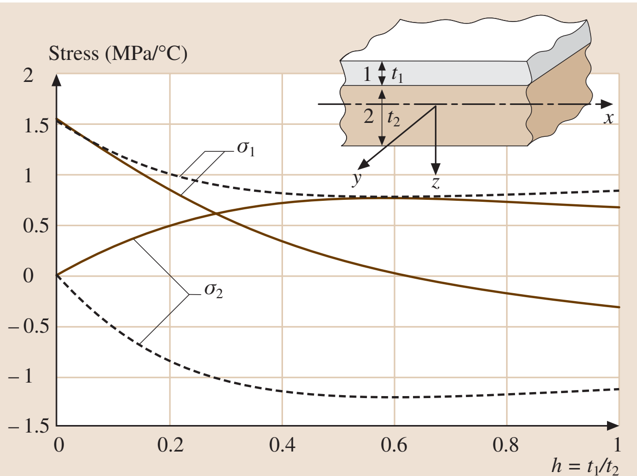

Fig. 35.12 Biaxial stress per unit temperature change, (35.24), for a gold/polysilicon bilayer ($m = 0.67$) for a 0.5-µm-thick gold film as a function of the polysilicon thickness $h = t_1/t_2$. Biaxial stresses are shown at four locations: the interface on the gold and polysilicon sides (*dashed lines*), and the surfaces of the gold and polysilicon (*solid lines*)

$m = 0.67$, and $t_1 = 0.5$ µm, representative of a gold film on a silicon substrate. Equation (35.24) shows, and we have previously discussed, that the biaxial stress varies linearly through each material. Thus we can completely specify the stress distribution by plotting it at four points: the top of material 1, the interface in material 1, the interface in material 2, and the bottom of material 2. Referring to Fig. 35.8, these positions are $z = z_0$, z_1, and z_2. Because of the perfect bonding between the two films, the total strain must be continuous across the interface. The elastic moduli are different for the two films, though, and so the stresses will be discontinuous at the interface. Hence we interpret $z = z_1$ as a position just above, or just below, the interface, and use M_k and α_k in (35.24) as appropriate. As $h \to 0$ the stresses at the top and at the interface in the film (layer 1) converge and take on a maximum value given by $\sigma = M_1 \Delta\alpha T$. The stress in the substrate vanishes in this limit. As the substrate thickness increases (increasing h) the stress in the film decreases with the maximum value occurring at the interface. The stress in the substrate increases at the interface but decreases on the bottom surface. In general this results in a stress distribution in the substrate that is compressive on the bottom surface and tensile at the interface. Depending on h, the stresses in the film are either tensile throughout or tensile on the interface and compressive on the surface. The difference in stress between the interface and the surface is a measure of the stress gradient in each layer; it increases with increasing h. For different values of m, the behavior with varying h is similar to that in Fig. 35.12, with the stress in the film increasing with increasing m.

Equation (35.25) is the theoretical basis of what is perhaps the most common technique to measure thin-film stresses – the wafer curvature method [35.6]. It involves measuring the curvature of a thick (compared to the film thickness) wafer with and without a film, and then using the curvature difference between the two in (35.25) to determine the film stress. It is particularly convenient because the film stress is obtained from the measured curvature regardless of the source of the stress and the thermoelastic moduli of the film. It is necessary, though, to know accurately the thickness of the film and substrate, as well as the elastic properties (biaxial modulus, $E/(1-\nu)$) of the substrate. An appealing feature of the method is that the elastic properties of the film, typically difficult to measure themselves, do not need to be known. This is because the much thicker substrate controls the deformation response.

Three-Layer Symmetric Plate. Considerable simplification also results for the technologically important case of a thin-film multilayer subject to a uniform temperature change T that consists of three layers, but the top and bottom layer are identical in terms of thickness ($t_3 = t_1$) and material properties ($M_3 = M_1, \alpha_3 = \alpha_1$). In this case, from (35.9) $[B] = [0]$, and thus the plate does not bend, i. e., $\kappa = 0$. Equation (35.11), with (35.12) and (35.13), then yields:

$$\varepsilon^0 = \frac{(2\alpha_1 mh + \alpha_2)\,T}{2mh+1}\,. \tag{35.26}$$

In the thin-film limit $h \to 0$, $\varepsilon^0 = \alpha_2 T$.

The equibiaxial stress distribution is such that it does not vary through the thickness within each layer, i. e., $\sigma(z)_3 = \sigma(z)_1 = \sigma_1$, and $\sigma(z)_2 = \sigma_2$. From (35.6) with $\kappa = 0$ and ε^0 from (35.26):

$$\sigma_1 = \frac{M_1 \Delta\alpha T}{2mh+1}$$
$$\sigma_2 = \frac{-2mh M_2 \Delta\alpha T}{2mh+1}\,. \tag{35.27}$$

In the thin-film limit, the stresses of (35.27) reduce to $\sigma_1 = M_1 \Delta\alpha T$ and $\sigma_2 = -2M_1 h \Delta\alpha T$.

Figure 35.13 shows the uniform biaxial stress in each material for a negative unit temperature change as a func-

tion of $h = t_1/t_2$ for $m = 0.65$, and $t_1 = 0.5\,\mu\text{m}$, again representative of a gold film on a silicon substrate. As $h \to 0$, the stresses in the films (layers 1 and 3) are given by $\sigma_1 = M_1 \Delta\alpha T$, and that in the substrate (layer 2) approaches zero. The stress in the films is tensile and decreases with increasing h while that in the substrate is compressive, increasing in magnitude with increasing h.

Beams. Our analysis thus far has focused on multilayer plates where both in-plane dimensions far exceed the thickness and where the transformation strains, and thus the stresses, are equibiaxial. When one in-plane dimension, say x, is much larger than the other, the structure is often referred to as a beam. In the classical treatment of the flexure of beams, it is assumed that only one nonzero normal stress component exists, σ_x. This greatly simplifies the analysis for homogeneous beams, but the situation is not as straightforward for multilayers with biaxial transformation strains. From the results in the previous section, one can obtain results for a beam theory by simply setting $\nu_1 = \nu_2 = 0$ in the formulae developed for biaxial stresses, but these results should be used with caution as the transverse component of the moment that results from the equibiaxial transformation strains cannot be neglected as shown by three-dimensional finite element calculations [35.27, 28]. *Swanson* [35.29] describes how to apply the results from a multilayer plate theory to beams and specifically focuses on the effect of the beam width, giving easily usable results for narrow and wide beams. The main results are an effective structural stiffness $(EI)_{\text{eff}}$ that can be used to replace EI (E is Young's modulus and I is the cross-sectional moment of inertia) in existing beam theory results, such as those that will be presented in Sect. 35.2 for electromechanics analysis. Insight into the behavior can be seen in the results in Table 35.2, which show measurements (using interferometry as described by *Dunn* et al. [35.30]) and predictions based on (35.18) for plates and the simplified version for beams obtained by setting $\nu_1 = \nu_2 = 0$. In all calculations both the gold and polysilicon are modeled as linear thermoelastic with isotropic material properties. Input parameters to the finite element calculations are $E_2 = 163\,\text{GPa}$, $\nu_2 = 0.22$, $E_1 = 78\,\text{GPa}$, $\nu_1 = 0.42$ [35.31]. The thermal expansion coefficients of the materials were assumed to vary linearly with temperature, and values at 100(24) °C used are $\alpha_2 = 3.1(2.6) \times 10^{-6}\,/°\text{C}$, and $\alpha_1 = 14.6(14.2) \times 10^{-6}\,/°\text{C}$ [35.31]. Although some uncertainty exists in the values of these material properties for the gold and polysilicon films, we think they are sufficiently accurate for the purpose of modeling the observed phenomena. Young's modulus and Poisson's ratio of the polysilicon are in line with many measurements over many MUMPS runs [35.32] and agree adequately with bulk polycrystal averages of single-crystal elastic constants. Good agreement exists between the predictions using plate theory and the measurements, while predictions based on beam theory are significantly less accurate, demonstrating the need to use plate, rather than beam, theory.

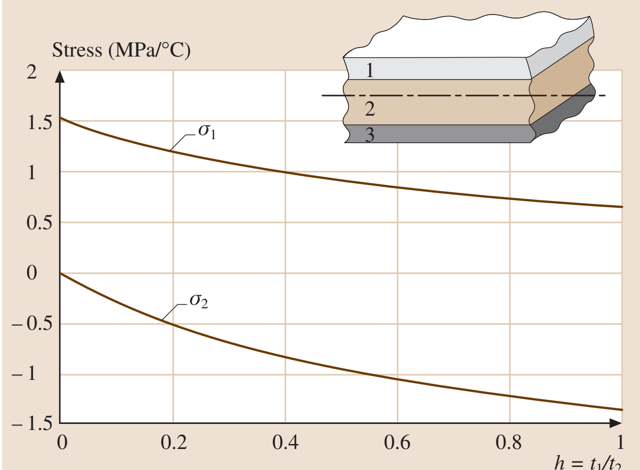

Fig. 35.13 Biaxial stress per unit temperature change for a gold/polysilicon/gold ($m = M_1/M_2 = 0.65$) three-layer film system. The calculations, (35.27), are for a 0.5-µm-thick gold film as a function of the polysilicon thickness $h = t_1/t_2$. Biaxial stresses are shown in the gold (*top curve*) and polysilicon (*bottom curve*)

Patterned Films. In microsystems applications, additional design freedom can be obtained by using multilayer films with patterned, rather than blanketed,

Table 35.2 Predicted and measured curvature per unit negative temperature change for gold/polysilicon microstructures as a function of the polysilicon thickness. In all cases the gold thickness is 0.5 µm. The microstructures are 300 µm long and 50 µm wide and cantilevered from one end

Polysilicon thickness (µm)	$d\kappa/dT$ (m^{-1}/°C) Measured	Predicted (plate)	Predicted (beam)
1.5	−5.36	−5.56	−4.86
3.5	−1.42	−1.44	−1.16

films. In general one can use the finite element method with multilayer plate elements to model the deformation and stresses in a multilayer with arbitrary patterned layers. A useful practical example is a beam of width w_2 that is covered with a film in the pattern of a stripe of width w_1 as shown in Fig. 35.14. A simple modification of (35.18) yields the curvature along the length of the patterned beam as a function of the nondimensional linewidth, $c = w_1/w_2$:

$$\kappa_{\text{patterned}} = \frac{6\Delta\alpha T}{t_2} hcm \times \left(\frac{1+h}{1+2hcm\left(2+3h+2h^2\right)+h^4c^2m^2} \right) . \quad (35.28)$$

Predictions from (35.28), normalized as $\eta = \kappa_{\text{patterned}}/T$, are shown in Fig. 35.14 for $m = 0.65$ (the gold/polysilicon bilayer) along with predictions from detailed finite element calculations and measurements over the entire range of $c = w_1/w_2$ [35.33]. Equation (35.28) accurately describes the effect of linewidth on curvature development and can be used to design bilayer beams.

Deflections. Thus far our discussion of deformation has been cast in terms of curvature. An important quantity for many applications where control of the deformation is important is the deflection of the multilayer. Formally this can be obtained by integrating the curvature-displacement relationship and applying the relevant boundary conditions. For example, assuming constant curvature, the tip deflection $w(x = L)$ for a cantilever beam of length L, is:

$$w(x = L) = \frac{\kappa L^2}{2} . \quad (35.29)$$

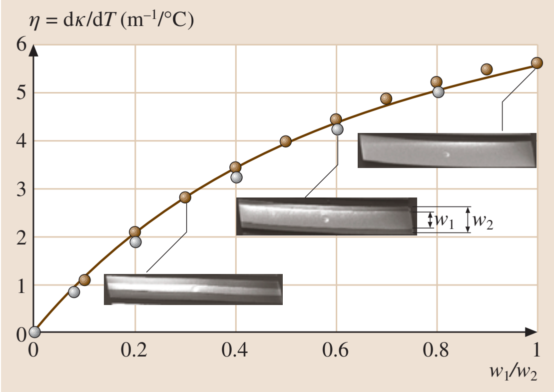

Fig. 35.14 Curvature per unit temperature change as a function of the ratio of gold to polysilicon film width w_1/w_2 for gold (0.5 μm thick)/polysilicon (1.5 μm thick) strip-patterned beams. *Grey circles* are finite element simulation results, the *solid line* is the analytical result of (35.28), and the *brown circles* are measurements

35.1.3 Nonlinear Geometry

In the previous section we noted that in general the deformation of a layered film microstructure subjected to transformation strains consists of three regimes but focused on the first, linear regime. Here we focus on the second and third regimes. To illustrate, consider the seemingly simple case of a plate with total thickness much less than the in-plane dimensions, composed of two isotropic layers with different material properties (elastic moduli and thermal expansion coefficients) subjected to a temperature change. Although we use a temperature change to demonstrate, the results hold for any type of transformation strains. In terms of the average curvature variation as a function of temperature change, three deformation regimes have been identified as illustrated in Fig. 35.15 [35.16–19, 22, 23]. The first regime, I, consists of a linear relation between the average curvature and temperature change where $\kappa_x = \kappa_y$, i. e., the average curvature is spherically symmetric. This deformation regime is characterized by both small transverse displacements and rotations, and so conventional thin-plate theory adequately describes the deformation. In Sect. 35.1.2 we outlined the analysis in this regime. The second regime, II, consists of a nonlinear relation between the average curvature and temperature, but again $\kappa_x = \kappa_y$. The behavior is due to *geometric nonlinearity* that results when the deflections become excessively large relative to the plate thickness, and they contribute significantly to the in-plane strains. It has been shown [35.15–19, 22, 23] that in these two regimes the symmetric deformation modes are stable. The second regime ends at the point when the deformation response bifurcates from a spherical to ellipsoidal deformation, i. e., $\kappa_x \neq \kappa_y$. At this point, the beginning of regime III, it becomes energetically favorable for the plate to assume the ellipsoidal shape because to retain the spherical deformation under an increasing temperature change requires increased midplane straining. After the bifurcation, the curvature in one direction increases while that perpendicular to it decreases; the plate tends toward a state of cylindrical curvature. This observation helps to explain the energetic argument, as unlimited cylindrical curvature can

be obtained with no midplane straining, while spherical curvature cannot. This discussion has been cast in the context of linear material behavior. Additional deformation regimes result if material nonlinearity is present, for example, yielding [35.18].

Analysis

The understanding described above derives from a number of studies with different technological motivations, primarily structural laminated composites and thin films for microelectronics. Most of these studies are analytical [35.15–19, 22, 23, 34] and build upon the original work of Hyer [35.13, 14]. To illustrate the computational approach in a reasonably simple setting, here we consider a two-layer plate with layer thicknesses t_1 and t_2. Each layer is isotropic and characterized by the Young's modulus E_i, Poisson's ratio ν_i, and thermal expansion coefficient α_i $(i = 1, 2)$. We consider a square plate with side length L; a similar analysis can be carried out for circular [35.22] or other plate shapes. The plate is subject to a uniform temperature change, T. In other words, the stress-free strains $\{\varepsilon^*\}_k$ are due to thermal expansion as given by (35.14).

In order to compute the deformed shape when the plate is subject to a temperature change we use the approach of *Hyer* [35.14] as applied by *Masters* and *Salamon* [35.16]. The basic idea is to assume an admissible displacement field $w(x, y)$ in terms of unknown parameters (d_i) that are suitably chosen to be consistent with observed deformation modes. Values of the parameters d_i are then determined via a Ritz procedure so as to minimize the total potential energy of the system. Different choices of the assumed displacement field have been considered, and details of the procedures are given in the above references. Such analyses are sufficient to qualitatively, and in many cases quantitatively, explain the three regimes of deformation shown in Fig. 35.15. In fact, quite simple closed-form expressions result for special cases that provide illuminating descriptions of observed phenomena (see for example [35.22]). A disadvantage of the analytical approaches is that for simplicity a displacement field consistent with a spatially constant curvature deformation mode is usually chosen. Additionally, these formulations are useful for only simple plate shapes. While this may be adequate for the structures demonstrated here, it is not for more complex in-plane shapes, of either or both layers, that arise in microsystems applications. In this more general case the best approach is probably to use the finite element method for the approximate analysis.

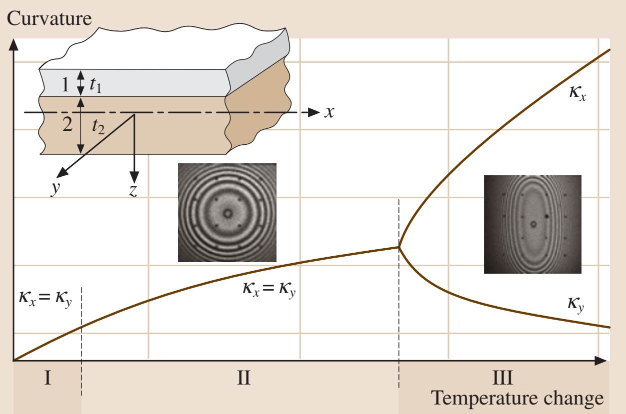

Fig. 35.15 General characteristics of the average curvature-versus-temperature change of a two-layer plate microstructure showing the three deformation regimes. The interferograms in the *inset* show measured displacement contours for gold/polysilicon plates in Regimes II and III

To proceed, we assume the transverse midplane displacement is of the form:

$$w^0(x, y) = d_1 x^2 + d_2 y^2 \,. \tag{35.30}$$

d_1 and d_2 are immediately recognized as one-half the curvature in the x- and y-directions, and the deformation is seen to be a constant curvature mode. The midplane displacements u^0 and v^0 are assumed to be described by third order polynomials in x and y, also with unknown constant coefficients d_3–d_8 to be determined:

$$\begin{aligned} u^0(x, y) &= d_3 x + \frac{d_5}{3} x^3 + d_7 x y^2 - \frac{d_1^2}{6} x^3 \\ v^0(x, y) &= d_4 y + \frac{d_6}{3} y^3 + d_8 x^2 y - \frac{d_2^2}{6} y^3 \,. \end{aligned} \tag{35.31}$$

The midplane strains are then computed from the nonlinear strain-displacement relations of the von Karman plate theory:

$$\begin{aligned} \varepsilon_x^0 &= \frac{\partial u^0}{\partial x} + \frac{1}{2}\left(\frac{\partial w^0}{\partial x}\right)^2 \\ \varepsilon_y^0 &= \frac{\partial v^0}{\partial y} + \frac{1}{2}\left(\frac{\partial w^0}{\partial y}\right)^2 \\ \gamma_{xy}^0 &= \frac{\partial u^0}{\partial y} + \frac{\partial v^0}{\partial x} + \left(\frac{\partial w^0}{\partial x}\right)\left(\frac{\partial w^0}{\partial y}\right) \,. \end{aligned} \tag{35.32}$$

The strains at any point through the thickness are then computed using the standard kinematic relations for thin plates, (35.2), and the stresses are computed from the strains using the conventional linear thermoelastic constitutive relations for each layer, (35.6) with $\{\varepsilon^*\}_k = \{\alpha\}_k T$. The first term in (35.32) is recognized as the conventional small deformation, and the second term arises from the large transverse deflections w^0, which result in straining of the midplane. This is shown schematically in Fig. 35.16 for the strain component ε_x^0; similar results are obtained for ε_y^0 and γ_{xy}^0.

The potential energy density of each layer is computed from the stress and strain in each layer, and the total potential energy of the plate is then computed by integrating it over the volume of the plate. This yields an expression for the potential energy of the plate in terms of the unknown coefficients d_i:

$$U(d_i) = \int_{-L/2}^{L/2}\int_{-L/2}^{L/2}\int_{-t/2}^{t/2} \{\varepsilon\}^T \{\sigma\}_k \, \mathrm{d}z \, \mathrm{d}x \, \mathrm{d}y \,, \tag{35.33}$$

where the superscript T denotes the transpose of the 3×1 column vector. The coefficients d_i are determined by application of the principle of minimum potential energy:

$$\frac{\partial U(d_i)}{\partial d_i} = 0 \,. \tag{35.34}$$

This yields eight equations for the eight unknown d_i and thus solutions for the deformation response of Fig. 35.15. Complete details regarding this analysis can be found elsewhere [35.14, 16]; here we present only the pertinent results in what we hope is an accessible form. When the displacements are small, the solution of (35.34) and (35.35) recovers (35.18) and (35.19).

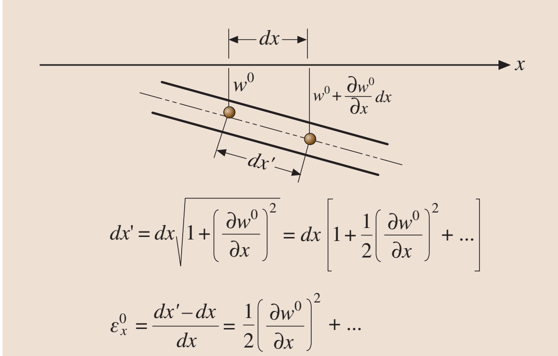

Fig. 35.16 Illustration of the development of midplane strain due to bending when nonlinear geometry effects arise

In the nonlinear but symmetric deformation regime II, the relationship between both the curvature and midplane strain, and the thermal expansion mismatch is too complex to present here. This is also the case in the nonlinear regime III after bifurcation. An important difference between the linear and nonlinear response, though, is that the nonlinear response depends on the plate size. The critical curvature at which bifurcation occurs, though, can be obtained explicitly and is given by:

$$\kappa_{\mathrm{cr}} = \frac{12\sqrt{2}}{L^2}\sqrt{\frac{6+A_{12}/A_{11}}{1+A_{12}/A_{11}}}\,\frac{\sqrt{A_{66}D_{66}-B_{66}^2}}{A_{66}^2} \tag{35.35}$$

for a square plate of side length t, where A_{ij}, B_{ij}, and D_{ij} are the composite moduli of (35.8). In the simplified case where there is no elastic mismatch between the layers and the elastic, response can be expressed in terms of the Young's modulus E and Poisson's ratio ν, (35.35) reduces to:

$$\kappa_{\mathrm{cr}} = 2\sqrt{6}\sqrt{\frac{6+\nu}{1+\nu}}\frac{t}{L^2} \,, \tag{35.36}$$

where $t = t_1 + t_2$. These results have also been obtained by *Finot* and *Suresh* [35.18]; similar results exist for a circular plate [35.22, 30].

The analysis just discussed is made tractable by assuming a displacement field consistent with a constant curvature. In the nonlinear case, this assumption is questionable. While the assumed displacement field used in the Ritz procedure could be modified to incorporate the dependence of curvature on position, perhaps the simplest approach to tackle these more general problems is to use the finite element method to solve the geometrically nonlinear equations over an arbitrary spatial domain. This is also the most viable approach for more complicated in-plane geometries, including patterned films. Complete details regarding the use of the finite element method to carry out such calculations can be found in *Dunn* et al. [35.30]. Here we will simply show the result of some of these calculations. The input parameters used are the same as those given in Sect. 35.1.2.

Deformation Behavior

In order to illustrate the nature of the deformation phenomena in the nonlinear regimes, Fig. 35.17 shows

contour plots of measured (using an interferometric microscope as described by *Dunn* et al. [35.30]) and predicted displacement fields $w(x, y)$ for square plates of four plate sizes that have been cooled from about 100 °C where they are flat to room temperature. Due to the thermal expansion mismatch between the polysilicon and gold, the $L = 150\,\mu m$ samples deform in a spherically symmetric manner; contours of constant transverse displacement $w(x, y)$ are nearly circles. This is also the case as the size increases to $L = 200$ and $250\,\mu m$, although the displacements increase as the plate size increases. At $L = 300\,\mu m$, though, the transverse displacement contours are not circular but elliptical, indicating that the deformation is no longer spherically symmetric. Thus when subjected to the same temperature change, both the magnitude and deformation mode depend on the plate size. As the in-plane dimension of the plate increases with the thickness held constant, the deformation mode changes from one of spherical symmetry to one more like cylindrical symmetry.

A complete picture of the deformation as a function of plate size and temperature change could be obtained by acquiring full-field displacements like those in Fig. 35.17 as a function of temperature. But a reasonable picture of the deformation behavior can be obtained in much simpler form by considering the *average* curvature in the x- and y-directions as a function of temperature. This is shown in Fig. 35.18, in which the average curvature in the x- and y-directions is plotted as a function of the magnitude of the temperature change during cooling. The temperature change is actually negative according to our convention, but its magnitude is plotted for convenience. The average curvatures are determined from the measured and computed $w(x, y)$ by averaging $\kappa_x = -\partial^2 w(x, 0)/\partial x^2$ and $\kappa_y = -\partial^2 w(0, y)/\partial y^2$ along the paths $y = 0$ and $x = 0$, respectively [35.30]. The x- and y-directions are taken to be aligned with the principal curvatures after bifurcation. The use of the average curvature as a measure of the plate deformation seems appropriate if the curvature is, or is close to, spatially uniform. This aspect will not be taken up in detail, but we refer the interested reader to [35.22, 30] for details. It is apparent from both the measurements and predictions that in regime I, the curvature-temperature response is

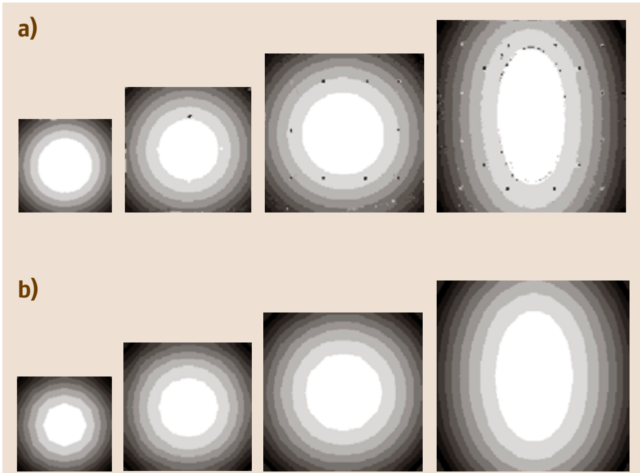

Fig. 35.17a,b Contour plots of the **(a)** measured, and **(b)** predicted transverse displacements $w(x, y)$ at room temperature following cooling from 100 °C for the four gold/polysilicon square plates: $L = 150$, 200, 250, and 300 µm from *left* to *right*. Each contour band represents a displacement of 0.23, 0.35, 0.45, and 0.6 µm for the $L = 150$, 200, 250, and 300 µm plates, respectively

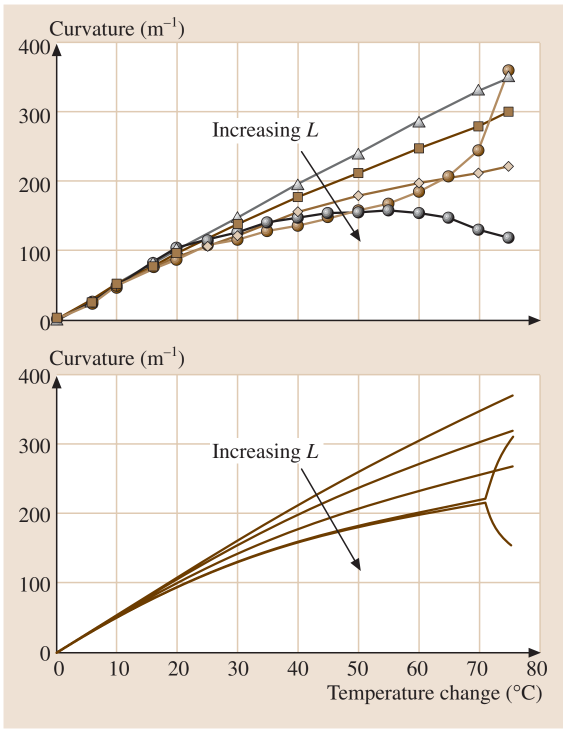

Fig. 35.18 Average measured (*top*) and predicted (*bottom*) curvature as a function of temperature change upon cooling from 100 °C to room temperature. The curves from *top* to *bottom* are for the $L = 150$, 200, 250, and 300 µm structures, respectively

Part E | 35.1

independent of plate size and shape. In regime II, though, there is a strong dependence on plate size, and this is also the case in regime III. The major discrepancy between the measurements and predictions is the sharpness of the bifurcation for the $L = 300\,\mu m$ plate; it is quite sharp in the predictions but much more gradual in the measurements. To understand this we note that the source of the bifurcation is an *imperfection* of some sort that breaks the ideal symmetry, and in general it is difficult to accurately model the detailed imperfection.

Figure 35.19 demonstrates the connection between the thermomechanical loading (the temperature change), the geometry (plate size, L), and the boundaries between the three deformation regimes for gold/polysilicon plate microstructures. Specifically, it shows the temperature change necessary to initiate nonlinear effects (the transition between regions I and II), and bifurcation (the transition between regions II and III) as a function of polysilicon thickness when the gold film thickness is kept constant at $0.5\,\mu m$. Despite the fact that the constant curvature approximation becomes questionable for larger plate sizes, (35.35) is a good approximation as seen by the agreement with the finite element calculations, at least for the elastic mismatch and plate sizes considered here. In fact, although not shown, the simplified result of (35.36) for no elastic mismatch is in reasonable agreement with the finite element and

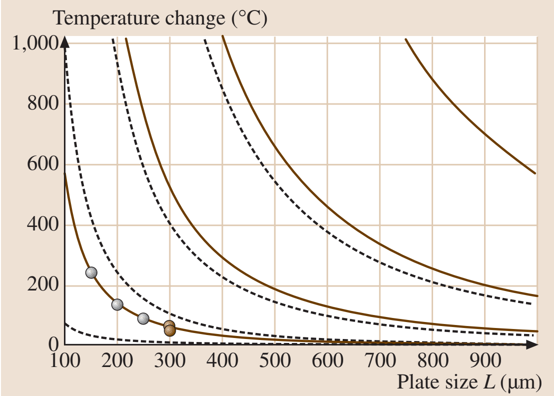

Fig. 35.19 Temperature change required for the initiation of nonlinear geometry effects (*dotted lines*) and critical temperature change for bifurcation (*solid lines*) as a function of square plate size and the thickness of polysilicon for the gold/polysilicon microstructures. Lines in each set from *left* to *right* represent $1.5\,\mu m$, $3.5\,\mu m$, $5.5\,\mu m$, and $8.5\,\mu m$ thick polysilicon, respectively. *Grey circles* are finite element calculations, and the *brown circle* is a measurement

the complete analytical results. The measurement for $L = 300\,\mu m$ is accurately described by both the analytical and finite element results.

In the analytical treatments discussed previously, it is assumed that the curvature is spatially uniform. The power of finite element calculations is that this requirement is relaxed and the spatial variation of the curvature can be studied theoretically. Full-field interferometry measurements allow one to study this experimentally as well. Briefly we discuss the resulting behavior for gold/polysilicon plate microstructures but refer the interested reader to [35.22, 30] for more details. In the linear regime, measurements and predictions both show that curvature is essentially uniform across the plate. In the nonlinear regime, though, the curvature varies appreciably with position, increasing by about a factor of two from the center to the periphery of the plate. The spatial nonuniformity of the curvature increases as the plate size increases. The spatial variation of the curvature raises concern regarding the suitableness of an analysis based on constant curvature. As mentioned previously, such an analysis may be adequate to describe the general deformation behavior but not for finer details.

35.1.4 Nonlinear Material Behavior

So far we have discussed in some detail the linear thermoelastic response of multilayer films and to a lesser degree, the effects of geometric nonlinearity. An additional complication is material nonlinearity. It can arise in numerous forms including plasticity, creep, stress relaxation, and evolution of the material microstructure (densification, grain growth, defect annihilation, etc.) during thermomechanical loading. In this section we briefly discuss nonlinear material behavior of multilayer films, focusing on the phenomena most relevant for the realization of reliable devices. The discussion in this section is concerned primarily with multilayer films where one of the films is a metal.

Nonlinear Material Behavior During Initial Thermal Cycles

As deposited, the material microstructure of a metal film is generally not stable. As the film is heated, microstructural evolution leads to the development of internal stress, which then can lead to changes in the curvature of the multilayer film. The general behavior is common to films made of many different metals, such as aluminum, copper, nickel, and gold. It has been studied extensively in the context of microelectronics applications (see for example [35.6, 35, 36]) where the substrate

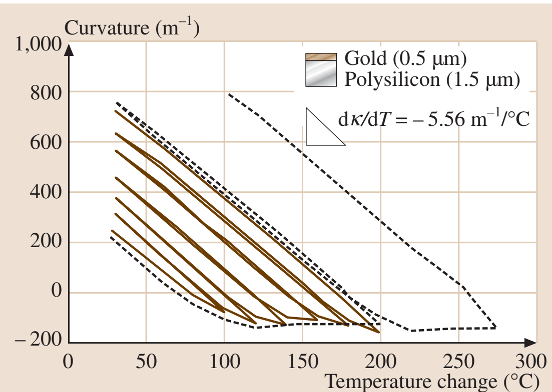

Fig. 35.20 Curvature versus temperature for gold (0.5-µm-thick)/polysilicon (1.5-µm-thick) 300 µm × 50 µm beam microstructures. The *solid lines* are tests with six cycles from room temperature to 200 °C with the maximum temperature in each successive cycle increasing by 20 °C. The *dashed lines* are tests with two cycles: the first from room temperature to 200 °C and then back to 30 °C, and the second to 275 °C and then back to 30 °C

is much thicker than the film and the thin-film limit results, which simplifies the interpretation of the results.

Figure 35.20 shows the general behavior of the curvature vs. temperature for a bilayer film consisting of a 0.5 µm gold film that was evaporated onto a 1.5 µm polysilicon film. During the initial heating the deformation is thermoelastic, characterized by a decrease in curvature with a constant $d\kappa/dT$, until the temperature reaches about 70 °C (the theoretical thermoelastic slope from (35.18) is shown on the figure). Between 70 °C and 100 °C, the curvature decreases at a much lower rate; in fact the curve flattens, i. e., $d\kappa/dT \approx 0$. Interestingly, between room temperature and 100 °C, the curvature changes from positive to negative, our convention being that a positive curvature means a beam with the gold on top is curved upward. The strong departure of the curvature from the thermoelastic behavior results because the microstructure of the evaporated film is not stable in the as-deposited condition. The temperature increase during the first cycle promotes microstructural changes in the film. These result in tensile straining of the film, which competes with the thermoelastic deformation (see for example [35.6, 36]). Upon cooling from 100 °C, the response is again thermoelastic, this time throughout the entire cooling process. Although it does not occur here, if the temperature change is large enough, yielding of the metal film can occur upon cooling. The curvature upon return to room temperature is greater than that initially at room temperature. It is important to understand this behavior because many post-fabrication and packaging processes expose a microstructure to elevated temperature excursions. During these, the film is susceptible to this nonlinear deformation. In the tests in Fig. 35.20, the material has not been taken to a temperature high enough to stabilize fully the gold microstructure in the first cycle. As a result, subsequent cycles going to successively higher temperatures appear to have the effect of continuing to stabilize the microstructure. The response during the second cycle is similar to the first with the exception that the temperature change required to initiate nonlinear behavior is increased. Indeed, over the range of temperature cycles studied, each subsequent cycle is similar, exhibiting thermoelastic response upon heating until a point where nonlinear κ-T behavior commences. The cooling process is again thermoelastic with the subsequent room temperature curvature increasing with each cycle. Also shown in Fig. 35.20 is a result for a second test on a nominally identical microstructure with only two cycles: the first from room temperature to 200 °C and back to 30 °C, and the second to 275 °C and back to 30 °C. The results of the first cycle to 200 °C neatly envelope the results of the set of tests with cycles up to 200 °C. This shows that although there is a path dependence of the deformation behavior, it is controlled by the maximum temperature reached during cycling, independent of how many increments are carried out to reach that temperature. The second cycle to 275 °C shows the same behavior observed in all cycles. The results in Fig. 35.20 have been obtained at a constant heating/cooling rate. In terms of the stabilization of the material microstructure that results in nonlinear material behavior, the rate, along with the time held at the elevated temperature, plays a significant role.

Figure 35.20 suggests that a simple description of the evolution of curvature with temperature can be obtained with parameters as shown in Fig. 35.21: the as-released curvature κ_r (and associated temperature, T_r), a critical temperature at which inelastic mechanisms are activated, T_{cr} (and the associated curvature, κ_{cr}), the slope of the inelastic κ-T behavior (assuming simple linear behavior) for $T > T_{cr}$, ξ, and the thermoelastic slope $\eta = d\kappa/dT$. The as-released curvature is determined primarily by the intrinsic stress development upon film deposition, cooling to room temperature, and release. These also influence T_{cr}. The parameter ξ is physically related to the curvature per unit temperature change due to inelastic mechanism(s) activated beyond T_{cr}. The situation in Fig. 35.20 is much simplified in that $\xi = 0$.

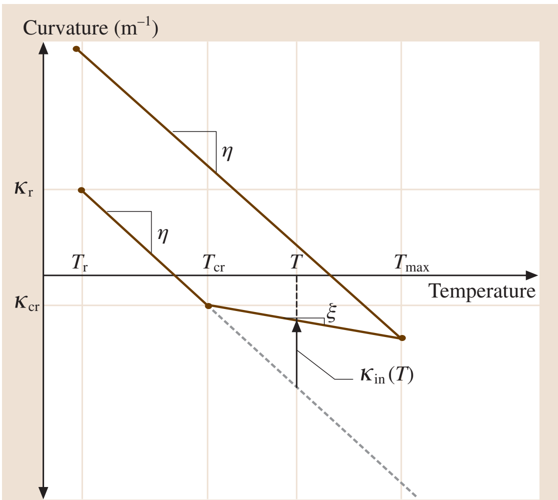

Fig. 35.21 Schematic diagram showing the parameters in the simple model that describes the curvature-versus-temperature behavior of the bilayer beam during thermal cycling after release

With knowledge of these parameters, one can compute the curvature following a defined thermal loading history. The qualitative behavior in Fig. 35.21 also results for a substrate with patterned lines (Sect. 35.1.2), and the same formalism can be used with κ_r, η, and ξ depending on linewidth [35.33]. For example, (35.28) gives the dependence of η on linewidth.

Plasticity

Plasticity in thin-film multilayers has been studied in depth for thin metal films on thick substrates (see, for example [35.6, 37, 38]), but little work has been directed toward freestanding multilayers. This is probably because, at least when subject to thermal loading, the stresses are typically smaller in freestanding multilayer films than in systems with thin films on thick substrates (see Fig. 35.12). Many interesting open issues exist with regard to the general issue of plasticity in microstructures including the understanding of size effects and strain gradient effects (see for example [35.39, 40]).

Creep and Stress Relaxation

For many microsystems applications, it is important to control accurately the deformation of thin-film microstructures over a significant period of time in order to meet performance and reliability requirements. This is especially important for microstructures subjected to thermal loading and/or operated at elevated temperatures. When one or more of the layers consists of a metal or polymer film, creep and stress relaxation in the film can significantly influence deformation and compromise device performance, and so their effects must be carefully considered. For example, *Miller* et al. [35.41] designed and fabricated microrelay switch arrays for RF communications applications using prestressed gold/polysilicon bimaterial beams as electrostatically actuatable switches. They observed a change in the switch shape and position over time and attributed it to stress relaxation in the gold. *Vickers-Kirby* et al. [35.42] report that creep in gold and nickel cantilever beams leads to voltage drops in micromachined tunneling accelerometers over time.

Creep and stress relaxation phenomena have been investigated in some detail for thin film on thick substrate systems, motivated primarily by microelectronics applications (see for example [35.11, 35, 43–46]). These studies have focused on measuring, understanding, and modeling the stress-versus-temperature behavior that occurs when a metal film-substrate system is heated from room temperature, then cooled back to room temperature, over one or a few cycles. The stress-temperature curves in the experimental works are typically obtained using the wafer curvature method that is now widely used to measure stress in thin films. During a typical test thermoelastic and inelastic mechanisms contribute to produce a complex nonlinear stress-temperature curve like that in Fig. 35.20. In most of these studies, the stress-temperature response is studied using wafer curvature measurements at a fixed heating or cooling rate so that rate dependent and independent phenomena are coupled in the response. Stress relaxation during an isothermal hold has been studied by [35.35, 43, 45, 47], among others. These studies all show that significant stress relaxation can occur over periods of only a few hours at modest temperatures of only about 100 °C for many metal thin-film systems. Due to the thin-film/thick-substrate system, the stress in the metal films is quite high, on the order of hundreds of MPa. Models incorporating power law creep of the metal film were successfully able to describe the observed response qualitatively and, to a large degree, quantitatively. The latter, however, sometimes required modification of the power-law exponent. *Shen* and *Suresh* [35.35] showed experimentally that a thin passivation layer on a metal film on thick silicon substrates can significantly reduce creep and stress relaxation. *Thouless* et al. [35.45] also studied the effect of a thin passivation layer on the stress

relaxation of thin films with a focus on the deformation mechanisms. Their experimental results suggest that the presence of a passivation layer on the surface of a film can have a substantial effect on relaxation rates likely by suppressing mechanisms associated with diffusion and dislocation motion.

Thermomechanical Fatigue

It is also important to understand the development of damage and its effect on deformation during cyclic thermomechanical loading. To date, only very limited attention has been directed toward this issue. *Zhang* and *Dunn* [35.33] showed that if gold/polysilicon multilayers were cycled (Fig. 35.20) to an elevated temperature and then cooled to room temperature, they followed the thermoelastic path on subsequent cycling to a temperature below the maximum reached during the initial thermal cycle. Presumably over this range of temperature and time, the gold microstructure has been stabilized by the first cycle, and the polysilicon microstructure is not changing. This was confirmed for only a few, perhaps ten, cycles. *Gall* et al. [35.48] have shown that for thousands of cycles, though, a gradual shift of the thermoelastic curve downward is observed, possibly due to creep and stress relaxation in the gold, although the thermoelastic slope is maintained.

35.1.5 Other Issues

There are a number of additional issues regarding the thermomechanical behavior of thin-film microstructures that warrant discussion. Due to space limitations, however, we will only mention them and refer the reader to appropriate references.

In addition to the deformation itself, the stiffness characteristics of a microstructure, such as for example a beam or plate, can depend significantly on the stress in the beam. *Senturia* [35.49] describes the phenomena and discusses implications for microstructure design. This includes tensile stresses that tend to stiffen beams and plates as well as compressive stresses that can lead to buckling.

An important strategy has emerged to characterize the effects of processing on the residual stress state and thermomechanical behavior of films: the use of on-chip test structures to extract material properties including film stresses. Many test structures, both passive and active, have been developed to measure residual stresses (tensile and compressive), stress gradients, elastic moduli, strength, toughness, thermal expansion, and many others. Nice surveys of many test structures are given by Masters et al. [35.12] and *de Boer* et al. [35.50] where further references to more extensive details can be found.

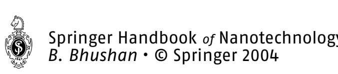
35.2 Electromechanics of Thin-Film Microstructures

Electromechanics, the coupling of electrostatics and mechanics, is perhaps the most common of the energy couplings used in microsystems technology for sensing and actuation. In this section we summarize the contemporary application of electromechanics, the analysis of fundamental electromechanics problems, and the practical issues that arise in the design of an electromechanical microsystem.

35.2.1 Applications of Electromechanics

Our reference to electromechanics will be limited to the coupling of electrostatics and the mechanics of constrained elastic media such as a cantilever beam. In this case, the electrical energy is transformed into strain energy of the elastic media but with typically negligible energy dissipated due to material damping. An alternative application of electromechanics is the coupling of electrostatics with rigid body mechanics. In this case the mechanical structure is not constrained by a compliant support to the substrate but by a kinematic constraint, which is a pin joint between multiple structural layers or anchor between the substrate and a structural element. An example of these rigid body constraints is the anchor in the electrostatic micromotors. In this case, the electrostatic energy is dissipated by friction (Coulomb type friction between structural elements and pin joints, other structural elements, and/or the substrate) and is stored in the kinetic energy of the rigid body. In this case, the energy stored as strain energy in the structural element is by design negligible. In both electromechanics cases, the energy is dissipated by viscous forces under dynamic conditions. Finally the coupling of electrostatics and mechanics can more broadly; consider the coupling of electrostatics and fluids or electro-thermo-mechanics.

Microsystems have enabled many different commercial applications of electromechanics. These applications have included pressure sensors, accelerometers, gyros, resonators, micropumps, optical mirrors, optical shutters/VOAs, and DC and RF switches. In these



examples, electrostatic forces are produced between a stationary electrode and a movable electrode, which is often the proof mass for an accelerometer or the diaphragm for a pump. The electrostatic forces are imparted by a voltage difference between the movable and stationary electrode. The electromechanics is typically implemented in two ways, with the first characterized by a stable, analog behavior, and the second characterized by an unstable, digital behavior. The stable behavior is implemented as a self-test capability for accelerometers such that a specific, stable displacement is produced with the application of the voltage. The unstable behavior is implemented with a switch so that when the instability point (snap-in or pull-in) is reached, the switch will instantaneously close.

Electrostatic actuation has been used for switches and microrelays [35.51–53], accelerometers [35.54, 55], micropumps [35.56, 57], and micromirror [35.58–65]. The specific case of switches and relays involves multiple regions of electromechanical behavior and represents one of the richer electromechanics design problems. The general behavior is shown in Fig. 35.22. The first region is the stable actuation region. In this region, the switch is actuated to an instability point in the voltage displacement curve called the pull-in or snap-in voltage. Up to the instability, the displacement increases monotonically until the pull-in voltage is reached. At the pull-in voltage, the switch instantaneously closes the gap because of the instability and establishes contact with the substrate. In the case of the switch, this means the closure of a contact. The electromechanics problem continues with a new set of boundary conditions in the next region because the switch is now "simply" constrained at the contact and fixed at its anchors to the substrate. In Fig. 35.22, the switches tip displacement is shown, which is the reason the displacement is unchanged as the voltage increases. Region 2 is then characterized by a constant displacement for increasing voltage. The shape of the beam continues to change as the voltage is increased to the point that the electrodes could short if necessary precautions are not taken.

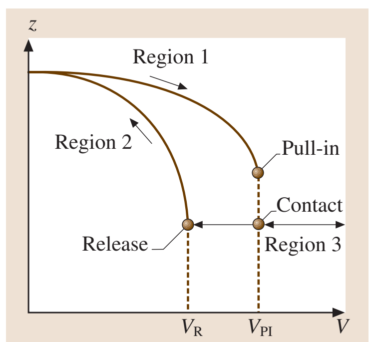


Fig. 35.22 Characteristic electromechanical hysteresis curve showing pull-in, contact, and release voltages

If the first consideration of the switch design is pull-in voltage, the second consideration of the switch design is the development of contact force, which is directly related to the contact resistance. The electromechanical analysis is continued beyond the pull-in voltage once contact is established to develop an increasing contact force. The electrostatic force is distributed between the anchor and the contacts, assuming other portions of the switch are not in contact. The electrostatic force increases as the square of the voltage difference, so the force acting on the contact will increase in proportion to this. Of course other physical limitations must be considered such as gas breakdown or a secondary pull-in that cause shorting between electrodes. The contact areas of the switch that are not the contacts should be minimized, so this does not detract from the contact force.

A third design consideration is the overdrive capability, defined as the maximum voltage the switch control electrodes can support before they touch and short. In some cases, the electrodes may be isolated from each other by a thin dielectric film, whose implications will be discussed in a later section. As suggested in the later section, the insulation material can be patterned to reduce the contacting area between the electrodes and the insulating material, in order to reduce charge accumulation. With the patterned isolation, the switch could be driven by such a large voltage to short the uninsulated regions. This failure mode could be evaluated by the same electromechanics analysis.

A fourth design issue would be the switch's release voltage, which is the voltage when the contact force reaches zero and the switch opens. This is shown as the beginning of region 3, where the deformation is reduced as the voltage is decreased. The release voltage is lower than the pull-in voltage because the electrostatic forces are much greater for the reduced gap than compared to the larger gap just before the pull-in instability. A fifth design consideration is the switch's self-actuation voltage, which is that which occurs across open contact and unintentionally causes the switch to close. By design, the switch's self-actuation voltage should be maximized in the electromechanical analysis. A final design issue is the determination of breakdown limits across the switch's control electrodes. This is not limited to the voltage supported across the equilibrium gap of the control electrodes and needs to be considered for

different cases. The breakdown will be described by the Paschen curve or by vacuum breakdown proportional to the gap.

35.2.2 Electromechanics Analysis

An electromechanics analysis requires modeling of the structural domain, the electrostatic domain, and the coupling between the electrostatic fields and the structural elements. It has been approached at three levels of complexity. The simplest approach is the development of lumped parameter models, which have provided the basic understanding of instability, the impact of nonlinear springs, and the pull-in voltage-gap relationship. The lumped parameter model is comprised of the parallel plate capacitor and a spring (linear or nonlinear). One plate is constrained in space, by a substrate for example. The second plate is elastically constrained to one degree-of-freedom, typically, of motion, which is usually closing the "air" gap. The spring element represents the effective spring stiffness K of the structural element that could be a beam, a plate, a membrane. The parallel plate capacitor represents the electrostatic coupling between the fixed and moving elements.

Increasing in complexity, the second level of analysis considers continuum structural elements with a distributed electrostatic load. For example, the solution for an isotropic homogeneous beam would satisfy the Euler–Bernoulli beam equation:

$$EI\frac{\mathrm{d}^4 w}{\mathrm{d}x^4} = q(x) , \tag{35.37}$$

where E is Young's modulus, I is the structure's moment of inertia, $w(x)$ is the transverse deflection of the beam, x is the coordinate along the length of the beam, and $q(x)$ represents the distributed electrostatic load. For a multilayer film, an effective EI can be used, as mentioned in Sect. 35.1.2. The third level of analysis is to model the fully coupled problem as continuum solids. The approach has used different implementations of finite difference (FD), finite element (FE), and boundary element (BE). A typical example would be to implement a finite element code to solve the continuum mechanics problem and a boundary element code to solve the electrostatics problem. Another implementation would use finite element methods to solve both the mechanics and the electrostatics problems. In each case, a similar algorithm is followed for developing a self-consistent solution to the coupled electromechanics analysis.

The coupled electromechanics problem can be described simply as a pair of conductors, where one conductor has a fixed constraint and the second conductor is attached to an elastic structure, such as a beam, a plate, a membrane, or an elastic substrate. The conductors support a voltage difference between them that causes charge to be induced on the surface of the conductors. This charge produces an electrostatic force that attracts the two conductors together. As the elastically supported conductor deforms toward the fixed conductor, the charge redistributes and modifies the field, thereby the force distribution. The process continues until a redistribution of charge is no longer necessary to maintain equilibrium. The typical algorithm begins by calculating the displacements of the undeformed geometry, which is updated before proceeding to the electrostatic analysis. In the electrostatic analysis, the surface charge density distribution is calculated and then used to calculate the electrostatic forces. The electrostatic force distribution is the important parameter because it is passed to the mechanical analysis as the loading condition on the conductors in the undeformed state to deform the structure until a state of equilibrium is reached.

Electromechanical Systems Energy Balance

A general analytical methodology can be applied to many different structures including parallel plate actuators with linear or nonlinear springs and plates supported by torsional suspensions [35.66]. They consider a single input system with charge control or voltage control. To begin, a generalized actuator is considered that consists of two conductors. One conductor is fixed. The second conductor is constrained by an elastic support.

In the charge controlled actuator, the total energy for the generalized actuator is written in terms of the mechanical energy as a function of the generalized coordinate χ and of the electrical energy stored in the capacitance of the actuator. The total energy is:

$$U_{\mathrm{T}}(\chi, Q) = U_{\mathrm{M}}(\chi) + \frac{Q^2}{2C(\chi)} , \tag{35.38}$$

where U_{T} is the total energy, U_{M} is the mechanical energy, and the electrical energy is determined by the charge Q, and the capacitance $C(\chi)$. The first derivative of the total energy with respect to the generalized coordinate set equal to zero determines the equilibrium. The second derivative of the total energy with respect to the generalized coordinate set equal to zero determines the stability. The first and second derivatives are determined and then combined to determine what is referred to as

the charge-controlled pull-in equation:

$$\frac{\partial U_M(\chi_{PI})}{\partial \chi}\frac{\partial^2}{\partial \chi^2}\left(\frac{1}{C(\chi_{PI})}\right) - \frac{\partial^2 U_M(\chi_{PI})}{\partial \chi^2}\frac{\partial}{\partial \chi}\left(\frac{1}{C(\chi_{PI})}\right) = 0 \quad (35.39)$$

and the pull-in charge Q_{PI}:

$$Q_{PI} = \left(\frac{-2\frac{\partial U_M(\chi_{PI})}{\partial \chi}}{\frac{\partial C(\chi_{PI})}{\partial \chi}}\right)^{1/2} . \quad (35.40)$$

In the voltage controlled case, the total co-energy for the generalized actuator is used because the capacitor is nonlinear, and the actuator is voltage controlled. The co-energy is written in terms of the capacitance between the generalized conductors, the voltage across the conductors, and the mechanical energy. The total co-energy is:

$$U_T^*(\chi, Q) = \frac{1}{2}C(\chi)V^2 - U_M(\chi) . \quad (35.41)$$

The relationship between energy and co-energy is shown in Fig. 35.23.

In a similar process to the charge-controlled system, the voltage-controlled pull-in equation is determined by the first derivative of the total co-energy with respect to the generalized coordinate and by the second derivative of the total co-energy with respect to the generalized coordinate. The equations for the first and second derivative are combined to determine the voltage-controlled pull-in equation

$$\frac{\partial U_M(\chi_{PI})}{\partial \chi}\frac{\partial^2 C(\chi_{PI})}{\partial \chi^2} - \frac{\partial^2 U_M(\chi_{PI})}{\partial \chi^2}\frac{\partial C(\chi_{PI})}{\partial \chi} = 0 \quad (35.42)$$

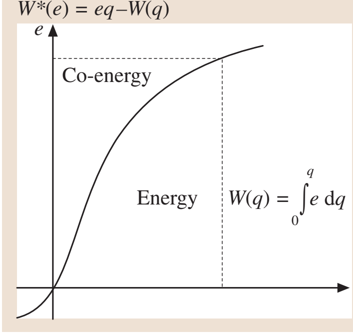

Fig. 35.23 Effort-Displacement curve showing the relationship between energy and co-energy

The pull-in voltage V_{PI} is:

$$V_{PI} = \left(\frac{2\frac{\partial U_M(\chi_{PI})}{\partial \chi}}{\frac{\partial C(\chi_{PI})}{\partial \chi}}\right)^{1/2} . \quad (35.43)$$

The application of this approach, to either the voltage-controlled or the charge-controlled case involves determining the mechanical energy and the capacitance. From the mechanical energy and the capacitance, the pull-in parameters and voltage are determined.

Lagrangian Approach to Electromechanics

Li and *Aluru* [35.67] and *Aluru* and *White* [35.68] have proposed a Lagrangian approach for both the electrostatic analysis and the mechanical analysis. Their algorithm begins by calculating the structural displacements for the undeformed geometry. They proceed to the electrostatic analysis to calculate the charge distribution on the conductors in the undeformed state. The charge distribution is used to calculate the electrostatic forces on the undeformed geometry until the system reaches equilibrium. The first advantage of their approach is that the algorithm does not require the structural geometry to be updated. A second advantage is the elimination of the integration error, wich occurs because flat panels are used in other approaches to approximate curved surfaces. The overall algorithm is shortened because the interpolation functions do not have to be updated as the structure shape changes.

35.2.3 Electromechanics – Parallel-Plate Capacitor

The classic element for understanding electromechanics is the simple parallel-plate capacitor model with one plate fixed and the second, moveable, plate, suspended by a spring. This basic electromechanics element is shown in Fig. 35.24. The capacitor is described by an area, A; an initial gap, g_0; and a dielectric constant of ε in the air gap (where ε is the product of the relative dielectric of the media filling the gap, ε_r, and the permittivity of free space, $\varepsilon_0 = 8.854 \times 10^{-12}$ F/m). The moveable plate is shown suspended by the spring, with spring constant K, and a single degree-of-freedom represented by the coordinate z. In this case, the equilibrium position is represented by having no charge on the plates (i.e. no electrostatic force) and no displacement of the spring (i.e. no spring force). It should be noted that as the spring length grows by increasing z, the gap decreases. The behavior of this simple model is described in detail in many sources including [35.49, 66].

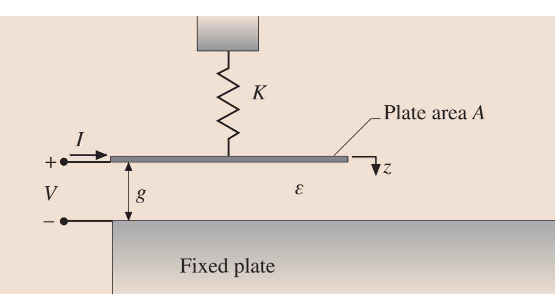

Fig. 35.24 Lumped parameter parallel plate capacitor electromechanical model

The parallel plate capacitor can be analyzed with either a voltage source or a current source. With a voltage source, the charge on the capacitor plates is

$$Q = \frac{\varepsilon A}{g} V \,, \tag{35.44}$$

where Q is the charge on the capacitor plates, ε is the dielectric constant in the gap, A is the capacitor plate area, g is the instantaneous gap between plates, and V is the voltage across the plates.

The electrostatic force on the capacitor plates is determined by the dielectric constant, the capacitor plate area, the instantaneous gap, and the voltage across the capacitor:

$$F = \frac{\varepsilon A V^2}{2g^2} \,. \tag{35.45}$$

The electrostatic force scales as the voltage squared and inversely diminishes as the instantaneous gap squared. This is the force that acts on the movable plate; hence the spring stretches (or is relaxed if the voltage is lowered). The amount of stretch in the spring is:

$$z = \frac{F}{K} \,. \tag{35.46}$$

The instantaneous gap is

$$g = g_0 - z = g_0 - \frac{\varepsilon A V^2}{2Kg^2} \,. \tag{35.47}$$

Electromechanics – Parallel Plate Capacitor with External Forcing

Nemirovsky et al. [35.66] examined the case of constant applied force acting on the suspended capacitor plate of a parallel-plate electrostatic actuator. This situation represents a force-balanced system, in which the electrostatic force is used to balance a pressure load acting on a membrane or an inertial load (e.g. acceleration induced) on a suspended proof mass. With an applied mechanical force, the mechanical energy is:

$$U_{\mathrm{M}}(z) = \frac{1}{2} K z^2 - F_{\mathrm{ext}} z \,, \tag{35.48}$$

where F_{ext} is the externally applied force. The solution to the pull-in equation is

$$\varsigma_{\mathrm{PI}} = \frac{z}{z_{\max}} = \frac{1}{3}\left(1 + 2\frac{F_{\mathrm{ext}}/K}{z_{\max}}\right) \,, \tag{35.49}$$

where ζ_{PI} is the ratio $z/z_{\max}$. It can be seen when the applied force is zero. Equation (35.49) reduces to the familiar result of $z = z_{\max}/3$. The pull-in voltage is

$$V_{\mathrm{PI}} = \left(\frac{8K\left(z_{\max} - \frac{F_{\mathrm{ext}}}{K}\right)^3}{27\varepsilon_0 A} \right)^{1/2} \,. \tag{35.50}$$

Electromechanics – Parallel Plate Stabilization

An important practical consideration is the stabilization of the parallel plate electrostatic actuator. *Seeger* et al. [35.69] and Nemirovsky et al. [35.66] showed that the addition of a series capacitance (feedback capacitance) stabilizes the actuator such that it does not pull-in to the substrate. The series capacitance and the variable actuator capacitance combine to form a voltage divider that provides passive control of the voltage across the actuator. In this case, Nemirovsky et al. [35.66] identified three regimes, defined in terms of δ, which is the ratio of the initial actuator capacitance to the series capacitance (Nemirovsky et al. [35.66] had defined the series capacitance in terms of a dielectric layer on one capacitor plate). The first regime is defined for $0 < \delta < 0.5$, when the series capacitance is less than half the nominal actuator capacitance. In this case, the actuator is stable so the pull-in effect is eliminated. The second regime is defined by $\delta > 0.5$ and the pull-in occurs between $1/3$ of the gap and the full distance of the gap. In the third regime $\delta \gg 1$, which means the series capacitance is much greater than the nominal capacitance. The pull-in parameter is given by:

$$\zeta_{\mathrm{PI}} = \frac{1}{3}\left(1 + \frac{1}{\delta}\right) \,, \tag{35.51}$$

which reduces to $\zeta_{PI} = \zeta_{max}/3$ when the series capacitance is eliminated. The pull-in voltage is:

$$V_{PI} = \left[\frac{8Kz_{max}^3}{27\varepsilon_0 A}\left(1+\frac{1}{\delta}\right)^3\right]^{1/2} . \qquad (35.52)$$

Electromechanics – Extending the Range of Motion

Electromechanical systems have two obvious characteristics: nonlinearity and instability. If one desires digital operation or fast switching times, the inherent electromechanical instability is a significant benefit. On the other hand if analog control is desired, the control is faced with both the nonlinearity and the instability. In both cases, the range of motion of the electromechanical device is limited. The range of motion to the instability was extended by the addition of a series capacitor, but this did not address the linearity. *Toshiyoshi* et al. [35.59] addressed the linearity of electrostatically actuated mirrors in an optical scanner. Their's was a two degree-of-freedom scanner, so the increased linearity was necessary to improve the crosstalk between the two different scanner modes. The scanner in question is a square plate suspended by torsion beams within a frame that is itself suspended by another pair of torsion beams. The plate and frame are suspended above the substrate, which has four stationary electrodes defined in the four quadrants of the plate as shown in Fig. 35.25. To actuate the mirror with increased linearity, a bias voltage V_{bias} was applied between each electrode and the plate. Independent differential control voltages are superimposed on the bias voltage supplied between each electrode and the plate. The driving voltages are described by two independent differential voltages such that $V_{diff1} = (V_x + V_y)/2$, $V_{diff2} = (-V_x + V_y)/2$, $V_{diff3} = (-V_x + -V_y)/2$ and $V_{diff4} = (V_x + -V_y)/2$. A second approach taken to improve the linearity was to consider the shape of the mirror, because of the geometric relationship that determines the net electrostatic torque. They considered such simple geometries as square, diamond (square rotated by 45), and a circular plate, as shown in Fig. 35.26, but more complex shapes could be considered. The square plate is presumed to have worse linearity because as the plate rotates the corners deflect toward the control electrodes, which increases the applied torque and further distorts the shape of the mirror. This suggested the removal of the corners could contribute to increased linearity and reduced distortion of the mirror surface. They found the circular plates reduced the distortion by 50% over the rectangular and diamond shaped plates, which is significant for the optical performance. The authors defined distortion as the normalized angle deviation from the ideal value. It is normalized relative to the maximum scan angle. *Nadal-Guardia* et al. [35.70] have described extending the range of travel by using current drive methods instead of voltage drive.

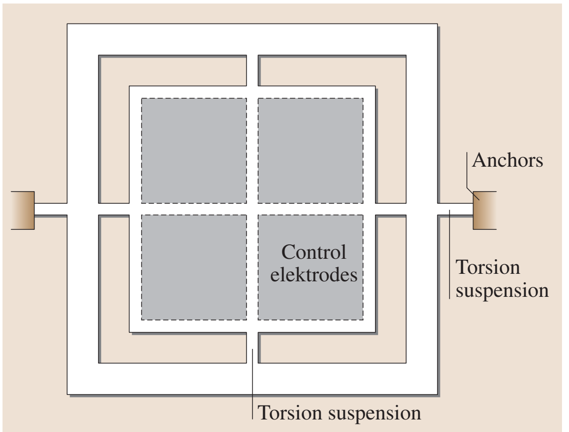

Fig. 35.25 Two degree-of-freedom torsional electromechanical actuator with a rectangular plate and a stationary electrode divided into four sections

35.2.4 Electromechanics of Beams and Plates

The basic understanding of electromechanics and pull-in phenomena has been developed around the simple parallel plate capacitor model developed above. Many MEMS designers innately understand that the electrostatic force is proportional to the square of the voltage, is inversely proportional to the square of the gap, and

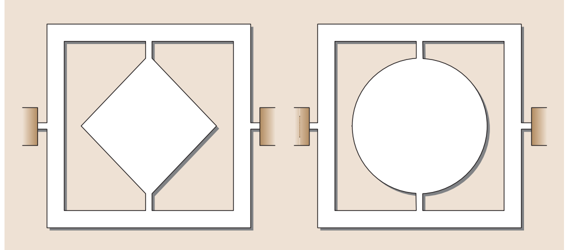

Fig. 35.26 Alternate two degree-of-freedom torsional, electromechanical actuators with diamond and circular plates

that the plate will pull in after displacing 1/3 of the gap. While this is good to first order, it is not adequate for the electromechanical design of other structures such as cantilevered beams/plates, beams/plates with multiple supports, plates with torsional supports, and other structures.

O'Brien et al. [35.71] and *Choi* and *Lovell* [35.72] have studied the electromechanics of cantilever beams by presenting two improved models for the cantilever beam electrostatic actuators. In both cases, the cantilever beam is a homogeneous material anchored to the substrate at one end and otherwise freely suspended along its length, which is supported above a stationary electrode. The new models are compared to the parallel plate capacitance model and a simple extension of the parallel plate model to a cantilever beam. The cantilever beam model uses a simple cantilever of width, W, length, L, thickness, T, and initial air gap of Z_0. The parallel plate capacitance model is based on a capacitance determined by the length and width of the beam. The beam deflection was represented by the displacement function of a beam with a force applied at the beam tip. The beam spring constant was determined by the ratio of the force at the beam tip to the displacement at the beam tip (maximum displacement). The capacitance was determined by integrating the parallel plate capacitance for a differential length element along the length of the beam, where the beam gap is defined by the initial gap in the mechanical displacement function. This showed the beam tip displaced 45% of the initial gap before pull-in occurred. In this case the pull-in voltage can be expressed as a function of the beam's Young's modulus E, cross-sectional moment of inertia I, length L, and width W, the initial gap Z_0, and the dielectric constant in the air gap as

$$V_1 = \sqrt{\frac{18EIZ_0^3}{5\varepsilon_0 L^4 W}} = 0.5477\sqrt{\frac{ET^3 Z_0^3}{\varepsilon_0 L^4}} \quad \text{(Volts)}\,. \tag{35.53}$$

In the first improved model, the cantilever beam is defined by the same characteristics, but the electrostatic force acting along the length of the beam is replaced by an equivalent bending moment M applied at the beam tip. The beam displacement was determined for a uniform, homogeneous beam with a bending moment applied at its end. The beam's spring constant was determined by the ratio of the force at the beam tip and the displacement at the beam tip. The capacitance was determined by integrating the parallel plate capacitance for a differential length element along the length of the beam, where the beam gap is defined by the initial gap in the mechanical displacement function. This model showed the beam tip displacement was approximately 46% of the initial gap before pull-in occurred. In this case the pull-in voltage is

$$V_2 = \frac{43}{50}\sqrt{\frac{18EIZ_0^3}{5\varepsilon_0 L^4 W}} = 0.471\sqrt{\frac{ET^3 Z_0^3}{\varepsilon_0 L^4}} \quad \text{(Volts)}\,. \tag{35.54}$$

In the second improved model, the cantilever beam was defined by a rigid beam, whose anchor was replaced by a simple hinge and continuum elasticity replaced by an equivalent spring at the beam's free end. Three new variables were introduced to describe the behavior in terms of radial coordinates centered at the hinge. The two radial coordinates describe the beginning of the electrode at r_0 and the end of the beam/electrode at r_1. The angle θ was introduced to describe the angular displacement of the beam. In this model, the tip of the beam displaced 44% of the initial gap before pulling into the substrate. The pull-in voltage is estimated by (35.55) or (35.56) where r_0 and r_1 have been replaced by 0 and L.

$$V_3 = \frac{11}{25r_1^2}\sqrt{\frac{77ET^3Z_0^3}{25\varepsilon_0\left[\frac{11(r_1-r_0)}{r_1-\frac{11}{25}r_0} - 14\ln\left(\frac{25r_1-11r_0}{14r_1}\right)\right]}}\,, \tag{35.55}$$

$$V_3 = \frac{11}{25L^2}\sqrt{\frac{77ET^3Z_0^3}{25\varepsilon_0}} = 0.4548\sqrt{\frac{ET^3Z_0^3}{\varepsilon_0 L^4}} \text{ (Volts)}\,. \tag{35.56}$$

As expected, the dependence on parameters, such as Young's modulus, beam thickness, beam length, initial air gap, and the air gap dielectric constant is the same for all cases presented. The difference in the three models is the coefficient of the pull-in voltage function and the tip deflection at pull-in. The coefficients of the pull-in voltage predictions are 0.5479, 0.471 and 0.4548, respectively. The beam tip deflected 45%, 44%, and 46% of the initial gap before pull-in occurred. This is in contrast to the parallel plate model that predicts the plate deflection will be 33% of the initial gap before pull-in. By comparison to experimental test results, the models presented in (35.54) and (35.56) were more accurate at predicting the pull-in voltage for cantilever beams. The parallel plate electromechanics model had greater error and under-predicted the pull-in voltage. The model represented by (35.53) over-predicted the pull-in voltage with greater error than either of (35.54) or (35.55). The beam models predicted more accurately for wider beams, which means they are better applied to beams

with dimensions representative of a parallel plate model used as a basis of the capacitance estimate. In all three cases, the beam models presented in (35.53)–(35.55) predicted poorly the pull-in voltage for narrow beams, which are dominated by the effects of nonuniform fringing fields and not the uniform parallel plate fields. The typical application of the parallel plate capacitor model is to geometries with a width W and length L that are much greater than the capacitor gap Z_0 ($W \gg Z_0$, $L \gg Z_0$; where greater than a factor of 10 is a common rule of thumb). In Fig. 35.27, two capacitors are shown such that in one case the plate dimensions are much greater than the gap, and in the second case the plate dimensions are much smaller than the gap. When the plate dimensions are much larger than the gap, the uniform fields in the gap dominate the capacitive coupling. A small contribution to the capacitive coupling comes from the *fringing* fields at the edge of the plate (or the perimeter of the plate in three dimensions). As shown in Fig. 35.6, the fringing fields could depend on the thickness of the plate. When the plate dimensions are of the same order as the gap, the fringing fields may dominate or be of the same order as the contribution of the uniform field in the gap. This is the nature of the narrow cantilever beams that were not predicted well by a parallel plate capacitor model. A correction can be introduced to the parallel plate model to approximate the contribution of the fringing fields. This approximation is often referred to as the Love approximation.

Segmented Control of Electromechanical Membrane Deformation

Wang and *Hadaegh* [35.62] describe the electrostatic actuation of a deformable membrane mirror with segmented electrodes on the substrate. The membrane mirror, in this case silicon nitride with a conductive film, was suspended above the substrate containing the segmented electrode. The segmented electrodes are defined along angular and radial pattern. A specified voltage can be applied between the membrane and each electrode segment to develop a specific deformation for the mirror. This increases the complexity of the control system but also the flexibility of controlling the shape of the mirror surface. The optical properties could be optimized by individual characterization of membranes or by feedback from the optical output. This basic concept was also applied by *Zhang* and *Dunn* [35.73] who were able to linearize the voltage–deflection relationship by tailoring the shape of the electrodes and the beam structure used to support them.

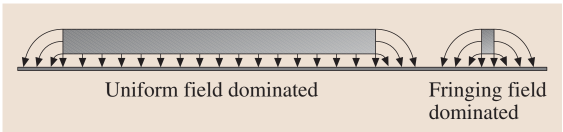

Fig. 35.27 Cross-sections of wide and narrow electrodes showing uniform electric fields in the gap and fringing fields at the edges (perimeter)

35.2.5 Electromechanics of Torsional Plates

The plate suspended by a torsional suspension instead of bending is the final configuration to be considered in terms of electromechanics. The electrostatic torsional plate has many applications, such as optical mirrors [35.58,63] and accelerometers [35.55]. The plate will define the optical surface of the mirror, the moveable plate of a varactor, or the proof mass of an accelerometer. It will be conductive or have a conductive film so that it can couple electrostatically to a stationary plate on the substrate. The moveable plate will be suspended by a torsional suspension such that the bending modes are suppressed and the primary kinematic mode is rotation of the plate. The variable capacitive coupling is used in two ways. First, it is used for actuation by applying a voltage between the moveable plate and a stationary plate. Second, it is used for sensing or use of the variable capacitance. Both actuation function and the variable capacitance function can be present in a device. The key elements of interest are the voltage-displacement function and the pull-in voltage.

Small Angular Deflection Approximation

Degani et al. [35.74], *Xiao* et al. [35.75], and Nemirovsky et al. [35.66] have considered the torsional electrostatic actuator from an analytical perspective with comparison to experimental results and other modeling results. The effective torsional spring constant is determined from the torque-twist angle relationship, where the torque is the electrostatic torque. The electrostatic torque is developed for both small and large angle cases. The pull-in angle and pull-in voltage are determined from the pull-in equations for voltage control (35.42, 43) and charge control (35.39, 40). Their method is an improved approach for modeling torsional electrostatic actuators over approximations involving parallel plate models and effective spring constants as they have shown by comparison to experimental measurements. The torsional plate considered is suspended by a torsional suspension, whose axis of rotation defines a gap

of d. It is assumed the plates extend into the page (z-axis) by a depth b and have a total length a. The torsional plate electrostatic actuator is shown in Fig. 35.28. The solution assumes the tilted plates are semi-infinite, ignoring the effects of fringing fields hence their corrections, and are tilted by angles that satisfy the small angle approximation ($\tan\alpha \approx \sin\alpha \approx \alpha$ and $\cos\alpha \approx 1$). The capacitance is:

$$C(\Theta) = \frac{\varepsilon_0 b}{\alpha_{\max}} \frac{1}{\Theta} \ln\left(\frac{1}{1-\Theta}\right) , \tag{35.57}$$

where $\alpha_{\max} = d/a$ and $\Theta = \alpha/\alpha_{\max}$.

The capacitance function and the linear relationship for the elastic restoring force ($F_\mathrm{M} = K\,a$) are used to develop the electrostatic and mechanical energy function to substitute in the pull-in equations. For voltage controlled actuation, the pull-in parameter is developed from (35.42) to yield:

$$4 + \frac{5\Theta_\mathrm{PI} - 4}{(1-\Theta_\mathrm{PI})^2} - 3\ln(1-\Theta_\mathrm{PI}) = 0 . \tag{35.58}$$

Equation (35.58) is solved numerically to show the voltage-controlled pull-in angle is $\Theta_\mathrm{PI} \approx 0.44$. The pull-in angle is substituted in (35.43) to determine the voltage controlled pull-in voltage:

$$V_\mathrm{PI} = \left(\frac{0.827 K \alpha_{\max}^3}{\varepsilon_0 b}\right)^{1/2} . \tag{35.59}$$

The charge-controlled pull-in parameter relationship is determined by substituting the electrostatic energy and mechanical energy functions in the charge-controlled pull-in parameter (35.39). This provides the nonlinear relationship for the charge controlled pull-in angle:

$$\ln(1-\Theta_\mathrm{PI}) - \frac{\Theta_\mathrm{PI}}{(1-\Theta_\mathrm{PI})^2} - \frac{2\Theta_\mathrm{PI}^2}{(1-\Theta_\mathrm{PI})^2 \ln(1-\Theta_\mathrm{PI})} = 0 . \tag{35.60}$$

The charge-controlled pull-in angle is given by $\Theta_\mathrm{PI} \approx 0.71$. The pull-in angle is used in the charge-controlled pull-in equation (35.40) to determine the pull-in charge relationship:

$$Q_\mathrm{PI} = (1.798 K \varepsilon_0 b \alpha_{\max})^{1/2} . \tag{35.61}$$

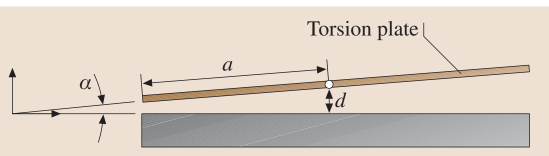

Fig. 35.28 Cross-section of a torsional actuator with a uniform cross section into the page showing the angular degree-of-freedom, α; plate length, a; and initial gap, d

Large Angular Deflection and Plate Geometry

Nemirovsky and *Bochobza-Degani* [35.66] have extended the work to the case of large angle deflections, which included using the trigonometric relationship in the capacitance function and a nonlinear relationship for the mechanical spring constant. These nonlinear relationships were used in the voltage-controlled pull-in equation. In addition, their methodology was extended to planar plates with different shapes (Fig. 35.29). They specifically considered triangular plates (the apex of the triangle is near the axis of rotation), a reversed triangular plate (the triangle apex is at the distal end of the plate), a square plate (with the rotational axis on the edge of the plate), and a circular plate (with the axis of rotation passing through a point on the perimeter and the opposite point on the perimeter defining the most distal point of the plate). Only simple geometries were considered, and their methodology can be applied to other more general geometry. The rectangular plate torsional, electrostatic actuator will provide the lowest actuation voltage relative to a fixed plate length. The reversed triangular plate has proved beneficial with regard to pixel area in mirror application and has been able to provide a higher torque for a specific plate length.

35.2.6 Leveraged Bending

As discussed, when the actuation electrode spans the entire length of the actuator, the stable controllable travel distance of the actuator plate is severely limited due to the pull-in instability. One can get around the problem of

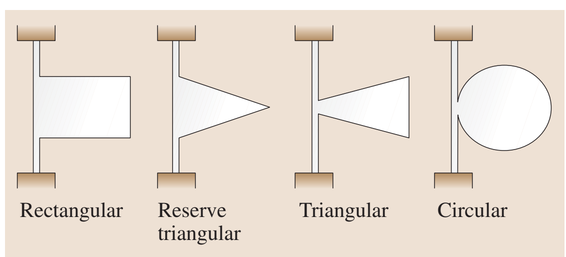

Fig. 35.29 Rectangular, triangular, reverse triangular, and circular plates are shown suspended by torsion beams for application to electromechanical mirrors or other actuators

pull-in by applying an electrostatic force to only part of the structure and using the rest of the structure as a lever to move the structure through a larger range of motion. This concept, referred to as leveraged bending [35.76], is shown schematically in Fig. 35.30 for a cantilever beam. The key idea is that the portions of the beam above the electrodes do not deflect far enough to violate the pull-in limit. The concept can be applied to other microstructure shapes and support conditions, but for fixed-fixed beams, the effect can be diminished by tensile residual stresses [35.76].

35.2.7 Electromechanics of Zipper Actuators

The design requirements for electromechanical actuators usually require minimizing the actuation voltage but maximizing the largest displacement. With the parallel plate actuator, be it a plate, beam, or torsional plate, the pull-in voltage is reduced by minimizing the air gap, but this limits the maximum displacement. Actuators with a zippering behavior have been implemented to achieve greater deflections for a lower actuation voltage. In one example (see [35.77, 78]), a plate is suspended by a torsional suspension. A long slender electrode extends from the plate and terminates with plate-like area. This electrode is supported above the fixed substrate electrode by a largely uniform gap. A voltage is applied between the substrate electrode and the extended electrode, such that the plate-like area is first pulled into the substrate. As the actuation voltage is increased, the long-slender electrode continues to collapse against the substrate electrode until a desired maximum deflection is achieved or until the drive voltage becomes impractical. This is the so-called zippering effect, which has been described for a motion perpendicular to the substrate. This uniform gap scenario is not the best suited for minimizing the pull-in voltage, so other configurations such as the curved electrode actuator have been proposed and applied to such devices as a switch and optical shutters as described by *Jin* et al. [35.79].

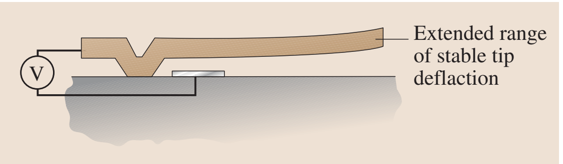

Fig. 35.30 Illustration of the concept of leveraged bending to increase the range of stable motion

Legtenberg et al. [35.80, 81] have described the basic operating features of the curved-electrode actuator. These actuators will provide large deflections in the plane of the substrate. The curved electrode actuator is composed of a stationary electrode and a compliant, moving electrode. The stationary electrode has a shape described by the function $s(x)$ shown in (35.62) and Fig. 35.31, which is written in terms of the maximum gap between electrodes $\delta_{\max}$, the length of the electrode L, the distance along the length of the electrode x, and the polynomial order of the curve n.

$$s(x) = \delta_{\max}\left(\frac{x}{L}\right)^n . \qquad (35.62)$$

A necessary feature of the curved electrode actuators and zipper actuators, in general, is the contact between the moving and stationary electrodes. Without due consideration, these electrodes will short upon contact and damage the actuator. Two isolation solutions are implemented to prevent the shorting scenario. First, a continuous insulation film can be added between the electrodes to prevent them from shorting. In this case, the simplest solution is to add the insulation layer to the fixed, curved electrode. The alternative solutions include adding the insulating film to only the moving electrode or to both the moving and stationary electrodes. If the insulation is added to the moving electrode, it will become part of the stiffness of the beam. A second solution would be to add discrete, isolated contact bumpers that are made from the same conducting material as the moving electrode. As it closes the gap, the moving electrode makes contact with the isolated bumpers but not the actuation electrode. These have their operational differences as described by *Legtenberg* et al. [35.81]. Three other issues that must be considered during the design of a curved electrode actuator or zipper actuators are dielectric charging, stiction, and dielectric breakdown.

Legtenberg et al. [35.81] found that as the polynomial order increased for the electrode curve, the pull-in voltage will decrease for about the same maximum displacement. This means larger displacements can be achieved for lower voltages when compared to the parallel plate actuator. Once the moving electrode is pulled in to the curved electrode, the moving electrode will collapse to the maximum displacement. It was shown for polynomial curves of order above $n = 2$ that the maximum tip deflection becomes stable because of the geometric constraints provided by the curved electrode. This means to achieve the maximum displacement with the lowest pull-in voltage, a polynomial curve of or-

der $n = 2$ should be specified. For polynomial curves with $n > 2$, stable continuous deflection along the curved electrode can be implemented with the maximum deflection occurring at lower voltages for polynomial orders just above two. If an approximate linear range of operation is desired (i. e. the tip deflection versus voltage is approximately linear), the higher order curves ($n > 2$) are desired. *Legtenberg* et al. [35.81] analyzed the curved electrode problem by application of analytical energy methods, specifically the Rayleigh–Ritz method and of three-dimensional self-consistent electromechanical numerical simulations using CoSolve-EM in MEMCAD (now integrated into CoventorWare). From an energy perspective, the total potential energy U_T is determined in terms of the mechanical energy associated with the strain energy of bending and the electrostatic energy stored in the electric field. For the curved electrode of Fig. 35.31, the total potential energy is:

$$\begin{aligned} U_T &= U_M + U_E \\ &= \frac{1}{2}\int_0^L EI\left(\frac{d^2 w(x)}{dx^2}\right)^2 dx \\ &\quad - \frac{1}{2}\int_0^L \frac{\varepsilon_0 h V^2}{\frac{d}{\varepsilon_r} + s(x) - w(x)} dx , \end{aligned} \tag{35.63}$$

where L is the beam length, E is the beam's Young's modulus, I is the beam's cross-sectional moment of inertia, h is the thickness of the beam, V is the voltage applied between the beam and electrode, d is the initial gap at the start of the electrode, ε_0 is the permittivity of free space, and $w(x)$ is the beam's deflection curve. The next step in the solution of this problem is to determine an admissible trial function that satisfies the beam boundary conditions and can adequately approximate the solution. In this case the deflection curve for a uniformly loaded cantilever beam is chosen as the trial function:

$$\omega(x) = cx^2\left(6L^2 - 4Lx + x^2\right) = c f(x) , \tag{35.64}$$

where c is a constant to be determined for specific cases.

The approach of Nemirovsky et al. [35.66] can be taken by substituting the potential energy functions in the voltage-controlled pull-in equations. The simultaneous solution of the pull-in equations will result in the pull-in voltage and an implicit equation in terms of the constant c at pull-in. The pull-in voltage relationship is

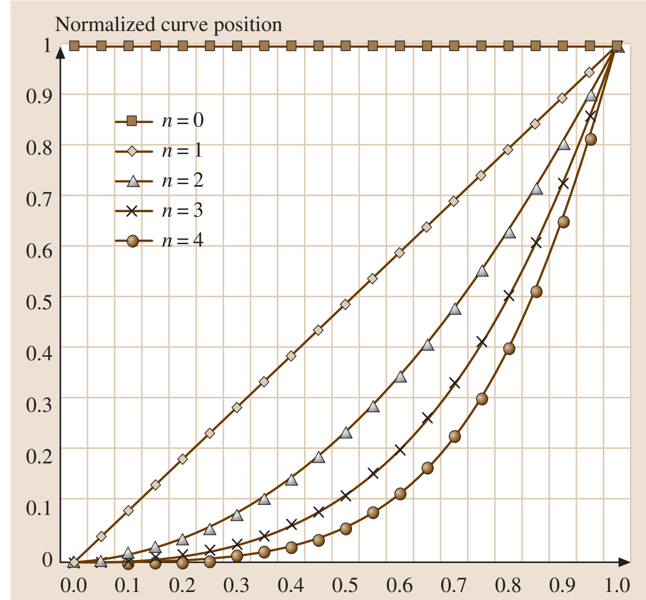

Fig. 35.31 Curved electrode shape curve shown as a function of order of the curve n

$$V_{PI}^2 = \frac{EI}{\varepsilon_0 h} \frac{\int_0^L \left(\frac{d^2 f(x)}{dx^2}\right)^2 dx}{\int_0^L \frac{f^2(x)}{[d/\varepsilon_r + s(x) - c_{PI} f(x)]^3} dx} . \tag{35.65}$$

The implicit equation to determine the coefficient of the beam deformation function is

$$\begin{aligned} &\int_0^L \frac{c_{PI} f^2(x)\,dx}{[d/\varepsilon_r + s(x) - c_{PI} f(x)]^3} \\ &= \int_0^L \frac{f(x)\,dx}{[d/\varepsilon_r + s(x) - c_{PI} f(x)]^2} . \end{aligned} \tag{35.66}$$

DeReus [35.82] designed the curved electrode actuator to convert the curvilinear motion into a translational motion at the tip of the moving electrode. The transformation is accomplished by a folded spring that connects the electrode to the body that will be translating. A solid model of this actuator design is shown in Fig. 35.32. A pull-in analysis was performed with the results before pull-in and after pull-in presented in Fig. 35.33. This shows that a 60 μm translation was accomplished

35.2.8 Electromechanics for Test Structures

Electromechanics test structures are an important contributor to the development of microsystems products as they are used to extract information about material properties of thin films for specific process parameters. They are also used to monitor the material property variation during the fabrication process. In this case, they are distributed around the wafer on specific test die or they may be included in the dicing streets of more mature processes. These distributed test structures enable the manufacturer to track the variation in material properties with its associated within-wafer variation, wafer-to-wafer variation, and lot-to-lot variation. Another application of test structures is to characterize the impact of the first level packaging on the performance of the product. With all the critical information being extracted from the test structures, it is important for the information to be easy to interpret. Test structures have been developed that involve electrical, optical, and mechanical interrogation of the structure, but these are not easily instituted at all levels of characterization. The purely electrical test structures offer simple evaluation at the wafer, die, and package level so manufacturers often prefer them. The most common electrical test structures used for extracting information on mechanical properties involve electromechanics, of course. This section has provided a basis for interpreting and modeling the behavior of specific test structures, such as a homoge-

neous cantilever beam, and can be extended to other structures.

Osterberg and *Senturia* [35.83] describe in detail the application of electromechanics to the extraction of mechanical properties for microsystems design. They labeled their test structures as M-TEST for mechanical test structure. Their test structures comprised arrays of cantilever beams, fixed-fixed beams, and clamped, circular plates of various lengths, widths, or diameters. With these test structures, they demonstrated the extraction of important mechanical properties such as Young's modulus, plate modulus, and the residual film stress. Why choose an electromechanics test structure unless for the breadth and ease of application? An additional reason is the inherent instability that has been described as the pull-in of an electromechanical structure. The pull-in voltage is very distinct and can be measured in terms of a single parameter, the pull-in voltage. Given a control range of pull-in voltages for different structural layers in the manufacturing process, the pull-in parameter can be used as a simple control parameter.

Osterberg and *Senturia* [35.83] describe the methodology for extracting the mechanical properties. Their methodology includes the measurement of plan-view dimensions (i. e., width and length), out-of-plane curvature, pull-in voltage, film thickness, and air gap. With these measured parameters, the mechanical properties can be extracted. Their extraction methodology includes general closed form expressions for pull-in voltage that depend on the material properties and geometry of a homogeneous, isotropic material.

35.2.9 Electromechanical Dynamics: Switching Time

Switching time is an important factor in the design of such electromechanical devices as electrical or optical switches. The switching time analysis requires consideration of the dynamic equations representing the device and the electrical source. *Castaner* et al. [35.84–86] have considered the optimization of the speed-energy product. In this case, a parallel plate electrostatic actuator is described by an equivalent mechanical circuit that includes the mass m, the damping b, and the spring k, and a variable gap g. The variable gap depends on the initial gap g_0 and the displacement of the moving electrode x, such that $g = g_0 - x$. In the parallel plate, variable gap model the damping is described by squeeze film damping. (Other electrostatic actuators that move parallel to the substrate with variable gaps defined by groups of moving and stationary fingers.) In these cases, the damping model will need to include squeeze film damping and shear flow damping (Couette or Stokes Flow models). The electrical source is modeled as a voltage source and a source series resistance. A schematic of the model is shown in Fig. 35.36.

The equivalent electrical circuit of the parallel plate electrostatic actuator is modeled by (35.67), where V_s is the source voltage, V is the voltage across the variable capacitance, R is the series source resistance, and Q is the charge on the capacitor plates

$$\frac{V_\mathrm{s}}{R} = \frac{V}{R} + \frac{\mathrm{d}Q}{\mathrm{d}T} . \qquad (35.67)$$

The equivalent mechanical circuit is described by:

$$m\frac{\mathrm{d}^2X}{\mathrm{d}T^2} + b\frac{\mathrm{d}X}{\mathrm{d}T} + kX = \frac{Q^2}{2C_0G_0} . \qquad (35.68)$$

Equation (35.68) includes the sum of the inertial force, the damping force, the spring force, and the electrostatic force. Equation (35.68) is written in terms of the mass of the moving capacitor plate, m; the damping coefficient due to squeeze film damping, b; the elastic constant of the spring by which the capacitor plate is suspended, k; the charge on the capacitor plate, Q; the initial gap, G_0; and the initial capacitance, C_0. The initial capacitance is written in terms of the area of the capacitor A, the dielectric constant of the capacitor air gap ε, and the initial gap:

$$C_0 = \frac{\varepsilon A}{G_0} . \qquad (35.69)$$

The dynamics of the parallel plate electrostatic actuation were divided into four events. The first occurrence is a short charging time for the capacitor. The second phase is the acceleration phase, which defines the rapidly increasing velocity of the mass, but the

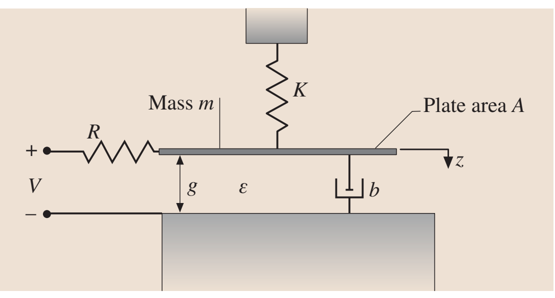

Fig. 35.36 Lumped parameter model of the parallel plate electromechanical actuator including damping and series resistance for dynamic analysis

position is still close to the initial equilibrium position. The third phase is the damping phase, defined by the velocity reaching a maximum, then decreasing due to the increased damping, and then finally increasing due to the increasing electrostatic forces as the gap closes. The fourth and final phase is the pull-in phase, characterized by a rapidly increasing velocity. *Hung* and *Senturia* [35.76] have described generating efficient dynamical models from a minimal set of finite element simulations. *Pons-Nin* et al. [35.87] have described the behavior of pull-in voltage and pull-in time for electromechanical actuators with current drives.

35.2.10 Electromechanics Issues: Dielectric Charging

Electrostatic actuators are operated in three different regimes depending on the application. In the first regime, the electrostatic actuator is operated over the voltage range that does not include the pull-in voltage. In this case, the actuated element does not contact the opposing substrate. In the second regime, the electrostatic actuator is operated through a voltage range that does include the pull-in voltage ($V_{act} \geq V_{PI}$). In this case, the desired response is to establish contact with or without some overdrive to achieve greater contact force or other response parameter. In the third regime, the electrostatic actuator is operated through a voltage range beyond the pull-in voltage. This is characteristic of electrostatic zipper actuators. In this case, the operating voltage is programmed to quickly establish pull-in, thereby contact, then the actuator operates in a range above the pull-in voltage ($V_{PI} < V_{act}$). In all three regimes, dielectric isolation layers are considered to prevent shorting between actuation electrodes. For the first and second case, the use of the insulating material is a preventative measure to protect against electrode shorting during an unintentional overdrive of the actuator. It is preventative because the actuation electrodes are not intended to touch. In the third case, the gap separating the moving and stationary actuation electrodes is reduced to zero so that an insulating layer is required. The insulating layer may be patterned or unpatterned.

The third regime defines the touch mode electrostatic actuators. *Cabuz* et al. [35.88] have described many of the failure modes that can be observed with the touch mode electrostatic actuators and that should be addressed during the design of the actuator and process. The observations and failure modes included: 1) a significant difference between the experimental actuation voltage (DC) and the theoretical actuation voltage, 2) a closed state electrostatic pressure lower than predicted, 3) an actuation voltage that increases with each subsequent cycle until electrical breakdown occurs, 4) actuator vibration observed between an open and a closed state, 5) actual release voltage is higher than theoretical, but the electrostatic forces should be much higher in the closed state such that the release voltage is always lower than the pull-in voltage, 6) the actuator remains closed temporarily after shorting, 7) permanent stiction will occur when in the closed state for a long period of time, 8) permanent stiction occurs after many actuation cycles.

Wibbeler et al. [35.89] have analyzed this problem in terms of one of the contributing factors, the accumulation and storage of localized charge in dielectrics. The common dielectrics in microsystems devices are SiO_2 and Si_3N_4, which show low mobility for surface charges and provide trap sites for positive or negative charge within their volume and at interfaces. *Kubo* et al. [35.90] showed this charge can be produced by the fabrication process by contact electrification, and by gas discharge in the air gap (the case focused on that by *Wibbeler* et al. [35.89]), and static electrification during handling (ESD). The contact electrification created electrical charge through the mechanical contact of two materials with different work functions and the separation of the two materials.

To understand the impact of the accumulated charge, *Wibbler* et al. [35.89] considered the impact of stored surface charge on the electrostatic force acting on a simple parallel plate capacitor. In Fig. 35.37, a simple capacitor is considered with a dielectric (ε_d) filling part of the air gap (ε). The dielectric has a surface charge of $\sigma_s(x, y)$. The capacitor plates carry charge shown as σ_1 and σ_2, which are provided by the battery, of voltage V, connected across the capacitor plates. The thicknesses of the dielectric and air gap are d_d and d, respectively. The force was estimated from the applied voltage and from the offset voltage due to the accumulated surface charge. The force acting on the capacitor plate as a function of the applied voltage, V; the offset

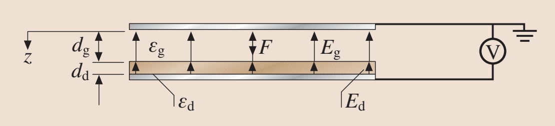

Fig. 35.37 Parallel plate capacitor with dielectric and parasitic charges

voltage, V_s; and the capacitance, C, is:

$$F = \frac{dC}{dz} \int_A \frac{[V - V_s(x,y)]^2}{2} \, dA \,. \tag{35.70}$$

The offset voltage is shown in (35.71) as a function of the surface charge; the thickness of the dielectric, d_d; the dielectric constant, ε_d; or the dielectric's contribution to the total capacitance, C_d. The capacitance of the dielectric layer, per unit area, being defined as $C_d = \varepsilon_d / d_d$.

$$V_s = -\sigma_s(x,y) \frac{d_d}{\varepsilon_d} = -\frac{\sigma_s(x,y)}{C_d} \,. \tag{35.71}$$

Electromechanical Pull-In with Dielectric Charging

Nemirovsky et al. [35.66] and *Chan* et al. [35.91] studied the effect of residual charge at the interface of a dielectric and the air in the capacitor gap. With the dielectric in the capacitor gap and the residual charge, the total energy for the actuator is:

$$U_T = \frac{1}{2} K z^2 + \frac{Q_{res}^2}{2(C(z) + C_d)} - \frac{C(z) C_d}{2(C(z) + C_d)} V^2 \,. \tag{35.72}$$

In (35.72), Q_{res} is the residual charge, $C(z)$ is the air gap capacitance, and C_d is the dielectric capacitance. From the total energy, the pull-in parameter and pull-in equations (35.42) and (35.43) can be solved for the pull-in parameter ζ_{PI} and pull-in voltage V_{PI}:

$$\varsigma_{PI} = \frac{1}{3}\left(1 + \frac{1}{\delta}\right) , \tag{35.73}$$

$$V_{PI} = \left[\frac{8 K z_{max}^3}{27 \varepsilon_0 A} \left(1 + \frac{1}{\delta}\right)^3 - \frac{Q_{res}^2}{C_d^2} \right]^{1/2} . \tag{35.74}$$

In (35.73), ζ_{PI} is the ratio z/z_{max} and δ is the ratio $\varepsilon_d z_{max}/z_d$. Equation (35.74) shows that the dielectric layer will increase the pull-in voltage and the residual charge will lower the pull-in voltage. It can be seen that the residual charge does not impact the normalized pull-in coordinate shown in (35.73).

Test structures were fabricated to verify the shift predicted by (35.70) that would result with a dielectric in the air gap. Test structures with a dielectric did show a shift in the voltage–deflection curve, whereas a shift was not observed when a dielectric was not present. A shift of −25 V was observed. Following electrostatic discharge events, the offset voltages of −210 V and 145 V were observed during different phases of a charge-discharge cycle. This demonstrates the significant bias the accumulated surface charge can create. As a result, *Wibbler* et al. [35.89] did not recommend trying the fix shorting by adding dielectric films over the electrodes. They did recommend estimating the influence of accumulated charge on the response of the device being designed. Instead of complete dielectric film coverage of an electrode, they recommended patterning the dielectric such that it was limited to the edges of the electrodes or patterned at locations that will touch first. By patterning small areas of insulation, the surface area available to store charge is smaller and the distance to the electrode is shorter for more timely dissipation of stored charge.

Cabuz et al. [35.88] identified the effects of humidity, DC or AC driving voltage, and SAM coatings on the performance of electromechanical actuators. With a DC operating voltage, the devices operated as expected below 35% RH except in dry air or dry N_2. In the dry environment the actuator would temporarily remain closed, would remain closed after high fields are applied, or would remain closed after a high number of cycles. When operated above 35% RH, the DC voltage was higher than expected, the closed state electrostatic pressure was lower, the actuator did not release when expected, the actuator vibrated, and the voltage increased with subsequent cycles. When an AC actuation voltage is used the actuators operated up to 55% RH. At higher RH, the actuation voltage increased. The dry condition operation was improved with AC driving compared to DC operation. AC voltage control is recommended for eliminating RC effects but cannot overcome the effects of humidity. To avoid the effects of humidity, two SAM coatings (octadecyltrichlorosilane (OTS) and perfluorodecyltrichlorosilane (PFTS)) were tried to influence the hydration of the surfaces. The OTS eliminated the effects observed for uncoated samples up to a 95% RH level for both DC and AC voltages. The PTFS improved operation up to 95% RH for AC voltages and 70% RH for DC control voltages. The residual in-use stiction was determined to be associated with accumulated and trapped charge on the surfaces or at interfaces.

35.2.11 Electromechanics Issues: Gas Discharge

As described in previous sections, the electromechanical actuation of a microstructure is performed by applying a voltage across two plates. The two plates can be defined by two conductors (e.g. Al to Al), by semiconductors

(e.g. polysilicon), or by a combination of a conductor and a semiconductor (e.g. Al and polysilicon). When these two plates (or other similarly described structures) are fabricated in proximity with each other, they are usually fabricated with an "air" gap less than 10 μm. With the electrostatic actuators, a small gap is desirable to minimize the voltage required for actuation.

The presence of small gaps in microsystems devices has prompted the further investigation of electrical breakdown in air and other ambient conditions at small gaps (i. e. less than 50 μm). *Slade* and *Taylor* [35.92] have demonstrated that breakdown in small gaps is defined by three regimes: less than 4 μm, 4 to 6 μm, and greater than 6 μm. In the first case, the breakdown event follows the behavior for a vacuum breakdown process at a larger gap. In the last case, the breakdown follows the behavior of Paschen's law for breakdown in air. The middle case of gaps between 4 and 6 μm, the breakdown process is in a transition from following the vacuum breakdown process to following the Paschen curve. In this case, the breakdown voltage is lower than predicted in either case, which indicates significant contributions from factors in both cases. The deviation from Paschen's curve was observed by *Torres* and *Dhariwal* [35.93] for gaps less than 4 μm.

The goal of this section is to describe some basic breakdown principles that can be used to determine whether or not a particular design will break down during an actuation event. Different processes will be considered for different gap regimes so that breakdown estimates can be made.

The vacuum breakdown region is characterized by a breakdown voltage that is a function of the gap separating the two electrodes. This contrasts with the breakdown behavior that follows the Paschen curve, which shows electrode gap-pressure product dependence. The breakdown voltage in vacuum is

$$V_B = K_V t_g \; . \tag{35.75}$$

Equation (35.75) shows the breakdown voltage V_B is proportional to the gap t_g where the proportionality constant is $K_v = 97\,V/\mu m$ for data from many sources as indicated by *Slade* and *Taylor* [35.92]. The breakdown data for vacuum was determined for electrode gaps between 35 and 200 μm. For electrode gaps between 0.2 and 40 μm in air, the proportionality constant was between 65 and 110 V/μm.

The electric field at the surface of the electrode is a critical parameter for determining breakdown in vacuum. This is estimated by the ratio of the voltage between the electrodes V and the gap between the electrodes t_g with a modification factors β_g. β_g is a geometrical enhancement factor that captures the field enhancement due to the macroscopic geometry:

$$E_g = \beta_g V/t_g \; . \tag{35.76}$$

The geometrical enhancement factor can be determined by performing finite element analysis to determine the macroscopic electric field as a function of the electrode gap for the electrode geometry under consideration. The geometric enhancement factor is determined from the ratio of the macroscopic electric field E_g, from finite element simulations, to the electric field estimated by V/t_g [35.92, 94]. The estimated electric field, V/t_g, can be used as a reasonable approximation when the electrode gap is much smaller than that radius of curvature of the cathode electrode. If this is not the case, the geometric enhancement factor needs to be estimated from numerical analysis such as finite element or boundary element methods. The geometric enhancement factor is shown, by *Slade* and *Taylor* [35.92], to be between 1.01 and 1.57 for gaps ranging from 0.2 to 40 μm, respectively, for the geometry of a needle cathode and a plate anode.

A second enhancement factor is attributed to the microscopic field enhancement due to the surface roughness of the electrodes. The electric field containing the effects of the geometric enhancement and the microscopic enhancement is:

$$E = \beta_m \beta_g V/t_g \; . \tag{35.77}$$

In (35.77) β_m is the microscopic enhancement factor. The total enhancement factor is $\beta_g \beta_m$, which can have a range of 100 to 250 for polished electrodes [35.95].

Following the estimate of the electric field at the surface of the electrodes, the current density for the field emission of electrons is calculated. This current density j_{FE} is described by the Fowler–Nordheim equation, which depends on the electric field E, the work function of the electrode material ϕ, and the dimensionless parameters of $t(y)$ and $\nu(y)$, where y is a parameter defined as $3.79 \times 10^{-5} \sqrt{E}/\phi$. Typically, $t(y)$ is one. $\nu(y)$ is given by $0.956 - 1.06y^2$. The Fowler–Nordheim equation is presented in (35.78) with j_{FE} in A/m², E in V/m, and ϕ in eV.

$$j_{FE} = \frac{1.54 \times 10^{-6} E^2}{\phi t(y)^2} \exp\left(\frac{-6.83 \times 10^9 \phi^{3/2} \nu(y)}{E}\right) \; . \tag{35.78}$$

Equation (35.78) can be rewritten with E substituted from (35.77) and the current density replaced by an emission current I_e and the area A_e of a microprojection where the emission occurs. Equation (35.78) is shown rewritten in (35.79), such that the slope from the Fowler–Nordheim plot will provide the field enhancement factor as shown in (35.80) where m is the slope. The Fowler–Nordheim plot is the plot of I_e/V^2 versus $1/V$, which is constructed by measuring the voltage across the electrode gap and measuring I_e.

$$\mathrm{Log}_{10}\left(\frac{I_e}{V^2}\right) = \mathrm{Log}_{10}\left(\frac{1.54\times10^{-6}A_e\beta^2}{\phi\, t(y)^2 t_g^2}\right) - \frac{1}{2.303}\left(\frac{6.83\times10^9\phi^{3/2}t_g\nu(y)}{\beta}\right)\frac{1}{V}\,, \tag{35.79}$$

$$\beta = -\frac{2.303m}{6.83\times10^9\phi^{3/2}t_g\nu(y)}\,. \tag{35.80}$$

For gaps larger than 6 μm, the electrical breakdown as a function of gap does follow the Paschen curve for air and does not follow the vacuum breakdown curve for these larger gaps. The electrode gap is now larger than the mean free path of the air molecules so it is expected that emitted electrons will collide with the air molecules in the gap. For these larger electrode gaps, it is assumed the electrical breakdown will follow the Townsend electron avalanche theory. A similar process is followed to estimate the breakdown. First, the electric field at the surface of the cathode electrode is estimated including the enhancement factors for geometry and surface microstructure. An estimate of the total field enhancement factor is required for this. The electric field is substituted into the Fowler–Nordheim equation (35.78) to estimate the field emission current. In this case, the emitted electrons will interact with the background gas molecules causing an avalanche in the current. The current avalanche process is described by (35.79) and (35.80), where t_g is the electrode gap, α is the first Townsend coefficient, and γ is the second Townsend coefficient. The first Townsend coefficient represents the number of electrons produced per unit distance along the direction of the electric field. The second Townsend coefficient is the number of electrons generated by secondary processes per each primary avalanche. Breakdown will occur when the denominator of the expression for current approaches zero: $\gamma\exp(\alpha t_g)$ approaches unity.

In the transition region, the breakdown voltage can be lower than predicted by the Paschen curve or vacuum breakdown. It is suggested that in this regime, the partial electron avalanche process enhances the vacuum breakdown process to lead to a lower breakdown voltage [35.92].

The choice of materials is another consideration for the design of an electrostatic microactuator. As mentioned, the electrode pairs could comprise the following combinations: conductor-conductor, conductor-semiconductor, or semiconductor-semiconductor. In *Torres* and *Dhariwal* [35.93], the breakdown voltage was measured for electrode pairs comprised of nickel, brass, or aluminum. A significant difference was not observed between the breakdown voltages of the different conductors or for the size of the electrode. At larger gaps, the breakdown voltage was different for different electrode shapes (cylindrical versus spherical) but this can be explained by the relative difference in the geometric enhancement factor for the electric field for the different electrodes. *Ono* et al. [35.96] made a comparison between electrode combinations where both a semiconductor (silicon) and a silicon–metal combination were used. In the case of a silicon electrode with a metal electrode, the breakdown voltage deviated from the Paschen curve at approximately 6 μm. It was lower than the breakdown voltage predicted by the Paschen curve and trailed off with an approximate linear dependence on the electrode gap. With the silicon as one electrode, Au/Cr or Pt/Cr was used as the second electrode but little difference was found for the different metals. With the silicon-silicon electrode combination, the breakdown voltage followed the Paschen curve for air. For similar gaps, the breakdown voltage was significantly higher for the silicon-silicon electrodes than for the silicon-metal electrode. This was true for a thin silicon film over a Cr/Pt/Cr electrode.

Another option for reducing the electric breakdown in the air gap is to introduce an insulating material over the electrode. But *Wibbeler* et al. [35.89] have demonstrated this does not solve the problem of breakdown by itself and can lead to parasitic charging of the insulator. An electric breakdown will produce a large current, as described previously, that is destructive to the electrodes without insulation. The dielectric limits the current so that the electrical breakdown event is not so destructive. *Wibbeler* et al. [35.89] demonstrated through highly chaotic behavior in the voltage–displacement response of an electrostatic actuator. It is reasoned that the local field strength at the electrode reached a magnitude

to cause an avalanche of free electrons and ions, as described here. These free charges travel the length of the air gap, but they are stopped and neutralized at the dielectric surface. This reduces the local electric field at the location of the surface charge so that the force on the cantilever is reduced and the process repeats itself. Throughout this process, a large amount of charge can be introduced onto the dielectric surface, which will typically have a very long dissipation time constant.

35.3 Summary and Mention of Topics not Covered

This chapter has focused on the thermomechanics and electromechanics of thin-film microstructures. Emphasis has been placed on the basic physical phenomena, approaches to analyze the phenomena, and the presentation of accessible results for special cases of practical importance in a variety of applications. We have not discussed many other energy domain couplings that play major roles in microsystems technology such as electrothermomechanics and magnetomechanics. We have also not discussed the role and behavior of materials such as piezoelectrics or shape memory alloys, which play important roles in electromechanics and thermomechanics, respectively. We refer the interested reader to *Senturia* [35.49] for an introduction and further references.

36. High Volume Manufacturing and Field Stability of MEMS Products

Low volume MEMS/NEMS production is practical when an attractive concept is implemented with business, manufacturing, packaging, and test support. Moving beyond this to high volume production adds requirements on design, process control, quality, product stability, market size, market maturity, capital investment, and business systems. In a broad sense, this chapter uses a case study approach: It describes and compares the silicon-based MEMS accelerometers, pressure sensors, image projection systems, and gyroscopes that are in high volume production. Although they serve several markets, these businesses have common characteristics. For example, the manufacturing lines use automated semiconductor equipment and standard material sets to make consistent products in large quantities. Standard, well controlled processes are sometimes modified for a MEMS product. However, novel processes that cannot run with standard equipment and material sets are avoided when possible. This reliance on semiconductor tools, as well as the organizational practices required to manufacture clean, particle-free products partially explains why the MEMS market leaders are integrated circuit manufacturers. There are other factors. MEMS and NEMS are enabling technologies, so it can take several years for high volume applications to develop. Indeed, market size is usually a strong function of price. This becomes a vicious circle, because low price requires low cost – a result that is normally achieved only after a product is in high volume production. During the early years, IC companies reduced cost and financial risk by using existing facilities for low volume MEMS production. As a result, product architectures are partially determined by capabilities developed for previous products. This chapter includes a discussion of MEMS product architecture with particular attention to the impact of electronic integration, packaging, and surfaces. Packaging and testing are critical, because they are significant factors in MEMS product cost. These devices have extremely high surface/volume ratios, so performance and stability may depend on the control of surface characteristics after packaging. Looking into the future, the competitive advantage of IC suppliers will decrease as small companies learn to integrate MEMS/NEMS devices on CMOS foundry wafers. Packaging challenges still remain, because most MEMS/NEMS products must interact with the environment without degrading stability or reliability. Generic packaging solutions are unlikely. However, packaging subcontractors recognize that MEMS/NEMS is a growth opportunity. They will spread the overhead burden of high-capital-cost-facilities by developing flexible processes in order to package several types of moderate volume integrated MEMS/NEMS products on the same equipment.

Solid-state pressure sensors were first reported in the 1960s and commercialized by a number of start-up companies in the 1970s. By 1983, a *Scientific American* cover story [36.1] described pressure sensors, accelerometers, and ink-jet print heads and featured a gas chromatograph that combined an injection valve, a detector, and a chromatographic column on a silicon wafer. The future of the budding micromechanical device industry looked bright, but commercial reality has seriously lagged the rosy market projections. The reason was simple: Market forecasters failed to recognize the difference between lab prototypes and high volume production of stable products. Many companies have demonstrated that small quantities can be produced for niche markets. However, routine high volume production of reliable packaged devices is much more challenging. It requires the production prototype skills plus the manufacturing disciplines that are critical to long-term stable production.

Successful companies understand and apply these lessons. Indeed, over a hundred million MEMS pressure sensor, accelerometer, gyro, gas flow, and optical projection devices are shipped to customers annually. There is no universally accepted definition of MEMS. This chapter focuses on silicon-based products with movable micromechanical elements. It excludes disk drive heads, ink-jet print heads, hearing aids, microscale plastic, ceramic, quartz and metal components, and test strips for in vitro diagnostics that are sometimes included within the definition of MEMS. Many MEMS products do not integrate support electronics with the MEMS element on the chip even though they are produced with IC equipment, materials, and processes. However, integrated MEMS products are becoming ubiquitous. By 2002 Analog Devices had shipped over a hundred million surface micromachined MEMS accelerometers with integrated electronics to customers.

The literature related to high volume production of MEMS products is quite uneven. Some suppliers have published detailed process and design descriptions, while others limit disclosures to market-focused publications. The two major suppliers of integrated MEMS products have discussed their designs and processes in detail. *Core* et al. [36.2], *Kuehnel* et al. [36.3], *Chau* et al. [36.4], and *Sulouff* [36.5] describe the Analog Devices *i*MEMS accelerometers and gyros. *Mignardi* et al. [36.6] give an in-depth review of the Texas Instruments DLP (Digital Light Processing) products.

MEMS devices are components in larger systems, so every MEMS product must define its system interface in a way that adds value from the perspective of the system designer. Some MEMS pressure sensor products are simply Wheatstone bridge elements in a circuit (Fig. 36.1). The image projection systems that use the Texas Instruments Digital Light Processing Technology™ could never be designed in this manner, because up to 1.3 million mirrors are driven on each chip (Fig. 36.2). Such a system would be impractical unless electronics are integrated with the MEMS mirrors on the chip. Air bag sensors also illustrate how integration adds value. Non-MEMS ball-and-spring air bag sensors were often used in the early 1990s. Upon impact, a ball would be released and detected as it passed through the sensor tube. Unfortunately, these binary sensors could not always distinguish a frontal collision from the jolt of a pothole or a side collision. Therefore, multiple ball-and-spring sensors were placed at different locations in a vehicle and wired together in order to reliably identify accidents that should result in air bag deployment. High cost limited the use of these distributed systems. Analog Devices changed the air bag market when it introduced the ADXL50 in 1993 (Fig. 36.3). The ADXL50 integrated electronics and an accelerometer on one chip to provide an analog output of deceleration versus time when an impact event occurred. This allowed automobile manufacturers to design air bag modules that compared the ADXL50 output to the known signature of a frontal collision. The result was greater reliability

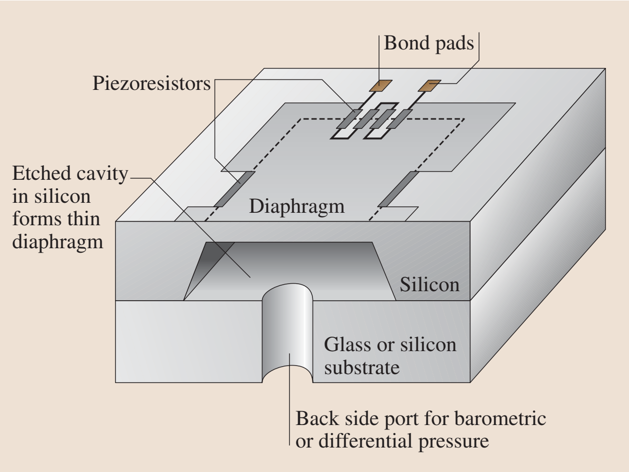

Fig. 36.1 Cross section of a piezoresistive silicon sensor after it is bonded to a silicon or glass substrate. When pressure is applied, the thin silicon diaphragm deforms. This causes changes in four implanted resistors that form a Wheatstone bridge. The resistors are located and oriented to cause resistance to increase in two resistors and decrease in the other two

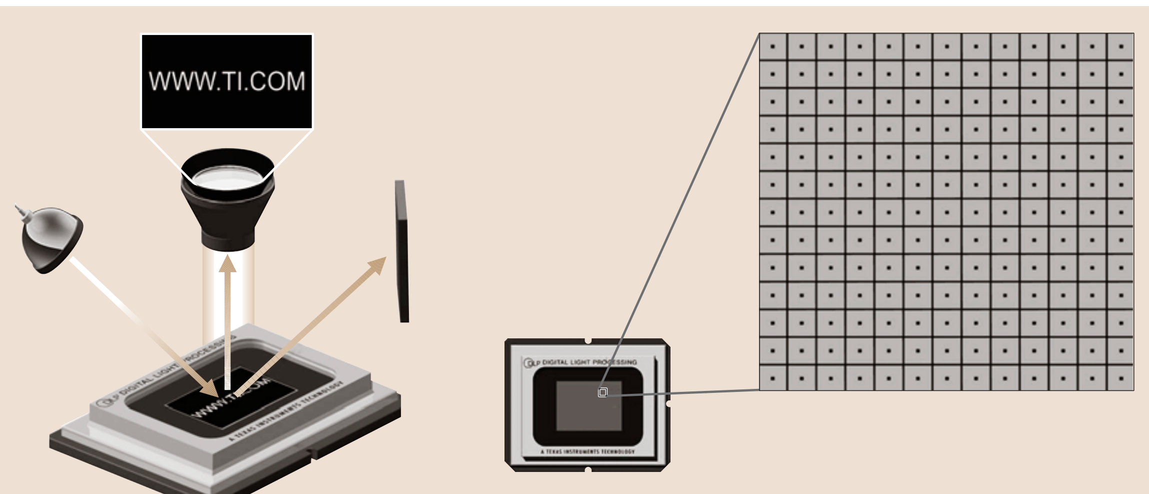

Fig. 36.2 Digital Light Processing technology^{TM} is based on Digital Micromirror Device (DMD) chips that address and drive a "sea of mirrors." The DMD is the key element in small computer-based projection systems. Each of the 14 or 17 μm mirrors represents one pixel. The diagram on the *left* represents light reflecting from a mirror to the system lens. The illustration on the *right* is an exploded view of a small region of mirrors in a packaged DMD. (Courtesy of Digital Light Processing^{TM}, Texas Instruments, Inc.)

and lower cost, which led to the installation of air bags in almost every new automobile.

This chapter will not recite detailed descriptions of particular commercial products. Instead, brief descriptions will be used to illustrate basic principles and concepts. Part of the chapter is organized according to MEMS-specific issues like wafer singulation. This is useful because some designs and unit processes are well suited for lab scale or low volume production, but impractical in a high volume manufacturing environment. Complete reliance on such an organization would be artificial, because partitioning omits the greatest challenge – combining these individual topics into a manufacturing flow that routinely produces products that meet cost, performance, and reliability expectations. The importance of process integration cannot be

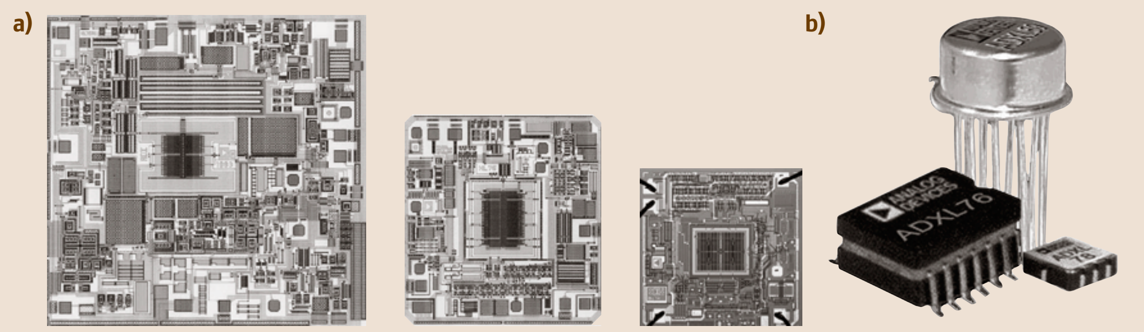

Fig. 36.3a,b Three generations of integrated accelerometers designed for single-axis air bag applications. **(a)** Die size is reduced by a factor of two about every four years. **(b)** Package technology also evolved to meet size, cost, and automated handling requirements. The ADXL50 was packaged in TO-100 seam-sealed metal headers. ADXL76 cerpacs (*bottom left*) are being replaced by the ADXL78 in 5 mm × 5 mm LCC packages (*bottom right*). (Courtesy of Micromachined Products Division, Analog Devices, Inc.)

overemphasized, because changes in one step almost always affect other steps. Solutions may involve design modifications, so design-for-manufacturability is an important topic. Manufacturing and business skills are included to the extent that they apply to stable production of reliable MEMS products.

36.1 Manufacturing Strategy

MEMS manufacturing is based on existing IC technology. However, there are only a few examples of routine MEMS and IC production intermixed on the same equipment (or of MEMS devices with electronics integrated on the chip). Even when a MEMS process step is nominally the same as a standard IC process, the specific conditions or end point or some quality such as film stress will differ. Technologists from Analog Devices and Motorola have discussed these thin film issues in depth [36.7–10].

Manufacturers prefer to use dry etch processes when possible in order to achieve better control of features, minimize waste disposal, and utilize automated equipment developed for the IC industry. However, anisotropic wet etching provides unique value in the production of some MEMS products like pressure, mass flow, and yaw rate sensors [36.11].

Although MEMS production economics is closely tied to the semiconductor model, useful lessons can be drawn from many industries. Some of the key characteristics that affect success are as follows:

36.1.1 Volume

Semiconductor economics is rooted in the principle that expensive processes are cost-effective when many devices are made simultaneously. Obviously, a MEMS product that is sold in low quantities loses this critical advantage. MEMS components are "disruptive technologies" – they are the key element in higher-level products that were previously impractical. It can take several years to develop a higher-level product and build its customer base. Therefore, it is prudent to include an incubation phase in the business plan for a novel MEMS device. Low sales volume during this phase causes high unit costs – batch process cost benefits are achieved only after the market develops.

Start-up companies often do not understand the implications of design-for-volume. It is a major challenge to transfer products made on lab tools to manufacturing equipment. The challenge is sufficient to justify the use of manufacturing people and equipment for product development.

Realistic price-volume estimates are also essential to a good business plan. The highest volume MEMS products (accelerometers and pressure sensors) all represent a small part of the total system cost, even though the functions they provide are absolutely critical to system performance.

Market-pull business models that respond to the needs of a specific large application in a particular industry are usually more successful than technology-driven models that seek applications for new devices. Given this reality, it is prudent to thoroughly understand the target industry and its quirks. Biotech, wireless, image projection, optical communications, and consumer markets offer tremendous growth potential. However, the past and present growth in high volume MEMS products have been driven primarily by the automotive industry, with pressure sensors also benefiting from medical applications. *Sulouff* [36.12], *Weinberg* [36.13], *Marek* et al. [36.14], *Eddy* et al. [36.15], and *Verma* et al. [36.16] discuss automotive applications and the challenges a successful supplier must master.

36.1.2 Standardization

Mature industries develop standards in response to equipment vendors, material suppliers, and customer interface requirements. The MEMS industry is fragmented, so even after 30 years it is not mature. Deviations from semiconductor industry standards are inevitable because MEMS products impose unique requirements on wafer processing, packaging, handling, and testing. For example, KOH wet etching raises mobile ion concerns. Gold used in some optical products is incompatible with CMOS. Any deviation from standard process and material sets is serious, because the price-volume relationship is a steep curve in high volume applications.

36.1.3 Production Facilities

The semiconductor industry is divided into front-end (wafer fabrication) and back-end (product assembly and test) operations. IC design rules are based on pre-

qualified fab, assembly, and test capabilities at specific sites. Consider how each of these functions matches the needs of MEMS production:

1. An IC product might be produced at an internal wafer fab, or designed to run on a standard foundry process. In contrast, production challenges and "know-how" have caused MEMS suppliers to retain wafer fab production within their internal facilities. High volume production in MEMS foundries was limited to pressure sensors. However, Motorola is now outsourcing accelerometer production. This suggests that the MEMS industry will follow the IC model, with foundry services becoming more substantial in the future.
2. IC suppliers have shifted assembly operations to subcontractor facilities located in Southeast Asia. Some MEMS suppliers have followed this model. It is common to assemble low volume products in North America, Europe, or Japan. However, semiconductor assembly and package technology are evolving rapidly and are driven by subcontractors based in Southeast Asia. MEMS companies that do not utilize these resources pay a significant cost penalty. Obviously, the break point at which offshore assembly is attractive differs from one product to the next. Products that have unique assembly requirements and support high market prices may never reach this point.
3. IC testing is often carried out at the assembly subcontractor site. MEMS package and testing comprise a substantial portion of the total product cost, so a high volume manufacturing strategy should consider Southeast Asia packaging and testing. This is complicated by the fact that MEMS testing requires unique stimuli that are not in the standard IC portfolio.

36.1.4 Quality

The goal in lab and low volume production environments is to make functioning devices. As quantities increase, other factors become more important: lot-to-lot repeatability, yield, device performance that meets well-defined specifications, process stability to ensure predictable on-time delivery, documentation and procedures that enable traceability and corrective actions when problems arise, etc. Methodologies that promote stable, high-quality manufacturing practices have been established in several industries. These standard procedures such as ISO9000, QS9000, and cGMP overlap to a large extent. QS9000 was developed to help automotive suppliers implement effective, well controlled processes to produce reliable products. It has several unique features, so it is used as the model in this chapter.

36.1.5 Environmental Shield

IC wafers are completely passivated before packaging in order to meet product stability and reliability requirements. Aside from ink-jet print heads, the active regions of all MEMS devices currently in high volume production replicate this hermetic barrier in some manner. This passivation requirement is noteworthy because it has been a primary limitation on the growth of the MEMS industry. For example, it limits electrochemical sensors to benign or "throw-away" applications.

36.2 Robust Manufacturing

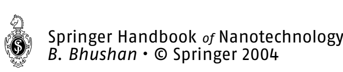
Stable production requires a manufacturing flow that is well controlled when measured against the product performance specifications. This has several implications.

36.2.1 Design for Manufacturability

Low maintenance products and processes must be designed to run on standard equipment. The semiconductor industry has invested billions of dollars to develop equipment that is automated, maintainable, reliable, and capable of supporting well controlled processes. Processes that are implemented on custom-designed equipment put this experience base aside and invariably have a long learning curve.

Equipment

Microstructure release illustrates this issue and how it changes over time. Virtually all semiconductor processes operate in vacuum or at atmospheric pressure. In a brief, unpublished 1992 study related to ADXL50 development, the author demonstrated the use of supercritical CO_2 mixtures for microstructure release and particle cleaning. Unfortunately, supercritical processes were incompatible with the industry infra-



structure, because they require pressures in excess of 7.38 MPa (72.8 atm; 1,070 psi). Implementation would have required process and equipment development, so a release process that ran on existing equipment was selected.

Supercritical equipment designed for MEMS release was introduced a few years later. However, maintenance and cycle time concerns, as well as single wafer capabilities limited its adoption to university and low volume manufacturing.

The intrinsic limitations of non-standard equipment have caused high volume MEMS suppliers to avoid supercritical processes. However supercritical equipment will continue to evolve and become competitive, particularly in applications where the design requirements make alternative processes unusable.

Materials

Process control can be no better than the materials used in the process. SAM (*s*elf-*a*ssembled *m*onolayer) coatings illustrate this limitation. These materials suppress stiction following aqueous release of microstructures by treating the wafers in a SAM solution before drying. Although straightforward in principle, high volume manufacturers have not (yet) adopted SAM processes (Sect. 36.2.3 reviews the processes that are used commercially). There are several reasons for this reticence. Classical SAM materials are chlorosilanes that have at least one organic substituent. Organosilanes have been used to treat the surface of inorganic materials for many years. Applications include coupling agents on the surface of fillers and reinforcing agents in polymers, as well as agglomeration control of particles. The chlorine sites hydrolyze when dissolved in solutions that contain a small amount of water. The resulting hydroxyl groups react with the microstructure surface oxide to produce a chemically bonded layer that reduces stiction due to the low surface energy and hydrophobic nature of the organic-rich surface. The concerns that cause manufacturers to use alternative stiction solutions include:

1. High variability due to the SAM chemical reactivity
2. Particles are common by-products of the reactivity
3. Many SAM process flows require organic baths. This raises health, safety, and waste disposal concerns
4. Possibility of chloride corrosion on aluminum interconnects

Maboudian et al. [36.17], *Srinivasan* et al. [36.18], *Kim* et al. [36.19], and *Pamidighantam* et al. [36.20] describe the use of SAM solutions to suppress stiction. There is also ongoing research focused on solving the manufacturing concerns [36.21–25].

Note that stiction also arises in packaged MEMS products. This yield and reliability problem is discussed in Sect. 36.3.1.

36.2.2 Process Flow and Its Interaction with Product Architecture

MEMS products have structures and functions that do not exist in standard IC devices, so it is unrealistic to expect that every fab, assembly, and test step will reapply a previously qualified IC process. The challenge is to maximize utilization of available IC technology within the constraints of the product function and cost requirements. This leads to fundamental choices in product architecture, product design, and process flow, as discussed below.

Integration of MEMS and Circuits

The integration of MEMS and electronics onto one chip has proven difficult. It adds little value in some MEMS products. However, as noted earlier, integration is essential to products based on the Texas Instruments (TI) DLP (Digital Light Processing^{TM}). The third (and largest) category consists of applications where integrated and non-integrated products compete for market share. Pressure sensors and accelerometers are examples of this group.

Image Projection. The first projectors based on the DLP technology were shipped in 1996. DLP chips are produced on CMOS wafers in a mature TI process. The circuitry addresses and drives aluminum mirror arrays that function as on-off pixels – 1.3 million mirrors in the latest SXGA products (Fig. 36.2). *Mignardi* et al. [36.6] describe the DMD (Digital Mirror Device) fabrication process and illustrate some of the factors that must be considered when manufacturing flows are changed. The manufacturing flow patterns three aluminum depositions over SRAM cells that are positioned with 14 or 17 µm center-to-center spacing (Figs. 36.4 and 36.5). The first of these metal films form electrostatic drive electrodes and landing pads. The yoke and hinge layer has spring tips that land on the first metal layer when mirrors are rotated (Fig. 36.6). Mirrors are mechanically connected to the yokes through center pedestals. Sacrificial organic films separate the metal layers. These organics, along with a protective organic cover film, remain on the device until after the wafer is sawn and the chips are mounted in a ceramic package. They are removed by dry etching.

Fig. 36.4 DMD pixel array with tilted and non-tilted mirrors. (Courtesy of Digital Light Processing™, Texas Instruments, Inc.)

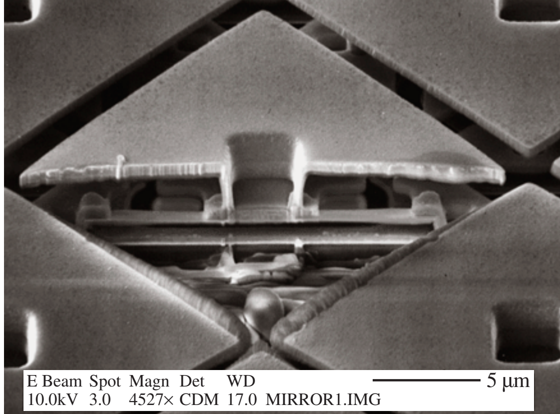


Fig. 36.5 Ion milled section of DMD pixel showing one mirror on its center support and its relation to the underlying layers. Note the close mirror spacing. (Courtesy of Digital Light Processing™, Texas Instruments, Inc.)

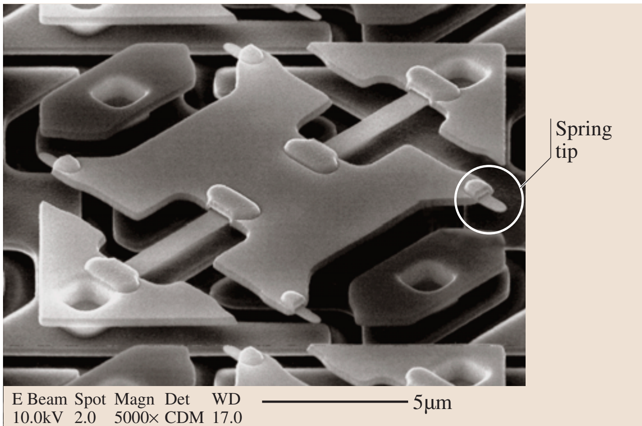

Fig. 36.6 DMD yoke and hinge layer. The spring tip touches landing pads when the drive electrode tilts the mirror. Elastic energy stored in the deformed spring is part of the restoring force that overcomes stiction when the drive electrode voltage is removed. (Courtesy of Digital Light Processing™, Texas Instruments, Inc.)

Following surface passivation, inspection, and testing, an optical glass sub-assembly is hermetically sealed to the ceramic package (Fig. 36.7). At this point, the device is ready for burn-in and final test – a significant task because each mirror is actuated on chips with as many as 1.3 million mirrors.

In operation, a (nominal) 26 V electrode bias generates an electrostatic force that causes the mirror/yoke assembly to rotate either plus or minus 10 degrees around the hinge. Over one million DMD devices had been shipped by 2002 [36.26].

Unlike the pressure sensors and accelerometers discussed below, TI had no choice but to integrate. It would be difficult, if not impossible, to devise a cost-effective multi-chip solution to control and drive a matrix of over a million mirrors. Successful integration of circuits and mirrors was only one step in the commercialization process. To remain competitive against lower cost LCD products, TI continues to develop their package and test technologies, because package and test comprise a major part of the total product cost. This is discussed further in Sect. 36.2.8.

Pressure Sensors. Early (1970s-era) bulk micromachined piezoresistive pressure sensors from Honeywell, ICT (later Foxboro-ICT), and Kulite were not integrated. However, in the 1980s, Motorola commercialized the

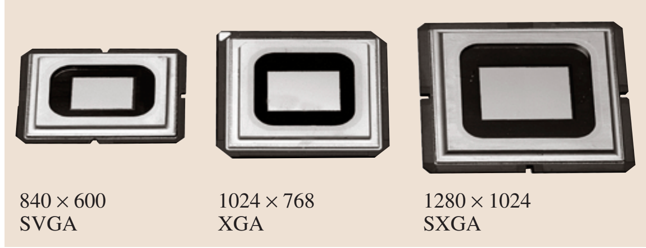

Fig. 36.7 DMD products in hermetic packages. (Courtesy of Digital Light Processing™, Texas Instruments, Inc.)

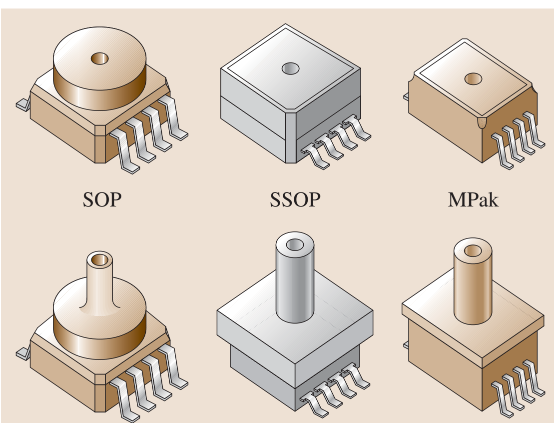

Fig. 36.8 Pressure sensor surface mount packages. (Courtesy of Semiconductor Products Sector, Motorola, Inc.)

first of its MPX5100 series piezoresistive pressure sensor products. These products had bipolar signal conditioning electronics and temperature compensation on the sensor chip. Current MPX products are offered in various plastic packages (Figs. 36.8 and 36.9) with maximum pressure ranges between 10 and 300 kPa (1.45–44 psi). Medical and tire pressure products are also available.

Integrated Motorola piezoresistive pressure sensor products are cited here for illustrative purposes, but capacitive and piezoresistive silicon pressure sensors are available from many companies. Capacitive designs are less temperature sensitive and require less power than piezoresistive designs. However, die size tends to be larger. The fabrication process and interface electronics are also more involved. Piezoresistive products (sensor plus signal processing) are less expensive, smaller, easier to manufacture and suitable for most applications. They rely on the fact that the resistance of silicon changes in response to strain. This effect is very temperature sensitive. However, configuring four piezoresistors as a Wheatstone bridge, judicious selection of the doping level and junction depth and the use of a temperature compensating resistor network minimizes temperature error.

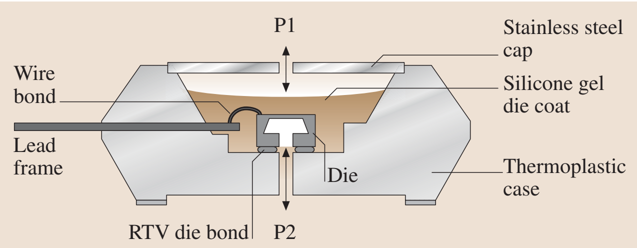

Fig. 36.9 Cross section of a typical gauge or differential pressure sensor. The silicon pressure sensor chip is bonded to a silicon substrate. This bonded unit is mounted in a pre-molded plastic package and protected from the ambient environment by silicone gel. (Courtesy of Semiconductor Products Sector, Motorola, Inc.)

Piezoresistive pressure sensors (Fig. 36.1) require double-sided polished wafers and front-to-back alignment. The piezoresistors are implanted into the front side of (100) wafers and precisely located with respect to the edges of thin diaphragms. The diaphragms are produced by anisotropically wet etching cavities into the back surface of the wafers. KOH etch solutions are usually used to avoid the safety, toxicity, and waste disposal concerns that arise when large quantities of organic etchants like EDP (Ethylenediamine-pyrocatechol-water) are used. Front-to-back side wafer alignment is critical in order to achieve precise resistor location with respect to the cavity edges. Alignment to the wafer crystal axis is also important, because the slow-etching (111) planes determine the cavity wall, and thus the location of the diaphragm edges. The piezoresistors are commonly placed near these edges to maximize the signal (the effect of pressure on diaphragm stress is greatest at the edges). An etch stop is sometimes used at additional cost because diaphragm thickness variations also have a large effect on sensitivity.

Control of mount stress is critical to achieving predictable performance. After wafer fab, some suppliers hermetically bond pressure-sensor wafers to a backup silicon wafer using glass frit. Others anodically bond them to a borosilicate glass wafer that has a thermal expansion coefficient close to silicon (Pyrex 7740 and Schott 8330 are two glasses used for this purpose). Absolute pressure sensors are produced when this bonding step is done in vacuum. As shown in Fig. 36.1 and Fig. 36.9, differential pressure and gauge pressure products incorporate through holes in the backup wafers. These ports allow fluid pressure to be applied through the cavities to the back side of the diaphragms.

After wafer singulation, the chips are mounted and sealed in cavity packages. Soft die attach materials, often silicone-based, are used to decouple the sensor from package and substrate stresses. In some products, the sensor chip is directly mounted to a substrate with a soft die attach without the intermediate backup wafer. Many package variations of MEMS pressure sensors are available, as summarized in Sect. 36.2.8.

The MEMS pressure sensor market is believed to exceed a hundred million pressure sensors annually [36.27]. Automotive applications like manifold absolute pressure (MAP) sensors and a wide range of gas and liquid pressure sensors form the largest market segment. Health care and medical uses such as disposable blood pressure transducers and sensors to measure pressure in angioplasty catheters, infusion pumps, and intrauterine products are the second largest market. Industrial products such as process control pressure and differential pressure transmitters, household appliance, and aeronautical products are also significant. *Maudie* et al. [36.28] review the performance and reliability issues related to appliance applications like household washing machines.

Accelerometers. Most MEMS accelerometer designs apply some variant of Newton's Law, $F = ma$, to sense the response of a proof mass. Many sensing principles, including piezoresistive, capacitive, piezoelectric, and resonant, have been examined [36.29]. Figure 36.10 has a conceptual view of the capacitive design used in Analog Devices ADXL accelerometers.

SensorNor was an early pioneer in silicon accelerometer manufacturing. Their product had a mass bonded to the end of a silicon piezoresistive element in an oil-filled package. However, the first MEMS accelerometer product to achieve large-scale market acceptance was the integrated ADXL50 air bag sensor from Analog Devices. When it was fully qualified in 1993, the ADXL50 was the first integrated surface-micromachined MEMS device of any type in production. The MEMS element in the ADXL50 was part of a closed loop differential capacitance circuit, but was designed to allow routine self-testing after the air bag module was installed in vehicles. This self-test capability eased concerns related to the adoption of a new technology in a critical safety application. The analog output feature also allowed the industry to design single point sensors – a significant system cost savings. *Core* et al. [36.2] and *Sulouff* [36.5] describe the ADXL wafer fabrication process. In essence, circuits are fabricated with a well-established BiCMOS process. The sensor polysilicon is deposited after these high temperature steps, followed by the lower temperature metal and passivation processes. The in situ doped polysilicon is connected to the circuit through N+ doped runners. Following wafer fabrication, thin film resistors are laser trimmed in an automated trim system to meet the specific end user's requirements. After wafer singulation (Sect. 36.2.5), the chips are assembled in hermetic cavity packages and screened in an automated test system to ensure compliance to the performance specification (Sect. 36.2.8).

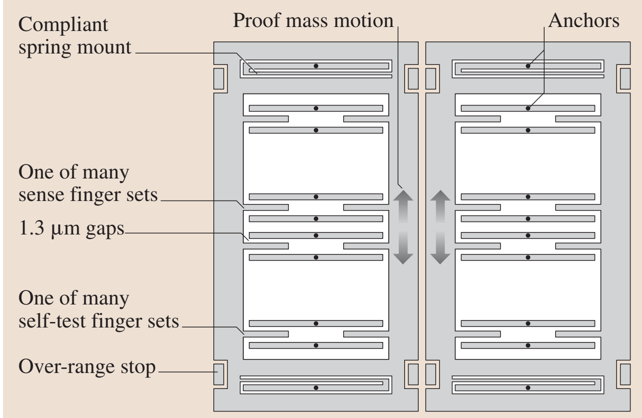

Fig. 36.10 Block diagram of the MEMS element in an ADXL78 single-axis accelerometer. The detailed design applies design-for-manufacturability principles to ensure close control of critical dimensions and residue-free removal of the sacrificial layer. (Courtesy of Micromachined Products Division, Analog Devices, Inc.)

Front air bag sensors have an output of 2 V at a full scale acceleration that is specified by the user (typically 35–50 g). Satellite air bag sensors are located in door pillars and near the front of the automobile and typically have higher ranges (250 g). Regardless of range, all air bag sensors must meet stringent cross-axis specifications, i. e., a front air bag sensor must not react to a side collision or to potholes in the road. This cross-axis requirement also applies to products that are designed to sense in two axes (Fig. 36.11).

Progressive reductions in chip and package sizes (Fig. 36.3) led to cost reductions and penetration into new markets. One example is the ADXL202 (Fig. 36.11). This two-axis, low-g accelerometer has a full scale of 2 g in each axis. It is widely used in industrial, consumer, and automotive applications. Production of integrated MEMS accelerometers at Analog Devices has grown rapidly in recent years (several million devices per month by 2001). It is worth noting that these products are developed using an organizational philosophy that emphasizes design-for-manufacturability. For example, development is conducted on production equipment and directly involves production personnel. This may appear to be expensive and unwieldy, however, it ensures that product designs remain within the bounds of practical man-

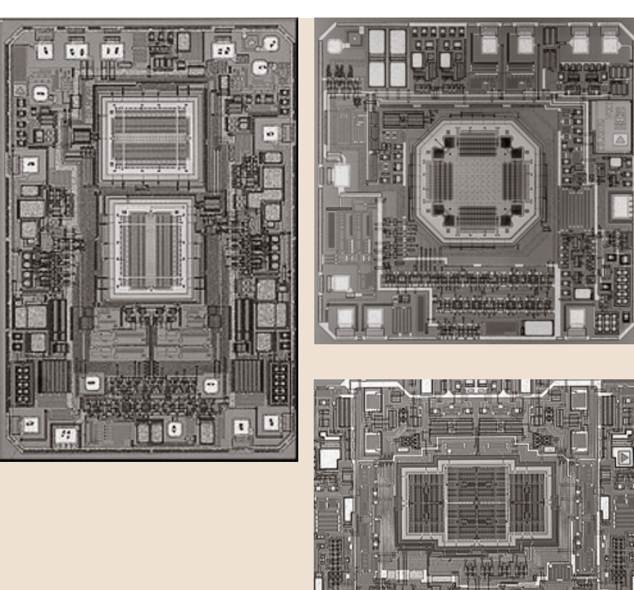

Fig. 36.11 Three two-axis accelerometers. *Top left:* ADXL276 was the first two-axis air bag accelerometer. The ADXL278 family (*bottom right*) is replacing it. *Top right:* 2-g ADXL202. The ADXL202 and ADXL278 are packaged in the LCC shown in Fig. 36.3. (Courtesy of Micromachined Products Division, Analog Devices, Inc.)

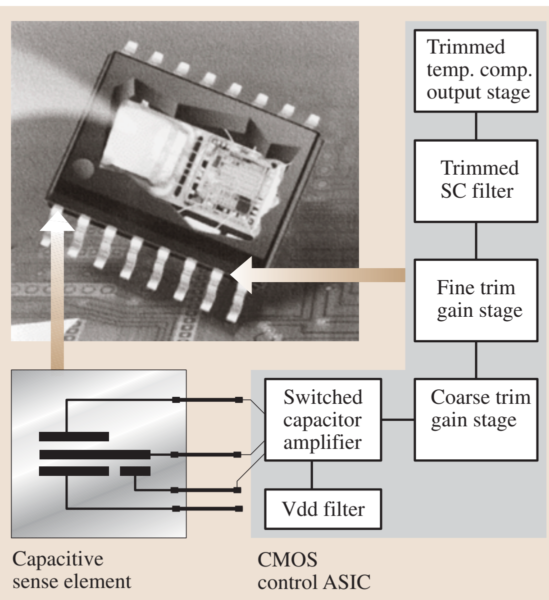

Fig. 36.12 Two-chip accelerometer in 16 lead plastic SOIC package. (Courtesy of Semiconductor Products Sector, Motorola, Inc.)

ufacturing. It also minimizes the difficulties that are normally encountered when new products are transferred to production.

Prior to the introduction of the ADXL50, most of the MEMS air bag candidates were nonintegrated, bulk-micromachined piezoresistive sensors [36.3]. However, Motorola and Bosch soon followed with an integrate-in-the-package strategy. Denso, Delphi, and VTI Hamlin are also active in some market sectors. The Motorola and Bosch products are nonintegrated capacitive MEMS products that are hermetically sealed at the wafer level (Sect. 36.2.4). By interconnecting a separate circuit chip and a sealed accelerometer chip in one package, they are able to use low cost CMOS for signal processing and near-standard plastic packaging (Sect. 36.2.8).

In contrast to the ADXL sensors, Motorola's MMA air bag products measure acceleration normal to the plane of the chip (z-axis). These differential capacitance sensors are formed from three layers of polysilicon. The middle layer is a "proof mass" that is suspended with ligaments and is free to move in response to an accelerating force. Ranges and outputs are similar to the ADXL products. Recent Motorola expansions add x-axis air bag products and a new line of low-g z-axis products (Fig. 36.12).

The Bosch x-axis sensor has interdigitated fingers that are patterned in a thick (11 μm) polysilicon film that is deposited in an epi reactor. Tight control of stress and stress gradients in these films is essential in order to meet sensor performance requirements [36.30, 31]. After patterning, the polysilicon is dry etched using fluorine-based chemistry [36.32] to form the differential capacitance sensor. An HF vapor process is used to remove the sacrificial oxide and release the microstructures. These thick structures have working capacitances near 1 pF [36.33]. *Laermer* et al. [36.34] explain how Bosch applies deep silicon etch processing to several production and experimental inertial sensors. Better known as the "Bosch etch," this deep reactive ion etching technique has pioneered the field of high-aspect-ratio silicon-based MEMS.

The Future of Integration. The high growth rate of integrated MEMS products demonstrates the value of integration in MEMS applications. To date, integration has been limited to large semiconductor companies that have in-house signal processing expertise and the willingness to invest substantial resources over a number

of years. Each company identified a large volume market that could support a profitable integrated product. This "large semiconductor company" barrier-to-entry for integrated MEMS products will diminish in the future due to new SOI wafer technology (Sect. 36.2.4), new flip-chip equipment, and the development of low temperature MEMS processes. With these capabilities, MEMS-only companies will be able to integrate microstructures on circuit wafers that are preprocessed in CMOS foundries. To be successful, they will also have to develop cost-effective manufacturing and quality expertise (Sect. 36.2.9).

Risk

High risk is normal in research programs. However, the tremendous financial investments required to manufacture new products make the risk of failure a key consideration. This section discusses how the perception of manufacturing risk changes with time and is influenced by available knowledge and expertise.

Every development program makes fundamental product architecture decisions. These decisions can lead competing companies down different paths. For example, Analog Devices pursued chip-level integration, while Bosch and Motorola chose package-level integration. Why did these companies choose different paths? The answer is related to available resources, cost, time-to-market, and technical maturity. Analog Devices chose to integrate because of its expertise in process innovation and signal processing. This path did have risks. When the ADXL50 was designed, the fatigue life of polysilicon MEMS devices was unknown. Therefore, a closed loop circuit architecture was chosen in order to keep the proof mass motion under 100 Å. Polysilicon actually has excellent fatigue life. Once this was established, Analog changed their ADXL products to an open loop architecture that can detect capacitance changes as low as 20 zF (10^{-21} F). Most companies do not have the expertise to work in this regime, but the decision to integrate on one chip allowed Analog to make full use of its signal processing knowledge.

The two-chip Motorola and Bosch designs allow the circuit chip to be fabricated on any IC process. This product concept also removed the concern that integrating MEMS and circuits onto one chip might reduce overall product yield. However, it does require higher output signals from the MEMS chip in order to overcome parasitics that arise in the bond wires between the circuit and sensor chips. This requirement led Motorola toward large-area z-axis designs, while Bosch utilized its deep-etch process capability. To minimize cost and ensure reliability, both companies seal the sensors with glass at the wafer level. Sensor and circuit chips are then molded together in one plastic package. Each company built on expertise that it already had in order to minimize risk and cost. Motorola had in-house manufacturing expertise in wafer-level glass frit sealing of pressure sensors that are subsequently molded in plastic packages. Bosch had deep-etch process capability and the world's largest hybrid manufacturing plant, so screen printing and glass sealing were well-established. These considerations plus the concern that MEMS yield loss would undermine product yield contributed to their two-chip decision.

Semiconductor companies continually drive down cost and serve evolving markets by shrinking product size. Analog Devices believes that this long-term roadmap requires an integrated product. They chose to deal with one-chip risks, rather than package uncertainties. ADXL50 chips had been capped and molded in plastic long before the first qualified products were shipped in 1993 [36.35]. However, production-worthy capping equipment did not exist at that time. The effects of plastic package stress on yield and long-term device parametrics were also uncertain. By introducing the initial product in TO-100 hermetic metal packages, the risks associated with custom equipment and package stress were removed.

Reusable Engineering and Facilities to Achieve Economies of Scale

The IC industry produces many products on each process flow. Foundries and packaging subcontractors routinely apply this "economy-of-scale" principle. Only basic items like mask sets and bond pad diagrams are changed. The MEMS industry has been less successful in this area, although techniques like wafer-level laser trim and blowing poly fuses allow accelerometer suppliers to offer "specialty" products without losing the advantages of high volume production.

If only a few devices are produced in a capital-intensive facility, unit costs are high. This issue is particularly critical during the first years of product life when sales volume is normally low. One solution is to build the market by manufacturing the new product in an existing facility. The two-axis low-g ADXL202 (Fig. 36.11) was built using a new mask set with an existing air bag sensor process. Many ADXL202 consumer, industrial, and automotive applications are too small to justify the capital investment risk required to

develop and produce a two-axis accelerometer, but use of an existing design and manufacturing base removed this constraint.

Market Dynamics Drive New Product Opportunities

In the 1980s, low cost and high reliability allowed MEMS pressure sensors to penetrate automotive applications like the measurement of manifold vacuum (MAP sensors). Once a technology is accepted, new opportunities usually develop. For example, tire pressure monitors with RF communication capability are now available in some car models. In the future, this type of monitor will be a safety feature expected by all consumers. Indeed, wireless communication capabilities will also be a common MEMS product requirement.

This example illustrates the fact that MEMS products are merely system components. They must support seamless integration into the larger system. MEMS opportunities in automobile safety systems will be affected by both communication protocols and interconnect technology (copper, fiber optic, and wireless). The growth spurt of the 1990s started with front-air-bag crash sensors located in the center module of automobiles. It has evolved to include satellite crash sensors behind bumpers, side-impact sensors in the B pillar (the vertical post between doors), impact sensors inside doors, rollover sensors, and vehicle dynamic control sensors to improve ride and handling. Each of these applications has unique characteristics that can favor one technology over another. For example, side-impact sensing systems must activate the air bags faster than front-impact systems. This response time characteristic can favor the use of pressure sensors that monitor air pressure inside door cavities – a good solution as long as the cavity remains sealed. An alternative is to place an accelerometer in the B pillar. These thin structural members have very little space, so z-axis accelerometers are sometimes easier to implement. Delphi and Motorola products have this characteristic. Analog's small x-axis accelerometers also meet this space requirement.

Gyros – New Products Produced with Preexisting Manufacturing Capabilities

Gyroscopes are transducers for rotational motion. They have a wide range of uses in platform stabilization and robotics, as well as automotive applications (dead reckoning backup for GPS navigation systems when satellite communication links are lost, skid control systems, and rollover detection). Unfortunately, the non-MEMS and resonant quartz gyros used in military and aerospace applications are rather expensive for many high volume applications. BEI Systron Donner tailored their high performance quartz gyro to meet automotive needs and has shipped several million gyros. Other lower cost gyro and angular rate products, like the Murata vibrating ceramic bimorph products, are used in cameras. However, as a group, these low cost products do not meet the performance required for many applications.

Analog Devices and Bosch reapplied their accelerometer capabilities to develop and manufacture low cost gyroscopes. *Geen* et al. [36.36] describe the Analog Devices product. *Funk* et al. [36.37] and *Lutz* et al. [36.38] describe the Bosch product. These three publications reference previous work and discuss the challenges of producing gyros that meet performance, reliability, and cost targets.

The Analog Devices ADXRS150 gyro (Fig. 36.13) illustrates the technology. It has a resonant microstructure that is integrated with two electronic systems on one chip. One of the electronic systems drives the MEMS resonator. When the ADXRS150 is rotated, Coriolis ac-

c)

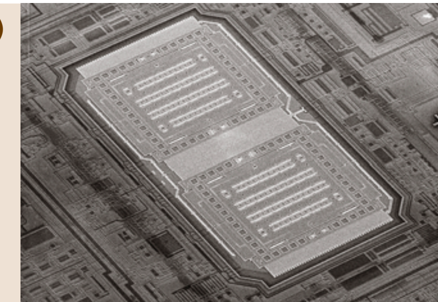

Fig. 36.13 (a) ADXRS150 gyro with integrated electronics in 7 mm × 7 mm BGA package. **(b)** ADXRS150 chip. **(c)** MEMS portion of the ADXRS150 chip. (Courtesy of Micromachined Products Division, Analog Devices, Inc.)

celeration is generated in a direction that is perpendicular to the vibration axis of the resonator. This motion is detected by the second accelerometer system. Full scale is rated at 150 deg/s, although it can sustain overloads up to 10,000 deg/s. Integration of electronics on the chip, microstructure modeling, and predictable manufacturing were essential to success, because the full-scale Coriolis motion is only about 1 Å. The combination of differential capacitance detection, area averaging, and correlation techniques allow this motion to be resolved from thermal noise down to about 0.00016 Å [36.36].

Resonant gyros are not new. However, as noted above, their high cost restricts them to specialty applications. Many are non-MEMS, or utilize the piezoelectric properties of quartz, so chip-level integration is not an option. Most require expensive vacuum packaging to achieve high mechanical Q at resonance. Unfortunately, vacuum packaging also makes them susceptible to mechanical damage. Viscous damping in gas-filled devices like the ADXRS150 suppresses the destructive impact events that occur in vacuum-packaged MEMS products during shipping and handling and in-use conditions. Equally important are ADXRS150 design features that allow the measurement to reject mechanical shock, vibration, and other environmental noise sources. As a result, under-the-hood location is practical in automotive applications, an unmatched characteristic that significantly reduces system cost.

Analog Devices and Bosch both needed several years to develop their gyro products. Use of existing accelerometer infrastructure during the prototype and early production phases significantly reduced development costs and manufacturing risks. Early ADXRS150 gyros were sold as engineering grade products in socketable side braze packages. This allowed the development team and customers to understand the design and process parametrics that affect performance, reliability, and yield. Side braze packages are unacceptable in high volume applications, so the ADXRS150 is sold in a hermetic, ceramic, surface mount package.

36.2.3 Microstructure Release

Release stiction occurs when microstructures stick together after the sacrificial material is removed in a wet etch. It can cause considerable yield loss and must be considered in devices like capacitive pressure sensors and accelerometers that have closely spaced, mechanically compliant microstructures. Piezoresistive pressure sensors are not susceptible to release stiction, because these sensing diaphragms are not near other surfaces.

Release stiction is most frequently observed in silicon MEMS devices that use a sacrificial oxide. The oxide is removed by etching in wet HF, rinsed in deionized water, and then dried. Water promotes growth of a hydrophilic surface oxide. It also has a high surface tension. To minimize energy, the high surface tension in the shrinking water droplets causes the microstructures to be pulled together. When they touch, clean oxide surfaces stick, thus destroying device functionality. *Maboudian* et al. [36.17] review release stiction mechanisms, as well as the solutions that have been reported in the literature.

Some manufacturers do not publicly discuss their fab process. Those that do avoid release stiction by using gas phase processes to remove the sacrificial material. Texas Instruments uses photoresist, rather than silicon dioxide as the sacrificial material in their DMD manufacturing process. Two photoresist layers are under the aluminum mirrors. The wafer is also covered with a third organic layer to provide mechanical damage protection and allow for particle cleaning after the wafer is singulated into individual devices. By removing these organics in a dry etch process, the stiction problems that characterize wet etch processes are avoided.

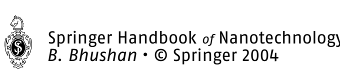
Analog Devices avoids release stiction by dividing its accelerometer process flow into several steps, each of which is well controlled with standard manufacturing equipment. After the microstructure is formed, a few small channels are etched in the sacrificial oxide and filled with photoresist. These photoresist pedestals hold the microstructures in place when the remaining sacrificial oxide is etched, rinsed, and dried. The pedestals are then removed in a dry etch process. *Core* et al. [36.39] and *Sulouff* [36.5] describe this technique in more detail.

Bosch avoids release stiction by holding accelerometer wafers above an HF solution. HF vapors from the solution react with the sacrificial oxide, converting it to gaseous SiF_4 and water. The wafers are heated to prevent water from condensing. This process is noted in *Offenberg* et al. [36.40]. *Anguita* et al. [36.41] describe a similar process.

36.2.4 Wafer Bonding

To date, the growth of MEMS wafer bonding has been driven by three factors:

- Sealing microstructures by bonding wafers together addresses two sources of yield loss in MEMS manufacturing: wafer singulation and particles.



- Wafer-level mounting can be a cost-effective way to control stress in products that are sensitive to variations in mount stress.
- Fabrication of 3-D microstructures from elements that are formed on multiple wafers.

Piezoresistive pressure sensor wafers have been anodically bonded to borosilicate glass wafers for about 25 years. The earliest products were manufactured using little more than a hot plate and a high-voltage power supply. The era of custom built manual equipment has passed, because both Electronic Visions and Karl Suss now offer automated production-worthy tools for anodic, glass frit, organic, and silicon-silicon wafer bonding. *Schmidt* [36.42] reviews wafer-wafer bonding processes, while *Mirza* [36.43, 44] addresses MEMS wafer-level bonding applications and equipment.

Anodic Bonding

Anodic bonding is commonly used to seal glass wafers to the back side of bulk micromachined pressure sensor wafers. The process requires that a silicon wafer be placed in intimate contact with a glass wafer that contains a mobile ion at elevated temperature. An applied electric field causes mobile ions (usually sodium) in the glass to move away from the silicon interface toward the cathode at the other side of the glass. Bound negative charges remain in the glass near the silicon interface. These charges produce an electric field that pulls the wafers together and drives oxygen across the interface to anodically oxidize the silicon surface. Hermetic seals are routinely produced between flat wafers when particles are rigorously excluded. Process conditions depend on the glass composition and thickness, but 500–1,000 V at 400 °C with 10 min cycle times is typical. Borosilicate glasses with thermal expansion coefficients close to silicon are used to minimize stress. Anodic bonding promotes surface conformation so hermetic glass-silicon seals can be formed with surface grooves as deep as 50 nm [36.45]. This process has been demonstrated to work with many material combinations [36.46].

Glass Frit Bonding

Glass frit bonding reapplies techniques and materials developed for hybrid processes and cerdip sealing. It is often used to seal pressure sensor wafers to silicon substrate wafers. A second common application is to glass-frit seal bulk-micromachined silicon cap wafers over the microstructures in accelerometer wafers. In this process, fine glass powder is dispersed in an organic binder to form a paste. This paste is screen printed or stenciled in the desired pattern on a wafer. The wafer is then passed through a furnace (typically 430–500 °C). This causes the organics to burn off and the individual glass particles to coalesce into the desired pattern.

The wafer bonding process starts with a wafer prepared as described in the preceding paragraph. This wafer is aligned to a second wafer, where they are held in intimate contact and heated until the glass softens. Liquid glass readily wets the surface of the adjacent wafer when at least trace amounts of oxygen are present. The liquid-wetting mechanism produces hermetic seals even when the wafer surfaces are relatively rough. However, seal widths less than 100 μm are difficult to achieve. Fixtures that maintain wafer alignment through the bonding process are also required. Low-melting lead oxide and boron oxide glasses are commonly used in processes that typically run at 450 °C. Glass wet-out occurs quickly, but process cycle times are limited by the cooling rate (rapid cooling can cause stress gradients and cracking in the glass if proper design practices are not followed). Glass frit bonding to semiconductor wafers requires a good understanding of glass composition effects and process conditions [36.47].

Silicon–Silicon Wafer Bonding

Silicon-silicon bonding has been demonstrated in many IC and MEMS applications over the last 30 years. These processes bring highly polished wafers into intimate contact and are often promoted by a thin hydrophilic oxide that is left on the surfaces by the aqueous cleaning process. Clean, well polished wafers will bond at room temperature. However, heating (800–1,200 °C) increases bond strength by an order of magnitude. A fundamental difference between MEMS silicon–silicon bonding and either anodic or glass frit bonding is that it is used to produce complex microstructures that cannot be made in one wafer. In contrast, most anodic and glass frit bonding applications address assembly and packaging issues.

Recent silicon-silicon advances have solved technical factors like stress control that had limited MEMS applications. For example, Analog Devices balances the stresses at oxide interfaces and the handle wafer to produce flat, three- and four-layer SOI wafers [36.48, 49]. The thickness of each layer is precisely controlled using grinding and CMP (chemical-mechanical polishing). Intermediate layers can be patterned, electrically isolated, electrically interconnected and locally etched to produce single-crystal silicon microstructures that are hundreds of microns thick on CMOS compatible wafers. With this new capability, several organizations are fab-

(Courtesy of Micromachined Products Division, Analog Devices, Inc.)

ricating MEMS devices for biotech, automotive, and communications applications. One example is the array of gimbal-mounted mirrors shown in Figs. 36.14 and 36.15. These mirrors can be tilted in any axis to steer light between fibers in optical fiber bundles. The mirrors are driven by electrostatic force applied from electrodes that are patterned under the mirrors. Capacitance measurements based on a second set of electrodes are also part of a closed loop control system that maintains position control. Integration of high voltage drive electronics, low voltage control electronics, and MEMS mirrors would be impractical without this SOI capability and related MEMS processes.

36.2.5 Wafer Singulation

The cooling water and the particles generated in a standard IC diamond saw will destroy MEMS wafers unless some form of protection is used. Manufacturers solve this problem in several ways. Bosch and Motorola bulk micromachine cap wafers that are glass frit bonded to surface micromachined wafers. The caps protect the microstructures from water, particles, and mechanical damage so the wafers can be sawn with standard equipment.

The optical function of DMD chips required Texas Instruments to find a different solution for DMD wafers. Originally, they used a partial saw process on wafers that were protected with an organic film. This allowed wafer-level testing, but caused particle contamination and die loss when wafers were broken along the partial saw cuts. They now use a standard saw process, but do it before the mirrors are released. The wafers have the protective organic film over the mirrors, so normal cleaning processes are used. The singulated chips are

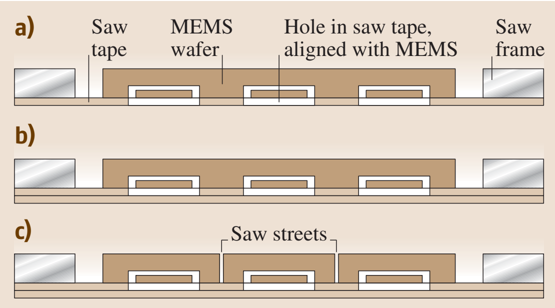

Fig. 36.16a–c Analog Devices "upside-down" saw process flow. **(a)** Saw tape is mounted on a saw frame. Holes are punched in the tape to match the microstructures on the wafer. The wafer is mounted-upside down on the saw tape and aligned so that the microstructures are in the holes. **(b)** A second layer of tape is placed over the first layer to form watertight pockets. **(c)** Wafer is aligned and sawn using standard equipment (adapted from [36.50])

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

mounted in ceramic packages before the organic layers are dry etched. This flow eliminates a primary source of particle contamination and problems associated with handling partially sawn wafers [36.6].

Analog Devices singulates uncapped MEMS wafers using an upside-down saw process and standard equipment and fixtures that are slightly modified (Fig. 36.16) (*Roberts* et al. [36.50]). A major attraction is that it allows wafer-level test and trim, so only chips that meet the product specification are assembled. It also avoids the added cost and yield loss associated with wafer capping. Although originally developed for accelerometers, this technology was extended to gyro wafers and to wafers that contain optical mirror arrays (see Figs. 36.13 and 36.14).

36.2.6 Particles

Particles cause yield loss in every product that has closely spaced movable microstructures. They also cause large area defects in anodic and silicon-silicon wafer bonded processes. Commercial MEMS suppliers use several solutions:

1. Cap the MEMS wafers before they leave the wafer fab clean area. Bosch and Motorola use this approach to produce accelerometer products (Fig. 36.12). It solves the wafer saw dilemma faced by most MEMS suppliers and allows the use of plastic packaging. Disadvantages include yield loss due to cap misalignment and stress, as well as the cost of the added capping steps. Hermeticity testing is also difficult because capped devices require sensitivity levels beyond the capabilities of standard analytical test equipment.
   Capping protects MEMS from particle contamination during assembly, but does not prevent wafer fab contamination. A greater concern is that glass-frit seal processes and equipment do not usually meet fab cleanliness standards. Once capped, inspection is essentially impossible.
2. Analog Devices and Texas Instruments assemble their MEMS products in clean rooms. This option increases capital costs. TI invested in environmental and process control, rather than develop optical quality capping for the DMD. Analog Devices had solved the wafer saw dilemma, so environmental and process control was the low risk path for particle control.

Particle control is central to high yield and reliability. The first control level is to minimize particle contamination through proper handling procedures, equipment maintenance, environment controls, and process design. The DMD protective organic film illustrates how process design can be used to control particles. This film allows the wafer to be cleaned after wafer saw and die attach.

Even with the best of controls, some particle contamination occurs in every clean room. Electrical tests in the automated wafer- and package-level test programs are designed to detect particles in Analog Devices products. Texas Instruments also finds particles in DMD products by driving each mirror in an array to ensure proper operation. Such screens are good but imperfect. Attempts have been made to replace visual inspection with automated particle inspection based on pattern recognition software. To date, however, machine vision systems have not been able to match the human eye and mind aided by a high quality microscope.

36.2.7 Electrostatic Discharge and Static Charges

Susceptibility to electrostatic discharges (ESD) led semiconductor manufacturers to make ESD avoidance a central criterion in equipment and fixture design, as well as handling procedures. Control of ESD events on the manufacturing floor is only the first step. Analog Devices and Texas Instruments incorporate ESD protective circuitry into their MEMS products as a standard practice to avoid failures in their customer assembly lines, as well as in the final system.

Most MEMS products use electrostatic force to actuate or control suspended microstructures. This design characteristic introduces performance parasitics and failure mechanisms that are not encountered in normal IC devices. For example, charges that build up on a dielectric surface can deflect unshielded microstructures, even when they are several millimeters apart. Such effects are insidious, because closed loop control systems do not always correct for electrostatic-induced errors.

Section 36.3.1 discusses surface treatments designed to suppress stiction caused by surface forces. These treatments often produce a dielectric surface. If the dielectric properties of the treatment and the device design cause the surface to hold a charge, that anti-stiction coating may actually promote electrostatic stiction! Thus, any "solution" must be critically evaluated in order to identify and remove undesirable side effects.

36.2.8 Package and Test

IC packages are environmental (mechanical, chemical, electromagnetic, optical) barriers that protect the chips from surrounding media. Only power and electrical signals and inertial forces pass unimpeded, so most MEMS sensors and actuators require that this barrier be selectively penetrated. Package and test functions are unique to each company's design and MEMS product type. Standard semiconductor packaging equipment and processes are modified when possible. However, even the line of demarcation that separates wafer fab from packaging is unique to each product.

High volume MEMS testing is even more challenging than MEMS packaging. In essence, the task is to measure and trim the response of products mounted in non-standard packages to calibrated stimuli over a range of temperatures. Automated IC test equipment does not have the calibrated pressure, acceleration, or optical test functionality required for this task. *Maudie* et al. [36.51] detail the test system elements that are required to support volume production of MEMS products.

Pressure Sensors

Pressure sensors are extremely susceptible to stress, so die-attach stress variations broaden performance distributions. The uniformity produced by wafer-level bonding is a primary reason why these processes are used to make the first-level package in many pressure sensor products. Soft silicone and fluorosilicone rubber products are often used to attach the sensor chip to the package to maximize isolation from mechanical stresses transmitted through the mount.

Most semiconductor products are assembled in plastic packages. The automated plastic presses transfer viscous epoxy compounds into multi-cavity molds at 175 °C and pressures near 6,900 kPa (1,000 psi). The hot liquid plastic creates high shear stress as it flows around devices in the mold cavities. Further stresses develop as the plastic hardens and cools. Even if this technology were adapted to create pressure ports in packages, the mold stresses would substantially affect pressure sensor performance.

Pre-molded plastic packages avoid the stress problem and incorporate pressure ports (Figs. 36.8 and 36.9). Polyphenylene sulfide (a high temperature thermoplastic) and medical-grade polysulfone are commonly used to make pre-molded pressure sensor packages.

The liquid or gas that is being measured can cause corrosion of interconnects and chip metallurgy, as well as parasitic leakage paths in the sensor. For that reason, a barrier such as silicone or fluorosilicone gel is often applied over the sensor. The soft gel transmits pressure with high fidelity over a wide temperature range and passivates the chip against many types of chemical attack. Parylene is also used for this purpose. This vapor-deposited organic coating is much stiffer than the gels, so thickness is typically controlled near 1 μm.

Petrovic et al. [36.52] tested the ability of fluorosilicone gels and several Parylene C thicknesses to protect powered pressure sensors against automotive and white goods benchmark liquids. One purpose of their study was to propose and demonstrate a formal media compatibility test protocol for pressure sensors similar to the IC industry standard tests. They found that the lifetime of sensors coated with both gel and parylene was considerably longer than sensors coated with either gel or parylene alone. *Petrovic* [36.53] later summarized the advantages and limitations of gels, parylene, and other techniques.

Figure 36.8 has examples of commercial plastic packaged pressure sensors. Pressure calibration equipment and software must be custom designed and built for these products. However, most pressure products are dimensioned to match IC packages in order to maximize compatibility with standard IC test handlers.

The harsh environment of some under-the-hood applications has been used to justify the high cost of metal cavity packages. For example, Bosch introduced a piezoresistive MAP sensor with signal conditioning that was hermetically sealed in an evacuated T08 header [36.54]. In-package trim was based on planar thyristors that were zapped as needed to bring the sensor within spec. The design avoided chip metallurgy corrosion and surface electrical parasitics by using the back surface of the silicon diaphragm as the fluid interface.

Much more expensive packaging is used in the pressure and differential pressure transmitters that are designed for industrial process control. These products seal the sensor in silicone oil behind thin metal diaphragms. Such products can measure pressure differences of 20 kPa superimposed on a pressure of 20,000 kPa (3,000 psi) over wide temperature ranges with high accuracy and stability. Soft die attach materials decouple the sensor from thermal stresses that arise when they are mounted in metal housings. Note, however, that silicone die attach materials cannot be used if the transmitter is filled with silicone oil. Fluorosilicones are one alternative. Piezoresistive sensors have been used in pressure and differential pressure transmitters since the 1980s. *Fung* et al. [36.55] describe a relatively new version. This product uses a piezoresistive polysil-

icon sensor to measure both absolute and differential pressure on the same chip. See *Chau* et al. [36.56] for early work on a multirange version of this technology.

Image Projection

The Texas Instruments DMD poses unusual challenges because the package lid must be an optical quality glass with anti-reflection coatings to improve optical performance and reduce heat load. The glass lid has opaque borders around the image area to minimize stray light effects and create a sharp edge on the projected image. It is fused to Kovar frames to produce lid sub-assemblies. The package base is a multilayer alumina substrate with co-fired tungsten to provide the electrical interconnects. The package sidewalls are formed by brazing a Kovar seal ring to the substrate. Heat dissipation through this substrate is a significant consideration because the service life of DMD mirror hinges (Fig. 36.6) is largely determined by operating temperature [36.57]. Excessive high temperature creep results in "hinge memory" and would cause a gradual drift in mirror orientation.

The DMD chips are die attached in the package cavity before the mirrors are released. A dry etch process is used to remove the organic sacrificial layers. The die are then passivated and tested. Getter strips are attached on the inside surface of the glass at the sides to control vapor composition in the package cavity before the lid is aligned and seam sealed to the package seal ring. Image quality requirements place stringent requirements on handling, alignment, and spacing tolerances. Thermal stresses also arise when dissimilar materials are joined in high temperature processes to produce the final hermetic package. The DMD packages (Fig. 36.7) and the related processes are discussed further in *O'Connor* [36.58], *Mignardi* et al. [36.6], *Bang* et al. [36.59], and *Poradish* et al. [36.60].

DMD mirror release does not occur until after die attach. This has advantages with respect to wafer saw and particle suppression, but it sacrifices the economic attraction of wafer-level testing. There is no commercial test system capable of combining CMOS electrical testing with 100% testing of optical mirrors. Therefore, a custom electro-optic test system was built around an x-y-θ translation stage with a CCD camera, light source, control hardware and software, and test programs [36.6]. A characteristic of the papers published by the DMD group is their effective use of this test system to examine problems and statistically validate the solutions.

Assembly of the DMD on the projector electronics board requires alignment with the system optics, in addition to electrical connections. Initially, the DMD was held with a plastic clamp and electrically connected through elastomer pads that had alternating layers of conductive and nonconductive material. This allowed easy replacement if a DMD was damaged during assembly. However, the impedance of this connector system was too high for new, higher speed products. Electrical intermittents were also observed. Therefore, it was replaced [36.61] by a grid of c-shaped springs (cLGA™, Intercon Systems, Inc., Harrisburg, PA).

The DMD has about 40% of the business and entertainment image projection market [36.62]. Products based on liquid crystal technology serve the balance of the market. Market share is largely driven by price, so considerable effort has been placed on reducing the cost of DMD package and board-level assembly. *Migl* [36.61] reports on the assembly benefits achieved by replacing the epoxied heat sink with a mechanically attached heat sink. *Jacobs* et al. [36.62] describes the effort to replace the seam sealed window mount with a lower cost epoxy-bonded design. In theory, such a bond is not hermetic. However, the team realized that proper material selection, design, analysis, and use of moisture getters would produce a low humidity package through the product life. This change was not released to production. If it is implemented, success will require that adhesive bond integrity also be maintained, because the adhesive joint sustains thermal expansion and mechanical clamp stress cycling each time the projector is used.

Accelerometers and Gyros

The Bosch and Motorola capping processes are a first-level package that is applied at the end of wafer fab. After capping, the wafers can be sawn using standard equipment and do not require clean room assembly conditions. In principle, capped devices are compatible with standard plastic packaging. However, molding stresses can be a serious problem. To minimize stress, capped sensor chips are mounted on lead frames with a soft elastomer and often coated with a silicone gel to isolate the sensors from the package stress. Motorola products are calibrated by burning EPROMS after molding. Their early air bag accelerometers were molded in DIP and SIP packages for assembly on through-hole circuit boards. The shift to smaller surface mount SOIC packages reduces the quantity of plastic, so package stresses are reduced. To maintain compatibility with standard tooling in small thin plastic packages, either the cap or the MEMS wafers must be backlapped.

Analog Devices uses a near-standard saw process (Sect. 36.2.5 and Fig. 36.16), so capping is not required

if hermetic cavity packages are used. Such packages are standard, but more expensive than molded plastic. A major attraction of cavity packages is that they eliminate plastic package stress (see page 1099), because the only mechanical connection between the chip and the package is through the die attach and bond wires. As a result, ADXL accelerometers and ADXRS gyro products are fully tested and trimmed on automated systems before the wafers are sawn. A lot-tracking system transfers this data to automated die attach systems. These systems are programmed to pick only chips that meet performance specifications from the wafer saw film frames. Thus, reject die are not assembled into packages. After packaging, devices are tested to ensure conformance to specification. However, package-level trim is not required, because the assembly process and cavity packages do not appreciably shift device parametrics.

The evolution of ADXL cavity packages is illustrated in Fig. 36.3. Initial products were packaged in TO-100 metal packages. This seam-sealed package is useful for development purposes. However, it is expensive and incompatible with the automated equipment used to assemble electronic circuit boards. Therefore, the early air bag sensors were soon switched to cerdips. Cerdips are made from low cost, molded, ceramic bases that have glass seal surfaces. The high process temperature requires use of a silver-glass die attach product. The full assembly flow includes two or three furnace passes near 450 °C to produce hermetic cavity packages.

IC products have been packaged in cerdips for decades, but through-hole circuit boards are seldom used today. A simple change in lead forming allows cerdips to be fully compatible with standard surface mount boards ("cerpacs"), so cerdips and cerpacs are assembled on the same equipment. Most of the ADXL products shipped in the late 1990s were packaged in cerpacs. However, small LCCs have become the package of choice for one- and two-axis accelerometers. The LCC (Leadless Chip Carrier) uses solder-sealed ceramic bases and metal lids. Organic die attach materials are practical, because the furnace gas is nitrogen, rather than air, and temperatures are about a hundred degrees lower than cerpac furnace temperatures. ADXRS gyros are assembled in a solder-sealed 7 mm × 7 mm ceramic ball grid array package (Fig. 36.13).

The fundamental message of this section is that IC package technology – both plastic and hermetic – is evolving very rapidly. Cost-competitive suppliers must remain cognizant of these trends in order to use them to best advantage. MEMS products that are packaged in a way that is not compatible with standard IC equipment and interfacing standards bear a significant cost premium. High package cost seriously limits market size because the price-volume curve is steep for most products. The package size trend is also critical to new market penetration. In summary, customer interface and new application requirements will continue to drive down both the cost and the size of most MEMS products.

The ADXL and ADXRS automated testers and handlers measure multiaxial linear and rotational acceleration. Analog Devices has a division that designs and manufactures automated test systems (many of the corporation's IC products have unique test requirements), so it avoided some of the problems associated with the procurement of custom-automated test equipment. MEMS suppliers have relied on custom-designed test equipment, but this situation is gradually changing. For example, Multitest GmbH now makes handlers with integrated shakers that are specifically designed for accelerometer testing.

36.2.9 Quality Systems

Quality systems are an intrinsic part of stable MEMS production. Management must drive a systemic approach to quality and set continuous improvement as a high priority goal.

Several quality systems define continuous improvement methodologies. In general, they formalize the process used to minimize defects and variations in products and in the processes used to manufacture them. Automotive supply companies must implement quality systems that meet QS-9000 [36.63] before product volume ramps up and continue them through the product life cycle. Four elements that are worthy of note:

1. *Failure Mode Effect Analysis* (*FMEA*). Early in the development phase, a team with representatives from several disciplines reviews the design (or process) in order to identify possible causes of failure. Each potential failure mode is given three numerical rankings. One ranking represents the likelihood of an occurrence, while the others rank the severity of that result and detectivity. These numerical scores are combined for each potential failure mode in order to identify the issues that merit the most attention before they become problems. FMEA spreadsheets are periodically updated as the product or process moves into production. More targeted versions are used in products or processes that are in stable production.

2. *Process Control*. Every significant process must have a "short loop" monitor to ensure stability. This measurement is tracked and statistically analyzed with respect to the control limits to identify changes before the process strays beyond the control limits.
3. *Review Boards*. Every change, unusual occurrence, and proposed solution is assessed by boards that meet on a regular basis to ensure that it does not put product quality at risk. Affected production material is put aside until the appropriate board approves its release. This may appear to be expensive and bureaucratic. However, the cost of a scraped wafer lot is insignificant when compared to the cost of a field replacement program.
4. *Procedures and Specifications*. Each step must be fully specified and identified in the process flow, along with the appropriate metrics for each lot. The compilation of this data in a retrievable form is an essential part of every continuous improvement program. By combining these product and process databases with lot tracking software, Pareto charts linking yield loss and test failures to process variations can be identified and eliminated. Experience has shown that unexpected second-order effects are present in every production line – but data-driven decisions on indirect effects cannot be made on small test populations.

Implementation of a continuous improvement program requires well-informed failure analysis teams, methodologies, and programs. Such analyses start with gathering facts and making relatively simple tests. Often this is sufficient. However, MEMS products are susceptible to uncommon failure modes, so *Walraven* et al. [36.64] gathered examples of more powerful analytical techniques and showed how they are applied to MEMS devices.

Each supplier uses the information and insights gathered from product performance, as well as control and yield data at different points in the process flow to refine their operations. *Douglass* [36.65], for example, outlined the yield loss and failure mechanisms observed in early Texas Instruments DMD products. Concerns like hinge memory, hinge fatigue, particles, stiction, and environmental robustness were each addressed and mitigated by focused teams. For example, *Mignardi* et al. [36.6] describe the partial wafer saw process used in the original DMD manufacturing flow process. Breaking these delicate wafers into individual product chips generated particles that caused yield loss and were potential sources of field failures. A new flow based on a standard full saw process eliminates this particle source. The result was an increase in both yield and reliability. Hinge fatigue characterization showed that bulk metal fatigue models do not properly describe thin film behavior. The hinge memory effort required an understanding of how thin film metal creep is affected by alloy composition and the environment [36.57]. Stiction control involves surface passivation, spring design, mirror dynamics, and moisture level [36.26,65]. These publications give an insight into the quantities of data and the time required to bring robust products to market. They also illustrate how data-based evaluations can uncover unexpected effects like the acceleration of hinge creep by adsorbed moisture [36.26].

The second continuous improvement example applies to MEMS integration. High yield loss is perceived to be a serious risk when electronics and MEMS are integrated on one chip. Indeed, the initial yields on the Analog Devices integrated MEMS accelerometers were not impressive. However, it increased each year due to the work of many mission-oriented teams. Yield has reached defect density limited levels because the teams eliminated all significant failure mechanisms.

Coincident with the annual yield increases were reductions in customer failure rates. Failure rates in Analog's accelerometer products are in the low single digit ppm range. Quality does pay.

36.3 Stable Field Performance

Some topics discussed in Sect. 36.2 like particles and ESD are equally relevant to long-term stability. Most microstructure products have elements that are in close proximity, so stability is also affected by surface characteristics and mechanical shock.

36.3.1 Surface Passivation

Early, 1970s-era piezoresistive pressure sensors were not passivated. Like early ICs, these wafers only had oxide over the piezoresistors. Performance was

inconsistent and drifted over time, because surface interactions with moisture and other atmospheric gases created a variety of shunts, parasitics, and charging issues.

Electrical Surface Passivation

The introduction of silicon nitride passivation and conductive field plates led to stable products that were hitherto unobtainable. The ability to achieve measurement stability was absolutely critical to growth of the MEMS pressure sensor industry.

Aside from pressure sensors, few MEMS products are passivated. Indeed, standard plasma nitride processes are usually impractical, because they produce dielectric coatings that support static charges. Such charges can cause electrical drift, or be the source of electrostatic forces that cause stiction.

There have been published reports attributing instability to the lack of passivation on microstructures. For example, Analog Devices implemented a special process in ADXL50 accelerometers before the product was released in order to suppress high temperature electrical drift [36.66]. This was not a moisture effect, because it occurred in dry nitrogen packages. Later ADXL designs eliminated the root cause.

Scientists at Lucent Technologies [36.67] observed anodic oxidation in polysilicon electrodes used to electrostatically drive mirrors in optical cross-connect products. If allowed to occur, this corrosion mechanism would cause the mirror position to drift and the product to eventually fail. The study concluded that, within the limits of the test, maintaining low moisture in these optical packages eliminates anodic oxidation.

The preceding paragraphs suggest that lack of MEMS passivation can affect long-term product stability. This issue is very design-related and can be driven by factors other than humidity. Even when low package humidity is determined to be adequate, design reviews should consider how normal manufacturing variations, outgassing and diffusion over the product life affect the moisture level in the gas adjacent to the microstructures.

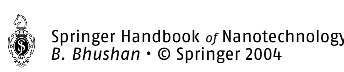
Mechanical – Stiction and Wear

In-use stiction is difficult to predict and may not become an issue until manufacturing volumes increase, or when endusers handle the part in ways that are not anticipated [36.68]. The resulting product liability and field replacement programs carry substantial financial costs and have caused MEMS suppliers to withdraw from the market. End users have little tolerance for failure. Since in-use stiction is a failure mechanism in MEMS devices, a company that solves this problem creates an effective market barrier against competitors.

The scale of this problem varies between product areas. For example, the Texas Instruments DMD has moving mirrors that are designed to touch down on a substrate and later release. This product must address both stiction and wear. In contrast, the accelerometer products from Analog Devices, Bosch, and Motorola have proof masses that are suspended on compliant springs. By design, an automobile collision only displaces the proof mass by a few percent of the gap that separates it from adjacent surfaces. It is difficult to generate a shock wave in an air bag module that is sufficient to cause these proof masses to contact adjacent surfaces (acceleration levels of several thousand g are required). However, handling of the discrete packaged parts during test, shipment, and module assembly frequently cause shock events that bring MEMS surfaces into contact. For example, *Li* et al. [36.69] used both math modeling and tests to show that dropping a packaged MEMS accelerometer from the height of a table top generates several tens of thousands of g in the device when it lands on the floor. Thus, noncontacting MEMS products must be designed to withstand at least transient stiction.

Design. When shock, vibration, or functional operation causes MEMS elements to touch, the mounting springs are designed to pull them apart (Fig. 36.10). High stiffness springs are desirable to suppress stiction, but low stiffness springs increase measurement sensitivity and signal-to-noise ratio. Thus stiction is a fundamental MEMS design constraint that often limits product performance. Each manufacturer has proprietary design practices to address this performance versus reliability trade-off. In general, designers suppress stiction by minimizing the sources and applying supplementary techniques to ensure recovery when contact occurs:

1. Thorough analysis and testing to move harmful resonances beyond the range where they might be excited. Note that MEMS component-level analysis is insufficient – this is a system issue based on the packaged part as it is handled through manufacturing, system assembly, and end use.
2. Surface modification (discussed in the next section).
3. Minimizing contact area by integrating bumps and "stoppers" into the design [36.70].
4. Elimination of dielectric surfaces that may accumulate surface charges and result in electrostatic attraction.



5. Release of DMD mirrors from the touchdown position is assisted by pulsing the reset voltage to excite a mirror resonant frequency [36.65, 71].
6. Use of gas-filled packages to reduce contact velocity, as discussed later in this chapter.
7. ESD-protected designs that prevent voltage transients that may cause electrostatic attraction.

The only product in significant production that contains MEMS elements that are designed to touch is the Texas Instruments DMD. The proprietary aluminum alloy springs used in the mirror contact points touch and release millions of times during the product life. Considerable development was required to overcome metal creep that occurred in early designs.

Surface Modification. In addition to the touchdown springs, early DMD die were treated with perfluorodecanoic acid vapor before the glass lid was sealed onto the package. This treatment [36.72] created a low energy monolayer coating that suppressed initial stiction. However, improvements were required to achieve longer wear life, higher production rates, and lower contamination levels. A new process [36.73] places capsules inside DMD packages. After cleaning, the packages are immediately sealed. An oven bake releases anti-stiction vapor from the capsules to create a monolayer organic coating on surfaces inside these sealed packages. Excess anti-stiction material in the capsules maintains a low vapor pressure in the package cavities throughout the product life. Therefore, wear damage at the mirror contact springs is continuously repaired to prevent stiction failures before they occur.

Maintaining a low level of organic vapor inside the DMD reapplies a concept used with other organics to prevent corrosion of electronic metallurgy and contact fretting of separable connectors (see, for example, [36.74, 75]). These treatments have been shown to add years to the useful life of electronic systems that are in enclosures but also exposed to aggressive environments.

Stiction can be minimized by design and process spin-offs – stiff springs, control of contact area, etch residues, etc. Some suppliers design within these limits; others seek to modify the MEMS surfaces. The requirements of any surface modification technology are quite substantial. In addition to normal manufacturing requirements (stable, scalable process and materials), the process must be conformal and must uniformly treat all areas, including microstructure bottom and side surfaces. If a conductive material is used, it must somehow be patterned in order to avoid electrical shorting. If a dielectric surface is formed, it must be extremely thin because thick dielectrics support surface charges. Such charges cause performance shifts and induce electrostatic stiction.

Since devices with movable microstructures are particularly susceptible to stiction, most suppliers who develop production-worthy surface modification processes consider this information a trade secret. Analog Devices chose to patent portions of its technology. The following paragraphs give an overview of the published Analog Devices surface treatment technologies. *Martin* [36.66] describes the evolution of these technologies from 1992 to 1999. Further information is contained in *Martin* et al. [36.76] and *Martin* [36.77].

The earliest of the published Analog surface treatment technologies was implemented after stiction was observed during automated testing and module assembly of air bag sensors that were packaged in cerdips. Cerdip assembly typically includes at least two furnace processes in air at 440–500 °C, so they seldom contain organic materials. The high temperature furnace air thermo-oxidizes adsorbed materials and removes them from the MEMS surface. The resulting surfaces are extremely clean. Unfortunately, clean inorganics have high surface energies. Therefore, adjacent microstructures readily stick together if shock and vibration during handling cause them to touch. Cerdips (and the surface mount cerpacs) have very low moisture levels (Mil specs allow up to 5,000 ppm moisture, but < 100 ppm moisture is common in a well controlled manufacturing line). Deliberately raising the moisture level was found to be a potential solution because, within limits, moisture adsorption reduces surface energy. However, the solution adopted by Analog Devices in the mid-1990s was the anti-stiction agent (ASA) process. This process involved dispensing a controlled amount of a pure siloxane liquid (ASA) into each package immediately before sealing. ASA selection was based on thermo-oxidative stability, low volatility, purity, and the requirement that it be a liquid at the dispensing temperature. As packages heat in the furnace, adsorbed material on the microstructures is removed, leaving chemically active, high energy surfaces. Further heating volatilizes the ASA. Before escaping into the furnace, the ASA vapor surrounds the reactive MEMS surfaces and chemically bonds to them. The result is infusion of organic groups into the native oxide surface. Organic-rich surfaces are unreactive and have low surface energy. Thus the treatment is self-limiting after the first vapor molecules react. Obviously, ASA volatilization must be complete before the glass softens and seals the package cavity. Some

ASA degrades in this process. However, silicone thermo-oxidation simply adds a few angstroms of silicon oxide to the native oxide, so the ASA process, by design, is non-contaminating.

Although variations and refinements of the ASA process were developed, this technology required that each individual package be treated. Automated dispense equipment made ASA acceptable when product volumes were moderate. However, as production approached several million per month, it became evident that a wafer-level anti-stiction process was desirable.

Assessment of candidate processes and materials led to a vapor treatment based on a custom-synthesized solid polymeric siloxane. This polymer is volatilized in a standard CVD furnace that treats up to a hundred wafers at a time. Repeatability is extraordinary because thickness variation within a furnace run, or from run to run, is only about one angstrom.

Package Environment Effects. The viscosity and density of the gas that contacts MEMS resonators limit the device Q, so resonant devices are often designed to operate in vacuum. Unfortunately, this makes them susceptible to handling damage. Viscous fill gases reduce destructive excursions of high-Q microstructures when they are mechanically shocked. They also provide squeeze film damping to cushion the contact event as surfaces approach each other. None of the high volume MEMS products on the market are evacuated. Presumably, this is due to the high cost of vacuum packaging and the susceptibility to handling damage.

Many investigators believe that suppression of in-use stiction requires low humidity in the package. This view is not surprising because most MEMS research groups have observed stiction caused by aqueous surface tension during microstructure release. However, in-use stiction and wear test results published by several investigators lead to a different conclusion [36.76, 78–83]. In general, they find high stiction in both dry and moist environments. However, stiction is substantially suppressed at intermediate humidity levels (approximately 15–40 % relative humidity at room temperature). This is equivalent to a moisture level of 3,000–10,000 ppm. Note that the limits cited by different authors vary considerably due to the use of different materials and test conditions. Stiction at low humidity is probably caused by high surface energy on inorganic oxides that do not have adsorbed surface films. The low stiction and wear rates observed at intermediate humidity are attributed to the passivating and lubricating effects of adsorbed water. Capillary forces caused by the high surface tension of water become dominant at high humidity.

36.3.2 System Interface

MEMS products are mounted in systems that have much greater mass than the device itself. For this reason, it is difficult to transmit a mechanical shock wave to a MEMS sensor that is sufficient to cause failure after it is installed in a module. However, failures are possible when the devices are handled during module assembly. Improper functional response is also possible if the module mount system has a mechanical resonance that amplifies or reduces mechanical transmission under different conditions. This is a particular concern in automotive safety applications because every automobile platform has a different mechanical signature. Proper module mount design is required to ensure that the impact signal from an automobile crash is properly transmitted to air bag modules.

Suppliers of large IC die closely examine board-level stresses in order to minimize solder joint fatigue. Such stresses are more serious in MEMS products because the device, as well as the package are susceptible to mounting conditions. Furthermore, customer processes impose these stresses, so a supplier may have little information with respect to their origin or existence. One solution is to define and qualify a product-specific mount system, as Texas Instruments has done with the DMD. The ideal, however, is to devise products that are compatible with standard board footprint and assembly processes. This challenge became more difficult with the shift from through-hole to surface mount technology, because the mechanical isolation provided by the package pins is no longer present. Small package size, in-package, and within-chip isolation techniques, as well as thorough package-board stress analysis are used to address this concern.

37. MEMS Packaging and Thermal Issues in Reliability

The potential of MEMS/NEMS technologies has been viewed as a comparable or even bigger revolution than that of microelectronics. These scientific and engineering advancements in MEMS/NEMS could bring applications to reality previously unthinkable, from space systems, environmental instruments, to daily life appliances. As presented in previous chapters, the development of core MEMS/NEMS processes has already demonstrated a lot of commercial applications as well as future potentials with elaborated functionalities. However, a low cost and reliable package for the protection of these MEMS/NEMS products is still a very difficult task. Without addressing the packaging and reliability issues, no commercial products can be sold on the market. Packaging design and modeling, packaging material selection, packaging process integration, and packaging cost are main issues to be considered when developing a new MEMS packaging process. In this chapter, we will present the fundamentals of MEMS/NEMS packaging technology, including packaging processes, hermetic and vacuum encapsulations, thermal issues, packaging reliability, and future packaging trends. The future development of MEMS packaging will rely on the success of the implementation of several unique techniques, such as packaging design kits for system and circuit designer, low cost and high yield wafer level, chip-scale packaging techniques, effective testing techniques at the wafer-level to reduce overall testing costs; and reliable fabrication of an interposer [37.1] with vertical through-interconnects for device integrations.

37.1 MEMS Packaging

MEMS are miniaturized systems in a size of micrometer to millimeter that may have mechanical, chemical, or biomedical features integrated with IC circuitry for sensor or actuator applications [37.2]. For example, pressure [37.3], temperature, flow [37.4], accelerometers [37.5], gyroscopes [37.6], and chemical sensors [37.7] can be fabricated by MEMS technologies for sensing applications. Fluidic valves [37.8], pumps [37.9], and inkjet printer heads are examples of actuation devices for medical, environmental, office, and industrial applications. Silicon is typically used as the primary substrate material for MEMS fabrication because it can provide unique electrical, thermal, and mechanical properties however also can be easily micromachined in a form of batch-processing and be incorporated with a microelectronic circuits by using most of the conventional semiconductor manufacturing processes and tools. As a result, smaller size, lighter weight, lesser power consumption and cheaper fabrication cost become the advantages of MEMS devices as compared with the existing macroscale systems with similar functionalities. With the advances of MEMS fabrication technology in the past decades, the MEMS market at the component-level is currently in excess of

$ 5 billion and is driving the end-product markets of large than $ 100 billion [37.10].

Nevertheless, the road to the commercialization of MEMS doesn't look as promising as expected. Many industrial companies took the advantages of MEMS technology of high production volumes and high added value created by product integrations. Therefore, cost-efficiency becomes the major factor driving MEMS toward commercialization. Several MEMS devices have been developed for and applied in automotive industry and information technology, and they dominate the MEMS market due to high production volumes. Most of custom-designed MEMS products are still very diverse, aiming for different applications, and their initial costs in small-to-medium-scale production are still much higher than market-acceptable levels. Consequently, high packaging and testing costs have slowed the commercialization of MEMS. Furthermore, based on the past experience of IC industry, the cost of packaging processes is about 30%, and sometimes can be more than 70%, of the total production expenses. MEMS packaging process is expected to be even more costly because of the challenging and stringent packaging issues with regard to the additional MEMS components, in addition to the microelectronic circuitry, in a typical MEMS product [37.11].

37.1.1 MEMS Packaging Fundamentals

The functions of conventional IC packaging are to protect, power, and cool the microelectronic chips or components and provide electrical and mechanical connection between the microelectronic part and the outside world. With the increase of the needs of high performance and multifunctional consumer electronic products, IC packaging processes have incorporated more complex designs and advanced fabrication technologies, such as Cu interconnects [37.12], flip-chip bonding [37.13], ball grid array [37.14], wafer-level chip scale packaging [37.15], and 3-D packaging [37.16], etc., in order to satisfy the need for high I/O density, large die area, and high clock frequency. In addition to the requirements of electrical interconnects, MEMS components may need to interface outside environment (for example, fluidic interconnectors [37.17]), some other components may need to be hermetically sealed in vacuum (for example, accelerometers [37.5]). Therefore, MEMS packaging processes have to provide more functionalities including better mechanical protection, thermal management, hermetic sealing, and complex electricity and signal distribution.

It has been suggested that MEMS packaging should be incorporated in the device fabrication stage as part of the micromachining process. Although this approach solves the need for some specific devices, it does not solve the packaging need for general microsystems. Many MEMS devices are now fabricated by various foundry services [37.18, 19], and there is a tremendous need for a uniform packaging process. Figure 37.1 shows a typical MEMS device being encapsulated by a packaging cap. The most fragile part of this device is the suspended mechanical sensor, which is a freestanding mechanical, mass-spring microstructure. This mechanical part must be protected during the packaging and handling process. Moreover, vacuum encapsulation may be required for these microstructures in applications such as resonant accelerometers [37.5] or gyroscopes [37.6, 20]. A "packaging cap" with properly designed micro cavity is to be fabricated to encapsulate and protect the fragile MEMS structure as the first-level MEMS post-packaging process. The wafer can be diced afterward, and the well-established packaging technology in IC industry can follow and finish the final packaging step. Unlike the packaging requirements for ICs, however, the common MEMS packaging requirement is hermetic seal and sometimes vacuum encapsulations. Hermetic seal is important to ensure that no moisture or contaminant can enter the package

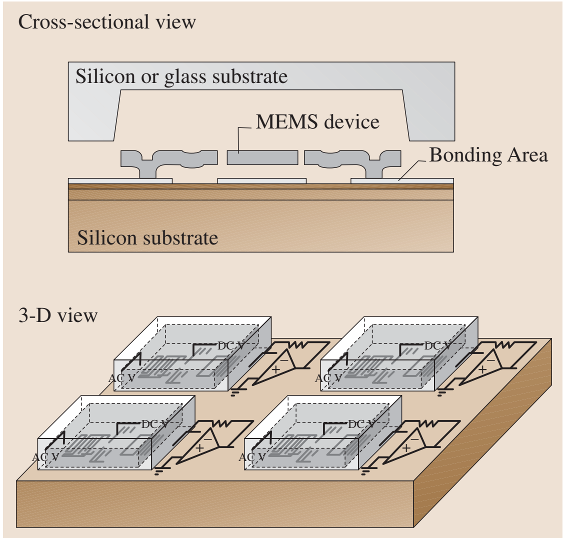

Fig. 37.1 A typical MEMS packaging illustration in which a MEMS structure is encapsulated and protected by the packaging cap

and affect the functionality of microstructures. This increases the difficulty of common IC packaging processes tremendously. Although most single function MEMS chips can employ typical IC packaging techniques, such as die-attached processes, wiring interconnects, molded plastic, ceramic, and metal for packaging [37.21], with the increase of complexity MEMS devices, more advanced packaging techniques, especially wafer-level packaging, are required for the integration of multi-chips for multifunctional applications.

Before the state-of-the-art MEMS packaging processes are discussed, several primary micro-fabrication processes for packaging applications are described. These processes may include Flip-Chip (FC) technique, Ball Grid Arrays (BGA), through-wafer etching, and plating. Other silicon-based processes, such as thin-film deposition, wet and dry chemical etching, lithography, lift-off, and wiring bonding processes can be found in many textbooks [37.22].

Flip-Chip Technique (FC)

This technique is commonly used in the assembly process between a chip with microelectronics and a package substrate [37.13]. The microelectronic chip is "flipped joined" with the packaging substrate, and metal solder bumps are used as both the bonding agents and electrical paths between bond pads on the microelectronic chip and metal pads on the package substrate. Because the vertical bonding space can be very small as controlled by the heights of the solder bumps, and the lateral distributions of bond pads can be on the whole chip instead of being only on the edge, this technique can provide high density Input/Output (I/O) connections. In the FC technique, solder bumps are generally fabricated by means of electroplating. Before the bumping process, multiple metal layers, such as TiW-Cu, Cr-Cu, Cr-Ni, TaN/Ta/Ni, have to be deposited as a seed layer for electroplating and as a barrier to prevent the diffusion of solder into its underneath electrical interconnect.

Ball Grid Arrays (BGA)

This technology is very similar to the FC technique. An area array of solder balls on a single chip module or multi-chip module are used in the packaging process as electrical, thermal, and mechanical connects to join the module with the next level package, usually a printed circuit board [37.14]. The major difference between a typical BGA and FC is the size of solder bump. In BGA chip, the bumps are in the order of 750 μm in diameter which is ten times larger than those commonly used in FC.

Through-Wafer Etching

This is a chemical etching process to make through-wafer channels on a silicon substrate for the fabrication of vertical through-wafer interconnects. The chemical etching process can be either wet or dry. Anisotropic or isotropic etching solutions can be used in the wet etching process. The dry etch process is based on plasma and ion-assisted chemical reactions that can be either isotropic or anisotropic. In order to create high density and high aspect ratio through-wafer vias, Deep Reactive Ion Etching (DRIE) is typically used. Two popular DRIE approaches, Bosch and Cyro, are well described in literature [37.23].

Electroplating

Electroplating is another common micro-fabrication process. It can be conducted for the deposition of an adherent metallic layer onto a conductive or nonconductive substrate. The process on a conductive substrate is called electrolytic plating, which utilizes a seed layer as the anode to transfer metal ions onto the cathode surface when a DC current is passed through the plating solution. The plating process without applying electrical current is called electroless plating, which can happen in both conducive and nonconductive surfaces. Electroless plating process requires a layer of noble metal such as Pd, Pt, or Ru on the substrate as the catalysis to trigger the self-decomposition reaction in the plating solution. The electroplating processes are very important for electrical interconnect and solder bump fabrications for packaging applications because of low process temperature and cost.

These processes are generally developed for providing electrical and thermal paths for various IC/MEMS packaging approaches.

37.1.2 Contemporary MEMS Packaging Approaches

Several MEMS packaging issues and approaches before 1985 were discussed in [37.24], and researchers have been working on MEMS packaging approaches continuously. For example, *Senturia* and *Smith* [37.25] discussed the packaging and partitioning issues for microsystems. *Smith* and *Collins* [37.26] used epoxy to bond glass and silicon for chemical sensors. Several MCM methods have been proposed. *Butler* et al. [37.27] proposed adapting multi-chip module foundries using chip-on-flex (COF) process. *Schuenemann* et al. [37.28] introduced a 3-D stackable packaging concept for the Top-Bottom Ball Grid Array (TB-BGA) that includes

electric, fluidic, optic, and communication interfaces. *Lee* et al. [37.29] and *Ok* et al. [37.10] presented a direct-chip-attach MEMS packaging using through-wafer electrical interconnects. *Laskar* and *Blythe* [37.30] developed a multi-chip modules (MCM) type packaging process by using epoxy. *Reichl* [37.31] discussed different materials for bonding and interconnection. *Grisel* et al. [37.32] designed a special process to package micro-chemical sensors. Special processes have also been developed for MEMS packaging, such as packaging for microelectrodes [37.33], packaging for biomedical systems [37.34], and packaging for space systems [37.35]. These specially designed, device-oriented packaging methods are meant for individual systems. There is no reliable method yet that would qualify as a versatile post-packaging process for MEMS with the rigorous process requirements of low temperature, hermetic sealing and long-term stability.

An integrated process by using surface-micromachined microshells has previously been developed [37.36]. This process applies the concepts of sacrificial layer and LPCVD sealing to achieve wafer-level post-packaging. Similar processes have been demonstrated. For example, *Guckel* et al. [37.37] and *Sniegowski* et al. [37.38] developed a reactive sealing method to seal vibratory micromachined beams. *Ikeda* et al. [37.39] adopted epitaxial silicon to seal microstructures. *Mastrangelo* et al. [37.40] used silicon nitride to seal mechanical beams as light sources. *Smith* et al. [37.41] accomplished a new fabrication technology by embedding microstructures and CMOS circuitry. All of these methods have integrated the MEMS process together with the post-packaging such that no extra bonding is required. These schemes are highly process dependent, however, and not suitable for prefabricated circuitry.

Recently several new efforts for MEMS post-packaging processes have been reported. *Butler* et al. [37.27] demonstrated an advanced MCM packaging scheme. It adopts the high density interconnect (HDI) process consisting of embedding bare die into pre-milled substrates. Because the MEMS structures have to be released after the packaging process, it is undesirable for general microsystems. *Van der Groen* et al. [37.42] reported a transfer technique for CMOS circuits based on epoxy bonding. This process overcomes the surface roughness problem, but epoxy is not a good material for hermetic sealing. In 1996, *Cohn* et al. [37.43] demonstrated a wafer-to-wafer to-wafer vacuum packaging process by using Silicon–Gold eutectic bonding with a 2-μm-thick polysilicon microcap. But experimental results show substantial leakage after a period of 50 days. *Cheng* et al. [37.44] developed a vacuum packaging technology using localized aluminum/silicon-to-glass bonding. In 2002, *Chiao* and *Lin* [37.45] demonstrated vacuum packaging of microresonators by rapid thermal processing. These recent and ongoing research efforts indicate the strong need for a versatile MEMS post-packaging process.

Bonding Processes for MEMS Packaging Applications

Previously, silicon-bonding technologies have been used in many MEMS fabrication and packaging applications, including epoxy bonding, eutectic bonding, anodic bonding, fusion bonding, and solder bonding. For example, such devices as pressure sensors, micro-pumps, biomedical sensors or chemical sensors require mechanical interconnectors to be bonded on the substrate (see for example [37.7, 17, 46]). Glass has been commonly used as the bonding material by anodic bonding at a temperature of about 300 ∼ 450 °C (see for example [37.47, 48]). *Klaassen* et al. [37.49] and *Hsu* et al. [37.50] have demonstrated different types of silicon fusion bonding and Si–SiO_2 bonding processes at very high temperatures of over 1,000 °C. *Ko* et al. [37.24], *Tiensuu* et al. [37.51], *Lee* et al. [37.52] and *Cohn* et al. [37.43] have used eutectic bonding for different applications. All of these bonding techniques have different mechanisms that determine the individual bonding characteristics and process parameters. This section discusses the details of these processes.

Fusion Bonding for MEMS Packaging

Silicon fusion bonding is an important fabrication technique of the SOI (Silicon On Insulator). The bonding is based on Si−O, Si−N, or Si−Si strong covalent bond. But very high bonding temperature (higher than 1,000 °C) and flat bonding surfaces (less than 6 nm) are the two basic requirements for strong, uniform, and hermetic bonding. Although hydrophilic surface treatment can lower the bonding temperature, an annealing step higher than 800 °C is still needed to remove possible bubble formation at the bonding interface. *Bower* et al. [37.53] proposed that low temperature Si_3N_4 fusion bonding could be achieved at the temperature under 300 °C. *Takagi* et al. [37.54] proposed that silicon fusion bonding could be made at room temperature by using Ar^+ beam treatment on the wafer surface, and the bond strength is comparable to the conventional fusion bonding. In summary, fusion bonding has been

a popular fabrication technique in MEMS fabrication and packaging.

Anodic Bonding for MEMS Packaging Applications

The invention of anodic bonding dates back to 1969 when *Wallis* and *Pomerantz* [37.55] found that glass and metal can be bonded together at about $200 \sim 400\,°C$ below the melting point of glass with the aid of a high electrical field. This technology has been widely used for protecting on-board electronics in biosensors (see for example [37.56–58]) and sealing cavities in pressure sensors (see for example [37.59]). Many reports have also discussed the possibility of lowering the bonding temperature by different mechanisms [37.60, 61]. Anodic bonding forms Si–O or Si–Si covalent bond and is one of the strongest chemical bonds available for silicon-based systems. The bonding process can be accomplished on a hot plate with a temperature between 180 °C and 500 °C in atmosphere or vacuum environment. When a static electrical field is built within the Pyrex glass (7740 from Dow Corning) and silicon, the electrostatic force can pull two surfaces close for a strong bond. In order to create high electrical field, a flat bonding surface with less than 50 nm roughness is required. In addition, the electrical field required for bonding is larger than 3×10^6 V/cm [37.24]. Such a high electrical field is generated by a power supply of 200 to 1,000 V, which may cause damages on integrated circuits. *Hanneborg* et al. [37.62] have successfully bonded silicon with other thin solid films, such as silicon dioxide, nitride, and polysilicon, together with an intermediate glass layer using anodic bonding technique. In practice, electrostatic bonding has become widely accepted in MEMS fabrications and packaging applications. Unfortunately, the possible contamination due to excessive alkali metal in the glass; possible damage to microelectronics due to the high electrical field; and the requirement of flat surface for bonding limit the application of anodic bonding to MEMS post-packaging applications [37.63].

Epoxy Bonding (Adhesive Bonding)

Four major components comprise epoxy : epoxy resin, filler – like silver slake, solvent or reactive epoxy diluent, and additives like hardener and catalyst [37.64, 65]. The bonding mechanism of epoxy is very complicated and depends on the type of epoxy. In general, the main source of bonding strength is the van der Waals force. Because epoxy is a soft polymer material and its curing temperature for bonding is only around 150 °C, low residual stress and process temperature are the major advantages of epoxy bonding. But the properties of epoxy can be easily changed with environmental humidity and temperature so the bonding strength decays over time. In addition, epoxy bonding has low moisture resistance and, due to its additives, is a dirty process. These disadvantages have made epoxy unfavorable for the special MEMS packaging need for hermetic or vacuum sealing.

Eutectic Bonding

In many binary systems, a eutectic point corresponds to the alloy composition with the lowest melting temperature. If the environmental temperature is kept higher than the eutectic point, two contacted surfaces containing two elements with the eutectic composition can form liquid phase alloy. The solidification of the eutectic alloy forms "eutectic bonding" at a temperature lower than the melting temperature of either element in the alloy. Eutectic bonding can be a strong bond. For example, in the case of Au/Si alloy system, eutectic temperature is only 363 °C when the composition is at the atomic ratio of 81.4% Au to 18.6% Si and bonding strength is higher than 5.5 GPa [37.66]. Because other alloy systems may have lower eutectic temperatures than Al/Si system, they present great potential for MEMS packaging applications. In addition to Au/Si, Al/Ge/Si, Au/SnSi, and Au/Ge/Si systems have been applied for MEMS packaging.

Solder Bonding

Solder bonding has been widely applied in microelectronic packaging [37.67]. Both low bonding temperature and high bonding strength are good characteristics for packaging. Furthermore, there are a variety of choices of solder material for specific applications. *Singh* et al. [37.68] have successfully applied solder bump bonding in the integration of electronic components and mechanical devices for MEMS fabrication [37.69]. In this case, indium metal was used for bonding two separated silicon surfaces together by applying 350 MPa pressure and the bonding strength was as strong as 10 MPa. Glass frits can also be treated as a solder material and have been extensively used for vacuum encapsulation in MEMS industry. Glass frits are ceramic materials that can provide strong bonding strength with silicon with good hermeticity. Its bonding temperature is lower than 400 °C and is suitable for electronic components. But a bonding area more than 200 μm wide is required to achieve good results, which may become a drawback because area is the measure of manufacturing cost in IC industry. Nevertheless, glass frit is the

Table 37.1 Summary of bonding mechanisms

Bonding methods	Temperature	Roughness	Hermeticity	Post-packaging	Reliability
Fusion bonding	very high	highly sensitive	yes	yes by LH	good

most popular bonding process used in the current MEMS products.

Localized Heating and Bonding

Low bonding temperature and short process time are desirable process parameters in MEMS packaging fabrication to provide less thermal budget and high throughput. Most chemical bonding reactions, however, require a minimum and sufficient thermal energy to overcome the reaction energy barrier, or activation energy, to start the reaction and to form a strong bond. As a result, high bonding temperature generally results in shorter processing time to reach the same bonding quality at a lower bonding temperature [37.70]. The common limitations for the above techniques are their individual bonding characteristics and temperature requirements. In general, MEMS packaging requires a good bonding for hermetic sealing while the processing temperature must be kept low at the wafer-level to have less thermal effects on the existing devices. For example, a MEMS device may have prefabricated circuitry, biomaterial, or other temperature-sensitive materials such as organic polymer, magnetic metal alloy, or pizeo-ceramic. Since the packaging step comes after the MEMS device fabrication processes, bonding temperature should be kept low to avoid high temperature effects on the system. Possible temperature effects include residual stress due to the mismatch of thermal expansion coefficient of bonding materials and substrates, electrical contact failure due to atom inter-diffusion at the interface, and contamination due to the outgas or evaporation of materials. In addition to the control of bonding temperature, Other factors to consider are the magnitude of applied force to create intimate contact for bonding and atmospherics environment control. Based on the heat transfer simulation study [37.71], it is possible to confine high temperature area in a small region by localized heating without heating the whole substrate. Assembly steps can therefore always be processed after device fabrication without having detrimental effects. As such, localized heating and bonding technique is introduced and implemented for the fabrication of MEMS packaging for post-processing approaches [37.70, 72].

Table 37.1 summarizes these MEMS packaging technologies and their limitations, including the localized heating and bonding approach. The localized heating approach introduces several new opportunities. First, better and faster temperature control can be achieved. Second, higher temperature can be applied to improve the bonding quality. Third, new bonding mechanisms that require high temperature such as brazing [37.73] may now be explored in MEMS applications. As such, it has potential applications for a widerange of MEMS devices and is expected to advance the field of MEMS packaging.

37.2 Hermetic and Vacuum Packaging and Applications

Hermetic packaging is desirable for MEMS packaging requirements in most cases because it provides a moisture free environment to avoid charge separation in capacitive devices, corrosion in metallization, or electrolytic conduction in order to prolong the lifetime of the electronic circuitry. In several device applications, vacuum encapsulation is necessary but can be costly. Many surface micromachined resonant devices need

vacuum to improve the performance including comb-shape μ-resonators and ring-type μ-gyroscopes that have very large surface-to-volume ratios and vibrate in a very tight space [37.20,39]. Two major approaches of MEMS hermetic and vacuum packaging have been demonstrated: (1) the integrated encapsulation approach and (2) the post-process packaging approach. Both are discussed in this section. Vacuum encapsulation by means of localized heating and bonding is discussed separately as another example for issues related to hermetic and vacuum packaging.

37.2.1 Integrated Micromachining Processes

Several MEMS hermetic and vacuum packaging processes have been demonstrated before based on the integrated micromachining processes. An integrated vacuum sealing process by LPCVD is presented here as the illustration example. This integrated process can encapsulate comb-shape microresonators [37.74] in vacuum at the wafer level. Figure 37.2 illustrates the cross-sectional view of the manufacturing process. First, standard surface-micromachining process [37.75] is conducted by using four masks to define the first polysilicon layer, anchors to the substrate, dimples and, the second polysilicon layer as shown in Fig. 37.2a. The process so far is similar to the MCNC MUMPs process [37.19], and comb-shape microstructures are fabricated at the end of these steps. In the standard surface micromachining process, the sacrificial layer (oxide) is etched away to release the microstructures. In the MEMS post-packaging process, a thick PSG (phosphorus-doped glass) of 7 μm is deposited to cover the microstructure and patterned by using 5:1 BHF (buffered HF) to define the microshell area as shown in Fig. 37.2b. A thin PSG layer of 1 μm is then deposited and defined to form etch channels as illustrated in Fig. 37.2c. The microshell material, low-stress silicon nitride, is now deposited with a thickness of 1 μm. Etch holes are defined and opened on the silicon nitride layer by using a plasma etcher. Silicon dioxide inside the packaging shell is now etched away by concentrated HF, and the wafer is dried using the supercritical CO_2 drying process [37.76]. After these steps, Fig. 37.2d applies. A 2-μm-thick LPCVD low-stress nitride is now deposited at a deposition pressure of 300 mtorr to seal the shell in the vacuum condition. Finally, the contact pads are opened as shown in Fig. 37.2e. Figure 37.3 is the SEM (Scanning Electron Microscope) microphoto of a finished device with protected microshell on top. The total packaging area

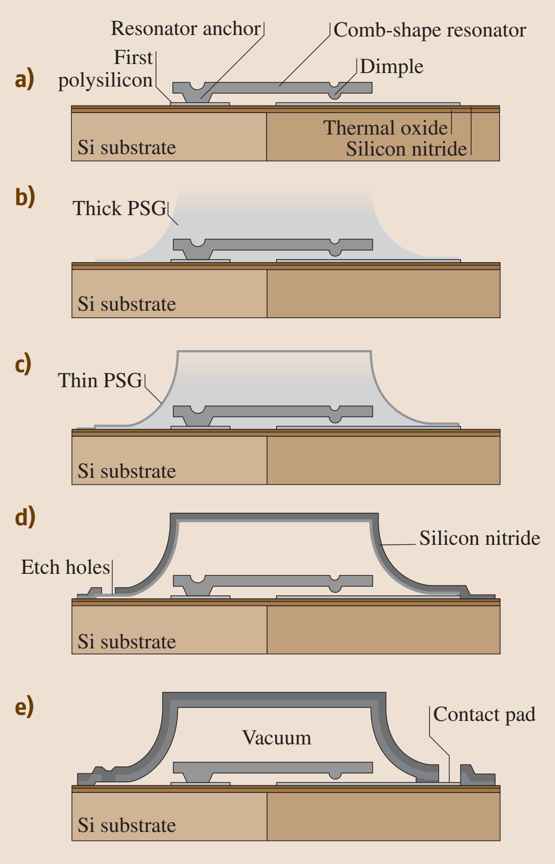

Fig. 37.2 An integrated vacuum encapsulation process using LPCVD nitride sealing to package micro-mechanical resonators [37.71]

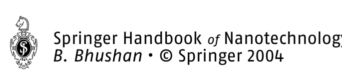
(microshell) is about $400 \times 400\,\mu m^2$. A contact pad is shown with the covering nitride layer removed. The shape of the microresonator, with beams of 150-μm-long and 2-μm-wide is reflected on the surface of the microshell due to the integrated packaging process. The total height of the nitride shell is 12 μm, as seen standing above the substrate. Spectrum measurement of the comb resonator inside the packaging reveals that a vacuum level of about 200 mtorr has been accomplished [37.77].

Although the above vacuum sealing process successfully achieves MEMS hermetic and vacuum packaging, it has several drawbacks. First, several high temperature steps were used after the standard surface-micromachining process. As such, no circuitry (such as those shown in Fig. 37.1) or temperature-sensitive materials



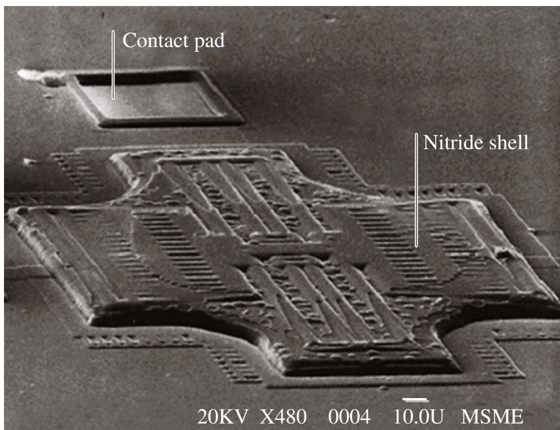


Fig. 37.3 SEM microphoto showing a vacuum packaged MEMS mechanical comb-shape resonator by an the integrated LPCVD sealing process as depicted in Fig. 37.2 [37.71]

will survive due to the global heating effect. Second, this post-packaging process is very specific and process dependent. MEMS companies or researchers have to adopt this post-packaging process with their own device manufacturing process. It can't be conducted in the multiuser MEMS process such as the MCNC MUMPs. Third, the thickness of the microshell is limited by the thin film deposition step that generally is in the range of a few micrometers. Wether the thin microshell can survive the high-pressure plastic molding process afterward in some device packaging design is a big concern. Finally, although integrated encapsulation can achieve low pressure by wafer-level fabrication and provide lower manufacturing cost, it does not provide the controllability of the cavity pressure.

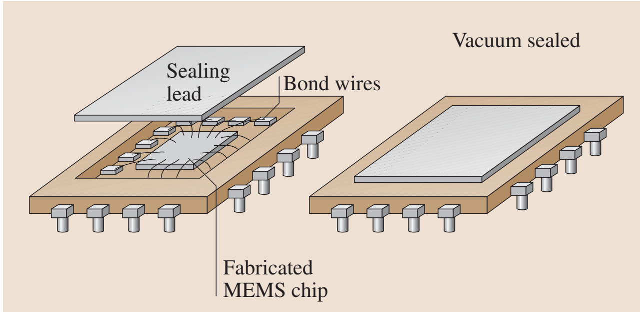

Fig. 37.4 The schematic diagram of industrial post-packaging (DIPS) using a ceramic holder to be covered by a sealing lid

37.2.2 Post-Packaging Processes

The second approach is defined as post-packaging process. The packaging process starts when the device fabrication processes are completed, so this approach has high flexibility for various microsystems. For example, Fig. 37.4 shows a common industrial post-hermetic packaging called Dual-in-line packaging (DIP) [37.78, 79]. A die is placed inside a ceramic holder covered by a sealing lid. Solder or ceramic joining is generally used for assembling lid and holder under a pressure-controlled environment. High cost is the major drawback of this method because of expensive ceramic holder and low fabrication throughput. Another example of post-packaging method is based on wafer bonding techniques combined with a microshell encapsulation. Devices are sealed by stacking another micromachined silicon or glass substrate as illustrated in Fig. 37.1. Integrated microsystems and protection shells are fabricated on different wafers, either silicon or glass, at the same time. After the two substrates are assembled together using silicon fusion, anodic, or low temperature solder bonding to achieve the final encapsulation, these micro-shells will provide mechanical support, thermal path, or electrical contact for the MEMS devices. Low packaging cost can be expected due to wafer-level processing.

The related packaging issues are discussed by using a specific example of hermetic and vacuum post-packaging by rapid thermal processing (RTP) that provides the advantages of wafer-level processing and low thermal budget. Figure 37.5 shows the

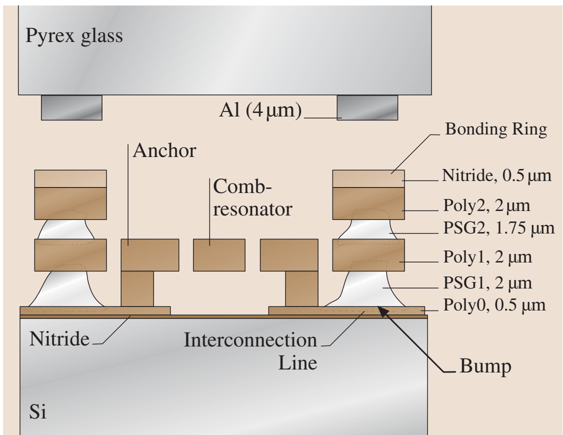

Fig. 37.5 The schematic diagram of the RTP (Rapid Thermal Processing) aluminum-to-nitride bonding setup [37.45]

B. Bhushan • © Springer 2004

schematic illustration of the RTP MEMS vacuum packaging process. Comb-shape microresonators are chosen as the vacuum packaging examples in this chapter, and a standard surface-micromachining process is used to fabricate these microresonators [37.19]. One major addition to a regular microstructure is that an integrated sealing ring using silicon nitride as the topmost layer is incorporated in the manufacturing process for the purpose of aluminum-to-nitride bonding [37.45]. A glass cap wafer is deposited and patterned with 4-μm-thick aluminum sealing-rings with width ranging from 100 to 250 μm and bonding area ranging from 450×450 to 1,000×1,000 μm^2. Before the vacuum packaging process, both the device and cap wafers are baked in vacuum at 300 °C for over four hours to dry water and gas species adhere at the surface. Afterward, the device and cap wafers are flip-chip assembled immediately and loaded into a quartz chamber and put into a RTP chamber. The base vacuum estimated at 10 mtorr inside the quartz chamber is achieved by using a mechanical pump. After heating for 10 seconds at 750 °C, the aluminum-to-nitride bond is formed. Figure 37.6 shows the measured spectrum of a vacuum-packaged, double-folded beam comb-drive resonator by using a micro-stroboscope [37.80]. The central resonant frequency is about 18,625 Hz and the quality factor is extracted as 1,800 ± 200 corresponding to a pressure level about 200 mtorr inside the package [37.81].

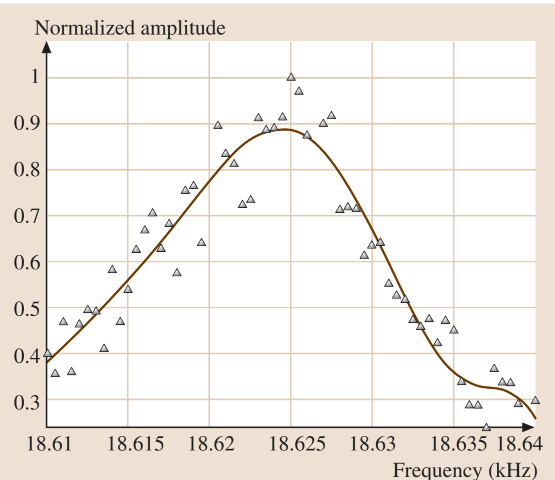

Fig. 37.6 Spectrum measurement results of a vacuum encapsulated comb-shape resonator by using the RTP aluminum-to-nitride bonding method [37.45]

This type of post-packaging process at wafer level has become the favorite approach to fabricate a hermetic encapsulation because it can provide lower cost and more process flexibility. But the packaging process relies on "good" bonding techniques. A strong and reliable bonding between two substrates should be provided, and this procedure should be compatible with the other microsystem fabrication processes.

37.2.3 Localized Heating and Bonding

The approach of MEMS post-packaging by localized heating and bonding is proposed to address the problems of global heating effects. In this chapter, resistive micro-heaters are used as the examples to provide localized heating, although several other means of localized heating have been demonstrated recently, including laser welding [37.82], inductive heating [37.83], and ultrasonic bonding [37.84]. The principle of localized heating is to achieve high temperature for bonding while maintaining low temperature globally at the wafer level. Resistive heating by using micro-heaters on top of device substrate is applied to form strong bond with silicon or glass cap. According to the results of a 2-D heat conduction finite element analysis as shown in Fig. 37.7, the steady-state heating region of a 5-μm-wide polysilicon micro-heater capped with a Pyrex glass substrate

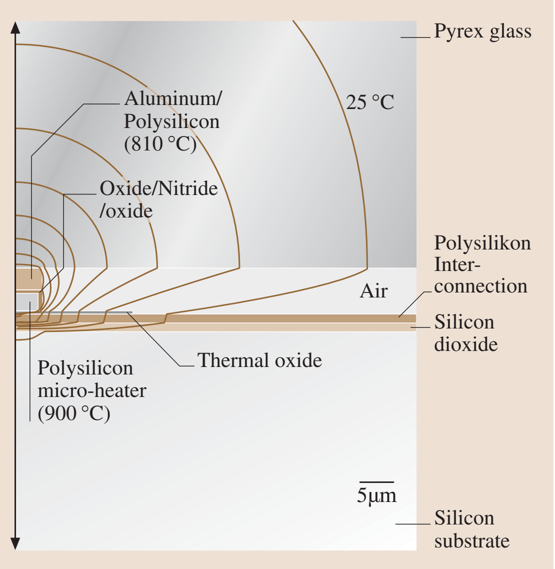

Fig. 37.7 The schematic diagram of 2-D heat transfer model, geometry and boundary conditions

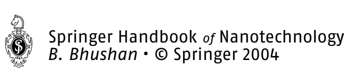

can be confined locally as long as the bottom of the silicon substrate is constrained to the ambient temperature. The physics of localized heating behind this design can be understood by solving the governing heat conduction equations of the device structure without a cap [37.81]. As long as the width of micro-heater and the thickness of silicon substrate are much smaller than the die size and a good heat sink is placed underneath the silicon substrate, the heating can be confined locally. The temperature of silicon substrate can be kept low or close to room temperature. Several localized resistive heating and bonding techniques have been successfully developed for packaging applications including localized silicon-to-glass fusion bonding, gold-to-silicon eutectic bonding, and localized solder bonding. Several solder materials have been successfully tested, including PSG, indium, and aluminum alloy [37.85].

The vacuum packaging example presented in this chapter is based on localized aluminum/silicon-to-glass solder bonding technique. Built-in folded-beam comb drive μ-resonators are used to monitor the pressure of the package. Figure 37.8 shows the fabrication process of the package and resonators. Thermal oxide (2 μm) and LPCVD Si_3N_4 (3,000 Å) are first deposited on a silicon substrate for electrical insulation followed by the deposition of 3,000 Å LPCVD polysilicon. This polysilicon is used as both the ground plane and the electrical interconnect to the μ-resonators as shown in Fig. 37.8a. Figure 37.8b shows a 2 μm LPCVD SiO_2 layer that is deposited and patterned as a sacrificial layer for the fabrication of polysilicon μ-resonators using a standard surface micromachining process. A 2-μm-thick phosphorus doped polysilicon is used for both the structural layer of microresonators and the on-chip micro-heaters. This

layer is formed over the sacrificial oxide in two steps to achieve a uniform doping profile. Lower input power and better process compatibility are two major advantages in using the on-chip micro-heater in the glass package. The resonators are separated from the heater by a short distance, 30 μm, to effectively prevent their exposure to the high heater temperature as shown in Fig. 37.8c. This concludes the fabrication of μ-resonators.

In order to prevent the current supplied to the micro-heater from leaking into the aluminum solder during bonding, a LPCVD Si_3N_4 (750 Å)/SiO_2 (1,000 Å)/Si_3N_4 (750 Å) sandwich layer is grown and patterned on top of the micro-heater as shown in Fig. 37.8d. Figure 37.8e and f show that aluminum (2.5 μm) and polysilicon (5,000 Å) bonding materials are deposited and patterned. The sacrificial release is the final step to form freestanding μ-resonators. Figure 37.8f shows a thick AZ 9245 photoresist is applied to cover aluminum/silicon-to-glass bonding system to ensure that the system withstands the attack from concentrated hydrofluoric acid. After 20 minutes sacrificial release in concentrated HF, the system as shown in Fig. 37.8g is ready for vacuum packaging. A Pyrex glass cap with a 10-μm deep recess is then placed on top with an applied pressure of ∼ 0.2 MPa under a 25 mtorr vacuum, and the heater is warmed using 3.4 watt input power (exact amount depends on the design of the micro-heaters) for 10 minutes to complete the vacuum packaging process as shown in Fig. 37.8h.

To evaluate the integrity of the resonators packaged using localized aluminum/silicon-to-glass solder bonding, the glass cap is forcefully broken and removed from the substrate. No damage is found on the μ-resonator and a part of the micro-heater is stripped away as shown in Fig. 37.9, demonstrating that a strong and uniform bond can be achieved without detrimental effects on the encapsulated device. Figure 37.10 shows a vacuum encapsulated unannealed μ-resonator (∼ 57 kHz) after

120 minutes of wait time. The measured Q-factor after packaging is 9,600. Based on the measurement of Q vs. pressure of a high Q unpackaged μ-resonator as shown in Fig. 37.11, it is demonstrated that the pressure inside the packaging is comparable to the vacuum level of packaging chamber.

The post-process packaging using localized heating and bonding technique includes four basic components: (1) an electrical and thermal insulation layer such as silicon dioxide or silicon nitride should be used for localized heating, (2) resistive micro-heaters will be fabricated to provide the heating source for localized bonding, (3) materials, including metal and polysilicon that can provide good bonding and hermeticity with silicon or glass substrates are considered as the bonding materials, and (4) a good heat sink under the device substrate for localized heating is provided during the bonding experiments. MEMS devices will be fabricated on the device chip and hermetically sealed in the cavity formed by the device chip, resistive micro-heaters, and protection cap. The process can be either die level or wafer level. The schematic design of wafer-level packaging process is shown in Fig. 37.12. The resistive micro-heaters are parallel to each other and connected in order to ensure that identical current density is applied for individual packages at the same time. These heaters can be fabricated either on the chip or protection cap and can be built in a larger wafer for current inputs. The interconnections for these packaging cavities can be built in the dicing area, so no extra space is required for the packaging process.

Part E | 37.3

37.3 Thermal Issues and Packaging Reliability

37.3.1 Thermal Issues in Packaging

The two key thermal issues related to MEMS packaging are: 1) heat dissipation from actuators and integrated circuitry components and 2) thermal stress generated during the packaging process. These two topics are discussed separately.

Heat Dissipation Issues

In IC, heat dissipation is a serious problem when the size of transistor continues to shrink and the density of transistor on a chip continue to increase with the advance of IC fabrication technology. The trend of power packing into smaller packages has created increasing thermal management challenges [37.86]. Since the electrical characteristics of transistors change with working temperature, inefficient power dissipation could raise the working temperature and affect device performance. Present MEMS devices don't need high power, high performance microprocessors so power dissipation is not a problem. Nevertheless, some functional components in packaged MEMS are very sensitive to temperature variation, such as biomaterials or laser diodes. Several MEMS chemical sensors and other applications such as micro PCR chamber for DNA replication actually require elevated temperature for operation and microthermal platforms are built for these devices. Thermal management to maintain working temperature on these chips for stable operation is still an essential issue for packaging considerations. The geometrical complexity of MEMS resulting from packing various functional components in the tight space increases the difficulty of the thermal management. As the MEMS packaging integration process becomes more complex, the fabrication constraint in the packaging process will have great impact on the heterogeneous integration process in the front-end MEMS and IC processes. For example, low temperature requirement at the packaging process generally limits the possible choices of materials in the back-end process. In general, conventional IC packaging employs a heat sink attached to the chip to remove heat. The heat sink is generally made of a copper or

stainless steel bar with an array of fin structures on one side for better natural or forced heat convection to dissipate heat into the environment. In addition to heat sinks, thermal vias, heat pipe cooling, immersion cooling, and thermoelectric cooling can also be used for effective heat removal. Because most MEMS packages still follow the typical IC packaging architecture, one promising thermal management method, heat pipe, is discussed for possible MEMS packaging applications.

A heat pipe is a sealed slender tube containing a wick structure and a working fluid, typically water in electronics cooling. It is composed of three sections, the evaporator section at one end, condenser section at the other end, and adiabatic section in the middle. In the evaporator section, heat is absorbed by the working fluid via phase transformation from liquid to vapor. In the section of condenser, heat dissipates into the outside environment. Thus the fluid goes back to liquid phase. Vapor phase is at a high pressure and temperature state that forces the vapor to flow into the condenser section at a lower temperature. Once the vapor condenses and gives up its latent heat, the condensed fluid is pumped back to the evaporator section by the capillary force developed in the wick structure. Therefore the middle adiabatic section contains two phases, the vapor phase in the core region and the liquid phase in the wick, flowing opposite to each other with no significant heat transfer between the fluid and the surrounding medium. Silicon has good thermal conductivity (1.41 W/cm/°C) and is easily micro-machined to fabricate the heat pipe. The implementation of the silicon micro heat pipe in IC and MEM packaging has therefore great potential and several approaches have been proposed on this topic [37.87–89].

Packaging Induced Thermal Stresses

Thermal based bonding processes have been used in MEMS packaging applications for many years, as introduced previously in this chapter. Thermal management is extremely important during the bonding process in order to avoid fracture in the substrate or MEMS device itself. Extremely high temperatures or rapid cooling conditions can cause damage and should be carefully evaluated both analytically and experimentally. There are many ways to provide heating energy including electrical resistive heating, oven heating or induction heating [37.83]. These bonding processes may be put into two categories. The first is localized bonding in which the heat is directly applied only to the adhesive material used to bond the package to the MEMS device. The second category is global heating where the entire system (MEMS device, adhesive, and packaging material) is heated to produce bonding of the materials. The latter is the common approach for all MEMS packaging processes. This section focuses therefore on the thermal stress effects during the heating and cooling procedures in MEMS packaging. The RTP aluminum-to-glass bonding process is used as the specific example for the discussion of thermal stresses [37.90]. The bonding process heats the packaging system to 750 °C for 10 seconds, and then cools it back to room temperature. To simulate this process, an ANSYS program [37.91] is established to examine the shear stress due to CTE (Coefficient of Thermal Expansion) variations in the bonding system as the result of temperature changes. The shear stress was recorded from the ANSYS analysis on the aluminum/Pyrex glass interface and the aluminum/silicon interface.

Two different models were analyzed. The first was the quartz-aluminum-silicon bonding system, and the second was the Pyrex glass-aluminum-silicon bonding system [37.92]. The results of the ANSYS analysis were then analyzed and compared with experimental observations. Figure 37.13 shows the ANSYS results for a Pyrex glass bonding system: the width of the aluminum solder is 100 μm and the maximum residual stress is be 60 MPa in glass, slightly lower than the fracture strength of Pyrex glass at 70 MPa. It was discovered that increasing the aluminum width leads to lower residual stresses. This likely occurred because the length of the Pyrex glass, quartz, and silicon remains constant. As a result, it will always want to contract the same amount with a constant temperature change independent of the aluminum width. When increasing the aluminum width, however, the stress is not in such a concentrated area and therefore decreases. For example, the maximum residual stress an-

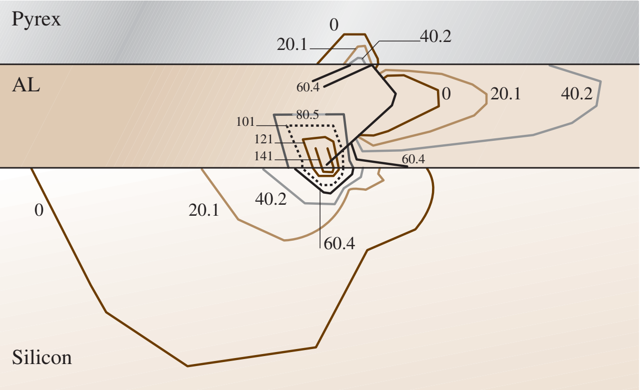

Fig. 37.13 Residual Stress (GPa) for an aluminum solder width of 100 μm under the RTP silicon-aluminum-glass bonding system

alyzed from ANSYS in the Pyrex glass bonding systems is 74.5 Gpa, 58 Gpa, and 60 GPa for aluminum widths of 30, 50, and 100 μm, respectively [37.92]. Pyrex glass has a documented strength of around 69 GPa [37.93]. Fracture should always occur with an aluminum width of 30 μm or less, according to the ANSYS analysis. Fracture may occur sporadically at widths of 50 or 100 μm, depending on the amount and magnitude of the flaws in the Pyrex glass. Experiments were done on the Pyrex glass bonding systems with a width of 100 μm. The samples were heated to 750 °C and then cooled by taking them out of the oven. In all four experimental cases, small cracks were observed in Pyrex glass as shown in Fig. 37.14. These cracks may have occurred consistently for several reasons. First, it may be a result of handling of the Pyrex glass before bonding. The Pyrex glass samples were kept in containers with each other, which may have resulted in abrasive contact and possibly caused flaws in the materials. These flaws can cause a reduced strength from the 69 GPa and therefore the predictions from the ANSYS analysis could be correct. Second, the observation is made that the cracks are small, only occurring tens of microns away from the aluminum and not propagating completely through the Pyrex glass. These cracks could be caused by the high stress applied, but the crack has not reached a critical size and therefore has not propagated completely through the Pyrex glass. Therefore, the strength remains at the theoretical strength of 69 GPa, and the Pyrex glass is only partially cracked. Experimental analysis done by *Chaio* and *Lin* [37.90] shows that fracture was not observed when using aluminum widths greater than 150 μm. This is consistent with the results of the ANSYS analysis which show that as the width of the aluminum is increased, the residual stress decreases.

The quartz bonding system ANSYS stress predictions are conducted, and the maximum stress predicted

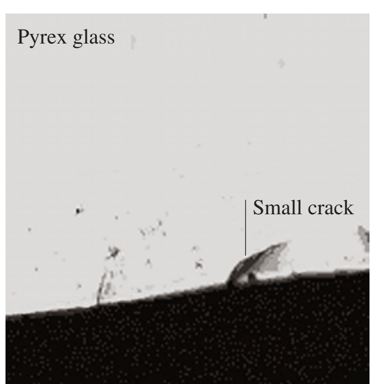

Fig. 37.14 Microphoto of the experimental result on Pyrex Glass-Aluminum-Silicon system. Small cracks can be observed

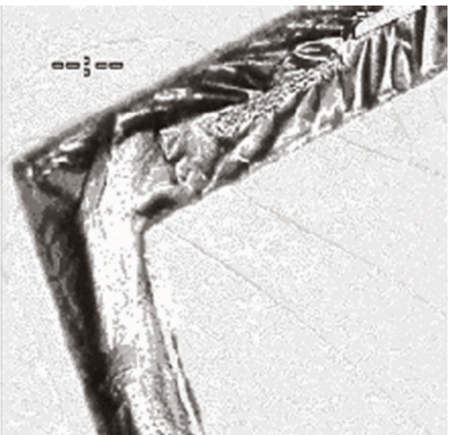

Fig. 37.15 Bonding result of Quartz-Aluminum-Silicon system, fracture can be observed

in the analysis is 207 GPa, 117 GPa, and 100 GPa, for aluminum widths of 30 μm, 50 μm, and 100 μm, respectively. All three of these stresses are much larger than the theoretical strength of Quartz at 48 GPa, and therefore fracture should always occur. Quartz has a much larger coefficient of thermal expansion (CTE) than silicon, which is why this was predicted. Experimentally, a quartz substrate was tested for the silicon-aluminum-quartz bonding test and the result is shown in Fig. 37.15.Cracks happen all over the place and cause serious damages on the quartz wafer. These cracks could be the failure mechanism of the hermetic package. Pyrex glass is therefore identified as a better bonding substrate than quartz.

The thermal stresses generated in the packaging process in quartz are much larger than the stresses in Pyrex glass because of the difference between the CTE in the two systems. Quartz has a low CTE ($0.54\times10^{-6}\,K^{-1}$) compared to the aluminum CTE ($23\times10^{-6}\,K^{-1}$) and silicon CTE ($3.5\times10^{-6}\,K^{-1}$). On the other hand Pyrex glass has a much closer CTE ($3.2\times10^{-6}\,K^{-1}$) to silicon and aluminum, resulting in smaller stresses. The practical implications of the ANSYS results and the preceding information are that materials must be chosen carefully when carrying out bonding. Material should not be used with a much higher or lower CTE than silicon to ensure fracture will not occur. This finding is a valuable component of this particular packaging system and should benefit the other packaging processes involving bonding MEMS packaging because it supports the prediction that Pyrex glass is an excellent material to use when bonding with silicon in MEMS packaging, as long as sufficiently wide adhesive material is used.

37.3.2 Packaging Reliability

The thermal stress induced by the CTE mismatch is one of the main factors that affect the packaging reliability. As a matter of fact, the formation of the stress can happen not only during packaging process but also during the operation of devices. In particular, during device operation, the package will go through various temperature cycles because of environment change. Such temperature variation causes the expansion of packaging materials when they are constrained by the packaged assembly. As a result of such thermal mismatch, significant stresses are induced in the package and finally cause the device to fail. In addition to thermal mismatch, corrosion creep, fracture fatigue, crack initiation and propagation, and delamination of thin films are all possible factors to cause failure of packaged devices [37.94]. These failure mechanisms could be prevented or deferred under proper packaging designs. For instance, the thermally induced strain inside the packaging material is generally below the tolerance of the material and can't cause immediate catastrophic damage. But cyclic loading can generate and accumulate stresses, eventually causing failure. Several common designs in IC packaging have been used to prolong the lifetime of devices. For example, the strain in solder interconnects of BGA or flip-chip packaging can be effectively reduced by introducing a polymer underfill material between the chip and the substrate to distribute thermal stress induced by CTE mismatch [37.95]. The strain can further be reduced if excellent thermal paths are built around interconnects to diminish the thermal stress originated from the temperature gradient between ambient and operation temperatures. Delamination phenomenon is another source to cause reliability problems, and it happens in the interface of adjacent material layers. In MEMS, components made of dissimilar materials are commonly bonded together to provide specific functions. Delamination can result in electrical or mechanical failures of devices in the package such as mechanically cracking through the electrical via wall to make an electrical open because of the propagation of the delamination of metal line from the dielectric layer or over heating of the die because of the delamination of die from its underneath to make an opening on the heat dissipation path. Because the stress and thermal loading, the geometry, and the material properties are complex in MEMS, the development of the packaging designs to increase the reliability is very important and requires more extensive investigations.

Reliability testing is required before a new device can be delivered to the market. The test results can provide the information for the following improvement of packaging design and fabrication. How to analyze the failure data, called the "reliability metrology", is thus very important in the packaging industry. The analysis method is to use the mathematical tools of probability and statistical distributions to evaluate data to understand the patterns and identify the sources of failure. For example, a failure density function is defined as the time derivative of the cumulative failure function

$$f(t) = \frac{\mathrm{d}F(t)}{\mathrm{d}t}\,, \tag{37.1}$$

$$F(t) = \int_0^t f(s)\,\mathrm{d}s\,. \tag{37.2}$$

The cumulative failure function, $F(t)$, is the fraction of a group of original devices that has failed at time t. The Weibull distribution function is one of the analytic mathematic models commonly used in the packaging reliability evaluation to represent the failure density function [37.21].

$$f(t) = \frac{\beta}{\lambda}\left(\frac{t}{\lambda}\right)^{\beta-1} \exp\left[-\left(\frac{t}{\lambda}\right)^{\beta}\right]\,, \tag{37.3}$$

where β and λ are the Weibull parameters. The parameters β, called a shape factor, measures how the failure frequency is distributed around the average lifetime. The parameter λ is called the lifetime parameter and indicates the time at which 63.2% of the devices faile. By integrating both sides of the equation (37.3). $F(t)$ becomes:

$$F(t) = 1 - \exp\left[-\left(\frac{t}{\lambda}\right)^{\beta}\right]\,. \tag{37.4}$$

Using the Weibull distribution function with the two parameters extrapolated by experimental data, one can estimate the number of failures at any time during the test. Moreover, by knowing the meaning and values of the parameters, one can compare two sets of test data. For example, the λ with greater number means this set of samples has longer lifetime. Because all of the mathematical models are statistical approximations based on the real experimental data, more testing samples can provide more accurate estimation.

37.3.3 Long-Term and Accelerated MEMS Packaging Tests

The reliability of MEMS packages is best characterized by means of long-term tests with statistical data analyses. But it is very difficult and time-consuming to obtain

these experimental data so accelerated tests that put samples in extreme environment for accelerated failure are commonly used to predict the lifetime of the devices. Unfortunately, few research publications deal with these two issues. In this section, two MEMS packaging examples that aim to address these two tests we discuss.

Figure 37.16 shows long-term measurements of the Q factor of a vacuum packaged μ-resonators using localized aluminum/silicon-to-glass bonding [37.81] vacuum encapsulation process is described in details as shown in Fig. 37.8. It is found that the vacuum package by means of localized heating and bonding provides stable vacuum environments for the μ-resonator and a quality factor of 9,600 has been achieved with no degradation for at least one year. Since the performance of high Q μ-resonator is very sensitive to environmental pressure as shown in Fig. 37.11, any leakage can be easily detected. The fact that this high Q value can hold for one year indicates the packaging process is well performed and both aluminum and Pyrex glass are suitable materials for vacuum packaging applications. According to a previous study of hermeticity in different materials, metal has lower permeability to moisture than other materials such as glass, epoxy, and silicon. With a width of 1 μm, metal can effectively block moisture for more than ten years [37.21]. In this vacuum package system, the bonding width is 30 μm so it can sufficiently block the diffusion process of moisture. On the other hand, the diffusion effects of air molecules into these tiny cavities have not been studied extensively, and the design guidelines for vacuum encapsulations are not clearly defined. Further investigations will be needed in this area, and the example presented here serves as a good starting point.

On the other hand, accelerated testing puts a large amount of samples in harsh environments, such as elevated temperature, elevated pressure, and 100% humidity, to accelerate the corrosion process. The statistical failure data are gathered and analyzed to predict the lifetime of packages under normal usage environment. As a result, the long-term reliability of the package can be predicted without going through the true long-term tests. Unfortunately, accelerated tests have not been addressed in MEMS research papers. Although the MEMS industry must have done some extensive reliability tests, they do not publish their results, probably due to liability concerns. Among the very limited publications, this section uses as the illustration example a specific MEMS packaging system that has gone through accelerated tests [37.45].

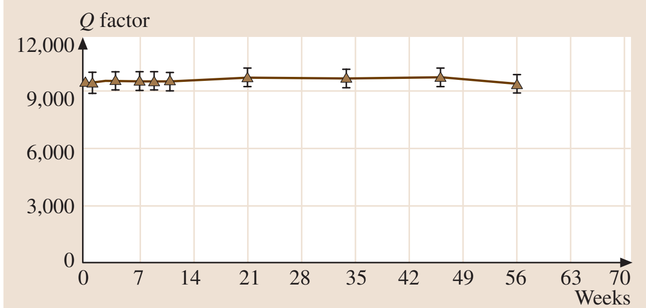

Fig. 37.16 Long-term measurement of encapsulated μ-resonators. No degradation of Q factors is found after 56 weeks

The MEMS package is accomplished by means of RTP (Rapid Thermal Processing) bonding as described previously in this chapter. The goal of the accelerated test is to examine the failure rate at the bonding interface. The accelerated tests start by putting the packaged samples into the autoclave chamber filled with high temperature and pressurized steam at 130 °C, 2.7 atm, and 100% relative humidity for accelerated testing. The pressurized steam can penetrate small cracks if any defect exists at the bonding interface [37.96]. Elevated temperature and humid environment speed up the corrosion process. A package is considered a failure if water is condensed or diffused into the package. Statistical failure data are gathered every 24 h under optical examination for a period of 864 h, during which time new failure is seldom observed. Because of the robustness of the samples, it is difficult to conduct the tests to the point at which all the packages may fail. The cumulative failure function is recorded, and it is found that most failures occur in the first 96 h and such high early failure rate reflects the yielding issue of the bonding process. Weibull and Lognormal models are compared to predict the lifetime of the packages, and it is found that Lognormal model better describes the statistical data. Figure 37.17 shows the inverse standard normal distribution function vs. ln(time) and the Maximum Likelihood Estimator (MLE) is then used to predict the mean, standard deviation, and the MTTF (mean time to failure). Table 37.2 shows the MLE calculation results of MTTF. The wide interval of confidence level comes from the fact that only a small number of samples failed at the end of the test. It is also observed that packages with larger bonding width and smaller bonding areas have larger MTTF values. The lower bound of the MTTF provides the worst-case scenario. For example, only 4 our of 31 samples failed when tests stopped in the case of ring width of 200 μm and sealing area of 450×450 μm^2. The MTTF predicts, in the worst-case scenario, that there

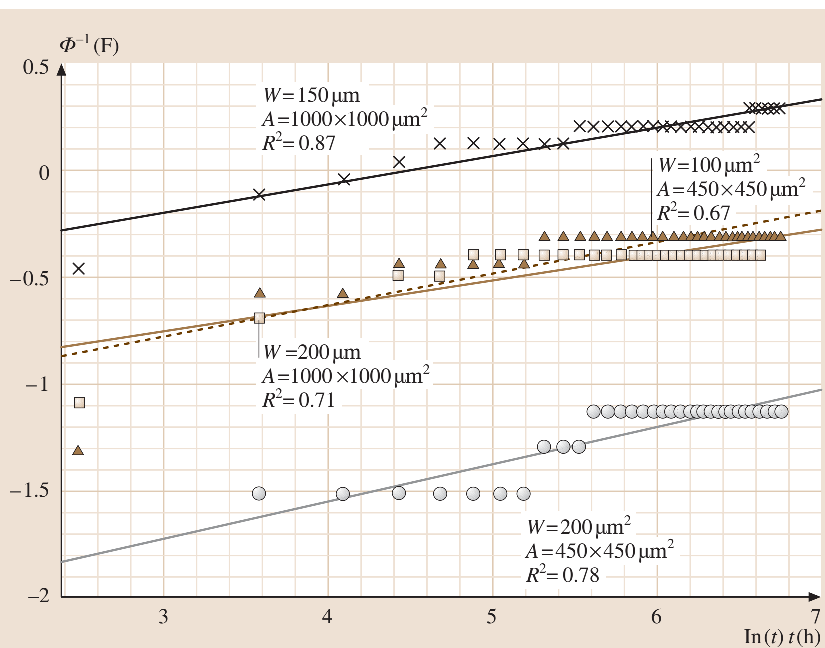

Fig. 37.17 Life data fitted by Lognormal distribution. R^2 is the coefficient of determination

Table 37.2 The Maximum Likelihood Estimation for Mean Time To Failure (MTTF)

MLE calculation resuls of MMTF[a]				
Bonding width, W (µm)	Area, A (µm²)	MTTF UB (years)	MTTF LB (years)	Worst cases in jungle condition (years)
200	450 × 450	1.8×10^7	0.57	1,700
100	450 × 450	5.3	0.10	300
200	1,000 × 1,000	6.5×10^3	0.09	270
150	1,000 × 1,000	0.50	0.017	50

[a] UB is the upper bound, and LB is the lower bound of the 90% confidence interval, respectively. The MTTF LB times AF is the worst case MTTF used in jungle condition.

is 90% chance a package will fail in 0.57 years in the autoclave environment.

It is widely accepted that the acceleration factor (AF) for autoclave tests follows the Arrhenius equation [37.21] and can be modeled as:

$$\mathrm{AF} = \frac{(\mathrm{RH}^{-n}\,\mathrm{e}^{\Delta E_\mathrm{a}/kT})_\mathrm{normal}}{(\mathrm{RH}^{-n}\,\mathrm{e}^{\Delta E_\mathrm{a}/kT})_\mathrm{accelerated}}\,, \qquad (37.5)$$

where RH is relative humidity (85%, RH = 85), k the Boltzmann constant and T the absolute temperature. The recommended value for n, an empirical constant, is 3.0 [37.97], and ΔE_a, the activation energy, is 0.9 eV for plastic dip package and 0.997 eV for anodically bonded glass-to-silicon package [37.58]. If $\Delta E_\mathrm{a} = 0.9$ is used to estimate the AF for the accelerated testing condition as compared with the jungle condition (35 °C, 1 atm and 95% RH), AF is about 3,000, and the worst-case lifetime values in jungle condition are also listed in Table 37.2. The high values of estimated MTTF in jungle condition could be a result of overestimation of AF because plastic dip package may have smaller AFs than those of glass packages. Nevertheless, these data and analyses provide important guidelines in the area of accelerated tests for MEMS packages.

37.4 Future Trends and Summary

In the past, the development of MEMS packaging is mainly originated from IC packaging advancement because existing packaging techniques can significantly reduce the development cost of MEMS. It is expected that the situation will be changed very soon, hoewever, in a way the MEMS packaging approaches will assist the IC packaging development. Recent advances in IC packaging aim to provide high I/O density and more chip integration capability for the needs of high speed and high data communication rate. In order to satisfy those requirements, several packaging concepts and techniques are developed, including 3-D packaging, wafer-level packaging, BGA, and flip-chip technique. Although all of the concepts and methods can provide a package with more I/O density, flexibility in chip integration, and lower manufacturing cost for IC fabrication, they are still insufficient for providing solutions for the future applications because of the increase of complexity and requirements of MEMS packaging. On the contrary, with the progress of MEMS fabrication technologies, several key processes such as DRIE (Deep Reactive Ion Etching), wafer bonding, and thick photoresist processes [37.98] have been utilized for IC packaging fabrication. Technologies developed in MEMS fabrication can therefore also assist the development of new IC packaging approaches.

In order to address the future needs of process integration, adaptive multi-chip module (MCM) [37.28] or 3-D packaging combined with vertical through substrate interconnects [37.10, 99] are promising approaches for the development of future MEMS packaging processes. Based on low temperature flip-chip solder bonding technique, these packaging methods can provide more flexibility in device fabrication and packaging. Devices can be fabricated before they are integrated to form microsystems to dramatically reduce the packaging cost. Vertical through substrate interconnects can have higher I/O density, smaller resistance, parasitic capacitance, and mutual inductance. Although this approach provides many possible advantages, technical challenges exist. For instance, metal is commonly used as the fill material inside the vertical vias as electrical interconnects, and it may introduce large thermal mismatch with respect to silicon substrate and generate huge thermal stress to cause packaging reliability problems. Moreover, it will be an interesting engineering challenge to fill the materials into those high aspect ratio vias.

The future development of MEMS packaging depends on the successful implementation of unique techniques as described in the following:

1. Development of mechanical, thermal, and electrical models for packaging designs and fabrication processes;
2. Wafer-level, chip-scale packaging with low packaging cost and high yield;
3. Effective testing techniques at the wafer level to reduce the testing costs;
4. Device integrations by vertical through-interconnects as an interposer [37.1] to avoid thermal mismatch problems.

In addition to these approaches and challenges, many other possibilities have not been listed but also require dedicated investigations. For example, several key nanotechnologies have been introduced in the previous chapters, but the packaging solutions for the NEMS devices have not been addressed. Because it is feasible to use MEMS as the platform for NEMS fabrication, all of the packaging issues discussed in the chapter can be directly applied to NEMS devices. On the other hand, nanotechnology may introduce new opportunities for MEMS/NEMS packaging applications by providing superior electrical, mechanical, and thermal properties [37.100–103]. For example, carbon nanotubes have very high thermal conductivity [37.102] and may be suitable to increase the thermal cooling effects for better IC/MEMS/NEMS packaging applications.

In summary, MEMS packaging issues have been introduced in the areas of fabrication, application, reliability, and future development. Packaging design and modeling, packaging material selection, packaging process integration, and packaging cost are the main issues to be considered when developing a new MEMS packaging process.

38 Social and Ethical Implications of Nanotechnology
William S. Bainbridge, Arlington, USA

38. Social and Ethical Implications of Nanotechnology

Nanotechnology will have very broad applications across all fields of engineering, so it will be an amplifier of the social effects of other technologies. There is an especially great potential for it to combine with three other powerful trends – biotechnology, information technology, and cognitive science – based on the material unity of nature at the nanoscale and on technology integration from that scale. Technological convergence highlights such existing issues as the treatment of the disabled, communication breakdowns, economic stagnation, and threats to national security. Nanotechnology itself may possibly raise distinctive ethical and social issues in the future, but much of the public discussion to this point has been misdirected and misinformed, lacking a firm social scientific basis. Thus it will be important to integrate social and ethical studies into nanotechnology developments from their very beginning.

Social scientific and economic research can help manufacturers and governments make the right decisions when deploying a new technology, maximizing its benefit for human beings. In addition, technically competent research on the societal implications of nanotechnology will help give policymakers and the general public a realistic picture free of unreasonable hopes or fears. The costs of premature or excessive regulation would be extremely high, harming the very people it was intended to protect, and failure to develop beneficial nanotechnology applications would be unethical.

The significance of nanotechnology depends largely on how its development relates to wider trends going on in the world such as the impending population declines of most advanced industrial nations, the apparent diminishing returns to increased medical research and health care investment, and the threatened deceleration of progress in microelectronics. Well established social-scientific explanations for unethical behavior – such as learning, strain, control, and subculture theories – could help us understand possible future cases in nanotechnology industries. Ethics and social implications are largely matters of social perception, and the public conception of nanotechnology is still in the early stages of developing. Social science can now begin to examine its unfolding impacts in all sectors of the economy, in most spheres of life, and both short-term and long-term time scales.

Part F | 38

Science and engineering have only begun to explore the potential for discovery and creativity at the nanoscale, but already some intemperate voices call for government regulation or outright banning of nanotechnology [38.1–4]. Such action would be extremely premature, because we have just started on a very long road of research that we must traverse before we will know what is technically practical, what real-world applications nanotechnology might actually have, and what the appropriate societal responses would be to any hazards that might be directly or indirectly related to these applications. Some writers in the popular press seem to treat nanotechnology as

B. Bhushan • © Springer 2004

a new kind of Frankenstein's Monster, but it is worth remembering that biological science is still not able to create such a monster, nearly two centuries after Mary Shelly imagined one.

A good starting point for consideration of social and ethical issues is a formal definition of the topic, but unfortunately a somewhat different definition has lodged in the public mind from that employed by professionals working in the field. For example, *Merriam-Webster's Collegiate Dictionary* defines *nanotechnology* as: "the art of manipulating materials on an atomic or molecular scale especially to build microscopic devices (as robots)." Similarly, the online reference About.com defines it thus: "The development and use of devices that have a size of only a few nanometres." Later, we will examine public conceptions more closely, but it is worth noting here that these definitions focus on robot-like devices constructed at the nanoscale and ignore the topics of most chapters in this volume.

A more authoritative if long-winded definition of *nanotechnology* has been provided by the U.S. Government's National Nanotechnology Initiative: "Research and technology development at the atomic, molecular or macromolecular levels, in the length scale of approximately 1–100 nm range, to provide a fundamental understanding of phenomena and materials at the nanoscale and to create and use structures, devices and systems that have novel properties and functions because of their small and/or intermediate size. The novel and differentiating properties and functions are developed at a critical length scale of matter typically under 100 nm. Nanotechnology research and development includes manipulation under control of the nanoscale structures and their integration into larger material components, systems and architectures."

While this definition includes the word "devices," it also covers materials, structures, and systems. Significantly, it envisions that many nanotechnology advances will be integrated into "larger material components, systems and architectures," which means that we would need to understand the social and ethical implications of the larger-scale systems of which nanoscale structures are only components.

There is good reason to believe that engineering at the nanoscale will have very broad applications across all fields of technology and most fields of science [38.5–7]. Therefore, it will be an enabler or amplifier of the effects of other technologies. This means that it is foolish to ask, "Is nanotechnology harmful?" Nanotechnology is not one thing, either ethical or unethical. Rather, it is a myriad of different things – many nanotechnologies – each of which has a range of potential uses and misuses in conjunction with other technologies and applied to different goals.

This line of reasoning could lead some people to conclude that we did not need to worry at all about the social and ethical implications of nanotechnology, because they will be subsumed by the implications of larger systems. Others might conclude that it is far too early in the history of nanoscale engineering to consider societal implications, because we cannot study the impact of a technology that does not yet exist.

However, the very fact that some writers are urging regulation or banning of nanotechnology suggests that the debate about its value to humanity has begun, and we need to bring the best possible thinking and information to that debate [38.8–10]. In addition, a few relatively simple but significant applications have begun to appear, so in those cases at least an impact can be observed. Social scientists, natural scientists, philosophers, and engineers have indeed begun considering the future of nanotechnology, so we can draw upon the very first serious intellectual efforts in this important field.

38.1 Applications and Societal Impacts

In the year 2000, the National Science and Technology Council sponsored a major workshop at the National Science Foundation, which led to a published report, *Societal Implications of Nanoscience and Nanotechnology* [38.11]. Sixty-four representatives of academic science, government laboratories, and corporate research listed a large number of potential nanotechnology applications, a few of which had already entered production, but many of which could be expected only after decades of research. Following are diverse examples of possible applications suggested by workshop participants concerning a variety of sectors of the economy and spheres of life:

- More efficient components for the semiconductor industry such as integrated circuits containing transistors constructed from carbon nanotubes.

- Nanostructured catalysts for the chemical industry and for more effective converters to handle pollution from automobile exhausts and other combustion.
- Lighter and stronger nanomaterials in bulk quantities to enable safer and more efficient transportation vehicles, including automobiles, aircraft, and train systems.
- Improved pharmaceuticals with features such as programmed delivery to desired targets like tumors and the ability to employ substances that are not soluble in water as medications.
- Cost-effective and reliable filters for water decontamination, desalination, containment of industrial pollutants, and air purification.
- More efficient solar energy conversion, thereby reducing current reliance on oil and offering an alternative to nuclear power for future electricity needs.
- Efficient fuel cells and hydrogen storage systems, leading to nonpolluting automobiles, trucks, and buses.
- More durable composite materials, such as nanoparticle-reinforced polymers, designed for optimal performance in specific uses with reduced waste and greatly increased lifetime.
- Molecularly engineered biodegradable fertilizers and insecticides designed for precision agriculture with efficient delivery to where they are needed and prevention of unwanted side effects.
- Revolutionary launch vehicles with high mass-ratios, nonpolluting but powerful engines, and low electric power needs in order to finally realize the promise of space exploration.
- Nanoscale components in sensor systems that can quickly detect and identify pollutants and disease organisms, as well as chemical or biological warfare agents to allow quick and appropriate medical treatment or security responses.
- Coatings that would give ordinary materials extraordinary properties like self-cleaning window glass and heat-reflecting exterior architectural surfaces.

Knowledgeable scientists and engineers reported that these and many other similar applications were plausible benefits of nanotechnology research, but they recognized that progress has costs. For example, the creation of a new industry often results in the decline or complete destruction of an older industry, as in the proverbial case of buggy-whip manufacturers who were rendered obsolete by the automobile. The potential benefit from a new technology must be calculated in a sophisticated manner, taking into account the full life-cycle costs [38.12]. For example, an electric car may reduce some forms of pollution while increasing others such as the release of lead or other dangerous substances into the environment during the manufacture of the electric battery and the disposal of it when the car is eventually junked.

Many ethical issues of fairness will arise within nanotechnology industries themselves. For example, it will be important to invest in appropriate safeguards for workers engaged in hazardous production processes. In general, scientific discoveries cannot be patented, whereas new products and production methods can, so there will be serious issues of intellectual property protection in nanoscience, a nontraditional field where the legal line between discovery and invention has not yet been clearly drawn. Often, it will be necessary to bring together information and expertise from several different sources in order to create an economically profitable application, drawing upon government-funded university research projects, as well as several specialized industrial corporations, which will require improved models of collaboration across organizations.

As the *Societal Implications* report observed, the general public has a significant stake in the National Nanotechnology Initiative (NNI) that must be managed both directly through public participation and indirectly through the involvement of social scientists:

> It is important to include a wide range of interests, values, and perspectives in the overall decision process that charts the future development of nanotechnology. Involvement of members of the public or their representatives has the added benefit of respecting their interests and enlisting their support. ... The inclusion of social scientists and humanistic scholars, such as philosophers of ethics, in the social process of setting visions for nanotechnology is an important step for the NNI. As scientists or dedicated scholars in their own right, they can respect the professional integrity of nanoscientists and nanotechnologists, while contributing a fresh perspective. Given appropriate support, they could inform themselves deeply enough about a particular nanotechnology to have a well-grounded evaluation. At the same time, they are professionally trained representatives of the public interest and capable of functioning as communicators between nanotechnologists and the public or government officials. Their input may help maximize the societal benefits of the technology while reducing the possibility of debilitating public controversies [38.11].

Social scientific and economic research can help manufacturers and the government make the right decisions when deploying a new technology, maximizing its benefit for human beings. In addition, technically competent research on the societal implications of nanotechnology will help give policymakers and the general public a realistic picture free from unreasonable hopes or fears. As the report notes, the National Nanotechnology Initiative is just now commencing, so "there is a rare opportunity to integrate the societal studies and dialogues from the very beginning and to include societal studies as a core part of the NNI investment strategy" [38.11].

The workshop developed a number of recommendations for government, academia, and industry suggesting how the social and ethical implications of nanotechnology could best be addressed [38.11]. Here are some of the most important principles in education, social science, and ethics:

- Nanoscale concepts should be introduced into science and engineering education at all levels, thereby giving the widest possible range of students a fundamental understanding of the field while intellectually linking nanotechnology to many other fields.
- The training of nanotechnologists should include societal implications and ethical sensitivity, so their future work will be guided by principles that will maximize human benefit.
- A sufficient number and variety of social and economic scientists should receive effective multidisciplinary training, so they will be well prepared to work in the nanotechnology area.
- Formal measurement methods, such as social and economic indicators, should be developed and consistently employed to chart the actual widespread changes in industry, education, and public welfare as they occur.
- Government agencies, private foundations, and industry should support a wide range of high-quality, theory-based social and economic research studies on nanotechnology, examining both the decision processes that shape the emerging technology and itsspecific societal impacts once it is deployed.
- A knowledge base and institutional infrastructure must be created to evaluate the probable future intellectual and societal impacts of nanoscience and nanotechnology over the short, medium, and long term.
- Government and the private sector should establish effective channels for informing the public promptly about new concepts, projects, potential applications, and ethical issues as they emerge.
- There should be formal organizations and mechanisms to ensure participation by diverse societal institutions and the general public in setting priorities for research and development and in providing timely input to decision makers.
- Government and industry should develop management plans and policies that can effectively incorporate all relevant information and legitimate stakeholder interests to ensure that we can respond flexibly to social, ethical, legal, and economic implications as they appear.

It will take time and effort to implement these recommendations, but some progress has already been made. The National Science Foundation has recently funded Rosalyn Berne at the University of Virginia to study the developing ethics of nanotechnology through a narrative analysis of discourse from engineers and scientists in the field, and a team headed by Michael Gorman at the same institution was funded to explore the potential for multidisciplinary research on social and ethical dimensions of nanotechnology. The Environmental Protection Agency, which has supported several research projects on how nanotechnology might remedy conventional forms of pollution, has funded Darrell Velegol and Kristen Fichthorn at Pennsylvania State University to study "Green Engineering of Dispersed Nanoparticles," exploring how valuable nanoparticles might be produced without the use of polluting additives. In its review of the National Nanotechnology Initiative, the National Research Council has recommended the development of "a new funding strategy to ensure that the societal implications of nanoscale science and technology become an integral and vital component of the NNI" [38.13].

38.2 Technological Convergence

In the year following the *Societal Implications* workshop, NSF and the U.S. Department of Commerce staged an even larger meeting to examine the potential for *nanotechnology* to combine with three other powerful scientific and engineering trends: *biotechnology*, *information technology*, and *cognitive science* – four "NBIC" fields. The resulting report, *Converging Technologies for Improving Human Performance* [38.14], examined benefits of technological convergence that would specifically enhance the ability of humans to satisfy their needs and achieve their legitimate goals.

Convergence of diverse NBIC technologies will be based on the material unity of nature at the nanoscale and on technology integration from that scale. This is the scale at which much future biotechnology and the hardware for information technology will operate, and it is the scale from which fundamental research on the human nervous system will take place. Key transforming tools, including research instruments and production methods, will arise in the conjunction of previously separated fields of science. Drawing upon advances in mathematics and computation, it will be possible to model phenomena from the nanoscale to the cosmic scale as complex, coupled, hierarchical systems.

The *Converging Technologies* scientists, engineers, and policymakers sketched six general areas in which the human benefits and social issues are likely to result:

- Overall potential of converging technologies
- Expanding human cognition and communication
- Improving human health and physical capabilities
- Enhancing group and societal outcomes
- National security
- Unifying science and education

Numerous valuable applications were sketched in greater or lesser detail that could reasonably be expected to result from a decade or two of vigorous research and development, including the following ideas that depend on partnerships between nanotechnology and one or more of the other NBIC fields:

- Comfortable, wearable sensors and computers will enhance every person's awareness of his or her health condition, the environment, chemical pollutants, potential hazards, and information of interest about local businesses, natural resources, and the like.
- The human body will be more durable, healthier, more energetic, easier to repair, and more resistant to many kinds of stress, biological threats, and aging processes.
- Machines and structures of all kinds, from homes to aircraft, will be constructed of materials that have exactly the desired properties, including the ability to adapt to changing situations, high energy efficiency, and environmental friendliness.
- A combination of technologies and treatments will compensate for many physical and mental disabilities and will eradicate altogether some handicaps that have plagued the lives of millions of people.
- National security will be greatly strengthened by lightweight, information-rich war fighting systems, capable uninhabited combat vehicles, adaptable smart materials, invulnerable data networks, superior intelligence-gathering systems, and effective measures against biological, chemical, radiological, and nuclear attacks.
- The ability to control the genetics of humans, animals, and agricultural plants will greatly benefit human welfare; widespread consensus about ethical, legal, and moral issues will be built in the process.
- Agriculture and the food industry will greatly increase yields and reduce spoilage through networks of cheap, smart sensors that constantly monitor the condition and needs of plants, animals, and farm products.
- Transportation will be safe, cheap, and fast due to ubiquitous real-time information systems, extremely high-efficiency vehicle designs, and the use of synthetic materials and machines fabricated from the nanoscale for optimum performance.
- The work of scientists will be revolutionized by importing approaches pioneered in other sciences, for example, genetic research employing principles from natural language processing and cultural research employing principles from genetics.
- Formal education will be transformed by a unified but diverse curriculum based on a comprehensive, hierarchical intellectual paradigm for understanding the architecture of the physical world from the nanoscale through the cosmic scale.

Several of these application areas depend upon the development of nanoscale components for sensor, computation, and communication networks. Others involve a synergy between inorganic nanoscale engineering and organic chemistry or biology. Others extrapolate that it will be possible to build large-scale structures that

are engineered at the nanoscale to enhance the qualities of architecture, transportation vehicles, or even the human body. Fundamental to all of the application areas is a conceptual revolution that unifies science and provides humanity with a comprehensive view of nature and technology.

Contributors to the report showed how nanoscale science and engineering were essential for progress in biology, information science, and cognitive science. The result of NBIC convergence will be the strengthening of science and the empowerment of humanity, as we will find solutions to many of humanity's problems in health, natural resources, environment, security, and even communication with fellow human beings. Often, the technologies based in the sister sciences will raise ethical issues. In such cases, nanotechnology may become implicated in controversies without being central to them. The correct policy response would then be to ignore the superficial nanotechnology aspects and focus directly on the core problem that lies in a different field. *Converging Technologies* contributors examined how technological convergence highlighted such existing issues as the treatment of the disabled, communication breakdowns, economic stagnation, and threats to national security.

For greater clarity, we can consider here the very specific example of the proliferation of nuclear weapons. Nuclear physics and atomic technology were specifically not included in the constellation of NBIC converging technologies considered by the workshop, so the following discussion supplements its findings. As scientists already understood in the early 1940s, there are fundamentally two ways that a rogue nation can build up its own supply of weapons-grade nuclear materials. One is breeding plutonium in a nuclear reactor fueled by uranium, transmuting the common uranium isotope of atomic weight 238. But this is hard to conceal from other nations, especially if reactors are open to international inspection. The other way is separation of the relatively rare uranium isotope ^{235}U, which, like plutonium, is suitable for use in weapons. The original separation method was gas diffusion, but then the centrifuge method was developed, and other approaches are possible such as laser or electromagnetic separation.

In the gas diffusion method, a chemical containing uranium (uranium hexaflouride) is passed through a porous barrier such as a ceramic wall that has tiny holes in it. Molecules containing ^{235}U travel through the barrier slightly faster than molecules containing ^{238}U. This is a very inefficient process, because the isotopes are very similar to each other, so many passes through a barrier are required to enrich the proportion of ^{235}U sufficiently for use in a nuclear weapon. The other approach uses centrifuges, rapidly spinning rotors containing the uranium hexaflouride to separate the two isotopes on the basis of their slight difference in mass. Both approaches are very difficult and costly, however. Conceivably, nanotechnology could slightly reduce the difficulty, by producing porous barriers with exactly the optimum sized holes and by providing lighter and stronger centrifuge rotors that could operate at higher speeds.

Therefore, without a more careful analysis someone might leap to the conclusion that nanotechnology is a danger because it facilitates proliferation of nuclear weapons. This ignores several crucial facts. First, the world already faces a very severe crisis of nuclear proliferation without nanotechnology. Second, the fundamental requirement for production of nuclear weapons is the availability of uranium, so the most logical preventive would be international monitoring and control over its mining and distribution. Third, there are many other technical requirements for production and delivery of nuclear weapons, and it is the whole collection of them that presents a threat, not any one alone. Fourth, nanotechnology is inherently nonnuclear, because nuclear reactions occur at a smaller scale than the nanoscale, so its connections to proliferation of nuclear weapons will always be highly indirect if they exist at all. Finally, the fundamental problem is not nuclear proliferation, but weapons of mass destruction in general, and nanotechnology has a major role to play in the defense against chemical and biological warfare agents in sensor systems that can detect them before they have caused harm.

Perhaps a very few nano products will need to be "controlled substances," analogous to narcotics, insecticides, asbestos, and antibiotics [38.15]. Conceivably, porous barriers with exactly the right pore size for uranium isotope separation would be controlled in some way. Some products could be produced and used under strict regulations, whereas a few others might be banned altogether. Most would not require restrictions of any kind.

Such decisions would need to be based on the careful analysis of facts related to the specific issue at hand. For example, it may be that no improvements in gas diffusion separation are possible through nanotechnology, or they are so slight as to be negligible. Perhaps technological developments in laser or electromagnetic separation, completely unrelated to nanotechnology, may render

both the gas diffusion and centrifuge methods obsolete. Therefore, the mere fact that we can imagine a way in which nanotechnology might possibly encourage the proliferation of nuclear weapons is far too weak a justification for international regulation. We would need to go beyond vague fears to precise analysis based on rigorous scientific research to distinguish real dangers from imaginary ones and design appropriate safeguards in those rare cases when they are necessary.

The costs of excessive regulation would be extremely high, harming the very human beings it was intended to protect. Porous barriers precisely designed at the nanoscale are among the high benefit applications we can anticipate early in the history of nanotechnology. They would have a wide range of applications, from water purification and desalination to separation of valuable substances in biotechnology production processes. Similarly, new high-performance materials with great strength but low weight will have a myriad of applications throughout the civilian sectors of the economy. Among the products that would benefit millions of ordinary people are light but indestructible eyeglass frames, safety helmets, and hand tools.

Nanotechnology has the potential to increase the effectiveness of biotechnology, information technology, and technologies based on cognitive science through NBIC convergence. Therefore, it could become entangled in ethical issues that already involve those other technologies such as the conflict over genetically modified foods, the dispute over information privacy, and the debate over treatment of mental illness. These are not fundamentally nanotechnology issues, however, and it will be important to keep a proper perspective on their real nature.

38.3 Major Socio-technical Trends

The significance of nanotechnology depends not only on its own accomplishments and on convergence with other technologies, but also on how these purely technical developments relate to wider trends going on in the world [38.16, 17]. At present, many of these trends are confused and are the subject of great controversy in the social science and public policy arenas. It is always hazardous to extrapolate trends from any particular moment in history, but the present time appears so chaotic that the events of a single day might send humanity down a very different road.

A few years ago, there was a broad consensus that the rapid growth in the number of people on the planet, the so-called *population explosion*, was the dominant quantitative trend that needed to be factored into any projections [38.18]. But by the mid-1980s, it became obvious that population growth had been replaced by the threat of population decline in most advanced industrial nations, with the possible exception of the United States [38.19, 20]. Even before collapsing fertility begins to reduce the number of people in the affected nations, their average age and pension costs increase, social dynamism and creativity decrease, and governments become gridlocked trying to deal with ultimately insoluble problems of funding demanded services. This is one of the explicit reasons why the United States has begun to discount the influence of its European allies and Japan [38.21, 22].

Although nanotechnology has little obvious direct connection with fertility, there are two potentially counterbalancing, indirect connections. Rapid progress in nanotechnology could revitalize economic expansion and technical creativity, thereby to some extent offsetting the negative consequences of fertility collapse. However, the aversion to change that marks societies having a high proportion of elderly citizens may dampen the intellectual inquisitiveness and investment risk-taking required to develop nanotechnology and technological convergence.

A related trend is the constant improvement in health resulting from progress in medical science and the economic growth needed to fund increasingly costly health care. Continued progress in health is by no means assured, however. During the nineteenth century, American health may actually have declined significantly for a number of decades, despite economic growth [38.23]. We tend to attribute the undeniable improvement in health over the twentieth century to medical progress, but health education and public sanitation may have been more important [38.24]. The U.S. Centers for Disease Control argue that substantial improvements in health and longevity could be achieved by lifestyle changes, notably, exercising more, reducing the fats in our diet, and avoiding smoking [38.25,26]. The introduction of antibiotics helped increase longevity, and modern cardiology saves the lives of many people who might otherwise die prematurely of heart attacks, but the progress against

cancer, AIDS, and most aging-related illnesses has been agonizingly slow. On balance, economists find that the increasing investments in heath care are paying off, but not necessarily in all areas, or with very great benefit [38.27–29].

There are several reasons to be pessimistic about the future benefits of medicine, unless there are very major scientific breakthroughs. We have yet to find a cure for any chronic viral infections, of which AIDS is merely the most publicized example. Bacteria are rapidly evolving resistance to antibiotics, yet the rate of development of new prescription medicines is declining.

The average white American male born in 1900 could expect to live 48 years, but in 2000 this life expectancy had increased to 74 years. For white females, the average life expectancy increased from 51 to 80. Projecting these figures forward at the same rate of increase suggests that life expectancy in 2100 might be 114 for males and 125 for females. However, using more realistic assumptions, the U.S. Census Bureau has projected that life expectancy for Americans born in the year 2100 might be only around 88 for males and 92 for females [38.30]. This does represent progress, but at a steeply declining rate, and it depends upon continued economic growth.

Perhaps the most economically significant technical trend of recent years has been *Moore's Law*, Gordon Moore's observation that the density of transistors on the most advanced microchip doubles about every 18 months. The rapid improvement of computer and communications hardware has been fundamental to the implementation of new software applications, networking, and information technology in general. These, in turn, have been responsible for much economic growth. However, the semiconductor industry is approaching physical limits in the traditional methods of making integrated circuits, including computer chips, so Moore's Law will stall without breakthroughs in nanoscale technologies such as molecular logic gates and carbon nanotube transistors [38.31–33].

Arguably, several of the great thrusts of twentieth-century technology have already stalled. Except for the improved capacity of scientific instruments to collect and process astronomical data, the space program has hardly advanced since the mid-1970s. Civilian aviation and ground transportation have improved only in relatively minor design details since the 1950s. Despite great efforts, little progress has been made in controlling nuclear fusion for power generation. Nuclear fission power generation has largely been halted by public controversies, and no technological breakthroughs in safe operation of reactors or disposal of radioactive wastes have assuaged the public's concerns. The social sciences seem no better able to define good public policies than they were decades ago. Outside of nanotechnology itself, the two main areas where rapid progress obviously continues are information technology and genetic engineering. Convergence with nanotechnology is essential for further progress in both of these areas.

What would happen to the world economy if technological progress slowed or even halted? First, the advanced industrial nations would lose the advantage they currently hold over developing countries. For example, the American semiconductor industry would probably collapse if it lost its technological superiority, because nations with lower wage rates could produce the same things more cheaply. Technological products, from computer chips to pharmaceuticals, would become commodities, manufactured wherever it was cheapest to do so. With their heavy pension burdens and costly social services, governments of advanced nations would face fiscal crises of unprecedented magnitude. Indeed, the economies of these nations could fall rapidly down to the average of all nations, unleashing social discontent that could lead to unpredictable violence.

At the same time, some developing nations would advance economically, which would mean increased net world industrial production with concomitant increase in environmental pollution and resource depletion. Without technological progress to solve these problems, the average human welfare could decline, rather than remaining stable. In order to improve human welfare, technological progress must continue. Perhaps the best way to achieve that is through nanoscience and nanotechnology in convergence with the other NBIC fields, gaining understanding and control at the physical scale that is the basis for most science and technology.

It is impossible to predict how rapidly the conditions in the richest nations would deteriorate, or whether humanity could navigate through these crises to achieve a stable world. But clearly a halt in technological progress would be a shock to the world economy, global political institutions, and human welfare – which it would be wise to avoid.

38.4 Sources of Ethical Behavior

Ethical questions related to nanotechnology are not limited to the ways people might use it to harm others intentionally, but also include obligations to avoid potentially harmful unintended consequences [38.34]. An example of the former might be a weapon and of the latter, a kind of environmental pollution. In either case, the harm might be morally justified, as when a nation employs a weapon to defend against attack, or when limited pollution of the environment is offset by substantial benefits to humanity. Other ethical questions concern harm to the owners of nanotechnology, for example, if a competing company violates a nanotech patent, or if a government bans a nano-related product without careful examination of scientific evidence about its value. News reporters or popular writers who spread false information about nanotechnology may also be acting unethically, whether they are willfully lying or merely failing to be professionally diligent in checking their facts.

It is important to recognize that there are sins of omission as well as commission. To fail to develop a beneficial nanotechnology application could also be unethical. Imagine, for instance, that a laboratory had discovered how nanotechnology could enable a much more effective form of chemotherapy to cure cancer reliably and cheaply, but the company owning the patents prevented it from being developed, because its less effective traditional chemotherapy products were more profitable. This could be considered just as unethical as doing aggressive harm.

For over a century, social scientists have been studying the origins of ethical behavior – or its opposite, unethical behavior – in fields like the social psychology of groups, the sociology of deviance, and criminology. Although it is impossible to predict when a particular person will commit a specific ethical or unethical act, we can identify with good confidence the general factors that steer human behavior in one direction or another. An individual's behavior is determined by a complex of factors, few of which can be measured accurately, and chance seems to play a significant role in human affairs. Thus, the findings of social science tend to be statistical or conditional in nature. This does not render them useless, because one can develop rational laws, government policies, and investment strategies based on probabilities rather than certainties.

The theoretical and empirical scientific literature on the topic is vast, including literally thousands of publications dating back to the 1840s, expressing the views of countless schools of thought, often employing idiosyncratic terminology. For present purposes, we must distill that huge and incoherent intellectual heritage down to its most meaningful essentials. A good start is the following set of four themes, each of which can be expressed as a theory about why people might violate an ethical rule:

1. Learning – A person violates a rule because the person has learned it is rewarding to do so.
2. Strain – A person violates a rule because the person is frustrated in the attempt to fulfill one of the expectations of society.
3. Control – A person violates a rule because the person lacks stable social bonds that might prevent it.
4. Subculture – A person violates a rule because the person belongs to a group or network of other people who encourage violation.

When each of these ideas first appeared in the social-scientific literature, the theory's proponents tended to present it as the complete explanation for deviant behavior, but now we understand that each of these four has merit and the correct explanation is usually a mixture of two or more. We will illustrate each of the theories with hypothetical illustrations, because actual examples may not exist yet.

Learning Theory is sometimes interpreted in economic or "rational choice" terms, as meaning that a person will do whatever he or she perceives it is profitable to do. But human life is not spent entirely in a marketplace where one can compare prices and shop for a good deal. Rather, there are many quite different contexts in which people make decisions. Regardless of whether options can be quantified in dollars, people tend to rely upon their own past experiences in selecting between familiar courses of action [38.35–37].

If the managers of an industrial corporation have learned they can achieve higher profits by ignoring regulations against polluting the environment, and they have not suffered heavy fines from the government for doing so, they will be more likely to pollute in the future. Therefore, a corporation guilty of polluting with conventional technologies is apt to continue with this history of pollution when it adopts new nanotechnologies. This suggests that one way to reduce the likelihood that industrial companies will pollute when they adopt new nanotechnologies is to enact and enforce strong regulations against pollution in general, to make them learn to avoid polluting.

In Strain Theory, a person violates a norm because he or she is frustrated in the attempt to achieve one of the values endorsed by society [38.38, 39]. This idea has been used to explain why many members of poor communities or groups that have been subject to discrimination turn to crime to gain wealth and status, but it can also explain why a major corporation might begin to engage in dubious accounting practices when its growth in real business stalls. The central idea is that an individual or group becomes committed to a particular kind of success that society encourages – whether it is wealth, political power, widespread fame, or honor within a particular sector of society – then experiences frustration in attaining success, which motivates ethical violations.

Conceivably, a nanotechnology corporation could be affected by strain if it has committed itself to a new and untested line of products that turns out to be less effective, more harmful, or more costly than originally estimated. The corporation has committed not only its money and effort, but also its public prestige to success, but success may elude it. It may then unethically advertise its products as more effective than they really are, conceal knowledge of their danger to human health or the environment, and cook its financial records to deceive investors. Of course, many ordinary companies have done this in the past, and, ironically, they sometimes solve their problems before the public becomes aware of them, thereby becoming ethical and successful again (e.g., [38.40]).

When Merton proposed the most influential version of Strain Theory in 1938, he identified three modes of adaptation to three increasing levels of strain. If a person was unable to achieve society's values by following conventional norms, frustration might drive him or her to violate the norms in pursuit of the value, what Merton called *innovation*. If this did not work, he or she might substitute both new values and new norms for those of society, in what he called *rebellion*. But if this failed as well, the person might abandon values, as well as norms and fall into a demoralized state of inaction called *retreatism*. Retreatism is inconsequential, and successful rebellion tends to radicalize society, but innovation (in Merton's sense of the term) can promote scientific and technical progress. In other work, Merton [38.41, 42] was one of the founders of the sociology of science and technology, but he never followed through on the implications of Strain Theory for science, and his distinctive concept of innovation was chiefly used to explain criminal behavior by poor people who violated the law in order to the get the values (i. e., money) endorsed by capitalist society.

There are many examples in the history of science in which Strain Theory can be used to explain scientific and technological innovations that turned out to be beneficial, rather than unethical, and others where the result was a mixture of benefit and harm that presumably could have been managed to emphasize the benefit. In the seventeenth century, England led the world in scientific progress, perhaps in a nationalistic reaction to its inferiority in population and other resources relative to France and Spain [38.43]. In the late nineteenth and early twentieth centuries, Germany lacked access to as abundant a supply of natural resources as had the great colonial powers, Britain and France. This inferiority may have stimulated many advances in German chemistry such as Adolf Bayer's synthesis of indigo dye and the nitrogen fixation method developed by Fritz Haber and Karl Bosch, which allowed Germany to continue producing explosives for World War I after it had lost access to foreign sources of nitrates. When the Treaty of Versailles concluding World War I limited German long-range artillery, the Germans developed the V-2 rocket largely to get around this restriction, thereby ushering in the age of space flight [38.44, 45].

In Control Theory, a person violates norms because he or she lacks stable social bonds that might prevent it [38.46–48]. This is a very successful scientific explanation of many common crimes, such as ordinary theft, and many kinds of criminals tend to lack stable friendships or family relationships that might restrain their deviant behavior. Control Theory might seem irrelevant to nanotechnology ethics because no isolated individual is in a position to make major decisions about new applications. The theory perfectly fits the Hollywood image of Dr. Frankenstein living like a hermit in a remote castle, where he is free to conduct any ghastly experiment he wishes, but no real scientist lives like this.

However, a variant of Control Theory explains that a community or organization can suffer from a partial but pervasive form of isolation, called *social disorganization*, in which communication channels are poor and many people deviate to a moderate degree because they are somewhat detached from each other. In a socially disorganized research laboratory studying the properties of a new nanostructured material, the quality of the science could suffer, pieces of information could fail to get to scientists who need them, and management would get incorrect impressions about the material's properties. This could lead to a chain reaction of unethical behav-

ior in which no one individual was primarily to blame. For instance, the result could be a corporate decision to put into production a new kind of aircraft component that was subject to unpredictable catastrophic failure, causing crashes and loss of life. In a case such as this, the unethical behavior is scattered in many small pieces, committed by many individuals, any time one of them presents a dubious observation as a scientific fact. The best way to reassert the truth-oriented professional norms of science would be to rebuild good channels of communication and cooperation, reattaching the researchers to each other and to the scientific community.

Subculture Theory is similar to Control Theory, but operates on the level of groups rather than individuals. A person violates a rule because he or she belongs to a subculture that rejects the rule and even encourages violation of it [38.49, 50]. A subculture is a group or network having a set of norms, roles, and values that differ from those of the surrounding culture. At the extreme, it can have a radical ideology or dogma, but practically every social group is a subculture to at least a very mild extent. Social psychologist *Janis* [38.51] has shown that even very powerful groups can become deviant subcultures, if they isolate themselves from the wider community, as the Nixon White House did during the Watergate episode.

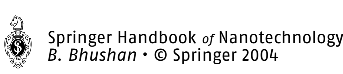
Even if a research laboratory is functioning properly, the organization of which it is a part can make harmful decisions if the top management is a subculture practicing what Janis calls "groupthink," the refusal to accept information that conflicts with the group's beliefs and commitments. Sometimes this may result in harm to others, for instance, if a new nanotechnology-enabled treatment for cancer were put into production before safe methods for administering it to patients in hospital settings were worked out. Or the harm could fall on the organization itself, for example, if a semiconductor company decided to invest its future in molecular logic gates without fully assessing the potential of carbon nanotube transistors instead. In that case, we might say the company deserves what it gets, but there is the ethical issue of its responsibility to stockholders and employees, including to the scientists in the research laboratory who were ready to do the studies needed for a correct decision.

As the example of Strain Theory illustrates, sometimes strain has positive consequences, rather than negative ones. Similarly, Learning Theory explains why an individual or organization might develop habits of ethical innovation, and both Control Theory and Subculture Theory could show that a person or group may innovate best when somewhat detached from conventional thinking. Thus, the issue is not one of avoiding these four factors, but of finding the right levels of them to encourage healthy innovation without unleashing serious unethical behavior. This is the fundamental trade-off in any free society: How to liberate human creativity while restraining greed, immorality, and inhumanity.

Strain Theory has been used to explain the emergence of collective behavior and social movements [38.52], including reform movements such as the environmental movement or crusades to establish professional codes of ethics. Concern about the social and ethical implications of nanotechnology can, therefore, energize the development of appropriate institutions to manage it wisely. Learning Theory suggests that a rewarding market for beneficial nanotechnology products could teach scientists, engineers, and managers to invest their energy in projects that would serve the needs of humanity. Both Control Theory and Subculture Theory stress the importance of strong networks of communication in restraining unethical behavior. Convergence of nanotechnology with the other NBIC fields would support healthy communication by unifying science, providing a universal technical language for interaction across fields, and creating a network of collaborative relationships across sciences, institutions, and sectors of society.

38.5 Public Opinion

Ethics and social implications are largely matters of social perception, and the public conception of nanotechnology is still in the early stages of developing. Nanoscale science and engineering are evolving from conventional work in materials science, physics, chemistry, and related fields, as the gradual emergence of new methodologies permits many kinds of observation and experimentation with inorganic structures having at least one dimension less than about 100 nm. This progress in *real nanotechnology* is solidly based in existing scientific knowledge, even as it achieves new discoveries and inventions.



At the same time, something quite different has been emerging that also calls itself nanotechnology: a social movement based on metaphors, approximations, and hopes. *Tolles* [38.53] calls it an "irrational vision." In social science, popular enthusiasm for a loosely defined set of unreasonable hopes is often called a *mania* [38.54], so I will call this movement *nanomania*.

The key moment in the emergence of nanomania, but not of nanoscience and nanotechnology themselves, was the 1986 publication of *Engines of Creation* by Drexler. This is a popular book, inspirational rather than technical, filled with verbal metaphors about what might possibly be accomplished if nanoscale assemblers could be created, rather like industrial robot arms and assembly lines. The plausibility of Drexler's argument, such as it is, comes from his constant reminder that biological systems include "machines" that assemble themselves and manufacture or manipulate other nanoscale structures: proteins, RNA, and DNA.

In a rambling discourse that reminds us that Leonardo da Vinci could not have predicted the details of late twentieth century technology, Drexler asserts that some time in the future it will be possible to build nanoscale assemblers that are able to make *anything that can be designed*. At this point he has outstripped his biological analogy, because the "nanomachines" of biology cannot do this; they can make only those specific things that evolution has programmed them to make [38.55]. Drexler says that suitably programmed assemblers will be able to make copies of themselves, as living organisms do.

The specific image he offers is of tiny robot arms grabbing atoms from the surrounding raw material and putting them together in the correct configurations. These imaginary assemblers can make anything, he suggests, so they can quickly replace all the factories and construction companies on Earth, giving humankind perfect abundance of anything we might want. The book then scans quickly through other dreams of science fiction, including artificial intelligence, cheap space flight, near immortality, and the danger to human life of uncontrolled self-replicating intelligent machines.

In some ways the book is laudable, inspiring nontechnical readers with many conceivable applications of nanotechnology, some of which might actually turn out to be practical in the long run, discussing their social implications, and offering potential solutions to problems that might arise. The problem is that many people have come to the unfounded conclusion that Drexler's self-replicating universal assemblers are not only theoretically possible, but likely to be created in the near future. This is the fundamental error of nanomania, and it has called forth a reaction in the form of a *nanophobia* – the fear that all kinds of horrible evils will soon emerge from nanotechnology.

At the 2000 *Societal Implications* workshop, Drexler's assemblers were debunked by several participants, including Nobel prize-winner Smalley, discoverer of fullerenes and a pioneer of carbon nanotubes. *Smalley* observes that technical details of chemistry and a correct understanding of the properties of atoms and molecules are largely absent from nanomania [38.56]. In particular, the universal nanoscale assemblers envisioned by Drexler are physically impossible: "Because the fingers of a manipulator arm must themselves be made out of atoms, they have a certain irreducible size. There just isn't enough room in the nanometer-size reaction region to accommodate all the fingers of all the manipulators necessary to have complete control of the chemistry. . . . Manipulator fingers on the hypothetical self-replicating nanobot are not only too fat; they are also too sticky: the atoms of the manipulator hands will adhere to the atom that is being moved. So it will often be impossible to release this miniscule building block in precisely the right spot" [38.57].

The difficulty of developing reasonable public policies about nanotechnology when popular thinking is dominated by fanciful notions is illustrated by Chen's paper, "The Ethics of Nanotechnology", distributed online both by the Markkula Center for Applied Ethics at Santa Clara University and by BioScience Productions, Inc., which describes itself as "a non-partisan organization whose goal is the promotion of public literacy in the biosciences". Following Drexler's approach, *Chen* takes assumes that nanotechnology means the creation of molecular machines, "which could be used as molecular assemblers and disassemblers to build, repair, or tear down any physical or biological objects" [38.58]. Recognizing that such "nanites" may not be practical in the near future, Chen nonetheless suggests that we consider taking three possible actions soon:

1. Nanotechnology R&D should be banned
2. A nongovernmental regulatory or advisory commission should be set up
3. Adopt design guidelines
   - Nanomachines should only be specialized, not general purpose
   - Nanomachines should not be self-replicating

– Nanomachines should not be made to use an abundant natural compound as fuel
– Nanomachines should be tagged so they can be tracked

Chen notes that the first choice would undesirably prevent beneficial applications of molecular machines, but might not prevent "rogue researchers" from developing nanites anyway. However, readers of his article who are unfamiliar with real nanotechnology may not realize that most research in the field has nothing to do with these hypothetical nanites. It would take considerable wisdom to figure out how a regulatory commission might be set up, empowered, and managed effectively in such a way that it could ensure nanotechnology will be used for human benefit without stifling worthwhile innovations. The design guidelines flow from Chen's assumptions about what nanotechnology is, but any formal regulations embodying them could have serious negative unintended consequences, given that they start with a flawed definition of nanomachines.

Chen's rule that nanomachines be "specialized, not general purpose" may mean little, because a fully "general purpose" machine is as mythical as a "universal solvent" or "perpetual motion machine." However, a regulatory commission could do great harm by adopting poorly conceived definitions of *nanomachine* and *general purpose*. Suppose a very useful new abrasive were developed consisting of nanoparticles that changed shape, perhaps in response to temperature or force fluctuations, in some complex way that helped them do their intended job. *Webster's II New Riverside University Dictionary* defines *machine* thus: "a system, usually of rigid bodies, constructed and connected to change, transmit, and direct applied forces in a predetermined way to accomplish a particular objective, as performance." By this definition, the nanoscale abrasive particles would be machines. If they could be used to shape a wide range of industrial materials, they could be called general purpose. Yet this abrasive could be no more dangerous to humanity than ordinary sandpaper.

Strictly speaking, no entities on Earth are "self-replicating." Living organisms cannot replicate themselves without the help afforded them by the particular environment in which they dwell. All life is part of an ecology. Any regulation prohibiting self-replication would have to define very clearly what *self-replication* meant in the context of particular environments. Today, factory robots build parts of robots, but nobody worries about the ethical implications, perhaps because anybody can see that the manufacture process is entirely under the control of human beings. Because nanites are imaginary, and only vaguely defined, there are no facts to give nontechnical people comparable confidence.

Chen's rule against nanomachines that use "an abundant natural compound as fuel" presumably would prevent a nanite from rampaging uncontrolled in the natural environment. But this could outlaw the development of non-replicating nanoscale devices that can function only in very restricted laboratory or industrial systems, because most chemicals used in motors or batteries are abundant natural compounds.

Requiring that all nanoscale machines be "tagged so that they can be tracked" is reminiscent of the British Red Flag Act of 1865, which required that each horseless carriage be preceded by someone on foot waving a red flag. In the context of Chen's recommendations, *tracked* would seem to mean located, not merely identified once found. This could add an extremely heavy technical burden such as radioactive tagging, addition of a distinctive adulterating chemical, or even complex design features above the nanoscale to allow the nanomachine to be detected by microwave radio locators. If the machines are incapable of escaping into the natural environment, this burden would be not only ill-advised but ludicrous.

Has nanomania distorted the reception real nanotechnology is receiving? A survey done in 1999 found that the American business community was rather unaware of nanotechnology, only 2% saying they knew what it was and a further 2% reporting they had heard of it, but did not know what it was [38.59]. Two years later, a Web-based survey sponsored by the National Geographic Society found that science-attentive members of the general public are very enthusiastic about nanotechnology, and a rather large number of ideas about its benefits have already entered popular culture [38.60]. Statistical analysis of responses from 3,909 people revealed that they associate nanotechnology with other science-based technology, but do not connect it with pseudoscience. Significantly, when 598 people wrote paragraphs about nanotechnology, not a single respondent expressed concern about hypothetical dangers from self-reproducing nanites. Future surveys can examine the deepening popular awareness of nanotechnology, as the field itself progresses, and assess any public concerns that develop.

38.6 A Research Agenda

Sociologist *Etzkowitz* [38.61] has noted that the social sciences can play three different but mutually supportive roles in the development of nanotechnology:

1. Analyzing and contributing to the improvement of the processes of scientific discoveries that increasingly involve organizational issues where the social sciences have a long-term research and knowledge base.
2. Analyzing the effects of nanotechnology, whether positive or negative, expected or unintended, hypothetically and proactively and as they occur in real-time.
3. Evaluation of public and private programs to promote nanoscience and nanotechnology.

There are several ways social scientists can study the nanotechnology innovation process as it occurs [38.11, 62]. Cultural anthropologists and participant observation sociologists can enter nanoscience research teams, ethnographically documenting the behavior of the researchers over time as they frame their scientific problems, seek solutions, and labor collectively to understand the meaning of research results [38.63]. Fruitful sites for research on the innovation process include academe, industry, government laboratories, federal agencies, and professional societies.

Historical methods for collecting and analyzing written documents are also useful, even in cases where the documents are only days or weeks old, rather than the decades-old materials employed by most professional historians. Formal interviews, content analysis of communications such as e-mail messages, and questionnaires can provide more systematic kinds of data.

Application of a scientific idea to a technical problem, a technology transfer, and the introduction of products into the marketplace can be tracked through economic statistics on research and development investments, patent applications, and advertisements for new products and services. Some geographic areas, strata of society, and kinds of individuals and institutions experience technological change earlier than others, notably, the first adopters who try out an innovation before influencing other people to try it as well [38.64, 65]. Start-up companies are in a sense early adopters, even though they are also innovators, and thus they may be an especially fruitful if logistically difficult field for research.

There is a long tradition of systematic research on scientific publication, tracking the introduction of new concepts, charting the changing patterns of citation in scientific literature, and measuring the bulk of publications in different areas [38.66]. The progress of nanotechnology in modern culture could also be studied by tracking the introduction of new topics and courses in school and university curricula, mentions of nanoscale phenomena in the popular press, and the proliferation of both commercial and noncommercial Websites dedicated to nanotechnology. Professional societies and entrepreneurs are already creating series of new forums, symposia, journals, and job fairs oriented toward nanoscience and nanotechnology.

Nanotechnology may have significant impacts in all sectors of the economy, in most spheres of life, and on both short-term and long-term time scales. The intended consequences of any particular innovation can be determined simply by interviewing its investors or promoters and by inspecting their publications about it. Unintended consequences are much harder to study, because they require not only extensive research on the impacts on diverse areas of society, but also good scientific intuition about where to look for them. Consequences have consequences, in a continuing cascade, so the second-order consequences will also have to be studied [38.67]. Ultimately, this would require an extensive, vigorous interdisciplinary scientific community that is dedicated to research on social and technological change in general.

Technology is an elaborate system, embedded in the even more elaborate system that is global society. Through feedback among complex social subsystems, major phenomena can produce chaotic and unpredictable effects. Nanotechnology will have substantial impacts on many aspects of society in often different ways, so predictions of its influence will be difficult to make and evaluate scientifically. This means that researchers will have to invest considerable sophistication and effort in their work.

The social and ethical implications of nanotechnology are the results not merely of what the technology itself does, but also of how people react to it. Therefore, it will be important to understand the social acceptance, resistance, or rejection of nanotechnology at different times and in different places and human contexts. Interviews, focus groups, and questionnaire surveys can measure emotional, cognitive, and psychosocial parameters [38.68]. The combined methodologies of political science, sociology, and socio-legal studies will be required to chart the process of regulatory review and approval, court decisions that actively permit or prohibit

the use of the technology, mobilization of political support and opposition, and the activities of relevant social movements.

Ultimately, the test of the various nanotechnologies will be their benefit for human beings, as measured by economic growth, improved health and longevity, environmental protection, strengthened security, social vitality, and enhanced human capabilities. Convergence with other NBIC technologies will complicate the challenge for researchers and policymakers who wish to understand the social and ethical implications of nanotechnology, but it will also magnify the potential benefits to humanity many times over. Success will be most complete and most probable if scientific research on these implications is an integral part of the effort from the very beginning.

Acknowledgements

4 Nanowires

by Mildred S. Dresselhaus, Yu-Ming Lin, Oded Rabin, Marcie R. Black, Gene Dresselhaus

The authors gratefully acknowledge the stimulating discussions with Professors Charles Lieber, Gang Chen, S. T. Lee, Arun Majumdar, Peidong Yang, and Jean-Paul Issi, Dr. Joseph Heremans, and Ted Harman. The authors are grateful for support for this work by the ONR Grant #000140-21-0865, the MURI program subcontract PO #0205-G-7A114-01 through UCLA, and DARPA contract #N66001-00-1-8603.

6 Stamping Techniques for Micro and Nanofabrication: Methods and Applications

by John A. Rogers

The author extends his deepest thanks to all of the collaborators who contributed the work described here.

8 MEMS/NEMS Devices and Applications

by Darrin J. Young, Christian A. Zorman, Mehran Mehregany

The authors wish to thank Wen H. Ko for the helpful discussions and suggestions and Michael Suster and Joseph Seeger for preparing the figures.

10 Therapeutic Nanodevices

by Stephen C. Lee, Mark Ruegsegger, Philip D. Barnes, Bryan R. Smith, Mauro Ferrari

The authors gratefully acknowledge many friends and colleagues whose input helped shape this article. Particularly, we acknowledge Beth S. Lee for many, many helpful discussions and for unflagging support. We also acknowledge Phil Streeter for many of the same services, performed in the office of friend rather than spouse. We acknowledge the support services of Anita Bratcher in manuscript preparation and the artistic stylings of Vladimir Marukhlenko for the figures incorporated in the manuscript. We also acknowledge Carol Bozarth for her kind and spontaneous support of the physical process of manuscript editing. This work is dedicated to the memories of Mildred A. Lee, Antonio Ferrari and Marialuisa Ferrari and the multitude of others whose lives have been tragically shortened by cancer, with the determination that therapeutic nanotechnology be used to help abolish the terrible power of the disease over human life.

13 Noncontact Atomic Force Microscopy and Its Related Topics

by Seizo Morita, Franz J. Giessibl, Yasuhiro Sugawara, Hirotaka Hosoi, Koichi Mukasa, Akira Sasahara, Hiroshi Onishi

Thanks to Tom Albrecht, Alexis Baratoff, Hartmut Bielefeldt, Gerd Binnig, Dominik Brändlin, Peter van Dongen, Urs Dürig, Christoph Gerber, Stefan Hembacher, Markus Herz, Lukas Howald, Christian Laschinger, Ulrich Mair, Jochen Mannhart, Thomas Ottenthal, Calvin Quate, Marco Tortonese, and the BMBF for funding under project no. 13N6918.

18 Surface Forces and Nanorheology of Molecularly Thin Films

by Marina Ruths, Alan D. Berman, Jacob N. Israelachvili

This work was supported by ONR grant N00014-00-1–0214. M. R. Luths thanks the Academy of Finland for financial support.

19 Scanning Probe Studies of Nano-scale Adhesion Between Solids in the Presence of Liquids and Monolayer Films

by Robert W. Carpick, James D. Batteas

We gratefully acknowledge the help of Ms. Erin Flater, who provided valuable assistance and insights into the literature on capillary formation. RWC acknowledges support of a career award from the National Science Foundation, grant #CMS-0134571.

24 Mechanics of Biological Nanotechnology

by Rob Phillips, Prashant K. Purohit, Jané Kondev

We happily acknowledge useful discussions with Kai Zinn, Jon Widom, Bill Gelbart, Andy Spakowitz, Zhen-Gang Wang, Ken Dill, Carlos Bustamante, Tom Powers, Larry Friedman, Jack Johnson, Pamela Bjorkman, Paul Wiggins, Steve Williams, Wayne Falk, Adrian Parsegian, Alasdair Steven and Steve Quake. RP and PP acknowledge support of the NSF through grant number 9971922, the NSF supported CIMMS center, and the support of the Keck Foundation. JK is supported

by the NSF under grant number DMR-9984471 and is a Cottrell Scholar of Research Corporation.

30 Nanotechnology for Data Storage Applications

by Dror Sarid, Brendan McCarthy, Ghassan E. Jabbour

The authors would like to thank Digital Instruments (Veeco) for contributing their Multi-Mode Nanoscope III, the Department of Energy (DE-FG-3-02ER46013/A001) for a generous grant, EMC for their generous gift, and the Vice President for Research, University of Arizona, for equipment support.

31 The "Millipede" – A Nanotechnology-Based AFM Data-Storage System

by Gerd K. Binnig, G. Cherubini, M. Despont, Urs T. Duerig, Evangelos Eleftheriou, H. Pozidis, Peter Vettiger

It is our pleasure to acknowledge our colleagues T. Albrecht, T. Antonakopoulos, P. Bächtold, A. Dholakia, U. Drechsler, B. Gotsmann, W. Häberle, D. Jubin, M. A. Lantz, T. Loeliger, H. E. Rothuizen, R. Stutz, and D. Wiesmann for their invaluable contributions to the millipede project.

In addition, thanks and appreciation go to H. Rohrer for his contribution to the initial millipede vision and concept and to our former collaborators, J. Brugger, now at the Swiss Federal Institute of Technology, Lausanne (Switzerland), M. I. Lutwyche, now at Seagate, Pittsburg, IL, and W. P. King, now at Georgia Tech, Atlanta, GA, as well as to K. Goodson, T. W. Kenny, and C. F. Quate of Stanford University, CA.

We are also pleased to acknowledge stimulating discussions with and encouraging support from our colleagues W. Bux and P. F. Seidler of the IBM Zurich Research Laboratory, J. Mamin, D. Rugar, and B. D. Terris of the IBM Almaden Research Center, San Jose, CA, and G. Hefferon of IBM, East Fishkill, NY.

Special thanks go to J. Frommer, C. Hawker, J. Mamin, and R. Miller of the IBM Almaden Research Center for their enthusiastic support in identifying and synthesizing alternative polymer media materials, and to H. Dang, A. Sharma, and S. Sri-Jayantha of the IBM T. J. Watson Research Center, Yorktown Heights, NY, for their contributions to the work on servo control.

35 Thermo- and Electromechanics of Thin-Film Microstructures

by Martin L. Dunn, Shawn J. Cunningham

We are most grateful for the assistance of Ms. Yanhang Zhang, a Ph.D. student at the University of Colorado, for her help with the preparation of figures. Many of the calculations and measurements also draw from her work. MLD acknowledges support from DARPA, Sandia National Laboratories, and the AFOSR for support of aspects of his research that appear in this work.

About the Authors

Chong H. Ahn

University of Cincinnati
Department of Electrical
and Computer Engineering
and Computer Science
Cincinnati, OH, USA
chong.ahn@uc.edu
http://www.BioMEMS.uc.edu/

Dr. Chong Ahn is a Professor of Electrical and Computer Engineering at the University of Cincinnati. He obtained his Ph.D. degree in Electrical Engineering from the Georgia Institute of Technology in 1993 and then worked as a postdoctoral fellow at IBM T.J. Watson Research Center. His research interests include all aspects of design, fabrication, and characterization of magnetic MEMS devices, microfluidic devices, protein chips, lab-on-a-chips, nano biosensors, point-of-care testing and BioMEMS systems. He is an associate editor of the IEEE Sensors Journal.

Boris Anczykowski

nanoAnalytics GmbH
Münster, Germany
anczykowski@nanoanalytics.com
http://www.nanoanalytics.com

Dr. Boris Anczykowski is a physicist with an extensive research background in the field of dynamic Scanning Force Microscopy. He co-invented the Q-Control technique and received the Innovation Award Münsterland for Science and Economy in 2001 for this achievement. He is a managing director and co-founder of nanoAnalytics GmbH, a company specialized in the characterization of surfaces and interfaces on the micro- and nanometer scale.

Massood Z. Atashbar

Western Michigan University
Department of Electrical
and Computer Engineering
Kalamazoo, MI, USA
massood.atashbar@wmich.edu
http://homepages.wmich.edu/~zandim

Professor Atashbar's main area of research is nanotechnology and wireless sensors. He has been working in the field of micro/nanosensors for chemical and physical sensing specifically integrated smart wireless surface acoustic wave sensors and systems. He is a senior member of IEEE and an associate editor of the International Journal of Modelling and Simulation

Wolfgang Bacsa

Université Paul Sabatier
Laboratoire de Physique des Solides (LPST)
Toulouse, France
bacsa@lpst.ups-tlse.fr
http://www.lpst.ups-tlse.fr/users/wolfgang/

Wolfgang Bacsa is an expert in the emerging field of Nano-Optics and Carbon Nanotubes. He has a Ph.D. from the Swiss Federal Institute of Technology (ETH) Zurich in Physics and has extensive experience in condensed matter physics, optics, microscopy, synthesis of ultra-thin films and nanostructured carbon. Professor Bacsa worked at the ETH Zürich, PennState Universiy and EPFL Lausanne.

William Sims Bainbridge

National Science Foundation
Division of Information
and Intelligent Systems
Arlington, VA, USA
wbainbri@nsf.gov
http://mysite.verizon.net/william.bainbridge

William Sims Bainbridge earned his Ph.D. in Sociology from Harvard University in 1975 and is the author of 10 books, 4 textbook-software packages, and about 150 shorter publications in information science, social science of technology, and the sociology of culture. He has represented the social and behavioral sciences on five US government advanced technology initiatives: High Performance Computing and Communications, Knowledge and Distributed Intelligence, Digital Libraries, Information Technology Research, and Nanotechnology.

Antonio Baldi

Institut de Microelectronica
de Barcelona (IMB)
Centro National Microelectrónica
(CNM-CSIC)
Barcelona, Spain
Antoni.baldi@cnm.es

Antonio Baldi received his PhD from the Universitat Autonoma de Barcelona, Spain, in 2001. He is a postdoctoral fellow at the University of Minnesota. His current research is focused on the fabrication and testing of bioMEMS, on the development of new sensors and microfluidic devices incorporating stimuli-sensitive hydrogels and on the development of inductively coupled wireless MEMS.

Philip D. Barnes

Ohio State University
Biomedical Engineering Center
Columbus, OH, USA
d_skill@yahoo.com

Phillip D. Barnes is a graduate student at the Biomedical Engineering Center at the Ohio State University. His background is in electrical engineering and his current interests are in sensors and imaging devices.

James D. Batteas

National Institute
of Standards and Technology
Surface and Microanalysis Science
Division
Gaithersburg, MD, USA
james.batteas@nist.gov
http://www.cstl.nist.gov/div837/837.03/

Dr. James D. Batteas is a research chemist in the Surface and Interface Research Group of the National Institute of Standards and Technology. The group's current research involves developing and charcterizing the organization and properties of nanoscale materials and devices on surfaces, this includes nanoparticles for use in optoelectric and optomagnetic gating, molecular electronics, and sensors. His group is also investigating friction, adhesion and wear mechanisms on the nanoscale.

Roland Bennewitz

McGill University
Physics Department
Montreal, QC, Canada
roland@physics.mcgill.ca

Roland Bennewitz studied physics in Freiburg and Berlin where he received his PhD for work on defects at surfaces of insulators. He is now assistant at the University of Basel where his research activities focus on high-resolution force microscopy as a tool in nanotribology and surface science.

Alan D. Berman

Monitor Venture Enterprises
Los Angeles, CA, USA
alan.berman.2001@anderson.ucla.edu

Alan Berman received his Ph.D. from the Chemical Engineering Department at the University of California, Santa Barbara. He is involved in technology commercialisation, assisting large technology companies to maximize return on R&D investments by finding and developing applications for their intellectual property outside of their core business. Value is realized through technology licensing, joint ventures and venture capital funded new entities. Technical interests are in fields of tribology, MEMS, and nanotechnology.

Bharat Bhushan

The Ohio State University
Nanotribology Laboratory
for Information Storage
and MEMS/NEMS
Columbus, OH, USA
bhushan.2@osu.edu

Dr. Bharat Bhushan is an Ohio Eminent Scholar and The Howard D. Winbigler Professor in the Department of Mechanical Engineering, a Graduate Research Faculty Advisor in the Department of Materials Science & Engineering, and the Director of the Nanotribology Laboratory for Information Storage & MEMS/NEMS (NLIM) at the Ohio State University, Columbus, Ohio. He holds two M.S., a Ph.D. in mechanical engineering/mechanics, an MBA, and three semi-honorary and honorary doctorates. His research interests are in micro/nanotribology and its applications to magnetic storage devices and MEMS/NEMS (Nanotechnology). He has authored 5 technical books, 45 handbook chapters, more than 450 technical papers in referred journals, and more than 60 technical reports, edited more than 25 books, and holds 14 U.S. patents.

Gerd K. Binnig

IBM Zurich Research Laboratory
Micro-/Nanomechanics
Rüschlikon, Switzerland
gbi@zurich.ibm.com

Gerd Binnig obtained his Ph.D. from the Johann Wolfgang Goethe University, Frankfurt, Germany, and joined IBM Research in 1978. He was corecipient of the 1986 Nobel Prize in Physics for the invention of the scanning tunnelling microscope, and he also invented the atomic force microscope. His current research interests are micro- and nanosystem techniques and "Fractal Darwinism", a theory he developed to describe complex systems.

Marcie R. Black

Massachusetts Institute of Technology
Department of Electrical Engineering and Computer Science
Cambridge, MA, USA
marcie@alum.mit.edu
http://web.mit.edu/mrb/www/prof.html

Marcie Black recently received her Ph.D. from Prof. Dresselhaus's research group at MIT studying the optical properties of nanowires. In particular, she identified the dominant optical absorption mechanism in the IR of bismuth nanowires as an indirect interband transition that is enhanced over bulk bismuth. Currently she is studying organic opto-electronics with an emphasis on photovoltaics.

Jean-Marc Broto

University Toulouse III
Laboratoire National des Champs Magnétiques Pulsés (LNCMP)
Toulouse, France
broto@insa-tlse.fr
http://www.insa-tlse.fr/

Jean-Marc Broto is Professor at the Universite Toulouse III, France. He is a specialist in electronic transport and magnetization properties under high magnetic fields and contributed to the discovery of the Giant Magnetoresistance in 1988.

Robert W. Carpick

University of Wisconsin-Madison
Department of Engineering Physics
Madison, WI, USA
carpick@engr.wisc.edu
http://www.engr.wisc.edu/ep/faculty/carpick_robert.html

Robert Carpick has a Ph.D. in Physics (1997) from the University of California at Berkeley. He has been an Assistant Professor at the University of Wisconsin-Madison since 2000. He carries out research and publishes in the areas of nanotribology, nanomechanics, nanostructured materials, and scanning probe development. He serves on the editorial board of Review of Scientific Instruments. In 2002 he received a Faculty Early Career Development award from the U.S. National Science Foundation.

Tsung-Lin Chen

National Chiao Tung University
Department of Mechanical Engineering
Shin Chu, Taiwan
tsunglin@mail.nctu.edu.tw

Tsung-Lin Chen received his B.S. and M.A. degrees in mechanical engineering from the National Tsing-Hua University, Taiwan in 1990 and 1992, respectively. He received Ph.D. degree in mechanical engineering from University of California at Berkeley, USA in 2001. He is currently an assistant professor in National Chiao Tung University in Taiwan. His research interests include MEMS devices design and MEMS fabrication process development.

Yu-Ting Cheng

National Chiao Tung University
Department of Electronics Engineering & Institute of Electronics
HsinChu, Taiwan
ytcheng@faculty.nctu.edu.tw

Yu-Ting Cheng received his Ph.D. degree in Electrical Engineering at the University of Michigan, Ann Arbor, in 2000. After his graduation, he worked for IBM Watson Research Center, Yorktown Heights, as a research staff member. He is a member of IEEE, IOP, and Phi Tau Phi. Currently he is Assistant Professor at the National Chiao Tung University, Taiwan. His research interests include the development of novel materials and fabrication technologies for MEMS/NEMS applications and microsystems integration.

Giovanni Cherubini

IBM Zurich Research Laboratory
Storage Technologies
Rüschlikon, Switzerland
cbi@zurich.ibm.com

Dr. Giovanni Cherubini received a Ph.D. degree in electrical engineering from the University of California, San Diego, in 1986, and joined IBM Research in 1987. His interests include high-speed data transmission and data storage systems. He is Editor for CDMA systems, for IEEE Transactions on Communications, and served as Guest Editor for the IEEE Journal on Selected Areas in Communications issues on access technologies (1995) and on multiuser detection techniques (2001–2002). He is co-author of the book Algorithms for Communications Systems and their Applications.

Jin-Woo Choi

Louisiana State University
Department of Electrical
and Computer Engineering
Baton Rouge, LA, USA
choi@ece.lsu.edu

Jin-Woo Choi received his B.S. and M.S. degree in Electrical Engineering from Seoul National University in Korea in 1994 and 1996, respectively. He received his Ph.D. degree in Electrical Engineering from the University of Cincinnati in 2000. Now he is an Assistant Professor at Louisiana State University, Baton Rouge, Louisiana. His current research activities include magnetic particle separators, microfluidic systems for biochemical detection, micro total analysis systems (μ-TAS), bioelectronics, and BioMEMS components and systems.

Shawn J. Cunningham

WiSpry, Inc.
Colorado Springs Design Center
Colorado Springs, CO, USA
shawn.cunningham@wispry.com

Shawn Cunningham is working on the development of RF MEMS switch and associated processes with wiSpry, Inc. His interests include materials characterization, reliability, and Design for MEMS Manufacturability. Prior to joining wiSpry, Shawn pursued MEMS research and product development at Coventor, Ford Microelectronics, and the University of Utah's Center for Engineering Design and in collaboration with the Univeristy of Colorado.

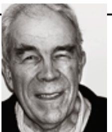
Michel Despont

IBM Zurich Research Laboratory
Micro-/Nanomechanics
Rüschlikon, Switzerland
dpt@zurich.ibm.com

Michel Despont received his Ph.D. in physics from the University of Neuchâtel, Switzerland, in 1996. After a postdoctoral fellowship at IBM's Zurich Research Laboratory, he was visiting scientist at the Seiko Instrument Research Laboratory in Japan in 1997. His current research at IBM focuses on the development of micro- and nanomechanical devices and of processes to fabricate so-called system-on-chip.

Gene Dresselhaus

Massachusetts Institute
of Technology
Francis Bitter Magnet Laboratory
Cambridge, MA, USA
gene@mgm.mit.edu
http://web.mit.edu/fbml/cmr/



Gene Dresselhaus received his Ph.D. in physics from the University of California in 1955. He was a faculty member at the University of Chicago, and assistant professor at Cornell before joining MIT Lincoln Laboratory in 1960 as a staff member. In 1976 he assumed his current position at the MIT Francis Bitter Magnet Laboratory. His area of interest is the electronic structure of nanomaterials and he has co-authored with M.S. Dresselhaus several books on fullerenes, nanowires, and nanotubes.

Mildred S. Dresselhaus

Massachusetts Institute
of Technology
Department
of Electrical Engineering
and Computer Science
and Department of Physics
Cambridge, MA, USA
millie@mgm.mit.edu
http://www.eecs.mit.edu/faculty/index.
html

Mildred Dresselhaus received her Ph.D. in physics from the University of Chicago in 1958. She joined the MIT faculty in 1967. She has been active in research across broad areas of solid state physics, especially in carbon science. Her present research activities focus on carbon nanotubes, bismuth nanowires, low dimensional thermoelectricity, and novel forms of carbon. She is the recipient of the National Medal of Science and 17 honorary degrees.

Martin L. Dunn

University of Colorado at Boulder
Department of Mechanical Engineering
Boulder, CO, USA
martin.dunn@colorado.edu

Martin L. Dunn received the Ph.D. in Mechanical Engineering from the University of Washington and was a postdoctoral appointee at Sandia National Laboratories. His research focuses on the micromechanical behavior of materials and structures. He has published over 75 articles in archival journals, and his research has been sponsored by NSF, DOE, NIST, DARPA, AFOSR, and Sandia National Laboratories.

Urs T. Dürig

IBM Zurich Research Laboratory
Micro-/Nanomechanics
Rüschlikon, Switzerland
drg@zurich.ibm.com

Urs Dürig received a Ph.D. degree from the Swiss Federal Institute of Technology, Zurich, in 1984. He joined IBM as a post-doc working on near-field optical microscopy. He is Research Staff Member since 1986: He worked in the field of scanning tunnelling and dynamic force microscopy. In 1997, he joined the Micro/Nanomechanics group focusing on polymer material issues and thermal modelling.

Evangelos Eleftheriou

IBM Zurich Research Laboratory
Storage Technologies
Rüschlikon, Switzerland
ele@zurich.ibm.com

He received a Ph.D. in Electrical Engineering from Carleton University, Ottawa, Canada, in 1985, and joined IBM Research in 1986. His research focuses on signal processing and coding for recording and transmission systems. His current research interests include nanotechnology, in particular probe-storage techniques.
Dr. Eleftheriou was elected IEEE Fellow in 2002.

Mauro Ferrari

Ohio State University
Biomedical Engineering Center
Columbus, OH, USA
Ferrari.5@osu.edu
http://bmew.bme.ohio- state.edu/bmeweb3/bme_faculty.htm

Mauro Ferrari is the Edgar Hendrickson Professor of Biomedical Engineering of the Ohio State University. A mechanical engineer by training, he also holds appointments in Internal Medicine, Mechanical Engineering and Materials Science. Professor Ferrari is a globally recognized figure in biomedical nanotechnology and micro and nanofabrication. His current interests are application of novel fabrication technologies to innovative drug delivery devices for treatment of cardiovascular disease, palliative care and oncology.

Emmanuel Flahaut

Université Paul Sabatier
CIRIMAT (Centre Interuniversitaire de Recherche et d'Ingénierie des Matériaux)
Toulouse, France
flahaut@chimie.ups-tlse.fr
http://eflahaut.nano.free.fr

Emmanuel Flahaut obtained his Ph.D in Materials Science in Toulouse working on CCVD synthesis of carbon nanotubes (CNTs) and dense ceramic-based composites including CNTs. He spent then more than one year as a post-doctoral researcher in Malcolm Green's Group in Oxford to work mainly on the filling of CNTs. He is now a permanent CNRS researcher at the University of Toulouse.

Lásló Forró

Swiss Federal Institute of Technology (EPFL)
Institute of Physics of Complex Matter
Lausanne, Switzerland
laszlo.forro@epfl.ch
http://nanotubes.epfl.ch

Professor László Forró is working on the synthesis, physical properties and manipulation of carbon nanostuctures and nanostuctured arrays, as well as, mechanical properties of carbon nanotubes, carbon onions, biological tubular systems. Transport and electron spin resonance studies of molecular materials, quasi-one-dimensional organic metals, organic superconductors, cuprates, manganates and fullerenes – up to high pressures. Tunneling spectroscopy in cuprate and fullerene superconductors. Optical properties of strongly correlated systems and biomaterials.

Jane Frommer

IBM Almaden Research Center
Department of Science and Technology
San Jose, CA, USA
frommer@Almaden.ibm.com

Following a Ph.D. in Organometallic Chemistry from Caltech, Dr. Jane Frommer has been involved in a diverse set of research areas, including electronically conducting polymers and scanning probe microscopy. Her present AFM lab at IBM collaborates with a wide variety of laboratories involved in materials research, including lithography, chromatography, and storage. Common to all these studies is Frommer's interest in the properties and structure of molecules in confined geometries.

Harald Fuchs

Universität Münster
Physikalisches Institut
Münster, Germany
fuchsh@uni-muenster.de
http://www.uni-muenster.de/Physik/PI/Fuchs

1984 Ph.D. Universität des Saarlandes with Prof. H. Prof Gleiter (nano crystalline Systems), 1984–1985, Post doc with IBM Research Lab. Zurich in the group of G. Binnig and H. Rohrer, 1985–1993 Project manager ‘Ultrathin Organic Films’ with BASF AG, Ludwigshafen, Germany. Since 1993 he is full Professor and Director at the Physical Institute of the University of Münster, 2000: Cofounder and Scientific Director of the Center for Nanotechnology (CeNTech).

Franz J. Giessibl

Universität Augsburg
Lehrstuhl für Experimentalphysik VI
Augsburg, Germany
franz.giessibl@physik.uni-augsburg.de
http://www.physik.uni-augsburg.de/exp6/

Dr. Giessibl is working in atomic force microscopy and scanning tunnelling microscopy in ultrahigh vacuum at room temperature and low temperatures. He is a Steering Committee Member of the International Conference on Noncontact Atomic Force Microscopy. He received the R&D 100 Award Chicago 1994, the German Nanoscience Award 2000, and the Rudolf Kaiser Price in 2001.

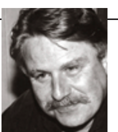
Enrico Gnecco

University of Basel
Department of Physics
Basel, Switzerland
Enrico.Gnecco@unibas.ch
http://monet.physik.unibas.ch/~gnecco/

Enrico Gnecco studied physics in Genoa, where he received his PhD for work on the mechanism of growth of nanostructured carbon films. He is now assistant at the University of Basel, where his research activities focus on friction force microscopy and molecular machinery.

Gérard Gremaud

Swiss Federal Institute
of Technology (EPFL)
Institute of Physics
of Complex Matter
Lausanne, Switzerland
gremaud@epfl.ch

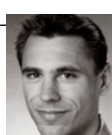


Dr. Gérard Gremaud is a physicist and senior lecturer at the Ecole Polytechnique Fédérale de Lausanne (EPFL). He is active in the research fields of dislocation dynamic, acoustic and atomic force microscopy and granular physics. He is also responsible for the teaching of metrology and practical works to the physics students.

Jason H. Hafner

Rice University
Department of Physics
& Astronomy
Houston, TX, USA
hafner@rice.edu
http://www.ruf.rice.edu/~hafner

Jason Hafner earned his Ph.D. in physics from Rice University in 1998. He then held an NIH postdoctoral fellowship at Harvard University working on nanotube probes for high resolution biological atomic force microscopy. In 2001 he returned to Rice as an assistant professor where his group is pursuing various biophysical applications of scanned probe microscopy and nanomaterials. Dr. Hafner received a Beckman Young Investigator award in 2002.



Stefan Hengsberger

University of Applied Science
of Fribourg
Fribourg, Switzerland
stefan.hengsberger@eif.ch
http://www.anwalt-homburg.de/Stefan-index.htm

Stefan Hengsberger received his diploma in physics from the University of Saarbrücken in 1997. He started as a research scientist at Fraunhofer/Miami (Florida) where he worked until mai 1998. In July 1998 he joined the swiss federal institute of Technology (EPFL) where he earned his PhD in biomechanics in spring 2002. He stayed for another year at EPFL as a postdoc in biomechanics and physics until summer 2003. Since October 2003 he is Professor of Physics at the University of Applied Science in Fribourg, Switzerland.

Peter Hinterdorfer

Johannes Kepler University of Linz
Institute for Biophysics
Linz, Austria
peter.hinterdorfer@jku.at
http://at22.bphys.uni-linz.ac.at/bioph/staf/hipe/hipe.htm

Peter Hinterdorfer earned a Dr. tech. from the University of Linz, Austria, Institute for Biophysics in 1992. He was a postdoctoral fellow at the University of Virginia, Department of Molecular Physiology and Biological Physics (1992/1993). Since then he is at the University of Linz, Institute for Biophysics, where he holds a position as Associate Professor. His current and ongoing research includes single molecule force spectroscopy and high resolution topography and recognition imaging of biological samples.

Roberto Horowitz

University of California at Berkeley
Department
of Mechanical Engineering
Berkeley, CA, USA
horowitz@me.berkeley.edu
http://www.me.berkeley.edu/~horowitz

Roberto Horowitz joined the Department of Mechanical Engineering at the University of California at Berkeley in 1982, where he is currently a Professor. Dr. Horowitz teaches and conducts research in the areas of adaptive, learning, nonlinear and optimal control, with applications to Micro-Electromechanical Systems (MEMS), computer disk file systems, robotics, mechatronics and intelligent vehicle and highway systems (IVHS).

Hirotaka Hosoi

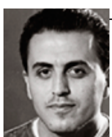
Japan Science and Technology
Corporation
Sapporo, Japan
hosoi@sapporo.jst-plaza.jp

Hirotaka Hosoi received the D.E. degree in electronic enginnering from Hokkaido University in 1999. Since 2002 he is at Innovation Plaza Hokkaido, Japan Science and Technology Corporation (JST). His main research focus is in high-resolution magnetic imaging of magnetic materials surfaces using a scanning force microscope. His current research interests includes magnetism on metal-oxide surfaces.

Jacob N. Israelachvili

University of California
Department of Chemical Engineering and
Materials Department
Santa Barbara, CA, USA
Jacob@engineering.ucsb.edu
http://www.chemengr.ucsb.edu/people/faculty/israelachvili

Jacob Israelachvili earned his Ph.D. 1971 at the Cavendish Laboratory, University of Cambridge, UK. He held various positions at the Department of Applied Mathematics at the Australian National University (1974–1986), including those of Professional Fellow and Head of Department. In 1986 he joined the faculty at University of California, Santa Barbara as Professor in the Department of Chemical Engineering and Materials Department. In 1988 he was elected a Fellow of the Royal Society of London, and in 1991 he was awarded the Alpha Chi Sigma Award for Chemical Engineering Research by the AIChE. He was elected as a foreign associate of the US National Academy of Engineering in 1996.



Ghassan E. Jabbour

University of Arizona
Optical Sciences Center
Tucson, AZ, USA
gej@optics.arizona.edu

Ghassan E. Jabbour is the head of the research group Organic Optoelectronic Materials and Devices at the Optical Sciences Center working on organic and hybrid materials and their applications to light emitting dvices, solar cells, memory storage, solid state lighting, and other areas. Professor Jabbour is a SPIE Fellow, Track Chair of the Nanotechnology Program for SPIE, and Associate Editor of the Journal of the Society for Information Display (JSID). He has over 200 publications, invited talks, and conference proceedings.

Harold Kahn

Case Western Reserve University
Department of Materials Science
and Engineering
Cleveland, OH, USA
kahn@cwru.edu

Harold Kahn is Researcher Associate Professor of Materials Science and Engineering at Case Western Reserve University, Cleveland, Ohio. His research is focused on MEMS device processing and testing, particularly wafer-level mechanical testing and shape-memory actuated microfluidics. He received a B.S. in metallurgical engineering from Lafayette College and a Ph.D. in electronic materials from the Massachusetts Institute of Technology.

András Kis

Swiss Federal Institute
of Technology (EPFL)
Institute of Physics
of Complex Matter
Lausanne, Switzerland
andras@igahpse.epfl.ch
http://www.andras.kis.name

András Kis is a Ph.D. student of Prof. László Forró at the Swiss Federal Institute of Technology (EPFL) where he works together with Andrzej Kulik. His main subject is the measurement of the mechanical properties of nanoscale objects, including carbon nanotubes and microtubules with the aim of understanding the interplay between their nanoscale structure and mechanical properties.

Jané Kondev

Brandeis University
Physics Department
Waltham, MA, USA
kondev@brandeis.edu
http://mattter.cc.brandeis.edu

Professor Kondev graduated with a PhD from Cornell University and did postdoctoral work at Brown University and Princeton University before joining the faculty at Brandeis University. He is a recipient of the CAREER award from the National Science Foundation and is a Cotrell Scholar of the Research Corporation.

Andrzej J. Kulik

Swiss Federal Institute
of Technology (EPFL)
Institute of Physics
of Complex Matter
Lausanne, Switzerland
andrzej.kulik@epfl.ch

Andrzej Kulik is the Head of the Biostructures and Nanomechanics Laboratory of the Swiss Federal Institute of Technology (EPFL) in Lausanne, Switzerland. His research concentrates on quantitative nanoscale materials properties, nanotribology. scanning probe microscopy, contact mechanics, nanoindentation, near-field ultrasonics, optical tweezers, nanolithography, and nanomanipulation.

Christophe Laurent

Université Paul Sabatier
CIRIMAT (Centre Interuniversitaire
de Recherche et d'Ingénierie
des Matériaux)
Toulouse, France
laurent@chimie.ups-tlse.fr
http://ncn.f2g.net/

Dr. Ch. Laurent is Professor of Materials Chemistry at University Paul Sabatier and is the head of the Nanocomposites and Carbon Nanotubes group of CIRIMAT. His research include in the synthesis, characterization and mechanical properties of ceramic-matrix nanocomposites, and since 1994, carbon nanotubes (synthesis of single- and double-walled CNTs, formation mechanisms, characterization, localized growth, hydrogen storage, ceramic-matrix composites).

Stephen C. Lee

Ohio State University
Biomedical Engineering Center
Columbus, OH, USA
Lee@bme.ohio-state.edu
http://medicine.osu.edu/mcbiochem/

Stephen C. Lee is a pioneer in the field of semi-biological nanodevices (nanobiological devices), having published the first monograph devoted to the topic in 1998. His interests are in enabling technologies for the incorporation of functional proteins and nucleic acids into nanodevices, particularly for application in oncology and cardiovascular disease. He is currently Associate Professor of Cellular and Molecular Biochemistry, Chemical Engineering and Biomedical Engineering at the Ohio State University.

Yunfeng Li

University of California at Berkeley
Department
of Mechanical Engineering
Berkeley, CA, USA
yunfeng@me.Berkeley.edu

Yunfeng Li received the B.S. and M.S. degrees from Beijing University of Aeronautics and Astronautics, Beijing, China, in 1992 and 1995, respectively. He is currently working towards the Ph.D. degree in the Department of Mechanical Engineering, University of California, Berkeley, CA, USA. His research interests include motion control, vibration control, control of MEMS devices, and mechatronics.

Liwei Lin

University of California at Berkeley
Mechanical Engineering Department
Berkeley, CA, USA
lwlin@me.berkeley.edu
http:// me.berkeley.edu/faculty/lin/index.html

Liwei Lin received his Ph.D. from the University of California, Berkeley, in 1993. He was an Associate Professor in the Institute of Applied Mechanics, National Taiwan University, Taiwan (1994–1996) and an Assistant Professor in Mechanical Engineering Department, University of Michigan (1996–1999). He joined UC-Berkeley in 1999 and is now an Associate Professor at Mechanical Engineering Department and Co-Director at Berkeley Sensor and Actuator Center.

Yu-Ming Lin

Massachusetts Institute of Technology
Department of Electrical Engineering and Computer Science
Cambridge, MA, USA
yming@mgm.mit.edu

Lin Yu-Ming performed experimental and theoretical studies on Bi-based nanowires for next-generation thermoelectric materials. The electronic transport properties of these systems are studied to investigate quantum size effects. He received the Masterworks Award of the Department of EECS, MIT (2000) and the Gold Medal, MRS Graduate Student Award (2002)

Huiwen Liu

Ohio State University
Nanotribology Laboratory for Information Storage and MEMS/NEMS
Columbus, OH, USA
liu.403@osu.edu

Dr. Huiwen Liu is the associate director of the Nanotribology Laboratory for Information Storage and MEMS/NEMS at The Ohio State University. His research interests are study of mechanical, tribological, and physical properties of advanced materials and MEMS/NEMS devices on micro/nano scale. He obtained an Alexander von Humboldt fellowship and the Japanese Science and Technology Agency Fellowship in 1997 and 1998, respectively

Adrian B. Mann

Rutgers University
Department of Ceramics and Materials Engineering
Piscataway, NJ, USA
abmann@rci.rutgers.edu

Dr. Mann's research focuses on the nanomechanics of materials and the fabrication of nanostructured materials. His research is predominantly on biomedical materials, but also includes ceramics, polymers and metals. He is currently an Assistant Professor at Rutgers University, New Jersey. Prior to this he was a lecturer at the University of Manchester, England and a Fulbright scholar at The Johns Hopkins University, Maryland.

Othmar Marti

University of Ulm
Department of Experimental Physics
Ulm, Germany
Othmar.Marti@physik.uni-ulm.de
http://servex.physik.uni-ulm.de/marti

Profesor Othmar Marti is Head of the Department of Experimental Physics at the University of Ulm. His main research topics are polymers, scanning force microscopy, friction, near-field optics, and the optics of nanoparticles. Studies: diploma from ETH Zürich, Dr. sc. nat. ETH Zürich, Habilitation University Konstanz. He worked at IBM Research Zurich, Switzerland, University of California, USA, ETH Zurich, Switzerland and University of Konstanz, Germany.

Jack Martin

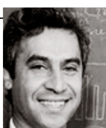
Analog Devices, Inc.
Micromachined Products Division
Cambridge, MA, USA
jack.martin@analog.com

Jack Martin has been a technologist and manager in the design, development and manufacture of industrial MEMS products for 25 years. His accomplishments include development of wafer fab and packaging processes that are used by Analog Devices to produce iMEMS integrated accelerometers and gyroscopes. He has a Ph.D. in Materials Science, a BS and MS in Chemical Engineering, and is a Licensed Professional Engineer.

Brendan McCarthy

University of Arizona
Optical Sciences Center
Tucson, AZ, USA
bmccarthy@optics.arizona.edu

Brendan Mc Carthy is a postdoctoral researcher in the Optical Sciences Center, University of Arizona. He received his PhD in 2001, from Trinity College, University of Dublin, Ireland. His thesis topic was the characterisation of composite materials based on carbon nanotubes and conjugated polymers, using optical and vibrational spectroscopy, scanning tunnelling microscopy, and transmission electron microscopy.



Mehran Mehregany

Case Western Reserve University
Department of Electrical Engineering and Computer Science
Cleveland, OH, USA
mxm31@cwru.edu
http://mems.cwru.edu/

Mehran Mehregany is currently the Chairman of the Electrical Engineering and Computer Science Department at Case and the Goodrich Professor of Engineering Innovation. His research interests include: silicon and silicon carbide micro/nano systems technology (including MEMS/NEMS); micromachining and microfabrication technologies; materials and modeling issues related to MEMS/NEMS and (in some cases) integrated circuits technologies; and MEMS packaging.

Ernst Meyer

University of Basel
Institute of Physics
Basel, Switzerland
Ernst.Meyer@unibas.ch
http://monet.unibas.ch/cgi-bin/people/meyer/

Ernst Meyer is professor of physics at the University of Basel. He is interested in friction force and dynamic force microscopy with true atomic resolution. He is also active in the field of sensors based upon micromechanics and magnetic spin resonance detection with force microscopy. Awarded from the Swiss Physical Society, he is member of the Swiss and American Physical Society, of the Editorial Board of Tribology Letters, and co-editor of books on atomic force microscopy.

Marc Monthioux

UPR A-8011 CNRS
Centre d'Elaboration des Matériaux et d'Etudes Structurales (CEMES)
Toulouse, France
monthiou@cemes.fr

Marc Monthioux has been working on carbon materials for more than 20 years. He is involved in research on carbon nanotubes since 1998, discovered the ability of single-wall nanotubes in being filled by foreign molecules the same year, associated with B. Smith and Prof. D.E. Luzzi from University of Pennsylvania. He is currently Director of Research at the French National Center for Scientific Research and European Associate Editor of CARBON Journal.

Markus Morgenstern

University of Hamburg
Institute of Applied Physics
Hamburg, Germany
mmorgens@physnet.uni-hamburg.de
http://www.nanoscience.de/group_r/stm-sts/

Markus Morgenstern earned his Ph.D. from the Institute of Interface Research and Vacuum Physics of the Forschungszentrum Jülich, Germany in 1996. After one year of research at the University of Paris VII he joined the Group of Prof. Dr. R. Wiesendanger in 1997 as a Senior Scientist. In 2002 he completed his Habilitation at the University of Hamburg with the subject Scanning tunnelling spectroscopy on semiconductor systems and nanostructures

Seizo Morita

Osaka University
Department of Electronic Engineering
Suita-Citiy, Osaka, Japan
smorita@ele.eng.osaka-u.ac.jp
http://www-e2.ele.eng.osaka-u.ac.jp/

Prof. Seizo Morita works in the atomic force microscopy (AFM). He has discovered two-dimensional friction with a lattice periodicity, and two-dimensional solid phase of densely contact-electrified electrons on SiO_2 thin films under ambient conditions. He has achieved mapping, discrimination and control of atomic force and atom with atomic resolution, and also atom manipulation based on a mechanical method using the noncontact AFM apparatus.

Koichi Mukasa

Hokkaido University
Nanoelectronics Laboratory
Sapporo, Japan
mukasa@nano.eng.hokudai.ac.jp
http://www.nano.eng.hokudai.ac.jp/nano/

K. Mukasa is a Professor of electronics at Hokkaido University, Sapporo, Japan. In 1980 he joined Alps Electric Co.Ltd, where he worked on the magnetic thin film heads and materials. In 1987 he moved to the university. His research interests include spin-polarized STM, exchange force microscopy, magnetic force microscopy, Mott spin detectors, nanostructure concerning electron spin and molecular/biological materials and devices.

Martin H. Müser

University of Western Ontario
Department of Applied Mathematics
London, Ontario, Canada
mmuser@uwo.ca
http://publish.uwo.ca/~mmuser/

Prof. Martin Müser received his Ph.D. (1995) and habilitation (2002) from the University of Mainz, Germany. He was a post doctoral researcher at Columbia University (1996/97) as Feodor Lynen fellow and at Johns Hopkins University (1998). He joined the faculty of the University of Western Ontario (U.W.O.) in 2002. His research interests are statistical physics with emphasis on computational materials science, tribology, and quantum solids.

Kenn Oldham

University of California at Berkeley
Department
of Mechanical Engineering
Berkeley, CA, USA
oldham@newton.berkeley.edu

Kenn Oldham is a graduate student in Mechanical Engineering at the University of California at Berkeley, pursuing M.S. and Ph.D. through National Science Foundation Graduate Fellowship. He received his B.S. from Carnegie Mellon University, Pittsburgh, PA. He is currently researching microdevices for hard disk drives. Research interests include MEMS design for control and reliability, optimal and robust control, and materials for microdevices.

Hiroshi Onishi

Kanagawa Academy
of Science and Technology
Surface Chemistry Laboratory
Kanagawa, Japan
oni@net.ksp.or.jp
http://home.ksp.or.jp/onishipro/home.eng/

Dr. Onishi Hiroshi is an experimental chemist at the Kanagawa Academy of Science and Technology interested in molecule-scale reaction kinetics at interfaces. He likes to observe molecules moving and reacting over metal oxide surfaces by time-lapse imaging with scanning probe microscopes. Domestic societies encouraged him with awards to further develop his research towards nano-scale chemistry.

René M. Overney

University of Washington
Department of Chemical Engineering
Seattle, WA, USA
roverney@u.Washington.edu
http://depts.washington.edu/nanolab/

René Overney received his Ph.D. in Physics at the University of Basel in 1992. After his postdoctoral years in Japan and at Exxon, CR, Annandale (NJ) he joined the University of Washington in 1996. His research interests are in mesoscale sciences involving nanorheological interpretations of processes that are as diverse as lubrication, membrane transport, or quantum yield in optoelectronic devices.

Alain Peigney

Université Paul Sabatier
CIRIMAT (Centre Inter-universitaire de Recherches et d'Ingénierie
des Matériaux) – UMR CNRS 5085
Toulouse, France
peigney@chimie.ups-tlse.fr
http://ncn.f2g.net/

Ceramic Engineer and Doctor in Physical-Chemistry – Associate Professor of Materials Chemistry at the Paul Sabatier University – Researches in the synthesis, sintering and microstructural characterization of ceramics and ceramic matrix nanocomposites, and from 1994 on the synthesis on single- and double-walled carbon nanotubes and preparation of nanocomposites containing carbon nanotubes.

Oliver Pfeiffer

University of Basel
Institute of Physics
Basel, Switzerland
Oliver.Pfeiffer@stud.unibas.ch

Oliver Pfeiffer is PhD student at the University of Basel. The main topic of his work is the energy dissipation of oscillating cantilevers in non-contact AFM. Related to this research field is the examination of damping of torsional oscillations of cantilevers when approaching the sample.

Rob Phillips

California Institute of Technology
Mechanical Engineering
and Applied Physics
Pasadena, CA, USA
phillips@aero.caltech.edu
http://www.rpgroup.caltech.edu/people/phillips.html

Rob Phillips is Professor of Mechanical Engineering and Applied Physics at CALTECH, Pasadena. Phillips' work aims to examine nanomechanics of both crystalline solids and biological molecules and their assemblies. Recent efforts have been aimed at investigating mechanics of DNA packing in viruses, the tension-induced gating of ion channels and the mechanical response of bio-functionalized cantilevers.

Haralampos Pozidis

IBM Zurich Research Laboratory
Storage Technologies
Rüschlikon, Switzerland
hap@zurich.ibm.com

He received the Ph.D. in electrical engineering from Drexel University, Philadelphia, PA, in 1998. After working with Philips Research, Eindhoven, the Netherlands, on signal processing and coding for optical storage technologies, with focus on DVD and Blue-Ray-Disc, Dr. Pozidis joined IBM Research in 2001. His research focuses on receiver design for alternative storage technologies, particularly scanning probe microscopy-based techniques.

Prashant K. Purohit

California Institute of Technology
Mechanical Engineering
Pasadena, CA, USA
prashant@caltech.edu
http://www.rpgroup.caltech.edu/~prashant/

Purohit Prashant is currently a Postdoctoral Scholar in Applied Mechanics in the Mechanical Engineering department at Caltech. The overall theme of his research is to develop systematic methods to understand the physics operative at the nanometer scales. His research falls broadly into two categories. The first concerns the subject of coarse-graining methods for crystalline solids and the second mechanics problems in biology. His group hopes to extend the coarse-graining methods in solids to the arena of biological macromolecules.

Oded Rabin

Massachusetts Institute
of Technology
Department of Chemistry
Cambridge, MA, USA
oded@mgm.mit.edu

Oded Rabin is a Ph.D. candidate in Prof. Mildred S. Dresselhaus' group working on the thermoelectric properties of bismuth-antimony nanowire systems, and on electrochemistry-based nanowire synthesis methods. He earned a B.A. degree in Chemistry from the Technion – Israel Institute of Technology, Haifa, Israel and an M.A. degree in Chemistry from the Weizmann Institute of Science, Rehovot, Israel.

Françisco M. Raymo

University of Miami
Department of Chemistry
Coral Gables, FL, USA
fraymo@miami.edu
http://www.as.miami.edu/chemistry/FMRaymo.html

Françisco M. Raymo is Assistant Professor in the Department of Chemistry at the University of Miami. His research interests lie at the interface of chemistry and materials science. In particular, he is exploring innovative strategies to process optical signals with molecular switches, design fluorescent probes for chemical sensing and assemble nanostructured films from electroactive building blocks.

Manitra Razafinimanana

Université Paul Sabatier
Centre de Physique des Plasmas
et leurs Applications (CPPAT)
Toulouse, France
razafinimanana@cpat.ups-tlse.fr
http://cpat.ups-tlse.fr

Manitra Razafinimanana was born in Analalava, Madagascar, on June 28, 1951. He received the 3rd cycle degree, and Doctorat d'Etat ès Sciences Physiques degree from the Université Paul Sabatier, Toulouse, France, in 1982 and 1986 respectively. Since 2000, he was held the position of Professor. He has worked on plasma diagnostics, arc-electrode interaction, transport coefficients and thermodynamical properties calculation.

Mark O. Robbins

Johns Hopkins University
Department of Physics
and Astronomy
Baltimore, MD, USA
mr@jhu.edu
http://www.pha.jhu.edu/~mr

Mark Robbins is a Professor in the Department of Physics and Astronomy of the Johns Hopkins University. His research focuses on non-equilibrium processes like friction, adhesion, spreading, fluid invasion, and shear-induced phase transitions. A common goal is to understand the atomic origins of macroscopic behaviour. He is a fellow of the American Physical Society and was a Sloan Fellow and Presidential Young Investigator.

John A. Rogers

University of Illinois
Department of Materials Science and
Engineering
Urbana, IL, USA
jrogers@uiuc.edu
http://www.mse.uiuc.edu/faculty/
Rogers.html

John A. Rogers earned the Ph.D. degree in physical chemistry from M.I. T. in 1995. Until 2002, he was at Bell Labs serving first as a Member of Technical Staff and subsequently as research Director. John is currently Founder Professor of Engineering at University of Illinois at Urbana/ Champaign. His research interests include methods for micro/ nanofabrication, plastic and molecular electronics, photonics

Mark Ruegsegger

Ohio State University
Biomedical Engineering Center
Columbus, OH, USA
mark@bme.ohio-state.edu

Mark Ruegsegger received his PhD in biomedical engineering at Case Western Reserve Unviersity and is currently an Assistant Professor of Biomedical Engineering at The Ohio State University. His research focus is the development of superparamagnetic particles that can target specific cell or tissue types, in particular atherosclerotic plaque. Other projects include biomimetic surface coatings on biomaterials and characterization of biomolecular flow in nanochannels.

Marina Ruths

Åbo Akademi University
Department of Physical Chemistry
Åbo, Finland
mruths@abo.fi

Marina Ruths received her Ph.D. from the University of California, Santa Barbara in 1996 followed by postdoctoral research at the University of Illinois at Urbana-Champaign, at the Max-Planck-Institute for Polymer Research, an at Åbo Akademi University. Her current research includes adhesion, friction and nanorheology of surfactant, polymer, and liquid crystal systems. She received an ASLA-Fulbright grant in 1991 and an Alexander von Humboldt fellowship in 1998.

Dror Sarid

University of Arizona
Optical Sciences Center
Tucson, AZ, USA
sarid@optics.arizona.edu
http://www.optics.arizona.edu/spm

Dror Sarid is Professor of Optical Sciences and Director of the Optical Data Storage Center. He is conducting research in scanning tunneling microcopy, atomic force microscopy and related systems and in particular probe storage, nano-optics and nano-technology. He published three books and more than 150 papers, mostly on optics and nanotechnology related topics.

Akira Sasahara

Kanagawa Academy
of Science and Technology
Surface Chemistry Laboratory
Kanagawa, Japan
ryo@net.ksp.or.jp
http://home.ksp.or.jp/onishipro/home.
eng/

Dr. Sasahara Akira is interested in local structures formed on solid surfaces. His current research focuses on elucidation of chemical and physical properties of nano-scale structures on metal oxide surfaces and their effect on chemical reaction.

André Schirmeisen

University of Münster
Institute of Physics
Münster, Germany
schira@uni-muenster.de
http://www.andre-schirmeisen.de

Dr. André Schirmeisen is currently working with his research group on nanoscale mechanical phenomena at Münster University. First to combine field ion microscopy with force microscopy to investigate atomically defined nanocontacts. He spent several years in Canada at McGill University to earn his PhD degree in physics. Before he worked as a strategic business consultant and is always interested in connecting nanoscience research with business applications.

Alexander Schwarz

University of Hamburg
Institute of Applied Physics
Hamburg, Germany
aschwarz@physnet.uni-hamburg.de
http://www.nanoscience.de/group_r/

Dr. Alexander Schwarz belongs to the scientific staff of the Center of Microstructure Research at the Institute of Applied Physics at the University of Hamburg, Germany. The group has 10 years (since 1993) experience in scientific research in the field of force microscopy and spectroscopy at cryogenic temperatures in ultrahigh vacuum and high magnetic fields. He is a Senior Scientist and works on Magnetic Force Microscopy (MFM) at low temperatures

Udo D. Schwarz

Yale University
Department
of Mechanical Engineering
New Haven, CT, USA
udo.schwarz@yale.edu
http://www.eng.yale.edu/
nanomechanics/

Udo D. Schwarz received his Ph.D. from the University of Basel in 1993 already using scanning force microscopy. Subsequently he moved to the University of Hamburg where he specialised on low-temperature scanning force microscopy and nanotribology. After spending a year at the Lawrence Berkeley National Laboratory he accepted a position as Associate Professor of Mechanical Engineering at Yale University in 2002.

Philippe Serp

Ecole Nationale Supèrieure d'Ingénieurs
en Arts Chimiques
et Technologiques
Laboratoire de Catalyse,
Chimie Fine et Polymères
Toulouse, France
Philippe.Serp@ensiacet.fr
http://www.ensiacet.fr/

Philippe Serp is associate professor in the LCCFP at ENSIACET. After receiving is PhD from Paul Sabatier University, Toulouse, in 1994 where he worked on the preparation of supported catalyst, he moved to Universidade do Porto to carry out post-doctoral research on catalytic CVD to prepare carbon fibers. His current research interests include CVD preparation of nanostructured materials and catalysis.

Bryan R. Smith

Ohio State University
Biomedical Engineering Center
Columbus, OH, USA
bryan@bme.ohio-state.edu

Bryan Smith is a Ph.D. candidate in biomedical engineering at The Ohio State University, specializing in the microfabrication and bioconjugation of micro- and nanoparticles for proteomics as well as imaging and drug delivery in breast cancer and atherosclerosis.

Anisoara Socoliuc

University of Basel
Institute of Physics
Basel, Switzerland
A.Socoliuc@unibas.ch
http://monet.physik.unibas.ch/gue/
uhvafm/

Anisoara Socoliuc studied physics in Iasi, Romania. She is now PhD student at the University of Basel. The main topic of her work is the study of wear processes on the nanometer scale by friction force microscopy.

Yasuhiro Sugawara

Osaka University
Department of Applied Physics
Suita, Japan
sugawara@ap.eng.osaka-u.ac.jp

Yasuhiro Sugawara received his Ph.D. in 1988 from Tohoku University and is Professor in the Department of Applied Physics of the Graduate School of Engineering at Osaka University since 2002. His research focuses on the further development of scanning probe microscopes and their applications, especially the noncontact atomic force microscope for the observation of solid surfaces at the atomic and molecular level. His aim is also to develop new nanomaterials and nanodevices by manipulation of single atoms and molecules using the atomic force microscope.

George W. Tyndall

IBM Almaden Research Center
Science and Technology
San Jose, CA, USA
tyndallgw@netscape.net

Dr. George Tyndall's current research focuses on the friction and adhesion in boundary lubricants especially as it pertains to the tribology of the magnetic recording head-disk interface in hard-disk drive applications.

Peter Vettiger

IBM Zurich Research Laboratory
Manager Micro-/Nanomechanics
Rüschlikon, Switzerland
pv@zurich.ibm.com

In 1963 Peter Vettiger joined IBM Research (Rüschlikon). He established and headed micro/nanoscale fabrication activities for superconducting, electronic and opto-electronic devices. Together with G.K. Binnig, he initiated Millipede probe-storage activities in 1995. His research interests are micro/nanomechanical devices and systems for probe-storage and biological applications. He is an IEEE Fellow and received a Doctor honoris causa from the University of Basel, Switzerland.

Darrin J. Young

Case Western Reserve University
Electrical Engineering
and Computer Science
Cleveland, OH, USA
djy@po.cwru.edu
http://home.cwru.edu/~djy

Darrin J. Young received his BS, MS, and PhD degrees from the EECS Department at University of California at Berkeley in 1991, 1993, and 1999, respectively. He pioneered RF MEMS high-Q tunable passive devices for wireless communications. He joined the EECS Department at Case Western Reserve University as an assistant professor in 1999. His main research interests include MEMS device design and fabrication.

Babak Ziaie

University of Minnesota
Department of Electrical
and Computer Engineering
Minneapolis, MN, USA
ziaie@ece.umn.edu

Dr. Babak Ziaie is an assistant professor in the Electrical and Computer Engineering Department of the University of Minnesota. His research interests are located at the boundaries between engineering and biology. He collaborates with physicians and biologists of all kinds and his lab is actively involved in the design and fabrication of biomedical micro and nanoelectromechanical systems.

Christian A. Zorman

Case Western Reserve University
Department of Electrical Engineering
and Computer Science
Cleveland, OH, USA
caz@po.cwru.edu
http://mems.cwru.edu/

Christian A. Zorman received a B.S. cum laude in physics and a B.A. cum laude in economics from The Ohio State University in 1988. He received M.S. and Ph.D. degrees in physics from Case Western Reserve University (CWRU) in 1991 and 1994, respectively. Dr. Zorman served in several research capacities at CWRU between 1994 and 2002, before being appointed an Associate Professor in 2002. His research interests involve materials and processes for MEMS.

Philippe K. Zysset

Technische Universität Wien
Institut für Leichtbau
und Flugzeugbau (ILFB)
Wien, Austria
philippe.zysset@epfl.ch
http://ilfb.tuwien.ac.at/

Philippe Zysset graduated in physics in 1987 and obtained a Ph.D. in biomechanics in 1994 at Ecole Polytechnique Fédérale de Lausanne (EPFL) in Lausanne, Switzerland. He completed his postdoctoral training at the Orthopaedic Research Laboratories of the University of Michigan and returned to EPFL as an assistant professor in 1997. His current research interests are in bone biomechanics.
